Transfer the number of embryos that can be injected in 30 to 60 min. Two drops are created to separate cell picking and injection. If the holding pipet is used in the presence of many ES cells it can get clogged with debris. By physically separating the loading and injection steps ES cells are never accidentally aspirated into the holding pipet.

BASIC PROTOCOL 2

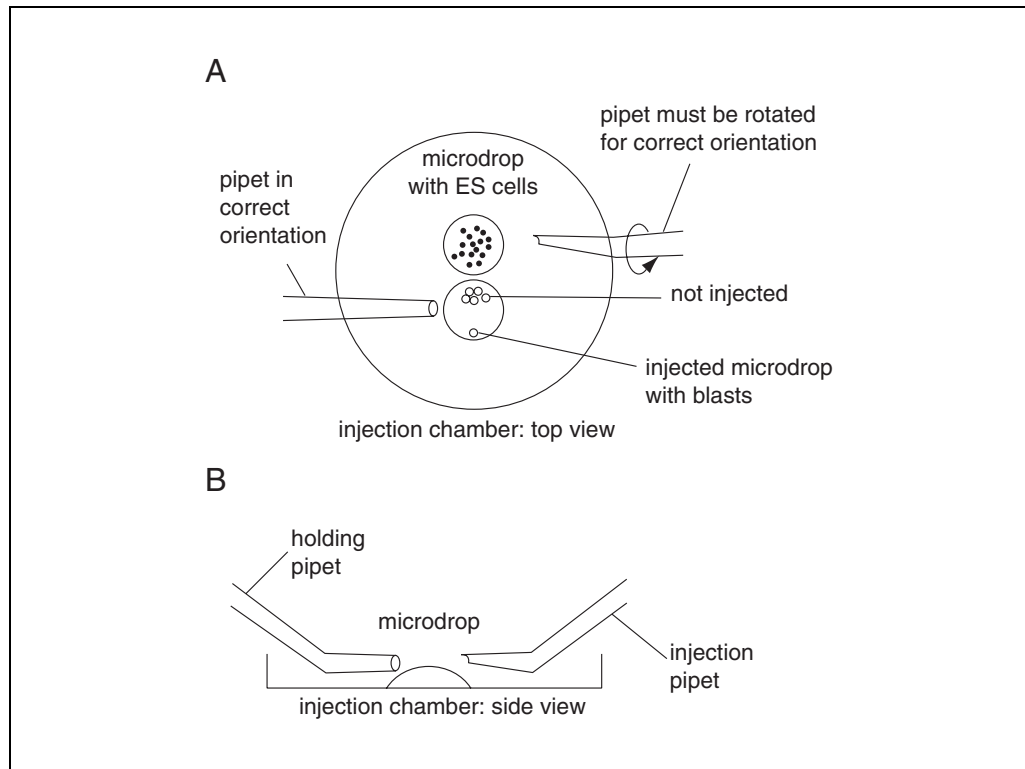

Figure 23.7.3 Injection chamber and pipet alignment. Diagram of the injection chamber with correct pipet orientation as viewed from the top and side. Note that the relative sizes are not drawn to scale. **(A)** Top view of the injection chamber. Two microdrops are illustrated with the ES cell drop at the top and the blastocyst drop below. Injected blastocysts should be moved to another part of the well to avoid confusion. Both pipet tips should appear straight when viewed from above, when they are in the correct orientation. The injection pipet on the right is not aligned properly and must be rotated in its holder in the direction indicated until it appears straight. **(B)** Side view of the injection chamber. The pipets are angled so that the bent tips are parallel to the surface of the plate.

Fine-tune the injection chamber manipulator controls

4. Fine tune as follows.

- a. Place the injection chamber on the microscope and focus under low power (4× objective) on the blastocysts.
- b. With oil-filled pipets, be sure to flush the line until there are no air bubbles. Insert the holding pipet into the pipet holder and push oil through the pipet until oil comes from the tip.
With air filled systems, the pipet can be inserted directly into the holder.
- c. Invert the holder and coarsely position the pipet tip over the microdrops. Adjust the angle of the pipet so that the tip is parallel to the surface of the plate (Fig. 23.7.3B).
- d. Lower the pipet tip to the top of the oil using the coarse manipulator controls. Bring the tip into the microscope field of view. Focus up on the pipet and then rotate the tip until it is in position.
- e. Repeat the procedure with the injection tip.

Make sure to adjust the orientation of the tips above the surface of the plate. Otherwise the tip can be broken on the surface of the injection chamber. A correctly oriented tip will appear straight when viewed from above. If the bend is visible, the pipet must be rotated in its holder until it appears straight (Fig. 23.7.3A).

- Center the tips of the two pipets in the field of view and then adjust the focus so the blastocysts are in view. Bring the pipets down slowly using the course manipulator controls until they are in focus (now the tips are in the same plane and close to the bottom of the injection chamber). Slowly back-fill the pipet with medium.

Only the tips of the pipets need to be back-filled with medium. As a rule of thumb, stop back-filling when the medium interface reaches the edge of the field of view. With oil-filled systems the tips are inverted under slight positive pressure: oil will be coming out the tips in the microdrop. The oil bubble can be removed from the tip by moving the tip between the medium and oil interface while slowly backing out the micrometer control. Immediately after back-filling there is often some movement of medium in the tip because of temperature differences of the various components. The movement should stop if the system is allowed to equilibrate for a few minutes. In oil-filled systems, air bubbles anywhere in the system can produce uncontrolled movement that will not abate with time; the bubbles must be flushed from the system.

- Change to the 10× objective and recenter the tips of the injection pipet and holding pipet. Make sure the blastocysts are also in focus so that all components are in the same plane. Repeat the procedure after switching to the 20× objective.
- Lift the tips above the surface of the plate using the fine manipulator controls and move the stage so the tips are in the microdrop containing ES cells. Focus on the ES cells and lower the injection tip until it is in the same plane of focus as the cells. Leave the holding pipet above the surface.

Whenever the stage is moved, the pipet tips should be raised to avoid breakage. The tips can be raised so they are just out of focus and appear as a hazy outline. Also make sure the tips are raised when they are near the blastocysts and the stage is moved. Otherwise the blastocysts can be inadvertently swept into the oil phase and destroyed. Note that “sweeping” with the pipet can be used intentionally to reposition groups of blastocysts in the microdrop. With practice, adjusting the vertical position of the tips will become automatic.

- Move the tip of the injection pipet to a healthy-looking ES cell (Fig. 23.7.4A) and gently load the cell by backing out the plunger of the injection pipet. Repeat the procedure until 15 to 18 cells have been collected in the injection tip. Raise the tip slightly and move the stage until the pipets are in the microdrop containing the blastocysts.

This step, although fairly easy to master, is the most time-consuming part of the procedure. Healthy looking ES cells should be round and have sharp refractal borders. Move around the microdrop by moving the stage. Do not pick up cells that are so big that they will be compressed as they enter the pipet; they may lyse. Feeder cells are larger than ES cells and will not appear round and refractal with sharp edges. Pairs of ES cells can be picked up together. The cells do not have to be packed tightly together in the pipet. If the ES cells touch the oil interface they will lyse. Do not let the oil interface pass over a cell in the pipet; the lysed debris will stick to the wall of the pipet and clog the tip often requiring pipet replacement. Do not move the tip into the oil phase when there are cells stuck near the outer mouth of the pipet; this also may result in tip clogging.

Inject the blastocysts

- Orient the blastocyst as follows.
 - Choose a blastocyst to inject and focus on it.

Figure 23.7.4, panels C to E, depict sequential steps of the injection procedure.

Figure 23.7.4 Blastocyst injections. Phase-contrast and Nomarski differential interference contrast micrographs of the injection procedure. When an injection pipet with a beveled tip is used, the inner cell mass should be oriented at 6 or 12 o'clock to avoid damage. **(A)** Single-cell suspension of ES cells. Pick up only those cells that are round and have sharp refractal borders (1). Avoid cells with rough borders and those beginning to "bleb" (2). The large cells (3) are fibroblasts and should be avoided. Pick cells that will fit into the injection tip without compression. **(B)** Blastocysts ready for injection. Note the large blastocoel cavities and the presence of the outer shell (zona pellucida). Blastocysts without zonae cannot be injected. **(C)** Blastocyst and pipets in correct orientation for injection. Note the tips of both pipets and the outer edge of the blastocyst are in the same focal plane. **(D)** Compressed blastocyst prior to penetration of the injection tip. Rolling of the blastocyst will be observed at this stage if the tips are not properly aligned. When using beveled injection tips (as compared to the blunt tip in the photograph) the blastocysts cannot be compressed to the same degree without penetration. **(E)** Ejection of ES cells into the blastocoel cavity. **(F)** Blastocysts at different stages of collapse and re-expansion. The blastocoel cavity will collapse almost immediately after injection and appear like a ball of cells as seen in the upper part of the photograph. Over time, most embryos will re-expand and display a characteristic blastocoel cavity.

- b. Rotate the blastocyst so the inner cell mass is at the 6 or 12 o'clock position and a joint in the trophoblast layer is adjacent to the injection tip (Fig. 23.7.5 and Fig. 23.7.4).

Note that Figure 23.7.4 illustrates the process using a blunt injection tip. In this case the tip is less likely to damage the inner cell mass, so that the embryo can be oriented with the inner cell mass at the 9 o'clock position. Tips purchased from Eppendorf are beveled, and therefore the blastocysts should be oriented with the inner cell mass in the 6 or 12 o'clock position.

Blastocysts must have a zona pellucida to be injectable and a cavity large enough to hold the entire beveled end of the injection tip. Rotate the blastocyst by "bating" it around with the injection pipet and the holding pipet. This requires a concerted 3-dimensional movement of the tip, which will take some practice. The blastocysts are oriented so that the injection tip will not damage the inner cell mass and so that the tip will penetrate a thin portion of the trophoblast layer.

10. Prepare the blastocyst for injection as follows.

- a. With the blastocyst in the correct orientation, grab the embryo with the holding pipet by applying gentle suction (Fig. 23.7.4C).

The blastocyst must be held fairly tightly. However, it is possible to apply too much suction. This will result in obvious damage to the embryo.

- b. Raise the blastocyst above the surface of the injection chamber and then lower it until the blastocyst just touches the surface.

This helps to place the holding pipet and blastocyst in the correct plane.

When the blastocyst is brought down onto the surface of the plate it will begin to roll. The beginning of the rolling motion indicates that the embryo has just contacted the surface of the plate.

- c. Focus on the outermost edge of the blastocyst. Move the injection tip until it is in focus at the 3 o'clock position (Fig. 23.7.4C and Fig. 23.7.5).

Figure 23.7.5 Blastocyst alignment for injections. Diagram of the correct blastocyst alignment prior to injection. The inner cell mass could also be oriented at the top of the field of view. The embryo is aligned to avoid damage of the inner cell mass. Note that the injection tip is aligned in opposition to a joint in the trophoblast layer. Attempts to inject blastocysts through a thick part of the trophoblast layer are often unsuccessful. The tip may not penetrate fully and the blastocyst can collapse before cells are introduced into the cavity.

The bottom of the blastocyst should be resting on the surface of the injection chamber and the tips of the injection pipet and holding pipet should be in the same plane at the equatorial edge of the blastocyst.

- d. Gently press the tip of the injection pipet into the edge of the embryo.

Before penetration, the embryo will compress slightly (Fig. 23.7.4D). If the holding pipet and injection tip are not at the ideal equatorial positions or not directly opposed, the embryo will begin to roll. Injecting at this point will usually push the embryo off the holding pipet. Instead readjust the heights of the pipet so the embryo is compressed between the two tips. Then push the injection tip into the blastocoel cavity in a quick fluid motion.

This step tends to be the most frustrating part of the whole procedure. The pipets must be in the same plane so that they trap the blastocyst between themselves and the surface of the injection plate. In addition, each new injection tip may behave slightly differently. Some will penetrate into the cavity easily even with a slow motion. Other tips will require a rapid jab.

11. With the injection tip inside the cavity, gently expel the cells (Fig. 23.7.4E). After all the cells are expelled, remove the injection pipet from the blastocyst slowly.

Positive pressure is built up inside the cavity as fluid and cells are expelled. If the tip is removed too quickly, many of the cells will spill out. If the tip is removed slowly, fluid can escape around the outside of the pipet and equalize the pressure. Often a single cell trails the pipet out. If the bevel of the tip is removed very slowly, the opening will close and prevent the escape of the last cell. However, the loss of a few cells is not critical.

12. Raise the injected blastocyst above the surface of the plate and move to the 6 o'clock position of the microdrop. Drop the blastocyst and move back to the drop containing cells to repeat the whole procedure.

The blastocysts will collapse immediately after injection (Fig. 23.7.4F) and then re-expand over the next few hours. After all the blastocysts on the plate have been injected, transfer them to a microdrop on the slide warmer. If additional blastocysts will be injected, prepare a new injection chamber or simply add fresh blastocysts to the existing microdrop. The entire procedure is tedious. On average, even an experienced injector may only inject one embryo every 3 to 5 min.

BASIC PROTOCOL 3

UTERINE TRANSFERS

Injected blastocysts must be surgically reimplanted into foster mothers to allow embryos to develop to term. Blastocysts are reimplanted into the uterine horns of 2.5-day post-coital pseudopregnant females. Approximately 17 days after reimplantation, pups will be born.

Materials

Embryos (injected blastocysts; see Basic Protocol 2)
Injection medium (see recipe)
2.5-day pseudopregnant female mice (see Support Protocol 1)
2.5% Avertin (see recipe)
95% ethanol

Embryo transfer pipets (see recipe)

Modeling clay

Surgical equipment (thoroughly washed and sterilized by autoclaving or with ethanol; individual investigators may prefer slightly different instruments)

The following are available from Biomedical Research Instruments (similar instruments are available from several suppliers):

Scissors, large (4.5 in.)

Scissors, small (3.5 in.)
Scissors, iris (3 in.)
Forceps, small (4 in.), curved
Forceps, large (4 in.), curved
Forceps, toothed (3.5 in.)
Serrefine clamps
The following are available from Fisher (similar instruments are available from several suppliers)
Wound clip applicator
Wound clips (surgical staples)
Dissecting microscope and fiber optic light source (stereo microscope, 0.8× to 4× zoom, with stand that allows illumination from above and below)
25-G needle
Suture, 5-0 Dexon II on T-31 needle (e.g., Kendall Health Care)

Prepare the embryo

1. Just prior to reimplantation, transfer embryos to a clean drop of injection medium without oil.

This helps to minimize the transfer of oil into the uterus. Reimplant all injected embryos unless the embryo is clearly destroyed. Many will have re-expanded and have a blastocoel cavity. However, embryos that have not re-expanded are not necessarily dead. Reimplantation of some embryos that will die will not affect the development of healthy embryos.

2. Load 6 to 10 embryos into each embryo transfer pipet (Fig. 23.7.6A). Place the loaded transfer pipets on the benchtop supported by a piece of modeling clay.

Air bubbles are introduced into the transfer pipet by gentle aspiration while the pipet tip is held out of medium. The primary purpose of the bubbles is to serve as a visual aid during reimplantation so it will be obvious when the medium containing the embryos has been ejected into the uterus. The medium “spacer” should be at least the same length (volume) as that taken up by the embryos and bubbles.

Reimplant the embryos

3. Anesthetize a 2.5-day pseudopregnant female by injecting intraperitoneally with 0.017 ml/g 2.5% Avertin.
4. Wet the skin on the back with 95% ethanol.
5. Using scissors, make an incision ~1 cm long in the skin on the midline of the back (Fig. 23.7.6B). Place the mouse under a dissecting microscope with overhead illumination. Slide the opening down the right or left side of the mouse until the ovaries or ovarian fat pad are visible through the peritoneal wall.

A larger incision (1.5 to 2 cm) may be helpful to those new to the procedure. In young females the ovaries (pink) and ovarian fat pad (white) are visible through the peritoneal wall. As the females age the ovaries are often obscured by fat. The ovarian fat pad is whiter than the obscuring fat, which is slightly yellow.

6. Make a small incision (~0.5 cm) in the peritoneal wall over the ovaries. Grasp the ovarian fat pad with blunt forceps and pull the ovaries and proximal end of the uterine horn out of the incision. Attach a small serrefine clamp to the ovarian fat pad and rest the clamp on the side of the animal to keep hands free (Fig. 23.7.6C).

The peritoneal incision can be made easily with fine iris scissors. Grasp the peritoneal wall with toothed forceps to make the cut. Avoid blood vessels. As indicated above, the ovarian fat pad can be distinguished from other fat in the body cavity by its distinct color.

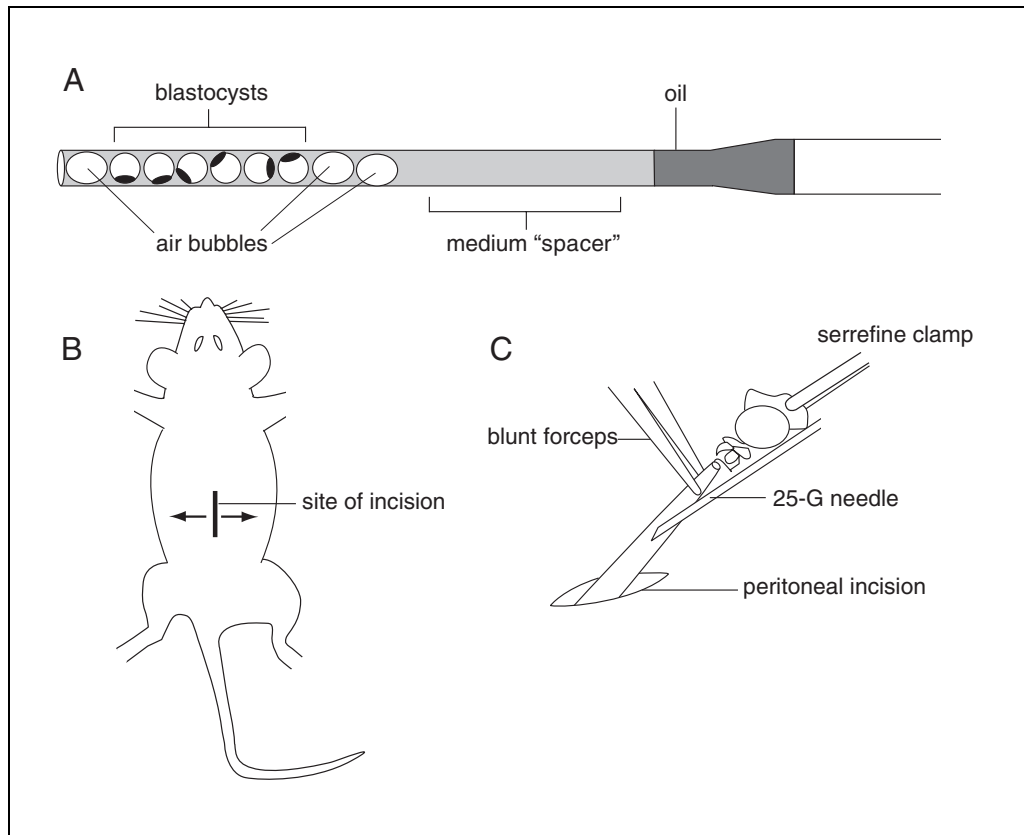

Figure 23.7.6 Reimplantation. Diagrams of various aspects of the reimplantation procedure. **(A)** A transfer pipet loaded for reimplantation. Air bubbles surround the blastocyst and act as markers that can be seen during surgery to ensure that the embryos are expelled into the uterus. Blastocysts do not have to be as tightly packed as illustrated. **(B)** Proper location of the skin incision for access to both uterine horns from a single site. The incision is on the midline of the back at the level of the last rib. The incision site can be slid to either side to gain access to either horn. Skin incisions can be made directly over the ovaries if the investigator prefers. Two incisions would be necessary to reimplant embryos in both horns. **(C)** Isolated uterine horn ready for puncture with a 25-G needle. The uterus is secured by a clamp attached to the ovarian fat pad. Blunt forceps are used to grasp the uterus near the oviduct junction as the tissue is punctured and the transfer pipet is inserted. The uterus should be held gently, to avoid damage.

7. Grasp the uterus near the oviduct junction with blunt forceps. Puncture the uterine wall with a 25-G needle (Fig. 23.7.6C). Make sure the needle enters the lumen.

The needle must enter the lumen of the uterus. Watch the surface of the uterus when the needle is removed. There is usually a landmark so the opening can be found with the transfer pipet. Typically the surface puckers slightly around the penetration site or there is a little bit of bleeding. Alternatively a preloaded pipet can be placed in the mouth pipettor prior to puncturing the uterus and held by modeling clay on the bench. After the hole is introduced in the uterus, it is possible to pick up the pipet while keeping an eye on the puncture site.

8. Insert the embryo transfer pipet into the opening and expel the embryos and air bubbles into the lumen.

Use the bubbles in the transfer pipet as a marker to ensure that the blastocysts are expelled into the lumen. The bubbles also serve as an indicator of how much of the transfer pipet has been inserted into the lumen. The tip should be inserted ~5 mm. Avoid introducing oil into the lumen. The medium/oil interface is usually visible.

9. Gently reposition the uterus and ovary in the peritoneal cavity. Use one suture to close the peritoneal wall.

10. Repeat the procedure on the other side.

Embryos do not have to be reimplanted on both sides.

11. Close the incision in the skin with surgical staples.

Staples are used rather than sutures because mice will often reopen an exterior wound that is closed with sutures. Two staples are sufficient for a 1-cm incision. Three may be necessary for a larger incision.

12. Place the mouse on a slide warmer until she begins to show signs of recovery (10 to 30 min). Place her in a clean cage.

Multiple recipients may be caged together. There are advantages and disadvantages to separating the foster mothers before the pups are born. With multiple births in the same cage, it is difficult to keep track of the successfulness of individual surgeries and the cages may become overcrowded. Alternatively, some new mothers, particularly those with small litters, often take better care of their litters when there are other new mothers in the cage. Swiss Webster foster mothers are generally very good mothers under all conditions.

PREPARATION OF PSEUDOPREGNANT FOSTER MOTHERS

Injected blastocysts must be reimplanted into foster mothers to develop to term. Foster mothers are produced by mating females with vasectomized males. After mating, the pseudopregnant female displays the hormone profile of a pregnant mouse for several days. Transfer of embryos into the oviduct or uterus at the appropriate time provides the final component necessary for the foster mother to carry a litter to term.

A variety of mouse strains can be used to produce foster mothers. The most important features of the strain are their maternal characteristics. Foster mothers that will care for litters of varied sizes and are not influenced dramatically by handling or noise are best. In general, outbred strains or F1 hybrids (offspring derived from mating 2 inbred strains) are most useful. In the author's laboratory, outbred Swiss Webster (Taconic) mice are routinely used for both foster mothers and sterile studs. Vasectomized males can be purchased directly from the vendor, obviating the need to perform the surgery in the laboratory. Vasectomized males should be test-mated to verify their sterility.

Materials

Vasectomized male mice (8 weeks to 16 months old; Taconic)

Female mice (8 weeks to 6 months old; Taconic)

1. Place female mice with individually caged vasectomized males on the fourth day of the injection time line (Fig. 23.7.1).

Two females can be mated with each male. With 2 females per male and 18 vasectomized male (36 matings), these random matings will almost always yield 2 or more pseudopregnant foster mothers each night.

2. Check for evidence of mating (plugs) the next day. Remove plugged females.

Mice typically mate in the middle of the dark cycle. A hard white or yellow mucous plug forms in the vagina after mating. The plug usually remains for 12 hr or longer. Females should be checked in the morning to avoid missing plugs. Check for plugs by picking up each female by the tail. Place her on a wire cage top and allow her to grasp the wires with her front paws. The vaginal opening can be observed by raising the hind legs off the cage top while lifting the tail. Plugs are often immediately visible. To ensure that a plug is not missed, the vagina can be probed gently with a disposable pipet tip (Gilson-style P-200). These tips are cheap, clean, and relatively blunt.

Plugged females should be separated and the date noted. The day of plugging is considered day 0.5 p.c. (post coitus). Uterine transfers are performed on 2.5 p.c. pseudopregnant females. If fosters will be required on consecutive days, the unplugged females can be left with the vasectomized studs and checked on subsequent days. Otherwise, all females should be separated. These random matings typically produce more plugged females on the second and third days than on the first day. By replacing plugged females with new females, 18 to 24 stud males can be used to produce 2 or more fosters on each of 5 consecutive days. This will provide enough fosters for a single injector for a week of injections. Mice are not always obliging; there will be some rare days when fosters are not available.

ES CELL PREPARATION

Single-cell suspensions of ES cells must be prepared for injections. The cells must be completely dispersed, but not treated so vigorously as to cause significant cell death.

Materials

Injection medium (see recipe)

Hanks' balanced salt solution (HBSS; calcium- and magnesium-free; UNIT 23.2)

Additional reagents and equipment for ES cell culture (UNIT 23.3)

1. Thaw ES cells several days before injection. Grow on feeders as described in UNIT 23.3.

Although very few cells are needed for injections, it is often convenient to use 25-cm² flasks. Split the cells at high density (1:2 or 1:3) the day before injections. This is done so the ES cells will greatly outnumber fibroblasts, and because it is easier to make single-cell suspensions from cells that have been passaged recently.

2. On the day of injection, wash the cells with calcium- and magnesium-free HBSS (5 ml for a 25-cm² flask). Remove the HBSS and add 1.5 ml DPBS/EDTA. Incubate at 37°C for 3 min, then add 1.5 ml prewarmed 0.05% trypsin/EDTA, mix, and return to the 37°C incubator.
3. After 1 to 2 min, check to see if the trypsinization is complete by tapping the flask. If the cells come off the plate the trypsinization is complete, otherwise return the flask to the incubator and check again after 1 min.

The idea is to generate a single-cell suspension with minimal damage to the cells. Preincubation with PBS-EDTA greatly reduces the time in trypsin.

4. When trypsinization is complete, add 7 ml of injection medium to the flask. Disperse the cells by pipetting the cell suspension up and down ~10 times in a 10-ml pipet, taking care to avoid introducing air bubbles. Transfer the cell suspension to a 15-ml conical tube and pellet the cells by centrifugation as described for routine ES cell culture (UNIT 23.3).
5. Resuspend the pellet in 10 ml of injection medium and centrifuge again, as before. Remove the supernatant.
6. Resuspend the cell pellet in injection medium. Keep the tube at room temperature or lower to prevent the cells from clumping.

Placing the tube on its side prevents the cells from concentrating in the conical tip of the tube and reduces the extent of clumping. A cell density of $1-3 \times 10^6$ cells/ml is most useful, although the exact density is not critical. Cells can be harvested prior to blastocyst isolation if the investigator is proficient (30 to 45 min to complete the isolation); otherwise, ES cells should be harvested just prior to the injections.

REAGENTS AND SOLUTIONS

All solutions should be prepared from tissue culture grade reagents. Water should be tissue culture grade—high resistance and endotoxin free. Sterilize all final solutions by filtration or prepare from sterile stocks. Use of disposable sterile plasticware is advised to prevent microbial and detergent contamination. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Avertin, 2.5%

Stock solution, 100%: Dissolve 5 g of 2,2,2-tribromoethanol (Aldrich) in 5 ml of *tert*-amyl alcohol (Aldrich). Make sure reagents are at room temperature before mixing. Shake the container until all the tribromoethanol is in solution.

Working solution, 2.5%: Add 2.5 ml of 100% avertin to 100 ml of phosphate buffered saline (PBS; APPENDIX 2) prewarmed to 37°C. Shake the container until the avertin is completely dissolved.

Store 100% and 2.5% avertin in the dark at 4°C. The solutions may be kept for several months. Toxic decomposition products can accumulate. Discard any questionable solutions. Purchase components in the smallest available amounts (5 g tribromomethanol and 5 ml tert-amyl alcohol). There is batch-to-batch variation. With some preparations, a dose that is 5% to 10% higher than the recommended dose of 0.017 ml/g must be administered for complete anesthesia.

Blunted 25-G needle

Prepare the blunted needle by removing the tip of the bevel on a whetstone. There is no need to remove the entire bevel. The purpose of blunting is to prevent a sharp tip from penetrating the uterine wall during blastocyst isolation.

Embryo transfer pipet

Prepare from 25- μ l disposable microcapillary pipets (e.g., Fisher). Pipets can be purchased with a mouth pipet apparatus that consists of a pipet connector, tubing, and a mouthpiece. It is often convenient to replace the tubing with a longer piece of Tygon tubing. Pipets are pulled over a small flame to produce a very fine capillary on one end. Hold the pipet over a small flame at its center. Gently rotate the capillary to ensure uniform heating. When the glass begins to turn orange from the heat, remove it from the heat and simultaneously pull the ends apart. Pull straight apart until the capillary breaks to produce two transfer pipets with flush ends. If the capillary is pulled while the glass is still in the flame, the ends will be too fine. The exact diameter of the opening is not critical (100 to 150 μ m); however, it must easily admit a blastocyst.

For maximum control, the capillary should be back-filled with mineral oil slightly beyond the point where the capillary thickens to its largest internal diameter as illustrated in Fig. 23.7.6A. A small volume of injection medium is aspirated prior to manipulating embryos. Note that there is no reason to use air bubble markers unless the pipet is being loaded for reimplantation. Practice is required to make the transfer pipets and to become comfortable moving embryos by mouth control of the pipet.

Figure 23.7.7 Injection apparatus. Diagram of a typical injection system. Note that the eyepieces are not included in the drawing. The injection pipet is illustrated as an oil-filled pipet with a syringe as an additional oil reservoir. The syringe for the injection pipet is usually placed on the left while the pipet and micromanipulator are placed on the right. The holding pipet and manipulator are placed on the left with its syringe on the right.

Injection apparatus

Many microscope configurations can be modified to work for blastocyst injections. The major components of the apparatus are illustrated in Figure 23.7.7. The basic microscope is an inverted microscope (standard microscopes can be used with a modified injection chamber) with a fixed stage. Under most circumstances the microscope must be placed on an air table to isolate it from sources of vibration. 4 \times , 10 \times , and 20 \times phase objectives are sufficient. A somewhat better image can be

continued

obtained using Nomarski differential interference contrast optics. Nomarski optics are particularly useful if the microscope will double as an oocyte injection microscope. A glass injection chamber must be used to take advantage of Nomarski optics. Joystick micromanipulators can be obtained from several sources (e.g., Nikon, Eppendorf). They should provide fine 3-dimensional control. The manipulators should also have 3-dimensional mechanical coarse controls. The pipet holders should be mounted directly to the microscope frame (preferred) or securely to the isolation table. In either case, the pipets should not move with the stage. Pipet controls consist of threaded syringes and PE tubing. The lines can be oil-filled or air-filled. The author prefers an oil-filled line, particularly for the injection pipet, because it provides slightly more control. Place a 10-ml oil-filled syringe in the line using a 3-way stopcock (Fig. 23.7.7) when using an oil-filled system. This provides easy access for refilling the system. The controls can be purchased (e.g., from Eppendorf or Nikon) or assembled. If assembling the components, use a 2.5-ml gas-tight Hamilton syringe with threaded plunger for the injection pipet and a 2-ml Gilmont Instruments syringe (VWR Scientific) for the holding pipet. This holding system can be used with or without oil. A typical set-up has the injection tip and manipulator on the right side with the syringe on the left side. This way the tip can be moved with one hand and suction can be applied with the other. The holding pipet is placed on the left side with its syringe on the right side. Air bubbles must be removed from oil-filled systems.

Injection medium

To a 1-liter packet of Dulbecco's Modified Eagle Medium (DMEM; Life Technologies), add:

20 ml 1 M HEPES

2.57 g NaCl

H₂O to 1 liter

pH should be 7.1 to 7.2

Sterilize the solution by filtration

Store in 40-ml aliquots up to 6 months at 4°C, protected from light

Prepare the final solution on the day of injection by combining:

40 ml of the DMEM solution

4.4 ml of heat-inactivated fetal bovine serum (10% v/v final)

0.5 ml of 100× penicillin/streptomycin (Life Technologies)

The final solution can be kept at room temperature for the day and then discarded.

Note that the NaCl replaces sodium bicarbonate in the DMEM. Do not add sodium bicarbonate as indicated on the package insert. With this modification and with the addition of HEPES the medium will maintain the proper pH in room air. Do not use this modified medium in a CO₂ incubator because the pH will be incorrect.

Human chorionic gonadotropin (HCG)

HCG (also known as Pregnyl) can be purchased from Organon, Inc. Store lyophilized powder at 4°C. Resuspend the lyophilized powder in sterile phosphate buffered saline (PBS; APPENDIX 2) to a final concentration of 50 U/ml. Store solution in 1-ml aliquots at -80°C for up to 6 months. Avoid multiple freeze/thaw cycles.

Microdrop cultures

Prepare by placing a small volume of injection medium (50 to 150 µl) on a 35 × 10-mm petri dish (Falcon). Cover the drop with light white mineral oil (Sigma) to prevent evaporation, and keep the dish warm on a slide warmer.

Pregnant mare's serum (PMS)

PMS (also known as Gestyl) can be purchased from Professional Compounding Centers of America (5 vials may be purchased at 1000 IU each). Prepare a sterile-filtered 1 mg/ml solution of bovine serum albumin (BSA) in phosphate buffered saline (PBS; *APPENDIX 2*). Resuspend the PMS in PBS-BSA to a final concentration of 50 U/ml. Store lyophilized powder at 4°C. Store the solution in 1-ml aliquots at -80°C for up to 6 months. Avoid multiple freeze/thaw cycles.

In the author's experience PMS purchased from this company works more consistently than that purchased from Sigma or Calbiochem.

COMMENTARY

Background Information

The methods described in this unit have their origins in studies of mammalian development and cellular differentiation. As early as 1961, the first true mouse chimeras were produced by the fusion of 8-cell embryos (Tarkowski, 1961). The potential for chimera production was enhanced with the development of injection techniques. Gardner (1968) described the first injection chimeras generated by the injection of cells from dissociated blastocysts into the blastocoel cavity of host blastocysts. Just like today, color differences were used to verify chimerism. Subsequently, Brinster (1974) demonstrated that cells that were not of immediate embryonic origin could produce chimeras. In his studies, the testicular teratocarcinoma cell line, OTT 6050, produced chimeras when injected into host blastocysts. One year later, Mince and Illmensee (1975) showed that the same teratocarcinoma cell line could produce a germ line chimera. These results were interesting primarily because of their implications for cell differentiation, but they also raised the possibility of creating genetic alterations in cell lines that could be transmitted through the mouse germ line by chimera production. However, this could not be done routinely with teratocarcinoma cell lines because they are unable to contribute to the germ line on a regular basis (Rossant and McBurney, 1983). In 1981 the final breakthrough occurred when Evans and Kaufman (1981) and Martin (1981) described the isolation of embryonic stem (ES) cells. Bradley et al. (1984) demonstrated that ES cells were capable of contributing to the germ line with much greater frequency than tumor-derived teratocarcinoma cell lines. Within a few years, genetically altered ES cells were shown to contribute to the germ line (Gossler et al., 1986; Robertson et al., 1986).

Although the injection of ES cells into blastocysts is the most common method for generating germ line chimeras, there are some alter-

natives. Chimeras can be generated by injecting ES cells under the zona pellucida of 2.5-day p.c. embryos (morula). Technically, there is no particular advantage to this over blastocyst injections. In fact, morula isolation is somewhat more difficult than blastocyst isolation because the embryos are still in the oviduct. On the other hand, aggregation chimeras are becoming a more accepted alternative. Two basic methods have been developed. Both involve the physical apposition of ES cells with morula (with zona pellucida removed). Attached ES cells are taken up by the embryo as it develops in culture to a blastocyst with relatively high efficiency. One method utilizes 10- to 15-cell clumps of ES cells that are placed in contact with 1 or 2 morulas in a microwell (Nagy and Rossant, 1993). The second method utilizes single-cell suspensions of ES cells (Hogan et al., 1994). Aggregation methods are technically less difficult and less expensive because the manipulations can be performed under a dissecting scope. However, these methods may be more sensitive to ES cell quality.

Critical Parameters and Troubleshooting

Creating chimeras by the injection of ES cells into blastocysts is a difficult procedure. Problems can occur in each of the three main steps: embryo isolation, injection, and reimplantation. Each of the steps requires both familiarity with the protocol and practice to avoid problems. It is best to practice the procedures separately before trying to combine them on a single day. Many of the problems are under the investigator's control. However, some aspects of these protocols rely on the basic biology of mice and are not entirely under the control of the investigator.

The two common problems encountered during embryo isolation are low embryo yields and poor embryo quality. A variety of factors can contribute to these problems including

housing conditions, animal age, the timing of superovulation, and reagent quality. Typically, the most consistent embryo yields will be obtained from mice that are housed in virus antibody free (VAF) or specific pathogen free (SPF) facilities with controlled temperature and humidity and consistent light/dark cycles. Animals should not be overcrowded. Mating efficiency can be reduced by noise and constant activity in the animal rooms. Animal age can dramatically affect embryo yields. The age effect will vary somewhat between strains. The C57BL/6 embryo donors that we use are purchased from Taconic. The best yields are obtained from females that are superovulated before their first estrus and from males that are between 8 weeks and ~7 months old. Note that there can be subtle strain variations between C57BL/6 mice obtained from different vendors. The mice must be superovulated at a consistent time during the day that is coordinated with the light/dark cycle. We have had the greatest success with PMS purchased from Professional Compounding Centers of America. Information about potential problems can be gleaned from the embryo yields. A large number of poorly developed (unfertilized) embryos indicates that the superovulation is working, but the males are performing badly. They may be getting too old or some may not be plugging females. For optimal yields, mating information can be kept for each male. Those that are not plugging females on a routine basis should be sacrificed. A low total embryo yield suggests a problem with the females or the superovulation procedure. No matter how much care is taken there will be some days when the mice will be disagreeable and embryo yields will be low.

The injection procedure is visual; it is fairly easy to judge success. The ES cells can be seen as they are introduced into the cavity. The health of the injected blastocysts can be assessed by their ability to re-expand. Although not all healthy injected blastocysts will re-expand, a large percentage should show some semblance of a blastocoel cavity within 1 to 2 hr after injection. However, there is no reason to postpone reimplantation for re-expansion unless there is a concern about embryo viability. Blastocysts will survive substantial damage to the trophoblast layer including penetration of both sides by the injection tip. Blastocysts are most severely damaged by partial aspiration into the holding pipet.

Reimplantation is straightforward but requires practice to acquire proficiency. The pro-

cedure should be repeated until most reimplanted unmanipulated embryos grow to term. Once this proficiency is achieved, and assuming that injections were successful, low pup yields or poor chimerism can be attributed to the quality of the ES cell line. Additional clones should be injected under these circumstances.

Anticipated Results

Pups should be born 16 to 17 days after reimplantation. Approximately 7 days after birth the coat color becomes visible. Assuming proficiency with the procedures, the number of live-born pups and the degree of chimerism are completely dependent on the quality of the ES cell line. Those new to the procedures should inject wild-type (not manipulated also known as parental) ES cells of known quality. Parental ES cells should produce high birthrates: >50% of the reimplanted embryos should survive. Eighty percent or greater should appear chimeric by coat color. With male parental ES cell lines, a significant male sex bias of the chimeras should be observed due to sex conversion of female blastocysts. A range of coat chimerism is usually observed. However, with parental cells many of the chimeras should display hair color that is entirely ES cell derived.

Results with manipulated ES cell lines can vary considerably. Assuming there is no phenotype of the altered gene, cells that have been well taken care of should produce results similar to parental cells. Typically, however, manipulated cells produce less extensive chimerism than parental cells. Birthrates are usually lower (25 to 30%) and the percent of pups that are chimeric may be lower. In extreme cases ES cell clones can be lethal (small litters with no viable chimeras) or appear not to contribute to the embryo at all (reasonable litter sizes with no apparent chimeras). Different clones with the same genetic alteration must be injected under these circumstances.

Time Considerations

Although the procedure spans 7 days, only the day of injection requires a significant time commitment. With experience blastocyst isolation should take 30 to 60 min. Injections should take 2 to 3 hr and reimplantations should take 30 to 60 min. Including cell preparation, the entire procedure should take 4 to 6 hr to produce 20 to 36 injected and reimplanted blastocysts. A novice investigator will spend a very long day trying to complete the procedure. Blastocyst isolation and reimplantation should be

mastered before attempting to complete the entire procedure.

Managing a colony of mice created by gene targeting is not complicated, but does require some strategic planning. Prior to beginning matings to generate experimental animals, the investigator should consider how the background strain might affect analyses. This unit describes basic mating procedures, a simple method to take advantage of coat-color differences between strains to screen for germline transmission, and the rationales for selecting strains for the generation of experimental animals. Because of the difficulty of regenerating an inbred background after outcrossing, it is recommended that, at a minimum, the allele be maintained in an inbred background whenever possible. In addition, the unit reviews common methods for marking mice and two simple methods to isolate genomic DNA for genotyping by polymerase chain reaction (PCR) or Southern blot. Finally, strategies and software for colony data management are reviewed.

COLONY ESTABLISHMENT, EXPANSION, AND MAINTENANCE

Housing

Mice should be housed in a specific-pathogen-free (SPF) facility if possible. SPF animals will typically live longer and display greater fecundity than comparable animals housed in open facilities with rampant viral and parasitic infections. Common mouse pathogens that are excluded in SPF facilities can affect experimental results. Rooms should have a consistent light/dark cycle to facilitate mating. Minimizing human activity and noise in the room during the light phase and particularly during the dark phase will increase mating performance. Males destined for mating should be housed separately. Mature males that have mated are likely to fight if placed together, even if they were originally littermates. In most cases unrelated females may be housed together at any stage of their lives. Facility housing guidelines should be followed to ensure that mice are not overcrowded and that cages are kept clean.

Choosing Potential Founders

A knockout colony begins with chimeric founders. In most cases, the level of chimerism is estimated by the level of embryonic stem

(ES) cell contribution to coat color. Because the typical protocol involves the injection of agouti ES cells into black host embryos (C57BL/6), the degree of chimerism is estimated by the percentage of the coat color that is agouti. There is no absolute rule regarding which chimeras should be mated. Most ES cell lines are male, and thus most germline chimeras will be male—high-level ES cell contribution to male host embryos will produce male chimeras and will convert the sex of female host embryos to male. This results in a preponderance of good male chimeras. However, some female chimeras do pass. The incidence of female chimera transmission is not well documented, because most groups only mate the male chimeras.

When injections result in a number of high-level chimeras (>90% by coat color) and sex conversion, there is a high likelihood of germline transmission. In this case, only good male chimeras need to be mated. When the level of chimerism is lower and there is no evidence of sex conversion, all reasonable male and female chimeras should be mated. The possibility of injecting other targeted clones should be considered. Low-level chimeras (<50% by coat color) do pass. However, this is more common when other littermates have high levels of chimerism.

Detection of Germline Transmission

Chimeras may be crossed with specific wild-type strains to facilitate the detection of germline transmission. For example, most of the common ES cell lines are homozygous wild-type *agouti* and are typically injected into C57BL/6 embryos. Crosses of the chimeras with C57BL/6 mice will yield agouti pups when germline transmission occurs and black pups in the absence of germline transmission. When transmission rates are low, a large number of offspring can be screened visually for germline transmission with minimal effort. Outbred mice with coat color characteristics similar to C57BL/6, such as Black Swiss (Taconic), may also be used. With increased litter sizes (compared to C57BL/6) and good maternal instincts, 100 offspring can be generated in as few as 8 litters from outbred females.

Matings are initiated by placing 7- to 8-week-old (or older) chimeras with wild-type females that are at least 6 weeks old. Two females can be placed with each male. The

females can be replaced weekly; the estrus cycle is 4 to 6 days in length. Alternatively, the investigator can check for plugs (UNIT 23.7, Support Protocol 1) daily and replace the plugged females with new females. It is often worthwhile checking plugs initially to ensure that the males are mating. Some males will never mate. This can be caused by infertility due to partial sex conversion. Other males may take several weeks to begin mating. Females that were mated to different males should be housed separately unless they are individually marked. Pregnant females should be separated prior to delivery to avoid confusion over the lineage of offspring and to avoid overcrowding.

Gestation is typically 18 to 21 days depending on the strain and the litter size (Fig. 23.8.1). The ability of new mothers to care for pups depends greatly on the strain. As a general rule, outbred mothers will produce larger litters and take good care of litters even if disturbed. Inbred mothers will typically have smaller litters and may be more sensitive to environmental stress. As a precaution, pregnant females can be placed in clean cages shortly before birth. The cages should not be disturbed until pups are at least 4 days old. Activity and noise in the room should be minimized. The addition of paper towels or nestlets from which nests can be made can be helpful. Poor mothers may be encouraged to care for their offspring in the presence of another mother with a similarly aged litter, or the litter may be removed and placed with another mother with a similarly aged litter. In this case, some of the pups from the foster mother should be removed so that the litter is not too large. These problems should not be encountered when using Black Swiss and C57BL/6 females.

Coat color should become apparent within 1 week after birth. Germline transmission can occur at variable rates ranging from 0% to 100% of the offspring being ES cell-derived. As a general rule, the author would generate ~100 offspring before giving up on a chimera. Chimeras usually pass at a consistent rate: an animal that is passing at 80% is unlikely to produce subsequent litters with no ES cell-derived pups. Obviously, there is no need to mate a poor transmitter if chimeras from the same ES cell clone are passing at a higher frequency. With genes targeted on autosomes, only half of the ES cell-derived offspring will inherit the altered allele, so the pups must be genotyped even if it is clear from the coat color that germline transmission has occurred.

Generating Mice For Analysis

Most ES cell lines are derived from inbred strains (Table 23.8.1). Inbred mice and the ES cells derived from them are genetically homogeneous and homozygous at all loci. Strains are defined as inbred after 20 generations of sequential brother-to-sister matings. Animals generated to screen for germline transmission by coat color may not be ideal for experimental analysis, because of the mixed genetic background (Fig. 23.8.2). Note that in the F1 generation the mice are genetically identical (half 129 and half C57BL/6 in Figure 23.8.2). The F1 generation can be used to study heterozygous phenotypes without concern of genetic heterogeneity. When mice that are heterozygous for the targeted allele are crossed to make an F2 generation with homozygotes, they will inherit a variable complement of alleles from the two strains. This may increase the variability of a phenotype and result in the masking of subtle phenotypes. In addition, the targeted alleles and linked loci will both originate from the chimeric strain while the wild-type alleles and linked loci will come from the other strain (C57BL/6 in Fig. 23.8.2). Phenotypic differences between homozygous mutants and wild-type littermates may be due to differences in the genes surrounding the altered locus. Because of these issues, it is good practice to maintain the mutant allele in an inbred background whenever possible.

An inbred line is established by mating a germline chimera with wild-type mice of the same strain from which the ES cell was derived. Table 23.8.1 lists common ES cell lines and their strains. There is no rapid way to re-establish an inbred line after the original chimeras are gone. Heterozygotes from the first generation can be crossed to produce wild-type and homozygous mutants for study. Homozygous wild-type and homozygous mutant lines can be maintained separately if the mutants are viable and fertile, avoiding the necessity of genotyping each new litter.

In many cases an investigator is stuck with a mutant allele in a mixed background. Under these circumstances, homozygous mutants and wild-type littermates should be generated by crossing heterozygotes. Even when homozygotes are viable and fertile, separate wild-type and homozygous lines should not be used to generate experimental animals because distinct lines with different phenotypes may develop. The investigator should also consider making a congenic line (see discussion of Generating

Figure 23.8.1 Mouse generation time line. Time line from copulation to sexual maturity of a typical mouse. By gestational day 14, pregnant mothers can be detected easily by their increased size. The age of a litter can be estimated from the time that the coat color is evident (~1 week after birth) or the day when the eyes open (~2 weeks after birth). Sexual maturity may occur as early as 4 weeks. However, the initial fertile mating does not usually occur until the mice are 6 to 8 weeks old. Females can often be mated at 6 to 7 weeks of age while males may not plug females until 7 to 8 weeks of age. There can be substantial differences in the generation time between strains. As a conservative estimate for calculations consider a generation to be 3 months.

Figure 23.8.2 Genetic heterogeneity in the F2 generation. Many investigators create a mixed background by crossing the 129 chimera with C57BL/6 mice to test for germline transmission. If the ES cell line was derived from an inbred strain, members of the F1 generation are genetically identical except for the mutant locus (Mut). The F1 generation may be useful for the analysis of heterozygous phenotypes. However, the F2 generation is genetically heterogeneous because of recombination and independent assortment. Some phenotypic differences between F2 homozygotes and their wild-type littermates may be caused by the background heterogeneity and not by the mutant allele.

Congenic Lines, below) to reduce the genetic heterogeneity.

There are many circumstances when outcrossing is appropriate. First, many of the inbred lines from which ES cells were established are difficult to obtain or to work with. Poor maternal instincts and small litter sizes can make it impossible to generate a sufficient quantity of experimental animals. Chimeras can be crossed with an inbred line, such as C57BL/6, with good mating behavior. Second, certain experiments cannot be performed in specific backgrounds. For example, 129/SvEvTac mice do not develop morphine tolerance (Kolesnikov et al., 1998). Under these

circumstances the mutant allele must be moved into a responsive background if studies regarding morphine tolerance are to be pursued. In these examples where outcrossing is necessary, the investigator should consider making a congenic line (see discussion of Generating Congenic Lines, below) to reduce the genetic heterogeneity. Third, outcrosses can be used to identify genetic modifiers of the mutant allele. Variation of the mutant phenotype between inbred and outcrossed or congenic backgrounds strongly suggest the presence of genetics modifiers. The modifiers may be interesting in their own right and can be mapped (and eventually identified) or they may simply make

Table 23.8.1 Common 129 ES Cell Lines and Strains of Origin^a

Cell line	Strain (new nomenclature)	Strain (old nomenclature)	Commercial strain source ^b

^aSeveral common 129-derived ES cell lines are listed with their strain of origin (Simpson et al., 1997; Threadgill et al., 1997; Festing et al., 1999). Because of recent name changes, both the old and new nomenclature has been included to avoid confusion. The nomenclature revision is based on an analysis with microsatellite markers and consists of the addition of a letter and number before the backslash. The letter P designates 129 strains derived from the original parent strain. The letter S designates a congenic strain made to introduce the steel mutation. The letter X designates a strain that was generated by an unknown outcross. The number differentiates substrains of the parental strains.

^bCommercially available sources of the mice are also listed where known. Most 129 strains are not good breeders: they produce small litters and do not care well for the pups. The 129S6/SvEvTac strain is an exception: litters average 6.3 pups and mothers tend to care for their offspring.

^cR1 ES cells were generated from a cross of two 129 substrains.

experimentation less difficult (e.g., homozygous mutants might live longer in a different background).

Generating Congenic Lines

A congenic strain is a mouse strain that is isogenic to an inbred strain, but contains a chromosomal segment from another background. Construction of a congenic strain using traditional methods will take ~3 years. Congenic strains are created by an initial outcross followed by sequential back-crosses to an inbred strain (Figure 23.8.3). For example, a C57BL/6 congenic can be generated by outcrossing a chimeric male with a wild-type C57BL/6 female. This produces an F₁ generation in which the offspring may be considered heterozygous at all loci—half the loci are derived from the chimera and half are derived from the C57BL/6. The second generation, N₂, and all subsequent generations are created by back-crosses of animals carrying the mutant allele to C57BL/6. The N₂ generation will retain only 25% of the chimera's genome. Each subsequent back-cross will reduce the original genome content by 50%. By N₁₀, only 0.1% of the chimera's original genome will remain and

the animals are considered congenic. The estimated genomic contributions are based on statistical arguments; the actual proportions in a specific mouse may vary considerably from the expected value. Genes that are tightly linked to the targeted locus will be retained in the congenic strain. The amount of the donor genome linked to the targeted locus can be estimated in centimorgans (cM) as 200/N (for N > 5), where N equals the number of back-cross generations (Silver, 1995). For the N₁₀ congenic ~20 cM surrounding the targeted locus remain in the congenic.

The production of congenics can be accelerated using a newer approach known as speed congenics (Lander and Schork, 1994; Wakeland et al., 1997). The mating strategy is identical to the traditional approach, except that the mouse containing the least amount of the donor genome is selected at each generation for subsequent matings. The relative genome contributions are determined by screening for polymorphic marker loci spread throughout the genome at generation N₂ and all subsequent generations. The contaminating donor genome contribution can be reduced to the same level seen in the N₁₀ congenic in 5 or 6 generations,

Figure 23.8.3 Generation of a congenic strain. Congenic lines are generated by an outcross to the host strain (C57BL/6) followed by successive back-crosses of mice carrying the mutant allele to the host strain. The strain is considered congenic after the tenth back-cross generation. Most loci except those tightly linked to the mutant locus are derived from the host strain and are homozygous. At this stage, brother-to-sister matings are initiated to generate experimental animals. Note that if all matings are performed with host females and donor males, the host Y chromosome will not be transferred. At least one back-cross between a donor female and host male followed by mating of a mutant male to a host female in the next back-cross is required to fix the C57BL/6 Y chromosome in the congenic line.

reducing the time required to make a congenic strain to 1.5 to 2 years. This rapid method requires larger colonies to select the “best” mouse for subsequent matings. In addition, few laboratories have the resources to perform the marker-assisted screening in house, although there are companies and core facilities that will perform the screening.

Long-Term Strain Maintenance

There are several options for maintaining mutant mouse lines when there is no immediate need to generate animals for experimentation. Most investigators do not choose to eliminate mouse lines, because of the time and effort required to regenerate them. A line can be maintained by keeping only a few mating pairs. Homozygous mutants, if viable and fertile, should be used, so that genotyping will not be necessary. Let the mating pairs breed actively. Most litters can be culled. Set up new mating pairs from the younger generations when the litter size becomes smaller or the litters become less frequent. The number of active mating pairs depends on the fecundity of the line: more pairs should be kept for lines that produce small litters or lines that have difficulty rearing pups. This may also be a good opportunity to perform back-crosses if a congenic line might be needed in the future. Alternatively, morula (2.5-day old embryos) can be frozen using a controlled-rate freezing protocol and stored in liquid nitrogen. Several of the major mouse suppliers provide morula-freezing services. There have been recent advances in sperm cryopreservation. However, this is not yet the method of choice because of the variable success of *in vitro* fertilization with frozen mouse sperm. Finally, some of the major mouse suppliers will freeze, maintain, and distribute interesting mutant mouse lines if the investigator is willing to relinquish control over their distribution.

MOUSE IDENTIFICATION

Individual animals must be identifiable when maintaining colonies of mice with different genotypes and backgrounds. A variety of methods have been used to mark individual mice including ear tagging, ear punching, toe clipping, subcutaneous transponder implantation, and tail tattooing. To a large extent, the method that a laboratory will use depends on personal preferences. However, the method must be acceptable to the institutional animal care committee. Note that there may be some variation in protocol acceptance between different institutions, so that the resident animal resource center should be consulted before choosing a protocol. None of the procedures will cause chronic pain. There are several practical factors to consider when choosing a method of identification (Table 23.8.2).

Subcutaneous transponders are the most expensive of the identification methods. The typical cost of each transponder is between \$5 and \$10. In most cases, they are not easily reused. Readers typically cost between \$500 and \$2000. Implanted animals can be identified easily and the method is permanent in most cases. However, because of the lack of standardization, transponders from different companies usually require specific readers. Subcutaneous insertion is not difficult, but may require more restraint than for the other methods: anesthesia may be necessary until the procedure becomes routine.

The cost of ear punching and toe clipping is negligible beyond the purchase of a punch or scissors. Marking the mice by these methods is simple, but may become tedious when large, continuous numbering schemes are used (see Hogan et. al., 1994 for numbering schemes). Reading the number may also be difficult when using continuous numbering schemes. Both methods are very useful for identifying neo-

Table 23.8.2 Methods of Identification

Method	Cost	Ease	Anesthesia	Comments
Ear tag	Low	Simple	No	Tags can tear out of older animals
Transponder	High	Simple	Yes/No	Lack of standardization requires transponder specific readers
Ear punch (toe clip)	Low	Simple	No	Good for identification of neonates Large numbering schemes can be difficult to read
Tail tattoo	Moderate	Requires training	Yes	Labeling with complex numbering schemes can be tedious

nates in a single litter when the mice are too small for other forms of identification. Note that neonates may also be marked with India ink for short-term identification.

Tail tattooing is permanent. Tattooing devices can be purchased for \$500 to \$1000. Marking of many animals this way can be tedious because of the technique and the requirement for anesthesia.

Ear tags are inexpensive and easy to apply. Mice should be tagged at weaning or later: tags are more likely to tear out when placed in the small ear of a younger animal. Tags should be clipped to the base of the ear, not to the edge. This will reduce the chance of tear-out. Tags may eventually tear out in older animals. Place even-numbered tags in the right ear and odd numbers in the left ear to reduce confusion when tags fall out; the torn or punctured ear will indicate whether the original tag number was even or odd.

DNA PREPARATION FOR GENOTYPE ANALYSIS

Typically, the mice are tagged for identification and tail biopsied for genotyping simultaneously at weaning (age 3 to 4 weeks). At this age, biopsies are thought to be less traumatic because the tip of the tail is still cartilaginous. Check institutional guidelines for recommended procedures: an inhalation anesthetic may be required for older animals. DNA can be isolated from tail samples in several ways depending on the method of genotype analysis. PCR screens should be used whenever possible for the sake of speed and convenience.

The following are step-by-step instructions for the abovementioned procedures.

Tail Biopsy

1. Remove 0.5 cm or less of the tip of the tail from a 3 to 4 week old pup using clean, sharp scissors. The same scissors can be used for multiple mice. The mice will not get infections at the cut site and cross-contamination of DNA samples by the scissors should not be a problem. A styptic pen can be used to stop the bleeding. However, there is very little blood loss at the cut site in normal mice.

2. Place the tail in a labeled 1.5-ml microcentrifuge tube. Samples can be collected over 1 hr or more at room temperature without affecting the quality of the final DNA. The biopsies can be frozen at -20°C or processed immediately after collection. When Southern analysis is used to detect large bands (>15 kb), samples should be processed after collection

because freezing will decrease the DNA quality, making the identification of large bands more difficult.

3. Prepare DNA using the standard protocol for Southern analysis and PCR, or the rapid protocol for PCR (see steps for each procedure below). The standard method produces DNA that is suitable for Southern analysis (*UNIT 2.9A*) or PCR (*UNIT 15.1*). It is an overnight procedure. The rapid method produces template for PCR in less than 30 min.

Standard DNA Isolation for Southern Analysis and PCR

1. Add 0.5 ml of digestion solution consisting of 100 mM Tris-Cl, pH 8.5 (*APPENDIX 2*), 5 mM EDTA, 200 mM NaCl, 0.5% Tween 20, and 1 mg/ml proteinase K to each tail biopsy. The proteinase K should be added fresh just prior to digestion.

2. Incubate overnight at 55°C . The tissue should dissociate completely leaving some undigested debris and hair at the bottom of the tube. Alternatively tails may be digested for ~ 4 hr at 65°C with intermittent agitation.

3. Mix the samples by gentle vortexing and centrifuge at top speed in a microcentrifuge at room temperature for 2 min.

4. Pour the supernatant into a new 1.5 ml microcentrifuge tube containing 0.5 ml isopropanol. Mix the tubes thoroughly by inversion and let stand at room temperature for 10 to 30 min.

5. Centrifuge at top speed in a microcentrifuge at room temperature for 2 min. Aspirate the supernatant and wash the pellet once with 70% ethanol.

8. Allow the DNA pellet to air dry and then resuspend in 100 μl TE buffer, pH 7.6 (*APPENDIX 2*). The DNA can be dissolved by gentle vortexing. If the DNA pellet is allowed to dry out completely it may become difficult to dissolve. The DNA concentration will range from 0.5 to 2 $\mu\text{g}/\mu\text{l}$, depending on the size of the tail biopsy. The DNA is suitable for restriction digestion or as a PCR template. Store the DNA at 4°C .

Rapid DNA Isolation for PCR Analysis

1. Add 0.5 ml of 0.05 M NaOH to each tail biopsy. Incubate for 10 to 20 min at 95°C .

2. Remove the samples from the heat and neutralize by adding 50 μl of a solution of 1 M Tris-Cl, pH 8 (*APPENDIX 2*), and 10 mM EDTA. Vortex to mix. The tail does not dissociate completely with this method, but DNA is released into solution. 1 or 2 μl can be used directly in a 20- μl PCR reaction (*UNIT 15.1*). The

protocol can be scaled to work in a 96-well format.

INFORMATION MANAGEMENT

Mouse colonies have a tendency to expand rapidly. Good record-keeping practices should be established immediately. Records serve several purposes. Colony sizes and expenses can be kept to a minimum when an accurate tally of mice is maintained. Phenotypic variation attributable to differences in strain background and subtle difference in fecundity are more easily detected when complete records are maintained. Paper-based records will become unwieldy for all but the smallest colonies. Fortunately, there are many options for computer-based record keeping. Table 23.8.3 lists some examples of colony management software including commercial and freeware options. Demos of most of the commercial applications can be tested prior to purchase. Many investigators may find that simple, locally constructed databases are most convenient. These can be adapted to individual lab requirements and are usually less expensive than commercial colony management software.

Whether using commercial, freeware, or locally constructed databases, it is a good practice

to record information both about individual animals and matings. Tables 23.8.4 and 23.8.5 each list a minimum set of data that should be collected for individual mice and matings, respectively. Mating data should be recorded even when there are no offspring. This type of database is easily created using Filemaker Pro. Filemaker Pro is relatively inexpensive, cross-platform (Macintosh and PC), and simple to program. Databases can be accessed through a network, allowing multiple users to log on simultaneously. Several Filemaker Pro colony databases can be downloaded from the Web site listed in Table 23.8.3 for MouSeek. These templates may be used directly or modified to individual lab requirements. In addition, handheld (Palm-compatible) versions of Filemaker Pro databases are easily created and can be synchronized with the desktop application. Handheld copies are convenient for data entry and review inside the animal facility.

Regardless of the record-keeping system, it is much more common to regret recording too little information than too much. However, a database is only as useful as the data it contains; the database must remain simple enough so that a laboratory group will actually record the information.

Table 23.8.3 Examples of Colony Management Software^a

Program	Source	Platform	Comments
Colony	Locus Technology, Inc. http://www.locusttechnology.com	Windows	Very complete packages, good for large-scale operations Options for barcode scanning and transponder interface
Big Bench Mouse	Big Bench Software http://www.bigbenchsoftware.com	Macintosh Windows	Basic management software that can be networked
Progeny	Progeny http://www.progeny2000.com	Windows	Pedigree software that can be used for colony management
Scion	Topaz Technologies http://www.topaztracks.com	Macintosh Windows	Primarily a subscription service to access remotely administered database with web browser
LAMS	Mark McKie www.hgu.mrc.ac.uk/Softdata/LAMS	Windows	Freeware for basic colony management
MouSeek	Caleb F. Davis http://Mickey.utm.edu/main/databases.html	Macintosh Windows	Freeware Filemaker Pro template; modifiable

^aSeveral software options are listed ranging from extensive commercial applications (Colony and Scion) to freeware alternatives (LAMS and MouSeek). Colony has the most options including handheld devices for editing data on site and may be most useful for managing large colonies. Big Bench Mouse is new and appears best suited for medium and small colonies. Progeny requires the user to define the relational database. This increases both flexibility and complexity. LAMS and MouSeek are inexpensive alternatives for medium and small colonies. Both are freeware, but MouSeek requires the purchase of Filemaker Pro. The Web site cited for MouSeek also provides links to two other free Filemaker Pro colony management templates. Most of the databases can be run on a network allowing multiple users to access data simultaneously.

Table 23.8.4 Mouse Data^a

Field	Type	Description
Unique ID	Number	A serial number that uniquely identifies the record; usually created automatically
Tag/ID	Text	The mouse tag number
Date of death	Date	Date of death
Cause of death	Text	Used to differentiate natural deaths from experimental deaths or those for colony culling
Mating number	Number	Unique mating number from the mating table
Genotype	Text	Genotype
Notes	Text	For any non-standard annotations
Sex	Text	Sex of the mouse

^aMother, father, strain, date of birth, and category are all defined in the corresponding mating record (Table 23.8.5).

Table 23.8.5 Mating Data^a

Field	Type	Description
Mating number	Number	Unique serial number to identify the mating record usually created automatically
Start date	Date	Date the mating was begun
Date of birth	Date	Date of birth of litter
Category	Text	Differentiates multiple targeted or transgenic lines
Strain	Text	The background strain of the mouse
Mother	Number	ID that uniquely identifies the mother—the unique number from the mouse table
Father	Number	ID that uniquely identifies the father—the unique number from the mouse table
Notes	Text	For any non-standard annotations
No. of Males	Number	Number of male offspring
No. of Females	Number	Number of female offspring

^aMouse (Table 23.8.4) and mating data tables list a minimum set of data that should be recorded in colony management software. With this basic data individual animals and their mating behavior can be tracked and genealogies can be reconstructed. A simple database in Filemaker Pro can be constructed from scratch by creating these two tables and linking them using the mating number. Each mouse has a record in the mouse table. Each mating, whether productive or not, has a record in the mating table.

Transgenic Mouse Production By Zygote Injection

Transgenesis by DNA injection into fertilized eggs (zygotes) is the most common experimental method used to modify the germline of mice with specific DNA constructs. Traditionally, the resultant mice have been used for the characterization of gene-specific phenotypes and for the characterization of gene regulatory elements that define tissue and developmental-specific patterns of expression. Transgenes have also been used to rescue mutant phenotypes, to create cell lineage markers, and to ablate specific cell lineages. In addition to gain-of-function transgenes, it is possible to produce transgenes that reduce the function of specific gene products or transgenes that have inducible expression.

Unlike animals created by homologous recombination in embryonic stem (ES) cells followed by blastocyst-mediated transgenesis, every traditional transgenic founder is unique. The site of DNA integration into the genome is usually random and the number of integrated copies cannot be completely controlled. This necessitates the generation of several independent founders to ensure that the phenotype is dependent on the transgene and not a result of alterations in the function of an endogenous gene. Regardless of this caveat, transgenic mice generated by DNA microinjection represent a powerful method to study the role of specific genes in a physiological setting.

The standard protocol involves the injection of DNA into the pronucleus of fertilized eggs (0.5-day-post-coital embryos). These injected eggs are then implanted into the oviduct of a pseudopregnant foster mother. The injected DNA integrates randomly into the genome in a fraction of the implanted embryos, typically as head-to-tail concatamers of the original linearized construct. The DNA usually integrates before the first cell division; however, the integration can occur later and result in mosaic founders. In either case, founders are mated to demonstrate germline transmission and to establish a transgenic line.

This unit presents protocols for the isolation of fertilized eggs (see Basic Protocol 1), the injection of DNA into fertilized eggs (see Basic Protocol 2), and the implantation of these injected eggs into pseudopregnant foster mothers (see Basic Protocol 3). In addition, methods for preparing plasmid DNA (see Support Protocol 1) and bacterial artificial chromosome (BAC) DNA (see Support Protocol 2) suitable for microinjection are provided. The types of surgical instruments and the preparation of equipment for embryo transfer and egg injection are also described (see Support Protocol 3).

The basic protocols are technically difficult, requiring proficiency with zygote isolation, zygote injection, and embryo reimplantation. Each of these techniques requires practice. Because of the steep learning curve and the expense of the equipment, the procedure should not be undertaken without a serious commitment (also see Commentary).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals. Animals should be handled following institutional guidelines to minimize undue pain and suffering. Pay strict attention to institutional guidelines pertaining to survival surgery.

NOTE: All mice used should be housed in a specific-pathogen-free (SPF) or virus-antibody free (VAF) facility.

NOTE: All solutions and equipment coming into contact with zygotes must be sterile. Additionally, proper sterile technique must be used when isolating, manipulating, or implanting fertilized eggs.

ISOLATION OF FERTILIZED EGGS

The method for generating transgenic mice by DNA microinjection uses 0.5-day-old fertilized eggs. At the stage of isolation, fertilized eggs are present in a clump of follicular cells (cumulus mass) in an enlarged region of the oviduct (ampulla) near the infundibulum (ovarian end of the oviduct). The fertilized eggs must be removed from the oviduct and separated from the mass of follicular cells so that they can be manipulated as single eggs for microinjection. Many different strains of mice may be used as egg donors. Factors that govern the choice of strains include the quantity and quality of eggs that can be obtained, and the effect the background strain may have on the transgene phenotype. As a general rule, outbred or hybrid strains yield more eggs of better quality than inbred strains. The B6D2F1 (first generation cross between C57BL/6 and DBA) strain is a commonly used hybrid strain. A few inbred strains, such as FVB, are particularly suited for egg donors because they will produce large numbers of good quality eggs.

Materials

- 50 U/ml PMS (see recipe)
- 3- to 4-week-old FVB female mice (Taconic or The Jackson Laboratory)
- 50 U/ml HCG
- 8-week- to 1-year-old fertile stud male mice, individually caged
- 95% ethanol
- M2 medium (Sigma or Specialty Media) containing 100 U/ml penicillin and 100 µg/ml streptomycin (add antibiotics just before use)
- 1 mg/ml hyaluronidase (Sigma H-3884) in M2 medium
- M16 microdrop cultures (see recipe)
- 1-ml, $\frac{3}{8}$ -in. tuberculin syringes with 26-G needles
- Surgical equipment (see Support Protocol 3):
 - Scissors
 - Fine forceps
 - Iris scissors
- 35 × 10-mm and 60 × 10-mm petri dishes
- Dissecting microscope: stereomicroscope with fiber-optic light source, 0.8× to 4× zoom, and a stand that allows illumination from above and below
- Embryo transfer pipet (see Support Protocol 3)
- 37°C, 5% CO₂ incubator
- Additional reagents and equipment for preparing foster mothers (UNIT 23.7)

Initiate superovulation

1. Initiate superovulation by injecting 5 units of 50 U/ml PMS i.p. into 3- to 4-week-old female FVB mice using a 1-ml, $\frac{3}{8}$ -in. syringe and 26-G needle, between 11 a.m. and 2 p.m., 3 days prior to egg isolation (Table 23.9.1).

Egg donors are superovulated to synchronize estrus and produce the greatest egg yields. Young female mice that have not yet cycled usually give the greatest embryo yields. The timing of injection is important: it must be coordinated with the light/dark cycle to ensure that the females ovulate in response to the exogenous hormones prior to mating. A typical lighting cycle consists of 10 to 12 hr dark beginning at 6 to 7 p.m. and extending to 5 to 6 a.m. This represents the range of values that works well with a standard workday. For a specific animal room, the timing and duration of the cycle should be held constant. Eight matings should generate enough eggs for 1 day of injection for fertile strains such as FVB

Table 23.9.1 Timeline for Zygote Microinjection

Day	Time	Action	Comments
0	11 a.m. to 2 p.m.	Initiate superovulation in egg donors by PMS injection	Procedure begins 3 days before the actual day of injection with the initiation of superovulation of the donor mice. Mating is considered to occur in the middle of the dark cycle.
1	—	No action	—
2	46 to 48 hr after PMS injection	Inject donors with HCG and set up foster matings	Donors mate at the transition of the third and fourth 24-hr period. By the middle of the injection day, they are post-coital day 0.5. Fosters are set up to mate the day before injection at the same time the donors are placed together. Fosters will also be p.c. day 0.5 on the day they will be used for reimplantation.
3	Morning	Check donors and fosters for plugs	Donors and fosters should be checked for plugs on the morning of the day of injection.
	Morning	Isolate fertilized eggs	Fertilized eggs should be harvested early in most cases.
	Afternoon	Inject zygotes; reimplant	Injections are performed through the rest of the day followed by reimplantation

or most F1 hybrids. As a general rule, mouse strains that breed well and produce large litters will be good egg donors, while strains that are poor breeders will produce few good quality eggs.

- Forty-six to 48 hr after the PMS injection (Table 23.9.1), i.p. inject each female with 5 units of 50 U/ml HCG.

Mate superovulated females and foster mothers with stud males

- Place single superovulated females with individually caged 8-week- to 1-year-old fertile stud males. On the same day, set up foster mother matings (*UNIT 23.7*).

Stud males are usually the same strain as the donor females. Mice should mate in the middle of the next dark cycle. If injections are planned on consecutive days, it is a good idea to maintain a large enough colony of stud males so that no male is mated on consecutive days, otherwise fertilized egg yields will usually drop on the second day. A mating record for each stud male should be maintained. Males that do not plug females regularly should be replaced.

Note that foster mothers for oviduct transfers are used on the day the plug is found (0.5 day p.c.). When preparing foster mothers, set up enough matings with vasectomized males to yield at least three plugged females for each day of injection.

- The next morning (Table 23.9.1), separate fertilized females and foster mothers from the males.
- Pick up each female by the tail and place her on a wire cage top, allowing her to grasp the wires with her front paws. Observe the vaginal opening for a plug, which is hard white or yellow mucus, by raising the hind legs off the cage top while lifting the tail. If necessary, probe the vagina gently with a disposable pipet tip.

The plug usually remains for 12 hr or longer. Females should be checked in the morning to avoid missing plugs.

Females plugged the morning after the mating was initiated are considered to be 0.5 day post-coital (p.c.). Fertilized eggs used for DNA injections are considered to 0.5-days-p.c. embryos. Most, but not all, of the superovulated females should plug when using highly fertile strains. The plugging rate may be significantly lower with strains that are poor breeders. Don't forget to check for plugged foster mothers at the same time. Check plugs as early in the day as possible, as plugs may be lost as the day progresses.

A disposable pipet tip such as a Gilson-style P-200 is recommended, as these tips are cheap, clean, and relatively blunt.

Isolate reproductive tract

6. On p.c. day 0.5, sacrifice donor females by an approved method of euthanasia. Place the mouse on its back and wet the abdomen with 95% ethanol.

Work through the protocol (steps 6 to 16) with one mouse at a time until comfortable with the procedure. When the mice are housed under standard light/dark cycles, eggs should be harvested before noon. Later in the day, the cumulus mass may begin to disperse and the eggs may not be grouped together in one region of the oviduct.

7. Tear the skin away from the abdomen and cut through the peritoneal wall with scissors.

The skin can also be cut, but with some practice, the skin can be torn away quickly.

Refer to Support Protocol 3 for a description of useful surgical instruments.

8. Remove the ovaries, oviducts, and uterine horns as a single unit in the following manner (Fig. 23.9.1A and B):

- a. First, grasp an ovary by its associated fat pad with forceps.
- b. Gently lift the ovary and uterine horn.
- c. Cut the attached tissue as necessary to free the uterine horn.
- d. Cut the cervix to release the other side.
- e. Place the tissue on a clean paper towel.

The ovary is easily found at the base of the kidney.

Isolate oviducts

9. Cut the uterine horn near the oviduct/uterus junction (Fig. 23.9.1B). Discard the uterus. Collect the ovaries and oviducts in a drop of M2 medium containing 1000 U/ml penicillin and 100 μ g/ml streptomycin in a 35 \times 10–mm petri dish.

The volume of medium is not critical. The medium is just used to prevent the tissue from drying out. Typically a drop of several hundred microliters is appropriate for sixteen to twenty four ovaries obtained from eight to twelve mice. As the procedure becomes more familiar, the process can be streamlined by removing the ovary and oviducts directly without first removing them as a unit with the uterine horns.

10. Place the dish under a dissecting microscope. Under low power, cut the ovary away from the oviduct as follows (see Fig. 23.9.2A and B):
 - a. Grasp the uterine end of the oviduct with fine forceps.
 - b. Place the open blades of a pair of iris scissors around the oviducts.
 - c. Close the blades slightly, but not enough to cut the tissue.

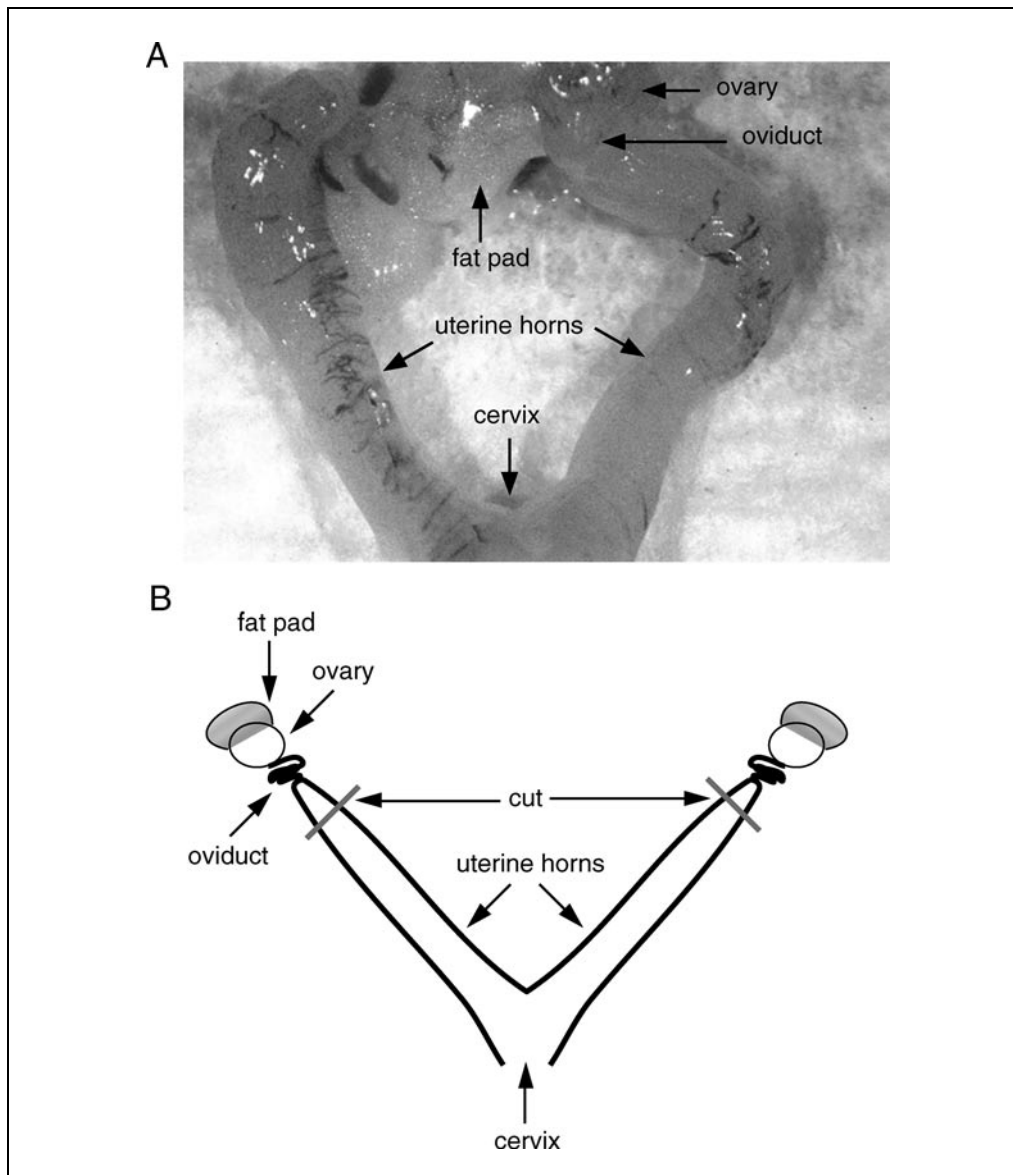

Figure 23.9.1 Uterine horns, oviduct, and ovaries during various stages of fertilized egg isolation. (A) Photograph of the uterine horns with oviduct, ovary, and fat pad still attached. Excision as a unit may be easier for the beginner than removal of the oviducts and ovaries alone. Note that the oviduct and ovary on the left side has been removed. (B) Diagram of similar structure seen in (A), with suggested cut sites to separate the oviducts and ovaries from the uterus. Grasp the ovarian fat pad with forceps to move the oviduct and ovary.

- d. Slide the blades gently toward the ovaries.
 - The blades will catch on the bulb of the ovary.*
 - e. Cut the bursa to separate the ovary from the oviduct.
 - f. Discard the ovary.
11. Place the oviduct in a fresh drop of several hundred microliters of M2 medium on a fresh 35 × 10–mm plate. Combine oviducts from eight to twelve mice.

Isolate cumulus masses

12. Release the cumulus mass by tearing the ampulla, an enlarged region of the oviduct near the ovarian end of the oviducts (Fig. 23.9.3), open with fine forceps under a dissecting microscope.

Figure 23.9.2 Oviduct and ovary after removal of the uterine horn. Note the location of the bursa, a thin transparent membrane that covers the gap between the oviduct and ovary. **(A)** The line indicates the cut site to separate the oviduct from the ovaries. **(B)** Diagram of the image seen in (A). Note the swollen region of the oviduct, the ampulla, near the ovarian end of the oviduct, which is often hidden under the folds of the oviducts. The dotted line indicates where to cut to separate the oviducts from the ovary.

At this stage of development, the fertilized eggs are present in a clump of follicular cells, known as the cumulus mass, in the ampulla. The clump is visible through the transparent wall of the ampulla.

13. After tearing open the ampulla and releasing the cumulus mass, remove the oviduct from the drop of medium. Continue the procedure until all the oviducts have been processed and the cumulus masses from eight to twelve mice are collected in a single drop of medium.

A typical cumulus mass is shown in Figure 23.9.4A.

Figure 23.9.3 Diagram of the isolated oviducts. Tear the swollen ampulla of the oviduct with fine forceps as shown to release the cumulus mass containing fertilized eggs and follicle cells.

Isolate fertilized eggs

14. Add an approximately equal volume of 1 mg/ml hyaluronidase in M2 to the drop of medium containing the eggs. Gently mix the solution by swirling the pipet tip around. Place the plate under a dissecting scope and observe the cumulus mass periodically over the next few minutes.

This will release the eggs by digesting the cumulus mass.

The exact concentration of hyaluronidase is not critical. In fact, a few crystals of powdered hyaluronidase can be sprinkled on the top of the medium drop and mixed in by gentle swirling with a pipet tip. If this method is used, the digestion should be watched closely under the dissecting scope and the solution diluted and eggs removed (step 15) as soon as the cumulus mass disperses. As the digestion progresses, gently swirl a pipet tip or an embryo transfer pipet through the solution to disperse the cumulus cells.

15. After digestion is complete, add an equal volume of M2 to further dilute the hyaluronidase solution. Using an embryo transfer pipet, pick up individual eggs and transfer them to a fresh drop of M2.

Figure 23.9.4B shows the isolated zygotes.

16. Transfer the eggs through several drops of M2 to dilute the remaining hyaluronidase. Then place the eggs in a microdrop of M16 microdrop culture. Store in a 37°C, 5% CO₂ incubator for the remainder of the procedure.

There isn't a specific time limit as to how long the eggs can be stored. The eggs are harvested and then injected over the course of the afternoon. It should be a continuous procedure completed within a single day.

If a CO₂ incubator is not available, the isolated eggs can be kept in an M2 drop under oil on a slide warmer set to ~37°C. Although not ideal, these conditions are usually adequate for eggs that will be injected immediately and then reimplanted into foster mothers on the same day.

Figure 23.9.4 Zygotes in the cumulus mass and after final isolation. **(A)** Photograph of the cumulus mass immediately after release from the swollen ampulla. Multiple fertilized eggs are visible in a mass of cumulus cells. **(B)** Photograph of zygotes after hyaluronidase treatment and subsequent transfer to a new microdrop. This is a mixture of fertilized and unfertilized eggs. Note the eggs with two pronuclei indicating fertilization. These are the eggs that are candidates for injection. The polar body is also visible in most eggs.

**BASIC
PROTOCOL 2**

INJECTION OF ZYGOTES

Conceptually, zygote injection is simple. Fertilized eggs are placed in a microdrop under a microscope. Individual eggs are gently grasped by aspiration with a pipet. A second pipet filled with DNA in solution is inserted into the pronucleus of the egg. The DNA solution is injected into the pronucleus by positive pressure and the pipet tip is rapidly removed. With this procedure, 100 to 200 eggs can be injected in 1 to 2 hr.

Materials

- M2 medium (Sigma or Specialty Media) containing 100 U/ml penicillin and 100 μ g/ml streptomycin (add antibiotics just before use)
- Embryo-tested mineral oil (Sigma)
- Zygotes (see Basic Protocol 1)

**Transgenic
Mouse
Production by
Zygote Injection**

23.9.8

M16 medium (Sigma or Specialty Media) containing 100 U/ml penicillin and 100 µg/ml streptomycin
Culture slide with a single ~18-mm-diameter 0.8-mm deep depression (i.e., depression slide, VWR)
Injection apparatus with holding pipet and injection pipet loaded with DNA solution (see Support Protocol 3)
Embryo transfer pipet (see Support Protocol 3)
37°C, 5% CO₂ incubator
Transgene in injection buffer (see Support Protocols 1 or 2)

Prepare injection apparatus

1. Prepare an injection chamber consisting of ~50 µl M2 medium containing 100 U/ml penicillin and 100 µg/ml streptomycin surrounded by embryo-tested mineral oil (Fig. 23.9.5A) on a culture slide with a single ~18-mm-diameter, 0.8-mm-deep depression.

A variety of injection chambers can be used. For example, a drop culture on a petri dish can also work; however, the sides of the petri dish may limit the angle at which the pipets can be placed. A depression slide has many advantages. It has good optical qualities and the pipet tips can be aligned at a very oblique angle without having to bend the ends.

2. Place the injection chamber on the stage of the injection apparatus. Focus on the drop under low power and then place zygotes at the 12 o'clock position in the injection chamber. Transfer only as many zygotes as can be comfortably injected in 20 to 30 min.

After they have been injected, the zygotes are transferred back to a drop culture of M16 pre-equilibrated in a CO₂ incubator (step 19).

The zygotes are placed in a specific region of the medium drop to separate injected and uninjected eggs. Injected eggs are moved to the 6 o'clock position (step 18). Obviously, any preferred organization of injected and uninjected eggs is acceptable as long as they can be separated.

Align holding pipet

3. Align the holding pipet with the tip above the injection chamber at an oblique angle to the microscope stage.
4. Using the course manipulator controls, bring the tip down to the top of the medium drop. Position the tip as illustrated in Figure 23.9.5B: in the 6 o'clock position and spanning the field of view.

In this orientation, when the tip is moved toward the 12 o'clock position, the pipet can be easily "found" as it crosses the field of view while looking through the eyepiece.

5. Look through the objective under low power while focused on the eggs and move the pipet across the field of view using course adjusters.

The tip will appear as a blur because it is out of focus, but it is easy to catch the motion.

6. Once the pipet is in the field of view, focus on it, and center the tip in the field. Then refocus on the zygotes and lower the pipet until the tip is in focus.

There are many ways to align the tips. The key is to be aware of the pipet tip and the bottom of the injection chamber. Don't lower the tip in the medium unless the tip is definitely in the field of view and the microscope is focused at the bottom of the microdrop. This will prevent breakage.

Figure 23.9.5 Injection chamber and pipet alignment. **(A)** Diagram illustrating top and side views of an injection chamber using a depression slide. **(B)** The upper diagram illustrates one method for bringing a pipet tip into alignment. Under low magnification, use the course controls to place the pipet in the 6 o'clock position with the top just at the surface of the microdrop. While looking through the microscope, focused on the zygotes in the bottom of the depression, move the pipet tip toward the 12 o'clock position. (The pipet will appear as an out-of-focus blur as it crosses the field of view.) Stop when the tip is centered in the field. Always know where the bottom of the chamber and the pipet tip are when moving the tip up and down, to avoid breakage. The middle diagram illustrates the correct orientation of both pipets for injection viewed from the side. The angle of the tips should be as oblique as possible while allowing the tip to reach the bottom of the chamber without the barrel of the pipet touching the rim of the chamber. The bottom diagram illustrates the correct orientation of both pipets for injection viewed from the top. Note that the pipet shafts are both oriented along the same straight line.

Align injection pipet

7. Repeat the procedure with the injection pipet. If the injection tip is open at the time the pipets are first aligned, make sure that the tip is under slight positive pressure before it is moved into the medium. Make sure the shafts of both pipets are oriented in the same straight line.

The final alignment is illustrated in the middle and bottom panels of Figure 23.9.5B.

If positive pressure is not applied before the tip enters the medium, it may backfill due to capillary action, possibly resulting in a full day spent injecting medium into zygotes instead

of DNA. Characteristics of the injection pipet are discussed in more detail elsewhere (see Support Protocol 3).

Prepare apparatus for injection

8. Center the pipet tips in the field of view. Focus on the zygotes and bring both tips into focus to ensure that all components are in the same vertical plane. Slowly backfill the holding pipet with a small volume of medium.
9. Change to the 10× objective and center the tips of both pipets again. Repeat the procedure after switching to the 20× objective and again with the 40× objective.

Whenever the stage is moved, the pipet tips should be raised to avoid breakage. The tips can be raised so they are just out of focus and appear as a hazy outline. Also make sure the tips are raised when they are near the zygotes and the stage is moved. Otherwise, the zygotes can be inadvertently swept into the oil phase and destroyed. Note that “sweeping” with the pipet can be used intentionally to reposition groups of eggs in the microdrop. With practice, adjusting the vertical position of the tips will become automatic. If a concave surface such as a depression slide is used for the injection chamber, take particular care with the location of the pipet tips when moving the stage. If the tips are close to the bottom of the depression slide and the stage is moved significantly, they may be broken on the higher rim of the chamber.

10. Check the flow of the injection pipet by placing the tip near an egg or small piece of debris and activating the injector.

The egg or debris should move slightly when exposed to the increased flow of DNA from the tip.

Grab egg with holding pipet

11. Look at the eggs under intermediate magnification (100× or 200×). Two pronuclei should be visible in the fertilized eggs (Fig. 23.9.4B).
12. Select a fertilized egg, and orient it so that the larger pronucleus is at the 3 o'clock position. Focus on the pronucleus and move the holding pipet up or down until it is also in focus.

The eggs can be moved and oriented in a variety of ways. They can be “batted,” rolled, or blown with the holding pipet. The shaft of the injection pipet can also be used to nudge or roll eggs; however, use of the tip of the injection pipet may result in clogging or damage and should be avoided. If a significant proportion of the eggs are not fertilized, it may be useful to separate unfertilized eggs from fertilized eggs by moving them to a different location on the drop. Note that there is often not much difference in the size of the pronuclei. Just pick the larger target if you can.

13. Bring the holding pipet into contact with the egg and gently increase the vacuum to grab it (Fig. 23.9.6A and B). Lift the egg slightly off the surface.

Inject the zygotes

14. Under high magnification (400×), refocus on the end of the holding pipet and the pronucleus. Bring the injection tip into focus at the 3 o'clock position.

When all three components are in focus, they should be in the same plane and ready for injection (Fig. 23.9.6A).

15. Bring the injection tip into light contact with the zona pellucida directly adjacent to the pronucleus. Check again to ensure the tip and pronucleus are in the same plane. Firmly push the tip into the egg and pronucleus in a firm, rapid, and continuous manner.

The path of the tip should be straight. Realignment of the tip while inside the egg will usually damage the egg. Avoid the nucleoli, as this material will often stick to the injection

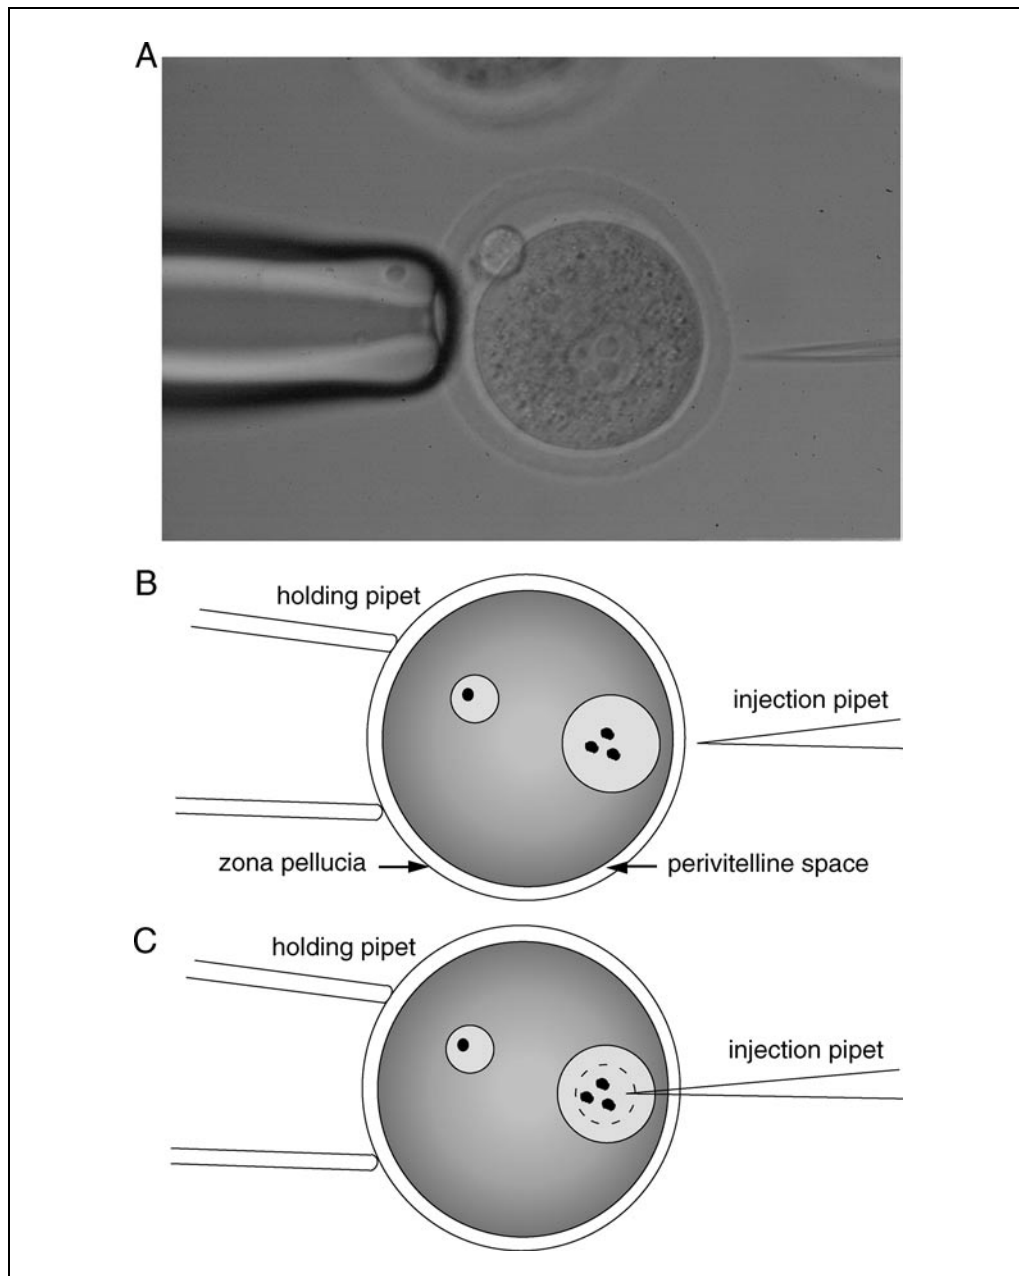

Figure 23.9.6 Alignment and injection. (A) Photograph of zygote attached to the holding pipet. The pronucleus that will be injected, the holding pipet, and the injection tip are all in focus. (B) Diagram of the same arrangement. Note the orientation of the zygote is such that the pronucleus that will be injected is adjacent to the injection pipet. (C) Diagram illustrating the injection tip after penetration. The pronucleus should swell visibly, but not lyse.

tip, resulting in clogging of the pipet and damage to the egg as the tip is pulled out with the adherent material. The egg should not roll. Rolling of the egg during injection indicates that the holding pipet, egg, and injection pipet were not properly aligned in the same plane.

16. Activate the injector. The pronucleus should swell noticeably (Fig. 23.9.6C) but not rupture.

The method of DNA injection will vary depending on the apparatus used. This is discussed in more detail in Support Protocol 3. The volume of DNA injected can be adjusted based on the swelling of the pronucleus. Use the visual feedback of the swelling pronucleus even when working with an automated injection system. Don't just assume that the equipment

is working properly. The formation of a bubble around the injection tip indicates that the egg membrane was not penetrated. Pull the tip back and try again.

17. Remove the injection tip in one quick, continuous motion when sufficient DNA has been injected.
18. Move the injected egg to the 6 o'clock position in the microdrop by moving the stage. Return to the 12 o'clock position and repeat the injection procedure.
19. After injecting all the fertilized eggs in the chamber, remove the injected eggs using an embryo transfer pipet and place them in a microdrop of M16 containing 100 U/ml penicillin and 100 µg/ml streptomycin. Transfer to a 37°C, 5% CO₂ incubator.

Typically, eggs are injected in batches that can be completed in 20 to 30 min and then collected in the incubator. In this way, several hundred eggs can be injected in the course of an afternoon without any individual egg spending more than ~30 min out of the incubator; however, the exact time that eggs spend in or out of the incubator is not critical. Fertilized eggs from most of the standard strains used for transgenics are fairly hardy. Injected eggs that have been severely damaged by the procedure will become obvious within the first 30 min, while surviving eggs will remain viable in the incubator for an entire afternoon.

20. Remove the remaining unfertilized or damaged eggs and discard.
21. Add more eggs to the injection chamber. Repeat the experiment, remembering to work with only as many eggs as can be injected in 20 to 30 min.

Expect to be able to inject 100 to 200 eggs in 1 to 2 hr with experience.

Monitor the number of eggs that survive injection within each group. If the number changes dramatically between groups, it may indicate that the injection tip is damaged or dirty and needs to be changed. Replace the injection pipet if there is debris stuck on the end or if the DNA is not flowing properly. Eggs that have died will look significantly different. The cytoplasm will expand to the edge of the zona pellucida; there will be no perivitelline space (Fig. 23.9.6B). Dead eggs will seem less dense and have a tendency to float or roll around when the microdrop is moved. The percentage of eggs that survive is dependent on many factors. Expect 60% to 80% of the eggs to survive under normal circumstances.

TRANSFER OF OVIDUCTS TO FOSTER MOTHERS

Injected zygotes must be surgically implanted into foster mothers to allow embryos to develop to term. Single-cell zygotes are reimplanted into the oviducts of 0.5-day-p.c. pseudopregnant females. Approximately 20 days after reimplantation, pups will be born.

Materials

- M2 medium (Sigma or Specialty Media) containing 100 U/ml penicillin and 100 µg/ml streptomycin
- Injected zygotes (see Basic Protocol 2)
- Modeling clay (VWR, WL6852)
- 0.5-day-p.c. Pseudopregnant females
- 2.5% avertin (see recipe)
- 70% ethanol
- Analgesics per institutional requirements
- Embryo transfer pipets (Support Protocol 3)
- 1-ml, $\frac{3}{8}$ -in. tuberculin syringes with 26-G needles
- Surgical equipment and supplies (Support Protocol 3):
 - Electric clippers
 - Scissors
 - Toothed and blunt forceps
 - Iris scissors
 - Serrefine clamp

BASIC PROTOCOL 3

Manipulating
the Mouse
Genome

23.9.13

Sutures
Surgical staples
Dissecting microscope with overhead illumination
30-G needle (VWR)
Heating element (see Support Protocol 3)
Fresh mouse cages

NOTE: Follow institutional animal care guidelines for survival surgery.

NOTE: Trying both oviduct puncture and infundibular transfer is recommended. Use whichever is least difficult.

Prepare embryos

1. Prior to implantation, transfer embryos to a fresh drop of M2 containing 100 U/ml penicillin and 100 µg/ml streptomycin but without oil.

This helps to minimize the transfer of oil into the oviduct. Inspect each egg at this stage. Transfer only those eggs which still look healthy. Healthy zygotes should have a distinct perivitelline space (Fig. 23.9.6B).

2. Load 10 to 20 embryos into each embryo transfer pipet. Place the loaded transfer pipets on the bench top, supported by a strip of modeling clay.

Zygotes for oviduct transfer should be packed fairly tightly with a minimum of space between each egg. This will minimize the total volume of fluid transferred into the oviduct.

Prepare ovaries for implantation

3. Anesthetize a 0.5-day-p.c. pseudopregnant female with 0.017 ml/g of 2.5% Avertin i.p. via a 1-ml, $\frac{3}{8}$ -in. tuberculin syringe and 25-G needle.

An analgesic (e.g., Flunixin 2.5 mg/kg SQ, Ketoprofen 5 mg/kg SQ, or buprenorphine 0.05 mg/kg) may be administered at this stage if recommended by the institution.

4. Shave the hair around the incision site (Fig. 23.9.7A) with electric clippers. Swab the area with betadine followed by 70% ethanol.
5. Using scissors, make an incision ~1-cm long in the skin on the midline of the back (Fig. 23.9.7A).
6. Place the mouse under a dissecting scope with overhead illumination. Slide the opening down the right or left side of the mouse until the ovaries or ovarian fat pad are visible through the peritoneal wall.

In young females, the ovaries (pink) and ovarian fat pad (white) are visible through the peritoneal wall. As the females age, the ovaries are often obscured by fat. The ovarian fat pad is often more white than the obscuring fat, which is slightly yellow.

7. Grasping the peritoneal wall with toothed forceps, make a small incision (~0.5 cm) in the peritoneal wall, over the ovaries, using fine iris scissors. Avoid blood vessels.
8. Grasp the ovarian fat pad with blunt forceps and pull the ovaries and proximal end of the uterine horn out of the incision. Attach a small serrefine clamp to the ovarian fat pad and rest the clamp on the side of the animal to free the hands (Fig. 23.9.7B).
9. Orient the oviduct by gently rotating the serrefine clamp so that the region just proximal to the infundibulum is visible (Fig. 23.9.8A and B).

Look for the infundibulum, which is best observed under 20× to 25× magnification, to achieve the proper orientation. This can be difficult to find. The infundibulum is under the transparent bursa and often hidden by folds of the oviduct. Once the oviduct opening is

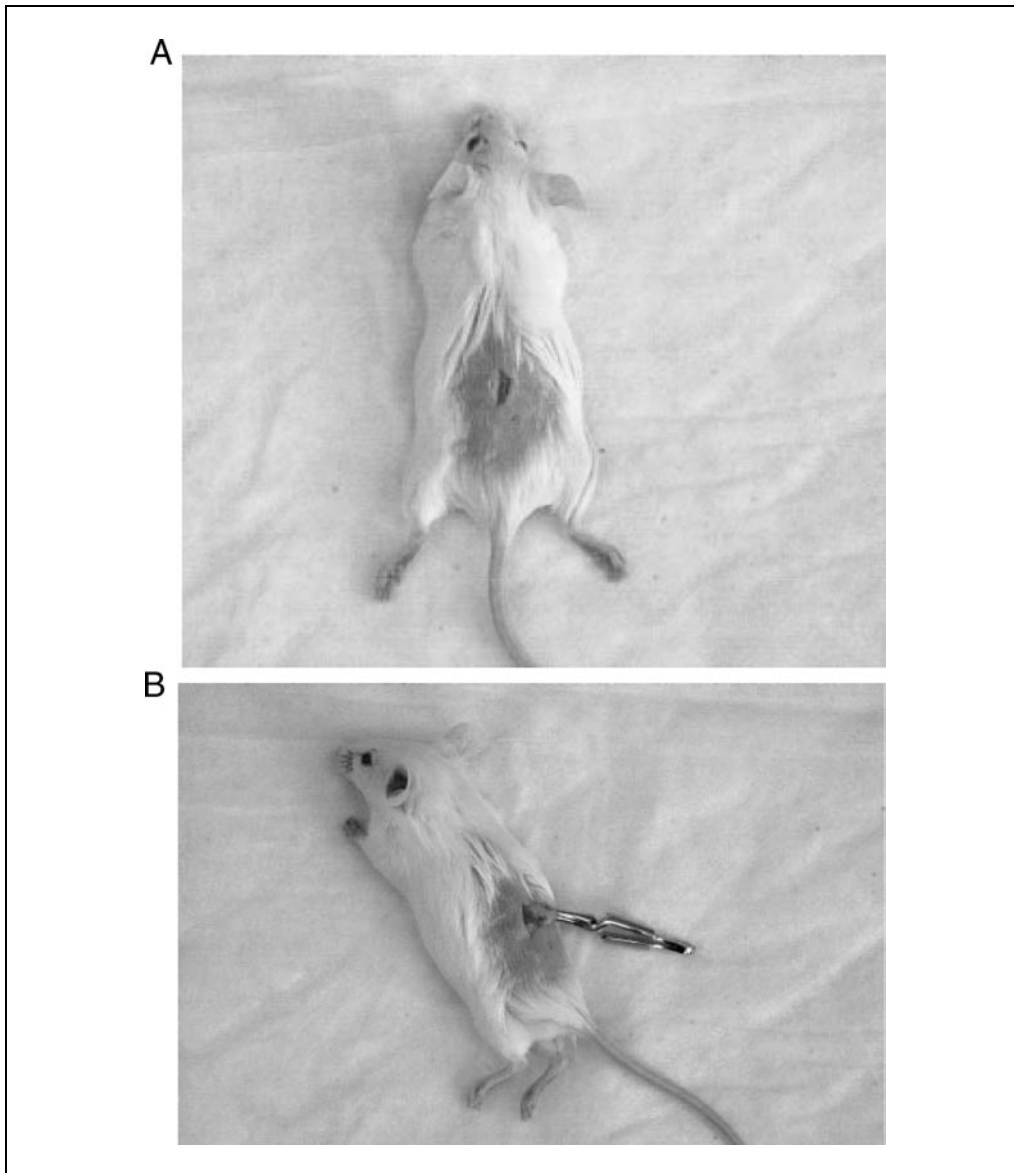

Figure 23.9.7 Oviduct Reimplantation. **(A)** Photograph showing the location of the central skin incision site. Note that the area around the site has been shaved. **(B)** Photograph showing the orientation of the mouse for reimplantation with an extruded ovary and fat pad held by a serrefine clamp.

found, follow it back past one bend to identify the site for a puncture transfer. This is the same region where the swollen ampulla is found in a superovulated female.

Implant injected zygotes

For oviduct puncture

- 10a. Grasp the region of the oviduct gently with fine forceps. Puncture the oviduct in the location indicated in Figure 23.9.8B by pushing a 30-G needle through the tissue and between the forceps tips, making sure it enters the oviduct lumen.

Minimize tissue damage with the needle and forceps. Observe the site of puncture as the needle is removed. The site is usually marked by a small indentation in the surface or by a small amount of bleeding. Observe how the tissue moves if the forceps are removed so that the opening can be found again to insert the transfer pipet.

- 11a. Insert the embryo transfer pipet into the opening and expel the embryos and air bubbles into the lumen.

Figure 23.9.8 Reimplantation in the oviduct. (A) Photograph of the oviduct ready for reimplantation. (B) Diagram of the oviduct and alternative reimplantation sites. Note the location of the puncture site for puncture transfers and the infundibulum for infundibular transfers.

Use the bubbles in the transfer pipet as a marker to ensure that the eggs are expelled into the lumen. The bubbles also serve as an indicator of how much of the transfer pipet has been inserted into the lumen. The ejected bubbles are visible in the oviduct lumen and function as a positive indicator of a successful transfer. Avoid introducing oil into the lumen.

For infundibular transfer

- 10b. Locate the infundibulum underneath the transparent bursa and under the folds of the oviduct (Fig. 23.9.8B). Gently tear open the bursa over the infundibulum using fine forceps.

Do not tear the fine blood vessels in the bursa: localized bleeding will obscure the view.

- 11b. Place the loaded transfer pipet into the infundibulum and expel the air bubbles and eggs into the oviduct.
12. Gently reposition the uterus and ovary in the peritoneal cavity. Use one suture to close the peritoneal wall.
13. If desired, repeat the procedure on the other side.

Embryos do not need to be implanted on both sides. Several factors may affect this decision. Distributing the injected eggs in more foster mothers decreases the loss caused by a surgical death or the loss caused by poor maternal care of a litter; however, these are not common problems for an experienced investigator using outbred pseudopregnant foster mothers. Alternatively, implanting into both uterine horns reduces the number of pseudopregnant females required and thus reduces the size of the mouse colony necessary to generate the pseudopregnant females. The transfers can be completed more quickly because fewer animals need to be prepared for surgery.

14. Close the incision in the skin with surgical staples.

Staples are used rather than sutures because mice will often reopen an exterior wound that is closed with sutures.

Allow mouse to recover

15. Place the mouse on a heating element (i.e., slide warmer or heating pad) until she begins to show signs of recovery (10 to 30 min). Place her in a clean cage.

Multiple recipients may be caged together. There are advantages and disadvantages to separating the foster mothers before the pups are born. With multiple births in the same cage, it is difficult to keep track of the success of individual surgeries and the cages may become overcrowded. Alternatively, some new mothers, particularly those with small litters, often take better care of their litters when there are other new mothers in the cage. Swiss Webster or ICR foster mothers are generally very good mothers under all conditions.

16. Monitor the mouse over several days. Administer analgesics as required by the institution.

With practice, there are virtually no complications. Bleeding should be minimal and usually only at the skin incision site. The mice should display normal behavior by the next day. Incision site infections are rarely observed.

PREPARATION OF PLASMID-BASED TRANSGENE DNA

Traditionally, transgenes have been constructed in plasmid-based vectors. Small quantities of DNA are required for the actual injection; however, the DNA preparation must be very clean to avoid toxicity in the zygote. In addition, vector sequences are commonly removed from the construct prior to injection to prevent these sequences from altering its expression characteristics. There are many protocols that will provide clean transgene fragments suitable for zygote injection. This protocol is a relatively simple procedure that involves separating the transgene from the vector using a low-melt agarose gel followed by fragment purification using an Elutip-d column.

Additional Materials

- Plasmid DNA containing transgene construct (*UNIT 1.7*)
- Low-melting-point agarose (e.g., Roche)
- TAE or TBE (*APPENDIX 2A*)
- Elutip low-salt solution (see recipe), 42°C

SUPPORT PROTOCOL 1

**Manipulating
the Mouse
Genome**

23.9.17

Elutip-d column (Schleicher & Schuell)

Elutip high-salt solution (see recipe)

70% ethanol

Plasmid injection buffer (see recipe)

42° and 65°C water baths

5- and 10-ml syringes

Additional reagents and equipment for restriction enzyme analysis (UNIT 3.1), agarose gel electrophoresis (UNITS 2.5A & 2.6), and ethanol precipitation (UNIT 2.1A)

Isolate fragments on a low-melting-point agarose gel

1. Cut ~50 µg plasmid DNA with restriction enzymes that will separate the contiguous transgene from the vector (UNIT 3.1).

Because the insert will be removed by subsequent purification steps, any standard method can be used to prepare the plasmid DNA, ranging from Qiagen kits to traditional alkaline lysis protocols (UNIT 1.6); however, the preparation should be relatively free of contaminating RNA and protein.

2. Prepare a 1% gel from low-melting-point agarose (UNIT 2.6) in TAE or TBE without ethidium bromide. Load one lane with size markers. Load the digested transgene in several adjacent lanes or a single broad lane. Run the gel.

Ethidium bromide in combination with UV light can cause DNA nicking, resulting in damage to the transgene.

3. After the gel has run long enough to separate the transgene from the vector, cut the gel lengthwise to include the standard lane and a small section of the sample lane if a broad lane was used or one of the lanes loaded with transgene if multiple sample lanes were loaded.

Be gentle when handling low melt 1% gels, because they will break apart very easily.

4. Stain the fragment of the gel containing the standard lane with ethidium bromide (UNIT 2.5A).

5. View the stained gel under UV light (UNIT 2.5A). Identify the transgene fragment based on its migration relative to the standard. Cut out the region of the gel containing the fragment.

CAUTION: Remember to wear appropriate eye protection and avoid exposure of any bare skin to the UV light source.

6. Realign the ethidium-stained gel fragment with the remaining untreated portion of the gel. Using the cut portion of the gel as a template, excise the region of the untreated gel containing the transgene fragment and transfer to a microcentrifuge tube.

This fragment of low-melt agarose contains the transgene fragment isolated from the vector and has never been exposed to ethidium bromide or UV light.

Purify fragment

NOTE: Care should be taken with all the solutions from this stage on. Use high-grade water and embryo- or cell-culture-tested reagents. This will prevent embryo-toxic contaminants from ending up in the final DNA preparation.

7. Add 10 gel volumes Elutip low-salt solution and melt the gel fragment at 65°C. After the gel fragment is completely dissolved, place the tube in a 42°C water bath.

8. Prepare the Elutip-d column by washing with 3 ml Elutip high-salt solution, room temperature, followed by 3 ml Elutip low-salt solution, 42°C, per manufacturer's instructions.

Use a clean syringe for the low-salt solution to avoid transfer of the high-salt solution to the Elutip column. The DNA binds to the Elutip in low salt.

9. Run the melted gel fragment through the Elutip column followed by an additional 3 ml low-salt solution, 42°C.

Don't press the syringe plunger with too much force. The column material can be pushed out of the column if too much force is applied.

10. Elute the bound DNA with 400 µl Elutip High-Salt Solution.

11. Ethanol precipitate the DNA (UNIT 2.1A) and wash several times with 70% ethanol to remove residual salt.

These washes are important because the DNA is eluted from the column in 1 M NaCl. This concentration of salt is toxic to the zygote. Do not use a carrier (e.g., glycogen) to facilitate the precipitation as this would also be injected into the zygote.

Prepare DNA for injection

12. Dry the pellet and resuspend in 50 to 100 µl plasmid injection buffer.

This solution may be stored frozen, but avoid repeated freezing and thawing.

13. Estimate the DNA concentration by running an aliquot on a 1% agarose gel with a known amount of size standards (UNIT 2.5A).

This step is also a good check for the purity of the prep. The fragment should appear as a single sharp band. There should be no smearing of the band which might indicate degradation or shearing of the fragment. There should be no visible vector band.

14. Dilute an aliquot of the preparation to a final concentration of 1 to 3 ng/µl in plasmid injection buffer.

PREPARATION OF BAC-BASED TRANSGENE DNA

Preparation of bacterial artificial chromosome (BAC) DNA for microinjection is somewhat different than for plasmid DNA. First, due to its large size, BAC DNA is much more susceptible to shearing damage. Tubes should never be vortexed or even shaken vigorously while the DNA is in solution. Second, there is little evidence that vector sequences affect BAC transgene expression; therefore, unlike plasmid-based transgenes, the insert does not need to be separated from the vector. Third, recent observations from many laboratories have shown that the BAC transgene does not need to be linearized prior to injection to produce founders efficiently.

There are a variety of methods to prepare BAC DNA. A method using the Nucleobond system from Clontech is described below. This system relies on a column containing an anion-exchange resin. The basic method is described in detail in the product literature but is slightly modified below to combine the endotoxin-free plasmid protocol with the low copy plasmid protocol. In addition, particular points relevant to transgene preparation are highlighted.

Materials

- BAC-transfected bacteria (e.g., UNITS 1.8 & 5.9)
- LB medium (UNIT 1.1)
- Nucleobond Plasmid EF Maxi Kit (BD Biosciences):
 - S1-EF buffer
 - RNase A

SUPPORT PROTOCOL 2

**Manipulating
the Mouse
Genome**

23.9.19

S3-EF buffer
N3-EF buffer
N5-EF buffer
Nucleobond AX 500 column
Filter
2-propanol
70% ethanol
BAC injection buffer (see recipe)

Additional reagents and solutions for agarose gel electrophoresis (*UNIT 2.5A*)

NOTE: Mega or giga kits can be used to process a larger volume of overnight culture. Remember to adjust the buffer volumes accordingly if larger cultures are used.

Isolate BAC DNA–containing bacteria

1. Prepare a 500-ml culture of BAC-transfected bacteria in LB medium and incubate overnight at 37°C, unless otherwise specified for the specific BAC or host bacteriological strain.
2. Transfer the culture to centrifuge bottles and centrifuge 10 min at 6000 × g, 4°C. Discard supernatant and gently resuspend the pellet in 24 ml Nucleobond S1-EF buffer plus RNase A.

Because the BAC is not processed after purification, the endotoxin-free (EF) system is used to ensure that the final preparation will not be toxic to zygotes. When following the Nucleobond protocol, note that the BAC protocols use a larger volume of many of the solutions. Do not use bacterial pellets from volume cultures that are larger than those recommended. The protocols are also optimized for LB medium cultures. If richer medium is used, the bacteria yield will be greater but may overload the columns, resulting in dirtier preps.

Lyse bacteria and remove insoluble fraction

3. Add an equal volume of S2-EF buffer and mix gently by inverting the tube. Incubate at room temperature for 2 to 5 min.

Do not vortex and do not shake the tube. Vigorous mixing will shear the BAC and will release bacterial DNA that will contaminate the prep.

Do not incubate the solution for longer than 5 min. Prolonged exposure to alkaline conditions (S2) can lead to irreversible denaturation of the BAC.

4. Neutralize the solution by adding 24 ml S3-EF buffer. Mix gently by inversion and place on ice for 5 min.

Steps 1 through 4 are essentially identical to any standard alkaline lysis plasmid prep. A white precipitate forms with the addition of the potassium acetate solution (S3). The majority of the bacterial protein and DNA should precipitate at this stage.

5. Centrifuge the suspension 15 min at 12,000 × g, 4°C. Collect the supernatant.
6. Pour the supernatant through the prewetted filter provided in the Nucleobond Plasmid EF Maxi kit and collect filtrate.

Purify and analyze BAC DNA

7. Pour the lysate onto a pre-equilibrated Nucleobond AX 500 EF column. Collect the eluent and pour it back through the column.
8. Wash the column twice with 18 ml N3-EF buffer.
9. Elute the BAC with 15 ml of buffer N5-EF buffer.

10. Add an equal volume of room-temperature 2-propanol. Mix gently and incubate 15 to 20 min at room temperature.
11. Centrifuge the mixture 30 min at $15,000 \times g$, 4°C .
12. Wash the pellet several times with 70% ethanol to remove residual salt. Allow the sample to air dry. Resuspend the pellet in BAC injection buffer.

DNA can be stored at 4°C . Larger DNA fragments are more likely to be damaged by freezing and thawing, therefore, freezing of the BAC DNA is not recommended.

Prepare BAC DNA for injection

13. Estimate the DNA concentration by running an aliquot on a 0.8% agarose gel with a known amount of size standards (UNIT 2.5A).

This step is also a good check for the purity of the prep. The fragment should appear as a single sharp band. It may be helpful to run uncut BAC and BAC digested with a restriction enzyme (UNIT 3.1) to get a better impression of the quality of the DNA. The intact BAC will not migrate very far. BAC digested with a restriction enzyme should display clear, crisp restriction fragments. Smearing of the fragments suggests that there may have been significant sheering of the original BAC. Smearing in the lane suggests that there is bacterial genomic DNA contamination of the prep.

14. Dilute an aliquot of the preparation to a final concentration of 1 to 2 ng/ μl in BAC injection buffer.

PREPARATION OF EQUIPMENT FOR SURGERY, EMBRYO TRANSFER, AND EGG INJECTION

SUPPORT PROTOCOL 3

Surgical/dissection equipment and instruments

Surgical instruments should be washed thoroughly before use and sterilized by autoclave or glass bead sterilizer. Table 23.9.2 presents examples of useful instruments. Similar instruments can be obtained from several companies. Individual investigators may prefer slightly different tools.

Table 23.9.2 Surgical Instruments^a

Instrument	Supplier
Betadine	VWR
Electric clippers	Harvard Apparatus
Forceps, small (4 in.) curved	BRI
Forceps, large (4 in.), curved	BRI
Forceps, toothed, 3.5 in.	BRI
Forceps, fine, $4 \frac{3}{8}$ in.	BRI
Glass bead sterilizer	Fine Science Tools
Scissors, large (4.5 in.)	Biomedical Research Instruments
Scissors, small (3.5 in.)	BRI
Scissors, iris, 3 in.	BRI
Serrefine clip	BRI
Suture, 5-0 Dexon II on T-31 needle	Kendall Health Care (or equivalent)
Wound clip applicator	Fisher
Wound clips	Fisher

^aA glass bead sterilizer provides a convenient and rapid bench-top sterilizer for surgical instruments.

Warming element

Anesthetized mice can suffer from hypothermia. The embryo transfer itself can be performed rapidly enough so that the surgical platform does not need to be heated; however, during the longer recovery phase, the mouse should be warmed until it shows signs of activity. Electric or chemical heating pads are useful portable warmers. A slide warmer is a good alternative in a dedicated surgical area, because the surface can be sterilized easily and the temperature can be controlled accurately.

Embryo transfer pipet

Embryo transfer pipets are prepared from 25- μ l disposable microcapillary pipets (e.g., Fisher). Pipets can be purchased with a mouth-pipet apparatus that consists of a pipet connector, tubing, and a mouthpiece. It is often convenient to replace the tubing with a longer piece of Tygon tubing. Hold the pipet over a small flame at its center. Gently rotate the capillary to ensure uniform heating. When the glass begins to turn orange from the heat, remove it from the flame and simultaneously pull the ends apart. Pull straight apart until the capillary breaks to produce two transfer pipets with flush ends. Note that if the capillary is pulled while the glass is still in the flame, the ends will be too fine. The exact diameter of the opening is not critical (100 to 150 μ m); however, it must easily admit a zygote.

For maximum control, the capillary should be back-filled with mineral oil slightly beyond the point where the capillary thickens to its largest internal diameter. A small volume of M2 medium is then aspirated prior to manipulating embryos. Before loading injected eggs for reimplantation, put two small air bubbles in the tube before the eggs and one bubble after. These act as markers that are highly visible to ensure that all of the eggs are transferred into the oviduct. Introduce the bubbles by gently aspirating air while the tip is out of the medium. Note that there is no reason to use air bubble markers unless the pipet is being loaded for reimplantation. Practice is required to make the transfer pipets and to become comfortable moving embryos using mouth control of the pipet.

Injection and holding pipets

Injection and holding pipets can be purchased from a variety of vendors (e.g., Eppendorf, The Pipette Company, Research Instruments, Zavos Diagnostic Laboratories). The pipets can also be made, but require the purchase of a pipet puller and microforge. The procedure also requires significant practice to produce quality pipets consistently. It is recommended that an inexperienced injector purchase premade tips until familiar with the injection procedure and the characteristics of properly designed pipets.

Injection pipets are typically loaded with the DNA solution (see Support Protocols 1 and 2) through the back end using a fine microcapillary pipet. Eppendorf sells a microloader for their injection pipets. Alternatively, a loading pipet can be made by pulling a microcapillary pipet (e.g., Fisher) in a flame similar to the procedure for making an embryo transfer pipet (see above); however, the glass is heated more intensely and pulled to produce a much finer end. Only several microliters of the DNA solution needs to be loaded into the injection pipet. Make sure that the pipet is loaded so that there are no air bubbles near the tip.

Injection apparatus

The injection apparatus consists of three main components: the microscope and table, the micromanipulators, and the microinjectors.

Figure 23.9.9 Injection apparatus. Photograph of a typical injection apparatus. This mixed system is based on a Zeiss Axiovert microscope with Narishige manipulators. The microinjector (not shown) for the holding pipet is a simple threaded syringe resting on the right side of the microscope connected by tubing to the pipet holder on the left side. The micromanipulator for the holding pipet is on the left side. Also on the left-hand side is an Eppendorf FemtoJet microinjector. This can be activated by a foot pedal (not shown). The entire system rests on an air isolation table.

Microscope and table

Many microscope configurations can be modified to work for zygote injections. The major components of the apparatus are illustrated in Figure 23.9.9. The basic microscope is an inverted scope with a fixed stage (e.g., Nikon, Leica Microsystems, or Zeiss). Several microscope vendors, as well as secondary vendors, market complete injection setups suitable for both zygote and blastocyst injections (e.g., Leica Microsystems, Nikon, McBain Instruments, Morrell Instrument). Under most circumstances the microscope must be placed on some type of isolation table, for example, a Micro-g (Fullam) or Kinetic Systems air table to prevent vibrations from adversely affecting the injection procedure.

It is convenient to have a range of objectives (e.g., 4 \times , 10 \times , 20 \times , and 40 \times) in combination with a standard 10 \times eyepiece. Pipets are aligned most easily under low magnification (40 \times), while the injections should be performed under high magnification (400 \times). The intermediate magnifications are useful for maintaining orientation, screening egg quality, and moving zygotes to different regions of the microdrop. Phase objectives are sufficient, but a better image can be obtained using Nomarski differential interference contrast optics. Note that a glass injection chamber must be used to take advantage of Nomarski optics. Also, consider the addition of a video camera and monitor. Although not necessary, a video system is an invaluable teaching tool.

Micromanipulators

Micromanipulators are another critical component of the injection apparatus. They are used to control the motion of the micropipets. There are several different types available. Narishige and Eppendorf controls are probably the most commonly used. These are

available in a variety of styles and are designed to attach to most standard microscopes. Manipulators that attach directly to the microscope frame are much preferred over those that rest on the microscope table. Purchase a system that allows both coarse and fine control of the pipets in all three dimensions. The coarse controls are used to set the general orientation of the pipet tips and the fine controls are used for the injections.

Microinjectors

The microinjectors are the devices used to control the action of the micropipets: aspiration or ejection. The microinjector connected to the holding pipet is basically a syringe connected by tubing to a pipet holder. The system can be oil or air filled. Some users find an oil-filled system provides slightly more control. Eppendorf and Narishige systems are probably used most commonly. The microinjector and micromanipulator for the holding pipet are placed on opposite sides of the microscope so that both controls can be manipulated simultaneously. The most common controller for the injection pipet is probably the Eppendorf FemtoJet (Fig. 23.9.9). This is basically a controllable compressor connected by tubing to a micropipet holder. Note that both microinjectors can be "homemade;" however, an inexperienced user will have less difficulty with devices designed specifically for pronuclear injection.

REAGENTS AND SOLUTIONS

Solutions should be prepared from tissue-culture or embryo-grade reagents whenever possible. Water should be tissue-culture grade (high resistance and endotoxin free) for all solutions that will come in contact with eggs. Sterilize all final solutions by filtration or prepare from sterile stocks. Use of disposable sterile plasticware is advised to prevent microbial and detergent contamination. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Avertin, 2.5%

Prepare a working stock solution (2.5% avertin) by adding 2.5 ml of 100% avertin (see recipe) to 100 ml PBS (APPENDIX 2A) prewarmed to 37°C. Shake the container until the avertin is completely dissolved. Store up to several months in the dark at 4°C.

Avertin, 100%

Dissolve 5 g 2,2,2-tribromoethanol (Aldrich) in 5 ml *tert*-amyl alcohol (Aldrich). Make sure reagents are at room temperature before mixing. Shake the container until all the tribromoethanol is in solution. Store up to several months in the dark at 4°C.

Toxic decomposition products can accumulate. Discard any questionable solutions. Purchase components in small amounts (5 ml and 5 g). There is batch-to-batch variation; therefore, with some preparations, a dose that is 5% to 10% higher than the recommended 0.017 ml/g must be administered for complete anesthesia.

BAC injection buffer

Prepare a 1000× stock solution of 30 mM spermine and 70 mM spermidine in water. Sterilize by passing through a 0.22- μ m filter. Prepare 1-ml aliquots and store up to 1 year, frozen at -20°C.

Prepare a base solution composed of 10 mM Tris-Cl, pH 7.4 (APPENDIX 2A), 0.1 mM EDTA, and 100 mM NaCl. Pass through a 0.22- μ m filter to sterilize and store up to 6 months at 4°C.

Dilute the spermine and spermidine stock solution 1:1000 in base solution just prior to use.

continued

NOTE: Reagents and water must be of the highest grade.

Although a simple plasmid injection buffer (Tris and EDTA) can be used for BAC injections, this modified buffer has been reported to increase the yield of transgenics when using large constructs (Montoliu et al., 1995). This is attributed to the stabilization of the larger constructs by the salt and polyamines.

The final concentrations are 10 mM Tris·Cl, pH 7.4, 0.1 mM EDTA, 100 mM NaCl, 30 μ M spermine, and 70 μ M spermidine.

Elutip high salt solution

1.0 M NaCl
20 mM Tris·Cl, pH 7.4 (APPENDIX 2A)
1.0 mM EDTA
Store up to 6 months at room temperature

Elutip low salt solution

0.2 M NaCl
20 mM Tris·Cl, pH 7.4 (APPENDIX 2A)
1.0 mM EDTA
Store up to 6 months at room temperature

HCG, 50 U/ml

Resuspend lyophilized human chorionic gonadotropin (HCG; also known as Pregnyl; Organon) powder in sterile PBS to a final concentration of 50 U/ml. (Store lyophilized powder up to the expiration date indicated on the vial at 4°C.) Store solution up to 6 months in 1-ml aliquots at -80°C . Avoid multiple freeze/thaw cycles.

Microdrop cultures

Prepare microdrop cultures by placing a small volume of M2 or M16 (50 to 150 μ l) on a petri dish. Cover the drop with mineral oil (Sigma, M-8410, embryo tested) to prevent evaporation. Equilibrate M16 microdrip cultures 30 min in a 37°C, 5% CO₂ incubator. Use fresh drops daily.

Note that M2 will maintain the proper pH in room air, while M16 requires 5% CO₂ to maintain proper pH.

Plasmid injection buffer

10 mM Tris·Cl, pH 7.4 (APPENDIX 2A)
0.1 mM EDTA
Pass the solution through a 0.22- μ m filter to sterilize
Store up to 6 months at 4°C

Reagents and water must be embryo or tissue culture grade.

PMS, 50 U/ml

Prepare a filter-sterilized 1 mg/ml BSA solution in PBS (APPENDIX 2A). Resuspend lyophilized pregnant mare's serum (PMS; also known as Gestyl; Professional Compounding Centers of America) in the BSA solution to a final concentration of 50 U/ml. (Store lyophilized powder up to the expiration date indicated on the vial at 4°C.) Store the solution up to 6 months in 1-ml aliquots at -80°C . Avoid multiple freeze/thaw cycles.

COMMENTARY

Background Information

The first transgenic mouse produced by pronuclear injection was described by Gordon et al. (1980). In this report, a pBR322-based plasmid containing herpes simplex virus and simian virus 40 DNA sequences was introduced into the mouse genome. Within months, several other groups reported similar success (Brinster et al., 1981; Constantini and Lacey, 1981; Harbers et al., 1981; Wagner et al., 1981a,b). These initial papers documented the fundamental aspects of a useful transgene: integration into the genome, expression in the resultant mouse, and transmission of the transgene to offspring. Pronuclear injection rapidly became the most common method for introducing specific DNA sequences into the mouse genome.

Alternative methods for the introduction of foreign DNA into the mouse genome do exist. Infection of preimplantation embryos with retroviruses had been reported during the period that pronuclear injection was gaining popularity (Jahner et al., 1985; van der Putten et al., 1985), but the method was not pursued extensively. Recent interest in the development of vectors for gene therapy has led to a reemergence of interest in the use of retroviruses for the production of transgenic mice. Lois et al. (2002) reported the germline transmission of transgenes introduced by lentiviral vector infection of single-cell embryos. The virus could be introduced by injection into the perivitelline space (Fig. 23.9.6B) or by co-incubation with denuded zygotes. The later method obviates the need for expensive injection equipment; however, there are some limitations that restrict the use of this methodology. For example, the transgene cannot exceed 10 kb, because of constraints of the lentiviral vector. In addition, the virus integrates as single segregating copies; therefore, transgenes requiring the integration of multiple linked copies for high level expression may not function effectively. DNA may also be introduced into mice by transfection into mouse embryonic stem (ES) cells followed by blastocyst-mediated transgenesis (see *UNITS* 23.5 & 23.7). This method is used primarily for the production of site-specific alterations in the mouse genome.

Historically, the vast majority of transgenes have been constructed in high-copy-number plasmids which restrict the insert size to <20 kb in most cases. Larger transgenes can be constructed in yeast artificial chromosomes

(YACs) and bacterial artificial chromosomes (BACs). YAC transgenics have been generated by pronuclear injection (Schedl et al., 1992) and by ES cell transfection followed by blastocyst-mediated transgenesis (Strauss et al., 1993). BAC transgenics created by pronuclear injection are now widely used for several reasons. Transgenes created from large genomic fragments typically display correct developmental and tissue-specific expression patterns. The availability of high quality, arrayed BAC libraries encompassing the mouse or human genome makes identification and isolation of specific clones relatively trivial. Finally, comprehensive sequence information obtained from genome sequencing projects in conjunction with new methodologies for site-specific modifications of BACs (Lee et al., 2001; Testa et al., 2004) have made the production of complex BAC transgenes a relatively simple procedure.

Critical Parameters and Troubleshooting

Creating transgenics by the injection of zygotes is a difficult procedure. Problems can occur in each of the three main steps: zygote isolation, injection, and reimplantation. To avoid problems, each of these steps requires both familiarity with the protocol and practice. It is best to practice the procedures separately before trying to combine them on a single day. Many of the problems are under the investigator's control; however, some aspects of these protocols rely on the basic biology of mice and are not entirely under the control of the investigator.

Low yield of eggs from superovulated females

Low egg yields can usually be attributed to the superovulation reagents or procedure, or to the female mouse. Check the concentration, age, and storage conditions of the PMS and HCG. Prepare new batches if there is any question. Make sure to administer the HCG 46 to 48 hr after the PMS and to coordinate the injections with the light/dark cycle. Check to make sure the light cycle has not been changed inadvertently. Verify the age of the female mice. Many strains produce their greatest egg yields before the females go through their first estrus cycle. This means that they should be used between 3 and 4 weeks of age. Females older than 2 months typically have smaller egg yields. The strain of the female mouse plays an

important role: some strains will never produce a large quantity of eggs. If a low-yield strain must be used, the number of matings should be increased. Finally, it is worth noting that any routine will have bad days because of the inherent biological variability of the system. The only way to ensure adequate egg yields for every day is to set up more matings, but this is probably not cost effective if egg yields are adequate for most days.

Low yield of fertilized eggs

Problems with the percentage of eggs that are fertilized can usually be attributed to the males or to factors that affect mating behavior. Check plugs on a regular basis. If there are few plugs, there will not be many fertilized eggs. Mating records should be kept for all stud males. Males that routinely injure females or that fail to plug regularly should be replaced. There is often a strain-specific decline in fertility as the males age, even if they plug females on a regular basis. As a general rule, males should be replaced when they reach 6 to 8 months of age, although many strains last longer. Try to stagger the ages of the stud males so that they are not all replaced at one time. Check the environment of the egg production colony. Verify the light cycle, humidity, and temperature in the room. Determine if there has been a sudden change in activity or noise in the room. Changes in these environmental factors can affect mating behavior dramatically.

Difficulty of injecting

Problems with a clogged injection needle are usually attributed to bad DNA preps; however, first make sure that the DNA concentration is correct. Some problems can be corrected by microcentrifugation for smaller transgene or filtration through 0.45- μ m syringe filters for both large plasmid and BAC transgenes. If the DNA concentration is correct and microcentrifugation or filtration does not correct the problem, a new prep of transgene DNA should be made. Note that it is not unusual to replace the injection pipet several times because of the accumulation of cellular debris on the tip. The visibility and size of the pronuclei can also affect the ease of injection. This can vary between strains and during the time the eggs are in culture. Some strains, such as FVB, have large, prominent pronuclei and are therefore particularly suited for pronuclear injections.

Poor survival of eggs

The death of a high percentage of eggs shortly after injection can be attributed to sev-

eral factors. For an experienced injector, the most common cause of rapid zygote death is a DNA prep of poor quality. Try injecting several eggs with injection buffer alone. If the majority of these eggs survive, then the DNA preparation is the most likely culprit. It may be advantageous to have a single individual prepare fragments for injection or to enforce rigid adherence to a successful transgene isolation protocol in order to ensure uniform quality of DNA preparations. When there is not a question of DNA quality and the injector is inexperienced, the technique itself is the most likely cause of problems. Monitor the volume of fluid injected; the pronucleus should swell visibly, but not lyse. Check the path of the injection pipet; the tip should pass directly into the pronucleus along a straight path and the zygote should not roll or turn during injection. Try to orient the zygote so that the pronucleus is adjacent to the injection tip to minimize damage to the egg. Withdraw the tip with a smooth and rapid motion along the path of entry; watch for the accumulation of debris on the end of the tip that may stick to DNA and proteins within the zygote.

Few pups or founders born

If there are few live-born pups, verify that the reimplantation protocol is not the problem and that the pseudopregnant females were used at the correct stage. Test the technique with zygotes that have not been manipulated. Most unmanipulated, healthy zygotes should produce pups. If the reimplantation technique is not suspect, look for other possible problems, such as the quality of the DNA prep. In some cases there may be a reasonable number of pups but a low yield of transgenics. If this is the case, check the concentration of the transgene prep: low concentrations will reduce the yield of founders. Check the injection system to ensure that there is proper compensation pressure; if there is backflow of medium into the injection tip, the founder yield will be low. Finally, consider the possibility that expression of the transgene may be toxic to the embryo.

Anticipated Results

Approximately 60% to 80% of injected zygotes should survive the injection procedure. DNA quality, DNA concentration, and injector experience are the major factors that affect zygote survival. After reimplantation, 25% to 35% of injected eggs survive to term. Pups should be born 19 to 20 days after reimplantation. About 10% to 20% of the pups can be

Table 23.9.3 Timeline of Transgenic Line Identification and Expansion

Day	Action
0	Zygote injection
20	Birth of potential founders
41	Wean, tag, and tail all pups; genotype to identify founders ^a
62	Initiate mating of founders ^b
83	Birth of first founder offspring
104	Wean, tag, and tail founder offspring ^c

^aPups are typically genotyped at weaning but they can be analyzed earlier.

^bFounders carrying the transgene are then mated after they reach sexual maturity.

^cThis generation, available 3.5 months after zygote injections, is usually the first generation that is subjected to experimentation.

expected to be transgene founders. Approximately 80% to 90% of the transgene founders are not mosaic and should transmit the transgene to half of their offspring.

Time Considerations

Although the procedure spans 4 days (Table 23.9.1), only the day of injection requires a significant time commitment. With experience, zygote isolation should take 30 to 60 min. Injection of 100 to 200 eggs should take 1 to 2 hr and reimplantations should take about 15 min for each foster mother. A novice investigator will spend a very long day trying to complete the procedure. Zygote isolation and reimplantation should be mastered before attempting to complete the entire procedure.

The length of time between zygote injection and the generation of a cohort of transgenic mice suitable for experimental studies is obviously much longer. In most cases, founder offspring, not the founders themselves, are the focus of experiments. The first generation of founder offspring are available a minimum of 3.5 months after zygote injection (Table 23.9.3).

Transgenic Mouse Colony Management

UNIT 23.10

Managing a colony of transgenic mice created by zygote microinjection (UNIT 23.9) is similar to managing a colony of mice created by gene targeting (UNIT 23.8). However, there are important differences because of the random nature of the genetic modification that results from microinjection. This unit describes an approach for identifying founders and developing genotyping strategies. In addition, animal husbandry concepts pertaining to transgenic mice are discussed.

The time course of identifying founders and expanding and maintaining independent lines is outlined in Figure 23.10.1, starting with the day of zygote injection. Offspring from zygote injections are born 3 weeks later. The mice are weaned, tagged, and tail biopsies are taken when they are ~3 weeks old. Potential founders are identified by screening genomic DNA for the presence of the transgene. Independent lines are established by mating transgene-positive founders with wild-type mice when the founders reach sexual maturity, ~6 weeks after birth. Offspring from these matings are screened for the transgene to verify germline transmission. For the majority of transgenic experiments, the first experimentally useful animals are these offspring (F1 generation) derived from the founders. These mice reach weaning age a minimum of 4 months from the day of zygote

injection. Representative transgene-positive mice from the F1 generation of each founder line are typically screened to determine transgene copy number, a crude estimator of transgene expression levels.

COLONY ESTABLISHMENT, EXPANSION, AND MAINTENANCE

Housing

Housing considerations for transgenic mice are identical to those for mice generated by gene targeting (UNIT 23.8). In brief, mice should be housed in a specific-pathogen-free (SPF) facility if possible. SPF animals will live longer and display greater fecundity than comparable animals housed in open facilities.

Identifying Potential Founders

A transgenic colony begins with founders that have stably integrated the transgene. All offspring from zygote injections should be screened for the presence of the transgene. Each transgene-positive mouse represents a unique line because the transgene typically inserts randomly, with variable copy number. Multiple lines must be established for several reasons. First, copy number and insertion site can affect transgene expression levels, and thus a single founder may not express the transgene at experimentally useful levels. Second, random insertion of the transgene may affect the

week 0: zygote injection
week 3: birth of potential founders
week 6: wean, tag, obtain tail biopsy, screen for transgene
week 9: set up transgene-positive founder matings
week 12+: birth of first founder offspring: F1 Generation
week 15+: wean, tag, obtain tail biopsy, verify germline transmission of transgene, determine transgene copy number

Figure 23.10.1 Time line for identifying founders and establishing independent lines, from zygote injection to verification of germline transmission. Potential founders can be identified by genotyping at the time of weaning, ~6 weeks after zygote injection. Both male and female transgene-positive founders should be mated to establish independent lines. Founder matings can be initiated when the mice are ~6 weeks old, although it may take several weeks before the first successful mating occurs. Most founders will transmit the transgene to 50% of their offspring. These offspring, the F1 generation, are used to verify germline transmission and determine transgene copy number. For most investigations, the F1 generation is the first experimentally useful generation. Thus, a minimum of 15 weeks must pass between zygote injection and the weaning of the first experimentally useful animals.

Manipulating
the Mouse
Genome

23.10.1

Supplement 71

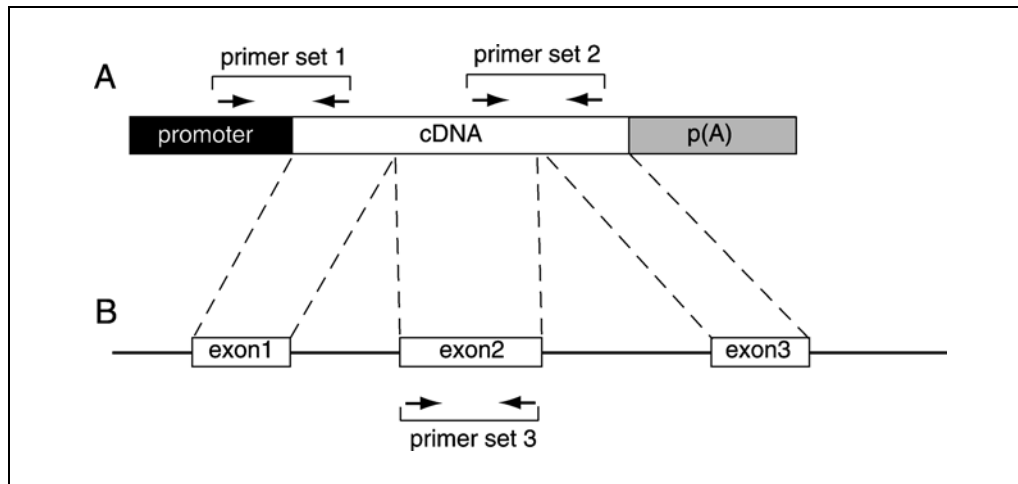

Figure 23.10.2 Genotyping primer selection. A typical transgene construct is illustrated (A), consisting of a heterologous promoter, a cDNA, and sequences containing a polyadenylation signal, p(A). The cDNA is derived from a hypothetical mouse gene (B), which consists of three exons. Three primer pairs are depicted for use as genotyping primers. Primer pair 3 would be unable to distinguish the transgene from the endogenous gene—a similar-size fragment corresponding to part of exon 2 would be amplified from both templates. Primer pair 2 could distinguish between the transgene and the endogenous gene. The primers span an intron and would amplify a longer fragment from the endogenous gene. Primer pair 1 is the most specific pair of primers. This primer pair may be the most useful in a mouse colony containing several different transgenic lines consisting of the same cDNA driven by different promoters.

function of an endogenous gene and create a phenotype that has nothing to do with expression of the transgene. With a single founder, it would be difficult to determine whether a phenotype was caused by expression of the transgene or by altered function of an endogenous gene at the site of insertion. Third, not all transgene-positive founders will transmit the transgene to their offspring. A fraction numbering 10% to 20% of the transgene founders will be mosaic and will not transmit the transgene with the predicted Mendelian frequency.

The two most common methods for identifying founders are the polymerase chain reaction (PCR; *UNIT 15.1*) and Southern blotting (*UNITS 2.9A & 2.10*). PCR is probably the best method to use at this stage because of its simplicity and sensitivity. At weaning, all offspring from the zygote injections should be marked, most commonly by ear tagging (*UNIT 23.8*). A tail biopsy should be obtained from each animal for DNA isolation (*UNIT 23.8*). Two methods, one standard and one rapid, for DNA isolation from tail biopsies are described in *UNIT 23.8*. The standard method, which yields sufficient DNA for both PCR and Southern blotting, is recommended at this stage in case PCR results need to be confirmed by Southern blotting.

DNA samples are analyzed by PCR using primers specific for the transgene. The primers

must be able to differentiate between the transgene and any highly similar endogenous genes (Fig. 23.10.2). For example, if the transgene construct contains a cDNA corresponding to an endogenous mouse gene, the primers can be designed to span an intron in the endogenous gene (primer set 2); PCR amplification of the endogenous gene would result in a larger product than the transgene product because of the inclusion of the intron. Alternatively, if the transgene construct combines a mouse cDNA with a novel promoter, one primer in the promoter and the other in the cDNA will amplify a unique product (primer set 1).

Primers should be selected to amplify relatively small products (~150 to 500 base pairs). This helps to ensure that the reaction will be robust. In addition, control primers should be included in the reaction. Control primers are typically a second pair of primers that amplify an entirely different single-copy locus present in all DNA samples. The product should be roughly the same size as the transgene-specific primer product, but still separable on a 3% to 4% agarose gel. Similar primer melting points should be selected so that transgene-specific and control primers can be run in the same reaction. Amplification of the control band verifies that the reaction conditions and the DNA samples are suitable for single-copy detection. All DNA samples should test positive with the control primers. A positive control for the

Table 23.10.1 Copy Number Standards for PCR and Southern Blotting

Transgene size (bp)	PCR single-copy standard (pg)	Southern blot single-copy standard (pg)
1000	0.067	3.3
5000	0.33	17
10000	0.66	33

transgene-specific primers can be constructed by spiking wild-type DNA with the transgene construct at a single-copy level per genome (Table 23.10.1). The reaction conditions and the primers must be optimized to ensure detection of the transgene (*UNIT 15.1*). It is important that founders not be lost at this stage because of false-negative PCR results.

Using the copy number standards indicated in Table 23.10.1, assume that the size of the haploid mouse genome is 3×10^9 base pairs. The following relationship can be applied:

$$\frac{\text{size of transgene in base pairs}}{3 \times 10^9 \text{ base pairs}} = \frac{\text{single copy mass}}{\text{genomic DNA mass}}$$

In Table 23.10.1, it is assumed that 0.2 μg of genomic DNA are used as the template in the PCR reaction and 10 μg of genomic DNA are used for digestion for the Southern blot. Therefore, for a 5000-bp transgene, the PCR reaction should be spiked with 0.33 pg of the transgenic construct to approximate the abundance of a single-copy target in 0.2 μg of genomic DNA. PCR primers should be able to detect this quantity of target DNA easily. Primer pairs should not be used if they do not work efficiently. Similarly, 17 pg of the transgenic construct should be used to spike 10 μg of genomic DNA for a single-copy standard in the Southern blot. For Southern blots, a series of several standard lanes spiked with increasing quantities of the transgene can be used to construct a standard curve to determine transgene copy number from unknown samples.

Establishing Separate Founder Lines and Determining Copy Number

Each transgene-positive animal represents the potential founder of a unique transgenic line. At this stage, all founders positive for the transgene should be crossed with wild-type mice to establish separate lines. Some founders may not pass the transgene because of mosaicism, insertion-site effects, or a transgene phenotype.

Some thought should be given to the choice of the wild-type strain used in these crosses. Background strain may affect the phenotype of a transgene. If an inbred strain, such as FVB (*UNIT 23.9*) was used as the zygote source, it may be worthwhile maintaining the transgene in the same inbred background. Recreating an inbred line after outcrossing is time-consuming. If outbred or F1 hybrid zygotes were used for the initial injection, it may be worthwhile considering the generation of congenic lines (*UNIT 23.8*) by successive crosses into a defined inbred strain, to create lines that are genetically identical except for the locus surrounding the transgene. If congenics are not created, successive inbreeding of littermates of separate founder lines derived from outbred or F1 hybrid zygotes will eventually generate inbred lines that are genetically different at many loci. This may confound phenotypic analysis.

Regardless of background-strain considerations, the first step in establishing a transgenic line is verifying that the founder can pass the transgene to its offspring. Subsequently, representative animals derived from each founder should be analyzed to determine relative transgene copy number, since there is a strong positive correlation between transgene expression levels and copy number. Copy number is usually determined by Southern blotting, whereas germline transmission can be assayed by PCR.

Mark all offspring from the first cross, typically with ear tags, and obtain a tail biopsy as described in *UNIT 23.8*. Genomic DNA should be prepared using the standard method for DNA isolation for Southern analysis and PCR (*UNIT 23.8*). Offspring from all founders should be screened for the presence of the transgene by PCR, using the same method described for founder identification.

Representative transgene-positive DNA samples from offspring of each of the founders and wild-type littermates should be analyzed by Southern blot (*UNITS 2.9A & 2.10*). Figures 23.10.3 and 23.10.4 illustrate two common combinations of restriction enzyme and probe that can be used to determine relative

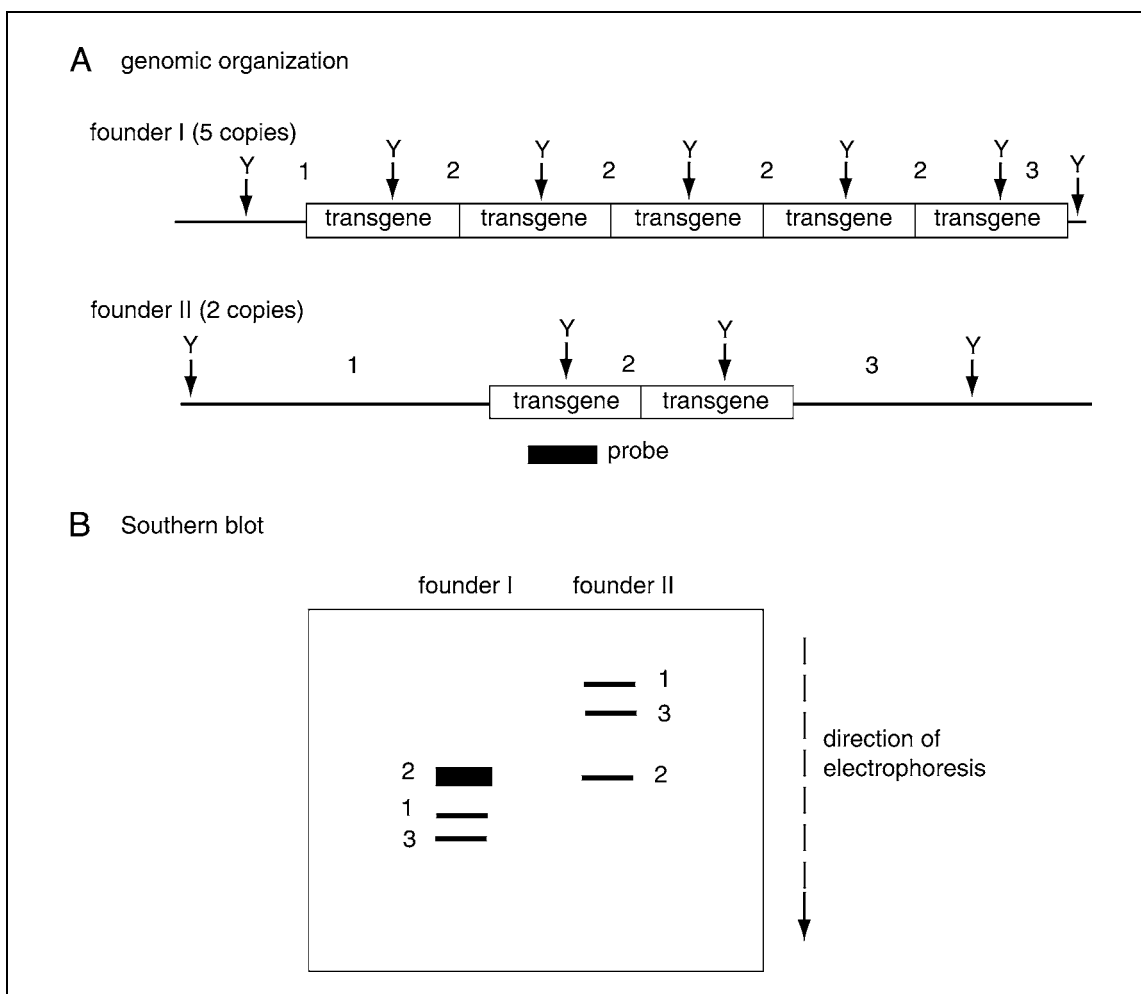

Figure 23.10.3 Southern analysis of founder lines: single site, short construct. **(A)** This panel depicts the genomic organization of two hypothetical founder lines. Founder I has five head-to-tail copies of the transgene and founder II has two head-to-tail copies of the transgene. Y represents the location of a hypothetical restriction enzyme site that cuts the transgene in a single location, and cuts outside the transgene at positions that will be determined by the site of integration. The black bar corresponds to a region of the transgene used as a probe for Southern blots. The unique fragments that are recognized by the probe are numbered 1, 2, and 3. **(B)** This panel depicts a hypothetical Southern blot of genomic DNA cut by restriction enzyme Y for founder I (first lane) and founder II (second lane) and hybridized with the probe shown in panel A. The intensity of the hybridization signal is represented by the size of the band. In the first lane, the probe hybridizes to four copies of fragment 2. Note that fragment 2 is the same size as the original transgene. The flanking fragments, 1 and 3, are present as single copies. In the second lane, the same band (2) is recognized, but in this case there is only a single copy. The flanking fragments, 1 and 3, are also present as single copies. Their sizes differ from the flanking fragments of founder I because of the difference in the site of integration. In this hypothetical example, the approximate relative difference in copy number between the two founders is determined by comparing the relative intensities of band 2, assuming that the same amount of DNA was loaded into each lane. The size of the single-copy flanking bands are unique to each insertion and can be used to identify a specific founder line. In this example, the flanking bands can also be used as single-copy internal standards to determine the absolute copy number of the transgene. Note that the flanking bands may not always be visible, because their size is dependent on the random location of restriction sites in the genome.

transgene copy number. In the first example, equivalent amounts of genomic DNA are digested with a restriction enzyme that cuts the construct at a single site. After separation on an agarose gel and transfer to a membrane (Southern blotting), the membrane is hybridized with a labeled probe that spans the restriction site. In this case, the probe will hybridize

to an internal fragment the size of the original construct because of the typical head-to-tail organization of the transgene concatamer. The relative intensity of the internal fragment when compared between different founders will be proportional to the copy number. Flanking fragments, present as single copies (Fig. 23.10.3), may also be detected. These

Figure 23.10.4 Southern analysis of founder lines: multiple sites, long construct. **(A)** This panel depicts the genomic organization of two hypothetical founder lines. Founder I has five head-to-tail copies of the transgene and founder II has two head-to-tail copies of the transgene. Z represents the location of a hypothetical restriction enzyme site that cuts the transgene in two locations, and cuts outside the transgene at positions that will be specific to the site of integration. The black bar corresponds to a region of the transgene that can be used as a probe for Southern blots. Only a single internal fragment (1) will be recognized by the probe. **(B)** This panel depicts a hypothetical Southern blot of genomic DNA cut by restriction enzyme Z for founder I (first lane) and founder II (second lane) and hybridized with the probe shown in panel A. The intensity of the hybridization signal is represented by the size of the band. In the first lane, the probe hybridizes to five copies of fragment 1. In the second lane, the same band (1) is recognized, but in this case there are only two copies. Note that no flanking fragments will be detected using this combination of probe and restriction enzyme. In this hypothetical example, the relative difference in copy number between the two founders is determined by comparing the relative intensities of band 1, assuming that the same amount of DNA was loaded into each lane.

can be used as internal single-copy standards to calculate the absolute copy number of the transgene.

In many cases, it may not be practical or possible to use a restriction enzyme that cuts only a single time in the construct. If the transgene is much longer than 20 kb, a restriction enzyme that cuts once will generate a fragment that is too large to resolve easily using standard Southern blotting protocols. Figure 23.10.4 illustrates an alternative method to assess copy number. In this example, a restriction enzyme that cuts two or more times within the construct is used. A probe corresponding to one

of the internal fragments is generated. The probe should hybridize to a single band in all founders; the relative hybridization intensity will be proportional to the copy number when equivalent amounts of genomic DNA are analyzed in each sample.

Copy number may also be assessed by comparing the hybridization signal from transgenic lanes with a series of control samples generated by spiking wild-type genomic DNA with known quantities of the transgene construct. The calculation used to determine the amount of transgene construct corresponding to a single copy per copy of the mouse genome is

shown in Table 23.10.1. Several samples with increasing amounts of the transgene can be used to create a standard curve. These should be run on the same blot as the unknown samples to control for variations in the specific activity of probes used in different experiments. The advantage of this approach is that a true copy number can be determined. However, in most cases it is sufficient to know the relative copy number between the different founder lines.

Expanding Founder Lines and Generating Experimental Animals

At this stage, transmitting founder lines have been identified and transgene copy number has been estimated as a crude indicator of transgene expression levels. Typically, this F1 generation represents the first experimental generation. Early experiments should usually include northern blots and immunoblots to establish that the transgene is expressed properly. In most cases, transgenic lines are maintained as heterozygotes by crossing transgene carriers with wild-type mice. Subsequent generations can be genotyped by PCR using the rapid DNA preparation (*UNIT 23.8*). Genotyping primers should be selected to be as specific as possible for the transgene. As indicated previously, without knowledge of the flanking sequence surrounding the transgene insertion site, it is not possible to develop a PCR assay that is specific for each founder line. However, it is usually possible to develop PCR primers that are specific for each transgene the laboratory pursues. For example, a laboratory may maintain multiple transgenic *lacZ* lines, each line differing by the promoter that drives the transgene. It may seem most efficient to use a pair of PCR primers that amplify part of the *lacZ* coding region; the primers can be used for all the lines. However, this is probably not a prudent approach. Accidental mixing of the lines would not be detected. In this case, PCR primers that sit in the *lacZ* coding region and in the unique promoter region of each transgene would be more likely to detect accidental mixing of the individual lines (e.g., primer set 1 in Fig. 23.10.2).

It is also common to maintain several lines from the same transgene. The lines will differ in insertion site, copy number, and, probably, expression level. Lines derived from the same transgene pose more of a problem with regard to the possibility of accidental mixing. Routine PCR genotyping will not distinguish the lines. It is a good habit to periodically genotype by Southern blotting to distinguish these lines by

copy number or by the presence of different-sized flanking fragments (Fig. 23.10.3).

In some cases, the generation of homozygous animals may be useful. Homozygous animals have a higher transgene copy number; therefore, they may express the transgene at a higher level. Homozygotes are also easier to maintain, since offspring from homozygote crosses do not need to be genotyped at every generation. However, it is a prudent practice to genotype homozygotes periodically to ensure that the lines are breeding true and that no accidental crosses have occurred. Homozygosity can be determined using semiquantitative Southern blotting. Equal amounts of genomic DNA from offspring of heterozygous crosses and from known heterozygotes are digested and analyzed by Southern blotting using the same method described for relative copy number determination. Homozygous DNA samples should have twice the hybridization signal as heterozygotes. Alternatively, quantitative PCR can be used to assess zygosity (Shitara et al., 2004). Putative homozygotes can be test-bred to wild-type mice to verify homozygosity; no wild-type offspring should be observed.

Long-Term Strain Maintenance

Transgenic mouse lines pose a slightly different problem with regard to long-term maintenance than lines created by gene targeting, although the options are the same (*UNIT 23.8*). An identical transgenic line can never be regenerated because of the random nature of the integration event. Therefore the decision to eliminate a line that is of no immediate use is permanent. There is no perfect alternative. Many investigators choose to maintain lines by keeping an active colony of a few mating pairs or a few males that can be mated periodically to produce a younger generation. This method is not labor-intensive, and is relatively inexpensive for a few lines. It is more problematic when many lines must be maintained. Two main alternatives exist, both of which can be performed by laboratories familiar with the manipulation of preimplantation embryos. Morulae can be frozen using a specialized controlled-rate freezer. Although the equipment is expensive, this method can accommodate large batches of embryos. Alternatively, morulae can be frozen by vitrification, which involves the osmotic dehydration of embryos by sequential equilibration in cryoprotectant solutions of increasing osmotic strength (Glenister and Rall, 2000). The latter method does not require expensive

equipment and is most appropriate for small batches of embryos. Several major mouse suppliers also provide morula freezing services (Taconic Farms, Charles River Laboratories). Mouse sperm cryopreservation is still not widely used because of strain-dependent variability in the success of *in vitro* fertilization with frozen sperm. However, there have been recent advances that make this method more appealing (Bath, 2002; Szczgiel et al., 2002). Current methods for sperm freezing are within the abilities of most laboratories (Sztein et al., 2001; Bath, 2002; also see <http://www.jax.org/cryo/sperm.html>). If a commercial or in-house cryogenic method of strain preservation is selected, there must be a rigorous quality-control program to ensure that frozen embryos or sperm are capable of regenerating live animals.

MOUSE IDENTIFICATION AND INFORMATION MANAGEMENT

Various methods for marking mice are reviewed in *UNIT 23.8*. The most common method is ear tagging, which is an inexpensive and quick procedure for an experienced investigator.

Mouse colonies tend to expand very rapidly, especially when several lines are maintained for each transgenic construct. It is imperative that complete records be kept, starting with the founders. A paper-based management system will be overwhelmed quickly. A variety of digital database software options are reviewed in Table 23.8.3. Information should be collected for individual animals, matings, and litters. Complete records collated in a digital database are invaluable for explaining unanticipated results. It is more common to regret keeping incomplete records than to regret keeping too much information.

TROUBLESHOOTING

Absence of Founders

The absence of founders may be a result of technical problems with zygote injections. These issues are discussed in *UNIT 23.9*. Alternatively, potential founders may be missed because of an inefficient PCR screen. New transgene-specific primers must be tested to ensure efficient amplification of a single-copy target per genome. In addition, control primers must be able to amplify a product from all DNA samples to verify the quality of the genomic DNA preparation and the efficiency of the reaction. There is also the possibility that expres-

sion of the transgene causes lethality, resulting in the death of all founders prior to birth or before weaning.

Problems with Germline Transmission

In most cases, the transgene will be passed to 50% of the offspring as expected. However, several problems may be encountered when screening the F1 generation to verify germline transmission. If transmission is not observed, the founder genotype should be verified; misidentification of the original founder is the simplest explanation. If the founder is truly transgene-positive, there are several other explanations for absent or aberrant germline transmission. A significant percentage of founders will be mosaic. These animals may never transmit the transgene or may pass the transgene at frequencies lower than expected. The transgene can integrate into the X chromosome, resulting in 100% transmission to female offspring and no transmission to male offspring of male founders. In some cases, transgenes will integrate into multiple sites. Offspring from these founders may inherit the transgene at unexpectedly high frequencies if the integration sites are not linked. In addition, these offspring may appear to have different transgene copy numbers depending on the number of separate loci that are inherited. Finally, there is always the possibility that lack of transmission of the transgene is a phenotype of the transgene expression or a result of an insertion-site mutation (see below).

Insertion-Site Mutations

Unexpected phenotypes may be a result of insertion-site mutations. Random integration of the transgene may affect the function of an endogenous gene near the site of insertion. Insertion-site mutations are more likely to have a recessive phenotype than a dominant phenotype. Therefore, the effects of these mutations may not be observed until heterozygous transgene carriers are crossed. Independent founder lines should not have the same insertion-site mutations. Investigators should suspect that a novel phenotype present only in a single founder line is a result of an insertion-site mutation, rather of transgene expression.

Transgene Silencing

In some cases, transgene expression may decrease as animals age, or in later generations (Robertson et al., 1996; Henikoff, 1998). This epigenetic phenomenon is called transgene silencing. It is most common in high-copy-number lines created with plasmid-based

transgenes. It is irreversible and unpredictable. The possibility of transgene silencing should be considered when there is a large phenotypic variation between animals of different ages or different generations.

Modification and Production of BAC Transgenes

The sequencing of entire genomes and assembly of physical maps of whole chromosomes has been greatly facilitated by the cloning of genomic DNA into bacterial artificial chromosome (BAC) vectors (UNIT 5.9). BACs are F-factor-based cloning systems that were designed for the specific purpose of cloning large-insert genomic DNA fragments in the 100- to 300-kb range. In vivo analysis of gene function and expression frequently relies on the production of transgenic animals by introducing DNA constructs into the mouse genome. Traditional transgenic constructs prepared in standard (pBR-type) plasmid vectors afford a maximal cloning capacity of ~20 kb. In contrast, BAC clones, owing to their larger insert size, are more likely to carry an entire transcription unit and its associated regulatory regions. As a consequence, BAC-based transgenic approaches offer improved and unique opportunities to study gene function, expression, and regulation in a genomic environment that is more consistent with the endogenous locus.

What makes the use of BACs particularly advantageous is the ease with which they can be engineered to incorporate DNA insertions, deletions, or substitutions. A variety of BAC modification protocols have recently been described that use homologous recombination-based approaches performed in *E. coli*. Most of the BAC modification methods use targeting vectors containing a recombination gene(s) (*recA*, *recE/recT*, or *lexo/beta/gam*), which transiently restores to the recombination-deficient host the ability to promote homologous recombination between the BAC of interest and the targeting DNA element (which may be a linear DNA fragment or circular vector). The flexibility in the design of the system makes it possible to introduce different types of modifications to the BAC DNA including insertion of reporter cassettes, deletion of specific gene or regulatory regions, or the substitution of one type of sequence for another.

In addition to the site-directed methods for modifying BAC DNA, other approaches utilizing in vitro transposition allow for the random integration of foreign DNA into BAC clones. This method is preferred when screening several BACs for reporter activity. In this case, the same reporter cassette can be introduced into multiple BACs.

This unit provides protocols for the modification of BAC DNA using homologous recombination in *E. coli* (see Basic Protocol 1) and in vitro transposition (see Basic Protocol 2). In addition, a simple and reliable procedure is described for the preparation of BAC DNA for pronuclear injection into fertilized mouse eggs (see Support Protocol), which is an alternative to the methodology outlined elsewhere in this manual (UNITS 2.1B & 23.9).

BAC MODIFICATION BY HOMOLOGOUS RECOMBINATION IN *E. COLI*

This protocol was developed in the laboratory of Dr. Nathaniel Heintz (Rockefeller University, New York, N.Y.) and was first published by Gong et al. (2002). It uses a shuttle vector, pLD53SC-AEB, with the following features: *recA* gene to mediate homologous recombination; R6K γ DNA replication origin for propagation in *E. coli* strains expressing the π replication factor; ampicillin resistance gene for positive selection; *sacB* gene for negative selection upon growth on plates containing sucrose; and the enhanced green fluorescent protein (eGFP) reporter gene. This BAC modification protocol is performed in three steps. The first step involves the preparation of a targeting construct using the pLD53SC-AEB shuttle vector. To introduce the eGFP reporter into a selected site within a BAC, homology arms A and B must be cloned on either side of the eGFP

BASIC PROTOCOL 1

Manipulating the Mouse Genome

23.11.1

Figure 23.11.1 BAC recombination system using the pLD53SC-AEB shuttle vector. The shuttle vector contains the R6ky replication origin; ampicillin-resistance gene (*Amp^r*); and *recA*, *sacB*, and enhanced green fluorescent protein (*eGFP*) genes. Homology arms can be cloned into *Ascl* or *SmaI* (for arm A) and *PacI*, *FseI*, or *StuI* (for arm B) restriction sites. The modification occurs through a two-step homologous recombination reaction: the co-integration of the shuttle vector into the BAC target through arm A (for example) and the resolution of the co-integrant through arm B. Integration through arm B is equally possible but is not shown. P1 and P2 indicate PCR primers used to verify co-integration. Abbreviations: amp, ampicillin; chl, chloramphenicol; Cm^r, chloramphenicol resistance gene.

cDNA in the pLD53SC-AEB shuttle vector, as described in the steps below. The second step involves the integration of the shuttle vector into the BAC of choice by homologous recombination. This recombination event will occur between arm A or arm B of the shuttle vector and the corresponding DNA sequence in the BAC (Fig. 23.11.1). In the third step (resolution), a second recombination event excises the backbone of the shuttle vector and positions the intended modification within the desired target DNA. This recombination event will also occur between homology arm A or arm B and the corresponding BAC DNA, resulting in either a BAC containing the modification of interest or the original BAC (Fig. 23.11.1). The modified BAC is identified by PCR.

To incorporate other modifications into a BAC (e.g., substitutions, deletions, or point mutations), the *eGFP* sequence in the shuttle vector is simply replaced with the chosen modification, and the homology arms are cloned as described. The *eGFP* can be removed from the vector by digesting at an appropriate combination of cloning sites. For example, to delete a target sequence in the BAC, the authors typically design primers for arm A and arm B on either side of the sequence to be deleted. For arm A, the upstream primer incorporates an *Ascl* site at its 5' end and the downstream primer is phosphorylated at its

5' end. For arm B, the 5' end of the upstream primer is phosphorylated and the 3' end of the downstream primer incorporates a *PacI* site. After PCR, the 5' and 3' homology arms are digested with *AscI* and *PacI*, respectively, and ligated in a three-way reaction with the *AscI/PacI*-digested shuttle vector.

Materials

Pir2 competent cells (Invitrogen)
pLD53SC-AEB shuttle vector (from the laboratory of Dr. Nathaniel Heintz, The Rockefeller University)
LB medium (UNIT 1.1)
LB plates (UNIT 1.1) supplemented with antibiotics as follows:
30 µg/ml ampicillin
15 µg/ml chloramphenicol and 50 µg/ml ampicillin
15 µg/ml chloramphenicol and 5% (w/v) sucrose (from 50% sucrose stock solution; sterilize with 0.45-µm filter; do not boil or autoclave)
50 mg/ml ampicillin
Appropriate oligonucleotide primers for amplifying homology arms A and B
Bacteria containing BAC clone to be modified (see Internet Resources)
Restriction enzyme and buffer appropriate for cloning site in shuttle vector:
AscI or *SmaI* for homology arm A
PacI, *FseI*, or *StuI* for homology arm B
Shrimp alkaline phosphatase (Roche)
GeneClean (Qbiogene)
Primers for verifying arm insertion:
SCAB1: 5'-AAGTTGTAAGGATATGCC-3'
SCAB2: 5'-CATATCGCAATACATGCG-3'
34 mg/ml chloramphenicol
10% (v/v) glycerol, ice cold
SOC medium (UNIT 1.8), optional
Oligonucleotide primers P1 and P2 (step 27)
37° and 42°C water baths
37°C incubator, with and without shaking
Thermal cycler
1.5-ml microcentrifuge tubes, sterile and prechilled on ice
0.1-cm electroporation cuvettes (Bio-Rad), prechilled on ice
Gene Pulser (Bio-Rad)
Sterile culture tubes, such as 15-ml (17 × 120-mm) tubes (Falcon)
Additional reagents and equipment for alkaline lysis miniprep (UNIT 1.6), PCR (UNIT 15.1), agarose gel electrophoresis (UNIT 2.5A), ethanol precipitation of DNA with ammonium acetate (UNIT 2.1A), DNA ligation (UNIT 3.16), DNA sequencing (see Chapter 7), electroporation (UNIT 1.8), Southern analysis (UNITS 2.9A & 2.10), and preparation of BAC DNA (see Support Protocol)

Propagate pLD53SC-AEB shuttle vector

1. Thaw one vial of Pir2 competent cells on ice and mix with 1 to 5 µl of pLD53SC-AEB shuttle vector (1 ng/µl final) by tapping gently. Incubate 30 min on ice.
The R6Kγ DNA replication origin is not compatible for replication in most lab strains of E. coli commonly used for transformation, including DH5α and XL1. As a result, Pir2 cells must be used to propagate the shuttle vector.
2. Place vial in a 42°C water bath for 30 sec and then on ice for 2 min. Add 250 µl LB medium to the vial and incubate 1 hr at 37°C.
3. Spread 50 µl from the vial on an LB plate with 30 µg/ml ampicillin and incubate overnight at 37°C.

4. Inoculate a single colony into 5 ml LB medium with 30 µg/ml ampicillin and shake (225 rpm) overnight at 37°C.
5. Isolate DNA using standard alkaline lysis miniprep method (UNIT 1.6).

Prepare and clone homology arm A

6. Amplify arm A by PCR (UNIT 15.1) in a thermal cycler using 50 ng appropriate oligonucleotide primers (with a melting temperature, T_m) and 1 ng desired BAC DNA as template.

30 cycles: 1 min 94°C
 1 min ($T_m - 5$)°C
 1 min 72°C.

*The following points should be taken into consideration when designing PCR primers for homology arm A and B. The optimal length of homology arms is between 300 bp and 500 bp. The cloning sites available in the shuttle vector are *AscI* and *SmaI* (for homology arm A) and *PacI*, *FseI*, and *StuI* (for homology arm B). The restriction sites selected for cloning should be absent from the homology arms. UNIT 15.1 describes general considerations for the design of PCR primers.*

7. Examine the product on an agarose gel (UNIT 2.5A). If the predicted size product is obtained, digest it with the appropriate restriction enzyme (either *AscI* or *SmaI*) and remove the end fragments by ethanol precipitation with ammonium acetate (UNIT 2.1A).

Alternatively, a commercially available kit (e.g., QIAquick PCR purification kit; Qiagen) can be used to remove end fragments.

If a product of the predicted size is not obtained, the PCR should be repeated with lower annealing temperature or higher Mg^{2+} . New primers may also need to be designed.

8. Linearize the pLD53SC-AEB shuttle vector with the same restriction enzyme used to digest homology arm A and dephosphorylate it with shrimp alkaline phosphatase as per manufacturer's instructions.
9. Examine vector digestion by gel electrophoresis to confirm that majority of vector is linearized and then gel purify linearized vector using GeneClean.
10. Ligate linearized shuttle vector with digested arm A (UNIT 3.16) and transform the Pir2 cells with the ligated product as described above (steps 1 to 4).
11. Isolate DNA from colonies and verify the insert by restriction digestion or PCR. In addition, confirm the sequence of the insert (see Chapter 7).

*When verifying the presence of an insert by PCR, the following set of primers should be used: SCAB1 (upstream of *AscI* site in the vector, 5'-AAGTTGTAAGGATATGCC-3') and the downstream oligo used for the amplification of arm A. These primers can also be used for sequencing.*

Prepare and clone homology arm B

12. Prepare and insert homology arm B into the shuttle vector containing arm A as described above (steps 6 to 10). Use one of the following three cloning sites: *PacI*, *FseI*, or *StuI*.
13. Isolate DNA from colonies and verify the insert by restriction digestion or PCR. In addition, confirm the sequence of the insert.

*When verifying the presence of homology arm B by PCR, the following set of primers should be used: upstream oligo (used for the amplification of arm B) and SCAB2 (downstream of *StuI* site in the vector, 5'-CATATCGCAATACATGCG-3'). These primers can also be used for sequencing.*

This is the final step in the design of the targeting vector. When modifying several BAC clones, the target vector with homology arms A and B should be prepared on a large scale (UNIT 1.7).

Make electrocompetent cells

14. Inoculate a single colony of bacteria containing the BAC clone to be modified into 2 ml LB medium with 15 µg/ml chloramphenicol and grow overnight with shaking at 37°C.
15. Transfer 0.1 ml overnight culture into 50 ml LB medium with 15 µg/ml chloramphenicol and incubate with shaking at 37°C until the OD₆₀₀ reaches 0.5 to 0.6.

Cultures usually require 3 to 5 hr to reach this density.

16. Harvest cells by centrifuging 10 min at 1500 × g, 4°C. Resuspend pellet in 50 ml of 10% ice-cold glycerol. Repeat this step once more.
17. Resuspend pellet in 200 µl of 10% ice-cold glycerol and dispense 40-µl aliquots into sterile prechilled 1.5-ml microcentrifuge tubes. Freeze and store at –80°C.

Electrocompetent cells can be stored for up to 6 months at –80°C.

Perform co-integration

18. Thaw 40 µl electrocompetent cells on ice, mix with 1 to 2 µl targeting vector (0.5 µg/µl), and place on ice for 1 min.
19. Transfer mixture to a prechilled 0.1-cm electroporation cuvette and carry out electroporation (UNIT 1.8). On a Gene Pulser apparatus, set the capacitance to 25 µF, the voltage to 1.8 kV, and the pulse controller to 200 Ω.
20. Immediately add 1 ml SOC (or LB) medium to the cuvette and transfer to a sterile culture tube. Incubate tube 1 hr with shaking at 37°C.

LB can be used, but SOC is known to ensure maximum transformation efficiency.

21. Add 5 ml LB medium with 15 µg/ml chloramphenicol and 30 µg/ml ampicillin to the culture tube, and incubate overnight with shaking at 37°C.
22. Transfer 5 µl overnight culture to a fresh culture tube containing 5 ml LB medium with 15 µg/ml chloramphenicol and 50 µg/ml ampicillin. Incubate 8 to 14 hr with shaking at 37°C.
23. Transfer 1 µl culture to a fresh culture tube containing 5 ml LB medium with 15 µg/ml chloramphenicol and 50 µg/ml ampicillin. Incubate with shaking at 37°C overnight.
24. Make a 1:10⁴ to 1:10⁵ dilution of the overnight culture and spread 50 to 100 µl on an LB plate with 15 µg/ml chloramphenicol and 50 µg/ml ampicillin. Incubate at 37°C overnight.
25. Individually pick and inoculate a handful of colonies (5 to 10) into 1 ml LB medium containing 15 µg/ml chloramphenicol and 50 µg/ml ampicillin and streak each colony onto a chloramphenicol/ampicillin master plate. Grow overnight at 37°C.

Verify co-integration by PCR

26. Make a 1:10 dilution of the overnight culture using sterile water and lyse 5 µl diluted culture in a PCR tube by boiling for 3 min in a thermal cycler.

This will be the template for PCR.

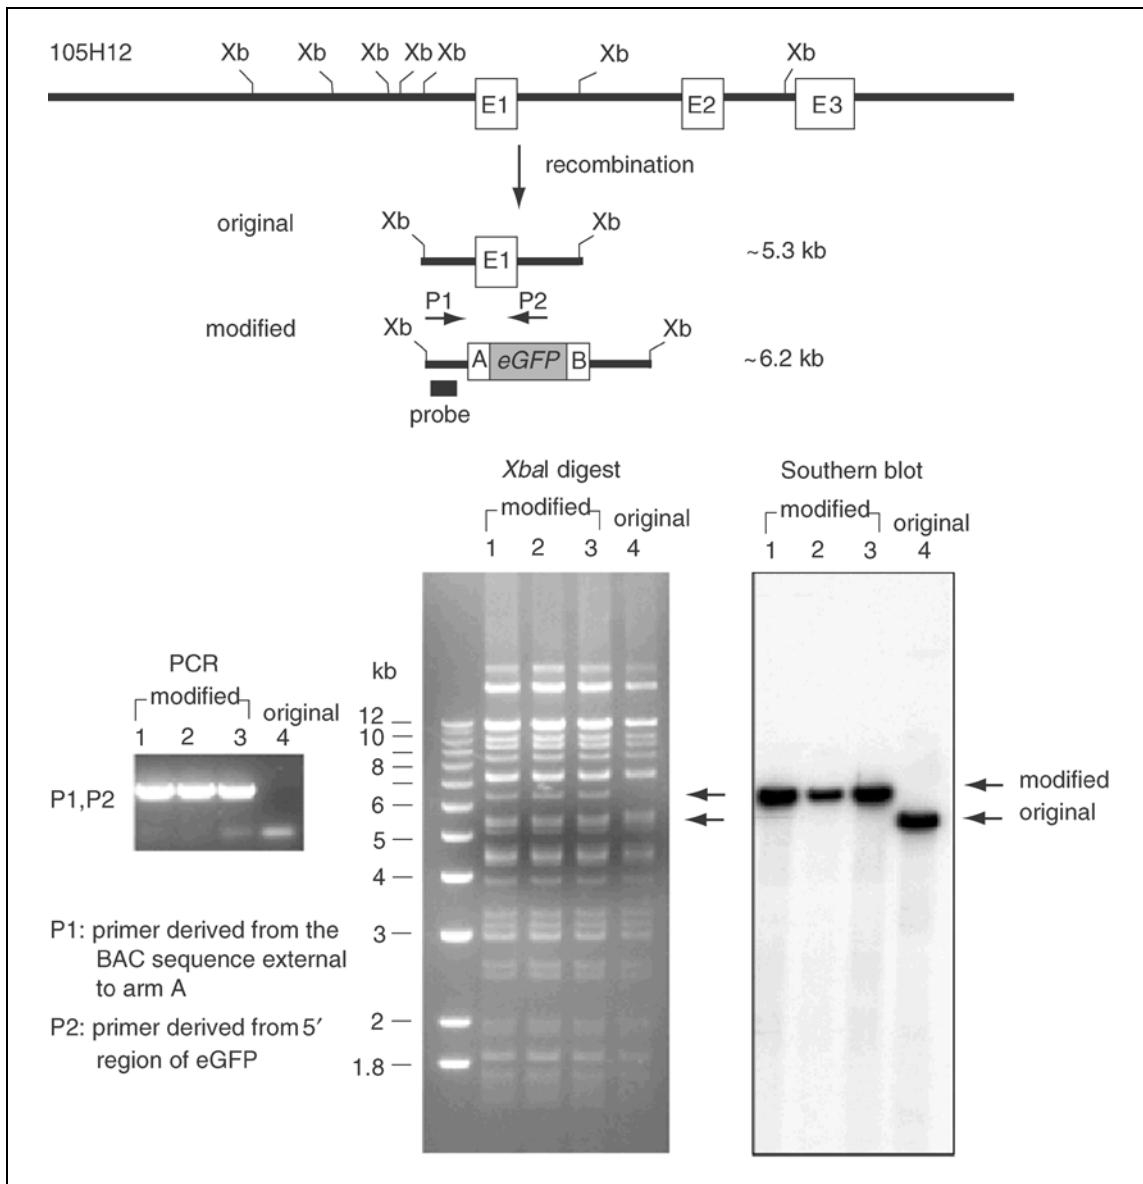

Figure 23.11.2 PCR and Southern analysis of a sonic hedgehog BAC clone modified by homologous recombination. Resolved BAC candidates were first screened by PCR using primers P1 and P2. DNA from PCR-positive clones was subsequently digested with *Xba*I (*Xb*), separated by electrophoresis on a 1% agarose gel, and transferred onto a nylon membrane. The blot was hybridized with a radiolabeled DNA probe located externally (5') to homology arm A. Lanes 1 to 3 are modified BAC clones. Lane 4 is the original BAC clone. E1, E2, and E3 are exons.

27. Use 5 μ l lysed diluted culture and 50 ng each of oligonucleotide primers P1 and P2 for PCR (Fig. 23.11.1) as follows:

30 cycles: 1 min 94°C
 1 min 55°C
 1 min 72°C.

P1 should be designed against the specific BAC sequence immediately external (5') to homology arm A. In the authors' laboratory, the *P2* primer is designed against the 5' end of the *eGFP* cDNA (5'-CCGGTGAACAGCTCCTCG-3').

Because homologous recombination can occur within arm B, screening for co-integrants can also be performed using primers that are derived from the 3' region of *eGFP* and the BAC sequence external to arm B.

The co-integration frequency may range from 30% to 70%.

Perform resolution step

28. Pick several colonies that were positive for co-integration from the master plates (step 25) and inoculate each colony into 1 ml LB medium with 15 µg/ml chloramphenicol. Incubate 1 hr with shaking at 37°C.
29. Spread 50 to 100 µl of each culture on an LB plate with 15 µg/ml chloramphenicol and 5% sucrose and incubate at 37°C overnight.

*This is the negative selection step. The *sacB* gene product, levansucrase, converts sucrose to levan, which is highly toxic to *E. coli*. Therefore, only those bacteria that have recombined out the shuttle vector are able to grow on LB plates with 5% sucrose.*

30. Pick small or intermediate-sized colonies, inoculate each colony into 2 ml LB medium with 15 µg/ml chloramphenicol, and incubate overnight with shaking at 37°C.
31. Screen for the resolution event by PCR as described (steps 26 and 27). Verify positive clones by Southern analysis (UNIT 2.9A & 2.10) using BAC DNA prepared from an overnight culture (see Support Protocol, steps 1 to 8) and a DNA probe external to homology arm A or B.

The modification frequency may range from 10% to 50%. An example of how to screen for the modified BAC by PCR, BAC DNA fingerprinting, and Southern blot analysis is shown in Figure 23.11.2.

To prepare a frozen stock of bacteria, 0.2 ml sterile glycerol is added to 0.3 ml bacterial culture, and the tube is inverted until glycerol is evenly dispersed. Frozen stocks can be stored indefinitely at -80°C.

BAC MODIFICATION BY IN VITRO TRANSPOSITION

This protocol uses a Tn7 transposon-based in vitro system (GPS; New England Biolabs) to randomly insert a *lacZ* reporter cassette into a BAC of interest. TnsABC transposases insert a transposon randomly into target DNA. Because of target immunity, only one insertion occurs per target DNA. Therefore, this system produces a population of target DNAs, each containing the transposon at a different position. This protocol uses the targeting vector pGPS1-βLacZ, which was modified from the original pGPS1 plasmid by Spitz et al. (2003; Fig. 23.11.3). This targeting vector contains transposable elements Tn7L/R; R6Kγ DNA replication origin, which allows for propagation only in *E. coli* strains expressing the π replication factor; kanamycin resistance gene; and a reporter cassette consisting of a minimal β-globin promoter, *lacZ* gene, and SV40 polyA signal.

Materials

- Pir2 competent cells (Invitrogen)
- pGPS1-βLacZ targeting vector (from the laboratory of Denis Duboule, University of Geneva, Switzerland)
- LB medium (UNIT 1.1)
- LB plates (UNIT 1.1) without antibiotics *and* supplemented with antibiotics as follows:
 - 20 µg/ml kanamycin
 - 20 µg/ml kanamycin and 15 µg/ml chloramphenicol
 - 20 mg/ml kanamycin
- E. coli* DH10B strain
- 10% (v/v) glycerol, ice cold
- BAC DNA prepared from overnight culture (see Support Protocol, steps 1 to 8)
- GPS kit (New England Biolabs), including:
 - 10× GPS buffer
 - TnsABC transposase
 - Start solution

BASIC PROTOCOL 2

SOC medium (UNIT 1.8), optional

34 mg/ml chloramphenicol

PCR primers:

β -globin: 5'-AGCCATCTATTGCTTACATTTGC-3'

lacZ: 5'-ATAGGTTACGTTGGTGTAGATGG-3'

Appropriate restriction enzyme to confirm insertion (e.g., *Mlu*I)

Primer for sequencing directed against the 3' end of the *lacZ* gene, optional

37° and 42°C water baths

37°C incubator, with and without shaking

1.5-ml microcentrifuge tubes, sterile and prechilled on ice

75°C heating block

0.1-cm electroporation cuvettes (Bio-Rad), prechilled on ice

Gene Pulser (Bio-Rad)

Thermal cycler

Additional reagents and equipment for alkaline lysis DNA miniprep (UNIT 1.6), electroporation (UNIT 1.8), PCR (UNIT 15.1), agarose gel electrophoresis (UNIT 2.5A), preparation of BAC DNA (see Support Protocol), pulsed-field gel electrophoresis (UNIT 2.5B), and DNA sequencing (see Chapter 7; optional)

Prepare shuttle vector

1. Thaw a vial of Pir2 competent cells on ice and mix with 1 to 5 μ l pGPS1- β LacZ targeting vector (1 ng/ μ l final) by tapping gently. Incubate 30 min on ice.
2. Place vial in a 42°C water bath for 30 sec and then on ice for 2 min. Add 250 μ l LB medium to the vial and incubate 1 hr at 37°C.
3. Spread 50 μ l from vial on an LB plate containing 20 μ g/ml kanamycin and incubate overnight at 37°C.
4. Inoculate a single colony into 5 ml LB medium containing 20 μ g/ml kanamycin and incubate overnight at 37°C with shaking (225 rpm). Isolate plasmid DNA by alkaline lysis miniprep (UNIT 1.6).

Make DH10B electrocompetent cells

5. Inoculate a single colony of *E. coli* DH10B strain grown on an LB plate without antibiotics into 2 ml LB medium without antibiotics and grow with shaking overnight at 37°C.
6. Transfer 0.5 ml overnight culture into 250 ml LB medium without antibiotics and incubate with shaking at 37°C until the OD₆₀₀ reaches 0.5 to 0.6.
Cultures usually require 3 to 5 hr to reach this density.
7. Harvest cells by centrifuging 10 min at 1500 \times g, 4°C. Resuspend pellet in 250 ml of 10% ice-cold glycerol. Repeat this step once.
8. Resuspend pellet in 1 ml of 10% ice-cold glycerol and dispense 40- μ l aliquots into prechilled sterile 1.5-ml microcentrifuge tubes. Freeze and store at -80°C.

Electrocompetent cells can be stored for up to 6 months at -80°C.

Perform transposition reaction

9. Mix the following in a tube by pipetting up and down two or three times.
 - 20 ng targeting vector (step 4)
 - 200 ng BAC DNA prepared from overnight culture
 - 2 μ l of 10 \times GPS buffer

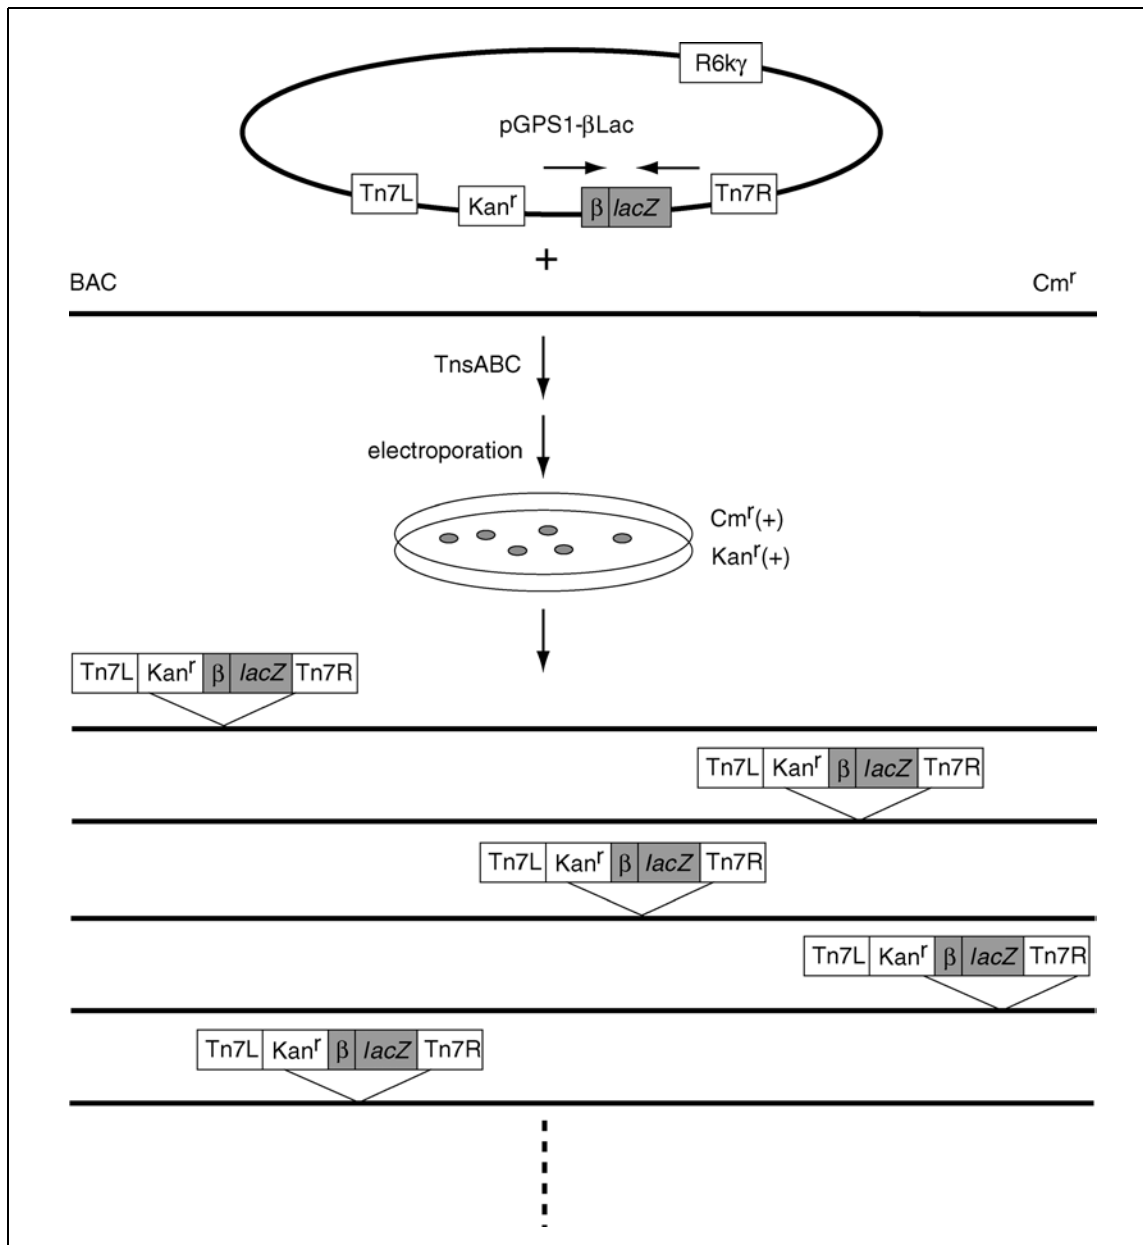

Figure 23.11.3 Overview of Tn7 transposon–mediated BAC modification. The targeting vector contains transposable elements (Tn7L/R), R6K γ DNA replication origin, kanamycin resistance gene (Kan^r), and a reporter cassette consisting of a minimal β -globin promoter (β) and *lacZ* gene (*lacZ*). The transposon cassette (Tn7L-Kan^r- β /*lacZ*-Tn7R) is inserted randomly into the BAC clone by transposases A, B, and C (TnsABC). Modified clones are selected by their ability to grow on plates containing chloramphenicol (Cm) and kanamycin.

1 μ L TnsABC transposase
 H₂O to a final volume of 18 μ L.

Incubate 10 min at 37°C.

This incubation is necessary for the assembly of the transposases, targeting vector, and BAC and must not be omitted.

10. Add 2 μ L start solution, mix well by pipetting up and down two or three times, and incubate 1 hr at 37°C.

11. Heat inactivate 10 min at 75°C.

It is essential that the heat inactivation be performed at the prescribed temperature, as the authors have found that 65°C is not adequate.

12. Thaw 40 μ l DH10B electrocompetent cells on ice. Make a 1:10 dilution of the reaction mix (step 11) with sterile water and mix with thawed cells.
13. Transfer mixture to a prechilled 0.1-cm electroporation cuvette and carry out the electroporation (*UNIT 1.8*). On a Gene Pulser apparatus, set the capacitance to 25 μ F, the voltage to 1.8 kV, and the pulse controller to 200 Ω .
14. Add 0.4 ml LB (or SOC) medium to the cuvette and transfer to a sterile culture tube. Incubate the tube with shaking at 37°C for 1 hr.

LB can be used, but SOC is known to ensure maximum transformation efficiency.

Figure 23.11.4 Restriction digest analysis of a sonic hedgehog BAC clone modified by the Tn7 transposon–based in vitro system. Modified BAC clones were first identified by PCR (data not shown). DNA from PCR-positive clones was digested with *Mlu*I and separated by pulsed-field gel electrophoresis on a 1% agarose gel. The original BAC (lane 1) contained two *Mlu*I sites and gave rise to two DNA fragments. The modified BACs gave rise to three *Mlu*I restriction fragments because of the presence of an additional *Mlu*I site in the transposon cassette. Because of the random nature of the integration event, the size of the modified *Mlu*I1 fragment varied from clone to clone.

15. Spread 100 μ l incubated cells on an LB plate with 20 μ g/ml kanamycin and 15 μ g/ml chloramphenicol and incubate at 37°C overnight.
16. Individually pick and inoculate colonies into 2 ml LB medium with 20 μ g/ml kanamycin and 15 μ g/ml chloramphenicol and incubate with shaking at 37°C overnight.

Verify insertion by PCR

17. Dilute 5 μ l overnight culture 1:10 using sterile water. Lyse 5 μ l diluted culture in a PCR tube by boiling for 3 min in a thermal cycler.
18. Use 5 μ l lysed culture as a template for PCR (*UNIT 15.1*) with 50 ng each of β -globin and *lacZ* primers and the following conditions:

30 cycles:	1 min	94°C
	1 min	55°C
	1 min	72°C.

19. Analyze product by gel electrophoresis (*UNIT 2.5A*).

The amplification product is ~350 bp.

Verify insertion by restriction digestion

20. Prepare BAC DNA from the original and modified BACs (see Support Protocol, steps 1 to 8) and digest with *MluI* or another restriction enzyme that cuts both the transposon insert and the BAC DNA.

MluI works well because it is a rare-cutting enzyme.

21. Analyze restriction fragments by pulsed-field gel electrophoresis (*UNIT 2.5B*; Fig. 23.11.4).

The authors typically run samples on a 1 \times TBE gel (using Bio-Rad PF-certified agarose) at 6 V/cm, 5- to 15-sec switch, for 20 hr at 14°C.

Verify insertion by sequencing (optional)

22. Sequence the modified BAC (see Chapter 7) using a primer directed against the 3' end of the *lacZ* gene to precisely map the transposon insertion site.

PREPARATION OF BAC DNA

Many methods are currently available to isolate BAC DNA (*UNITS 2.1B & 23.9*). This protocol describes a simple and reliable method of BAC DNA purification using phenol/chloroform extraction. BAC DNA purified by this method is suitable for many purposes including restriction digestion, sequencing, and (with the optional purification steps) pronuclear microinjection.

Materials

- Bacterial strain containing BAC of interest (see Basic Protocols 1 and 2 and see Internet Resources)
- LB medium (*UNIT 1.1*)
- Antibiotics appropriate for BAC strain of interest
- Resuspension solution: 50 mM Tris-Cl, pH 8.0 (*APPENDIX 2*)/10 mM EDTA
- 10 mg/ml RNase A
- Lysis solution: 200 mM NaOH (*APPENDIX 2*)/1% (w/v) SDS
- Neutralization solution: 3.0 M potassium acetate, pH 5.5
- 25:24:1 (v/v/v) phenol/chloroform/isoamyl alcohol, pH 6.7
- Chloroform

**SUPPORT
PROTOCOL**

75% and 100% (v/v) ethanol
TE buffer, pH 8.0 (APPENDIX 2)
3 M sodium acetate, pH 7.0 (for pronuclear microinjection only)
Microinjection buffer: 10 mM Tris·Cl, pH 7.4 (APPENDIX 2)/0.1 mM EDTA
(store ≤6 months at room temperature; for pronuclear microinjection only)
Size markers for gel electrophoresis (e.g., DNA Quanti-Ladder, OriGene Technologies; for pronuclear microinjection only)
PI-SceI and 10× reaction buffer (New England Biolabs; for pronuclear microinjection only)
37°C incubator, with shaking
Microcentrifuge, room temperature and 4°C
Pipet tip with large orifice
65°C heat block (for pronuclear microinjection only)
Additional reagents and equipment for agarose gel electrophoresis (UNIT 2.5A) and pulsed-field gel electrophoresis (see Basic Protocol 2)

NOTE: Reagents and water for pronuclear microinjection buffer must be tissue culture grade.

Prepare bacterial culture

For restriction digestion and Southern analysis

- 1a. Inoculate a single bacterial colony containing the BAC of interest into 2 ml LB medium with appropriate antibiotic(s) and incubate overnight at 37°C with shaking (225 rpm).
- 2a. Transfer 1.5 ml culture to a microcentrifuge tube, harvest cells by centrifuging 1 min at 10,000 × g, and resuspend pellet in 200 μl resuspension solution containing 2 μl of 10 mg/ml RNase A (100 μg/ml final).

For pronuclear microinjection

- 1b. Prepare an overnight culture as above, using a single colony in a volume of 10 to 20 ml LB medium with appropriate antibiotic(s).
- 2b. Harvest cells as above, but split culture into 5 to 10 tubes and process in parallel.

Isolate BAC DNA

3. Add 200 μl lysis solution and mix by gently inverting.

No incubation time is necessary.

Vortexing or vigorous shaking at this point will cause E. coli chromosomal DNA contamination.

4. Add 200 μl neutralization solution and mix by gently inverting. Centrifuge mixture 10 min at 12,000 × g, 4°C.

No incubation time is necessary after adding neutralization solution.

5. Transfer supernatant to a new microcentrifuge tube and add 500 μl of 25:24:1 phenol/chloroform/isoamyl alcohol. Vortex 5 sec and centrifuge 2 min at 12,000 × g, room temperature.

The mixture can be vortexed because supercoiled BAC DNA does not shear.

6. Transfer upper phase to a new tube and add 500 μl chloroform. Vortex 5 sec and centrifuge 2 min at 12,000 × g, room temperature.

7. Transfer upper phase to a new tube and add 900 μl of 100% ethanol. Centrifuge mixture 30 min at $12,000 \times g$, 4°C .
8. Carefully remove supernatant and wash pellet with 75% ethanol. Remove ethanol and let pellet air dry for 5 to 10 min. Resuspend pellet in 20 μl TE buffer.

This BAC DNA (1 to 2 μg) can be used for restriction digestion and subsequent Southern analysis.

Purify BAC DNA for pronuclear microinjection

9. Pool DNA samples into a single microcentrifuge tube.
10. Adjust volume to 400 μl with TE buffer and add 40 μl of 3 M sodium acetate and 800 μl of 100% ethanol.

The DNA will immediately precipitate and form an aggregate. This step will remove most, but not all, of the contaminating bacterial RNA.

11. Transfer aggregate to a new tube using a pipet tip with a large orifice. Pulse-spin aggregate down to the bottom of the tube.
12. To remove remaining trace amounts of bacterial RNA, dissolve pellet in 500 μl TE, add 1 μg RNase A, and incubate 30 min to 1 hr at room temperature.
13. Add 500 μl phenol/chloroform/isoamyl alcohol. Vortex 5 sec and centrifuge 2 min at $12,000 \times g$, room temperature.
14. Transfer upper phase to a new tube and add 500 μl chloroform. Vortex 5 sec and centrifuge 2 min at $12,000 \times g$, room temperature.
15. Transfer upper phase to a new tube and add 50 μl of 3 M sodium acetate and 900 μl of 100% ethanol. Centrifuge 30 min at $12,000 \times g$, 4°C .
16. Wash pellet with 75% ethanol, let air dry, and resuspend final pellet in 10 to 20 μl microinjection buffer.

BAC DNA can be stored at 4°C for up to 6 months. Freezing and thawing will cause shearing.

17. Run an aliquot on a 0.8% (w/v) agarose gel (UNIT 2.5A) with a known amount of size markers and estimate DNA concentration. Immediately before microinjection, dilute an aliquot of DNA to a final concentration of 0.5 to 1 ng/ μl with microinjection buffer.

*Although circular BAC DNA can be used for microinjection, the authors prefer to control the linearization site by digesting the BAC DNA with *PI-SceI* as described below. The recognition site for *PI-SceI* is extremely rare, occurring once in every 7×10^{10} base pairs of random sequence. It has been incorporated into the backbone of BAC vectors derived from CHORI.*

Linearize BAC DNA (optional)

18. Mix together the following:

2 μg BAC DNA
2 μl 10 \times reaction buffer
2 U *PI-SceI*
H₂O to a final volume of 20 μl .

Incubate ≥ 3 hr at 37°C and heat inactivate 20 min at 65°C .

19. Verify that digestion is complete by pulsed-field gel electrophoresis (see Basic Protocol 2, step 21).

20. Add the following to the tube:

80 μl H₂O
15 μl 3 M sodium acetate
300 μl 100% ethanol.

Centrifuge 30 min at 12,000 $\times g$, 4°C.

21. Wash pellet with 75% ethanol, let air dry, and resuspend DNA in 20 μl microinjection buffer.

22. Estimate DNA concentration on an agarose gel (step 17). Immediately before injection, dilute an aliquot to a final concentration of 0.5 to 1 ng/ μl using microinjection buffer.

The concentration should be ~100 ng/ μl after linearization.

Linearized BAC DNA can be stored at 4°C for up to 2 months.

COMMENTARY

Background Information

Bacterial artificial chromosomes (BACs) are a derivative of the *E. coli* F-factor-based plasmid. As an alternative to YACs (yeast artificial chromosomes), BACs have been developed for the construction of large genomic DNA libraries (Shizuya et al., 1992). Although they may propagate inserts approaching 500 kb in length, BAC insert sizes are typically 100 to 300 kb. BAC clones have several notable advantages over YACs. These include high stability and minimal insert rearrangements because of the F-factor genes *parA* and *parB*, which prevent more than one BAC from growing in an *E. coli* host. In addition, BACs are relatively easy to manipulate and propagate because they exist as supercoiled circular plasmids that are resistant to shearing. These advantages have made BACs the vector of choice for a variety of genomic-based research projects.

Despite a wide variety of applications, cloning strategies that rely on DNA restriction enzyme and DNA ligase reactions are often difficult to carry out because of limitations in the size of the DNA that can be manipulated or because of the lack of convenient restriction sites. Homologous recombination has provided an alternative approach to engineering DNA, and various systems have been developed to perform these manipulations in *E. coli*. These systems include recombination between two linear DNAs (Chartier et al., 1996), between linear and circular DNAs (Zhang et al., 1998; Lee et al., 2001), or between two circular DNAs (Gong et al., 2002). Many of the modification systems rely on targeting vectors that contain a conditional replication origin, so that recombination function can be transiently supplied.

In addition to these approaches, a new method to modify BACs was recently developed using in vitro transposition steps (Spitz et al., 2003). This protocol utilizes the Genome Priming System (GPS; New England Biolabs), which was initially developed for generating a population of DNA sequencing templates with randomly interspersed primer-binding sites. As the pGPS vector contains multiple restriction sites, it is highly conducive to cloning different types of inserts, including reporter constructs, and thus provides a rapid and convenient way to randomly introduce DNA of interest into BACs.

Critical Parameters and Troubleshooting

The recommended length of homology arms ranges from 300 bp to 500 bp. Homology arms >500 bp should also work well (although this has not been tested), but shorter ones may cause a decrease in the recombination frequency.

With electroporation, the transformation efficiency should approach $\sim 10^8$. Competent cells prepared from overgrown cultures (>0.8 OD₆₀₀) will result in a 10- to 100-fold reduction in transformation efficiency.

In transposition reactions, a starting molar ratio of $\sim 1:1$ targeting vector (pGPS1- β LacZ) to BAC is optimal. In a 20- μl reaction, 20 ng of targeting vector and 200 ng of BAC target usually works well. It is recommended to try several different ratios. Saturating amounts of the targeting vector will inhibit the reaction, however, and may result in an increased number of BAC clones carrying double insertions.

During the assembly step in the transposition reaction, TnsB binds to the Tn7 transposon

elements, and TnsA recognizes the TnsB:DNA complex. TnsC binds to the target DNA and interacts with TnsB. When these three proteins are properly bound in a two-DNA:three-protein complex, the strand transfer will occur. If the start solution is added before this assembly, the proportion of complicated products will greatly increase.

The transposition reaction must be stopped by heating at 75°C for 10 min to inactivate the transposase. Heating at 65°C for 20 min does not effectively disrupt the reaction complexes. Few or no recombinants will be obtained if this step is omitted or not executed properly.

Anticipated Results

In Basic Protocol 1, targeting can approach frequencies of 5% to 10%. If no recombinants are obtained, check the shuttle vector design (e.g., orientation of the homology arms). In Basic Protocol 2, the targeting efficiency ranges from 10% to 30%.

Time Considerations

Basic Protocol 1 can be executed in ~1 month (2 weeks for cloning homology arms into the shuttle vector, 1 day for making electrocompetent cells, 5 days for the co-integration step, and 7 days for the resolution step including confirmation of recombinants). Basic Protocol 2 can be executed in 7 to 8 days (3 days for preparing the targeting vector, 1 day for making electrocompetent cells, 3 to 4 days for the transposition step including the confirmation of recombinants). The Support Protocol can be executed in 1 day, with bacterial cultures started the evening before. BAC preparation for pronuclear microinjection may take another day or so.

Regulation of Transgene Expression Using Tetracycline

UNIT 23.12

**BASIC
PROTOCOL**

Transgenesis has been an efficient means of remodeling the mouse genome, and numerous gain-of-function and loss-of-function models have been and are being made. Although transgene expression was initially driven by systemic promoters, it quickly became apparent that more precise tools were needed, and the development of organ-specific or cell-type-specific promoters capable of driving high levels of transgene expression now provides investigators with the reagents needed to carry out precise transgenic expression that is targeted to a particular cell type.

Although a spectrum of different promoters have resulted in the spatial control of transgenic expression, by themselves they do not allow the ability to *reversibly* control expression at specific developmental times, and the developmental patterns of expression are dictated by the promoter construct used. For example, in the heart, the α -myosin heavy chain promoter has been widely used to drive cardiomyocyte expression, but it is only activated at 18 days of gestation and remains active in the adult (Ng et al., 1991). Thus, despite cell-type- and developmental-stage-specific expression, this approach limits the investigator to irreversible transgene activation at levels dictated by the copy number present (James and Robbins, 1997).

To circumvent these issues, inducible and reversible transgene expression systems have been developed (Shockett et al., 1995; Tsai et al., 1998). These systems normally are bigenic, with the activator and responder transgenes being driven in the same cell type in the animal. The most widely used system is based upon a transactivator fusion protein consisting of the *E. coli* tetracycline repressor linked to the strong transcriptional activation domain derived from the VP16 protein of herpes simplex virus, and both tet-on (the transgene is on in the presence of the drug) and tet-off systems have been described (Gossen et al., 1994; Baron et al., 1997). Although these systems have been used with great success in many different cell lines, their use in transgenic animals has been more limited, mainly because of the technical difficulties in obtaining a bigenic line that is not leaky, but that can be induced to produce the transgenic product at high levels and can subsequently be inactivated. This often necessitates the production of as many as 15 to 25 lines before usable ones are generated. Considering the expense and labor needed for even the preliminary analyses of the lines, this precludes the easy and widespread use of inducible systems for organ-specific or cell-type-specific expression within a transgenic context.

This protocol outlines the parameters involved in preparing a robust, reversible, and inducible system capable of driving high levels of transgenic expression in a cell-type-specific manner. Because these systems are necessarily cell-type-specific, a procedure is described that results in cardiac-specific inducible expression as an example. This protocol describes the administration of doxycycline to transgenic mice as a way of regulating gene expression. Previous units have described the cloning and production of DNA to be used in making transgenic mice (UNIT 23.10) as well as the generation of the transgenic animals (UNIT 23.9). The transgene consists of the coding region of the gene to be inducibly expressed cloned behind a modified attenuated promoter that is capable of being activated when a *trans*-acting factor driven from the second transgene binds to it. Two choices are available in selecting a doxycycline-dependent *trans*-activating factor; one is active in the absence of doxycycline (the tet-off system, tTA), while the

Supplement 71

Figure 23.12.1 Cell-type-specific inducible transgene expression. The two lines of mice needed for the experiments are shown. Mouse 1 contains the cell-type-specific promoter driving the fusion tet-VP16 protein that, in the presence of tetracycline (or doxycycline, a more stable form), will not bind to the responder promoter in mouse 2. The responder promoter is not active in the absence of tet-VP16 binding.

other is active in the presence of doxycycline (the tet-on system, rtTA). This protocol specifically describes inducible cardiac-specific expression using the tet-off system. The components of the system are illustrated in Figure 23.12.1, and a flow chart for the method is illustrated in Figure 23.12.2.

Materials

- Mouse line that expresses tTA in cell- or tissue-specific manner
- Mouse line that contains the cDNA of the gene of interest cloned behind the responder promoter
- Ear clip digest buffer (see recipe)
- PCR primers for screening the tet-off (tTA) construct:
 - AGCGCATTAGAGCTGCTTAATGAGGTC (forward)
 - GTCGTAATAATGGCGGCATACTATC (reverse)
- PCR primers for the cDNA being expressed (see *UNIT 15.1* for principles of primer design)
- Drinking water containing doxycycline (0.2 to 2 g/liter; see recipe) or prepackaged, irradiated mouse chow containing doxycycline (e.g., 625 mg/kg; Harlan Teklad)
- Light-protected (dark-glass or foil-wrapped) water bottles for mice
- 4.5-cm stainless steel ear punch (Fine Science Tools)
- Additional reagents and equipment for maintenance and care of transgenic animals (*UNITS 23.8 & 23.10*), PCR (*UNIT 15.1*), northern blotting (*UNIT 4.9*), quantitative PCR (*UNIT 15.7*), and immunoblotting (*UNIT 10.8*)

Mate and maintain animals

1. Mate the mice containing the transactivator and the responder components to one another.

Transgenic animal care and maintenance is covered in UNITS 23.8 and 23.10. Ideally the mice should be housed in a virus- and pathogen-free facility.

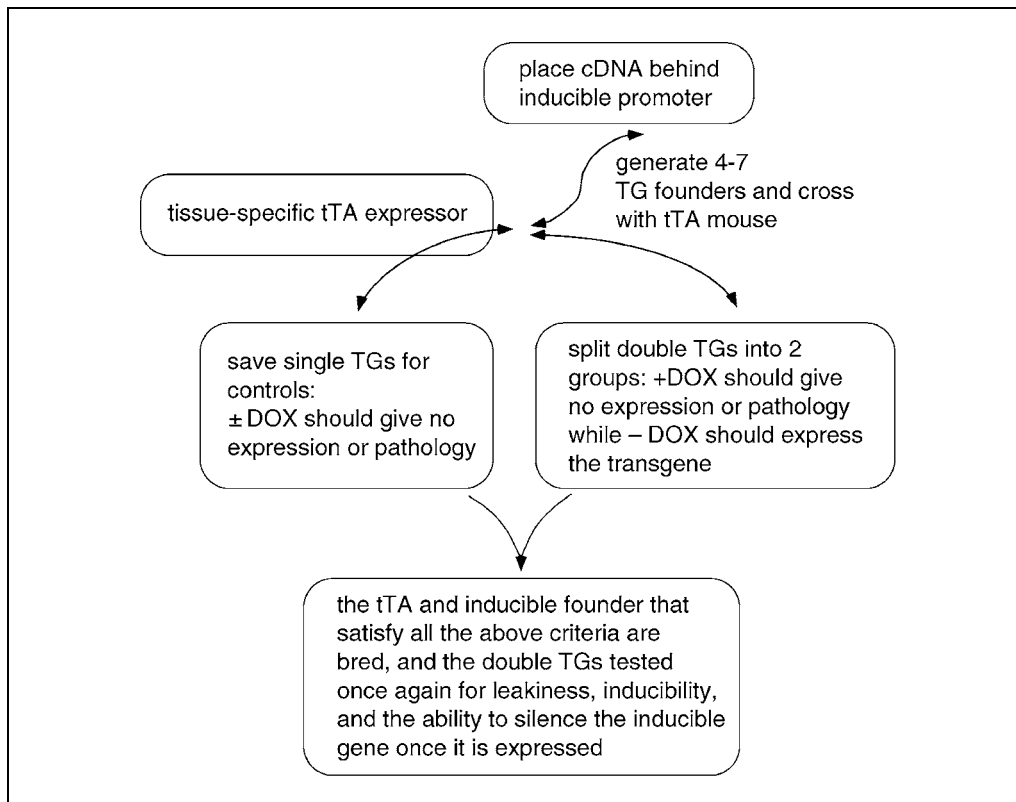

Figure 23.12.2 Flow chart for tet-off inducible transgene expression.

The myosin heavy chain promoter has been used to drive expression of the tTA in a cardiac-specific manner as previously described (Sanbe et al., 2003). For the responder side of the inducible system, a modified, attenuated myosin heavy chain promoter was used to drive expression of the specific cDNA, providing an additional level of specificity. Both constructs needed for cardiomyocyte-specific expression are available from the authors at jeff.robbs@cchmc.org.

2. If necessary, provide dams with doxycycline after mating to shut off transgene expression in gestating pups. See step 8 for administration routes and concentrations.

Some of the pups will be positive for both arms of the system. If the gene that is being expressed is expected to be embryonic-lethal, it may be necessary to shut off the transgene until later in development. Doxycycline can penetrate the placental barrier, inactivating transgene expression during gestation.

Genotype pups by PCR

3. When the pups are about 10 to 12 days of age, clip one ear using a 4.5-cm stainless steel ear punch for identification purposes. Retain the clipped ear tissue for genotyping.
4. Digest 0.2 to 2 mg of tissue from the ear clip overnight at 65°C in 100 µl ear clip digest buffer.
5. At end of incubation boil for 10 min to inactivate the proteinase K.
6. Use 1 µl of the reaction mix in a 50-µl amplification reaction (UNIT 15.1). Perform PCR to screen the tet-off construct using the following cycling program:

1 cycle:	3 min	94°C	(initial denaturation)
35 cycles:	20 sec	94°C	(denaturation)
	30 sec	65°C	(annealing)
	30 sec	72°C	(extension)
1 cycle:	10 min	72°C	(final extension).

7. Perform a separate amplification reaction to screen the cDNA being expressed, using the appropriate primers and PCR conditions.

See UNIT 15.1 for additional details on PCR amplification.

Administer doxycycline to double-transgenic animals

- 8a. *To administer doxycycline via water:* To keep transgene expression off, supply mice with drinking water containing doxycycline, in dark bottles, changing the water at least three times per week.

Dark water bottles are used, as doxycycline is light-sensitive. If not available, the water bottles can be wrapped in foil, although the mice have a tendency to shred the foil.

- 8b. *To administer doxycycline via food:* Supply commercial prepackaged, irradiated mouse chow containing the appropriate concentration of doxycycline. Change food weekly.

The authors have used chow containing 625 mg/kg doxycycline successfully, but chow containing higher dosages can be purchased if necessary. Gamma-irradiated food allows the doxycycline to be fed to mice housed in virus- and pathogen-free facilities. Since the doxycycline may break down over time, the food should be stored in a cool, dry place such as a cold room, used within 6 months of initial purchase, and changed regularly.

Analyze transgene response

9. Determine levels of RNA resulting from transcription of the transgene by northern analysis (UNIT 4.9) or quantitative PCR (UNIT 15.8).

Usually, the 3' untranslated region of the transgene consists of a viral polyadenylation signal, such as one derived from SV40, which can be probed on a northern blot. In the case of the α -myosin heavy chain responder, a human growth hormone (hGH) poly(A) signal was used, but, as this sequence is also present in the α -myosin heavy chain inducer line, a probe specific for the cDNA should be used instead.

10. Monitor levels of protein resulting from translation of the transgene by immunoblotting (UNIT 10.8), using antibodies specific for the translated protein to detect changes in protein levels.

Under certain circumstances, it may be necessary to add a tag to the cloned gene so that the translation of the protein can be verified.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Drinking water containing doxycycline

H₂O containing:
0.2 to 2 g/liter doxycycline
1% (w/v) sucrose
Use dark (or foil-wrapped) bottles in cages
Change at least three times per week
Prepare fresh solution for each change

The amount of doxycycline to be used is determined empirically. The authors have found that 0.2 g/liter works well in most cases, turning a lacZ reporter off in the tet-off system. In a few cases, 1 g/liter was necessary, possibly due to the responder lines containing relatively more copies of the transgene or due to chromosomal influences at the site of transgene integration. The authors have noted no specific adverse effects from higher doses of doxycycline except for a 10% to 15% reduction in liver mass. Adding doxycycline to the drinking water of pregnant or nursing dams at 2 g/liter will inactivate transgene expression in utero or until the pups are weaned.

Ear clip digest buffer

1 × PCR buffer (*UNIT 15.1*) containing:
0.45% (v/v) Nonidet P-40 (NP-40)
0.45% (v/v) Tween 20
10 mg/ml proteinase K
Store indefinitely at -20°C

COMMENTARY

Background Information

An overview of the technical basis for a tet-based inducible system can be found in *UNIT 16.14*. While good results can often be achieved in tissue culture with both the transactivator and responder components being driven by viral promoters, with transgenic animals, additional levels of specificity are necessary. Thus, despite the obvious advantages of reversibly altering cardiac transgene expression, the number of successful studies carried out in vivo with inducible cell-type-specific transgene expression remains limited. Current systems are plagued by a need for bi-genic breeding and by the large number of lines needed before a nonleaky, inducible line is isolated. Although a heterologous, viral-based minimal promoter such as the cytomegalovirus (CMV) promoter is often used in the responder line to drive inducible expression, the authors of this unit have found that this exacerbates the difficulties, as those promoters are often position-dependent or can be methylated and subsequently inactivated as the line is propagated from one generation to the next. The TetR-VP16 fusion protein, at least in some tissues, is not benign. Bujard and colleagues have explored the potential of creating modified proteins that exhibit decreased generalized transcriptional squelching, improved DNA-activator binding characteristics, increased sensitivity, and expanded induction range (Baron et al., 1997; Urlinger et al., 2000). Although these transactivators appear to work very well in cells, the authors of this unit have now tested a number of the constructs in transgenic mice and found that, when expressed in the heart, they cause cardiovascular disease. The single transactivator lines must therefore be tested carefully for pathology in the target tissue before being used.

This unit describes a “tet-off” system, but “tet-on” systems have also been described and, in a few instances, used successfully in transgenic animals (Russell et al., 2004). However, in the authors’ experience with the cardiovascular system, these systems are more often leaky, and also difficult to induce fully,

necessitating the creation of a large number of lines before a satisfactory one is found. Other inducible systems have also been adopted successfully for transgenic use (Wang et al., 1997), but these systems use less innocuous inducers that can have undesired pleiotropic effects on the animals. At this point, the tetracycline-based systems have clear advantages for long-term animal-based studies because the required drug treatment is minimally intrusive on the animals’ general physiology.

Critical Parameters

Activator line

The availability or creation of a stable activator line is critical. The line should produce enough activator homogeneously in the target cell population so that, in the presence of the inducer, gene expression is rapidly initiated in a cell-type-specific, homogeneous manner. The authors have found that, for the cardiac system, very low levels of expression yielding only trace amounts of protein are desirable, as higher levels invariably lead to morbidity and detectable cardiac pathology, despite the use of supposedly more benign classes of fusion proteins (Sanbe et al., 2003). Once an activator line is obtained, it should be used exclusively, and the animals should be bred only when they are young adults, so as to avoid more robust variants that might be gradually selected for as the colony ages. Although it is desirable to carry the transactivator transgene in a homozygous animal for ease of generating the double-transgenic animals necessary for the experimental cohorts, this may not be possible because of the transactivator’s potential toxicity. For the cardiac-specific transactivator line prepared in the authors’ laboratory (Sanbe et al., 2003), the homozygote tTA mice are viable, with the males being used for breeding. The mice cannot be maintained as homozygous lines, however, because the dams die shortly after giving birth. In addition, detectable cardiovascular disease is present as early as 5 months after birth in these animals, and they are normally not used for breeding after 20 weeks.

The choice of the fusion protein, either “tet-on” or “tet-off,” and the promoter that drives its expression is critical. Clearly, it would be more desirable to use a “tet-on” system in which drug administration is only necessary for transgene induction. Although the modified fusion proteins that result in a tet-on system have been described, and only a few amino acid changes are needed to convert a tet-off transactivator to a tet-on protein, in the authors’ hands these lines have been problematic. Even with carefully engineered promoters in both the activator and responder lines, they have invariably shown leaky expression or inefficient induction. Additionally, the tet-on transgene is quite toxic when expressed in the heart, even more so than the tet-off transactivator. Therefore, if the tet-on system is used in its present stage of development, the investigator should be prepared to generate a large number of lines before finding one that works satisfactorily. In contrast, the tet-off system described in this unit often requires breeding the transactivator line to only a few responder lines (see below) before a satisfactory bigenic animal is isolated.

Many cell-type-specific promoters have been described and used to make transgenic animals. The promoter driving the tTA activator should drive uniform expression in only the target cells, so that the responder transgene is activated in a specific cell background. Thus, the more restricted the expression pattern of the promoter that is used, the more precise the inducible experiment will be. The promoter should be stable and not subject to large variations in expression as a result of feedback inactivation/activation in the presence of a pathological response, as this could have the effect of modifying expression of the activator during the course of the experiment. High levels of expression are not a requirement, as only very low levels of transactivator are needed, or even desired, due to the toxic effects that may be observed. Thus, weak promoters can be used as long as they are expressed in all of the target cells and do not show a patchy expression pattern.

Responder line

The responder arm of the bigenic system normally consists of a minimal CMV promoter linked to multiple copies of the tet operator. Depending upon the target tissue, this general strategy can also present a series of significant experimental problems. For cardiac-specific inducible expression, although it was possible to obtain lines of mice that showed minimal expression levels when noninduced

and responded appropriately during induction, isolating a line that displayed those characteristics necessitated the production of many (9 to 23) lines of animals. Thus, transgenic mice obtained with such constructs only rarely yield the necessary inductive range, presumably because of the sensitivity of the minimal CMV promoter construct to chromosomal context. To circumvent these difficulties and decrease the number of lines needed before a satisfactory one is obtained, the authors redesigned this part of the system around the well-characterized α -myosin heavy chain promoter, the goal being to create a construct from the endogenous DNA that showed low background expression levels, that could be highly induced, and that was relatively insensitive to chromosomal location. This promoter has a potential advantage over the other minimal promoter constructs in that it also is highly cardiac-specific and appears to be relatively independent of chromosomal context in its expression pattern (Palermo et al., 1996). For any tissue-specific expression, the object is to create a minimally active promoter that retains these characteristics. For adult cardiomyocyte-specific expression, a successful strategy involved taking an already cell-type-specific promoter and crippling it by ablating those sites responsible for high levels of expression. Thus, for the α -myosin heavy chain promoter, three GATA sites and two thyroid-like response elements, each of which plays a role in maintaining high levels of cardiac-specific expression, were ablated (Subramaniam et al., 1993; Robbins et al., 1995). When induced, this otherwise crippled promoter drives high levels of expression. With only a limited number of lines (three to six) being produced, one or more show no expression of the transgene in the single-transgenic animal or in double-transgenic mice in the presence of doxycycline, but high levels of expression in double-transgenic animals when the drug is withdrawn. The authors believe that this general approach, using a crippled endogenous promoter rather than an ectopic viral promoter, results in a more robust system.

Mouse strains

Strain variation can play a significant role in modulating phenotype. If the activator or responder lines are in different strains, there is no guarantee that they will behave as anticipated, either because of modifier effects or because of patterning of the exogenous DNA in the different genetic background. Thus, each transgene should be placed in the same strain,

and the background maintained in the bigenic animal.

Troubleshooting

Activator lines

For cardiac-specific inducible expression, a stable and robust system has been described in this unit, which should lead to the rapid growth of the number of inducible lines for this organ system. Development of inducible transgenic systems for other cell types has also been described (e.g., unique cell types in the lung: Clark et al., 2001; Perl et al., 2003), and the list is expected to grow. However, if an activator line is not available for the desired cell type, its development can be difficult, and many different promoters and combinations with different tet-on or tet-off constructs may need to be tried before a line with the desired characteristics is obtained. If no transactivator protein is detected, the sensitivity of the immunoblot should be confirmed either with recombinant protein or with extracts obtained from previously characterized transactivator lines known to effectively induce expression. Even if no protein can be detected, the transactivator may be present in sufficient quantities to activate a responder transgene, and should be bred to an indicator line in order to determine if a biological read-out can be obtained.

The lack of production of detectable protein in the transactivator line could also be due to illicit splicing between the promoter and transactivator DNAs, so the transcript species may need to be sequenced in order to determine where the illicit splice junction lies so that it can be removed. Once again, the potential pathology due to the transactivator's expression needs to be carefully considered, with the organ system or cell type under study carefully followed over the animal's lifetime. Only lines that yield no detectable pathology in the heterozygote state should be chosen for the transactivator production line.

Responder lines

The responder lines should be carefully tested for expression in the absence of the transactivator or transactivator/inducer. If expression is observed, the investigator will need to decide whether the levels can be tolerated or additional lines need to be generated. In this cardiac-inducible system, only a limited number of lines are needed in order to generate one with the desired characteristics (Sanbe et al., 2003). In a number of cases, the lines are not leaky, but cannot be induced.

Generating additional lines invariably solves this problem. Finally, for some lines, it is impossible to silence the transgene after it has been activated, or a second cycle of transgene activation/inactivation is somewhat attenuated (J. Gulick and J. Robbins, unpub. observ.). The reasons for these phenomena are unknown, but they appear to be line-dependent, so that any difficulties encountered can usually be circumvented by generating additional lines.

Anticipated Results

In the authors' experience, the transactivator line, once established, is stable and can be repeatedly used as long as the mouse strains are kept constant. The responder line—once a stable construct is established, such as that reported for the cardiac-specific induction detailed in this unit—is also stable and quite robust in its ability to drive both strong biological effectors and structural proteins that are abundant in the cardiomyocyte. Normally, five or fewer lines will yield at least one that is not leaky and can be effectively induced and subsequently silenced.

The time course of induction and silencing will, of course, depend upon the half-life of the transgene's RNA and protein, but expression levels are usually detectable within 24 to 48 hr after the drug is withdrawn. Even long-lived RNAs and proteins can be silenced within a week or so after the drug is added in the tet-off system.

Time Considerations

These are time-consuming experiments and take considerably longer than standard, cell-type-specific transgenesis. The flow diagram (Fig. 23.12.2) assumes that a suitable activator mouse is available and that a generic responder promoter also exists. In that case, a responder line needs to be designed and made; this can be a lengthy process that is dependent upon the responder promoter's efficacy. Responder promoters that have been tested in other organ systems may very well work in a heterologous cell or tissue, and should be tried before undertaking a completely new design. Even so, the particular construct under study will need to be made and placed into the responder locus, and the mice will then have to be generated—a process that can take anywhere from 2 to 4 months. Subsequently, that line needs to be tested for transgene expression in the absence of the second transactivator transgene to confirm that leaky expression has not occurred. This can take another 2 months. Coincident with those experiments,

the double transgenics are bred and this cohort is split so that transgene expression can be induced in some of the animals. Finally, after the lines have been chosen on the basis of nonleaky expression, inducibility, and ability to silence the transgene after it has been activated, the double-transgenic cohorts need to be raised in sufficient quantities for the experiments. The complete process can easily take from 6 months to 1 year.

Overview of Agents from Combinatorial Nucleic Acid and Protein Libraries

UNIT 24.1

UNIT 24.1 will be published in an upcoming supplement.

Generation and
Use of
Combinatorial
Libraries

24.1.1

Design, Synthesis, and Amplification of DNA Pools for Construction of Combinatorial Pools and Libraries

This unit describes the design, synthesis, and amplification of a random sequence DNA pool. Functional nucleic acid-binding or catalytic species can be selected from these random sequence pools. In designing the DNA pool, careful consideration should be given both to the degree of randomization and the length of the random sequence region (see Strategic Planning). Following pool design, chemical synthesis on a commercial DNA synthesizer will yield a single-stranded DNA pool. The newly synthesized oligonucleotide pool can then be purified (see Basic Protocol 1). Prior to amplification, the initial complexity of the pool should be determined (see Support Protocol 1), the skewing of the pool should be determined (see Support Protocol 2), and amplification reaction conditions should be optimized (Support Protocol 3). If the nascent synthetic oligonucleotide is judged to be suitable for large-scale amplification, it can be enzymatically converted into a double-stranded DNA library (see Basic Protocol 2). Multiple copies of a single-stranded DNA pool can be derived from each double-stranded DNA library, or the library can be transcribed to yield a RNA pool or a modified RNA pool (see UNIT 24.3). Figure 24.2.1 outlines the procedure.

NOTE: The above comments and the protocols in this chapter are most relevant to the design of pools from which nucleic acids with binding activities (aptamers) or other enzymatic activities can be selected. However, many of the concepts and procedures are relevant for the design and synthesis of nucleotide pools that encode peptides of variable sequence. Considerations specific to the construction of nucleotide pools designed to encode peptides of variable sequence are given in UNIT 23.4.

STRATEGIC PLANNING

Designing the Initial DNA Pool

The nucleic acid pools used for in vitro selection experiments typically contain a randomized central core flanked by constant sequences that are required for enzymatic manipulations, such as PCR amplification, in vitro transcription, or restriction digestion (see also Fig. 24.2.2).

Since a pool is relatively expensive to synthesize, both in terms of time and cost, some effort should be devoted to pool design. There are many subtle parameters to consider that can greatly influence the outcome of a selection experiment, including the degree of randomization, pool length, and pool modularity (see Table 24.2.1 for references to selection experiments that have previously been successfully executed with different types and sizes of pools).

Type of selection and degree of randomization

Most researchers who carry out in vitro selection experiments wish to either better define or optimize a known binding site (binding-site selection), or to identify a nucleic acid that binds a particular ligand or site (aptamer selection; UNIT 24.3). Each of these tasks in turn requires the synthesis of different types of pools. The sequences and structures that contribute to known binding sites are frequently best defined by selections that start from partially randomized pools. One example of binding-site definition that started from a partially randomized pool was a selection that defined critical residues of the Rev-respon-

sive element (RRE) of HIV-1 Rev (Bartel et al., 1991). This experiment is also described in more detail below. Biased pools can also be used for the optimization of a previously isolated motif. For example, aptamers that could bind to the Rex protein of HTLV-1 were selected from a partially randomized pool based on the wild-type Rex-binding element (XBE) but in the end bound Rex 9-fold better than the XBE (Baskerville et al., 1995).

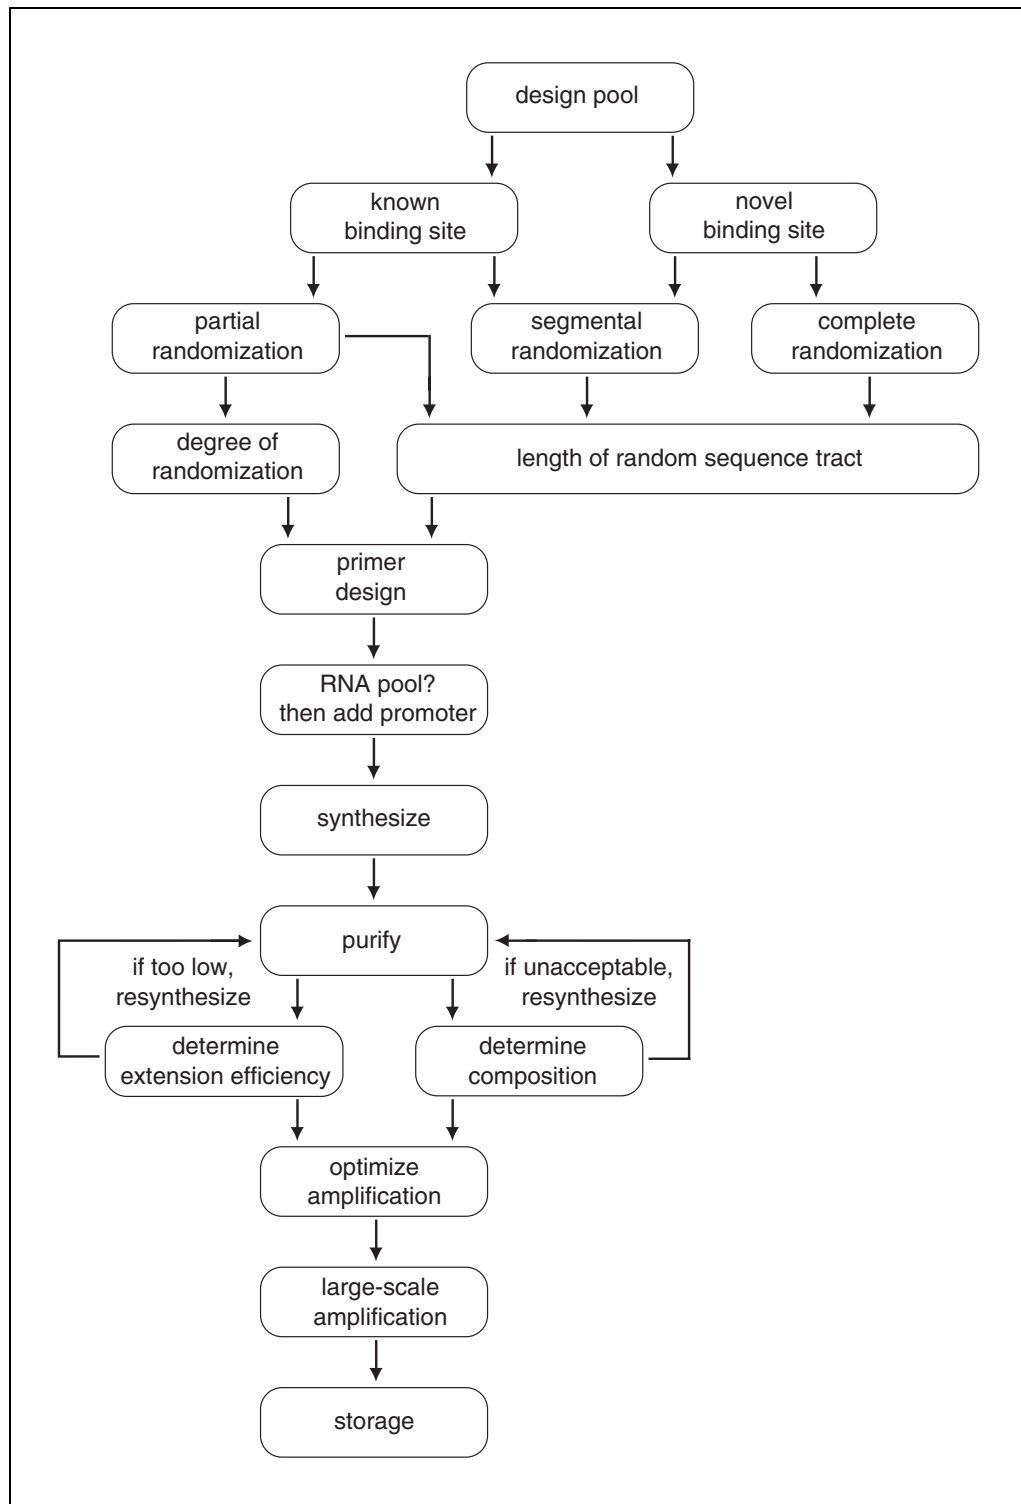

Figure 24.2.1 Flow chart outlining pool design, synthesis, and large-scale amplification.

Intermediate between partially random and completely random sequence pools are segmentally random sequence pools. In a segmentally random pool, short tracts of sequence are completely randomized. Segmental randomization thus allows all possible sequences within a short region or set of residues to be examined. Thus, if a natural binding site is known, but a portion of that binding site is suspected to be particularly important for function, then a segmentally random pool can be used to identify all possible, functional sequences within the wild-type sequence context. For example, Tuerk and Gold (1990) selected aptamers that bound T4 DNA polymerase from a pool that contained 8 random sequence positions flanked by wild-type residues. Similarly, many binding sites are known to be presented within a particular structural context, such as a stem-loop or stem-bulge structure. In these cases, a portion of the structure can be completely randomized, and all possible functional stem-loops or stem-bulges can be identified. For example, the Rev-binding element was known to form a stem-internal loop-stem structure. Giver et al. (1993) segmentally randomized only the internal loop portion of the structure and selected Rev-binding species. Many of the anti-Rev aptamers had sequences that were significantly different than the wild-type, yet were still presented in the context of a stem-internal loop-stem structure.

Partially random (doped) pool design (binding site selection)

The most important issue in the synthesis of a doped pool is the level of randomization (the probability of sequence substitution/position). As a general rule, the substitution frequency of a doped pool should roughly correspond to the number of positions thought to be required for function. For example, if 10 residues within a nucleic acid binding site are thought to be functional, then the rate of substitution might be set to yield single mutants at least half the time. If the substitution frequency is set too low, there may be too few varying residues or combinations of residues to yield information about functional sequences or structures. In contrast, if the substitution frequency is set too high, the sequence space nearest the wild-type motif will only be sparsely sampled, and many of the highly mutated molecules may be nonfunctional because their sequences will have diverged too far from the wild-type.

For example, an in vitro genetic analysis has been used to uncover the critical structural interactions between the HIV-1 Rev protein and its primary RNA binding site, the Rev-binding element (Bartel et al., 1991). The RBE had previously been mapped by deletion analysis to a short segment of HIV-1. Bartel and his co-workers assumed that the minimal RBE was smaller even than the region identified by deletion analysis, and thus decided to heavily dope a portion of a 66-nucleotide sequence at a frequency of 35% substitution/position. The initial RRE library contained $\sim 10^{13}$ molecules that had an average of 23 substitutions/template (0.35 probability substitution/position \times 66 positions = ~ 23 substitutions); less than 1 in 10^{12} molecules were completely wild-type. Following selection, a 20-nucleotide core-binding site within the 66-nucleotide pool was readily defined by sequence conservations and covarying residues. A lower substitution rate might not have precisely defined the relatively small binding site, while an even higher substitution rate might have created a mutational load that would have limited the selection of functional molecules or even have allowed the selection of novel, non-wild-type anti-Rev aptamers (Giver et al., 1993; Tuerk and MacDougall-Waugh, 1993). Conversely, if the binding site were larger than originally hypothesized, the relatively high rate of substitution might have meant that few functional molecules could have survived the selection unscathed.

The number and type of sequence substitutions, as opposed to the probable target size for mutation, can also be used to plan the synthesis of a doped sequence pool, as described by the following equations. Typically, a 1- μ mol synthesis of a 100-residue template yields

Figure 24.2.3 Comparison of substitution distributions for a 66-nucleotide pool doped to either 18% or 35%.

a pool of $\sim 10^{15}$ amplifiable molecules. Regardless of the degree of partial randomization or the precise doping strategy employed, the number of different mutational combinations is given by:

$$3^n \{L!/[n!(L-n)!]\}$$

where n is the number of sequence substitutions/template in a template of length L . For example, in the case of the 66-nucleotide RRE pool discussed earlier, there were $\sim 2.17 \times 10^9$ possible 5-residue substitutions and $\sim 1.25 \times 10^{16}$ possible 10-residue substitutions.

To calculate what fraction of a given set of substitutions are actually contained in a doped pool, the binomial probability distribution can be used:

$$P(n,L,f) = \{L!/[n!(L-n)!]\}(f^n)(1-f)^{(L-n)}$$

where P is the fraction of the template population when f is the probability of substitution/position. If primarily single-base substitutions are desired, then f should be maximized for $n = 1$; if multiple mutations (e.g., double or triple substitutions) are desired, then f should be correspondingly higher. If the doping strategy is optimized for n substitutions, then this number of substitutions will occur most frequently, “ $n - 1$ ” and “ $n + 1$ ” substitutions will occur less frequently but in roughly equal numbers, and so forth. Higher levels of sequence substitution skew the mutant frequency distribution, allowing the sampling of some regions of sequence space at the exclusion of others (Fig. 24.2.3).

Therefore, in the RRE example already cited, a pool of 1×10^{13} molecules doped at a frequency of 35% would contain few 5-residue substitutions [$1 \times 10^{13} \times P(5,66,0.35) = \sim 1.82 \times 10^6$ 5-residue substitutions out of $\sim 2.17 \times 10^9$ possible 5-residue substitutions]. In contrast, if the pool were doped at a frequency of 18%, all 5-residue substitutions would almost certainly be included [$1 \times 10^{13} \times P(5,66,0.18) = \sim 9.3 \times 10^{10}$ 5-residue substitutions].

Note that in a pool of only 1×10^{13} total molecules, neither doping scheme would yield all possible 10-residue substitutions.

Completely random pool design (aptamer selection)

Completely random sequence pools are used to initiate selection experiments when no functional nucleic acid sequence or structural motif is known in advance. There is really only one parameter to consider when designing a completely random pool: the length of the random region. While we will consider this parameter in detail below, we must first dismiss a frequent bogey of selection neophytes, the issue of complexity and representation.

Random sequence space is a vast landscape of possibilities of which only a vanishingly small fraction can be sampled by either nature or man. Assuming a 4-monomer repertoire from which pools can be constructed, there are $\sim 1.6 \times 10^{60}$ unique individual sequences in a sequence space bounded by a 100-residue template ($4^{100} = \sim 1.6 \times 10^{60}$), a quantity of nucleic acid greater than an Avogadro's number of Earth masses. While this grotesquely large value is clearly beyond the realm of experimental possibility, modern methods of chemical nucleic acid synthesis do allow the sampling of nearly as much sequence information as may be contained in the Earth's biosphere. As a back-of-the-envelope calculation, consider that there are on the order of $\sim 1 \times 10^9$ species in the biosphere, each with $\sim 1 \times 10^5$ genes. If each of these genes in turn is composed of $\sim 1 \times 10^3$ residues, then there are $\sim 1 \times 10^{17}$ residues worth of information in a biosphere. In contrast, a typical 1- μ mol synthesis of a 100-residue random sequence pool would contain 1×10^{15} molecules $\times \sim 1 \times 10^2$ residues/molecule = $\sim 1 \times 10^{17}$ unique residues or roughly 1 biosphere's worth of information. Obviously, the connection and ordering of sequence information in organisms is important as well.

Typically, a random sequence pool contains $\sim 1 \times 10^{15}$ molecules, and thus can potentially sample on the order of all possible 25-mers ($4^{25} = \sim 1.1 \times 10^{15}$). In fact, since different 25-mers can be found in different "reading frames," a slightly larger sequence space will likely be sampled. Because of this physical restriction, it is sometimes thought that random sequence pools should be no more than 25 residues in length—any longer, and only a fractional sampling would be possible, and many potential sequences would be lost. While this is true, it should be realized that longer pools do not lose any of the numerical complexity of smaller pools (except in those instances where long syntheses are extremely inefficient) and in fact gain access to some fraction of longer sequence and structural motifs as well. For example, tRNA molecules are roughly 76 nucleotides in length. It might prove more difficult to select tRNA mimics from a random sequence population containing 30 randomized residues than from a pool spanning 80 randomized residues. However, any short functional tRNA mimics present in the shorter population should also be present in equal or greater number in the longer population. In most instances, the relative completeness of the pool is not a consideration in the success of a selection. Indeed, it has been shown that functional nucleic acids are not extremely rare (for recent reviews see Gold et al., 1995; Fitzwater and Polisky, 1996) and can be isolated both from "complete" pools that span 20 random sequence positions and from very "incomplete" pools that span 90 random sequence positions.

Having dismissed considerations of complexity and representation, the one guiding principle that emerges from this analysis is that longer pools are more generally useful for selection experiments than shorter pools. However, this principle must be applied with appropriate caveats. First, aptamers derived from shorter pools are easier to analyze. Sequence and structural motifs embedded within a 30-nucleotide random sequence region are much more readily apparent than sequence and structural motifs embedded within a

90-nucleotide random sequence region, especially if the motifs are not colinear. Second, longer pools are more difficult to synthesize than shorter pools. Finally, longer pools are more likely to yield amplification or other selection artifacts than shorter pools. For example, pools that contain random regions greater than 90 nucleotides in length can form self-aggregates that precipitate from solution upon prolonged incubation, and thus require immobilization on a solid support prior to selection (Bartel and Szostak, 1993; Lorsch and Szostak, 1994). Because of these considerations, pools used for the *in vitro* selection of aptamers typically contain from 20 to 80 random sequence positions.

Longer pools are not only desirable but are likely required in selections for complex functions, such as catalysis. Pools used for the selection of ribozymes typically contain from 50 to 220 random sequence positions (for recent reviews see Gold et al., 1995; Fitzwater and Polisky, 1996). The optimal length of the random region is an active area of research (Sabeti et al., 1997) where many of the fundamental parameters remain to be defined. Practically, though, longer pools must be synthesized as oligonucleotides of 150 residues or fewer in length because of the constraints of DNA synthetic chemistry. For this reason, pools longer than 150 bases are typically generated in a modular fashion by ligating together individual, synthetic oligonucleotides (Bartel and Szostak, 1993). Segments of shorter DNAs can be stitched together by the inclusion of unique restriction sites (Bartel and Szostak, 1993). Asymmetric restriction sites, such as *Ava*I (CIYCGRG), *Ban*I (GIGYRCC), and *Sty*I (CICWWGG), are very useful for this task since they minimize intra-pool dimerization via self-ligation. Also, these enzymes are cost-effective for digesting large amounts of DNA. Alternatively, an overlapping region can be included at the 3' end of each synthetic oligonucleotide and mutually primed synthesis (e.g., UNIT 8.2) of a longer template can be carried out. After assembling pool modules, the complexity (yield) of the new, aggregate pool will need to be freshly assessed. The upper bound of the complexity of an assembled pool (e.g., 10^{11} 100-mer modules \times 10^{11} 100-mer modules) will likely be much larger than its actual complexity (e.g., 100 micrograms of ligated 200-mer, 9.12×10^{14} molecules).

Segmentally random pool design (binding site and aptamer selection)

In general, the rules governing the design of segmentally random pools are idiosyncratic, depending on experimental purpose. If the desire is to better define a known binding site, then relatively short sequence tracts (i.e., from four to ten residues) should be completely randomized. The randomization of longer sequence tracts may lead to the selection of novel binding sites rather than variants of a known binding site. The residues can either be colinear (as is the case for many DNA binding sites) or dispersed (as is the case for many RNA binding sites). If the desire is to identify a binding site within the context of a known structural element, then from four to twenty residues can be completely randomized. In this instance, the fewer the number of residues that are randomized, the more likely it will be that the selected sequences will resemble a wild-type binding site or retain an engineered structure. The greater the number of residues that are randomized, the more likely it will be that a novel aptamer sequence or structure will be discovered.

Primer design

Generally, the constant sequences at the 5' and 3' ends of a pool function as primer-binding sites and can be almost any sequence or length. Primers of 20 nucleotides in length are convenient because their melting temperatures are convenient for the PCR and they can easily be synthesized in high yields. In designing constant sequences and complementary primers, obvious artifacts associated with the PCR, such as secondary-structure formation or self-association that could lead to the production of primer dimers, should be avoided. Computer programs such as the Genetic Computer Group's PRIME or the Whitehead's PRIMER3 assist in designing constant regions. Other primer design programs include

Table 24.2.2 Representative Calculations Based on the Masses and Efficiencies for Couplings that Utilize the Canonical Tetrazole Activation Chemistry and Phosphoramidites Bearing Standard Protecting Groups

Phosphoramidite	Molecular mass (g/mol)	Mass correction	Coupling efficiency correction	Overall correction
5'-CE-dA	858	0.87	0.67	0.58
5'-CE-dC	834	0.89	0.67	0.60
5'-CE-dG	840	0.89	1.00	0.89
5'-CE-dT	745	1.00	0.83	0.83

discovered (A. Friedman, pers. comm.) that when pools and primers are synthesized on identical ports of a DNA synthesizer, there is some mixing of the molecules. The contamination is sufficient to yield a positive signal following extensive (30 to 50 PCR cycles) amplification of a no-template negative control. The unprogrammed interleaving of pools and primers can lead to extreme skewing of amplified materials, such that only a few species from the original pool may comprise a significant fraction of a subsequent amplification reaction. Therefore, pools and their cognate primers should be synthesized on different synthesizer ports and/or the machine should be extensively flushed with acetonitrile between syntheses.

Most synthesizers can be programmed for in-line, degenerate mixing of bases. While this method is useful when only a few positions must be randomized, because of the extremely fast reaction of the activated phosphoramidite with the newly deprotected 5' hydroxyl, random sequences will be skewed towards the phosphoramidite that first enters the column. Therefore, for longer pools or pools that should contain a statistically random distribution of nucleotides, it is better to manually mix the phosphoramidites off-line and use this mixture for the synthesis of degenerate sequence positions. A more stochastic distribution can be obtained by including larger amounts of A and C phosphoramidites in the mix to compensate for the faster coupling times of G and T phosphoramidites (Zon et al., 1985). Suggested ratios include a 3:3:2:2.4 molar ratio of A:C:G:T phosphoramidites (D.P. Bartel, pers. comm.), and a 1.5:1.25:1.15:1 molar ratio of A:C:G:T (see User's Manual for PE Biosystems Models 392 and 394 DNA/RNA Synthesis).

Doped pools are perhaps the most difficult to synthesize (Hermes et al., 1989; Bartel et al., 1991). Doping can be accomplished by using phosphoramidite mixtures that have been adjusted to ensure the proper level of partial randomization of a given nucleotide. For example, if a doped pool is to be synthesized in which non-wild-type residues are included at a rate of 10%/position, then for the adenosine bottle a molar ratio of 33.43:1.50:1.00:1.21 of A:C:G:T phosphoramidites should be used. These ratios were derived by first adjusting for the relative molecular mass and coupling differentials of the individual phosphoramidites and then mixing the phosphoramidite solutions on a percent

Table 24.2.3 Volumes of Acetonitrile Needed to Dissolve 1 g of Phosphoramidite

Phosphoramidite	Dissolved in X ml of acetonitrile
5'-CE-dA	11.6
5'-CE-dC	12.0
5'-CE-dG	17.8
5'-CE-dT	16.6

Table 24.2.4 Amidite Mixtures for Synthesis of Doped Pool in Which Non-Wild-Type Residues Are Included at a Rate of 10%/Position

Phosphoramidite	Mutagenesis (%)	Total volume (ml)	Volume each amidite to mix (ml)			
			A	C	G	T
A	10	10	9.00	0.33	0.33	0.33
C	10	10	0.33	9.00	0.33	0.33
G	10	10	0.33	0.33	9.00	0.33
T	10	10	0.33	0.33	0.33	9.00
A	20	10	8.00	0.67	0.67	0.67
C	20	10	0.67	8.00	0.67	0.67
G	20	10	0.67	0.67	8.00	0.67
T	20	10	0.67	0.67	0.67	8.00

volume basis to yield the desired extent of doping. This process is described in greater detail below.

To normalize the coupling of different phosphoramidites, relative correction factors that take into account different coupling efficiencies and molecular masses must be calculated. Multiplying together these correction factors gives an overall correction factor to provide equal molar coupling of each phosphoramidite. Table 24.2.2 displays representative calculations based on the masses and efficiencies for couplings that utilize the canonical tetrazole activation chemistry (UNIT 2.11; Beaucage and Caruthers, 2000) and phosphoramidites bearing standard protecting groups [cyanoethyl for the phosphates along either isobutyryl (N-2 of guanine) or benzoyl (N-6 of adenine and N-4 of cytidine) groups]. Other chemistries and protections may require the substitution of other correction factors.

Most modern synthesizers require that ~1 g of phosphoramidite be dissolved in ~20 ml of acetonitrile to be used in the coupling reaction. Applying this constraint along with the combined mass-coupling (overall) correction factor gives the volumes shown in Table 24.2.3 to dissolve 1 g of each phosphoramidite. Therefore, if equal volumes of each of these solutions are mixed, equal molar coupling should occur since the molar concentrations have been adjusted to account for both the mass and coupling differentials.

As in the example above, if a doped pool is to be synthesized in which non-wild-type residues are included at a rate of 10%/position, then the amidites should be mixed as in Table 24.2.4.

In addition to varying nucleotide composition, it is also possible to vary the length of random sequence that is synthesized. Deletions can be stochastically incorporated during a synthesis by replacing the capping step with an acetonitrile wash (Bartel et al., 1991). It is more difficult to stochastically incorporate insertions, but the lengths of segmental random sequences in a pool can be mixed. For example, in Giver et al. (1993), four columns were used to generate a pool with two random regions of 6 to 9 positions separated by a constant domain. The first column was synthesized with 6 random positions, the second with 7 random positions, etc. Following the addition of the intervening constant sequence, the synthesis was stopped, the four columns were opened, and the resins from the four columns were mixed. The mixed resins were then equally redivided into four new columns and the synthesis was resumed. The first column incorporated 6 positions, the second column 7 positions, etc. Thus, the first column

contained oligonucleotides in which the first random segment was 6, 7, 8, or 9 residues long and a second random segment that was uniformly 6 residues long. The second column contained oligonucleotides in which the first random segment was 6, 7, 8, or 9 residues long and a second random segment was uniformly 7 residues long, and so forth. Following the completion of all four syntheses, the reactions were combined to generate the final random sequence pool.

PURIFICATION OF A RANDOM SEQUENCE POOL

A newly synthesized oligonucleotide pool should be purified on a denaturing polyacrylamide gel (see e.g., *UNIT 2.12*) prior to amplification. Oligonucleotides can also be purified using an HPLC or commercially available spin columns, but HPLC purification is not recommended for ssDNA pools, due to concerns about cross-contamination. Since oligonucleotides of equivalent length but different sequence migrate at slightly varying rates (see User's Guide for PE Biosystems Expedite Nucleic Acid Synthesis System), a pool should appear as a broader band than a homogeneous sequence. In fact, because of the presence of capped failure sequences and depurinated, cleaved fragments, it is likely that the oligonucleotide product will appear even more heterogeneous.

As a general note, since sequences exist as single copies prior to amplification, individual species can be easily lost. Therefore, it is important to wash and elute the various filters, tubes, and tips described below one or more times. The eluates can then be pooled for a final precipitation and eventual amplification.

Contamination of primers or other solutions with a synthesized or isolated pool should be avoided by using aerosol barrier tips. Similarly, gel plates used during purification should be washed thoroughly to ensure that they are free of contamination with other pools or primers.

Materials

DNA pool
Ammonium hydroxide
n-butanol
TE buffer, pH 8.0 (*APPENDIX 2*)
Urea loading buffer, 2× (*UNIT 2.12*)
5 M NaCl
Ethanol

Fluorescent TLC plate (VWR), wrapped in plastic wrap
UV lamp
Razor blades
Small-bore syringes
13-ml centrifuge tubes capable of withstanding temperature extremes (Sarstedt)
90°C water bath
Rotary shaker

Additional reagents and equipment for denaturing polyacrylamide gel electrophoresis (e.g., *UNIT 2.12*)

1. After synthesis, deprotection, and cleavage from the solid support, lyophilize the oligonucleotide solution (in concentrated ammonium hydroxide) to dryness or precipitate with a 10-fold volume of *n*-butanol.

The n-butanol precipitation can occur quite quickly at room temperature for longer oligonucleotides. Shorter (<20 base) oligonucleotides may require longer or colder

incubations. To ensure more efficient recoveries of oligonucleotides it is safest to precipitate for ≥ 1 hr at -70°C .

2. Pour a denaturing polyacrylamide gel (e.g., UNIT 2.12).

To allow for good separation of near-full-length from non-full-length products, the acrylamide concentration should be chosen so that the full-length oligonucleotide will migrate approximately one-half to three-fourths of the way into the gel by the time the loading dye reaches the bottom.

3. Resuspend the lyophilized or precipitated pellet in ~ 100 to $200\ \mu\text{l}$ of water or buffer (e.g., TE buffer, pH 8.0) and add an equal volume of $2\times$ loading dye. Heat denature samples at 75°C for 5 min prior to loading. Load $\sim 20\%$ of a $1\text{-}\mu\text{mol}$ synthesis per $2\ \text{cm} \times 2\ \text{cm} \times 1.6\ \text{mm}$ well and perform electrophoretic separation.
4. Place gel on a fluorescent TLC plate that has been wrapped in plastic wrap and excise the oligonucleotide product from the gel with the aid of a UV lamp, using razor blades.

The desired oligonucleotide product is generally the darkest, shadowed band on the gel (excluding UV-absorbing material that runs at the dye front). If stepwise synthetic efficiency has been low, the product will appear as a smear instead of as a clear band. Since many of the N-1, N-2, etc. products can be converted into full-length products by the polymerase chain reaction, a fairly wide band of near full-length products can be cut from the gel. The excision should be carried out relatively quickly, since unnecessarily long UV exposure can damage the oligonucleotide product.

The full-length oligonucleotide product should be the slowest-migrating band. However, if deprotection has been incomplete, lighter bands that migrate considerably above the major fully deprotected band may be observed.

Unpolymerized acrylamide absorbs strongly at $211\ \text{nm}$ and may cause shadowing at the edges and wells of the gel. This can obscure the resolution or recovery of bands in the outer lanes.

5. Elute the oligonucleotide from the gel slices as follows.
 - a. To aid in the diffusion of the oligonucleotide from the acrylamide matrix, chop gel slabs into fine particles by forcing the gel through a small-bore syringe.
 - b. Place the crushed gel slabs in a 13-ml centrifuge tube capable of withstanding temperature extremes.
 - c. Add 3 ml of TE buffer, pH 8.0, per 0.5 ml of gel slab (typically corresponding to one to two wells), and place the sample at -80°C for 30 min or until it is frozen solid.
 - d. Quickly thaw the tube in a hot water bath and then let it soak at 90°C for 5 min. Elute the DNA overnight at room temperature on a rotary shaker.

This freeze-rapid thaw approach (Chen and Ruffner, 1996) allows ice crystals to break apart the acrylamide matrix, increasing yield and decreasing elution time. Typically, 80% of a 20-mer oligonucleotide can be recovered after 3 hr of rotary shaking, making this technique comparable to electroelution (see UNIT 2.7).

Because elution is a diffusion-controlled process, higher elution volumes or serial elutions from the same gel slice can increase the amount of DNA recovered. Longer oligonucleotides diffuse from the gel more slowly than shorter sequences. Samples of especially long synthetic DNAs and RNAs that are particularly resistant to elution with aqueous buffers may be eluted more easily in 6 vol of formamide (>5 hr at room temperature), followed by a brief elution with an aqueous buffer (~ 1 hr). Isoamyl alcohol extraction (UNIT 2.12) can be used to bring the extracts to a convenient volume for subsequent precipitation.

- Precipitate the eluted oligonucleotide pool by adjusting the salt concentration to 0.3 M using a 5 M NaCl stock solution, then adding 3 vol of ethanol. Keep at -20°C for 3 hr, then microcentrifuge at maximum speed 4°C . Lyophilize to dryness. Resuspend the synthetic pool in TE buffer, pH 8.0 (to protect against nuclease contamination or drastic pH changes).

If the volume of the eluted oligonucleotide is too large to conveniently precipitate, concentrate the sample by extracting against an equal volume of n-butanol. Remove the upper butanol layer and repeat until the aqueous volume is convenient for precipitation. About 1/5 of the aqueous layer is extracted into the organic butanol layer for every volume of butanol used. If too much butanol is used, thereby completely extracting the aqueous layer into the butanol, add more water and repeat the concentration.

DETERMINING THE POOL COMPLEXITY

The number of different molecules present in a population can affect the outcome of a selection experiment (see Troubleshooting). If the pool complexity is too low for a given application, the pool will have to be resynthesized.

Pool complexity is, in turn, a function of yield and of the number of molecules in the pool that can be fully extended by a polymerase. The overall yield of the synthesis can be calculated by determining the UV absorption of the pool. However, deletions, incompletely deprotected residues, or backbone lesions that arise during chemical synthesis decrease by 10% to 40% the fraction of molecules in a synthetic pool that can be fully extended by polymerases. For example, the rate of insertions (presumably due to DMT cleavage via tetrazole) has been measured to be as high as 0.4% per position, and the rate of deletions (presumably due to incomplete capping) has been found to be as high as 0.5% per position (A. Keefe and D. Wilson, pers. comm.). The number of usable DNA molecules that are actually present in a nascent pool can be calculated by determining the fraction of the pool that can be extended by *Taq* polymerase.

Materials

Purified ssDNA pool and labeled primers
50 mM Tris-Cl, pH 7.5 (APPENDIX 2)
10 mM MgCl_2
5 mM DTT
[γ - ^{32}P]ATP (>3000 Ci/mmol)
T4 polynucleotide kinase
1:1 phenol/chloroform (UNIT 2.1A)
Chloroform
4.0 M ammonium acetate
Taq DNA polymerase
TE buffer, pH 8.0 (APPENDIX 2)
PCR amplification buffer (see recipe)
2 \times formamide loading buffer (see recipe)
15 \times 17-cm denaturing polyacrylamide gel (UNIT 2.12)
Thermal cycler
Phosphor imager plate and phosphor imager
Additional reagents and equipment for quantitation of DNA (e.g., APPENDIX 3D), end-labeling of DNA (e.g., UNIT 3.10), phenol/chloroform and chloroform extraction of DNA (UNIT 2.1A), PCR amplification (e.g., Chapter 15), and denaturing polyacrylamide gel electrophoresis (UNIT 2.12)

SUPPORT PROTOCOL 1

1. Quantitate DNA by UV absorption assuming that A_{260} of 1.0 indicates $\sim 37 \mu\text{g/ml}$ of single stranded DNA.

Also see APPENDIX 3D.

2. Label the 5' end of the 3' PCR primer with $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ by preparing the following reaction mixture.

For 30- μl reaction (volume of reaction and concentration of DNA and $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ will vary depending on application):

50 mM Tris-Cl, pH 7.5
10 mM MgCl_2
5 mM DTT
1 to 50 pmol dephosphorylated DNA, 5' ends
50 pmol (150 μCi) $[\gamma\text{-}^{32}\text{P}]\text{ATP}$
50 $\mu\text{g/ml}$ BSA
20 U T4 polynucleotide kinase

Incubate 60 min at 37°C , then stop reaction by adding 1 μl of 0.5 M EDTA. Phenol/chloroform and chloroform extract the labeled oligonucleotide (UNIT 2.1A), and precipitate by adding an equal volume of 4.0 M ammonium acetate and 2 vol ethanol. Microcentrifuge to collect the pellet, remove the supernatant, and redissolve the labeled DNA pellet in 10 μl of TE buffer, pH 8.0.

This procedure ensures that most of the unincorporated label remains in the supernatant.

3. Incubate ~ 50 pmol of labeled primer with a 2- to 5-fold molar excess of pool in a 50- μl extension reaction, under the same conditions that will be used in the final amplification, in a thermal cycler as follows (see UNIT 15.1).
 - a. Denature and anneal the primer and template DNA in PCR amplification buffer (usually 94°C for the denaturation step and $\sim 50^\circ\text{C}$ for the annealing step).
 - b. Add *Taq* or other DNA polymerase (scaled to the anticipated enzyme concentration to be used in the large-scale amplification), then increase the temperature to 72°C for 20 min.

It may be useful to take time points to determine whether the reaction has gone to completion.

- c. Finally, terminate the reaction by the addition of $2\times$ formamide loading buffer.
4. Heat the extension reaction to 90°C for 3 min and load the reaction on a $15 \times 17\text{-cm}$ denaturing polyacrylamide gel with appropriate radiolabeled size markers. Electrophorese until the dye is at or near the bottom of the gel, but do not let the radiolabeled primers run off.

It is also useful to load a separate well with an aliquot of the primer alone. Choose an acrylamide percentage that allows efficient separation of small primers from larger extended products.

5. Dry and expose the gel to a phosphor imager plate. Using a phosphor imager, quantify the control primer band and the extended product band.

There may be a smear leading up to the extended band. One should use one's best judgment in determining how much near-full-length material will be included in the quantitation. Calculate the percent extension by dividing counts of labeled, extended product by counts of labeled primer. Percent extension for a gel-purified ssDNA pool can range from 10% to 30%. The complexity of the pool is then the yield (determined in step 1) multiplied by the extension efficiency (percent extension determined above). If the complexity of the pool is insufficient for planned experiments, then the pool must be resynthesized.

DETERMINING THE POOL BIAS

Following extension, the reaction should be repeated using a cold primer and the nonradioactive double-stranded DNA pool should be amplified in a PCR reaction, cloned (e.g., using a TA cloning kit from Invitrogen), and individual members sequenced to determine the degree of partial or completely randomness. The cloning step could also be carried out following PCR optimization (see Support Protocol 3). From 20 to 30 clones should be sequenced to determine the base composition of the starting pool. The random region should be composed of roughly 25% of each base. A pool with the random region skewed toward one or more bases (>30%) should be resynthesized.

**SUPPORT
PROTOCOL 2**

SMALL-SCALE PCR OPTIMIZATION OF POOL AMPLIFICATION

To enhance yield and further avoid bias, the amplification conditions for a pool should be optimized prior to carrying out a large-scale amplification. Moreover, since amplifying a pool is costly in terms of both time and money, any optimization of the PCR should first take place on a small scale. The more involved large-scale amplification can then be carried out with confidence.

**SUPPORT
PROTOCOL 3**

Materials

dNTPs (*UNIT 3.4*)

Taq DNA polymerase (e.g., Boehringer Mannheim)

PCR amplification buffer containing 1.5 mM Mg²⁺ (see recipe)

dsDNA mass markers (e.g., Life Technologies)

4% Nu Sieve agarose gel (FMC Bioproducts)

Thermal cycler

Densitometer

Additional reagents and equipment for agarose gel electrophoresis (*UNIT 2.5*)

1. Carry out a 0.1 ml PCR reaction using 2 nM of synthetic pool oligonucleotide as template, 2 μM primers, and PCR buffer with 1.5 mM magnesium. Use the manufacturer's suggested quantity of *Taq* (e.g., 2.5 U of Boehringer Mannheim *Taq*) in a reaction containing 200 μM dNTPs. A suggested temperature regime is:

10 to 15 cycles: 2 min	95°C	(denaturation)
1 min	55°C	(dependent on primer composition)
		(annealing)
3 min	72°C	(extension).

After 10 to 15 cycles of amplification, check the length and purity of the amplified DNA on a 4% Nu Sieve agarose gel in 1× TBE buffer (*UNIT 2.5*).

A 0.1 ml reaction typically yields ~1 μg, but the amount can vary from 0.1 to 10 μg. A fuzzy band may indicate that too many cycles of PCR have been carried out. In this case, set up the reaction again and perform fewer cycles.

2. Dilute the double-stranded PCR DNA product 1:128, and repeat the PCR reaction, removing a 5- to 10-μl aliquot during the last 10 sec of the cycle-7 extension step. Serially dilute the amplified product 1:2, 1:4, ... 1:128. Electrophorese all of the samples on a large agarose gel.

Note that it is quite difficult to accurately pipet solutions at 72°C. It may therefore be desirable to pipet an amount slightly larger than that intended for use in the serial dilution.

**Generation and
Use of
Combinatorial
Libraries**

24.2.15

3. Calculate the average PCR efficiency by identifying to what extent the cycle-7 PCR reaction is the result of progressive doublings of the original synthetic DNA. Determine which dilution lanes lack detectable DNA.

The largest dilution that lacks detectable DNA is also the dilution that is a minimum estimate of the number of doublings. For example, if the 1/64 dilution is the largest dilution without detectable DNA, this implies that 6 “doublings” of the synthetic DNA yielded at least 64-fold more DNA. This is expressed as follows:

(average efficiency)^{no. of theoretical doublings (i.e., PCR cycles)} = fold increase in DNA

Thus, if 7 cycles of PCR were performed, then the average number of doublings per cycle is ~1.81 [from $(-1.81)^7 = 64$].

4. Modulate PCR conditions to enhance PCR efficiency.

If the pool's average number of doublings per cycle is <1.8, then the PCR conditions chosen may skew the representation of the pool. In that case PCR conditions should be modulated to enhance PCR efficiency. The following parameters or variables are most amenable to modification. It is best to begin the optimization with a single set of reaction conditions, modify individual parameters relative to this one reference reaction, and then combine all advantageous alterations into a single reaction. In addition, one may wish to consult UNIT 15.1.

Theoretically PCR can proceed until the primers or dNTPs are depleted. Therefore, primer and dNTP concentrations should be well above those used for the amplification of small amounts of DNA. Primer concentrations from 1 μ M to as high as 5 μ M have been used (although concentrations >5 μ M are generally not helpful). It may be useful to scan both above and below 2.5 μ M in 0.5- μ M increments.

Magnesium concentration affects both primer annealing and the fidelity of Taq (which decreases with increasing magnesium concentration). Starting at the magnesium supplied in the PCR buffer (usually 1.5 mM), scan in 1-mM increments toward 5 mM as a maximal concentration.

DNA denaturation at temperatures above 95°C is usually impractical since this greatly reduces Taq's half-life. While other thermostable polymerases can be more resistant to higher temperatures, they usually have a lower extension efficiency and are more expensive than Taq. Annealing temperatures are dependent upon both primer sequence and length. The primer annealing temperatures should already be known from the primer design process, or may be calculated via an algorithm that can be found at <http://paris.chem.yale.edu/extinct.html>. This algorithm takes into account nucleotide composition, stacking energies (according to Turner's rules), and empirical data. An annealing temperature ~5°C less than the calculated annealing temperature is a good place to begin optimization. The amplification is more efficient at a lower annealing temperature, but mispriming and secondary structural problems are more pronounced. Higher temperatures improve the specificity, but decrease the overall yield of the reaction. To determine the optimum annealing temperature for a given primer and magnesium concentration, one should scan in both directions around the annealing temperature in 5°C increments. Finally, extension temperatures are modulated by the properties of Taq, which will extend (although inefficiently) at temperatures as low as 65°C. When extending at temperatures above Taq's optimum temperature (70° to 75°C) somewhat more polymerase may be required; scanning of the enzyme quantity should be done in 2.5-U increments. However, too much Taq may be harmful to structured single-stranded nucleic acids (Lyamichev et al., 1993).

5. Confirm the results of the extension reaction described in Support Protocol 1 by the optimization method as follows. After optimizing pool PCR conditions for >1.8 average number of doublings per cycle, determine the pool complexity by performing another 0.1-ml PCR reaction with 2 nM of the original, synthetic pool oligonucleotide under the now optimized reaction conditions. After 7 or more cycles of PCR, perform agarose gel electrophoresis on serial dilutions of the PCR reaction adjacent to serial

dilutions of dsDNA mass markers. Calculate the amount of amplified DNA using either a densitometer or by estimating which dilutions are most similar. Calculate the approximate pool complexity as follows:

$$\frac{\text{g of PCR DNA after } N \text{ cycles of PCR}}{\text{g avg no. of doublings per cycle (see step 4)}} = \text{g of starting extendable ssDNA}$$

$$\frac{\text{g of starting extendable ssDNA}}{330 \text{ g/mol} \times (\text{no. of bases in full-length product})} = \text{mol of starting extendable ssDNA}$$

$$\text{mol starting extendable ssDNA} \times (6.02 \times 10^{23}) = \text{molecules of starting extendable ssDNA}$$

$$\frac{\text{molecules of starting extendable ssDNA}}{\text{starting molecules}} = \text{fraction of extendable ssDNA}$$

$$\text{fraction of extendable ssDNA} \times \text{no. of synthetic pool molecules} = \text{pool complexity}$$

PCR efficiency should be optimized to balance the average number of doublings per cycle against the total reaction volume. A pool of 1×10^{15} molecules ($\sim 1.7 \times 10^9$ mol) at a starting template concentration of 2 nM will require 0.85 L for amplification. Therefore, it is greatly desirable to amplify the pool at the highest template concentration that still gives a reasonable number of doublings per cycle. The amplification should generate at least 8 copies of pool DNA if the pool complexity is to be archived and preserved (see Basic Protocol 2).

LARGE-SCALE PCR AMPLIFICATION OF POOL DNA

Very long and complex pools often require PCR amplification on a multiple-milliliter scale. Large-scale PCR differs from conventional PCR in that it is typically conducted in water baths using 15 ml, 17 × 120-mm, screw-capped (Sarstedt) thermostable tubes to accommodate the larger volumes. Amplification reactions of up to 2.5 L have been carried out in this way. Medium-scale amplifications can sometimes be carried out in thermal cyclers that can accommodate multiple samples (e.g., 96-well PCR plates).

Materials

Purified ssDNA pool and primers

EDTA

1:1 phenol/chloroform (UNIT 2.1A)

Chloroform

4 M ammonium acetate

Ethanol

TE buffer, pH 8.0, containing 50 mM of a salt such as potassium chloride

Thermal cycler or three water baths (one must be a circulating water bath)

96-well PCR plate or 13-ml thermostable tubes (Sarstedt)

Thermometer

Styrofoam racks

Spectrophotometer or fluorometer

Additional reagents and equipment for PCR amplification (UNIT 15.1; see Support Protocol 3 for determination of conditions on a small scale) and phenol/chloroform and chloroform extraction of DNA (UNIT 2.1A)

BASIC PROTOCOL 2

Generation and
Use of
Combinatorial
Libraries

24.2.17

Plan the reaction

Since large-scale reactions are quite expensive in terms of nucleotides and enzyme, preparedness and planning for the large-scale amplification cannot be overemphasized. Primers <20 bases in length usually do not need to be gel purified and can instead be purified by precipitation.

1. After identifying the optimal PCR conditions on a small scale (see Support Protocol 3), prepare reagents for the large-scale reaction. Set aside time for the large-scale amplification, which will probably consume an entire day.

The size of the large-scale reaction will be determined in part by the amount of DNA pool to be amplified and by the number of copies of the library that are desired. For example, assume that 100 (extendable) μg of a pool are to be amplified 16-fold. Since the typical amount of DNA recovered from a 100- μl PCR reaction is 1 μg , then each 100- μl reaction should have $1 \mu\text{g}/16 = 60 \text{ ng}$ of DNA. $100 \mu\text{g total}/60 \text{ ng}/100 \mu\text{l} = 1667 \times 100 \mu\text{l}$, or a 167-ml reaction.

Choose how the amplification will be carried out

If the volume of the large-scale amplification reaction is to be $\leq 100 \text{ ml}$

- 2a. Use a commercially available thermal cycler repetitively. Set the reaction mixture up in advance, and pipet 100- μl aliquots into individual wells of a 96-well PCR plate.
- 3a. Carry out several small amplification reactions in advance to ensure that the optimized conditions determined in Support Protocol 3 work with the PCR plate format, and that amplification is uniform across the PCR plate.
- 4a. Perform thermal cycling on the entire reaction using eleven PCR plates.

For larger volumes

Reactions will be divided into aliquots in 13-ml thermostable (Sarstedt) tubes and amplified in a series of water baths. Construct floating racks by cutting off the bottom of the tubes' Styrofoam packing material. Reinforce these racks by wrapping their edges with heavy tape. Place the racks iteratively in three circulating or static water baths held at the denaturation, annealing, and elongation temperatures previously determined (see Support Protocol 3).

- 2b. Determine how long it will take for the reaction mixture in a tube to come to thermal equilibrium by constructing a temperature probe, placing a thermometer through the top of a Sarstedt tube filled with 10 ml of water. Place the probe in a rack with other, similar tubes.

Typical equilibration times range from 2 to 8 min, depending on the temperature differential. Annealing, and extension times of 5, 6, and 7 min are typical. It should be noted that these ramping temperature profiles are very slow relative to a commercial PCR machine and can yield more amplification artifacts.

- 3b. To ensure that the reaction conditions actually work as planned, fill the rack with tubes of water, a single amplification reaction, and the temperature probe. Denature the sample for 30 min, and then add *Taq* after the first annealing step. Take aliquots at each cycle to monitor the progress of the reaction.
- 4b. When reaction conditions have been confirmed, proceed with the remaining amplification reactions. Allow the final extension step to proceed for at least 20 min to ensure that all templates are completely double-stranded.

Do not be alarmed if the solution becomes cloudy; the detergent in the buffer causes the turbidity.

Amplification efficiencies of 3 to 4 doublings in 5 cycles can typically be achieved using this method.

5. Following the amplification, pool the reactions from the individual wells or tubes. Chelate the magnesium in the buffer by adding 1.1 molar equivalents of EDTA, pH 8.0.

The reactions can be left at 4°C overnight.

6. Add an equal volume of 2-butanol and extract to concentrate the reaction to a manageable volume (usually 10- to 20-fold). Mix the layers by vortexing and then separate by centrifuging 5 min at $1200 \times g$ at room temperature, then discard the upper, butanol layer. Repeat as necessary.

About one-fifth of the aqueous layer is extracted into the organic butanol layer for each volume of butanol used.

7. After concentrating the DNA, carry out a phenol/chloroform extraction, followed by two successive chloroform extractions (UNIT 2.1A).

At this point, it should be possible to easily precipitate the DNA. Be sure to temporarily save all of the organic layers in case of a mishap. Falcon tubes (50 ml) work well for these extractions, as they are conveniently sized and have a small surface area. Alternatively, a Teflon extraction funnel may be useful since nucleic acids will not stick to its surface.

8. Precipitate the DNA by adding an equal volume of 4 M ammonium acetate (final concentration, 2 M) and 2 vol ethanol in 13-ml Sarstedt tubes if possible.

If larger tubes are required, prepare a set of Beckman 250-ml high-speed centrifugation jars. Wash the jars with 15 ml of 3% hydrogen peroxide for 30 min and then rinse three times with 100 ml of distilled water to remove any residual DNases that may remain from previous use (typically bacterial cell pelleting).

9. Resuspend the amplified DNA in TE buffer, pH 8.0, containing 50 mM of a salt such as potassium chloride.

It is unwise to resuspend a double-stranded DNA pool in water, since the random segments may denature, reassort, and become transcriptionally incompetent.

If it is suspected that the pool has become denatured (for example, if a large single-stranded DNA component is seen on a nondenaturing agarose gel), simply repeat one to two cycles of PCR.

10. Quantitate the PCR DNA.

This can be done by carrying out gel electrophoresis in parallel with a DNA ladder of known concentration. The concentration can also be determined spectrophotometrically or by monitoring the change in absorbance of an intercalated fluorescent dye, Hoechst 33258 (Sigma) on a fluorometer (e.g., DyNA Quant 200, Amersham Pharmacia Biotech). These latter methods are much more quantitative (although the fluorometer method may not be accurate for sequences <100 nucleotides in length). However, these methods may not distinguish precipitated double-stranded DNA from residual, precipitated nucleotides or single-stranded primers. Determine the overall PCR efficiency and the final number of DNA molecules.

The amount of DNA obtained from large-scale amplification is often referred to in terms of the number of copies of the original synthetic pool's complexity. For example, if the starting pool had a complexity of 1×10^{15} molecules and 8×10^{15} total DNA molecules were recovered, then, on average, 8 copies of the original starting pool were obtained from the amplification. It should be noted that skewing that may arise during amplification, and sampling errors that occur during the use of the amplified pool, may cause this estimation to be grossly inaccurate; nevertheless, it is empirically useful.

11. Following large-scale amplification, store at least 4 copies of the pool at -80°C .

Because of the aforementioned sampling errors, archiving at least 4 copies worth of the pool DNA ensures the preservation of most of the pool's complexity. The amount of preserved pool complexity can be calculated using the following equation:

$$\% \text{ of the pool complexity in a given sample} = 100 \times \{1 - [(x - y)/x]^x\}$$

where x is total number of pool copies, and y is the number of pool copies archived.

Therefore, in the example given above, if 4 of the 8 copies of the pool generated through amplification are archived, then $\sim 99.6\%$ of the original starting pool's complexity is preserved. Similarly, at least 4 copies of the pool should be used whenever manipulations such as ligation, transcription, or biotinylation, are carried out, so that the original complexity is also manifest in the manipulated or synthesized copies.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Formamide loading buffer, 2 \times

Prepare in deionized formamide:

0.05% (w/v) bromphenol blue

0.05% (w/v) xylene cyanol FF

20 mM EDTA

Do not sterilize

Store at -20°C

PCR amplification buffer, 10 \times

500 mM KCl

100 mM Tris \cdot Cl, pH 8.3 (APPENDIX 2)

x mM MgCl_2

0.1% (w/v) gelatin

Store in aliquots at -20°C

This solution can be sterilized by autoclaving. Alternatively, it can be made from sterile water and stock solutions, and the sterilization omitted.

15 mM MgCl_2 is the concentration (x) used for most PCR reactions. However, the optimal concentration depends on the sequence and primer of interest and may have to be determined experimentally (also see recommendations in UNIT 15.1).

COMMENTARY

Critical Parameters

Synthesis

Depending on the size of the pool to be synthesized, the operation of the DNA synthesizer may first need to be optimized. Short pools (<80 total nucleotides in length) can be synthesized using standard protocols (see, e.g., PerSeptive Biosystems, 1998). In order to synthesize longer pools (>80 total nucleotides in length), all reagents should be fresh and special care should be taken to exclude water from the synthesis (see UNIT 2.1A). To ensure equimolar base incorporation in the random region of longer pools, the phosphoramidites must be

mixed in a skewed ratio (see Strategic Planning). Coupling efficiency should be monitored throughout the synthesis by following the trityl output (see UNIT 2.1A).

Amplification

Optimization of PCR conditions according to established protocols is vital to the success of the large-scale amplification. Cycle temperatures and times, as well as the concentrations of polymerase, primers, and dNTPs (see UNIT 15.1) should be addressed prior to the large-scale workup. Most importantly, since extremely large quantities of relatively expensive reagents (e.g., *Taq* polymerase) may be required, care

Figure 24.2.4 Typical extension reaction. The pool used (N30P) is shown below the figure of the gel. Lane 1 is a size standard, lanes 2 and 3 show control reactions, and lanes 4, 5, and 6 follow the extension efficiency after different incubation times.

should be taken to make sure that all reagents and procedures are in readiness. Different priming sequences often require distinct PCR buffers for optimal extension efficiency; the best buffer for a given pool and primer combination can be easily and systematically identified through the use of a PCR optimization kit (e.g., the PCR Optimizer Kit from Invitrogen).

Troubleshooting

The most common problem with the synthesis of a random sequence pool is the overall synthetic yield. However, researchers should carefully decide how many sequences are really necessary for their selection experiments. In selection experiments from a pool with a relatively limited potential diversity (i.e., a segmentally random pool with only 1×10^{11} possible sequences or less), even a low synthetic yield should be sufficient. However, *in vitro* selection from a pool with a very high potential diversity (i.e., a completely random pool with 1×10^{15} possible sequences or more) should use at least 1×10^{14} different sequences initially in order to adequately sample the potential sequence space. Pools that contain fewer than 1×10^{13} possible sequences should not be used.

The most likely sources of low yields and coupling efficiencies are old (i.e., water-contaminated) synthesis reagents. Thus, instead of attempting to amplify an incomplete pool, the

pool should be resynthesized with fresh reagents; the old and new pools can then be combined, if desired. If fresh synthesis reagents do not significantly raise yields, then more serious problems, such as line or valve blockage, may be the cause, and the instrument service representative should be contacted.

The second most common problem is that the base composition of a partially or completely random region is skewed. Unfortunately, skewing cannot be detected until after completion of a large-scale amplification. Fortunately, unless the degree of skewing is extreme, it should not seriously affect the outcome of a selection. Moreover, if the degree of skewing is known in advance of a selection, it can be taken into account when analyzing the results of the selection. For example, Baskerville et al. (1995) selected functional Rex-binding elements from a partially randomized pool. Despite the fact that the initial pool did not contain equimolar representation of non-wild-type bases at partially randomized positions, these authors were able to determine the relative importance of individual residues by comparing the degree of conservation or variance before and after selection. If a researcher decides that extant skewing of base ratios is unacceptable, this can only be fixed by adjustment of the randomized phosphoramidite mixture and resynthesis of the pool.

Figure 24.2.5 Cycle course. The gel follows amplification of the N71 pool after 0, 2, 4, 6, 8, and 10 cycles. The pool used in the cycle course is depicted below the figure of the gel.

The third most common problem is that the pool fails to efficiently elongate. With the proviso that the efficiency of extension may be as low as 10% of the available pool, it should not be much lower (i.e., 1% of the available pool). If extension or PCR efficiency is dauntingly low, the PCR conditions should be reexamined and optimized as described, including buffer and enzyme concentrations, temperatures, and extension times. Switching to a different thermostable polymerase, or to a combination of polymerases, will sometimes improve primer extension. If all possible PCR optimization conditions have been addressed, poor extension efficiency could reflect a problem with the synthetic DNA. For example, the pool may not have been completely deprotected or a primer binding site may have become largely depurinated during the course of a long synthesis. Although incomplete deprotection is rarely a problem, small aliquots of the pool can be further treated with ammonia, and extension and amplification can again be assessed. If additional deprotection instead yields oligonucleotide degradation, then it is likely that apurinic sites have accumulated, and the pool will have to be resynthesized.

Anticipated Results

It is apparent from the discussion earlier in this unit that there is no one correct way to design and amplify a random sequence pool.

However, by following the protocols described above, results similar to the following should be observed.

If the integrity of the nascent, synthetic pool is good, then the primer extension efficiency (described in Support Protocol 1) should be relatively high. Figure 24.2.4 shows a typical extension reaction for a pool synthesized in the authors' laboratory (N30P, a segmentally random pool). Lane 1 is an RNA size standard; lanes 2 and 3 show a control reaction with "no template" and "no enzyme," respectively. In these lanes, only the radiolabeled 3' primer (24 nucleotides in length) is visible. Lanes 4, 5, and 6 show the primer extension reaction at various incubation times. Molecules that were incapable of full extension make up the smear leading to the full-length product. By determining the number of counts in the full-length product relative to the radiolabeled primer, the extension efficiency for the N30P pool was calculated to be ~8%. Moreover, it appeared as though the extension reaction had gone to completion within 2 min.

Assuming that the nascent pool is intact and can serve as a template for the primer extension reaction, then it should be possible to amplify the pool via the polymerase chain reaction. Figure 24.2.5 shows the results of an amplification "cycle course" for a different pool (N71, with a 71-nucleotide random sequence core). An 8-ml PCR reaction was placed in a 15-ml

Falcon tube and cycled through a series of three water baths. The samples in the figure were drawn at 0, 2, 4, 6, 8, and 10 cycles. This initial PCR reaction was only a trial, and for the final, large-scale amplification of the entire pool, a 150-ml PCR reaction was distributed to 18 Falcon tubes and 7 PCR cycles were carried out. Following amplification, a portion of the N71 pool was cloned into a TA cloning vector (Invitrogen) and ten clones were sequenced. The proportions of different nucleotides in the final pool reflected almost perfect equimolar coupling efficiencies: A, 25.22%; C, 25.37%; G, 25.82%, and T, 23.58%.

Time Considerations

The amount of time required for the protocols described in this section should not be underestimated. Pool design will require at least one day, depending on the degree of background research. It is strongly recommended that pool design be discussed with one or more colleagues prior to synthesis. The synthesis of oligonucleotides <150 bases in length can be easily accomplished in one day, allowing 1 hr to ensure proper instrument setup. Pool purification and optimization of PCR conditions should take 1 to 2 additional weeks. Finally, the actual large-scale amplification and subsequent isolation of the dsDNA pool will require the researcher's undivided attention for ~2 days.

In Vitro Selection of RNA Aptamers to a Protein Target by Filter Immobilization

While there are multiple possible configurations for in vitro selection experiments, this unit will describe one of the most common: selection of aptamers that bind to a protein target from a single-stranded RNA pool. Aptamers generated from these types of selection experiments can potentially function as protein inhibitors, and may find applications as therapeutic or diagnostic reagents. In short, a double-stranded DNA pool (see *UNIT 24.2*) will be transcribed to generate a single-stranded RNA pool (Basic Protocol 1). The initial concentration of protein target to be used is determined by labeling an aliquot of the pool (see Support Protocol 1) and performing the binding assay as described in Support Protocol 2. Following purification, the pool is mixed with the protein target. Binding species are separated from nonbinding species by filtration (see Basic Protocol 2). RNA:protein complexes are then eluted from the filter and binding species are amplified by a combination of reverse transcription, the polymerase chain reaction (PCR), and in vitro transcription (see Basic Protocol 3). The progress of the selection will be monitored by assaying the affinity of the radiolabeled RNA pool for the protein target after several rounds of selection (see Support Protocol 3). These steps are then repeated until a significant increase in binding is observed or until the diversity of the pool has been completely plumbed. The procedure is summarized in Figure 24.3.1.

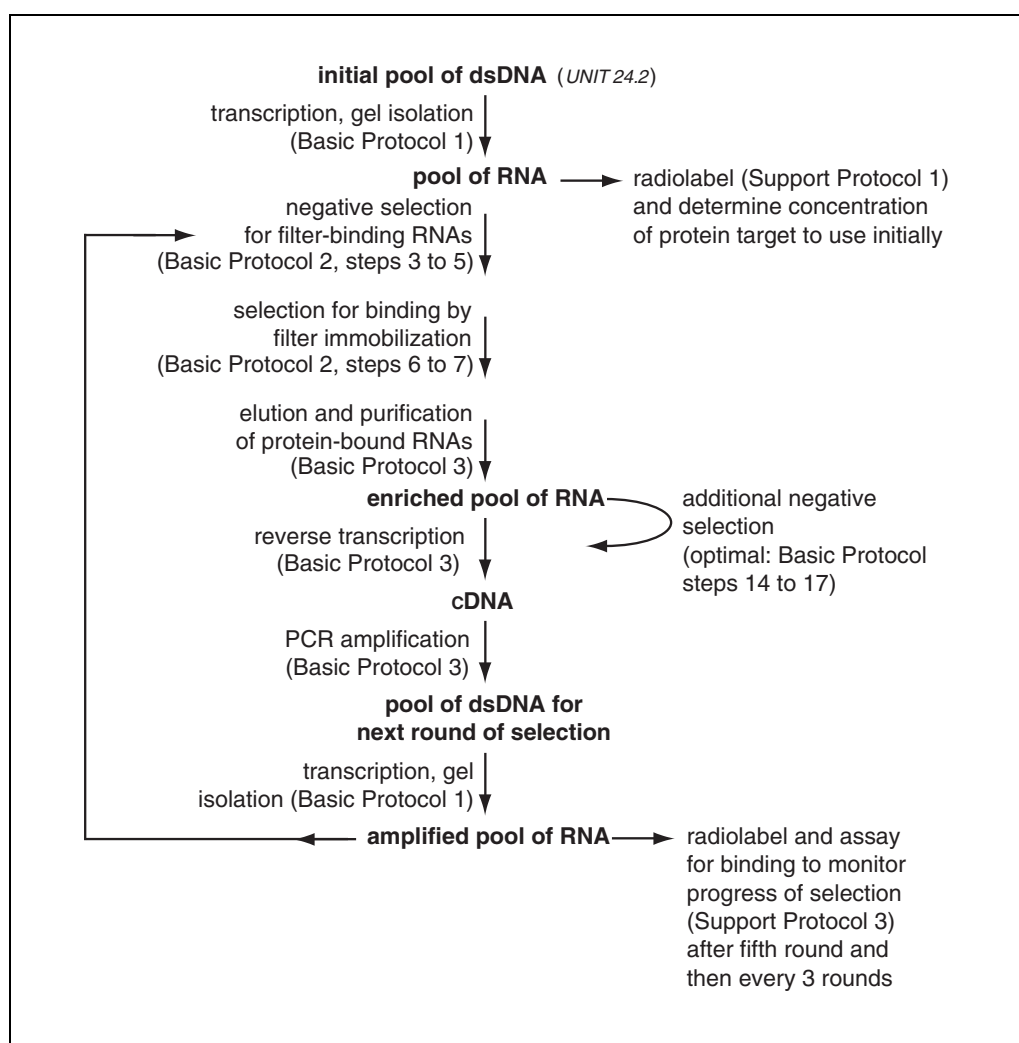

Figure 24.3.1 Steps involved in in vitro selection of RNA aptamers.

Generation and Use of Combinatorial Libraries

24.3.1

Supplement 52

TRANSCRIPTION AND ISOLATION OF RNA POOLS

The following protocol describes the preparation of the RNA pool to be used for selection. Starting from the dsDNA pool, the RNA is transcribed and purified by denaturing polyacrylamide gel electrophoresis. Recovery of the RNA from the gel is followed by ethanol precipitation of the RNA. Additional instructions can be found in *UNIT 3.8*. The directions provided here are specific for the isolation of nucleic acid pools. As is the case for the original amplification of DNA pools (*UNIT 24.2*), many of the procedures described here can potentially lead to the cross-contamination of different RNA selection experiments or different generations of the same selection experiment. To avoid cross-contamination, it is wise to always use barrier tips and to use disposable plastic Pasteur pipets rather than automatic micropipettors for large-volume transfers.

Materials

Double-stranded DNA pool (*UNIT 24.2*)
Transcription mix (see recipe)
RNase-free DNase (e.g., RQ1 DNase; Promega)
10% polyacrylamide denaturing gel (see recipe and *UNIT 2.12*)
2× denaturing dye (see recipe)
TBE buffer (*APPENDIX 2*)
5 M NaCl
90% and 100% ethanol
TE buffer, pH 8.0 (*APPENDIX 2*)
37° to 42°C and 65° to 75°C water baths
Fluorescent TLC plate (VWR) wrapped in plastic wrap
Spectrophotometer
Additional reagents and equipment for denaturing polyacrylamide gel electrophoresis (*UNIT 2.12*)

NOTE: All solutions and buffers should be freshly treated with DEPC (*UNIT 4.1*). Use sterile, disposable plasticware where possible. See Chapter 4 introduction and *UNIT 4.1* for guidelines on standard methods to protect against contaminating RNases.

Perform initial round of transcription

Use the double-stranded DNA pool generated in *UNIT 24.2* as a template for in vitro transcription with T7 RNA polymerase.

1. Add ~1 µg of double-stranded DNA template generated as in *UNIT 24.2* to transcription mix for a 20 µl total reaction volume. Incubate reaction overnight at 37° to 42°C.

Depending on the length and initial complexity of the pool, 1 µg of double-stranded DNA will represent ~10¹³ different sequences. The transcription reaction will yield ~10 to 50 µg of RNA, and thus from 20 to 100 copies of each sequence originally present. If more RNA is desired for initial or subsequent rounds of selection, a proportionately larger transcription reaction should be attempted.

The success of the transcription reaction can sometimes be monitored by observing the formation of a precipitate over time. This precipitate is likely a complex between magnesium and the pyrophosphate released from each polymerized ribotide. However, this rule is not absolute: many successful transcription reactions have no precipitate; some unsuccessful reactions have a precipitate.

In general, though, the authors have found that much higher yields of RNA can be obtained from commercial transcription kits (e.g., Ampliscribe from Epicentre Technologies or Megashortscript from Ambion) than from home-made in vitro transcription reactions. The use of such kits reduces the amount of time necessary to generate an adequate amount of

transcript (1 to 4 hr rather than overnight). Depending on the amount of RNA that is desired for each round of selection, such kits may also (surprisingly) represent a more cost-efficient alternative.

In some instances it will be desirable to radiolabel the RNA. For example, it is relatively easy to determine whether and how much RNA binds to a filter in the presence or absence of a protein target by radiolabeling the initial pool (see Support Protocol 1). An [α - 32 P]nucleoside triphosphate—e.g., 0.5 μ l [α - 32 P]UTP (NEN Life Science Products) in a 20- μ l total volume—can be included in the reaction mixture in addition to all the other reagents. Varying the proportion of “hot” to “cold” nucleoside triphosphates can control the specific activity of the RNA pool. Since the overall yield of the transcription reaction will generally be important, the specific activity of the nucleoside triphosphate mixture should be varied by increasing the amount of radioactive nucleotide added, rather than by decreasing the amount of unlabeled nucleotide present. Again, commercial transcription kits can be obtained that are geared towards the incorporation of labeled nucleoside triphosphates (RiboScribe, Epicentre).

2. In order to remove DNA from the transcription reaction, after the transcription incubation has been completed, add 5 to 10 U of RNase-free DNase and incubate 25 min at 37°C.

Because individual members of the double-stranded DNA library can potentially bind nonspecifically to either the target or to the selection matrix and subsequently be amplified, the DNA template should be removed from the transcription reaction according to this step, prior to proceeding with the selection.

It is essential that RNase-free DNase, such as RQ1 DNase (Promega) be used, otherwise contaminating ribonucleases may destroy the newly transcribed RNA pool. An alternative would be to add RNase inhibitors to impure DNases, but such inhibitors themselves frequently contain endogenous ribonucleases that can be released during the incubation.

Purify the RNA pool

The RNA pool should generally be purified by denaturing gel electrophoresis.

3. Prepare a 0.75-mm thick, denaturing 10% acrylamide gel (see Reagents and Solutions and, e.g., UNIT 2.12).

A 10% acrylamide concentration is convenient for the purification of RNA molecules from 45 to 70 nucleotides in length. However, the concentration of acrylamide used to separate the full-length transcript from incomplete transcripts is ultimately contingent upon the size of the RNA and should be chosen so that the RNA will migrate approximately half-way through the gel when the loading dye has reached the bottom (see UNIT 2.12).

If the RNA sample contains a significant amount of nascent structure (for example, a doped sequence population that is based on a tightly folded secondary structure) it may not fully denature. Thus, it may be advisable to warm the gel to ~55°C by first pre-running the gel at a higher voltage (300 to 400 V). The temperature of the gel can be monitored using adherent thermometers (VWR).

In some cases, very large amounts of RNA may need to be purified (for example, the initial transcription of an extremely complex DNA library may yield upwards of a milligram or more of an RNA library). In these instances, it may be desirable to purify the RNA library by either gel-filtration or ion-exchange chromatography (e.g., Qiagen RNA kit). However, the purification of the initial or subsequent pools should never be neglected, as fore-shortened amplicons can arise and overtake selected populations.

4. Fully denature the RNA pool by adding an equal volume of 2× denaturing dye, and heat the RNA-dye mix 3 min at 65° to 75°C.

Although each species in the pool has a different sequence and shape, they should migrate similarly when fully elongated.

Using a higher temperature or longer denaturing time risks hydrolysis of the RNA into smaller fragments by the high concentration of Mg^{2+} present in the transcription buffer.

5. Thoroughly rinse each well with TBE buffer using a plastic Pasteur pipet prior to loading (to remove urea, which will otherwise leach into the wells and form a barrier between the loaded sample and the gel). Load samples directly on the gel at 10 to 20 μg per 1-cm-wide lane (i.e., load a single transcription reaction in 2 to 3 lanes of the gel). Run electrophoresis for 1 to 2 hr at 150 to 250 V, until the bromophenol blue dye front reaches the bottom of the gel.

If the wells are not cleaned prior to loading, the resolution of the separation can be compromised, especially if large amounts of RNA are being isolated.

6. Visualize the RNA bands by UV shadowing on a fluorescent TLC plate covered with plastic wrap, then excise the bands. Be sure to cut with a sharp razor blade and cut only the shadowed regions that contain the bulk of the RNA.

There may be extra bands in the lane that correspond to incomplete transcripts or undigested DNA. The use of a size standard in a neighboring lane is recommended. Note, however, that the size standard should not itself be amplifiable, as cross-contamination of a single sequence with the RNA pool would drastically skew the distribution of sequences in the purified pool. Similarly, the razor blade used for excision should not have come into contact with other potentially amplifiable sequences, and should either be fresh or should have been cleaned extensively. Finally, if multiple selections are being carried out in parallel they should not be purified on the same gel.

7. Immerse the gel slices in RNase-free water at $\sim 400 \mu\text{l}$ water/ cm^2 of gel (typically, slices from 2 lanes) and incubate at 37°C overnight with agitation to elute the RNA pool.

For a quicker elution step, incubate the slices at 65° to 75°C for 1 hr. However, the amount of RNA recovered will be lower, and there is a greater risk of degradation. The gel can be macerated to increase the speed or efficiency of recovery, but in this case small fragments of acrylamide may remain in the eluant. The eluate can be filtered through an $0.45\text{-}\mu\text{m}$ nitrocellulose membrane to remove acrylamide fragments.

Collect and quantitate the RNA

8. Use a plastic Pasteur pipet to separate the RNA-containing eluate from the gel slice. Add NaCl (from 5 M stock) to a final concentration of 0.3 M and ethanol precipitate the RNA by adding 2 vol ethanol. Mix and incubate at -20°C for 30 min or -70°C for 10 min. Microcentrifuge 20 to 40 min at maximum speed, 4°C , to recover the precipitate.

Smaller RNA molecules (20 to 80 nucleotides in length) can be more efficiently precipitated with 2.5 vol of ethanol.

The authors frequently include 1 μl of a 1 mg/ml glycogen solution to increase the yield of nucleic acid precipitate and to better visualize the pellet. If the selection target binds to or interacts with glycogen, then this step should be omitted. Transfer RNA can also be used as a carrier, but will obfuscate the quantification of the pool RNA (see below).

9. Wash the RNA pellet with cold 90% ethanol and dry the pellet.

The pellet can be air dried, dried under a nitrogen or argon stream, or dried in a SpeedVac evaporator. The first method is least likely to result in cross-contamination of nucleic acid species; the last method is least likely to lead to degradation. In any event, keep the tube covered with Parafilm to avoid inadvertent nuclease contamination (poke holes in the Parafilm with a sterile needle to allow evaporation to proceed).

If the RNA pool is particularly short (≤ 50 nucleotides) use cold 95% ethanol for the wash step.

10. Resuspend the RNA pellet in 25 μ l TE buffer, pH 8.0.

To avoid disturbing the composition of the selection buffer, the pellet can also be resuspended in RNase-free water. However, the small amount of EDTA present in TE buffer will limit ribonuclease degradation of the pool, since ribonucleases frequently require a divalent metal. In some instances, though (e.g., small-volume PCR reactions), the presence of EDTA may have to be compensated for by adding more magnesium to the reaction.

11. Estimate the quantity of the RNA photometrically by measuring the absorbance at 260 nm.

Use an extinction coefficient of 0.025 ml cm^{-1} μg^{-1} (see, e.g., APPENDIX 3D). In practical terms, measure the A_{260} of a 1:500 dilution of the sample (2 μ l dissolved in 1 ml RNase-free water) and multiply the absorbance by 20 to obtain the number of $\mu\text{g}/\mu\text{l}$ in the original sample. Do not attempt to calculate concentrations using absorbance readings less than ~ 0.03 . The A_{260}/A_{280} ratio should be somewhere between 1.8 and 2.2. Ratios outside of this range make the purity of the original RNA sample suspect (with residual acrylamide being the most likely contaminant), and the sample should be reprecipitated prior to use.

RADIOLABELING THE RNA FOR USE IN AN INITIAL AFFINITY ASSAY

Radioactive RNA can be generated either by incorporation of an [α - ^{32}P]nucleoside triphosphate during transcription or by transfer of the terminal phosphate of γ - ^{32}P ATP to the 5' terminus of a dephosphorylated RNA molecule. The authors tend to prefer the latter method, despite the additional labor involved in preparation, because the specific activity of the sample is higher, less RNA is required for assays, and dissociation constants are correspondingly easier to compute.

Materials

- RNA pool (see Basic Protocol 1)
- 10 \times alkaline phosphatase buffer (Boehringer Mannheim)
- Calf alkaline phosphatase (Boehringer Mannheim)
- 1:1 phenol/chloroform (UNIT 2.1A)
- Chloroform
- 5 M NaCl
- 90% and 100% ethanol
- 10 \times PNK buffer (New England Biolabs)
- T4 polynucleotide kinase (PNK; New England Biolabs)
- 167 mCi/ml [γ - ^{32}P]ATP (7000 Ci/mmol; ICN)
- 4 M ammonium acetate
- 42 $^{\circ}$ and 75 $^{\circ}$ C water baths

NOTE: All solutions and buffers should be freshly treated with DEPC (UNIT 4.1). Use sterile, disposable plasticware where possible. See Chapter 4 introduction and UNIT 4.1 for guidelines on standard methods to protect against contaminating RNases.

Dephosphorylate the 5' triphosphate termini of the isolated RNA pool

1. Mix the following components:

- 1 μg RNA in <3.5 μl volume
- 0.5 μl 10 \times alkaline phosphatase buffer
- 1 μl (1 U) calf alkaline phosphatase
- x μl RNase-free water for a total reaction volume of 5 μl .

The RNA sample may need to be reprecipitated to obtain an adequately concentrated sample. If so, the precipitate can be resuspended directly in the reaction buffer or mixture.

SUPPORT PROTOCOL 1

Generation and Use of Combinatorial Libraries

24.3.5

Calf alkaline phosphatase is preferred over bacterial alkaline phosphatase because the activity can be heat-killed (see step 4) prior to the addition of the radiolabel.

2. Incubate at 42°C for 20 min to 2 hr.
3. Add 95 µl RNase-free water.
4. Heat denature the calf alkaline phosphatase 10 min at 75°C.
5. Perform a phenol/chloroform extraction (see Basic Protocol 2, step 10).

If the sample will be gel-isolated, this step can be omitted. If the radiolabeled sample will merely be precipitated prior to use, this step should be included.

6. Ethanol precipitate the RNA in the presence of 0.3 M NaCl and wash the pellet with 90% ethanol (see Basic Protocol 1, steps 8 and 9).

Avoid precipitating RNA in the presence of ammonium acetate since ammonium ions inhibit the T4 polynucleotide kinase used in the next step.

7. Resuspend the dried pellet in a minimal volume (3 to 10 µl) of RNase-free water.

Perform kinase reaction

8. Set up the kinase reaction as follows:

0.5 to 3 µl dephosphorylated RNA pool (from step 7)
0.5 µl 10× PNK buffer
1 µl (10 U) T4 polynucleotide kinase (PNK)
0.5 µl (83 µCi) [γ -³²P]ATP (7000 Ci/mmol, ICN)
x µl RNase-free H₂O for a total volume of 5 µl.

Only a very small amount of RNA will be used in the binding assay (~50 pM in a 100 µl reaction). Unless multiple experiments are contemplated, the specific activity of the sample can be kept quite high by using a very small amount of RNA in the kinase reaction.

9. Incubate for 1 hr at 37°C.
10. Add 95 µl RNase-free water.
If the sample will be gel-isolated, this step can be omitted.
11. Perform a phenol/chloroform extraction (see Basic Protocol 2, step 10).
If the sample will be gel-isolated, this step can be omitted.
12. Ethanol precipitate the RNA in the presence of 2.0 M ammonium acetate (i.e., by adding an equal volume of 4.0 M ammonium acetate).

The use of ammonium acetate inhibits the precipitation of nucleotides and small transcripts. However, if the RNA pool is short, the precipitation may also be inefficient. If the sample will be gel-isolated, then this step can be omitted.

13. *Optional:* In order to fully separate the radiolabeled RNA pool from unincorporated nucleotides, partially degraded transcripts, and enzymes, isolate the transcript as described in Basic Protocol 1, steps 3 to 9).

If this is done, the phenol/chloroform extractions and the final precipitation of the RNA (steps 10 to 12 of this protocol) can be omitted. The chief disadvantages of gel isolation are the time required for sample preparation and the relatively low efficiency of recovery of the radiolabeled RNA pool. However, since only a small amount of RNA pool is required for the binding assay such low yields can frequently be tolerated. The authors frequently gel isolate radiolabeled RNA pools to ensure the integrity of RNA samples prior to carrying out binding assays.

BINDING ASSAY WITH THE END-LABELED RNA POOL TO DETERMINE THE OPTIMAL PROTEIN CONCENTRATION FOR SELECTION

To determine the initial concentration of a protein target to be used in a selection experiment, it is necessary to measure the affinity of the unselected pool for the protein target. The aggregate dissociation constant of the pool:protein complex can be calculated by determining the fraction of radioactively labeled RNA that can be bound at various protein concentrations.

The radiolabeled RNA is incubated in the binding buffer and protein solutions are added. The binding reaction is filtered through a vacuum manifold containing nitrocellulose and nylon membranes and the fraction of RNA bound to the target is calculated to obtain a value for the dissociation constant. The nitrocellulose membrane will capture RNA:protein complexes, while the nylon membrane will capture all free RNA that flows through the nitrocellulose membrane.

Materials

Radiolabeled RNA pool (Support Protocol 1)
Binding buffer (see Critical Parameters)
Target protein
65° to 75°C water bath
Milliblot apparatus (Schleicher & Schuell)
Nylon transfer membrane (Hybond N+, Amersham Pharmacia Biotech)
0.45- μ m nitrocellulose transfer and immobilization membrane (Midwest Scientific)
Glass plate
Phosphorimager (Molecular Dynamics) and screen *or* X-ray film and densitometer
Graphing software (e.g., Kaleidograph from Synergy Software)

NOTE: All solutions and buffers should be freshly treated with DEPC (UNIT 4.1). Use sterile, disposable plasticware where possible. See Chapter 4 introduction and UNIT 4.1 for guidelines on standard methods to protect against contaminating RNases.

Set up binding reactions

1. Collect the RNA precipitate by centrifugation and resuspend the radiolabeled RNA in a minimal volume (i.e., 5 to 10 μ l) of RNase-free water. Dilute the RNA sample with binding buffer to a final concentration of 100 pM.

The concentration can be very roughly estimated by assuming full recovery of the RNA sample. Differences between estimated and actual concentrations are less important because the RNA sample will be limiting relative to the amount of protein sample present in the binding reaction.

The binding assay will yield 11 data points in triplicate (see below). Since each data point will be generated from a 50- μ l binding reaction, 2 ml of the RNA solution should be adequate. If the specific activity of the RNA is not high enough, a higher concentration of RNA may be used, but that will complicate the assumption that RNA is limiting and hence the calculation of the K_d .

2. To ensure that each species in the RNA pool folds into the most accessible or most stable conformation, heat the RNA pool in 25- μ l binding buffer to 65° to 75°C for 3 min and then allow the sample to cool to room temperature over ~10 min.
3. Add 25 μ l of the protein target in binding buffer to the thermally equilibrated RNA from step 2. Use ten different protein concentrations ranging from 1 μ M to 50 pM.

Also include one data point with no protein to measure the filter-binding ability of the pool itself.

The original protein solution should be sufficiently concentrated for all of the dilutions. To ensure consistency between samples, serial dilutions of the 1 μM sample can be made. The authors suggest the following concentrations: 1 μM , 333 nM, 111 nM, 37 nM, 12 nM, 4.1 nM, 1.4 nM, 460 pM, 152 pM, 51 pM, (i.e., 1 μM , and subsequent 1/3 dilutions) and a “no protein” control. For statistically significant results perform the binding assay in triplicate.

4. Incubate the binding reaction at room temperature for 15 min to 1 hr (see Critical Parameters).

Perform filter binding

5. Assemble the Milliblot apparatus (Fig. 24.3.2). Lay the nylon transfer membrane on top of the perforations in the middle section. Moisten the nylon membrane and lay the nitrocellulose membrane on top of the nylon membrane, taking care to avoid the formation of bubbles between the two membranes. Cover and tighten the brackets.

Prior to filtering the binding reactions, wash the wells that will be used with binding buffer and check for leaks. When the manifold is used in conjunction with an aspirator; turn the water faucet to a level that causes liquid to pass slowly through the membranes (i.e., 100 μl every 3 sec).

Since there are so many binding reactions, it is more convenient to use a manifold apparatus that can accommodate multiple filtrations (up to 96 slots) than to assemble 33 individual filter holders.

6. Filter the binding reactions and wash three times with binding buffer.

When pipetting onto the manifold, dispense the liquid slowly and evenly. Try to keep the membrane constantly hydrated during each wash step. Keep the pipet tip close to the membrane to avoid bubble formation, but not so close as to risk damaging the membrane.

7. Disassemble the manifold apparatus and transfer the membranes to a clean paper towel. Air dry for ~5 min. Handle membranes with a clean pair of forceps or tweezers.

The forceps or tweezers can be quickly cleaned with ethanol and RNase-free water prior to contacting the filters.

8. Transfer the membranes to a glass plate, cover with plastic wrap, and expose to a phosphor screen (e.g., Phosphorimager) or X-ray film for 4 to 12 hr.

Figure 24.3.2 Assembly of the Milliblot apparatus used for binding assays.

If the samples have a very high specific activity, the exposure time can be reduced to 5 to 60 min.

9. Measure the radioactivity using the Phosphorimager or a densitometer if X-ray film was used to develop the image, and calculate the binding percentages as follows:

$$\text{Fraction bound} = \text{cpm on nitrocellulose} / (\text{cpm on nitrocellulose} + \text{cpm on nylon})$$

If X-ray film was used to develop the image, then a digitizer (densitometer) should yield similar results to those obtained with a Phosphorimager.

10. Plot the fraction bound as a function of the concentration of unbound protein. Fit the points to a curve using graphing software (e.g., Kaleidograph) and obtain a value for the aggregate parent dissociation constant. Within the Kaleidograph program, fit the curve using the equation $y = m_1 m_0 / (m_0 + m_2)$, where y = the fraction of RNA bound, m_0 = concentration of unbound protein, m_1 = the extrapolated activity of the RNA at an infinite protein concentration (maximal value of fraction bound), and m_2 = the apparent dissociation constant.

The apparent K_d is equal to the concentration of unbound protein at half the maximal value of fraction bound.

ISOLATING A FUNCTIONALLY ENRICHED POOL

In the following protocol, the RNA pool is partitioned to isolate those species that bind to the target protein and not to the filter. RNAs that are coimmobilized with the target are eluted off the filter under denaturing conditions and subsequently isolated and amplified.

Materials

RNA pool (see Basic Protocol 1)
Binding buffer (see Critical Parameters)
Elution buffer (see recipe)
1:1 phenol/chloroform (see UNIT 2.1A), ice-cold
Chloroform
Isopropanol
65° to 75°C and 100°C water baths
Filter holders (Nuclepore)
13-mm, 0.45- μm HAWP nitrocellulose disk filters (Millipore)
5-ml syringe
Vacuum manifold

NOTE: All solutions and buffers should be freshly treated with DEPC (UNIT 4.1). Use sterile, disposable plasticware where possible. See Chapter 4 introduction and UNIT 4.1 for guidelines on standard methods to protect against contaminating RNases.

Partition the pool

1. Use ~5 μg of the RNA pool (~ 10^{13} to 10^{14} sequences) for selection.

Using significantly lower quantities of RNA may affect the diversity of the population in the initial rounds of selection. Using significantly higher quantities may lead to precipitation of the nucleic acid pool. Irvine et al. (1991) have devised a formula to determine the optimum protein and RNA concentration in order to minimize the number of rounds of selection, based on the K_d of the starting pool, the desired K_d , and the fraction of free RNA molecules that partitions as nonspecific background versus the fraction of RNA molecules that forms specific RNA:protein complexes. Empirically, the concentrations of many available protein targets will be in the nanomolar range, and a 1- to 10-fold excess of the RNA pool should suffice for early rounds of selection.

BASIC PROTOCOL 2

If only a small amount of RNA pool is initially recovered from the gel, be sure to save at least some sample for the “no protein” control (see below).

2. To ensure that each species in the RNA pool folds into the most accessible or most stable conformation, heat the RNA pool in 50 to 100 μl binding buffer (see Critical Parameters for discussion on choosing a binding buffer) to 65° to 75°C for 3 min and then allow the sample to cool to room temperature over ~10 min.

Since ionic strength, monovalent and divalent cation concentrations, pH, temperature, and buffer concentrations can all influence interactions with the target, it is usually wise to keep all of these parameters constant during the early rounds of selection when productive binding species are accumulating. Hence, the binding buffer, equilibration time, and preparation of the RNA for selection should be kept uniform until a significant interaction between pool and target is observed (see Critical Parameters for discussion of stringency of selection).

Higher temperatures can be used for thermal equilibration, but the presence of divalent metal ions in the selection buffer can lead to RNA degradation.

3. Prior to the addition of the protein target, perform a negative selection to remove any filter-binding species that may be in the population. Moisten a filter disk with buffer and lock it into a filter holder (Fig. 24.3.3).

Negative selection to remove filter-binding species is an extremely important step in the selection procedure. Filter-binding species are typically more numerous in a naive RNA population than are aptamers. If filter-binding species are not efficiently sieved from the population, they will quickly accumulate to the point where it may be difficult (and likely impossible) to select protein-binding species. If the potential for accumulating filter-binding species is large (i.e., the target has a low initial affinity for a pool, or selections with DNA pools), then repeat the preselection filtration to remove any filter-binding species that may persist or carry out a post-selection filtration (see optional steps 14 to 17, below). If filter-binding species do accumulate during a selection experiment, it is usually wisest to repeat the selection starting with a different pool that can be amplified with different primers.

In addition to filter-binding species, replication parasites (see Critical Parameters for discussion on parasites) can accumulate in and overrun a selected population. A separate regime is required to avoid these selection predators.

4. Load the binding buffer onto the filter. Place the pipet tip just above the filter to avoid the formation of any bubbles. Lock a 5-ml syringe to the top of the filter holder and apply gentle pressure to force the liquid out of the filter holder and into a collecting tube.

Prior to filtering the RNA, it is important to wash the nitrocellulose filter disk with binding buffer and check for leaks in the assembled filter holder. The syringe should form a tight seal with the filter holder. The pressure applied should be just enough to force the liquid through without rupturing the membrane. The formation of foam at the bottom of the filter holder or the presence of a hissing sound when pressure is applied indicates that the pressure is too high, and the integrity of the seal or the membrane may have been breached. Test for leaks every time the filter holder is assembled in order to avoid substantial loss of sample.

5. Load the RNA solution onto the filter. Place the pipet tip just above the filter to avoid the formation of any bubbles. Lock a 5-ml syringe to the top of the filter holder and apply gentle pressure to force the liquid out of the filter holder and into a collecting tube.

Since there will still be some amount of liquid retained by the filter and filter holder, it is necessary to wash the filter with an equal amount of binding buffer to maximize the collection of non-filter-binding species. Discard the filter.

Figure 24.3.3 Components and assembly of filter holder used during selection.

6. Add the protein target and any competitors, specific and/or non-specific, to the filtrate. Allow the binding reaction to equilibrate.

In selection experiments that targeted the cytokine bFGF, the authors used an equimolar protein-to-RNA ratio for the first two rounds of selection and decreased it 10-fold after two rounds and 60-fold after another two, yielding a functionally-enriched pool after 6 rounds of selection and amplification (Table 24.3.1). The final volume of the binding reaction should be from 100 to 200 μ l. In addition, to ensure that the selected RNAs are actually binding to the target and not to the filter, a parallel binding reaction in the absence of protein can be carried out intermittently. The authors strongly suggest that “no protein” controls be scrutinized after 0, 5, 8, and 11 rounds of selection.

The choice of selection conditions is probably the second most important determinant (following the choice of target) for whether a selection experiment will succeed or fail. While general guidelines for modulating the stringency of selection can be recommended (see Critical Parameters for comments on the stringency of selection), every target and every selection are different and no precise guidelines for success can be provided. In general, the stringency of selection should be lower in the early rounds of selection and higher in the later rounds. This will give binding species an opportunity to establish themselves in the population relative to filter-binding species.

It should be noted that there is some danger of cross-contaminating the selected pool with the “no protein” control. Basically, executing the “no protein” control is identical to selecting for protein-independent (filter) binding species, hence DNA arising from the “no protein” control should be handled with care.

7. Attach the filter holder to a vacuum manifold (which is used here to maintain a constant negative pressure during filtration, so that each round of selection is similar and reproducible). Apply a negative pressure of 5 in. of Hg to the filter holder. Pipet the binding reaction directly onto the filter with the tip just above the filter, avoiding the formation of bubbles, which may lead to an uneven application of the sample to

Table 24.3.1 Progress of N30 Selection Against bFGF^a

Round	Input (RNA) nM	Input (BFGF) nM	(RNA):(bFGF)	% bound to protein	% bound to filter
1	800	760	1.05	2.1	2.3
2	800	760	1.05	—	—
3	800	76	10.5	—	—
4	800	76	10.5	6.0	4.0
5	800	13	61.5	—	—
6	800	13	61.5	17.0	0.4

^aPools were assayed in a 50- μ l reaction at a concentration of 75 nM in the presence and absence of equimolar protein.

the filter and impede the flow of liquid through the filter. Wash the filter with 3 vol of binding buffer.

Varying the strength of the vacuum, uneven application of the sample, and formation of bubbles during wash steps may result in inefficient sieving of binding from nonbinding species, and hence may reduce the efficiency of an individual round of selection. However, the selection as a whole is fairly robust with respect to changes in these parameters. In other words, even if steps are not performed perfectly, the selection can be carried forward.

Elute RNA off the filter

8. Remove the filter containing RNA:protein complexes from the filter holder using sterile forceps and place it in a 1.5-ml microcentrifuge tube. Transfer the filter quickly, in order to avoid ribonuclease contamination from the surrounding environment.
9. Add 200 μ l of elution buffer and heat for 5 min at 100°C to elute RNA molecules from the protein and filter. Remove the eluate to a tube and repeat with fresh elution buffer.

Two shorter, smaller-volume elutions will more efficiently recover intact RNA than one long, large-volume elution.

10. To remove residual peptide fragments or proteins that may have coeluted with the RNA, add an equal volume (i.e., 400 μ l) of cold, 1:1 phenol/chloroform. Vortex, then microcentrifuge 1 min at maximum speed to separate the liquid phases (the RNA should be in the top, aqueous phase). Transfer the aqueous phase to a new 1.5-ml microcentrifuge tube.

Avoid transferring phenol/chloroform with the aqueous layer, as it can interfere with subsequent enzyme reactions. Nevertheless, the aqueous phase will sometimes appear milky, especially at low temperatures, due to the presence of dissolved phenol-chloroform.

11. Extract the eluate with a similar volume of chloroform to remove any residual phenol.

Avoid transferring chloroform with the aqueous layer, as it can interfere with subsequent enzyme reactions.

12. Dilute the eluate with an equal volume (~400 μ l) of RNase-free water and add 800 μ l of isopropanol, then chill 20 min at -20°C to precipitate.

A carrier such as glycogen can be added to aid precipitation.

The elution buffer contains a high concentration of urea. Dilution with 400 μ l water and precipitation with isopropanol is necessary to avoid the formation of salt precipitates, which appear as oily, unstable droplets in the bottom of the microcentrifuge tube following

centrifugation. If such “salt pellets” appear, additional water should be added to the sample, the mixture should be homogenized, and the precipitation repeated.

13. Microcentrifuge 30 min at maximum speed, remove the supernatant, and resuspend the RNA sample in 12 ml sterile RNase-free water.

Perform an additional negative selection (optional steps)

An extremely effective method for ridding the population of filter-binding species is to carry out an additional negative selection following the selection for binding species, but prior to amplification. However, at early stages of the selection, an additional post-selection filtration step may reduce the complexity of the selected population. Therefore, it is recommended that post-selection filtration only be carried out following the second round of selection. Post-selection filtration can also be used to successfully remove filter-binding species that have begun to accumulate and overrun a selected population. However, once filter-binding species have established themselves, even a combination of pre- and post-selection filtrations may not allow specific binding species to regain a selective advantage. If a simple regime of pre- and post-filtration negative selections does not succeed in drastically reducing or eliminating established filter-binding species, the selection should be repeated with a different RNA pool that can be amplified with different primers, as recommended above.

14. Resuspend the selected RNA pellet in 50 μ l binding buffer.
15. Assemble the filter holder with a fresh filter disk as described above.
16. Filter the sample and wash as described above.
17. Discard the filter disk and ethanol precipitate the RNA filtrate.

A carrier (glycogen) can be added to improve the efficiency of precipitation.

If the binding buffer contains a high (>0.5 M) salt concentration, dilute the filtrate with an equal volume of RNase-free water and precipitate with isopropanol instead.

AMPLIFYING SELECTED BINDING SPECIES

In the following steps, RNA species that survived the positive and negative selection steps are reverse transcribed to generate a cDNA library, which is subsequently amplified by PCR. The double-stranded DNA resulting from these steps comprises the pool from which the next round of selection will begin. While the authors have found that reverse transcription and PCR steps can be combined (steps 1a to 3a) for some of our selections, this is not universally true. To obtain the highest yield of RNA and DNA products, it is frequently desirable to carry out separate reverse transcription and PCR reactions (steps 1b to 3b).

Materials

- Selected RNA pool (see Basic Protocol 2)
- TE buffer, pH 8.0, or RNase-free water
- RT-PCR mix (see recipe)
- 10 \times RT buffer (see recipe)
- 20 μ M 3'-end primer
- 20 μ M 5'-end primer
- PCR mix (see recipe)
- 4 mM dNTP mix (*UNIT 3.4*)
- AMV reverse transcriptase (USB)
- 6 \times nondenaturing dye: 0.6% bromphenol blue in TBE buffer
- 4% NuSieve agarose gel (FMC Bioproducts; also see e.g., *UNIT 2.6*)
- 10 μ g/ml ethidium bromide solution (*APPENDIX 2*)

**BASIC
PROTOCOL 3**

**Generation and
Use of
Combinatorial
Libraries**

24.3.13

TBE buffer (*APPENDIX 2*)
4 M ammonium acetate
100% ethanol
Thermal cycler (e.g., MJ Research)

Additional reagents and equipment for the polymerase chain reaction (Chapter 15)
and agarose gel electrophoresis (e.g., *UNIT 2.6*)

NOTE: All solutions and buffers should be freshly treated with DEPC (*UNIT 4.1*). Use sterile, disposable plasticware where possible. See Chapter 4 introduction and *UNIT 4.1* for guidelines on standard methods to protect against contaminating RNases.

Amplify selected binding species

To amplify selected binding species via combined RT-PCR reactions

1a. Resuspend the RNA in 12 μ l TE buffer or RNase-free water and add 4 μ l of this RNA suspension to 96 μ l RT-PCR mix.

Since only 1/3 of the total sample recovered is used for amplification this will obviously restrict the proportion of successful species that are carried into the next round of selection. This is only a potential problem in the early rounds of selection. For example, if the diversity of the RNA pool was such that each species was represented only a few times on average, then a population bottleneck is unavoidable. For this reason, it is always desirable to start with an RNA pool in which each species is represented numerous times. However, the amount of sample that is committed to amplification should probably not exceed one-half to two-thirds of the sample. If the reverse transcription or any subsequent steps are unsuccessful, then the archived RNA serves as an inviolate reservoir for proceeding forward in the selection experiment. Otherwise, one will have to return to material from an earlier round.

2a. Run the following controls in parallel with the amplification of selected RNA species in order to detect nonspecifically bound RNA species and replication parasites (see Critical Parameters for discussion of parasites).

a. *No template control:* To ensure that none of the stock solutions have been contaminated with exogenous RNA or DNA amplicons, set up a RT-PCR reaction without adding any template.

b. *No RT control:* To ensure that amplified products are in fact derived from selected RNA species and not from endogenous or cross-contaminating DNA molecules, set up a RT-PCR reaction without the reverse transcriptase.

3a. Run the RT-PCR reaction on the thermal cycler as follows:

- a. 10 min at 65°C
- b. 10 min at 50°C
- c. 45 sec at 94°C
- d. 60 sec at 50°C
- e. 90 sec at 72°C.

Repeat steps c to e six more times, then follow with:

- f. 150 sec at 72°C.

Step a allows for primers to anneal to the RNA, while step b allows the RT to generate cDNA. Steps c through e comprise the PCR cycle, and the final elongation step (f) at 72°C completes the extension of any incomplete DNA templates. The number of cycles that should initially be carried out is considered below.

It should be noted that the listed conditions have been optimized for the pool used in the selections described, the N30 pool. Different pools and primers may require very

different amplification conditions (see UNIT 15.4 for comments on primer selection and for the experimental parameters that govern reverse transcription and PCR).

If using a PCR machine without a heated bonnet, cover the amplification reaction with mineral oil (e.g., Mallinckrodt). In order to avoid the accumulation of replication parasites, it may be desirable to use one of a number of “hot-start” methods for the PCR reaction (see Chapter 15). The technically simplest of these is to add reverse transcriptase following heating to 65°C in step a, and to add Taq or another thermostable polymerase following heating to 94°C in step c.

To amplify selected binding species via separate RT and PCR reactions

1b. Resuspend the RNA in 12 µl TE buffer or RNase-free water, and set up the RT reaction as follows:

- 4 µl RNA, diluted as described above
- 2 µl 10× RT buffer
- 10 µl 20 µM 3'-end primer
- 4 µl 4 mM dNTP mix
- 0.3 µl (10 U) AMV reverse transcriptase.

Also set up “no template” control without the RNA template and “no RT” control without the reverse transcriptase.

2b. Incubate reactions 30 min at 42°C.

3b. Add 10 µl of each RT reactions to an individual tube containing 100 µl PCR mix.

Conduct the PCR reaction as follows:

- a. 45 sec at 94°C
- b. 60 sec at 50°C
- c. 90 sec at 72°C.

Repeat steps a and b six more times, then follow with:

- d. 150 sec at 72°C.

See UNIT15.1 for additional information on PCR amplification.

Check for the presence of amplified, double-stranded DNA

4. Add 1.5 µl of 6× non-denaturing dye to 5 to 10 µl of the PCR reaction. Load the sample onto a 4% NuSieve agarose gel which has been presoaked in 10 µg/ml ethidium bromide solution for 10 min (e.g., UNIT 2.6). Run the gel in TBE at 125 V for 15 min. Look for products with a hand-held UV lamp or UV light box.

An estimate of the minimal number of cycles needed to visualize a product band on the agarose gel can be roughly calculated. Consider that, of the 5 µg of RNA added to the selection, ~3% likely binds to the filter and is lost during the negative selection step. Approximately 1% of the population may bind to the target. When the selected RNA is precipitated, one-third of the sample is used for RT-PCR. Therefore:

$$(5.0 \mu\text{g})(0.97) (0.01)/3 = 0.016 \mu\text{g RNA.}$$

Assuming that every thermal cycle doubles the amount of DNA, a minimum of seven thermal cycles would be necessary to obtain 1 to 2 µg of DNA. This would imply that 0.1 to 0.2 µg could be loaded and readily visualized on the ethidium bromide-stained agarose gel. Thus, from 7 to 8 thermal cycles should initially be carried out and the products analyzed by gel electrophoresis. The authors frequently find this rough estimate to be true.

5. If no product bands are apparent, then carry out an additional 4 to 5 thermal cycles and again analyze the products by gel electrophoresis. If only faint product bands are

apparent, then one may want to accumulate additional template via an additional 2 to 4 thermal cycles.

The accumulation of double-stranded DNA is closely monitored in order to avoid “over-PCR” of the sample and the concomitant accumulation of high-molecular-weight species. DNA that has been over-amplified will look blurry and disperse following analysis by gel electrophoresis. These large DNA molecules are often the result of the 3' end of a single-stranded DNA folding back and internally priming its own extension, resulting in a long stem-loop that can be amplified by a single PCR primer (also known as single-primer artifacts). Overamplified DNA templates can also yield RNA molecules of the incorrect size following transcription. Adding 2 μ l of the RT-PCR reaction to 100 μ l of a fresh PCR mix and carrying out 2 to 3 additional thermal cycles can clean up DNA that has been over-amplified.

If one primer is more abundant or efficient than the other is, a smaller, single-stranded DNA band or bands may also be present.

The hiatus between carrying out the amplification reaction and running the agarose gel allows the sample to cool to room temperature, and can potentially result in mispriming and the accumulation of replication parasites. However, this is unavoidable and is not as serious for samples that have been partially amplified as it is for samples that are just beginning the amplification procedure. To avoid this potential problem, it is sometimes desirable to take one-fourth to one-third of the selected RNA and carry out a “ranging” RT-PCR reaction to establish the optimal number of cycles for amplification. Another one-fourth to one-third of the selected RNA can then be continuously amplified to this optimum level.

The various controls (“no protein,” “no template,” “no RT”) should be amplified in parallel with the actual sample. If specifically bound RNA is templating the accumulating amplicons, then the “No RT” sample should lag the RT-PCR reaction by at least three cycles. It is devoutly hoped that no bands will be observed in the “no template” control, but if they do arise, they should lag the RT-PCR reaction by at least five cycles. If bands do arise, a distinction should be made between full-length PCR products (indicating contaminating replicons) and smaller products (likely primer amplification artifacts). If product bands in the control lanes are as prominent as product bands in the experimental lanes, then it is necessary to check or remake reagents and go back and repeat the previous round of selection. There is one exception to this rule: in the initial rounds, it is common to see a band in the “no protein” control lane because the proportion of the population that binds to the filter is typically greater than the proportion that binds specifically to the target. However, subsequent rounds of selection should result in the diminution or disappearance of the “no protein” band.

Although we will consider methods for closely monitoring the progress of the selection experiment, observing the number of thermal cycles needed to visualize a double-stranded DNA band can loosely monitor the progress of the selection. The number of thermal cycles should be roughly proportional to the amount of RNA pool that originally binds to the protein. Therefore, if the RNA eluted from the “no protein” control requires more thermal cycles for full amplification than does the RNA selected in the presence of protein, it can be tentatively assumed that the selected RNA is binding to the protein. Occasionally, in the early rounds of selection, this may not be true, since a very small fraction of the pool will bind to the protein relative to the small fraction of the pool that adheres to the filter.

Counting PCR cycles is, however, only a very rough (and frequently inconsistent) measure of success. In fact, it is common for the number of thermal cycles required to fully amplify selected nucleic acids to vary greatly between rounds. Direct binding assays of the RNA pool (Support Protocol 3) are a much more accurate and useful gauge of the progress of a selection experiment.

6. When a product band does appear, precipitate the PCR reaction by adding an equal volume of 4 M ammonium acetate, and, to the resulting mixture, an equal volume of ethanol (i.e., 2 \times the original PCR reaction volume).

If a large amount of sample has been used for gel analysis (for example, if only ~50 μ l of the original RT-PCR reaction remains), then one may wish to return to the selected RNA reservoir and amplify a new DNA template using the already determined “optimal” number of thermal cycles.

Use amplified DNA template for the next round of selection

7. Centrifuge the sample and resuspend in 10 to 20 μ l TE buffer. Proceed with the next round of selection starting with step 1 of Basic Protocol 1.

A 100- μ l RT-PCR reaction yields ~1 to 2 μ g DNA, so approximately half of the resuspended DNA sample should be used for the next transcription reaction. The remaining DNA can serve as a long-term, archival sample.

ASSAYING THE ACCUMULATION OF BINDING SPECIES

In order to verify that the RNA pool has been or is being winnowed to those few sequences that bind the protein target with high affinity and specificity, the selected RNA pool should periodically be assayed for its ability to bind the target protein. The authors recommend an initial binding assay after five rounds of selection and amplification, then again every three additional rounds (the same recommendation that was made with regard to checking for filter-binding species; the two tests can be carried out in parallel). While the initial binding assay is carried out at a series of protein concentrations to gauge the amount of protein that should be used in the selection, the progress of the selection can be most simply monitored by radiolabeling the RNA and determining how much binds to a single, convenient concentration of the protein target.

Materials

Pool of dsDNA after n rounds of selection

Binding buffer

Target protein

13-mm, 0.45- μ m HAWP nitrocellulose disk filters (Millipore)

Filter holders (Nuclepore)

Vacuum manifold

Glass plate

Plastic wrap

Phosphoimager and screen or X-ray film

Additional reagents and equipment for purifying a radiolabeled DNA pool (see Basic Protocol 1) and performing the filter binding assay (see Support Protocol 2)

1. Generate radiolabeled RNA pool via a “hot transcription” with α -labeled nucleoside triphosphates and purify as described in the final annotation to step 1 of Basic Protocol 1.
2. Thermally equilibrate 1 μ g of the radiolabeled RNA pool after a round of selection in binding buffer as described in Support Protocol 2, step 2.
3. Add an equimolar amount of protein to the RNA pool. Incubate the binding reaction under conditions similar to those used for selection (see Support Protocol 2, steps 3 and 4).

If the amount of protein sample is limited or limiting, less protein can be used in the binding reaction. However, one should be cognizant of the fact that less than 100% binding is possible. Alternatively, less protein and less RNA sample can be used, although the diminution of both components will mean that one is assaying binding under conditions more stringent than those actually used for selection. While the volume of the binding reaction could also be diminished to conserve protein, it is difficult to uniformly apply volumes less than 30 μ l to the filter.

SUPPORT PROTOCOL 3

**Generation and
Use of
Combinatorial
Libraries**

24.3.17

4. Prior to filtration, take a small aliquot of the binding reaction (i.e., 5 μ l out of a 100 μ l binding reaction) to determine the total amount of radioactive RNA in the binding reaction. Pipet the sample onto a nitrocellulose filter disk and set the disk aside on a glass plate.
5. Filter the binding reaction and wash 3 times with 200 μ l binding buffer (see Support Protocol 2, steps 5 and 6).
6. Place the filters on the glass plate next to the initial aliquots of the binding reaction.
7. Cover the membranes with plastic wrap and expose to a phosphor screen (e.g., Phosphor imager or X-ray film for 4 to 12 hr).
8. Count the radioactivity using the Phosphorimager or a densitometer and calculate the fraction bound as follows:

Fraction bound = (cpm of filtered solution)/[(cpm of aliquot from step 4) \times (vol. of filtered solution/vol. of aliquot from step 4)].

A good result at this point would be 0.15 to 0.20 fraction bound above background (see Table 24.3.1., round 6). If binding to filter alone is too high, then filter binders are being selected and more negative selection is needed.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Denaturing dye, 2 \times

TBE buffer (APPENDIX 2) containing:

0.1% (w/v) bromophenol blue

7 M urea

Store up to 6 months at -20°C

Denaturing polyacrylamide gel, 10%

TBE buffer (APPENDIX 2) containing:

10% (w/v) acrylamide

0.5% (w/v) bisacrylamide

7 M urea

See UNIT 2.12 for full details on pouring and running the gel.

Elution buffer

7 M urea

100 mM sodium citrate

3 mM EDTA

Store up to 3 months at -20°C

Prepare with RNase-free water.

PCR mix

10 mM Tris-Cl, pH 8.4 (APPENDIX 2)

50 mM KCl

1.5 mM MgCl_2

0.2 mM each dNTP

5% (w/v) acetamide

0.05% (v/v) Nonidet P-40 (NP-40)

0.5 μ M each primer

0.2 U *Taq* DNA polymerase (Promega)

RT buffer, 10×

500 mM Tris·Cl, pH 8.0 (APPENDIX 2)
400 mM KCl
60 mM MgCl₂
Store up to 6 months at −20°C

RT-PCR mix

10 mM Tris·Cl, pH 8.4 (APPENDIX 2)
50 mM KCl
1.5 mM MgCl₂
0.2 mM each dNTP
5% (w/v) acetamide
0.05% (v/v) Nonidet P-40 (NP-40)
0.5 μM each primer
0.2 U *Taq* polymerase (Promega)
10 U AMV reverse transcriptase (USB)

Transcription mix

40 mM Tris·Cl, pH 7.9 (APPENDIX 2)
26 mM MgCl₂
0.01% (v/v) Triton X-100
2.5 mM spermidine trihydrochloride
5 mM dithiothreitol
2.5 mM each ribonucleotide triphosphate
20 U RNasin (Promega)
100 U T7 RNA polymerase (New England Biolabs)
Prepare fresh

COMMENTARY**Background Information**

Sol Spiegelman and coworkers developed a working system for the in vitro replication and evolution of small RNA molecules over 25 years ago (Mills et al., 1967; Levisohn and Spiegelman, 1969; Kramer et al., 1974). The development of more advanced (although conceptually identical) methods for in vitro evolution as described in this chapter was potentiated by advances in the chemical synthesis of oligonucleotides and the amplification of nucleic acids, such as PCR, in vitro transcription, and 3SR (Guatelli et al., 1990). The adaptation of these methods to in vitro evolution of RNA molecules was partially due to a recognition that early evolutionary events, such as the genesis of ribozymes, could be recapitulated in a test tube, and partially due to a recognition that the ability to tailor RNA binding species and catalysts might have numerous biotechnological applications. Following the publication of key papers outlining and proving selection technologies (Ellington and Szostak, 1990; Tuerk and Gold, 1990), a much wider array of selection experiments has been attempted. To date,

RNA molecules that can bind targets as small as zinc and as large as viruses and organs have been selected. RNA molecules that interact with both nucleic acid-binding proteins and non-nucleic acid binding proteins can be selected with almost equal facility from random sequence populations. These results have been thoroughly reviewed in numerous recent publications (Gold et al., 1995; Uphoff et al., 1996; Famulok and Jenne, 1998).

Critical Parameters**Choosing protein targets**

As briefly described above, a wide variety of proteins have proven to be successful targets for selection experiments, including enzymes, transcription factors, cytokines, antibodies, and viral capsids (Gold et al., 1995; Uphoff et al., 1996; Famulok and Jenna, 1998). There is no common functional theme uniting these targets, nor can many generalities be drawn regarding their biochemistry or structure. However, it is safe to say that “good” selection targets tend to fall into two classes. First, proteins that nor-

mally bind nucleic acids will also be able to extract aptamers from a random sequence pool. The notion of a nucleic acid-binding protein can to some extent be expanded to include proteins that bind nucleotides. For example, kinases and dehydrogenases bind nucleotide cofactors and have proven to be good selection targets.

Second, proteins that for whatever reason contain basic patches in their primary sequences or on their surfaces also frequently yield high-affinity aptamers. For example, many cytokines and other signal-transduction proteins bind heparin or other sulfated oligosaccharides, and can also be used to select aptamers from random sequence populations. The anti-cytokine aptamers frequently bind to the same sites as heparin (Jellinek et al., 1993). Similarly, proteins that bind phosphate or phosphomonoester or phosphodiester bonds frequently have positively charged active sites and can be used to elicit aptamers. For example, anti-phosphatase aptamers have been selected from random sequence pools (Bell et al., 1998).

This is not to say that proteins that do not fall into these categories will of necessity be poor selection targets, merely that they are not sure selection targets. For example, antibodies have frequently proven to be excellent selection targets irrespective of whether or not they bind negatively charged antigens (Keene, 1996). This likely implies that proteins that have large pockets or clefts on their surface are good selection targets. This hypothesis is further bolstered by another line of reasoning. Aptamers selected to bind proteins frequently inhibit protein function. That is, anti-antibody aptamers block interactions with antigens, anti-enzyme aptamers inhibit enzymatic activities, and so forth. This so-called “homing principle” may be due to the fact that aptamers have to not only form a surface that is chemically complementary to a target, but also must fold into a structure that properly presents the chemically complementary surface. The most informationally parsimonious way to achieve both functions is to fit into a pocket on a target, rather than to form a “grasping” structure that can enfold a surface protrusion of a target. Thus, the most common (and most highly represented) aptamers may be those that fit into surface crevices. In contrast, antibodies have a preformed structure for the presentation of chemically complementary surfaces, and thus can more easily grasp protruding epitopes and less easily fit into surface crevices.

Overall, though, researchers should be guided not so much by these considerations, but by the results of initial binding assays with their particular protein target. If the target binds to the filter (not a given, since small, acidic proteins such as the Rop protein from *E. coli* will frequently pass through the filter) and shows some affinity for a random sequence pool, then it is highly probable that there will be some sequences or structures within the pool with greatly enhanced affinities for the target.

Choosing a binding buffer

The binding buffer should promote specific binding of nucleic acids to a protein target. The first consideration in choosing a buffer is to identify conditions under which the protein is active, or at least stable. In addition, if the selected nucleic acid species are to eventually be used in a particular environment, the selection buffer should reflect this environment. For example, if the selected nucleic acids are to be expressed in a cell, then the selection buffer should be at physiological pH and contain physiological ion concentrations. Second, there are a variety of parameters that can be used to make the RNA pool more or less “sticky.” These parameters are discussed in much greater detail in the following section on the stringency of selection.

A typical binding reaction is built from one of the commonly used buffers, such as Tris-Cl, phosphate, or HEPES, which can hold the pH near 6 to 8, together with 50 to 200 mM NaCl or KCl and 1 to 10 mM MgCl₂. However, these are merely suggestions, and aptamers have in fact been selected under a variety of buffer conditions. For example, in the selection that targeted bFGF, phosphate-buffered saline was used even though it lacked divalent cations. Similarly, ribozyme selections have been carried out in which a variety of divalent metal ions are mixed, and nascent ribozyme species “decide” which combination of metals most enhance their activities (Lehman and Joyce, 1993). An equivalent strategy could be used for the selection of aptamers.

Selection matrices

Due to the tremendous ratio of matrix surface area to protein surface area, matrix-binding aptamers can quickly and easily eclipse target-binding aptamers. Proteins are likely captured on nitrocellulose or modified cellulose filters via hydrophobic interactions. Nucleic acids are, by and large, too hydrophilic or charged to be similarly captured. This distinc-

tion is the basis for most filter-binding assays. However, the nucleobases of nucleic acids obviously contain large hydrophobic surface areas, and it is easy to select nucleic acids that can present nucleobases and be captured by the filter. Selected filter-binding sequences frequently contain purine (especially guanosine) tracts presented as single-stranded loops or bulges. Interestingly, hydrophobic-binding sequences selected on one hydrophobic matrix are frequently cross-reactive with other hydrophobic matrices: i.e., microtiter plate-binding species can bind tubes and filters, filter-binding species can bind tubes and microtiter plates, and so forth.

In order to avoid filter-binding sequences, the authors have filtered RNA samples multiple times in the absence of protein, and in some cases filtered samples following selection but prior to the RT-PCR step. Matrix-binding sequences can also be avoided by altering the matrices used for selection. For example, techniques such as gel mobility shifts, immunoprecipitation, and affinity chromatography have all been successfully used to sieve pools and select target-binding aptamers (Conrad et al., 1996). If filter-binding species predominate in a population even after appropriate precautions are taken, these alternative selection techniques can be used either to rid the selected population of the filter-binding species or, better yet, to restart the selection. For example, if the immunoprecipitation of RNA:protein complexes has been worked out in advance, then immunoprecipitation can be interspersed with rounds of filter-binding.

Even though the selection of filter-binding sequences can be a problem, filter binding is still generally recommended as the technique of choice for most selections. Gel mobility shift experiments tend to be much more sensitive to parameters such as sample preparation, ionic strength, pH, and electrophoresis conditions than are filter-binding experiments. Moreover, just as filter-binding species can be inadvertently selected during filtration selection, RNA species with altered electrophoretic mobilities (e.g., dimers) can be selected during gel-mobility shift selections. Immunoprecipitation experiments require an additional protein reagent and in consequence anti-antibody rather than anti-target aptamers are frequently selected. Affinity chromatography or similar techniques generally require that very large amounts of target proteins be committed to the preparation of affinity matrices. If affinity elution is to be used, then even larger amounts of target pro-

teins will be required. Moreover, aptamers that bind to agarose matrices can be selected almost as easily as aptamers that bind to nitrocellulose or modified cellulose filters (although the two, thankfully, do not cross-bind to one another's matrices). Finally, microtiter plate panning selections encourage the accumulation of the same sorts of matrix-binding aptamers that are elicited by filter-binding selections.

Stringency of selection

Overall, most selection experiments are generally competitions between specifically and nonspecifically binding nucleic acid species. The authors tend to initially choose conservative binding conditions in hopes of promoting the early establishment of binding species in the population. While this may mean that low-affinity species are isolated from the pool along with high-affinity species, the low-affinity species can eventually be removed by increasing the stringency of selection. In essence, time (the number of cycles required to purify high-affinity species) can be traded for the assurance that filter-binding species will not accumulate and predominate.

A variety of parameters can be modulated in order to increase or decrease the stringency of a selection experiment. These parameters should initially be chosen based on the results of Support Protocol 2, which assays the affinity of the pool for the target and should be made progressively more stringent based on the results of Support Protocol 3.

The amount of protein target. The more protein there is to bind, the easier it is to capture nucleic acid binding species. Using low amounts of protein increases competition among binding species. However, the amount of protein target available to researchers is usually limited, and thus it is easier to use a set amount of protein (usually from 0.1 to 10.0 μ m per binding reaction) and to vary the RNA:protein ratio.

RNA:protein ratio. By increasing the ratio of pool to target, more binding species will compete for a smaller number of targets. Typically, after a few initial rounds with an equimolar pool-to-target ratio, the ratio is increased to between 10:1 and 100:1. This increase can be effected either by increasing the amount of RNA or by decreasing the amount of protein. Because of the underlying competition between specifically binding species and nonspecifically binding species, increasing the amount of RNA is preferable to decreasing the amount of protein. For a more detailed treatment of this

subject, see Irvine et al. (1991). However, the general conclusions of these mathematical models are similar to the empirical advice given here.

Competitors. High concentrations of non-specific, non-amplifiable competitors such as tRNA or bulk cellular RNA will compete with low-affinity binding species that adhere to basic patches on the surface of a protein. Typically, a 100-fold excess of tRNA is used. Similarly, specific competitors can be used to block the access of low-affinity binding species to a preferred site. Wild-type nucleic acid ligands can be used to block the binding sites of nucleic acid binding proteins. For example, during the selection of anti-Rev aptamers, Giver et al. (1993) included a 10-fold excess of the wild-type Rev-binding element. The anti-Rev aptamers that were obtained could bind with high affinity to the RNA-binding domain of Rev and could effectively compete with the wild-type Rev-binding element. Other ligands or substrates can also be used to block the binding or catalytic sites of non-nucleic acid binding proteins. For example, during the selection of anti-bFGF aptamers, Jelinek et al. (1993) included heparin, a natural ligand for bFGF. The anti-bFGF aptamers that were obtained could bind with high affinity to the heparin binding site and could effectively compete with heparin.

Cation concentration. Monovalent cations (such as Na⁺) and divalent cations such as Mg²⁺ stabilize the structure of RNA molecules and contribute to both specific and nonspecific binding. Decreasing monovalent and/or divalent cation concentrations therefore can therefore increase the stringency of the selection. However, it is unclear, in advance, whether specific or nonspecific binding species will be more favored by such a change. Moreover, since binding species that require a monovalent and/or divalent cation to fold into shapes that are chemically complementary to a target may be favored in the early rounds of selection, potentially high-affinity binding species may be lost by changing the binding buffer late in the selection experiment. It is better to attempt to change the buffer dependency of aptamers by partial randomization and re-selection following the initial selection experiment, rather than to attempt to change the buffer dependency during the selection.

Conversely, higher concentrations of monovalent cations (generally sodium or potassium) increase the structural integrity of folded nucleic acids by neutralizing the close approach of nucleic acid strands. However, higher mono-

valent ion concentrations also suppress electrostatic interactions with targets. Thus, paradoxically, both “low” and “high” monovalent ion concentrations can be used to increase the stringency of a selection experiments. Higher concentrations of divalent cations such as magnesium help to maintain the structural integrity of RNA molecules and potentially facilitate the formation of salt bridges between acidic residues and the phosphate backbone.

Equilibration time. Longer equilibration times give stronger binding species a greater chance to bind to the target, since weaker binding species more quickly dissociate from the target. In general, though, species with nanomolar dissociation constants or lower can be readily selected by allowing the reaction to equilibrate for 5 min or more. The authors usually allow up to 30 min for the binding reaction in order to allow for slow folding or refolding steps in the presence of the target. However, longer equilibration times may not be possible for proteins that are inherently unstable or that themselves undergo slow, buffer- or temperature-induced conformational changes.

Dilution of binding buffer. Similarly, diluting the binding reaction by 10- to 20-fold just prior to filtration will favor the selection of RNA:protein complexes with low dissociation constants over RNA:protein complexes with higher dissociation constants. Baskerville et al. (1995) have successfully used this technique to select high affinity anti-Rex aptamers.

Amount and composition of wash. Increasing the number of times a filter is washed and the volume of the buffer used for the washes should preferentially increase the retention of high-affinity binding species relative to low-affinity and nonspecific binding species. It is generally recommended that the same buffer be used for selection and for wash steps, in order to avoid changing the conditions under which aptamers are selected. However, the stringency of the selection can potentially be manipulated by changing the buffer used for the wash steps. For example, if monovalent cation concentrations are limited in the binding buffer due to requirements for the stability or activity of a protein target, a separate wash buffer that contains a higher salt concentration can be used to challenge captured RNA:protein complexes.

Parasites

Replication parasites differ from matrix-binding aptamers, but can interfere with the selection of target-binding aptamers in the

same way. Reverse transcriptase, *Taq* polymerase, and T7 RNA polymerase all have some preference for which sequences they will copy or reproduce. These preferences are generally not obvious when constant sequence nucleic acids are being synthesized. However, in selection experiments many cycles of amplification are carried out, and differences in the rates of synthesis are also proportionately amplified, leading to the selection of sequences that have no function other than to replicate optimally. For example, during the polymerase chain reaction if a primer designed to bind to a constant sequence region instead recognizes a partially complementary sequence within a random sequence region, it can set down and generate a smaller amplicon. The smaller amplicon will generally be amplified more quickly than the larger amplicon, and thus can potentially out-compete full-length species selected for binding function. Depending on the relative advantage of the replication parasite relative to an aptamer, even if the replication parasite is partially removed from the population during each selection step, enough molecules may remain to overrun the amplification reaction and displace the functionally selected aptamer. This is especially true if the amplification parasite also happens to be a filter-binding species. It is for this reason that the authors of this unit strongly recommend that DNA templates and/or RNA molecules be size-selected in each round.

The nascent reproductive differences between nucleic acid species can be grossly amplified by amplification methods that allow continuous reproduction of the nucleic acids, such as isothermal amplification or 3SR (Guatelli et al., 1990). For example, Breaker and Joyce (1994) generated an extremely robust replication parasite, RNA Z, during a selection designed to generate catalytic variants of a group II intron. Similarly, the authors have generated replication parasites of isothermal amplification reactions from completely random sequence pools (K. Marshall, pers. comm.). Interestingly, these isothermal amplification parasites were actually larger than the initial RNA species and represented recombination events between individual members of the pool. Airborne copies of these replication parasites can readily “seed” isothermal amplification reactions and overrun pool molecules that are initially present in even million-fold excess. In this respect, the replication parasites of isothermal amplification reactions resemble the midi-variants or “monsters” of Q β replicase amplification reactions, and are equally hard to

vanquish, once established. It is for this reason that the authors strongly recommend the sometimes tedious but inherently faithful regime of reverse transcription, PCR, and in vitro transcription for the amplification of RNA pools. However, successful selections have been carried out that have relied upon isothermal amplification (see, for example, Breaker et al., 1994; Wlotzka and McCaskill, 1997; Wright and Joyce, 1997), and this admonition can most confidently be challenged if the starting pool is a partially randomized binding site or ribozyme. The reason is that isothermal amplification parasites are more likely to be found in or derived from a “deep random” pool than in a pool that centers on a given functional sequence.

Anticipated Results

Table 24.3.1 shows the progression of a selection carried out in the authors’ lab against bFGF with an RNA pool with a 30 nucleotide randomized region. In order to evaluate the success of a selection experiment, it was necessary to compare the affinity of the selected pool versus the affinity of the unselected pool for the protein target (see Support Protocol 3). When assaying the pool after a round of selection, it was necessary to validate the fraction of the pool that bound to the protein by including a no protein control. If the accumulation of matrix-binding species had been evident, more stringent negative selections could have potentially been used to control or reduce their numbers.

The affinity of the RNA aptamer for the protein target cannot be anticipated. Affinity typically varies between micromolar and subnanomolar, depending presumably on the makeup of the nucleotide pool and on the targeted protein. However, it might be worth mentioning that, of the first 100 selections carried out at two commercial entities using the technology—Gilead Sciences and NeXstar—just under 80% yield aptamers with affinities under 10^{-9} M (Brody et al., 1999).

Time Considerations

The time required to go from one pool of selected DNA templates to the next is ~24 to 72 hr, depending on the researcher and the demands of the particular selection experiment. Minimally, a transcription reaction takes ~4 hr, and the ensuing DNase, heat denaturation and gel purification steps can take another 2 to 3 hr. Elution for 8 to 10 hr yields an adequate amount of RNA to be used in the subsequent binding

reaction. After precipitation and quantification of the RNA (1 hr), the preselection filtration, incubation with target, and selection steps can be performed in 2 hr. Elution of protein-RNA complexes, subsequent extractions, and another precipitation step take another 2 hr. The amount of time needed to see a DNA product varies according to the number of PCR cycles needed to amplify the pool to a certain amount, and that number is inversely related to the abundance of target-binding species that survived the selection. Nevertheless, the RT-PCR steps, followed by precipitation of the DNA templates that can be added to the transcription mix, should consume ~3 to 4 hr.

The amount of time it takes to carry out the entire selection is contingent upon the number of rounds needed to accumulate target-binding species. That number, in turn, varies depending upon the initial affinity of the unselected pool for the target and on the stringency with which each round of the selection is carried out. When additional steps such as radiolabeling and assaying unselected and selected pools are taken into account, an entire selection experiment can take up to 2 to 3 weeks. It is for this reason that the authors have recently developed automated methods for selection experiments (Cox et al., 1998) that can speed the entire process by an order of magnitude.

Peptide Aptamers: Dominant “Genetic” Agents for Forward and Reverse Analysis of Cellular Processes

Peptide aptamers are a new class of dominant “genetic” agents that facilitate the analysis of cellular processes in diploid and genetically intractable organisms. They are defined as protein-based recognition agents that consist of a constrained combinatorial peptide library displayed on the surface of a scaffold protein. Peptide aptamers function *in trans*, interacting with and inactivating gene products without mutating the DNA that encodes them. Combinatorial libraries of peptide aptamers contain aptamers that, in principle, can interact with almost any gene product.

The dominant combinatorial nature of peptide aptamers makes them useful as genetic agents for the reverse and forward analysis of cellular processes. Reverse analysis with peptide aptamers involves isolating aptamers that interact with a specific protein and monitoring the resulting aptamer-induced phenotype. A two-hybrid system is used to screen combinatorial libraries of peptide aptamers for those aptamers that interact with a specific protein. The isolated aptamers are then expressed within an organism to identify the aptamer-induced phenotype. Forward analysis with peptide aptamers involves expressing combinatorial libraries of aptamers within an organism and screening for aptamer-induced variations in their phenotypes. The specific protein(s) targeted by the aptamers are identified using a two-hybrid system.

This unit describes methods to construct and use thioredoxin peptide aptamers as genetic agents for the analysis of cellular processes. The interaction trap two-hybrid system (UNIT 20.1) is used to isolate peptide aptamers that interact with specific proteins (reverse analysis) and to identify the proteins targeted by aptamers (forward analysis).

Basic Protocol 1 describes the construction of a combinatorial library of thioredoxin peptide aptamers. The peptide aptamers consist of a conformationally constrained twenty–amino acid peptide displayed from the active site of thioredoxin. The peptide aptamers are subcloned into one of the pJM yeast expression vectors shown in Figure 24.4.1, depending on whether they are used for reverse or forward analysis.

Basic Protocol 2 describes a yeast-based *in vivo* screening method to obtain peptide aptamers for reverse analysis of cellular processes. Combinatorial libraries of peptide aptamers are screened for interactions with a specific protein using the interaction trap two-hybrid system (UNIT 20.1). The peptide aptamer is expressed as a fusion to a transcription activation domain, referred to as the “prey.” The target protein is expressed as a fusion to a LexA DNA binding domain, referred to as the “bait.” DNA-binding sites for the LexA fusion protein are located upstream of the two reporter genes, *Leu2* (CD8) and *lacZ*. Interaction between a peptide aptamer prey and the bait protein are detected by activation of these reporter genes.

Basic Protocol 3 describes the use of the yeast mating interaction assay to evaluate the specificity of peptide aptamers. Haploid yeast exist in two mating types (**a** or α), where opposite mating types can mate to form diploids (**a**/ α). The mating interaction assay detects aptamer/protein interactions by generating panels of aptamer preys in one mating type and panels of target bait proteins in the opposite mating type. Mating of the haploid strains forms diploid strains that carry both the bait and prey. Interactions between baits and preys are detected using the interaction trap reporters. The mating interaction assay

allows aptamer specificity to be assessed against large arrays of different but related proteins and against mutants of the same protein.

Basic Protocol 4 describes an affinity maturation strategy for enhancing the affinity of peptide aptamers to their target proteins. PCR mutagenesis is used to introduce random mutations into the variable region of a peptide aptamer. Peptide aptamers with enhanced affinity are isolated using a modified version of the interaction trap that contains a more

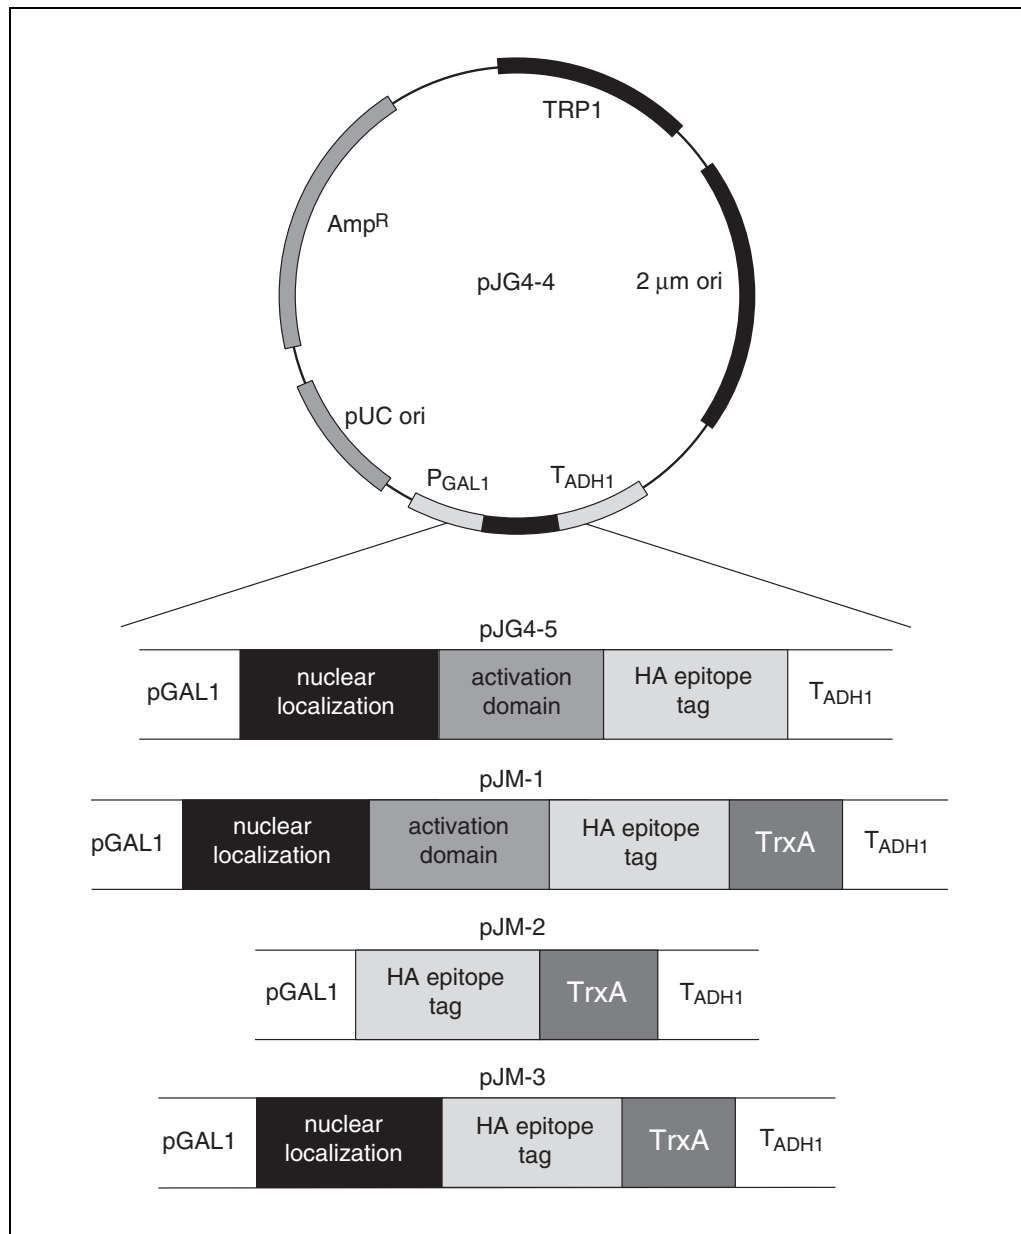

Figure 24.4.1 Expression vectors for interaction trap and genetic selection. pJG4-5 is the prey vector used in the interaction trap (*UNIT 20.1*). pJM-1 is the peptide aptamer prey vector. pJM-2 and pJM-3 are used in yeast genetic selections. These yeast-*E. coli* shuttle vectors are derivatives of pJG4-4 (Gyuris et al., 1993), and contain one of the following expression cassettes. pJG4-5: yeast GAL1 promoter (P_{GAL1}), SV40 nuclear localization signal, B42 activation domain, haemagglutinin epitope tag, *Eco*RI and *Xho*I cloning site, and yeast ADH1 transcription terminator (T_{ADH1}) (Gyuris et al., 1993). See Figure 20.1.3 for a more detailed map of pJG4-5. pJM-1: P_{GAL1}, SV40 nuclear localization signal, B42 activation domain, haemagglutinin epitope tag, *E. coli* thioredoxin (TrxA), and T_{ADH1} (Colas et al., 1996). pJM-2: P_{GAL1}, haemagglutinin epitope tag, TrxA, and T_{ADH1} (Geyer et al., 1999). pJM-3: P_{GAL1}, SV40 nuclear localization signal, haemagglutinin epitope tag, TrxA, and T_{ADH1} (Geyer et al., 1999).

stringent *lacZ* reporter. The stringency of the *lacZ* is increased by reducing the number of *LexA* operators upstream of the *lacZ* reporter gene.

Basic Protocol 5 describes a method to use peptide aptamers for the forward analysis of cellular processes. Combinatorial libraries of peptide aptamers are used as dominant genetic agents that randomly inhibit gene function. Forward analysis involves: (1) expressing combinatorial libraries of peptide aptamers in organisms, (2) isolating organisms that display aptamer-induced phenotypes, and (3) identifying peptide aptamer targets using the interaction trap.

CONSTRUCTION OF A COMBINATORIAL THIOREDOXIN PEPTIDE APTAMER LIBRARY

BASIC PROTOCOL 1

Combinatorial libraries of peptide aptamers are constructed by inserting a random twenty–amino acid peptide into the short disulfide-constrained loop (-CGPC-) in the active site of *E. coli* thioredoxin. The active site loop contains a unique *RsrII* restriction site that allows the insertion of *AvaII*-cut DNA, which encodes for random amino acids. Random peptide libraries are constructed using twenty repeats of the codon NNK, where N is A, G, C, or T and K is G or C. Using G or C in the third position of the codon reduces the number of stop codons while maintaining codons for all twenty amino acids. Depending on the application, the random peptide libraries are subcloned into one of the pJM yeast expression vectors shown in Figure 24.4.1. pJM-1 is used in the interaction trap to generate peptide aptamers against specific proteins. pJM-2 and pJM-3 are used in genetic selections to produce aptamers that alter an organism's phenotype. All of the pJM vectors use the *galI* promoter to control the expression of the peptide aptamers. The *galI* promoter induces aptamer expression in the presence of galactose and represses expression in the presence of glucose. The resulting aptamer/thioredoxin vector is transformed into *E. coli* by electroporation (also see *UNIT 9.3* for electroporation techniques).

Materials

- 5 U/μl Klenow DNA polymerase and 10× reaction buffer (New England Biolabs)
- 5 mM 4dNTP mixture: 5 mM each dTTP, dATP, dGTP, and dCTP
- 10 U/μl *AvaII* and 2 U/μl *RsrII* restriction enzymes and 10× reaction buffers (New England Biolabs)
- 10 mM Tris·Cl, pH 8 (*APPENDIX 2*)
- Nondenaturing loading buffer (see recipe)
- DNA elution buffer (see recipe)
- Thioredoxin expression vector plasmid: pJM-1, pJM-2, or pJM-3 (Fig. 24.4.1)
- 10 U/μl calf intestinal alkaline phosphatase (CIP) and 10× reaction buffer (New England Biolabs)
- 2000 U/μl T4 DNA ligase and 10× reaction buffer (New England Biolabs)
- QIAquick gel extraction kit (Qiagen)
- Ultrapure water (sterile water for irrigation preferred; Fisher Scientific)
- E. coli* MC 1061 (Bio-Rad), electroporation competent (*UNIT 9.3*)
- SOC medium (*UNIT 1.8*), prewarmed to 37°C
- LB plates and liquid medium (*UNIT 1.1*) containing 50 μg/ml ampicillin
- Large-scale plasmid preparation kit (various commercial sources, e.g., Qiagen; optional)
- DNA synthesizer
- 16° and 95°C water baths
- PCR purification column (e.g., Qiagen; optional)
- Electroporator (e.g., Bio-Rad Gene Pulser) with 0.2-cm-gap electroporation cells

Generation and Use of Combinatorial Libraries

24.4.3

Additional reagents and equipment for DNA synthesis; phenol/chloroform extraction and ethanol precipitation (*UNIT 2.1A*); polyacrylamide gel electrophoresis (*PAGE*; *UNIT 2.7*); UV shadowing and elution of DNA (*UNIT 2.7*); UV spectroscopy (*APPENDIX 3D*) or ethidium bromide dot quantitation (*UNIT 2.6*); bacterial transformation (*UNIT 1.8*); and ethidium bromide/cesium chloride gradients (optional; *UNIT 2.4*)

NOTE: Activity units of enzymes are described for enzymes obtained from New England Biolabs. Other commercial sources can be used, but units should be confirmed.

Prepare random peptide DNA cassette

1. Prepare the following 91-base random oligonucleotide and 17-base primer using an automated DNA synthesizer. Dissolve oligonucleotides separately in water to a final concentration of 1 $\mu\text{g}/\mu\text{l}$.

Oligonucleotide: 5'-GACTGACTGGTCCG(NNK)₂₀GGTCCTCAGTCAGTCAG-3', where N is A, G, C, or T and K is G or C.
Primer: 5'-CTGACTGACTGAGGACC-3'.
2. Add the following (in order) to a 1.5-ml microcentrifuge tube (final 890 μl):
 - 200 μg primer (10-fold excess)
 - 100 μg random oligonucleotide
 - 490 μl water
 - 100 μl 10 \times Klenow polymerase reaction buffer.
3. Anneal primer to random oligonucleotide by heating sample to 95°C in a water bath for 5 min. Slowly cool to room temperature (~30 min).
4. Add 90 μl of 5 mM 4dNTP mixture and 20 μl (100 U) Klenow polymerase and incubate 3 hr at 37°C.
5. Phenol/chloroform extract the mixture (*UNIT 2.1A*) and ethanol precipitate the DNA (*UNIT 2.1A*).
6. Dissolve DNA pellet in 0.8 ml water.
7. Add 100 μl of 10 \times *Ava*II reaction buffer and 100 μl (1000 U) *Ava*II. Incubate 4 hr at 37°C.
8. Repeat step 5.
9. Dissolve DNA pellet in 150 μl of 10 mM Tris-Cl, pH 8, and add 50 μl vol nondenaturing loading buffer.
10. Separate DNA on a preparative 10% nondenaturing polyacrylamide gel (*UNIT 2.7*).
11. Locate the DNA band in the gel by UV shadowing (*UNIT 2.7*) and cut out the DNA band.
12. Elute DNA from the gel by shaking in DNA elution buffer overnight (*UNIT 2.7*).
13. Ethanol precipitate the DNA and dissolve in 200 μl of 10 mM Tris-Cl, pH 8. Determine DNA concentration by UV spectroscopy (*APPENDIX 3D*), or estimate DNA concentration using ethidium bromide dot quantitation (*UNIT 2.6*).
14. Choose one of the thioredoxin expression vectors (pJM) in Figure 24.4.1 and add 12 μg of the chosen vector to 420 μl sterile water.

Prepare thioredoxin expression vector

14. Choose one of the thioredoxin expression vectors (pJM) in Figure 24.4.1 and add 12 μg of the chosen vector to 420 μl sterile water.

15. Add 50 μ l of 10 \times *Rsr*II reaction buffer and 30 μ l (60 U) *Rsr*II. Incubate overnight at 37°C.
16. Dephosphorylate *Rsr*II-cut pJM vector by adding 10 μ l (100 U) CIP and incubating 1 hr at 37°C.
17. Purify dephosphorylated, *Rsr*II-cut pJM vector using a commercially available PCR purification column or by phenol/chloroform extraction.

Ligate random peptide cassette in thioredoxin expression vector

18. Combine 8 μ g DNA cassette (step 13) and 12 μ g vector (step 17) in water to a total volume of 860 μ l.
19. Add 100 μ l of 10 \times T4 DNA ligase reaction buffer and 40 μ l (80,000 U) T4 DNA ligase. Incubate 16 hr at 16°C.
20. Purify ligated DNA using a QIAquick gel extraction kit according to manufacturer's instructions. Elute DNA from the column using 30 μ l ultrapure water.

It is important to remove as much salt, buffer, and protein from the ligated DNA as possible prior to electroporation.

Electroporate ligated DNA

21. Thaw 350 μ l electroporation-competent *E. coli* MC1061 on ice and add 30 μ l purified ligated plasmid. Transfer mixture to a 0.2-cm-gap electroporation cell.
22. Electroporate using the following conditions: 2.5 kV, 200 Ω , and 25 μ F.
23. Recover cells in 25 ml prewarmed SOC medium and incubate 1.5 hr at 37°C with gentle rocking.
24. Determine transformation efficiency by plating serial dilutions on LB plates containing 50 μ g/ml ampicillin.
25. Transfer remaining cells to 1 liter LB liquid medium containing 50 μ g/ml ampicillin and incubate overnight at 37°C.
26. Purify plasmid DNA using a commercially available large-scale plasmid preparation kit or using successive ethidium bromide/CsCl gradients (UNIT 2.4). Determine concentration and bring to 40 μ g/ml for screening (Basic Protocol 2).

ISOLATION OF PEPTIDE APTAMERS FOR SPECIFIC PROTEINS USING THE INTERACTION TRAP TWO-HYBRID SYSTEM

The interaction trap two-hybrid system (Gyuris et al., 1993; UNIT 20.1) is an established method for screening proteins for interactions with genomic and cDNA libraries (reviewed by Bai and Elledge, 1996; Finley and Brent, 1997). The interaction trap can also be extended to screen combinatorial libraries of peptide aptamers for interactions with specific proteins (Yang et al., 1995; Colas et al., 1996). The interaction trap consists of the following parts: (1) a constitutively expressed target protein fused to a *LexA* DNA-binding domain, referred to as the “bait;” (2) a galactose-induced combinatorial library of thioredoxin peptide aptamers fused to an activation domain, referred to as the “prey;” and (3) *LexA*-operator-*leu2* and *LexA*-operator-*lacZ* reporter genes for detecting interactions between the peptide aptamer prey and target protein bait. The bait protein binds to the *LexA* operators upstream of the reporters, but does not activate transcription of the reporters. Interaction between a peptide aptamer prey and target protein bait is detected by activation of reporter genes in the presence of galactose and not in the presence of

Libraries**

24.4.5

glucose. Figure 20.1.2 illustrates the isolation of proteins that interact with specific targets using the interaction trap.

In the first part of this protocol, the bait plasmid (pBait) is constructed by inserting DNA that encodes for the target protein into the polylinker of pEG202, in frame with *LexA*. The chimeric *LexA*-bait fusion protein is constitutively expressed using the ADH1 promoter. It is transformed into the appropriate yeast strain (EGY48) by a standard lithium acetate transformation procedure (UNIT 13.7). To be useful in the interaction trap two-hybrid system, the bait proteins must enter the nucleus, bind to the *LexA* operators, and not self-activate the *leu2* and *lacZ* reporters. After construction, pBait is characterized using protocols described elsewhere (UNIT 20.1).

The pJM-1 peptide aptamer library is used to select aptamers that bind specific protein targets using the interaction trap. pJM-1 contains a thioredoxin aptamer fused to a nuclear localization signal, a transcription activation domain, and an epitope tag under the control of the *gal1* promoter. Peptide aptamer expression is induced in the presence of galactose and repressed in the presence of glucose. A high-efficiency lithium acetate transformation procedure (Gietz and Schiestl, 1995; outlined below) is used rather than the standard procedure (UNIT 13.7) to introduce the aptamer library into the yeast strain EGY48, which contains an integrated *LexA*-operator-*leu2* reporter gene, *LexA*-operator-*lacZ* reporter plasmid and a bait plasmid. Interactions between the bait protein and the peptide aptamer prey are initially detected on galactose plates that lack leucine. Galactose induces the expression of the peptide aptamer and the absence of leucine selects for peptide aptamer/bait protein interactions that activate the *leu2* reporter. Interactions are verified by subsequently testing for galactose-dependent growth on –Leu plates and galactose-dependent blue color on Xgal plates.

The lithium acetate transformation procedure used here typically yields 10^5 to 10^6 transformants per μg of plasmid DNA. The protocol should be optimized for individual strains to achieve maximum transformation efficiency. In particular, variables such as cell concentration and heat shock time need to be optimized. The highest transformation efficiencies are obtained with $1 \mu\text{g}$ plasmid DNA per $50 \mu\text{l}$ competent yeast cells and generally do not scale up with similar efficiencies. The protocol below is designed for the transformation of $50 \mu\text{g}$ of peptide aptamer library.

Materials

- DNA encoding bait protein of interest
- Plasmid DNA: pEG202 (Fig. 20.1.3), pSH18-34 (Fig. 24.4.2)
- Yeast strain: EGY48 *ura3 trp1 his3 3LexA-operator-leu2*
- Complete minimal (CM) dropout medium (UNIT 13.1) and plates supplemented with either 2% (w/v) glucose (Glu) or 2% (w/v) galactose and 1% (w/v) raffinose (Gal/Raf):
 - Glu/CM –His,–Ura (10-cm plates and liquid medium)
 - Glu/CM –His,–Ura,–Trp (10- and 15-cm plates)
 - Glu/CM –His,–Ura,–Trp,–Leu (10-cm plates)
 - Gal/Raf/CM –His,–Ura,–Trp (liquid medium)
 - Gal/Raf/CM –His,–Ura,–Trp,–Leu (10- and 15-cm plates)
- 100 mM and 1 M lithium acetate, pH 7.5, filter sterilized
- 50% (w/v) polyethylene glycol, mol. wt. 3350 (PEG 3350; Sigma)
- 2 mg/ml single-stranded carrier DNA (sodium salt Type III from salmon testes; Sigma) TE buffer (APPENDIX 2)
- 40 $\mu\text{g}/\text{ml}$ peptide aptamer library DNA (pJM-1 aptamer plasmid; see Basic Protocol 1)

2× glycerol storage solution: 65% (v/v) glycerol, 0.1 M MgSO₄, 25 mM Tris-Cl, pH 7.4 (APPENDIX 2)
10-cm Xgal plates (UNIT 13.1)
Glu/CM –His,–Ura,–Trp, Xgal
Gal/Raf/CM –His,–Ura,–Trp, Xgal
PCR primers for thioredoxin
30° and 42°C incubators or water baths

Additional reagents and equipment for subcloning DNA (UNIT 3.16); manipulating yeast (UNIT 13.2); lithium acetate yeast transformation (UNIT 13.7); characterizing bait plasmids (UNIT 20.1); determination of cell density (UNIT 13.2) and plating efficiency (UNIT 20.1); replica plating (UNITS 1.3 & 13.2); yeast plasmid preparation (UNIT 13.11); plasmid sequencing (UNIT 7.3); *E. coli* transformation (UNIT 1.8); agarose gel electrophoresis (UNIT 2.5A); and PCR (UNIT 15.1)

Construct bait plasmid (pBait)

1. Using standard subcloning techniques (UNIT 3.16), insert DNA that codes for the bait protein into the polylinker of pEG202 to create the bait plasmid (pBait).
2. Transform pBait and pSH18-34 (*lacZ* reporter) into the interaction trap selection strain (EGY48) by lithium acetate yeast transformation (UNIT 13.7).
3. Plate transformants on Glu/CM –His,–Ura plates and place in a 30°C incubator.

Characterize bait protein

4. Confirm that the bait protein does not self-activate the reporter genes by performing plate assays for *lacZ* activation and leucine requirement (UNIT 20.1).

If the bait protein activates the leu2 and/or lacZ reporter genes, variations of the interaction trap that reduce reporter sensitivity should be tried. Yeast strains and/or plasmids containing less-sensitive leu2 and lacZ reporters reduce the background reporter output to reasonable levels. Yeast strains (Table 20.1.2) and plasmids (Fig. 24.4.2) with less sensitive reporters are described in UNIT 20.1. Truncating or separating the protein target can also eliminate transcription self-activation.

5. Confirm bait protein synthesis using the repression assay described in UNIT 20.1.

Baits that do not repress the expression of β-galactosidase in the repression assay may not be expressed correctly or may be incapable of entering the nucleus. Expression of full-length baits can be verified by immunoblotting. If full-length baits are expressed, their entry into the nucleus can be facilitated by adding a nuclear localization signal (J. Kamens, unpub. observ.). See Table 20.1.1 for description of plasmid pJK202 (a bait vector that contains a nuclear localization signal).

Transform peptide aptamer library into pBait-containing yeast

6. Inoculate 20 ml Glu/CM –His,–Ura liquid medium with transformed EGY48 (step 3) and incubate overnight at 30°C with shaking.
7. Take an OD₆₀₀ measurement and dilute to a concentration of 5 × 10⁶ cells/ml in 250 ml Glu/CM –His,–Ura.

An OD₆₀₀ of 0.1 corresponds to ~3 × 10⁶ cells/ml. This value should be confirmed for each yeast strain used (UNIT 13.2).

8. Incubate cells at 30°C with shaking until they reach an OD₆₀₀ of 0.6 to 0.8 (~5 to 6 hr).

This will yield enough yeast for 50 transformations.

Figure 24.4.2 *lacZ* reporter plasmids. The *lacZ* reporter plasmids are derived from a plasmid that contains a wild-type GAL1 promoter fused to the *lacZ* gene (Yocum et al., 1984). *lacZ* reporters with different sensitivities are constructed by inserting different numbers of *lexA* operators into a plasmid (pLR1Δ1) that has the GAL1 upstream activating sequences (UAS_G) deleted (West et al., 1984). The *lacZ* reporters pSH18-34 (Gyuris et al., 1993), pJK103 (Kamens and Brent, 1991), and pRB1840 (Brent and Ptashne, 1985) contain eight, two, or one *lexA* operator(s). The sensitivity of the *lacZ* reporter decreases with the number of *lexA* operators.

9. Divide culture into five 50-ml conical centrifuge tubes and centrifuge 5 min at 3000 × *g*, room temperature.
10. Decant supernatant and resuspend each yeast pellet in 25 ml sterile water. Repeat centrifugation.
11. Decant supernatant and resuspend each yeast pellet in 1 ml of 100 mM lithium acetate. Transfer to a 1.5-ml microcentrifuge tube and pellet yeast by centrifuging 15 sec at 20,800 × *g*, room temperature.
12. Remove supernatant with a pipet and resuspend each yeast pellet in 350 μl of 100 mM lithium acetate (final volume ~500 μl).
13. Split the contents of each tube into ten 50-μl portions and pellet yeast by centrifuging 15 sec at 20,800 × *g*, room temperature.

14. Remove supernatant with a pipet and add the following ingredients to each sample in the order listed:

240 μ l 50% (w/v) PEG 3350
36 μ l 1 M lithium acetate
50 μ l 2 mg/ml single-stranded carrier DNA (100 μ g)
25 μ l 40 μ g/ml peptide aptamer library DNA (1 μ g).

Single-strand carrier DNA needs to be heated to 95°C for 5 min and cooled on ice prior to use.

15. Vortex the transformation mixture vigorously until the yeast pellet is completely resuspended and incubate 30 min at 30°C.
16. Heat shock 20 min at 42°C.
17. Pellet yeast by centrifuging 15 sec at 20,800 \times g, room temperature.
18. Remove supernatant with a pipet and resuspend pellet in 500 μ l sterile water.
19. Plate 48 transformations on individual 15-cm Glu/CM –His,–Ura,–Trp plates.
20. Plate 400 μ l of the two remaining transformations on 15-cm Glu/CM –His,–Ura,–Trp plates.
21. Use the remaining 100 μ l to determine the transformation efficiency. Perform a series of 10-fold dilutions in sterile water and plate on 10-cm Glu/CM –His,–Ura,–Trp plates.
22. Incubate 2 to 3 days at 30°C (until colonies are ~1 mm in diameter).

Pool transformants

23. Pool yeast from all 50 transformation plates (steps 19 and 20) in a 50-ml centrifuge tube.

See UNIT 20.1 for protocol on scraping yeast from plates.

24. Add an equal volume of 2 \times glycerol storage solution to the pooled yeast cells. Divide into 1-ml aliquots and store at –70°C.
25. Determine the plating efficiency of the frozen aliquots as described in *UNIT 20.1*.

Screen for peptide aptamers that interact with target protein

26. Inoculate ten library equivalents of the peptide aptamer library in 2 ml Gal/Raf/CM –His,–Ura,–Trp liquid medium. Incubate 4 hr at 30°C with shaking.

One library equivalent equals the total number of yeast transformants containing the peptide aptamer library, as determined in step 21.

27. Centrifuge 4 min at 3000 \times g, room temperature.
28. Remove supernatant with a pipet and resuspend yeast in 1 ml sterile water.
29. Spread yeast at a density of 10⁶ yeast cells/plate on 15-cm Gal/Raf/CM –His, –Ura, –Trp, –Leu plates.
30. Incubate at 30°C and monitor plates daily for growth.
31. Streak colonies onto 10-cm Glu/CM –His,–Ura,–Trp master plates. Incubate 1 to 2 days at 30°C.

32. Replica plate the master plates on the following indicator plates:

Glu/CM –His,–Ura,–Trp,–Leu
Gal/Raf/CM –His,–Ura,–Trp,–Leu
Glu/CM –His,–Ura,–Trp, Xgal
Gal/Raf/CM –His,–Ura,–Trp, Xgal.

33. Identify colonies that show galactose-dependent growth on –Leu plates and galactose-dependent blue color on Xgal plates.

Isolate peptide aptamers

34. Isolate the desired peptide aptamer expression plasmid (UNIT 13.11).

The plasmid preparation will contain a mixture of the three plasmids used in the interaction trap (pJM-1 aptamer plasmid, pSH18-34, and pBait).

35. Use plasmids as templates for sequencing the peptide aptamer variable regions (UNIT 7.3).

36. To separate the aptamer plasmid from pBait and pSH18-34, transform *E. coli* (UNIT 1.8) and identify the appropriate transformants by PCR (UNIT 15.1) using primers that amplify thioredoxin.

*Colonies that contain the peptide aptamer will appear as a bright band on an ethidium bromide agarose gel (UNIT 2.5A) after 20 cycles of PCR. Colonies that do not contain the peptide aptamer will appear as a faint band that is 20 base pairs shorter than the aptamer. This shorter band is due to the presence of native *E. coli* thioredoxin.*

BASIC PROTOCOL 3

DEFINING RECOGNITION SPECIFICITY WITH INTERACTION MATING

Interaction mating is a variation of the interaction trap. It allows interactions between large panels of proteins to be analyzed (Finley and Brent, 1994). Haploid yeast exist in one of two mating types (**a** or **α**). Haploid yeast that contain protein targets or related protein baits in one mating type and peptide aptamer preys in the opposite mating type can mate to form diploids that carry both the aptamers and their targets or related proteins. Interaction between the peptide aptamer prey and protein target bait is detected by the activation of two reporter genes: LexAop-LEU2 and LexAop-LacZ. Using the mating interaction assay, panels of related or mutated proteins can be assayed simultaneously for interactions with panels of peptide aptamers. See Figure 24.4.3 for schematic of the interaction mating assay.

Materials

Plasmid DNA: pBait(s) (see Basic Protocol 2), peptide aptamer preys (see Basic Protocol 2), pEG202 (Fig. 20.1.3), pJG4-5 (Fig. 24.4.1), pSH18-34 (Fig. 24.4.2)

Yeast strains:

EGY42: *Matα ura3 trp1 his3 leu2*

EGY48: *Matα ura3 trp1 his3 3LexA-operator-leu2*

10-cm complete minimal (CM) dropout plates (UNIT 13.1) supplemented with either 2% (w/v) glucose (Glu) or 2% (w/v) galactose and 1% (w/v) raffinose (Gal/Raf):

Glu/CM –Trp

Glu/CM –His,–Ura

Glu/CM –His,–Ura,–Trp,–Leu

Gal/Raf/CM –His,–Ura,–Trp,–Leu

YPD plates (UNIT 13.1)

Xgal plates (UNIT 13.1):

Glu/CM –His,–Ura,–Trp, Xgal

Gal/Raf/CM –His,–Ura,–Trp, Xgal.

30°C incubator

Additional reagents and equipment for lithium acetate yeast transformation (UNIT 13.7) and replica plating (UNITS 1.3 & 13.2)

1. Transform individual peptide aptamer prey plasmids and a control plasmid (pJG4-5) into EGY48 (*Mata*) using lithium acetate transformation (UNIT 13.7). Select transformants on 10-cm Glu/CM –Trp plates.

Figure 24.4.3 Mating interaction assay (Finley and Brent, 1994). Peptide aptamer preys in the yeast strain EGY48 (*Mata*) are streaked vertically on Glu/CM –Trp plates. Target protein baits and *lacZ* reporter (pSH18-34) in the yeast strain EGY42 (*Mata*) are streaked horizontally on Glu/CM –His,–Ura plates. The yeast strains are replica plated perpendicular to each other on YPD plates. The haploid strains carrying the baits and preys mate where the two strains intersect, forming (*a/α*) diploids that contain the bait, prey, and *lacZ* reporter. The YPD plates are replica plated onto the following interaction detection plates: Glu/CM –His,–Ura,–Trp,–Leu; Gal/Raf/CM –His,–Ura,–Trp,–Leu; Glu/CM –His,–Ura,–Trp, Xgal; Gal/Raf/CM –His,–Ura,–Trp, Xgal. Interacting baits and prey display galactose-dependent growth and blue color on –Leu and Xgal plates, respectively.

2. Transform individual target protein baits (pBaits) with pSH18-34 (*lacZ* reporter) and a control plasmid (pEG202) with pSH18-34 into EGY42 (*Mata*). Select transformants on 10-cm Glu/CM –His,–Ura plates.
3. Streak, in parallel lines, individual peptide aptamers and their control prey strains on 10-cm Glu/CM –Trp plates.
4. Streak, in parallel lines, individual protein targets and their control bait strains on 10-cm Glu/CM –His,–Ura plates.
5. Incubate all plates overnight at 30°C.
6. Replica plate the protein target bait and peptide aptamer prey strains on the same replica velvet by first replica plating the bait strains and then replica plating the prey strains perpendicular to the baits (see Figure 24.4.3 for schematic).
7. Transfer the yeast imprint to a 10-cm YPD plate and incubate overnight at 30°C.
8. Replica plate the YPD plate onto a replica velvet. Transfer the yeast imprint to the following indicator plates:
 - Glu/CM –His,–Ura,–Trp,–Leu
 - Gal/Raf/CM –His,–Ura,–Trp,–Leu
 - Glu/CM –His,–Ura,–Trp, Xgal
 - Gal/Raf/CM –His,–Ura,–Trp, Xgal.
9. Analyze plates for mating.

Mating occurs at the intersection of the Mata α and Mata strains. Diploid colonies should grow on the Xgal plates. Interactions between the peptide aptamer preys and protein target baits produce blue color on the galactose Xgal plates and growth on the galactose –Leu plates at the intersection of the strains.

BASIC PROTOCOL 4

AFFINITY MATURATION OF PEPTIDE APTAMERS

The binding affinity between a peptide aptamer and its protein target can be improved by mutating the peptide aptamer variable region and reselecting for aptamers that bind the target protein using a more stringent interaction trap. In this protocol, peptide aptamers are mutated by random PCR mutagenesis as described by Cadwell and Joyce, 1994. Alternatively, degenerate oligonucleotides that code for the variable region and have varying degrees of randomness can be synthesized using an automated DNA synthesizer (UNIT 2.11). The stringency of the interaction trap selection is enhanced by decreasing the number of *LexA* operators upstream of the *lacZ* reporter gene. A series of *lacZ* reporter genes containing eight, two, and one *LexA* operator(s) (Brent and Ptashne, 1985) are used to select aptamers with increased affinity toward their targets.

Materials

- 5 U/ μ l *Taq* polymerase and 10 \times buffer (Life Technologies)
- 1 M MgCl₂
- 100 mM dATP
- 100 mM dGTP
- 100 mM dCTP
- 100 mM dTTP
- 20 μ M primer 1: 5'-CCGCCGCCTGAATTCATGAGCGATAAAATTATTAC-3'
- 20 μ M primer 2: 5'-CGGGGCGATCATTTTGCACGGACC-3'
- Plasmid DNA: peptide aptamer plasmid (see Basic Protocol 2), pBait (see Basic Protocol 2), pJM-1 (Fig. 24.4.1), pRB1840 (1-LexAop-LacZ reporter plasmid; Fig. 24.4.2), and pJK103 (Fig. 24.4.2)

Mg²⁺/Mn²⁺ solution: 45 mM MgCl₂ and 5 mM MnCl₂

PCR purification column (optional; e.g., Qiagen)

Yeast strain: EGY48 *Mata ura3 trp1 his3 3LexA-operator-leu2*

Complete minimal (CM) dropout medium (*UNIT 13.1*) and plates supplemented with either 2% (w/v) glucose (Glu) or 2% (w/v) galactose and 1% (w/v) raffinose (Gal/Raf):

Glu/CM –His,–Ura (10-cm plates)

Glu/CM –His,–Ura,–Trp (10-cm plates)

Gal/Raf/CM –Ura,–His,–Trp (liquid medium)

Xgal plates (*UNIT 13.1*)

Glu/CM –His,–Ura,–Trp, Xgal (10-cm plates)

Gal/Raf/CM –His,–Ura,–Trp, Xgal (10- and 15-cm plates)

PCR tubes

Automated thermal cycler

30°C incubator

Additional reagents and equipment for agarose gel electrophoresis (optional; *UNIT 2.5A*), digesting and cloning peptide aptamer mutants (see Basic Protocol 1), lithium acetate yeast transformation (see Basic Protocol 2 and *UNIT 13.7*), determination of plating efficiency (*UNIT 20.1*), plasmid rescue (*UNIT 13.11*), and plasmid DNA sequencing (*UNIT 7.3*)

Mutagenize peptide aptamer variable region

1. Prepare PCR premixture (total 3.775 ml):

500 µl 10× *Taq* polymerase buffer

5 µl 1 M MgCl₂

10 µl 100 mM dATP

10 µl 100 mM dGTP

50 µl 100 mM dCTP

50 µl 100 mM dTTP

125 µl 20 µM primer 1

125 µl 20 µM primer 2

2.9 ml water.

2. For each sample, add the following reagents to a PCR tube:

12 µl water

1 µl peptide aptamer expression vector

10 µl Mg²⁺/Mn²⁺ solution

76 µl PCR premixture

1 µl *Taq* polymerase (5 U).

3. Amplify the reaction using the following PCR reaction program:

4 cycles: 30 sec 95°C (denaturation)

 1 min 55°C (annealing)

 1 min 72°C (extension).

4. Remove 13 µl reaction mixture and add to a new PCR tube containing:

10 µl Mg²⁺/Mn²⁺ solution

76 µl PCR premixture

1 µl *Taq* polymerase.

Amplify using the same PCR program.

5. Repeat for a total of ten rounds of amplification.

6. Purify the PCR product with a commercially available PCR purification column or by agarose gel electrophoresis (*UNIT 2.5A*).

Construct mutagenized peptide aptamer expression vector

7. Digest purified PCR product with *Ava*II and subclone it into *Rsr*II-cut pJM-1 using standard subcloning techniques (*UNIT 3.16*). Electroporate the ligated product as described above (see Basic Protocol 1, steps 20 to 26).

Select mutagenized aptamers by the interaction trap

8. Transform EGY48 with pBait and pRB1840 by standard lithium acetate yeast transformation (*UNIT 13.7*). Select transformants on 10-cm Glu/CM –His,–Ura plates.
9. Using the high-efficiency lithium acetate procedure (see Basic Protocol 2, steps 6 to 22), transform 10 to 50 µg of mutagenized peptide aptamer library into EGY48 containing pBait and pRB1840. Select transformants on 10-cm Glu/CM –His,–Ura, –Trp plates.
10. Pool transformants and determine plating efficiency as described in *UNIT 20.1*.
11. Inoculate approximately five library equivalents in 1 ml Gal/Raf/CM –His, –Ura, –Trp liquid medium. Incubate 4 hr at 30°C with shaking.

One library equivalent equals the total number of yeast transformants containing the peptide aptamer library as determined in step 9.
12. Centrifuge 4 min at 3000 × *g*, room temperature. Remove supernatant and resuspend yeast pellet in 1 ml sterile water.
13. Spread yeast on 15-cm Gal/Raf/CM –His,–Ura,–Trp, Xgal plates and incubate at 30°C until colonies appear (~2 days).
14. Streak blue colonies onto a 10-cm Glu/CM –His,–Ura,–Trp master plate and incubate 1 day at 30°C.
15. Replica plate the master plate onto 10-cm Gal/Raf/CM –His,–Ura,–Trp, Xgal and Glu/CM –His,–Ura,–Trp, Xgal plates.
16. Rescue plasmids (*UNIT 13.11*) from the galactose-dependent blue colonies and reintroduce (*UNIT 13.7*) the plasmids into the yeast strain EGY48 that contains pBait and pRB1840 to reconfirm the phenotype.
17. Rescue the plasmids from the galactose-dependent blue colonies and sequence (*UNIT 7.3*) the variable regions.

BASIC PROTOCOL 5

FORWARD ANALYSIS OF CELLULAR PROCESSES USING PEPTIDE APTAMERS

Combinatorial libraries of peptide aptamers can function as dominant agents for the forward analysis of cellular processes. Peptide aptamers function as “mutagens”, randomly inhibiting gene function and altering the phenotype of an organism. Forward analysis with peptide aptamers involves expressing combinatorial libraries in organisms and screening or selecting for aptamer-induced changes in their phenotypes. The peptide aptamer targets are subsequently identified using the interaction trap. The protein targets can be identified from panels of proteins using a mating interaction assay (Finley and Brent, 1994) or by screening for aptamer interactions against genomic or cDNA libraries using the interaction trap (*UNIT 20.1*). Currently, complete panels of proteins are not available for any organisms except yeast. As a result, panels of known proteins will need

Peptide Aptamers

24.4.14

to be combined with cDNA and genomic libraries of proteins to identify peptide aptamer targets.

The design of a genetic selection is beyond the scope of this protocol. A typical genetic selection requires the transformation of an organism selection strain with a peptide aptamer expression library containing 10^6 to 10^7 members. Peptide aptamers are expressed under the control of an inducible promoter, allowing the aptamer-induced phenotype to be confirmed by comparing the effects of the aptamer expression plasmid in the presence or absence of the inducer. The protocol described below for a genetic selection using yeast may be adapted to a variety of organisms.

Materials

Yeast strain for genetic selection

Peptide aptamer library: pJM-2 or pJM-3 (Basic Protocol 1; Fig. 24.4.1)

Complete minimal (CM) dropout liquid medium (*UNIT 13.1*) and plates supplemented with either 2% (w/v) glucose (Glu) or 2% (w/v) galactose and 1% (w/v) raffinose (Gal/Raf):

Glu/CM –Trp (10-cm plates)

Gal/Raf/CM –Trp (10-cm plates and liquid medium)

30°C incubator

Additional reagents and equipment for high-efficiency lithium acetate yeast transformation (see Basic Protocol 2), determination of plating efficiency (*UNIT 20.1*), isolation of plasmids (*UNIT 13.11*), plasmid DNA sequencing (*UNIT 7.3*), and target identification (see Support Protocol)

1. Transform 50 to 100 μg of the peptide aptamer library (in pJM-2 or pJM-3) into a yeast selection strain (10^6 to 10^7 transformants) using the high-efficiency lithium acetate transformation procedure (see Basic Protocol 2, steps 6 to 22). Plate transformants on 10-cm Glu/CM –Trp plates and incubate at 30°C until colonies are ~1 mm in diameter (~2 to 3 days).
2. Pool yeast cells and determine the plating efficiency as described in *UNIT 20.1*.
3. Inoculate ten library equivalents in 1 ml Gal/Raf/CM –Trp liquid medium. Incubate 4 hr at 30°C with shaking.

One library equivalent equals the total number of transformants containing the peptide aptamer library as determined in step 1.
4. Centrifuge culture 4 min at $3000 \times g$, room temperature. Remove supernatant with a pipet and resuspend the yeast pellet in sterile water.
5. Plate yeast on 10-cm Gal/Raf/CM –Trp selection plates and incubate under selection conditions.
6. Streak positive colonies on Glu/CM –Trp master plates.
7. Confirm galactose-dependent phenotype by replicating master plate onto Glu/CM –Trp and Gal/Raf/CM –Trp plates and incubate under selection conditions.
8. Isolate peptide aptamer expression plasmids (pJM-2 or pJM-3) from the yeast colonies that show the galactose-dependent phenotype (*UNIT 13.11*).
9. Reconfirm the peptide aptamer phenotype by transforming the isolated plasmid into the selection strain and testing for galactose-dependent phenotype.
10. Isolate the peptide aptamer expression plasmids (*UNIT 13.11*) for sequencing (*UNIT 7.3*) and target identification (see Support Protocol).

IDENTIFICATION OF PEPTIDE APTAMER TARGETS

The protein targets of the genetically selected peptide aptamers (Basic Protocol 5) can be identified using the interaction mating assay (see Basic Protocol 3) or by interaction hunts against cDNA or genomic libraries (*UNIT 20.1*). Genomic and cDNA libraries are constructed as preys since they contain many sequences capable of activating transcription in the bait configuration. As such, the peptide aptamers need to be transferred to the bait plasmid pEG202 to identify their targets in these libraries. Protocols for constructing cDNA and genomic libraries can be found in *UNITS 5.7, 5.8A & 5.8B*.

Putative peptide aptamer targets identified with either mating interaction panels or hunts should be verified using genetic tests such as: (1) immunoprecipitation to confirm the aptamer interactions *in vivo*, (2) epistasis analysis to confirm that the aptamer functions in the same area as the target protein, or (3) comparison of the phenotype(s) caused by deletion and overexpression of target protein with the phenotype caused by the aptamer.

Materials

DNA encoding thioredoxin peptide aptamer (Basic Protocol 5)

Plasmid DNA: pEG202 (Fig. 20.1.3), pSH18-34 (Fig. 24.4.2), pJG4-5 (Fig. 24.4.1)

Yeast strains:

EGY42, *Mat α ura3 trp1 his3 leu2*

EGY48, *Mata ura3 trp1 his3 3LexA-operator-leu2*

Complete minimal (CM) dropout liquid medium (*UNIT 13.1*) and plates

supplemented with either 2% (w/v) glucose (Glu) or 2% (w/v) galactose and 1% (w/v) raffinose (Gal/Raf):

Glu/CM –His,–Ura (10-cm plates)

Glu/CM –Trp (10-cm plates)

Prey library (see Table 20.1.3)

Additional reagents and equipment for PCR (*UNIT 15.1*), standard subcloning (*UNIT 3.16*), standard lithium acetate yeast transformation (*UNIT 13.7*), interaction mating (see Basic Protocol 3), interaction trap (*UNIT 20.1*)

Transfer peptide aptamers from pJM-2 or pJM-3 into pEG202

1. PCR amplify the DNA encoding the thioredoxin peptide aptamer using primers that contain restriction sites compatible with the polylinker of pEG202 and in frame with *LexA* (Fig. 20.1.3).
2. Using standard subcloning techniques (*UNIT 3.16*), insert the PCR product into pEG202 to create the peptide aptamer bait.
3. Transform the individual peptide aptamer baits and pSH18-34 (*lacZ* reporter) into EGY48 (*Mat α*) by standard lithium acetate yeast transformation (*UNIT 13.7*). At the same time transform a control plasmid (pEG202) and pSH18-34 into EGY48.
4. Select transformants on 10-cm Glu/CM –His,–Ura plates.

Identify targets

For mating interaction assay:

- 5a. Construct a panel of desired proteins by inserting coding regions of proteins into the polylinker of pJG4-5 (prey plasmid, Fig. 24.4.1).
- 6a. Transform prey plasmids and a control plasmid (pJG4-5) into EGY42 (*Mata*) by standard lithium acetate transformation. Select transformants on 10-cm Glu/CM –Trp plates.

- 7a. Mate strains containing peptide aptamer baits and target protein preys and score interactions as described (see Basic Protocol 3, steps 3 to 9).

For interaction trap library hunts:

- 5b. Transform strains containing individual peptide aptamers and pSH18-34 (step 3) with a library of genomic or cDNA preys. Follow the protocol in *UNIT 20.1* for transforming cDNA and genomic prey libraries.
- 6b. Select peptide aptamer target(s) using the interaction trap hunt protocol described in *UNIT 20.1*.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

DNA elution buffer

- 10 mM Tris·Cl, pH 7.5 (*APPENDIX 2*)
- 1 mM EDTA, pH 8 (*APPENDIX 2*)
- 50 mM NaCl
- Store up to 1 year at room temperature

Nondenaturing loading buffer

- 50 mM Tris·Cl, pH 8 (*APPENDIX 2*)
- 50 mM EDTA, pH 8 (*APPENDIX 2*)
- 50% (v/v) glycerol
- Store up to 1 year at 4°C

COMMENTARY

Background Information

Understanding cellular processes within organisms relies on forward and reverse genetic approaches to identify genetic network members and connections. In forward genetic analysis, genes are identified by isolating randomly generated mutants and mapping the genes responsible for their mutant phenotypes. Reverse genetic analysis, by contrast, involves mutating individual genes and monitoring the resulting phenotype. While both approaches are effective, they are difficult to perform, especially in diploid organisms. In diploid organisms, the identification of recessive mutations requires two generations of breeding to generate homozygotes. Consequently, genetic approaches requiring homozygous recessive mutations can only be fully applied to organisms with well-developed genetics such as phage, bacteria, yeast, *C. elegans*, and *Drosophila*.

Dominant agents that affect gene products in *trans*, instead of genes, have been developed to overcome problems associated with the analysis of recessive mutations in diploid organisms. A variety of dominant agents exist for the reverse analysis of cellular processes. These include: small molecule inhibitors (Mitchison,

1994), dominant negative proteins (Herskowitz, 1987), antibodies (Gorbsky et al., 1998), antisense RNA (Branch, 1998), ribozymes (Bramlage et al., 1998), and nucleic acid aptamers (*UNIT 24.3*; Thomas et al., 1997). These agents have improved the ability to analyze processes in diploid organisms; however, they too have limitations. For example, forward analysis requires large-scale generation of agents that are capable of inactivating the function of almost any gene product, but agents such as small molecule inhibitors and dominant negative proteins may not exist for all gene products. Similarly, although it should, in theory, be possible to generate agents such as antibodies, ribozymes, nucleic acid aptamers, and antisense RNA against almost any gene product, antibodies are not membrane permeable, and large-scale injection is tedious and impractical for most organisms. RNA agents are not very stable and it is difficult to predict sites on RNA that are exposed for inhibition by antisense RNA and ribozymes. Furthermore, agents that inhibit at the RNA level (antisense RNA and ribozymes) are affected by the stability of the protein target, which can affect the onset and/or the extent of the phenotype.

The development of combinatorial technologies for obtaining biomolecules with desired properties (*UNITS 24.2 & 24.3*; Ellington and Szostak, 1990; Scott and Smith, 1990) presents new avenues for generating “genetic” agents for characterizing genetically intractable organisms. This unit describes methods to construct combinatorial libraries of “genetic” agents referred to as peptide aptamers. Peptide aptamer libraries consist of scaffold proteins that display variable peptides constrained at both ends on their surface. They are designed to interact and interfere with the biological function of proteins. Peptide aptamers are well suited for analyzing cellular processes in diploid organisms because they act in *trans* to inhibit gene products without altering their encoding DNA. Moreover, because they are isolated from combinatorial libraries, peptide aptamers can in principle be generated to inactivate almost any gene product.

Design of intracellular peptide aptamers

Peptide aptamers are designed to interact with their protein targets through variable peptide regions displayed on the surface of a scaffold protein. To date, only a limited number of scaffold proteins have been used within organisms to display linear and constrained peptides. These include: *E. coli* thioredoxin (Colas et al., 1996), Gal4 activation domain (Yang et al., 1995), green fluorescent protein (Caponigro et al., 1998), and staphylococcal nuclease (Norman et al., 1999). A comparison of the binding constants of these aptamers shows that constrained variable regions can bind their targets between 100- and 10,000-fold better than linear peptides (Geyer and Brent, 2000). Unconstrained peptides are also known to be unstable in *E. coli* (Davidson and Sauer, 1994). Constrained peptide libraries are therefore the preferred method for displaying combinatorial peptide libraries for intracellular applications. When choosing aptamer scaffolds, they should also be small, stable, soluble, and expressed at high levels without toxicity. The scaffold should be tolerant to the addition of protein moieties such as localization sequences, epitope tags, and purification tags.

Basic Protocol 1 describes the construction of a peptide aptamer library using *E. coli* thioredoxin as the scaffold protein. Thioredoxin was first used as a scaffold protein for displaying peptides as fusions to flagellin on the surface of *E. coli* (Lu et al., 1995). Thioredoxin possesses many characteristics that make it an excellent scaffold for intracellular applications.

Structural studies on thioredoxin reveal that its active site contains a 4–amino acid loop (–CGPC–) that is constrained by the two terminal cysteines (Katti et al., 1990). This loop is tolerant to peptide insertion (LaVallie et al., 1993) and provides a site for displaying variable peptides. Thioredoxin is a small (12 Kd) cytoplasmic protein that is nontoxic when expressed at high levels (LaVallie et al., 1993). Thioredoxin is often fused to proteins to enhance their solubility (LaVallie et al., 1993). This is a useful property for expressing random sequence libraries where many of the sequences may aggregate. Thioredoxin interacts with a variety of disulfide-containing protein substrates (Wetterauer et al., 1992), suggesting that it may also contribute to the binding interactions between peptide aptamers and their protein targets.

Reverse “genetic” analysis using peptide aptamers

Reverse genetic analysis using peptide aptamers involves isolating aptamers that interact with a specific gene product and monitoring the aptamer-induced phenotype. Peptide aptamers that interact with a chosen protein are selected using yeast two-hybrid systems or a variation thereof (Chien et al., 1991; Dalton and Treisman, 1992; Durfee et al., 1993; Gyuris et al., 1993; Vojtek et al., 1993). These systems share the following features: (1) a DNA-binding domain/target protein fusion, (2) a transcription activation domain/peptide aptamer fusion, and (3) reporter gene(s) to record interactions between the peptide aptamer and protein target (see *UNIT 20.1* for a detailed description of the yeast two-hybrid system).

Basic Protocol 2 describes the interaction trap two-hybrid system as a method for obtaining peptide aptamers that interact with a selected protein target. The interaction trap is an effective method for obtaining high-affinity peptide aptamers that bind specific proteins. Aptamers obtained using the interaction trap have dissociation constants greater than the 1 μ M detection limit required to activate the interaction trap reporters (Estojak et al., 1995).

To date, the interaction trap has been used to isolate peptide aptamers against a variety of protein targets including Cdk2 (Colas et al., 1996), Ras (Xu et al., 1997), HIV-1 Rev (Cohen, 1998), and E2F (Fabbrizio et al., 1999). The dissociation and half-inhibitory constants of these aptamers range from 10^{-8} to 5×10^{-11} M.

An advantage of using the interaction trap to select peptide aptamers is that selection occurs in an intracellular environment. This increases the probability that the aptamers will retain their function when expressed in the appropriate organism. Moreover, aptamers isolated using the interaction trap function effectively under a variety of *in vivo* conditions such as cell cultures (Cohen et al., 1998; Fabbri et al., 1999) and in *Drosophila* (Kolonin and Finley, 1998).

Specificity of peptide aptamers

To be useful for genetic analysis, a peptide aptamer must interact specifically with its protein target. Peptide aptamer specificity can be evaluated by analyzing the aptamer's ability to interact with related target proteins using the interaction trap. Basic Protocol 3 describes the mating interaction assay, an extension of the interaction trap developed by Finley and Brent (1994) for determining the specificity of peptide aptamers against a large panel of related proteins. The interaction mating assay allows panels of individual aptamers to be simultaneously screened for interactions with panels of related target proteins. Using this method, Colas et al. (1996) determined the specificity of aptamers isolated against cyclin-dependent kinase 2 (Cdk2). The majority of aptamers tested were highly specific for Cdk2 and not other closely related kinases with one exception: some of the aptamers also interacted with the closely related kinase Cdk3. Their results demonstrate that aptamers can be generated against different epitopes on Cdk2, some of which are conserved between different members of the cyclin-dependent kinases.

The mating interaction assay is also used to determine the specific regions and/or amino acids that aptamers recognize on the target protein. For example, Cohen et al. (1998) showed that one of the aptamers isolated against Cdk2 (Colas et al., 1996) acts as a competitive inhibitor of the Cdk2-dependent phosphorylation of histone H1. Interaction mating with a panel of mutant Cdk2 proteins revealed that specific active site residues are required for aptamer binding, supporting the competitive inhibition mechanism. In summary, interaction mating assays using panels of related and mutated proteins can be used to classify both the specificity and binding interactions of different aptamers targeted to the same protein.

Affinity maturation

Peptide aptamer selections using the interaction trap are limited to screening $\sim 10^6$ to 10^7 unique aptamers per experiment. This is a small representation ($\sim 9 \times 10^{-6}\%$) of the entire sequence space available to aptamers containing 20-mer variable regions (20^{20} possible sequences). In addition to the small sample size, many of the aptamers will contain stop codons within the variable region. As a result, it is likely that aptamers isolated using the interaction trap do not contain the optimal binding sequences for their target proteins.

Basic Protocol 4 describes a method to obtain aptamers with increased binding affinity. The protocol involves mutating the aptamer variable region and reselecting for binding to its target protein using an interaction trap that contains a more stringent reporter gene (Cohen, 1998; Colas et al., 2000). Mutations can be introduced using mutagenic PCR or by synthesizing degenerate oligonucleotides with varying degrees of randomness (see *UNIT 2.11* for a discussion on the construction of degenerate oligonucleotides). The stringency of the interaction trap is enhanced by reducing the number of *LexA* operators upstream of the reporters. The interaction trap in *UNIT 20.1* contains eight *LexA* operators in the *LexA-lacZ* (pJG4-5) and *LexA-leu2* (EGY48 strain) reporters. These reporters are capable of detecting interactions with dissociation constants of $<1 \mu\text{M}$ (Estojak et al., 1995). Other *lacZ* reporters, developed by Brent and Ptashne (1985), contain only one (pRB1840) or two (pJK103) *LexA* operators (Fig. 24.4.2). These operators have lower affinity for the *LexA* DNA-binding domain and detect interactions with dissociation constants between 20 nM and $<1 \mu\text{M}$ (Estojak et al., 1995).

The affinity maturation described in Basic Protocol 4 has been successfully used to enhance the affinity of aptamers isolated against Cdk2 (Cohen, 1998; Colas et al., 2000). The variable region of the anti-Cdk2 aptamer was mutated by PCR and reselected for binding to a *LexA*-Cdk2 fusion using the 1-*LexA*-operator *lacZ* reporter (pRB1840). Isolated aptamers all contained the same two amino acid substitutions. The dissociation constant of the mature aptamer was reduced to 5 nM, a 20-fold decrease from the starting aptamer ($K_d = 0.1 \mu\text{M}$).

Forward "genetic" analysis with peptide aptamers

Combinatorial libraries of peptide aptamers can function as dominant agents to randomly

Table 24.4.1 Degenerate Codons for Designing Combinatorial Peptide Libraries^a

Codon ^b	Properties	Amino acids ^c	No. of codons	Stop codons
NNN	All 20 amino acids	A(4), C(2), D(2), E(2), F(2), G(4), H(2), I(3), K(2), L(6), M(1), N (2), P(4), Q(2), R(6), S(6), T(4), V(4), W(1), Y(2)	64	TAA(1), TAG(1), TGA(1)
NNS	All 20 amino acids	A(2), C(1), D(1), E(1), F(1), G(2), H(1), I(1), K(1), L(3), M(1), N(1), P(2), Q(1), R(3), S(3), T(2), V(2), W(1), Y(1)	32	TAG (1)
NNC	15 amino acids	A(1), C(1), D(1), F(1), G(1), H(1), I(1), L(1), N(1), P(1), R(1), S(2), T(1), V(1), Y(1)	16	None
NWW	Charged, hydrophobic	D(1), E(1), F(1), H(1), I(2), K(1), L(3), N(1), Q(1), V(2), Y(1)	16	TAA (1)
RVK	Charged, hydrophilic	A(2), D(1), E(1), G(2), K(1), N(1), R(1), S(1), T(2)	12	None
DVT	Hydrophilic	A(1), C(1), D(1), G(1), N(1), S(2), T(1), Y(1)	9	None
NVT	Charged, hydrophilic	A(1), C(1), D(1), G(1), H(1), N(1), P(1), R(1), S(2), T(1), Y(1)	12	None
NNT	Mixed	A(1), C(1), D(1), F(1), G(1), H(1), I(1), L(1), N(1), P(1), R(1), S(2), T(1), V(1), Y(1)	16	None
VVC	Hydrophilic	A(1), D(1), G(1), H(1), N(1), P(1), R(1), S(1), T(1)	9	None
NTT	Hydrophobic	F(1), I(1), L(1), V(1)	4	None
RST	Small side chains	A(1), G(1), S(1), T(1)	4	None
TDK	Hydrophobic	C(1), F(1), L(1), W(1), Y(1)	6	TAG (1)

^aBased on a table described by Sidhu and Weiss (2000).

^bAbbreviations: D = A, G, T; K = G, T; N = A, G, C, T; R = A, G; S = C, G; V = A, C, G; W = A, T.

^cNumbers in parentheses indicate the number of codons for each amino acid.

inactivate gene products without altering their genetic material. The forward analysis of cellular processes using peptide aptamers involves expressing libraries of peptide aptamers within cells and screening for aptamer-induced phenotypes. The protein(s) and protein interactions disrupted by the aptamers are then identified. Basic Protocol 5 describes methods for performing forward analysis of cellular processes in yeast. Methods are also described for identifying peptide aptamer target(s) using interaction trap hunts with genomic or cDNA libraries or by mating interaction assays using protein panels (Support Protocol). Combining aptamer library screening with interaction trap hunts and mating interaction assays provides a new strategy for analyzing processes in diploid organisms and in multicopy gene phenotypes.

Peptide aptamers have been used for the forward analysis of phenotypes in yeast (Caponigro et al., 1998; Geyer et al., 1999; Norman et al., 1999) and bacteria (Blum et al., 2000). In yeast, peptide aptamers were isolated that inhibited mating pheromone response (Caponigro et al., 1998; Geyer et al., 1999; Norman et al., 1999) and spindle checkpoint (Norman et al., 1999) signal transduction pathways. In bacteria, peptide aptamers were isolated that specifically inhibited thymidylate synthase or that caused growth inhibition (Blum et al., 2000). The peptide aptamer targets for forward analysis in yeast were identified using yeast two-hybrid systems. Mating interaction assays identified protein targets from panels of proteins known to be involved in the yeast pheromone response pathway (Caponigro et al., 1998; Geyer et al., 1999) or from large

Peptide Aptamers

24.4.20

panels of proteins containing almost all of the proteins in the yeast genome (Norman et al., 1999). Peptide aptamer targets were also identified using interaction trap hunts against a partial-coverage yeast genomic library (Geyer et al., 1999). Interestingly, the peptide aptamer targets identified with the mating interaction assay were not obtained with the interaction trap hunt using the partial-coverage yeast genomic library (Geyer et al., 1999). The inability of the genomic library screen to identify aptamer targets is partly due to the representation of targets in the partial-coverage library. Nevertheless, the results demonstrate a better success rate for identifying aptamer targets using mating interaction assays with arrayed panels of protein targets. Mating interaction assays have the following advantages: (1) they present protein targets as fully normalized libraries, (2) they allow reporter outputs that result from interactions to be directly compared with outputs caused by the bait alone, and (3) they allow the detection of interaction strengths independent of the differences in plating efficiencies caused by differential reporter activation (Estojak et al., 1995). Currently, protein panels that cover an organism's entire proteome are not commercially available. Consequently, the identification of targets for peptide aptamers isolated using genetic screens will consist of limited panels of known proteins complemented with cDNA or genomic libraries.

Inhibitory mechanisms of peptide aptamers

Peptide aptamers inhibit protein function by a variety of mechanisms. For example, peptide aptamers can bind to protein targets and disrupt their interactions with other proteins. They can disrupt protein interactions within cells (Xu et al., pers. comm.) and in two-hybrid assays (Geyer et al., 1999), and they can inhibit enzymes by competing with their substrates for active site binding (Cohen et al., 1998). In addition to disrupting protein interactions, peptide aptamers can also inhibit protein function by mislocalizing protein targets. Peptide aptamers modified with a localization signal can transport their target proteins into various cellular compartments (Colas et al., 2000). Peptide aptamers fused to catalytic domains can also direct the substrate specificity of enzymes. They can be used to localize enzyme activities to specific protein targets (Colas et al., 2000) or locations in the cell.

Peptide aptamers are particularly useful for the analysis of genetic networks since they can disrupt specific interactions with protein targets

that have multiple protein interactions (Geyer et al., 1999). This allows phenotypes caused by the disruption of individual interactions in a network to be observed, while leaving other interactions in the same network intact. Peptide aptamers can be isolated against allelic variants of proteins (Xu et al., 1997). Their high specificity can be used to functionally characterize variants of polymorphic proteins. In addition, controlling their expression using inducible promoters allows the penetrance and timing of the aptamer-induced phenotype to be varied. Finally, performing genetic selections with peptide aptamers targeted to different locations in the cell can provide information on the cellular location of the target protein.

Together, these properties point to the many ways in which peptide aptamers can be used to analyze cellular processes. The successful use of peptide aptamers in the reverse analysis of processes in cell cultures and in *Drosophila*, and in the forward analysis of processes in yeast, illustrates their potential as "genetic" agents in the analysis of genetically intractable organisms.

Critical Parameters and Troubleshooting

Peptide aptamer libraries

The first critical parameter to consider is the method for synthesizing peptide aptamer libraries. Preferably, peptide aptamer libraries are constructed to minimize the amount of stop codons while maintaining amino acid diversity. In general, two methods of automated DNA synthesis are used to generate DNA templates that code for combinatorial peptide libraries. The first method generates DNA templates by sequentially coupling mixtures of the four-nucleotide phosphoramidites. The second method generates DNA templates by sequentially coupling mixtures of codons.

The sequential nucleotide incorporation method uses completely random or biased mixtures of nucleosides to construct DNA templates. DNA templates constructed using equimolar mixtures of the four-nucleotide phosphoramidites contain all 64 possible codons, including 41 redundant codons and three stop codons. The completely random libraries are biased for amino acids encoded by multiple codons. In addition, the presence of stop codons produces truncated aptamers at a frequency of $3n/64$, where n is the length of the peptide library. The sequential nucleotide incorporation method is improved by restricting the nu-

cleotides that are incorporated at the third position in the codon (see Table 24.4.1 for examples of degenerate codons). The third position of a codon is responsible for most of the redundancy in the genetic code. DNA templates that contain all four nucleosides in the first two positions of the codon and only G or C at the third position consist of 32 codons, which code for 20 amino acids and one stop codon. Codons limited to G or C at the third position are biased for amino acids that are coded by multiple codons. However, the frequency of a stop codon is reduced to $n/32$, where n is the length of the peptide. The presence of stop codons in a completely random or third position–biased library limits the complexity that is obtainable with long combinatorial peptide libraries. The construction of longer peptide libraries requires the ligation of shorter DNA templates that are pre-screened to eliminate sequences that contain stop codons (Cho et al., 2000). Alternatively, combinatorial peptide libraries can be constructed that contain no stop codons, but with reduced amino acid diversity. Table 24.4.1 provides examples of degenerate codons that can be used to design peptide libraries.

The sequential codon incorporation method is used to generate DNA templates that contain 20 amino acids and no stop codons. Three strategies are used to generate codons. The first strategy involves sequentially coupling individual nucleotide phosphoramidites to generate 20 codons each of which is on a separate column (Lam et al., 1991). The beads from each column are subsequently mixed together and repacked into new columns for the synthesis of the next codon. The second strategy involves the synthesis of 20 trinucleotide phosphoramidite codons (Virnekas et al., 1994). Combinatorial peptide libraries are synthesized by coupling random or biased mixtures of the codon phosphoramidites. The third strategy combines aspects of the first two strategies and involves sequentially coupling either an A, G, C, or T phosphoramidite followed by a specific dinucleotide phosphoramidite to complete the codon (Neuner et al., 1998). After the completion of each codon, the beads from the columns are mixed and repacked into new columns for the synthesis of the next codon. The advantage of the codon incorporation method is that it generates unbiased libraries without stop codons. However, there are drawbacks to this method. For example, the bead splitting can become extremely laborious for long peptides. Also, the synthesis of dinucleotide and trinucleotide phosphoramidites is not trivial, and

these phosphoramidites are not currently commercially available.

Once the combinatorial peptide libraries are constructed and inserted into the scaffold protein, they need to be transformed into *E. coli* and amplified. Electroporation is the most efficient method for transforming high-diversity libraries into *E. coli*. DNA uptake by *E. coli* is maximized under conditions of high field strength and low current flow (see Sidhu and Weiss, 2000, for conditions to maximize transformation efficiency in *E. coli*). To reduce the current flow, the conducting species must be removed from the DNA using affinity purification columns.

The number of peptide aptamers that can be screened is generally limited by the transformation efficiencies of the organism used in the selection. In yeast, the highest transformation efficiencies are obtained using the lithium acetate transformation protocol developed by Geitz and Schiestl (1995). The diversity of peptide aptamer libraries in yeast are limited to $\sim 10^6$ to 10^7 unique aptamers. This is much lower than the 10^9 to 10^{10} libraries typically obtained in *E. coli*. Particular care should be taken to optimize the transformation efficiencies in yeast or other selected organisms. To obtain optimal transformation in yeast, it is important to perform trial transformations to optimize parameters such as heat shock time and cell density.

Screening peptide aptamers

A second critical parameter is the spontaneous reversion rate in the screen used to isolate the peptide aptamers. *UNIT 20.1* discusses critical parameters that should be taken into account when selecting peptide aptamers against specific proteins using the interaction trap. False positives that occur in either the interaction trap or other genetic screens can be eliminated more efficiently using peptide aptamers that are expressed under the control of an inducible promoter.

Identifying protein targets

A third critical parameter is the identification of proteins targeted by peptide aptamers that have been isolated based on their ability to disrupt cellular processes. In general, peptide aptamer targets are more reliably obtained from panels of known proteins rather than from genomic or cDNA libraries. Once putative peptide aptamer targets have been identified using interaction trap hunts and mating interaction assays, it is important to verify these targets

using other means. For example, immunoprecipitation can be used to confirm that aptamers form complexes with their targets under *in vivo* conditions. Genetic tests such as epistasis analysis can be used to identify the location of the aptamers relative to a known protein. Peptide aptamer targets can be deleted or overexpressed and the resulting phenotype compared to the aptamer-induced phenotype. Similarly, whole-genome transcript arrays can test whether aptamers cause the same response as known inhibitors or mutations.

Anticipated Results

In general, approximately one out of every 10^5 peptide aptamers screened using the interaction trap interacts with a given target protein (Colas et al., 1996; Xu et al., 1997; Fabbri et al., 1999). Based on results using the yeast pheromone response pathway as a model process, approximately one out of every 10^5 to 10^6 peptide aptamers can inhibit a cellular process (Geyer et al., 1999). These results apply to 20mer combinatorial peptide libraries displayed on the surface of *E. coli* thioredoxin.

Time Considerations

Basic Protocol 1: Construction of the thioredoxin peptide aptamer library and its subsequent electroporation and amplification in *E. coli* will take ~1 week.

Basic Protocol 2: Isolation of peptide aptamers that interact with a specific bait protein takes ~3-4 weeks. The bait plasmid (pBait) and the pJM-1 peptide aptamer library are constructed during the first week. During the second week the pBait and the *lacZ* reporter plasmid (pSH18-34) are transformed into EGY48. The bait protein is also assayed to determine if it self-activates the reporter genes. During the third week the peptide aptamer library is transformed into EGY48 that contains pBait and pSH18-34. The aptamers are screened for their ability to interact with the bait protein and putative interacting aptamers are obtained. A fourth week is required to isolate the aptamer plasmids from the yeast and sequence their variable regions.

Basic Protocol 3: Determination of the peptide aptamer specificity using interaction mating takes ~1-2 weeks. The time required to construct the bait proteins, which will be used to evaluate the aptamer specificity, varies depending on the number of baits chosen and difficulty in cloning the baits. Once the bait proteins are constructed it takes ~1 week to transform both the baits and *lacZ* reporter into

EGY42 and the peptide aptamer preys into EGY48. Mating EGY48 with EGY42 and scoring interactions between the peptide aptamer preys and baits takes an additional week.

Basic Protocol 4: Affinity maturation of peptide aptamers takes ~3-4 weeks. The mutagenesis of the peptide aptamer and subsequent cloning into pJM-1 (prey vector) takes ~1 week. Isolation of mutant aptamers that interact with the bait protein using the interaction trap with a more stringent *lacZ* reporter takes 3 weeks as described above in Basic Protocol 2.

Basic Protocol 5: Construction of the thioredoxin peptide aptamer library (pJM-2 or pJM-3) takes ~1 week as described in Basic Protocol 1. The time required to isolate peptide aptamers that disrupt a cellular process varies depending on the organism and selection or screen used. Before the targets of the peptide aptamers can be identified, it is necessary to transfer the thioredoxin peptide aptamers from the expression vector used in the screen (pJM-2 or pJM-3) to the bait plasmid (pEG202). This transfer takes ~1 week. Identification of the peptide aptamer target(s) using the interaction trap mating (Basic Protocol 2) or cDNA or genomic library (*UNIT 20.1*) hunts takes ~4 weeks.

Protein Selection Using mRNA Display

mRNA display is an *in vitro* technique that may be used to search natural or synthetic DNA libraries for the functional proteins and peptides they encode. mRNA-displayed proteins are constructs in which a protein is covalently attached to the RNA that encodes it. This direct covalent association of phenotype (protein) and genotype (RNA) renders the protein directly amplifiable. This in turn allows successive cycles of selection, enrichment, and, optionally, mutagenesis, to be performed upon libraries of displayed proteins. At the end of this process, functional sequences will dominate the library; cloning and sequencing will reveal the identity of the selected functional proteins. mRNA display allows new functional proteins to be discovered without resorting to protein design.

mRNA-displayed proteins are generated by the *in vitro* translation of mRNA display templates which are mRNA molecules 3'-terminated in puromycin (Fig. 24.5.1). Puromycin is a translation inhibitor that is able to enter the ribosome during translation and form a stable covalent bond with the nascent protein. This allows a stable covalent linkage to be formed between the mRNA display template and the protein it encodes, resulting in an mRNA-displayed protein (Fig. 24.5.2).

STRATEGIC PLANNING

The first issue that needs to be addressed when embarking upon protein selection using mRNA display is the design and construction of the library at the DNA level. If the goal of the selection is the "improvement" of an existing protein aptamer or enzyme, then the starting point for the selection will be the DNA sequence encoding this protein. If the goal of the selection is to discover a new class of protein aptamers or enzymes, then the starting point for the selection will be a DNA sequence in which some or many of the positions

Figure 24.5.1 Puromycin is an antibiotic that functions by inhibiting translation. The molecular structure of puromycin resembles the acceptor arm of an amino-acylated tRNA. Puromycin is a nucleotide-amino acid chimera and ultimately forms the nucleic acid-protein junction in the mRNA displayed protein.

are randomized. In either case, the DNA library may originate from a fixed natural sequence (clone) and subsequently be randomized by some process such as mutagenic PCR (Cadwell and Joyce, 1992) or DNA shuffling (Stemmer, 1994). Alternatively, the DNA library may be synthetic, in which case it can be synthesized as a fixed sequence and treated as above, or it may be synthesized in a high-diversity form directly, using mixtures of nucleotide phosphoramidites on a DNA synthesizer. In a third approach, the DNA may be isolated from a natural high-diversity source, either cDNA derived from biological mRNA or genomic DNA using a diverse mixture of PCR primers, or DNA sampled directly from the environment originating from a multitude of uncultured organisms. In all of these approaches, the DNA library will ultimately need to encode terminal constant regions to permit PCR amplification. These may also encode protein affinity tags that will facilitate the purification of the resulting displayed proteins. It is also desirable to encode restriction sites close to the random-constant sequence boundary to enable these constant regions to be changed should reengineering of the library be necessary.

If the DNA library is to be synthesized in more than one piece, then a strategy of restriction and ligation of different DNA cassettes needs to be designed. This strategy ultimately

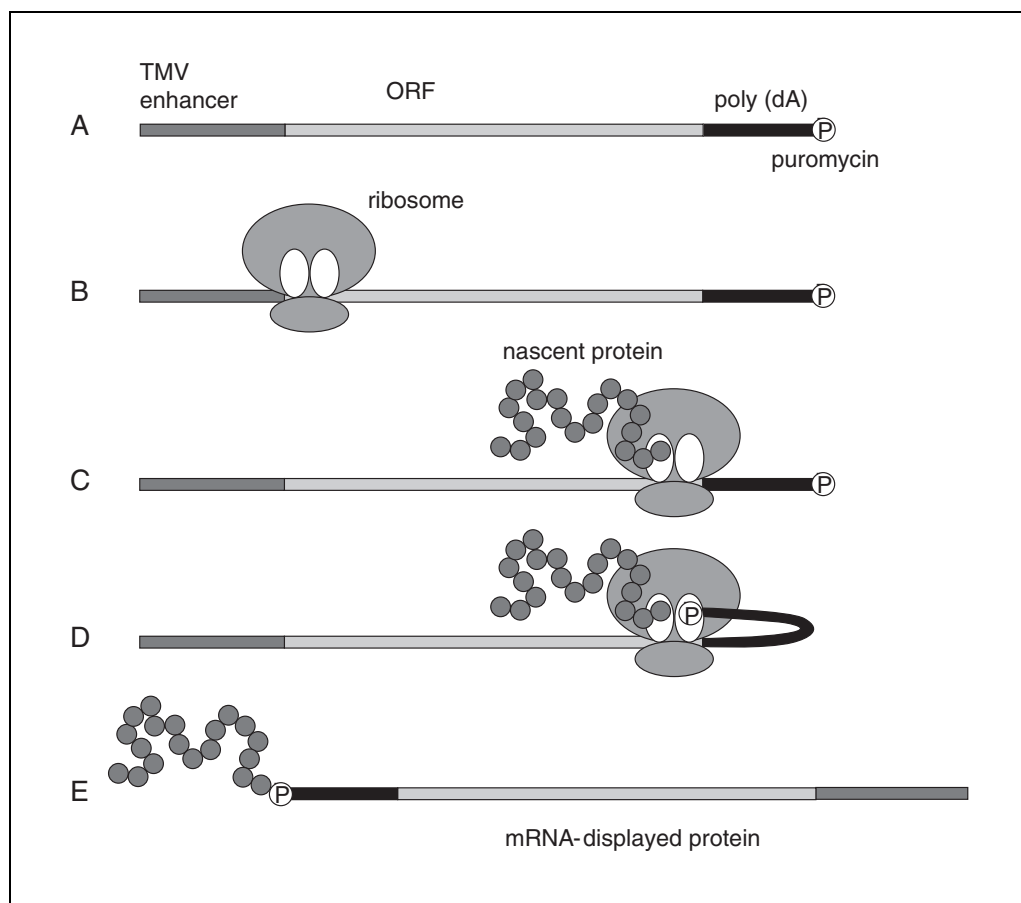

Figure 24.5.2 mRNA-displayed protein formation. **(A)** The mRNA display template consists of a Tobacco Mosaic Virus (TMV) translation enhancer sequence followed by the open reading frame encoded in RNA. This is followed by poly(dA) that is 3'-terminated with puromycin. **(B)** The ribosome initiating the translation of the mRNA display template. **(C)** The ribosome pausing at the RNA-DNA junction of the mRNA display template after it has translated the mRNA display template into protein. **(D)** The puromycin attached to the 3'-terminus of the mRNA display template entering the A site of the ribosome and forming a stable amide bond with the nascent protein. **(E)** The mRNA display template displaying the protein that it encodes after the ribosome has been released during purification.

yields the full-length library, and additionally offers the opportunities of purification and amplification of the individual DNA cassettes before they are ligated together. Amplification of the cassettes at this stage can greatly increase the library diversity in a combinatorial sense. Purification of the cassettes at this stage can decrease the proportion of cassettes that contain deletions, insertions, and stop codons. This “preselection” strategy can greatly increase the effective diversity of the DNA library since the proportion of resultant mRNA display templates, which are able to display frameshift-free proteins, will also increase in a combinatorial fashion once the DNA cassettes are ligated together. The steps in a preselection strategy are shown in Figure 24.5.3, and a detailed description is given in Cho et al. (2000).

Once the library has been designed and synthesized, the translation conditions need to be optimized for the formation of displayed proteins, and the purification strategy also needs to be optimized and subsequently piloted in a serial manner. However, the most important part of the strategic planning phase of the project is the design of the selection strategy. The first selection step needs to be designed to retain as many as possible of the functional displayed proteins that are present in the library, while discarding the great majority of those that are not functional. In this manner, the diversity of the library is taken advantage of to the maximal extent, but the diversity of the library is sufficiently reduced that the first amplification step is able to give several copies of the selected proteins for input into the next selection step. Subsequent to the first amplification step, the selection steps need to be designed to have the maximal possible reasonable discrimination between mRNA displayed proteins that exhibit the function of interest and those that do not. If at all possible, the extent of this discrimination should be assayed with positive and negative controls.

The steps within a single round of selection and amplification are shown in Figure 24.5.4.

Library Design

Library synthesis and preselection

A synthetic DNA library encoding a short open reading frame (ORF; up to ~35 amino acids) may be synthesized as a single oligonucleotide. Longer libraries of ORFs will need to be synthesized in two or more DNA cassettes that are then ligated together. Synthetic DNA has a deletion rate of ~0.5% and random regions will contain stop codons. Deletions will cause parts of the resultant proteins to be out of frame, and stop codons will prevent translated proteins from being displayed upon the mRNA that encodes them. For example, if the target ORF is 100 amino acids long, has an equal distribution of all four nucleotides at every position, and the deletion rate is 0.5%, only 0.18% will be in-frame over their entire lengths and free of stop codons. Consequently, unless the ORF is very short, one may wish to preselect the individual cassettes for being in-frame and free of stop codons. This preselection strategy is most easily accomplished by encoding different protein affinity tags close to the 3'- and 5'-termini of the cassettes. Synthesizing mRNA-displayed proteins from each individual DNA cassette, and purifying these upon the basis of the presence of each of these tags, will enrich the resultant library in those sequences that have initiated before the 5' tag, terminated after the 3' tag, and do not contain stop codons. These are likely to be in-frame over their entire sequence. The full-length DNA library should then be constructed from these preselected cassettes using RT-PCR followed by restriction and ligation. Any reduction in diversity that results from the preselection process is regained by the combinatorial ligation of the amplified DNA cassettes during the assembly of the full-length library. The steps in a preselection strategy are shown in Figure 24.5.3, and a detailed description is given in Cho et al. (2000).

Figure 24.5.3 The steps that comprise the preselection process. A DNA cassette library that, when assembled into a full-length DNA library will encode a protein library, is enriched in those cassettes that are free of stop codons, insertions, and deletions. These cassettes are then used to construct the full-length library that is used for protein selection using mRNA display (*continues on next page*).

RNA polymerase promoter sequence

The library will need a transcription promoter at the 5'-end. This can be added or changed by PCR. The promoter sequences, TAATACGACTCACTATA and TTCTAATACGACTCACTATA, have both been successfully used. Transcription is most efficient if the RNA transcript starts with at least two guanines. To avoid pyrimidines (T or C) in the first few nucleotides of the transcript, it is common for the transcribed RNA sequence to commence with GGG.

Translation enhancer sequence

The library will need a translation enhancer before the initiating methionine codon; the truncated 5'-UTR from the Tobacco Mosaic Virus sequence (ACAATTACTATTCAATTACA) has been used successfully.

Initiating methionine

The initiating methionine (ATG) immediately follows the translation enhancer sequence.

N-terminal constant ORF sequence

It is extremely helpful to have amino acid sequences within the protein that can act as affinity tags. These are invaluable when purifying the displayed proteins. If two different affinity tags are used and these are located close to each of the termini of the expressed

protein, then they may be used to ensure that the expressed protein, mRNA-displayed or not, is full-length and in-frame at both ends. This double purification may optionally be performed when the DNA library is still at the individual cassette stage in order to increase the proportion of library members that are full-length, in-frame, and do not contain stop codons (see Fig. 24.5.3). FLAG and His₆-tag sequences are obvious choices.

Some constant amino acid sequence is likely to result from the ligation junctions used to construct libraries from synthetic DNA with long random regions; the identity of these

Figure 24.5.4 Continued.

amino acids and their frame can be adjusted in order to avoid “inappropriate” amino acids such as several consecutive hydrophobic residues or a proline. What is considered to be inappropriate will depend upon what the library is to be used for. Regardless of how the library is to be constructed, having different restriction sites encoded within the 3’ and 5’ ends of the open reading frame will allow for the changing of one or other of the protein terminal constant sequences if design considerations change, or should reengineering be required for troubleshooting.

Long stretches of uridines in the RNA sequence should be avoided since these may anneal to the poly(dA) sequence of the puromycin-terminated linker oligonucleotide. This will interfere with the ligation used to construct the mRNA display template. Also, the double-stranded RNA-DNA, which can result from the self-annealing of the resulting

mRNA display template, will act as a substrate for the RNase H, which is present in reticulocyte lysate, resulting in degradation of the mRNA display template.

C-terminal constant ORF sequence

All of the considerations described with regard to the N-terminal constant ORF sequence also apply to the C-terminal constant ORF sequence. There are also additional considerations that are specific to the C-terminal sequence.

In the synthesis of the mRNA display template (see Fig. 24.5.4), the 3' terminus of the mRNA encoding the ORF is ligated to a short DNA oligonucleotide, which is itself 3'-terminated with puromycin (the linker). The 3' terminus of the mRNA and the 5' terminus of the DNA linker are coannealed to a short DNA oligonucleotide (the splint), which is complementary to both of them and presents the junction to be ligated as a nicked double-stranded nucleic acid. Consequently, the secondary structure of the splint, the mRNA, and the linker should be checked for self-structure likely to interfere with the assembly of the splinted nicked double-stranded complex. This can most easily be done using a computer algorithm such as MFOLD (<http://www.ibc.wustl.edu/~zucker/rna/form1.cgi>).

The mRNA-displayed protein is attached to the mRNA via its C terminus. It seems appropriate, therefore, to make the last few amino acids at the C terminus “structureless,” i.e., a stretch of glycines and serines. Incorporating extra methionines into the constant sequence will increase the signal resulting from the incorporation of ³⁵S-methionine into the protein. Extra methionines are best placed in the C-terminal constant region downstream of the C-terminal protein affinity tag. Should they result in misinitiation, then the resultant proteins will not contain either of the protein affinity tags and will not copurify with the mRNA-displayed full-length proteins. Placing out-of-frame stop codons close to the C terminus, either before or after the tag, in both the +1 and –1 frames will prevent those members of the library that are out-of-frame at the C terminus from forming mRNA-displayed proteins. This is especially useful in the context of a preselection (see Fig. 24.5.3). Incorporating a protein kinase (phosphorylation) site to allow ³²P-labeling of the protein may assist in assaying the free proteins.

Statistical appearance of different amino acids within the random region

Most DNA libraries designed for protein selection encode a wide range of amino acids in their random regions. Using a mixture of all four nucleotides at each of the three positions in the library codons will ensure that all 20 amino acids have some probability of appearing in every position of the resulting protein sequence. During the library design process it is helpful to consider the average composition of amino acids that will result from the chosen nucleotide distribution, the consequent average proportions of hydrophobic and charged amino acids, and whether these proportions are suitable for the library and its intended target. Additionally, it is useful to consider the frequency with which certain individual amino acids will appear in the random region. Cysteines can coordinate transition metal ions or form disulfide bonds, histidines can accept or donate protons or coordinate transition metal ions, and prolines may disrupt secondary structure. Other specific amino acids may be suitable for interacting with intended substrates.

Frequency of stop codon appearance in random libraries

Using a mixture of all four nucleotides at each of the three positions in the library codons in the DNA encoding the protein library will also introduce stop codons. This will reduce the proportion of expressed protein that is displayed because stop codons will cause the ribosome to release the mRNA before the terminating puromycin is able to react with the nascent peptide. By altering the proportions of the nucleotides in the DNA synthesis mixtures, the frequency of stop codons can be reduced, although this will also influence

the proportions of other amino acids in the library. Alternatively, the DNA cassettes used to construct the library can be synthesized from mixtures of nucleotides chosen only with regard to the average amino acid composition they encode. The resultant cassettes can then be “preselected” as described above in order to enrich the resultant library with those that do not contain stop codons. As shown in Fig. 24.5.3, if this procedure is done using two different affinity tags at the different termini of the ORF, then the resultant library will also be enriched in cassettes without deletions. A nucleotide distribution encoding a target amino acid composition can be iteratively approached using computer algorithms that are available on the Internet (e.g., <http://gaiberg.wi.mit.edu/cgi-bin/CombinatorialCodons>; Wolf and Kim, 1999).

Codon usage

Statistical studies of sequenced genomes have shown that, for the majority of amino acids for which more than one codon exists, certain codons appear more frequently than others. The more frequently used codons tend to end in G or C, which may relate to the extra stability that results from having three hydrogen bonds in the wobble position of the tRNA-mRNA complex. Consequently, it may be helpful to design the library so that G and C are the only nucleotides in the third position of each codon. The symmetry of the genetic code is such that the composition of the wobble position has very little effect upon the composition of the resultant protein, so this approach need not affect the amino acid composition of the protein library it encodes. However, this strategy will amplify the effect that frameshifts will have upon the resultant proteins.

Periodicity and stop codon avoidance

Some mixtures of nucleotides may result in the total omission of stop codons, $(VNN)_n$ for example (where V is a mixture of A, G, and C) does not encode any stop codons. Unfortunately, such approaches always result in the loss of some of the 20 amino acids; $(VNN)_n$ also does not encode Cys, Phe, Trp, and Tyr for example. Mixing different such codons together can give a DNA library that encodes all 20 amino acids but no stop codons. This approach, however, necessarily introduces an element of design into the library, since the statistically different codons must be placed at specified points in the sequence, most usually in a periodic fashion. Periodicity can also result in an increased tendency for protein structural units to be encoded; for example, alternate hydrophobic and hydrophilic amino acids will encourage the formation of β sheets, while alternate pairs of hydrophobic and hydrophilic amino acids will encourage the formation of α helices. Alternatively, there are nonperiodic nucleotide distributions that reduce the occurrence of stop codons to ~1%. For an example of this approach see LaBean and Kauffmann (1993).

Mutagenesis

Mutagenic procedures such as mutagenic PCR (Cadwell and Joyce, 1992) or DNA shuffling (Stemmer, 1994) may be used to generate a diverse DNA library from a less diverse DNA library or a single DNA sequence (a minimum of two homologous sequences is required for DNA shuffling). Mutagenic procedures may be used to generate the initial DNA library for an mRNA display protein selection, or to increase the diversity at any stage between cycles of selection and amplification during an mRNA display protein selection. In general, in vitro selection proceeds by the gradual loss of diversity as functional sequences are preferentially amplified and nonfunctional sequences are lost. Consequently, increasing the diversity of the library at a stage after the first selection step may appear to be a retrogressive step; however, this is not necessarily the case. Protein libraries that are generated by stochastic means, such as those generated from DNA made on a DNA synthesizer using mixtures of nucleotide phosphoramidites, sample protein sequence space extremely sparsely. For example, a member of a library of 10^{13} proteins

each of which is 72 amino acids long, with each amino acid being equally likely to appear at each position, will, on average, have a sequence with 26 differences (“mutations”) from the next most similar member of the library. If a solution to a particular problem is chanced upon using such a library, it is highly unlikely to be the optimal solution. The solution in question may be a small number of mutations away from many other superior solutions, but the initial library is extremely unlikely to have contained any of the sequences in question because the sampling was so sparse. Once a selection strategy has given one or many such nonoptimal solutions, one or more mutagenic steps will enable the exploration of the local sequence space around such solutions and, after subsequent selection, is likely to yield improved solutions closely related to one or more of the originally selected sequences.

Specific directions for the preparation of a DNA library for an mRNA display selection vary greatly depending upon the source of the DNA, the selection target, and the precise assembly strategy chosen. See *UNITS 24.2, 24.3, & 24.4* for further details. A more detailed discussion of both preselection and mRNA display library construction strategy is given in Cho et al. (2000). A generalized library construction strategy is also shown in Fig. 24.5.5. Once the DNA library has been synthesized, but before the selection has commenced, it is important to sequence some of the individual library members to ensure that the library sequence is as intended, and that the proportion of error-free sequences is appropriate for the selection strategy envisaged.

Selection

In vitro selection strategies, such as mRNA display, offer a generalized method for the discovery of functional molecules, only if the molecules in question can be enriched upon the basis of their function and subsequently directly amplified. Enrichment upon the basis of function is termed selection. The appropriate design of the selection step is absolutely crucial to the success of the project as a whole. Most in vitro selection experiments have been performed upon libraries of nucleic acids rather than proteins (Wilson and Szostak, 1999), although some protein selection experiments have been successfully performed using ribosome display (Jermutus et al., 1998) and most recently mRNA display (A.D. Keefe and J.W. Szostak, pers. commun.). Phage display (Smith and Petrenko, 1997) and the 2-hybrid system (Fields and Song, 1989; Colas et al., 1996) are similar in vivo techniques that have also been successfully used for the selection of functional peptides and proteins.

In vitro selections are divided into two main categories, (1) selections for aptamers (i.e., specific binding to a chosen target) and (2) selections for catalysts (i.e., enzymes). This is not an appropriate place for an exhaustive overview of the various approaches that have been used to discover new aptamers and catalysts, but some general points can be made.

Aptamer selections

Aptamer (specific binder) selections are in general undertaken by incubating the library with the immobilized target molecule. The target molecule immobilization is by way of covalent attachment to a solid matrix such as agarose, usually through a spacer molecule. Many immobilized target molecules are commercially available. After incubation, the flowthrough is drained away, the immobilized target molecules are washed several times, and then an elution fraction is collected by incubating the matrix and the immobilized target molecules with an elution buffer that contains the dissolved target molecule. Those library members that are contained in the elution fraction are amplified, and the process is repeated until functional molecules dominate the library. At this stage, the functional molecules are identified by cloning and sequencing. It is important to realize that in the early rounds of selection, the vast majority of the library members contained in the elution

fraction are nonspecific binders or nonbinders. Consequently, several rounds of selection and amplification will be required before the functional (specific binding) sequences dominate the library.

The composition of the selection binding and selection elution buffers is likely to influence the aptamers that are ultimately discovered using this system. It may be important to use a buffer that promotes protein folding, but discourages aggregation. The use of high concentrations of cosmotropic compounds such as ammonium sulfate will promote folding, while the use of nonionic detergents such as Triton X-100 will discourage aggregation. The oxidation potential of the buffer should also be considered. The inclusion of a reducing agent such as DTT is likely to lead to the selection of protein aptamers active under reducing conditions, while the inclusion of oxidizing agents such as glutathione disulfide is likely to lead to the selection of protein aptamers active under oxidizing conditions. It is important to ensure that the binding and elution buffers are as similar as possible. Changes in ionic strength and/or pH between these buffers will increase the proportion of nonspecific binders in the elution fraction, possibly to such an extent that the specific binders will never dominate the library and consequently will never be identified. Obviously the binding and elution buffers cannot be identical since the elution buffer contains the target molecule. In order to make the selection binding and

Figure 24.5.5 Assembly of a full-length mRNA display template library from DNA cassettes that result from the RT-PCR amplification of pre-selected mRNA display cassette templates. In this example, the cassettes are divided into 2 aliquots that are restricted with either *BbvI* or *BbsI*, subsequent ligation with T4 DNA ligase gives a new cassette in which the DNA between the restriction sites doubles in length while the flanking regions remain the same. The doubling of the length of this region may be repeated any number of times by repeating the restriction and ligation process.

selection elution buffers as similar as possible, it may be desirable to balance the effect of the target molecule upon the elution buffer by adding a similar molecule to the binding buffer. If the target molecule interacts with one of the buffer components, such as a nucleotide with magnesium, it may be desirable to add back an extra amount of this component to maintain the free concentration of the component in question at the concentration of that in the binding buffer. It is also possible to collect the elution fraction by disrupting the binding with denaturant or extremes of pH, although the background is likely to be higher.

Catalytic (enzyme) selections

Catalytic (enzyme) selections are a little more complex in a conceptual sense—although carefully designed, they can have lower intrinsic background rates than aptamer selections, and consequently be quicker and easier to perform in the laboratory. Enzyme selections must be performed in such a manner that those sequences which catalyze a reaction are separated from those that do not. The most obvious way to achieve this separation is to arrange the selection so that library members that catalyze the desired reaction covalently attach themselves to the substrate. If the substrate is in turn covalently attached to a tag (such as biotin), then the attachment of the tag to library members that catalyze the reaction can be used as a basis for the separation of these library members from those that do not catalyze the reaction (such as by binding to immobilized streptavidin). Alternatively the substrate may be immobilized before it is incubated with the library. Since both of these approaches effectively turn the catalysis selection into a binding selection, there will still be a background rate of isolation of sequences that do not catalyze the desired reaction. Consequently it may still be necessary to perform several rounds of selection and amplification before functional sequences dominate the library. Similar catalytic selection strategies can be envisaged in which all of the library members are immobilized, and those that successfully catalyze the desired reaction cut themselves free.

It should be noted that since the successfully selected library members are required to modify themselves in some respect, they are not acting as catalysts in the true sense of the word. However, molecules selected using such a procedure are usually easily reengineered to give true catalysts by detaching the active site part of the selected construct from the substrate part. One consequence of this limitation is that it is difficult to select for catalysts that act faster than the rate with which they can be manipulated in the laboratory, and it is not possible to select for catalysts with high turnover rates at all. Strategies in which the library member is encapsulated along with several substrate molecules may lead to systems in which the selective pressure is directly for the turnover rate.

Selection controls

The importance of selection controls cannot be emphasized strongly enough. mRNA display selection protocols in which functional library members are enriched much less than ten-fold over nonfunctional library members are unlikely to lead to the isolation of functional library members in the laboratory. Biases are present in many steps of the mRNA display amplification protocol, especially translation and protein display efficiencies, and these can overwhelm the enrichment in functional members that results from the selection step. Suitable positive controls are molecules known to catalyze or bind to the intended substrate, and need not be proteins, although the best control will usually be a similar functional protein displayed upon its reverse-transcribed mRNA display template.

Nomenclature

mRNA-displayed proteins are referred to by a variety of names in the literature, such as “RNA-protein fusions” and “profusions.”

PREPARATION AND PURIFICATION OF mRNA-DISPLAYED PROTEINS

This protocol describes the preparation of the mRNA display template from an appropriate DNA template, DNA splint, and DNA linker 3'-terminated with puromycin, the use of the mRNA display template to prepare mRNA-displayed proteins and their subsequent purification, and an example selection. The protocol steps are also shown in Figure 24.5.4. For additional details see Liu et al. (2000).

Materials

DNA library
1 M MgCl₂
100 mM nucleotide triphosphate solutions
10× transcription buffer (see recipe)
Deionized, ultrafiltered water
10 U/μl T7 RNA polymerase
Solid EDTA
Urea
0.5× TBE buffer (*APPENDIX 2*)
3 M NaCl
100% and 70% ethanol
100 mM EDTA
Puromycin-terminated DNA linker
100 mM ATP
T4 polynucleotide kinase buffer
T4 polynucleotide kinase
10× T4 DNA ligase buffer
10 U/μl T4 DNA ligase
3 M potassium acetate solution, pH 5.3
Rabbit reticulocyte lysate translation kit (e.g., Red Nova Lysate kit, Novagen)
Control RNA
12.5× methionine-free translation mix
2.5 M potassium chloride
25 mM magnesium acetate
Nuclease-free water
Rabbit reticulocyte lysate
³⁵S-methionine

Electroeluter (VWR or Schleicher & Schuell)
Denaturing PAGE gel (*UNIT 2.12*)
Gel filtration columns (Pharmacia)

Additional reagents and equipment for preparative denaturing PAGE purification (*UNIT 2.12*), determining nucleic acid concentration by spectrometry (*APPENDIX 3D*), synthesis of oligonucleotides (*UNIT 2.11*), and SDS-PAGE in Tris-tricine buffer systems (*UNIT 10.2A*)

BASIC PROTOCOL 1

Transcribe DNA

1. Make up a 1-ml transcription reaction on ice as follows. Add the T7 RNA polymerase last.

DNA library (add volume sufficient for 5 to 50 nM final concentration)
35 μ l 1 M $MgCl_2$
50 μ l each 100 mM nucleotide triphosphate (final 5 mM each NTP)
100 μ l 10 \times transcription buffer (final 1 \times)
Up to 980 μ l deionized, ultrafiltered water
20 μ l 10 U/ μ l T7 RNA polymerase (final 200 U/ml).

Incubate the transcription reaction for 3 to 16 hr at 37°C. Halt the reaction by cooling on ice, or by adding solid EDTA to a final concentration of 50 mM.

The size of the transcription reaction can be adjusted to give an appropriate amount of RNA, but care should be taken to ensure that the diversity of the DNA used is several times larger than the diversity of the displayed proteins that will ultimately result. The effect of varying the concentration of $MgCl_2$ should be explored in pilot transcriptions.

Purify RNA

2. Purify resultant RNA using denaturing PAGE (UNIT 2.12). Add solid urea to the transcription reaction to give a final concentration of 5 M and solid EDTA to give a final concentration of 50 mM, heat for 2 min at 90°C, and load onto a denaturing PAGE gel.
3. After the gel has been run, visualize by UV-shadowing and excise the band containing the purified RNA. Extract the RNA into 300 mM NaCl by passive elution or into 0.5 \times TBE buffer in an electroeluter according to the manufacturer's instructions.
4. Precipitate the RNA by adding 3 M NaCl (final concentration 300 mM) and 2.5 volumes of 100% ethanol. Cool for 20 min at -80°C or overnight at -20°C.
5. Centrifuge for 10 min at 12,000 \times g, 4°C. Decant the supernatant, wash the pellet with 70% ethanol, dry under reduced pressure, bring up to 0.5 ml with deionized, ultrafiltered water, and measure the concentration by UV-visible spectroscopy at 260 nm.

Further instructions may be found in UNIT 2.12.

This purification step separates truncated RNA molecules and PCR primers from the full-length RNA transcripts. It is important to remove the PCR primers from the transcribed RNA since they will inhibit the formation of the mRNA displayed proteins in the translation step.

Synthesize linker

6. Synthesize the linker, a DNA oligonucleotide 3'-terminated in puromycin, that is ~30 nucleotides long and "unstructured" (e.g., according to one of the following examples; see UNIT 2.11 for oligonucleotide synthesis):

Example a. AAAAAAAAAAAAAAAAAAAAAAAAAAAAAACCP.

Poly(dA) is the most obvious choice.

Example b. AAAAAAAAAAAAAAAAAAAAAA999ACCP.

In example b, "9" is phosphoramidite spacer 9 (Glen Research) and "P" is puromycin, derived from CPG-puromycin (Glen Research). This linker may give a higher yield of displayed proteins.

Linkers much longer or shorter than 30 nucleotides will give greatly reduced yields of displayed proteins, or none at all.

The puromycin-terminated DNA oligonucleotide is gel purified by denaturing PAGE (UNIT 2.12), extracted from the gel, and precipitated as described earlier. Dissolve the DNA linker in deionized water and measure the concentration using UV-visible spectroscopy at 260 nm.

Each of the spacer 9 units result in the incorporation of a triethylene glycol phosphate ester; this adds extra flexibility to the region of the template close to the puromycin and may result in a higher proportion of the resultant mRNA display templates displaying protein.

7. Kinase (5'-phosphorylate) the DNA linker using polynucleotide kinase by making up the following 1-ml kinase reaction mixture:

300 μ l 100 μ M DNA linker (final 30 μ M)
10 μ l 100 mM ATP (final 1 mM)
100 μ l 10 \times T4 polynucleotide kinase buffer (final 1 \times)
490 μ l water
100 μ l 10 U/ μ l T4 polynucleotide kinase (final 200 U/ml).

8. Incubate the reaction mixture for 2 hr at 37°C, add 200 μ l of 100 mM EDTA, heat for 5 min at 90°C, and desalt on a gel-filtration column.

It is important to heat-denature the polynucleotide kinase to prevent it from acting in the subsequent ligation reaction. The size of the kinase reaction should be adjusted to give an appropriate amount of 5'-phosphorylated DNA linker.

Synthesize splint

9. Synthesize the splint, a DNA oligonucleotide with a sequence (reading from the 5' end) of ≥ 10 nucleotides complementary to the 3' end of the RNA library and ≥ 10 nucleotides complementary to the 5' end of the linker, usually T₁₀ (see UNIT 2.11 for oligonucleotide synthesis methods). Purify by denaturing PAGE (UNIT 2.12).
10. Extract DNA from gel as in step 3 and precipitate as in step 4.
11. Dissolve the purified splint in deionized water and measure the concentration using UV-visible spectroscopy at 260 nm (see step 5).

Prepare mRNA display template

12. Ligate the linker and RNA template with T4 DNA ligase in the presence of the splint to give the mRNA display template. Set up the following 1-ml ligation reaction:

100 μ l 100 μ M 5'-phosphorylated DNA linker (final 10 μ M)
100 μ l 100 μ M RNA library (final 10 μ M)
100 μ l 100 μ M splint (final 10 μ M)
580 μ l water.
13. Heat this mixture for 2 min at 95°C, then add 100 μ l of 10 \times T4 DNA ligase buffer (final 1 \times).
14. Vortex the resultant mixture and cool on ice for 10 minutes, allow to warm to room temperature, then add 20 μ l of 2000 U/ μ l T4 DNA ligase (final 40 U/ml).
15. Incubate the reaction for 20 min at room temperature. Add 150 μ l of 100 mM EDTA and 500 mg of solid urea, and heat for 5 min at 90°C.

Table 24.5.1 Translation Reactions for mRNA Display Proteins

Reagent	Final concentration	A	B	C	D	E	F
Control RNA	—	1 μ l	0 μ l	0 μ l	0 μ l	0 μ l	0 μ l
5 μ M mRNA display template	2/4/800 nM	0 μ l	0 μ l	0 μ l	1 μ l	2 μ l	4 μ l
5 μ M unligated RNA	400 nM	0 μ l	0 μ l	2 μ l	0 μ l	0 μ l	0 μ l
12.5 \times Met-free translation mix	1 \times	2 μ l	2 μ l	2 μ l	2 μ l	2 μ l	2 μ l
8.6 μ M labeled methionine	0.69 μ M	2 μ l	2 μ l	2 μ l	2 μ l	2 μ l	2 μ l
2.5 M KCl	100 mM	1 μ l	1 μ l	1 μ l	1 μ l	1 μ l	1 μ l
25 mM magnesium acetate	500 μ M	0.5 μ l	0.5 μ l	0.5 μ l	0.5 μ l	0.5 μ l	0.5 μ l
Water	—	8.5 μ l	9.5 μ l	7.5 μ l	8.5 μ l	7.5 μ l	5.5 μ l
2.5 \times rabbit reticulocyte lysate ^a	1 \times	10 μ l	10 μ l	10 μ l	10 μ l	10 μ l	10 μ l
Total		25 μ l	25 μ l	25 μ l	25 μ l	25 μ l	25 μ l

^aEnsure that the rabbit reticulocyte lysate is added last.

- Gel purify ligated mRNA display template by denaturing PAGE (UNIT 2.12), extract from gel (see step 3), and precipitate as in step 4, except use 3 M potassium acetate, pH 5.3, in place of 3 M sodium chloride.
- Dissolve the purified ligated mRNA display template in deionized water and measure the concentration by UV-visible spectroscopy at 260 nm.

If the template is <500 nucleotides long, it should be possible to resolve the ligated and unligated RNA on the PAGE gel, which will give some idea of the yield of the ligation reaction. Otherwise, the unresolved bands will have to be co-excised from the gel and optionally further purified using oligo(dT) cellulose as described below. It is important to perform this gel purification even if it is not possible to resolve the ligated and unligated RNA, since the presence of the splint in the translation reaction will greatly reduce the yield of displayed proteins, and RNase H in the reticulocyte lysate will cause degradation of the mRNA display template if it is annealed to the splint. It should be noted that this splinted RNA-DNA ligation is far less efficient than the ligation of sticky-ended pieces of DNA.

Translate mRNA display template and prepare mRNA displayed proteins

Before the mRNA display template is used for large-scale translation, a small-scale translation should be attempted alongside various control translations to aid the identification of the band on the protein gel that corresponds to the mRNA-displayed proteins.

- Set up the translation reactions in Table 24.5.1 on ice, adding the rabbit reticulocyte lysate last.
- Incubate for 1 hr at 30°C, then add 1.7 μ l of 1 M MgCl₂ and 7.8 μ l of 2.5 M KCl to each of the reactions and allow them to stand for 5 min at room temperature.

The reaction mixtures may be optionally stored for up to 1 week at -20°C at this point.

- Analyze the different translations using Tris-tricine SDS-PAGE as described in UNIT 10.2A, Alternate Protocol 1.

The SDS-PAGE analysis should show a number of bands in lane A, which is the control RNA supplied by the manufacturer; this is the positive control and demonstrates that the translation reaction was set up correctly. Lane B is the no-template control, and may show no bands or may show a band corresponding to tRNA charged with methionine; in either case it should show no bands with mobilities equal to those assigned to the free protein and to the displayed protein. Lane C should show a band of high mobility that can be

assigned to the free protein. Lanes D, E, and F should also show bands that can be assigned to the free protein, but also bands of much lower mobility that can be assigned to the mRNA-displayed protein. If the density of the band assigned to the displayed protein in F is of equal or lesser density to the equivalent band in E, then the mRNA display template is likely to be of high quality.

For better proof that the band assigned to the mRNA displayed proteins is done so correctly, add splint (final 1 μ M) and $MgCl_2$ (final 10 mM) to an aliquot of the translation mixture before the salt incubation, and incubate for 30 min at 37°C. RNase H within the lysate will cause the RNA part of the mRNA-displayed proteins to be digested and leave the protein displayed upon the DNA linker alone, consequently the original displayed protein band will disappear and a new band will appear of intermediate mobility between the mRNA displayed protein and the free protein.

21. Once the displayed proteins have been observed by SDS-PAGE, optimize the magnesium acetate and potassium chloride concentrations in the translation reaction. Perform a succession of translations in parallel with added magnesium acetate concentrations ranging from 0.5 mM to 2 mM and added potassium chloride concentrations ranging from 50 mM to 200 mM.

The relative proportions of the mRNA display templates that end up displaying proteins will be readily apparent when the samples are run out on a gel together, and the optimal concentrations of both magnesium acetate and potassium chloride can be chosen.

If a preselection procedure is being used to synthesize the full-length mRNA display template library, the translation magnesium acetate and potassium chloride concentrations will have to be optimized separately for each cassette used in the preselection protocol, and then again for the full-length library. Despite the fact that the 3'-terminal region of each of the cassettes and the full-length library are the same, the optimal magnesium acetate and potassium chloride concentrations for the formation of mRNA-displayed proteins are likely to be different.

22. Prepare a 1-ml translation reaction on ice as follows, adding the reticulocyte lysate last.

80 μ l 5 μ M mRNA display template (final 400 nM)
80 μ l 12.5 \times methionine-free translation mix (final 1 \times)
20 μ l 8.6 μ M [35 S]methionine (final 0.17 μ M)
2.5 M KCl (as optimized)
0.5 μ l magnesium acetate (as optimized)
Water to 600 μ l
400 μ l 2.5 \times rabbit reticulocyte lysate (final 1 \times)
Total, 1000 μ l.

23. Incubate for 1 hr at 30°C, then add 65 μ l of 1 M $MgCl_2$ and 235 μ l of 2.5 M KCl to each of the above reactions and allow them to stand for 5 min at room temperature.

The translation reaction mixtures may be optionally stored for up to a week at -20°C at this point.

One may wish to decrease the concentration of mRNA display template if there is concern about sequence-dependent bias in translation and protein display efficiencies affecting the distribution of different sequences in the library. As the concentration of the mRNA display template is reduced, the proportion of this template that ends up displaying protein increases, with a concomitant increase in the fidelity with which the mRNA library sequence distribution is represented in mRNA-displayed protein sequence distribution. This is an advisable precaution at all stages in which the library is of relatively low diversity.

**PURIFICATION AND REVERSE TRANSCRIPTION OF THE
mRNA-DISPLAYED PROTEINS**

It is extremely advisable to pilot each of the following protocol steps before attempting the large-scale treatment of translation reaction mixture containing mRNA-displayed proteins.

In order to separate the mRNA display templates that display proteins from those that do not, it is necessary to use a purification step upon the basis of a protein affinity tag. In this protocol the His₆ tag is used, although other protein affinity tags may be utilized.

Materials

- Oligo(dT) cellulose (Amersham Pharmacia Biotech)
- Oligo(dT) binding buffer (see recipe)
- 1.3-ml translation reaction mRNA displayed proteins (see Basic Protocol 1)
- Oligo(dT) wash buffer (see recipe)
- Ni-NTA agarose (Qiagen)
- Ni-NTA binding buffer (see recipe)
- 2-Mercaptoethanol
- Ni-NTA wash buffer 1 (see recipe)
- Ni-NTA wash buffer 2 (see recipe)
- Ni-NTA elution buffer (see recipe)
- 10 mg/ml salmon sperm DNA (Life Technologies)
- 1 mg/ml BSA
- 200 μM DNA splint
- 5× Superscript II reverse transcriptase buffer (NEB)
- 0.1 M DTT
- 30 μl (each) 25 mM deoxynucleotide triphosphates (final 0.5 mM)
- 200 U/ml Superscript II reverse transcriptase (NEB)
- 25 mM deoxynucleotide triphosphate solutions
- ATP-aptamer selection binding buffer (see recipe)
- ATP-aptamer selection elution buffer (see recipe)
- Chromatography columns (Bio-Rad)
- Gel filtration columns (e.g., NAP-5, Amersham Pharmacia Biotech)

For additional reagents and equipment for preparative denaturing PAGE purification (*UNIT 2.12*) and SDS-PAGE in Tris-tricine buffer systems (*UNIT 10.2A*)

Purify mRNA displayed proteins

1. Wash 20 mg of oligo(dT) cellulose repeatedly with deionized water in the chromatography column within which it will be used. Resuspend the cellulose several times and apply positive pressure to force it to drain rapidly. Finally, wash once with oligo(dT) binding buffer.

Oligo(dT) cellulose contains fine particulate matter that can drastically reduce the flow rate of aqueous solutions. These fine particles can also pass through the frit during use of the chromatography column, which will result in the loss of mRNA-displayed proteins. This step forces the finest particles through the frit, and is especially important with the use of larger amounts of oligo(dT) cellulose.

2. Dilute the 1.3-ml translation reaction containing the mRNA-displayed proteins with added KCl and MgCl₂ (from Basic Protocol 1) into 8.7 ml of oligo(dT) binding buffer and incubate with the washed oligo(dT) cellulose for 15 min at 4°C with rotation.

Retain an aliquot of the undiluted translation reaction for SDS-PAGE and scintillation counting analyses.

3. Allow the diluted translation reaction mixture and the oligo(dT) cellulose to pass through a chromatography column so that the oligo(dT) cellulose is retained on the frit, and retain the flowthrough.
4. Wash three times with 1 ml oligo(dT) binding buffer.
5. Wash once with 1 ml oligo(dT) wash buffer.
6. Elute three times with 0.5 ml deionized water.
7. Analyze the undiluted translation reaction mixture, the flowthrough, and all of the washes and elutions using Tris-tricine SDS-PAGE as described in *UNIT 10.2A*, Alternate Protocol 1, and by scintillation counting.

The volume of the oligo(dT) eluate may be reduced by lyophilization by up to a factor of 5.

The oligo(dT) cellulose purification step anneals the poly(dA) region of the mRNA display template to immobilized oligo(dT) cellulose. Consequently, mRNA display templates not displaying protein and other mRNA molecules present in the lysate will co-purify with the displayed proteins. Long stretches of adenines in the RNA region of the mRNA display template should be avoided since they will also anneal to the oligo(dT) and present a substrate for RNase H which is present in the reticulocyte lysate; this will cause mRNA display template degradation.

The oligo(dT) cellulose purification step also presents a quick approximate method for the absolute measurement of the concentration of mRNA displayed proteins in the translation reaction mixture. The scintillation counter readings give the proportion of ³⁵S-methionine that is contained in the oligo(dT) eluates by counting equal proportions of the whole translation mixture and the oligo(dT) eluate and dividing one by the other. The ratio of the intensities of the bands corresponding to mRNA-displayed proteins in these two samples on the SDS-PAGE gel gives the yield of the oligo(dT) purification.

8. Calculate the concentration of mRNA displayed proteins in the translation reaction mixture with the following equation:

$$[\text{mRNA-displayed proteins}] = Y^{-1} \times C \times [\text{methionine}] \times N^{-1}$$

where *Y* is the yield of the oligo(dT) cellulose purification determined by SDS-PAGE; *C* is the number of counts in the combined oligo(dT) elution fractions divided by the number of counts in an equal proportion of the translation reaction mixture determined by scintillation counting; [methionine] is the total concentration of hot and cold methionine in the translation reaction mixture before the high salt incubation; and *N* is the average number of methionines in a single displayed protein.

This calculation assumes that the initiating methionine is still present on the protein and that the concentration of methionine in the reticulocyte lysate is known (~5 μM before addition to the translation reaction); this last error can be reduced by adding a known amount of cold methionine to the translation reaction mixture.

A potentially more accurate method for the direct measurement of the concentration of mRNA displayed proteins is to construct the mRNA display template using a mixture of DNA linker that has been kinased (5'-phosphorylated) with labeled ATP as well as the cold kinased (5'-phosphorylated) linker. This labeled template can then be translated in the presence of only cold methionine. It is generally not possible to observe the difference in mobility on a SDS-PAGE gel between the mRNA display template displaying protein and the mRNA display template alone. The addition of a DNA oligonucleotide, complementary to a region of the RNA part of the mRNA display template close to but not right at the 3' end of the RNA, to the translation reaction mixture, as well as magnesium chloride to 10 mM, will cause the RNA part of the mRNA-displayed proteins to be digested away by RNase H, which contaminates reticulocyte lysate, leaving proteins displayed upon the ³²P-labeled DNA linker only. These may easily be resolved from the DNA linker not displaying protein using SDS-PAGE. The ratio between these two bands gives a more direct measurement of

the proportion of mRNA display template that displays protein, and using this the concentration of mRNA-displayed proteins in the translation reaction mixture may easily be calculated. The proportion of mRNA display template that ends up displaying protein can vary from <1% to 40% depending upon the sequence, the myc epitope sequence is at the upper end of this range.

Ni-NTA purification

The Ni-NTA purification is upon the basis of the His₆ tag and is only appropriate if this is present in the library sequence (see also *UNIT 10.11*).

9. Wash 100 µl of Ni-NTA agarose three times with 1 ml deionized water.
10. Mix 0.5 ml of the oligo(dT) eluate with 2× Ni-NTA binding buffer, vortex to dissolve, add 0.7 µl of 2-mercaptoethanol, incubate with the washed Ni-NTA agarose for 1 hr at 4°C with rotation.

The 2× Ni-NTA binding buffer is the solid residue obtained by evaporation to dryness of 1× Ni-NTA binding buffer.

11. Allow the Ni-NTA binding buffer and the Ni-NTA agarose to pass through a chromatography column so that the Ni-NTA agarose is retained on the frit, retain the flowthrough.
12. Perform the following washes on the chromatography column:
 - a. Wash two times with 500 µl Ni-NTA wash buffer 1.
 - b. Wash once with 500 µl of a 4:1 solution of Ni-NTA wash buffer 1:Ni-NTA wash buffer 2.
 - c. Wash once with 500 µl of a 3:2 solution of Ni-NTA wash buffer 1:Ni-NTA wash buffer 2.
 - d. Wash once with 500 µl of a 2:3 solution of Ni-NTA wash buffer 1:Ni-NTA wash buffer 2.
 - e. Wash once with 500 µl of a 1:4 solution of Ni-NTA wash buffer 1:Ni-NTA wash buffer 2.
 - f. Wash once with 500 µl Ni-NTA wash buffer 2.
 - g. Wash two times with 500 µl of a 19:1 solution of Ni-NTA wash buffer 2:Ni-NTA elution buffer.
 - h. Elute for 30 min at 4°C with rotation two times with 250 µl Ni-NTA elution buffer.
13. Analyze the starting material, the flowthrough, and all washes and elutions using Tris-tricine SDS-PAGE as described in *UNIT 10.2A*, Alternate Protocol 1, and by scintillation counting.

EDTA should be added to the eluate to give 5 mM to bind to eluted Ni²⁺.

The volume of the eluate may be reduced by lyophilization by up to a factor of 5.

If the mRNA-displayed proteins are prone to aggregation, then it may be necessary to maintain denaturing conditions throughout the Ni-NTA agarose purification process by the addition of urea or guanidinium hydrochloride to the wash and elution buffers in addition to that which is in the binding buffer.

If it is not desired to completely denature the mRNA-displayed proteins, the denaturant can be omitted from all buffers including the binding buffer; using such a native Ni-NTA agarose purification procedure is likely to result in decreased yields compared to the denaturing Ni-NTA agarose purification procedure described above.

The Ni-NTA agarose purification is upon the basis of the His₆ tag. Alternatively, other protein-affinity tags may be encoded within the protein sequence and used as a basis for

purification, such as the FLAG tag (see Support Protocol 1). The Ni-NTA purification will separate the mRNA-displayed proteins from the mRNA display templates not displaying proteins and other mRNA molecules that were not purified away in the oligo(dT) purification. The Ni-NTA agarose eluate will, however, contain contaminating free library protein if this is present in the input mixture; in this protocol this is removed in the preceding oligo(dT) purification. If it is desired to purify the free library protein, then it is best to purify the translation mixture initially upon the basis of a FLAG tag, with the Ni-NTA agarose purification subsequent to this. Additionally, a denaturing His₆ tag purification may be used to purify selected mRNA-displayed proteins away from the selection binding buffer if more than one selection step is to be used between amplification steps and the denaturing and renaturing of the mRNA-displayed proteins is desired.

Strong chelating agents such as EDTA, EGTA, and DTT must be avoided in Ni-NTA binding and wash buffers since they will compete with the immobilized NTA for complexation of the Ni²⁺, and may elute it from the agarose.

Purify on gel filtration column

14. On a NAP-5 gel filtration column, exchange the elution buffer into water by allowing 10 ml of deionized water to flow through the gel-filtration column.
15. Add 100 μ l of 10 mg/ml salmon sperm DNA and 10 μ l of 1 mg/ml BSA to 890 μ l of deionized water, vortex, and allow this to flow through the gel filtration column.
16. Allow 10 ml of deionized water flow through the gel filtration column.
17. Allow 0.5 ml of sample to flow through the gel filtration column.
18. Add 1 ml of deionized water to the column and collect the 1-ml eluate issued from bottom of column.
19. Analyze the starting material and the elution fraction using Tris-tricine SDS-PAGE as described in UNIT 10.2A, Alternate Protocol 1 and by scintillation counting.

Imidazole does not inhibit reverse transcription, so this buffer exchange is optional, it may be possible to reverse transcribe the mRNA display templates by diluting the Ni-NTA eluate directly into the reverse transcription reaction mixture. Reverse transcription may not proceed if denaturants are present in the reaction mixture.

Reverse transcribe mRNA-displayed proteins

20. Set aside a small sample of the mRNA-displayed proteins that are not reverse-transcribed for use in the no-RT control PCR amplification.
21. Make up the following reverse transcription reaction mixture on ice. Mix mRNA displayed proteins and DNA splint (functions as the RT primer) together first before adding RT buffer, and add reverse transcriptase last:

900 μ l mRNA-displayed proteins
15 μ l 200 μ M DNA splint (final 2 μ M)
300 μ l 5 \times reverse transcription buffer (final 1 \times)
150 μ l 100 mM DTT (final 10 mM)
30 μ l (each) 25 mM deoxynucleotide triphosphates (final 0.5 mM)
5 μ l water
10 μ l 200 U/ μ l Superscript II reverse transcriptase (final 1333 U/ml)
Total, 1500 μ l.

Incubate the reverse transcription reaction for 50 min at 42°C.

22. Analyze the starting material and the product of the reverse transcription using Tris-tricine SDS-PAGE as described in UNIT 10.2A, Alternate Protocol 1, and by scintillation counting.

The volume of the eluate may be reduced by lyophilization by up to a factor of 5. The reverse-transcribed mRNA-displayed proteins have greater mobility on the SDS-PAGE gel compared to those that have not been reverse transcribed. This difference in mobility provides a simple method for the accurate assay of the proportion of the mRNA displayed proteins which have been reverse transcribed. However, this change in mobility may only be observed if the cDNA-RNA association is preserved during the treatment of the sample during gel loading, which may not be the case if it is heated too strongly (much above 90°C).

It is common practice in reverse-transcription reactions to heat denature the primer and RNA template before the addition of the reverse transcriptase; this may influence the conformation of the mRNA displayed proteins, and depending on the project may not be advisable. Mixing the primer and the mRNA display template together under low-salt conditions, before the addition of the buffer, should promote their association.

The use of mRNA displayed proteins in selection experiments may yield functional RNA sequences unless the mRNA display template is reverse transcribed before the selection step. This will also reduce the likelihood that the mRNA display template will disrupt the structure of the protein that it displays. Free proteins originally selected using mRNA display may need to be incubated under reverse transcription conditions in order to achieve their active conformations.

Purify RT products

23. Exchange the buffer into selection buffer on a NAP-5 gel filtration column according to the manufacturer's instructions.
24. Allow 10 ml of selection binding buffer to flow through the gel filtration column.
25. Add 100 μ l of 10 mg/ml salmon sperm DNA and 10 μ l of 1 mg/ml BSA to 890 μ l of selection binding buffer, vortex, and allow this to flow through the gel filtration column.
26. Allow 10 ml of selection binding buffer to flow through column and 0.5 ml of sample to flow through column.
27. Add 1 ml of selection binding buffer to the top of the gel filtration column and collect the 1-ml eluate issued from bottom of column.
28. Analyze the starting material and the elution fraction using Tris-tricine SDS-PAGE as described in *UNIT 10.2A*, Alternate Protocol 1, and by scintillation counting.

The selection binding buffer used here is specific to the selection being performed.

Alternatively, a protein-folding step may accompany the buffer exchange into selection buffer. In this approach a denaturant such as guanidinium hydrochloride or urea is added directly to the mRNA-displayed proteins after reverse transcription, and this is dialyzed away over several hours into selection buffer. It is important to ensure that the denaturing conditions are not so denaturing that the association between the cDNA and the mRNA display template is broken; this may be assayed using SDS-PAGE.

BASIC PROTOCOL 3

SELECTION AND AMPLIFICATION OF THE mRNA-DISPLAYED PROTEINS

Selection protocols are highly project-dependent. The following protocol was successfully used to select ATP-binding proteins from a random sequence library and is included as an example. Cycles of selection and amplification, as described in this protocol, should be repeated until the proportion of the resultant mRNA-displayed proteins in the selected fraction is no longer increasing—typically, 8 to 12 cycles are required. At this point the selected library sequences should be determined by cloning and sequencing (see Chapters

1 and 7), and individual clones should be assayed for activity under the selection conditions both as mRNA-displayed and free proteins.

Materials

ATP agarose (Sigma)
ATP-aptamer selection binding buffer (see recipe)
Purified mRNA-displayed proteins (see Basic Protocol 2)
ATP-aptamer selection elution buffer (see recipe)
100 mM EDTA (*APPENDIX 2*)
1 M NaOH (*APPENDIX 2*)
1 M HCl
10 mg/ml salmon sperm DNA
1 mg/ml BSA
100 μ M 3' primer (specific for cDNA library)
100 μ M 5' primer (specific for cDNA library)
25 mM (each) deoxynucleotide triphosphates
10 \times PCR buffer containing 15 mM MgCl₂ (Boehringer Mannheim)
5 U/ μ l *Taq* DNA polymerase (Boehringer Mannheim)
25:24:1 (v/v/v) phenol/chloroform/isoamyl alcohol
Chloroform
1-Butanol
3 M NaCl
100% ethanol
Gel filtration columns (e.g., NAP-25, Amersham Pharmacia Biotech)
Additional reagents and equipment for butanol extraction (*UNIT 2.1A*)

Select for ATP-binding proteins

1. Wash 10 mg of ATP-agarose three times with 1 ml of deionized water followed by two times with 1 ml of ATP-aptamer selection binding buffer.
2. Incubate 1 ml of the purified mRNA-displayed proteins, from Basic Protocol 2, with the washed ATP-agarose for 1 hr at 4°C with rotation; drain for flowthrough.
3. Wash six times with 1000 μ l ATP-aptamer selection binding buffer at 4°C; allow to stand 10 min between washes.
4. Elute six times with 250 μ l ATP-aptamer selection elution buffer at 4°C; allow to stand 10 min between elutions.
5. Assay all fractions using scintillation counting.

If the proportion of mRNA-displayed proteins in the elution fraction is high (>5%), it may be helpful to perform more than one selection step between amplification steps. In the case of an aptamer selection, this will necessitate the purification of the selected mRNA-displayed proteins away from the elution buffer. This purification can be performed while preserving native conditions, and often directly in the selection buffer, upon the basis of the FLAG tag, as described in Support Protocol 1. Alternatively, this purification can be performed with a denaturing and renaturing step, optionally upon the basis of the His₆ tag under denaturing conditions, as described above.

Purify selected cDNA sequences that encode selected mRNA-displayed proteins

6. To 1.5 ml of eluted mRNA displayed proteins, add 200 μ l of 100 mM EDTA and 200 μ l of 1 M NaOH, heat for 10 min at 90°C, cool on ice, and add 200 μ l of 1 M HCl.
7. Exchange the buffer into deionized water on a NAP-25 gel filtration column according to the manufacturer's instructions.

8. Allow 25 ml of deionized water to flow through the column.
9. Add 200 μl of 10 mg/ml salmon sperm DNA and 20 μl of 1 mg/ml BSA to 1780 μl of deionized water, vortex, and allow this to flow through column.
10. Wash with 25 ml of deionized water and allow water to flow through the gel filtration column.
11. Measure the sample volume and pass through column, then add a volume of deionized water to the column such that the total volume added to the column is 2.5 ml.
12. Add 3.5 ml of deionized water to the top of the gel filtration column and collect the 3.5-ml eluate issued from the bottom of column.

With the exception of the hydrolysis step, this buffer exchange procedure may be optionally repeated after the volume of the sample has been reduced to ≤ 2.5 ml by evaporation under reduced pressure.

Amplify selected sequences by PCR

13. Amplify selected sequences by PCR (see also *UNIT 15.1*). Make up a PCR reaction mixture on ice as follows:

3500 μl selected cDNA library (from step 12)
 100 μl 100 μM 3' primer (final 2 μM)
 100 μl 100 μM 5' primer (final 2 μM)
 40 μl (each) 25 mM deoxynucleotide triphosphates (final 0.2 mM)
 500 μl 10 \times PCR buffer containing 15 mM MgCl_2 (final 1 \times)
 735 μl water
 25 μl 5 U/ μl *Taq* DNA polymerase
 Total, 5000 μl .

The number of cycles, temperatures, and durations of the incubation periods within each cycle need to be determined for the specific library being used (UNIT 15.1). The PCR amplification of DNA libraries should be piloted, and care should be exercised not to over-PCR amplify DNA libraries since they will not reanneal once denatured. If PCR is continued upon a denatured DNA library, rare sequences will be amplified to a greater extent than common sequences, which will reduce the enrichment factor of the selected functional sequences.

14. Perform a no-RT control (set aside in Basic Protocol 2, step 20) alongside this PCR reaction.

In this control a small amount of the mRNA display template that has not been reverse transcribed is used in place of the selected cDNA library. This should not give any observable product after an equivalent amount of amplification. If it does, then either the buffers are contaminated or the purification of the mRNA-displayed proteins is not stringent enough. In either case the problem must be addressed or the selection is unlikely to give the desired result. It is also often useful to perform an additional no-template control in which no template, reverse transcribed or otherwise, is added. If this gives observable product after an equivalent amount of amplification, then this is usually a sign of contaminated reagents.

Mutations will be introduced into the DNA library during PCR amplification. The mutagenic rate can be decreased by using a high-fidelity DNA polymerase such as Pfu DNA polymerase (e.g., Stratagene). The mutagenic rate can be increased by using the mutagenic PCR protocol described in Support Protocol 2. Mutagenic procedures such as mutagenic PCR may be used to increase library diversity by exploring parts of sequence space proximate to the starting sequence(s).

Purify double-stranded PCR product

15. Add 1:1 molar equivalents of 100 mM EDTA to chelate the Mg^{2+} .
16. Vortex the PCR reaction mixture with an equal volume of 25:24:1 (v/v/v) phenol/chloroform/isoamyl alcohol, centrifuge for 1 min at $10,000 \times g$, room temperature, remove and retain upper aqueous phase.
17. Re-extract aqueous phase with an equal volume of chloroform three times; centrifuge to clear on each occasion, remove and discard lower organic phase after each centrifugation.
18. 1-Butanol extract the aqueous phase to 20% of the initial volume at minimum (*UNIT 2.1A*, Support Protocol 2), remove and discard the upper 1-butanol phase.
Perform extraction in a polypropylene tube, as butanol will damage polystyrene.
19. Add 3 M NaCl to final 300 mM (include the salt that originates from the PCR buffer in calculating concentration) and 2.5 volumes of 100% ethanol.
20. Cool for 20 min at $-80^{\circ}C$ or overnight at $-20^{\circ}C$. Centrifuge for 10 min at $12,000 \times g$, $4^{\circ}C$. Decant and discard the supernatant.
21. Centrifuge the pellet for 1 min at $12,000 \times g$, remove remaining supernatant with a plastic pipet tip, make up in 30 mM NaCl, and measure the concentration by agarose gel (more explicit instructions may be found in *UNIT 2.12*).
The dsDNA library will not re-anneal if denatured, so care should be taken not to expose it to low-salt or high temperature conditions.
22. Transcribe the DNA into RNA, (see Basic Protocol 1) and repeat the entire procedure (see Basic Protocols 1, 2, and 3).

FLAG TAG PURIFICATION

The FLAG tag purification may optionally be used in place of or in addition to the His₆ tag purification in the purification of mRNA-displayed proteins. The FLAG tag purification is usually performed in addition to the His₆ tag purification during the preselection of individual cassettes during the library construction process. In this instance, the FLAG tag and His₆ tag are placed at opposite protein termini; purification upon the basis of the presence of both tags ensures that the protein is full-length and in-frame at both termini. This in turn ensures that the mRNA cassette that encodes the protein is free of insertions, deletions, and stop codons, and is suitable for the preparation of the full-length library by restriction and ligation of the resulting PCR-amplified cDNA sequences. In addition, FLAG tag purification may be used to purify selected mRNA-displayed proteins away from the selection binding buffer if more than one selection step is to be used between amplification steps and the denaturing and renaturing of the mRNA-displayed proteins is not desired.

Alternatively, FLAG tag purification may be used to purify free proteins away from reticulocyte lysate.

The FLAG purification is upon the basis of the FLAG tag sequence (DYKDDDDK) and is only appropriate if this is present in the library (see Strategic Planning).

Additional Materials (also see Basic Protocol 1)

- Anti-FLAG M2 agarose (Sigma)
- FLAG clean buffer (see recipe)
- FLAG binding buffer (see recipe)
- FLAG peptide (Sigma)

SUPPORT PROTOCOL 1

1. Wash 100 μ l of anti-FLAG M2 agarose three times with 1 ml of FLAG clean buffer, and then three times with 1 ml of FLAG binding buffer.
2. Exchange sample buffer into FLAG binding buffer according to the directions presented in Basic Protocol 1 for other buffer exchanges.

Optionally, dilute the sample buffer into the FLAG binding buffer or attempt purification directly from selection elution buffer.

3. Place 1 ml of the sample containing the mRNA-displayed proteins onto the washed anti-FLAG agarose and incubate for 1 hr at 4°C with rotation, drain, and retain flowthrough.
4. Wash the anti-FLAG agarose three times with 1 ml of FLAG binding buffer.
5. Elute from the anti-FLAG agarose two times with 0.5 ml FLAG binding buffer containing 10 μ M of the FLAG peptide, 30 min for each elution at 4°C with rotation.

If the FLAG tag purification is to be followed by a denaturing His₆ tag purification, then the elution fraction may be added directly to the 2 \times Ni-NTA binding buffer.

SUPPORT PROTOCOL 2

MUTAGENIC PCR

Mutagenic PCR may be used to increase the diversity of the DNA library that encodes the protein library. Mutagenic PCR may be used to generate the initial library, or to explore parts of sequence space proximate to the starting sequence(s). A broader discussion of the use of mutagenic PCR may be found in Cadwell and Joyce (1992).

Before the entire mutagenic protocol is enacted, it is important to pilot the PCR conditions to ensure that primer dimers are not taking over, and that the amplification per cycle is at least 1.7 to 1.8. The optimum PCR amplification conditions may be different from non-mutagenic PCR amplification performed upon the same library. One may wish to redesign the primers, since the part of the template sequence they anneal to will not be mutagenized.

Additional Materials (also see Basic Protocol 3)

- 2.5 M KCl
- 100 mM MnCl₂ solution
- 100 mM Tris·Cl, pH 8.3 (APPENDIX 2)
- 100 μ l PCR tubes (Sarstedt)

Additional reagents and equipment for agarose gel electrophoresis (UNIT 15.1)

1. Make up the following PCR reaction mixture on ice:

- 100 μ l 100 μ M 3' primer (final 2 μ M)
- 100 μ l 100 μ M 5' primer (final 2 μ M)
- 60 μ l (each) 25 mM dCTP and dTTP (final 1 mM)
- 12 μ l (each) 25 mM dATP and dGTP (final 0.2 mM)
- 30 μ l 2.5 M KCl (final 50 mM)
- 10.5 μ l 1 M MgCl₂ (final 7 mM)
- 7.5 μ l 100 mM MnCl₂ (final 0.5 mM)
- 150 μ l 100 mM Tris·Cl, pH 8.3 (final 10 mM)
- 943 μ l water
- 15 μ l 5U/ μ l *Taq* DNA polymerase
- Total, 1500 μ l.

- Pipet 16 90- μ l aliquots of PCR reaction mixture into 100- μ l PCR tubes and label them 1 to 16.

These may be stored for up to a few hours at 4°C.

- Add the DNA library or sequence to tube 1 to give 10 nM, make up to 100 μ l with PCR reaction mix.
- Perform 4 cycles of PCR amplification. During the final extension incubation, place the next-numbered tube alongside the current one in the PCR block. Before the final extension is complete but ensuring that the next-numbered tube is at the extension temperature, transfer 10 μ l of PCR reaction mixture. Retain the amplified PCR reaction mixture at 4°C.
- Repeat step 4 fourteen times. Every four transfers, analyze the PCR reaction using agarose gel electrophoresis (UNIT 15.1), quantitate the bands in successive PCR amplifications, and adjust the transfer volume in order to maintain the concentration of amplified DNA at a constant level.

It is important not to over-PCR the DNA. If PCR amplification ceases before a concentration of 100 nM is reached, then the initial DNA concentration should be reduced accordingly.

If the initial DNA was of one or a small number of known sequences, then it is possible to directly measure the average mutagenic rate by sequencing some of the individual library members from the final mutagenic PCR amplification sample. Assuming that the mutagenic rate is constant throughout the procedure allows for the direct control of the extent of mutagenesis by choosing one, or a mixture of more than one, of the successive mutagenic PCR amplification mixtures to serve as the source of the new DNA library. This sample may then be further amplified with PCR, optionally with further mutation. It is expected that the mutagenic rate will be about 0.2% per nucleotide per transfer (ten-fold amplification).

REAGENTS AND SOLUTIONS

The water used to make the following buffers should be deionized, ultrafiltered and subsequently tested for the absence of RNase by incubation with ³²P-labeled RNA and denaturing PAGE analysis. All buffers should be analyzed similarly. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

ATP-aptamer selection binding buffer

39.0 mg MgCl₂ (mol. wt. 95.2; 4.1 mM final)
2.92 g KCl (mol. wt. 74.6; 392 mM final)
476 mg HEPES (mol. wt. 238; 20 mM final)
3.07 mg glutathione (mol. wt. 307; 2 mM final)
3.06 mg glutathione disulfide (mol. wt. 612; 1 mM final)
3.72 mg EDTA·2Na⁺ (mol. wt. 372; 100 μ M final)
250 μ l Triton X-100 (0.25% final)
Bring up to 100 ml with water
Store at -20°C

Deoxygenate the buffer before the addition of the glutathione by bubbling an oxygen-free grade of an inert gas such as argon or nitrogen through it, and adjust the pH to 7.4.

ATP-aptamer selection elution buffer

285 mg ATP·2Na⁺ (mol. wt. 569; 5 mM final)
84.7 mg MgCl₂ (mol. wt. 95.2; 8.9 mM final)
2.92 g KCl (mol. wt. 74.6; 392 mM)
476 mg HEPES (mol. wt. 238; 20 mM final)

continued

3.07 mg glutathione (mol. wt. 307; 2 mM final)
3.06 mg glutathione disulfide (mol. wt. 612; 1 mM final)
3.72 mg EDTA·2Na⁺ (mol. wt. 372; 100 μM final)
0.25 g Triton X-100 (0.25% w/v final)
Bring up to 100 ml with water
Store at -20°C

Deoxygenate the buffer before the addition of the glutathione by bubbling an oxygen-free grade of an inert gas such as argon or nitrogen through it, and adjust the pH to 7.4.

FLAG binding buffer

877 mg NaCl (mol. wt. 58.4; 150 mM final)
1.19 g 50 mM HEPES (mol. wt. 238; 50 mM final)
0.25 g Triton X-100 (0.25% w/v final)
Adjust the pH to 7.4 with NaOH/HCl
Bring up to 100 ml with water
Store at -20°C

FLAG clean buffer

751 mg glycine (mol. wt. 75.1; 100 mM final)
0.25 g Triton X-100 (0.25% w/v final)
Bring up to 100 ml with water
Store at -20°C
Adjust pH to 3.5 with NaOH/HCl.

Ni-NTA binding buffer

57.4 g guanidine hydrochloride (mol. wt. 95.5; 6 M final)
2.93 g NaCl (mol. wt. 58.4; 500 mM final)
1.42 g Na₂HPO₄ (mol. wt. 142; 100 mM final)
121 mg Tris(hydroxymethyl)aminomethane (mol. wt. 121; 10 mM final)
0.25 g Triton X-100 (0.25% w/v final)
701 μl 2-mercaptoethanol (mol. wt. 78.1; 10 mM final)
Adjust the pH to 8.0 with NaOH/HCl
Bring up to 100 ml with water
Store at -20°C

In order to prepare 2× Ni-NTA binding buffer, the 1× Ni-NTA binding buffer should be evaporated to dryness under reduced pressure. Upon using the resultant 2× Ni-NTA binding buffer, the 2-mercaptoethanol will have to be added again.

Ni-NTA elution buffer

2.93 g NaCl (mol. wt. 58.4; 500 mM final)
121 mg 10 mM Tris(hydroxymethyl)aminomethane (mol. wt. 121; 10 mM final)
0.25 g Triton X-100 (0.25% w/v final)
1.70 g imidazole (mol. wt. 68.1; 250 mM final)
701 μl 2-mercaptoethanol (mol. wt. 78.1; 10 mM final)
Adjust pH to 8.0 with NaOH/HCl
Bring up to 100 ml with water
Store at -20°C

Ni-NTA wash buffer 1

48.1 g urea (mol. wt. 60.1; 8 M final)
2.93 g NaCl (mol. wt. 58.4; 500 mM final)
1.20 g NaH₂PO₄ (mol. wt. 120; 100 mM final)
121 mg Tris(hydroxymethyl)aminomethane (mol. wt. 121; 10 mM final)
0.25 g Triton X-100 (0.25% w/v final)

continued

701 μ l 2-mercaptoethanol (mol. wt. 78.1; 10 mM final)
Adjust the pH to 6.3 with NaOH/HCl
Bring up to 100 ml with water
Store at -20°C

Ni-NTA wash buffer 2

2.93 g NaCl (mol. wt. 58.4; 500 mM)
121 mg Tris(hydroxymethyl)aminomethane (mol. wt. 121; 10 mM final)
0.25 g Triton X-100 (0.25% w/v final)
701 μ l 2-mercaptoethanol (mol. wt. 78.1; 10 mM final)
Adjust the pH to 8.0 with NaOH/HCl
Bring up to 100 ml with water
Store at -20°C

Oligo(dT) binding buffer

7.46 g KCl (mol. wt. 74.6; 1 M final)
1.21 g Tris(hydroxymethyl)aminomethane (mol. wt. 121; 100 mM final)
372 mg disodium EDTA (mol. wt. 372; 10 mM final)
0.25 g Triton X-100 (0.25% w/v final)
Adjust the pH to 8.0 with NaOH/HCl
Bring up to 100 ml with water
Store at -20°C

Oligo(dT) wash buffer

746 mg KCl (mol. wt. 74.6; 100 mM final)
121 mg Tris(hydroxymethyl)aminomethane (mol. wt. 121; 10 mM final)
0.25 g Triton X-100 (0.25% w/v final)
Adjust the pH to 8.0 with NaOH/HCl
Bring up to 100 ml with water
Store at -20°C

Transcription buffer, 10 \times

255 mg spermidine trihydrochloride (mol. wt. 255; 10 mM final)
4.84 g Tris(hydroxymethyl)aminomethane (mol. wt. 121; 400 mM final)
770 mg DTT (mol. wt. 154; 50 mM final)
0.1 g Triton X-100 (0.1% w/v final)
Adjust the pH to 8.0 with NaOH/HCl
Bring up to 100 ml with water
Store at -20°C

COMMENTARY

Background Information

In vitro selection experiments were first successfully performed upon nucleic acid libraries, for reviews see Szostak and Ellington (1993), Gold et al. (1993), and Joyce (1993). Nucleic acids are the only molecular systems that are capable of being replicated directly in vitro and which also can contain more than trivial amounts of amplifiable information. Nucleic acid selections have the advantage that the target functional entity, and the information encoding the functional entity, are the same. Within nucleic acid selections, large libraries (i.e., up to 10^{17} different molecules) are sub-

jected to successive cycles of selection and amplification until functional sequences dominate the library, at which point they may be identified by cloning and sequencing. The idea of extending the in vitro selection approach to proteins was an obvious one; what was not obvious, however, was how to extract the sequence information from selected proteins in order to permit their amplification and ultimately their identification.

One way to extract the sequence information from selected proteins is to covalently attach each of them to the mRNA sequence that encodes it (Roberts and Szostak, 1997; Roberts,

1999; Roberts and Ja, 1999). In this manner the function (phenotype) and amplifiable sequence information (genotype) are part of the same molecule. Selection may be performed upon the basis of the function of the protein, while the protein may be amplified upon the basis of the mRNA that encodes it and is attached to it. The problem was how to arrange things so that proteins may be attached to the mRNA that encodes them in parallel while mixed within one reaction mixture. The molecule that makes this possible is puromycin (Fig. 24.5.1). Puromycin is an antibiotic that functions by inhibiting translation. It sufficiently closely resembles a charged tRNA that it is able to enter the A-site of the ribosome and react with the activated C-terminal of the nascent peptide. Since this reaction results in the formation of a stable amide bond, rather than the hydrolyzable ester bond that connects the tRNA to the amino acid in an amino-acyl tRNA, translation is halted. If the puromycin is already attached to the mRNA that is being translated, a stable covalent linkage results between a protein and the mRNA that encodes it and the ribosome may be purified away.

In a conceptual sense, the most similar systems to mRNA display are phage display (Smith and Petrenko, 1997) and ribosome display (Jermutus et al., 1998). All three systems may be used to search nucleic acid libraries for the functional proteins or peptides they encode. In phage display, the protein library is encoded within the phage genome and is expressed upon the surface of the phage as a fusion with the phage coat protein. Phage may be selected upon the basis of the functionality of their surface proteins, and the protein may then be amplified by allowing the selected phage to replicate. The diversity of phage display selection experiments is limited to the numbers of phage that may reasonably be transformed or packaged, which is $\sim 10^8$ to 10^9 . Recent advances have shown that it is possible to display libraries of proteins upon the surface of phage (Sche et al., 1999), but phage display has yet to be used to discover a new protein from an entirely random sequence library, as distinct from a library derived from a known folded protein. In ribosome display, paused ribosomes display the protein library in a ternary complex with the mRNA that encodes the displayed protein. In order to synthesize this ternary complex, an mRNA library is prepared without a stop codon. Upon translation of this template the ribosomes will pause at the end of the open reading frame. Because the ribosome is unable to release itself

from the message, it displays both the nascent protein and the mRNA that encodes it. These constructs may be used for in vitro selection experiments upon the basis of the function of the displayed nascent protein. Selected proteins may then be amplified using RT-PCR amplification of the associated mRNA. The ribosome display constructs are relatively large, and selections can only be performed under conditions that preserve the ribosome-mRNA-nascent protein association. Also, since the ribosome display constructs also display a single-stranded mRNA, there is a possibility that functional RNA sequences may be selected in place of the desired functional proteins. This problem can be avoided by reverse transcribing the mRNA associated with the ribosome.

Critical Parameters

After designing and synthesizing the mRNA display library, it is important to have it sequenced in order to ascertain the proportion of the library which is error-free and appropriate for the selection. If the proportion of library members with insertions, deletions, or stop codons is too high, the library may have to be resynthesized with extra purification steps incorporated at the DNA cassette stage (pre-selection, see Fig. 24.5.3). Alternatively, considerable library quality improvement may result from the careful denaturing PAGE purification of small amounts of the DNA cassettes.

The various purification steps performed after the initial synthesis of the mRNA-displayed proteins should be individually optimized, with assays performed by SDS-PAGE to ascertain that the mRNA displayed proteins are still attached to full-length mRNA. Subsequent to this, a pilot (“round zero”) purification should be performed in which the various optimized purification steps are applied sequentially to the same sample. Only upon the satisfactory completion of round zero should the large-scale translation reaction be made up for the first round of selection (“round one”).

The various purification steps that form part of each cycle of the selection of mRNA displayed proteins must be assayed by SDS-PAGE in order to confirm that the mRNA display template has not become degraded at any stage in the process.

Both positive and negative controls need to be used to assay the selection step; this should then be optimized to discriminate between the two controls to the maximum possible reasonable extent. This maximal discrimination selection protocol should be adopted after round two

or three; at this stage the absolute yield of the selection step is no longer a concern owing to the high copy number of selected sequences that have passed through ≥ 1 amplification step.

Alongside the PCR amplification that follows each selection step, a no-RT control should be performed. In this control a small amount of the mRNA display template that has not been reverse-transcribed is used in place of the selected cDNA library. This should not give any observable product after an equivalent amount of amplification. If it does, then either the buffers are contaminated or the purification of the mRNA-displayed proteins is not stringent enough. A no-template control PCR amplification will distinguish between these two possibilities. In either case, the problem must be addressed or the selection is unlikely to give the desired result.

Troubleshooting

Problems that may be encountered with this procedure are detailed in Table 24.5.2.

Anticipated Results

The results of a selection largely depend upon how many of the initial library members can perform the task for which they are being selected and how well they can perform it under the selected conditions. Ideally, the observed activity in each round of selection will exponentially rise to a high value and then plateau. Assuming that there are a relatively small number of members of the initial library with activity that causes them to be selected, it is likely that several rounds of selection and amplification will have to be performed before any significant increase in activity is observed.

Once the selection activity has peaked or reached a plateau, then the library members should be sequenced. If there were relatively large numbers of members of the initial library with activity that causes them to be selected, then the library at this stage may still be fairly diverse. Since the cycles of selection and amplification preferentially amplify the most active members, a high-diversity library at the end of the selection is likely to indicate a failed selection or a selection that is not yet finished. Successful selections are likely to yield one or a small number of families of very closely related protein sequences each of which has diverged from a single ancestral protein sequence owing to errors accumulated during the many cycles of PCR amplification to which they have been subjected. Assays of individual members of these selected families of se-

quences should yield mRNA-displayed proteins with the desired function; these are also likely to be functional as free proteins, unless the mRNA display template greatly interferes with the conformation of the displayed protein that it displays.

Early indications are that proteins selected using mRNA display may fold into multiple conformations, only some of which have the desired functionality. This behavior causes the proportion of the selected library observed to demonstrate the desired activity to rise by a factor of much less than might be expected during successive rounds of selection. The individual selected proteins behave similarly, whether mRNA displayed or not. Mutagenesis and reselection of such selected individual library members, or libraries of them, has given large families of related proteins with greatly improved characteristics in this respect (A.D. Keefe, G. Cho, and J.W. Szostak, pers. commun.).

It should always be borne in mind that selections will give a solution to the problem that is set; it is up to the experimenter to arrange the selection conditions sufficiently carefully to ensure that this solution is a consequence of the desired functionality.

The range of acceptable yields of various parts of the mRNA-displayed protein selection protocol are listed in Table 24.5.3. Observed yields falling at the lower end of these ranges may or may not be increased upon optimization.

Time Considerations

The construction of the library may take anywhere between 2 weeks and 2 months. Doing pilot preparative and purifying experiments on mRNA displayed protein may take ≥ 1 month. A single round of selection and amplification will take 2 to 4 days and the initial rounds of selection may take 1 to 2 months. Mutagenesis will take 1 to 2 weeks and subsequent rounds of selection and amplification will take 1 to 2 months. Sequencing and assays of selected proteins may take ≥ 1 month.

Table 24.5.2 Troubleshooting Guide to Problems That May Be Encountered In Protein Selection Using mRNA-Displayed Proteins

Problem	Possible cause	Solution
Sequencing of initial library or library cassettes reveals many insertions and/or deletions	Synthetic DNA is of low quality	Repeat synthesis and/or careful denaturing PAGE purification to resolve n from $n+1$ and $n-1$ oligonucleotides
Sequencing of initial library or library cassettes reveals many insertions and/or deletions and/or stop codons	Synthetic DNA is of low quality and/or stop codons appear in random region as a consequence of library design	Perform “preselection” in which mRNA displayed proteins are synthesized at the cassette stage; these are purified upon the basis of the presence of both terminal tags, and the resulting cDNA is used to construct the full-length library (see Fig. 24.5.3)
mRNA-DNA ligation does not yield any/enough mRNA display template	3'-end of mRNA and/or splint have self-structure arising from internal complementarity	Redesign mRNA and/or splint sequences
	Puromycin-terminated linker was not sufficiently 5'-phosphorylated	Repeat 5'-phosphorylation, optionally with extra enzyme
	Too much salt in the ligation reaction mixture	Desalt mRNA, splint and linker
	RNA is degraded	Repeat transcription and gel purification
No mRNA-displayed proteins observed on gel	Ligation failed	See above
	mRNA display template is degraded	Repeat ligation
	No methionines present in library except initiating methionine which is degraded away in lysate	Redesign protein library with more methionines
Oligo(dT) cellulose purification low-yielding	Elution buffer not sufficiently denaturing	Further deionized water washes are needed to wash away residual salt
Ni-NTA purification low-yielding	His ₆ tag not accessible	Use more denaturing conditions for the binding step or redesign library
	Product precipitates	Add denaturant to the wash and elution buffers
	EDTA, EGTA, DTT, or other chelating agents present in the binding buffer	Redesign protocol to exclude chelating agent
Library DNA observed in no-template control PCR amplification	PCR amplification components contaminated with library DNA	Determine which PCR amplification components are contaminated and replace them
Library DNA observed in no-RT control PCR amplification	Library DNA has not been purified away from mRNA displayed proteins, or mRNA displayed protein purification buffers are contaminated	Increase the stringency of the mRNA displayed protein purification protocol, or determine which mRNA displayed protein purification components are contaminated and replace them
Activity does not rise through selection	There are no functional sequences in library	Redesign or mutagenize library and reselect
	Selection step not designed appropriately	Test selection step with positive and negative controls, redesign to maximize distinction

continued

Table 24.5.2 Troubleshooting Guide to Problems That May Be Encountered In Protein Selection Using mRNA-Displayed Proteins, continued

Problem	Possible cause	Solution
	Biases in PCR, transcription, translation, or protein display overwhelming selection bias	Adjust conditions so that biases are reduced, especially in low-yielding steps; e.g., reduce mRNA display template concentration in translation
	Immobilized target not accessible to mRNA-displayed proteins	Repeat selection with different matrix and/or linker and/or target linkage point
No families observed in sequencing data at end of selection	Not enough cycles of selection and amplification performed	Continue with cycles of selection and amplification
	There are many sequences in the selected library that are active	Assay individual selected sequences
Selected sequences not active as mRNA-displayed proteins	Not enough cycles of selection and amplification performed	Continue with cycles of selection and amplification
	There are no functional sequences in library	Redesign or mutagenize library and reselect
Selected sequences active as mRNA-displayed proteins, but not as free proteins	Assay does not treat free proteins in exactly the same manner as mRNA-displayed proteins	Repeat assay, treating free proteins in the same manner as mRNA-displayed proteins, for example include the reverse transcription step
	Selected mRNA-displayed proteins have mRNA-dependent conformations	Redesign or mutagenize library and reselect

Table 24.5.3 Results Obtained During mRNA-Displayed Protein Selection Procedure

Step	Range of acceptable yields
5'-phosphorylation of DNA linker	90%-100%
Splinted RNA-DNA ligation	20%-60%
Proportion of mRNA display template displaying protein	1%-40%
Oligo(dT) cellulose purification	30%-90%
Denaturing Ni-NTA purification	30%-90%
Anti-FLAG purification	50%-80%
Gel filtration chromatography (NAP column)	85%-100%
Reverse transcription	80%-100%
Proportion of mRNA displayed proteins in initial elution phase of aptamer selection	0.01%-1%
Proportion of mRNA displayed proteins in final elution phase of aptamer selection	3%-60%
<i>Other statistics relating to mRNA display protein selections</i>	
Number of rounds of selection until activity peaks or plateaus	8-12
Initial diversity of mRNA display library	10 ¹² -10 ¹³
Final diversity of mRNA display library	≥1-10 ⁴

CHAPTER 25

Discovery and Analysis of Differentially Expressed Genes in Single Cells and Cell Populations

INTRODUCTION

For decades, molecular biologists have been discovering and analyzing genes that are differentially expressed. Initially, discovery and analysis was one gene at a time. This was followed by cDNA cloning methods to identify genes that were expressed in a given tissue; however, this left the investigator with a large number of genes to screen for differential expression. A major advance was the development of subtractive cloning in the 1980s, which greatly enriched for genes that were expressed in one cell or tissue type rather than another. With the advent of PCR using thermostable DNA polymerases in the late 1980s, older methods have been refined and many new techniques have been developed that make discovery of differentially expressed genes much more facile and permit the analysis of differential gene expression at the single cell level.

This chapter consists of protocols—some of them older, some of them newer—for two kinds of methods. The first of these are amplification-based methods for analysis of individual cells and are contained within Section 25A. *UNIT 25A.1* describes the use of laser-capture microdissection of histological specimens so that one can analyze nucleic acids, in particular individual cells, using PCR. *UNIT 25A.2* describes methods for fixation of tissues and subsequent dissociation of the fixed tissue into single cells whose nucleic acids can be analyzed by PCR-based methods.

Section 25B contains molecular methods for discovery of differentially expressed genes. *UNIT 25B.1* (formerly *UNIT 5.8B*) describes production of a subtracted cDNA library while *UNIT 25B.2* (formerly *UNIT 5.9*) describes the refinement of PCR-based subtractive cDNA cloning with a support protocol for slot blot hybridization to monitor sublibraries. Subtracted cDNA libraries provide a method where cDNAs are synthesized from mRNA from the desired tissue or cell type and then sequences that are also expressed in a control tissue or cell type are removed by hybridization and selection.

UNIT 25B.3 describes a powerful application of PCR to gene discovery, differential display. This technique allows the identification and subsequent isolation of differentially expressed genes that requires no knowledge of sequences, but rather PCR amplification using arbitrary oligonucleotides and high resolution polyacrylamide gel electrophoresis. *UNITS 25B.4 & 25B.5* describe variations on differential display, restriction-mediated differential display (RMDD) and amplified fragment length polymorphism (AFLP) based transcript profiling, which make use of frequently cutting restriction enzyme sites in cDNAs and may offer advantages to the practitioner.

UNITS 25B.6 & 25B.7 contain different PCR-based approaches for determining what genes are expressed in a given cell or tissue type. *UNIT 25B.6* describes serial analysis of gene expression (SAGE). This technique generates concatemers of short cDNA sequence tags that have been ligated together. These concatemers can be cloned, sequenced, and analyzed with the aid of specialized software to identify differentially expressed genes. The unit also contains a protocol for cloning cDNA starting with a given sequence tag.

Supplement 64

UNIT 25B.7 describes representational difference analysis (RDA). RDA combines PCR-mediated kinetic enrichment with subtractive hybridization to generate 0.2–2 kbp sequences that are distinct to genomic DNA or mRNA in one cell type versus another. These can then be cloned and sequenced or otherwise analyzed.

UNIT 25B.8 describes a protocol in which both PCR and reverse transcription have been optimized to permit the detection and semi-quantitative analysis of transcripts from single cells, small tissue biopsies, and microdissected samples. These protocols extend and complement those provided in *UNITS 25A.1 & 25A.2*.

Further additions to this chapter on analysis of gene expression in single cells are anticipated.

NUCLEIC ACID AMPLIFICATION FROM INDIVIDUAL CELLS

SECTION A

Laser Capture Microdissection

UNIT 25A.1

Mammalian tissues are histologically and biologically heterogeneous, and typically contain multiple cellular components, such as epithelial, mesenchymal (i.e., stromal), and inflammatory cells. Laser capture microdissection (LCM) offers a rapid and precise method of isolating and removing specified cells from complex tissues for subsequent analysis of their RNA, DNA, or protein content, thereby allowing assessment of the role of the cell type in the normal physiologic or disease process being studied. LCM has been utilized to study molecular changes during the neoplastic progression of specific cell types (Sgroi et al., 1999; Paweletz et al., 2000), and to understand the role of particular cell types in normal organ function (Glasow et al., 1998; Jin et al., 1999) and in various disease processes (Fend et al., 1999a; Sawyer et al., 2000). LCM has the potential to contribute to the understanding of many cellular processes, particularly processes involving multiple cell types, such as embryonic development, tissue differentiation and function, aging, and disease.

There are methods for tissue microdissection other than LCM, such as laser microbeam microdissection and laser-pressure catapulting, in which a fine laser beam is used to cut around individual or groups of cells and then laser energy is used to “catapult” the cells out of the tissue section and allow their collection (P.A.L.M. Mikrolaser Technologie; <http://www.palm-mikrolaser.com>); however, currently, Arcturus Engineering is the only manufacturer of instrumentation for LCM. Arcturus Engineering (<http://www.arctur.com>) can be contacted for details about the various LCM systems available and the current prices of instrumentation and consumables.

In this unit, protocols for the preparation of mammalian frozen tissues (see Basic Protocol 1), fixed tissues (see Basic Protocol 2), and cytologic specimens (see Basic Protocols 3 and 4) for LCM, including hematoxylin and eosin staining (H&E; see Basic Protocol 5 and UNIT 14.5), are presented, as well as a protocol for the performance of LCM utilizing the PixCell I or II Laser Capture Microdissection System manufactured by Arcturus Engineering (see Basic Protocol 6). Also provided is a protocol for tissue processing and paraffin embedding (see Support Protocol), and recipes for lysis buffers for the recovery of nucleic acids and proteins (see Reagents and Solutions). The Commentary section addresses the types of specimens that can be utilized for LCM and approaches to staining of specimens for cell visualization (see Critical Parameters). Emphasis is placed on the preparation of tissue or cytologic specimens as this is critical to effective LCM. Resources available on-line are given at the end of the unit (see Internet Resources).

PREPARATION OF FROZEN SECTIONS FOR LCM

Embedding and freezing is a way to preserve specimens and stabilize them for long-term storage and sectioning (also see UNIT 14.2). Tissue is embedded in a viscous compound, such as optimal cutting temperature (OCT; Tissue-Tek) medium, and rapidly frozen on dry ice. For long-term storage (i.e., months to years), liquid nitrogen offers the best preservation of protein and RNA. Storage at -80°C is adequate for shorter time periods (i.e., a few days to several weeks).

BASIC
PROTOCOL 1

Discovery of
Differentially
Expressed Genes

25A.1.1

Materials

Embedding medium (e.g., OCT; Tissue-Tek)
~1-cm maximum-dimension tissue samples
Cryomolds (Tissue-Tek)
Dry-ice container with lid
Aluminum foil
Microm cryostat, refrigerated to -20°C with tissue platform (chuck) and appropriate blades (Richard-Allan Scientific)
Glass slides (e.g., Gold Seal plain uncoated slides; Becton Dickinson)
No. 2 pencil or slide marker
Slide boxes (optional)

Embed tissue

1. Place a labeled empty cryomold on dry ice in a container for 1 min. Keep on dry ice during the entire embedding procedure.
2. Cover the bottom of the cryomold with ~2 to 3 mm embedding medium.
3. Place the tissue to be frozen against the bottom of the cryomold in the medium before it hardens (this may take <1 min depending on the amount of OCT used).

To facilitate cutting, the tissue should be relatively small (i.e., 1 cm in maximum dimension) and the desired cutting surface should be flush against the bottom.

4. Fill the cryomold containing the base of embedding medium and frozen tissue with more embedding medium. Cover the dry ice container and allow the embedding medium to harden (several minutes).

The medium will turn from translucent to white when frozen.

5. Wrap the resulting tissue block, still in the cryomold, in aluminum foil and keep in a -80°C freezer or in liquid nitrogen until cutting.

Tissue for RNA extraction should be frozen as quickly as possible after resection. The method described here is preferred for LCM because tissue processed in this manner is more amenable to cryostat sectioning and offers acceptable histomorphology. More rapid methods of freezing tissue, such as direct immersion into liquid nitrogen, isopentane chilled to -160°C (Sheehan and Hrapchak, 1987a), or the vapor phase of liquid nitrogen, can also be utilized; however, these methods are more technically difficult when incorporating cryostat embedding media and are more likely to result in cracking of the tissue block. Tissues that were rapidly frozen without embedding medium can be postembedded in cryostat embedding medium, but will thaw somewhat in the process. This can compromise RNA preservation and introduce undesirable histologic artifacts.

Section tissue

6. Remove the tissue block from the cryomold and attach it to the tissue platform (chuck) in the cryostat, with additional embedding media serving as the “glue” at the interface. Apply just enough embedding media to cover the surface of the chuck and quickly attach the frozen tissue block before the “glue” hardens completely.

The cutting surface should be as parallel as possible to the chuck surface.

7. Allow the block to equilibrate to the cryostat temperature (i.e., -20°C) ≥ 15 min.
8. Cut 5- to 10- μm sections onto glass slides that have been sitting at room temperature and previously labeled with identifying numbers and or letters using a no. 2 pencil or a permanent marker designed for labeling slides.

Glass slides can be plain uncoated, charged, or silanized. The properties of glass slides that allow tissue adherence are variable among different brands, even with plain uncoated slides. It is important to use slides that allow tissue sections to adhere well enough that they do not fall off during staining, but not so tightly that the tissue cannot be captured. It is likely that different brands and types of slides will have to be tried, and that slides used successfully for formalin-fixed paraffin-embedded sections may not be optimal for frozen ones. The authors have found the Becton Dickinson Gold Seal plain uncoated slides work well for LCM of frozen sections in their laboratory. It is best to begin with plain uncoated slides, and if tissue sections do not adhere well enough to allow staining, to try charged or silanized slides. Adhesives, such as Sta-On (Surgipath) can be applied directly to the slides or gelatin, or can be added to the water bath during histologic sectioning; however, these may limit the transfer efficiency of LCM.

It is important to mount the tissue as close to the center of the slide as possible. If the tissue is too far off center, the slide cannot be positioned so that the vacuum slide holder can function during microdissection.

If sections are particularly friable and thus difficult to cut, the tissue may be too cold; therefore, the time allowed for the block to equilibrate to -20°C may need to be extended. Sections should be without folds and lie as flat as possible on the slides.

Sections with $>10\text{-}\mu\text{m}$ thickness are difficult to visualize. The authors prefer sections of 5- to $6\text{-}\mu\text{m}$ thickness. Thicker sections will require a larger spot size and therefore a higher laser-energy level.

9. Keep the slides in the cryostat or on dry ice if LCM is to be performed that day. Alternatively, store in slide boxes at -80°C until needed.

The duration of preservation of RNA and protein in frozen sections at -80°C is not well documented and likely depends on the tissue and the desired analyte. Although storage over several weeks or even months at -80°C may preserve the analyte of interest well, if this has not been assessed, we recommend limiting storage of frozen sections prior to microdissection to one week.

10. Stain slides (see Basic Protocol 5) just prior to LCM.

IMPORTANT NOTE: *Do not allow the slides to dry or thaw at room temperature prior to staining and dehydration. This is critical for successful LCM. Drying and thawing causes the tissue to adhere tightly to the slide and will decrease the transfer efficiency of LCM. Additionally, it may contribute to the degradation of RNA.*

PREPARATION OF FIXED PARAFFIN-EMBEDDED SECTIONS

Paraffin embedding is a process in which fixed tissue—utilizing neutral buffered formalin (NBF) or another fixative—is infiltrated and then placed into liquefied paraffin to stabilize it for long-term storage and easy sectioning (UNIT 14.1). While fixation is performed to preserve the morphology of the tissue for histologic examination, it also effects the DNA, RNA, and protein content. Formalin fixation is the standard for morphologic preservation of tissue and has been used by most pathology laboratories for decades; however, it creates cross-links between nucleic acids and proteins, and between different proteins. This cross-linking interferes with recovery of DNA, RNA, and proteins from fixed tissue, as well as the amplification of DNA and RNA by PCR (Arnold et al., 1996; Coombs et al., 1999; Goldsworthy et al., 1999; Masuda et al., 1999); however, short lengths of DNA, up to ~ 200 bp, can be reliably amplified after extraction from formalin-fixed paraffin-embedded (FFPE) tissue. RNA is a more labile species, and formalin fixation and paraffin embedding greatly interfere with its recovery. Attempts to break cross-links and thereby improve recovery of nucleic acids and protein have been utilized with varying degrees of success (Ikeda et al., 1998; Coombs et al., 1999; Masuda et al., 1999). Optimization and standardization of methods to break the cross-links caused by formalin fixation is a goal

25A.1.3

of many researchers. Studies have shown that, among commonly used fixatives, formalin has the worst effects on RNA, while ethanol (i.e., 70% or 95% ethanol) or ethanol-based fixatives, available from suppliers of histology-related materials (e.g., Richard-Allan Scientific), offer the best RNA preservation (Goldsworthy et al., 1999; Shibutani et al., 2000).

In this protocol, it is assumed that most researchers will procure fixed and embedded tissue from pathology laboratories or other sources and may have no control over fixation and processing of tissues; however, a suggested protocol for fixation and tissue processing (see Support Protocol) has been included in the event the researcher is prospectively collecting human or animal tissues and has some degree of control over these processes.

Materials

Paraffin-embedded tissue block mounted on appropriate microtome chuck (see Support Protocol)

Xylene

100%, 95%, and 70% ethanol

Microtome and microtome blades (disposable preferred; Richard-Allan Scientific), clean

43° to 44°C water bath

Histologic slides, plain uncoated, charged, or silanized

37° to 42°C oven (optional)

Coplin jars or other solvent containers

Section tissue

1. Cut 5- to 10- μ m sections of a paraffin-embedded tissue block mounted on an appropriate chuck on a clean microtome with a clean blade.

IMPORTANT NOTE: Careful attention should be given during sectioning and mounting of paraffin-embedded tissue to prevent carryover. Carryover contamination of one specimen from another or transfer of material from one region of a section to another can lead to spurious results. The microtome used to cut sections should be kept clean and excess paraffin and tissue fragments should be wiped from the area with a simple gauze pad. A fresh microtome blade should be used for each block and disposable blades used if possible.

Sections of 5- μ m thickness are optimal for LCM, but the thickness should be dependent on the size of the cells to be microdissected.

2. Float resulting paraffin ribbons on 43° to 44°C deionized water in a water bath to smooth out and eliminate folds and wrinkles.

The water should be changed frequently to avoid contamination of sections by tissue fragments from other tissues and to minimize growth of environmental microorganisms. The authors currently do not recommend using formalin-fixed paraffin-embedded tissue for RNA analysis; however, the authors and others have successfully performed RT-PCR on alcohol-fixed paraffin-embedded tissues. If sections will be microdissected for RNA, consideration should be given to using RNase-free water (UNIT 4.1).

Some histopathology laboratories use an adhesive in the water bath to better adhere the tissue section to the slide. As this may result in reduced LCM transfer of tissue, it is not recommended.

3. Mount sections on histologic glass slides.

Clean uncoated plain, charged, or silanized histological slides can be used. The authors have successfully performed LCM utilizing many brands of uncoated glass slides, as well as charged slides, with fixed and paraffin-embedded tissues.

It is important to mount the tissue as close to the center of the slide as possible. If the tissue is too far off center, the slide cannot be positioned so that the vacuum slide holder can function during microdissection.

- Air dry the paraffinized sections overnight or bake up to 8 hr at 37° to 42°C.

As with frozen sections, the desired result is for the tissue to remain adherent to the slide during staining, but not be so adherent as to prevent tissue transfer by LCM. Baking the slides will cause the sections to be more adherent than air drying. Relevant variables that affect LCM include the type of slide, whether the sample is air dried or baked, the duration of baking, and the type of tissue being microdissected.

Remove paraffin

- Allow the slide containing the tissue section to remain in the following solutions, in Coplin jars or other solvent containers, for the specified times in the specified order:

Xylene	5 min
Xylene	5 min
100% ethanol	30 sec
95% ethanol	30 sec
70% ethanol	30 sec

In order to proceed with histologic staining and LCM following sectioning, paraffin must be removed from the tissue sections.

If RNA is to be analyzed, consideration should be given to preparing the 95% and 70% ethanol solutions with RNase-free water. The authors routinely utilize sterile or distilled water and typically achieve good RNA recovery.

- Proceed with hematoxylin and eosin staining (see Basic Protocol 5).

PREPARATION OF CYTOLOGIC SPECIMENS FOR LCM: DIRECT SMEARS

Cellular elements in body fluids or fine-needle aspirates and cultured cells do not readily lend themselves to sectioning, but can easily be prepared for LCM by making direct smears or cytopsin preparations. The choice as to which to use will depend upon the anticipated cellularity of the sample. Highly cellular samples can be easily and rapidly prepared as direct smears and effectively utilized for LCM, whereas less cellular samples are better concentrated and prepared as cytopsin preparations. To determine if the sample requires concentration, make a direct smear as described below and examine it under the microscope. If the concentration of cells is such that the desired number of cells for LCM can be located in 1 to 4 areas each with a diameter of 0.5 cm (the appropriate diameter of the “cap” used to capture the cells of interest during LCM), the specimen does not require concentration. If however, the concentration of cells is so low that the number of desired cells is not present or the cells are so widely spaced that it will require five or more caps to obtain them, specimen concentration is recommended. For specimens contaminated with undesired blood elements (i.e., red blood cells or white cells that are not intended to be microdissected), use the protocol for cytologic smears or cytopsin preparations containing excessive blood as the contaminant (see Alternate Protocol 1). The same basic caveats apply to cytologic specimens as histologic sections—i.e., ethanol is the preferred fixative (especially for RNA analysis), the cells should never be allowed to dry on the slide prior to fixation, and the fixed and stained cells should be adequately dehydrated prior to LCM.

Materials

- High-cellularity sample: cellular fluid (e.g., fine-needle aspiration, suspended cultured cells) or fresh tissue
- 95% ethanol
- Hemocytometer cover (optional)
- Glass slides, clean
- Scalpel blade (fresh tissue)

BASIC PROTOCOL 3

Discovery of Differentially Expressed Genes

25A.1.5

- 1a. *For cellular fluid:* Place a drop of cellular fluid (i.e., fine-needle aspiration samples or cultured cells suspended in medium), no larger than 5 mm in diameter, towards the label end of a clean glass slide. Quickly utilize the edge of another glass slide, or preferably a hemacytometer cover, to thinly spread the drop (i.e., as if making a blood-smear preparation) on the slide in a single motion, relying on capillary action between the liquid and the two slides to spread the liquid in a uniform, thin-layer across the length and width of the slide. Do not apply excessive force which might result in crushing or shearing of cells.

Plain uncoated, charged, or silanized glass slides can be used.

We prefer to prepare cytologic smears with a hemocytometer cover because its width is slightly less than that of the standard glass microscopic slide and the resulting smear (i.e., cells) is not spread to, or off, the edge of the slide.

- 1b. *For fresh tissue:* Quickly sample by scraping tissue with a scalpel blade and then rapidly spread the scraped sample on a glass slide with the blade.

This is a quick and useful method of specimen preparation for tissues in which the desired cells can be readily identified cytologically, such as highly malignant cells.

2. Immediately after spreading, immerse the smear in 95% ethanol without allowing it to dry. Incubate 10 min.
3. Transfer to 70% ethanol for 30 sec.
4. Proceed to hematoxylin and eosin staining (see Basic Protocol 5).

BASIC PROTOCOL 4

PREPARATION OF CYTOLOGIC SPECIMENS FOR LCM: CYTOSPIN METHOD

Cytospin preparations can be used for any cytologic sample but are preferred for samples of low cellularity. Cytospin instrumentation allows cellular fluids to be simultaneously concentrated and placed on a glass slide. Using centrifugation, these instruments spin cell suspensions onto a microscope slide as the suspension medium is simultaneously absorbed by a blotter. The result is a monolayer of well-preserved well-displayed cells within a 6-mm² area on the slide. Another alternative for samples of low cellularity is to centrifuge the sample, decant the supernatant, and make a direct smear (see Basic Protocol 3) from the sediment. Particularly bloody specimens may benefit from the protocol provided below (see Alternate Protocol 1). To avoid RNA, DNA, or protein degradation, the cytologic samples should be processed and fixed in 95% ethanol shortly after collection. Microdissection after fixation is preferable, particularly for RNA analysis.

Materials

- Low-cellularity sample: fine-needle aspiration or cultured cells suspended in medium
- 95% and 70% ethanol
- Cytospin instrument and appropriate single sample chamber cytospin device (e.g., Shandon/Lipshaw)
- Glass slides, clean

Assemble and load cytospin devices

1. Assemble the sample chamber cytospin device with clean glass slides according to the manufacturer's instructions.

Plain uncoated, charged, or silanized glass slides can be used.

2. Load the assembled collection chamber devices into the support plate of the cytopsin instrument.

They must be secure, freely tiltable, and symmetrically distributed.

Add samples and spin

3. Pipet low-cellularity sample into sample chambers.

The optimal amount of specimen will vary with its cellularity. Samples of low cellularity will require 300 to 400 μ l per chamber; highly cellular samples will require only 100 to 200 μ l per chamber.

4. Press closure cap on each sample chamber.
5. Lock the lid of sealed head and close the cytopsin cover.
6. Program cytopsin for 3 min at 1500 rpm on high acceleration and press start.

Rapidly fix cytopsin

7. When the alarm signaling the end of the spin sounds, quickly remove the assembled collection chambers. Open the chambers and remove the slides by lifting the blotter away from the slide

This method avoids damage of cell membranes and thus smearing.

8. Quickly transfer slide into 95% ethanol without allowing the specimen to dry. Fix 10 min. Transfer slide to 70% ethanol for 30 sec.
9. Proceed to H&E staining (see Basic Protocol 5) or other stain of choice.

REMOVING BLOOD FROM SAMPLES FOR CYTOLOGIC SMEARS OR CYTOSPINS

ALTERNATE PROTOCOL 1

Particularly bloody specimens may benefit from separating red blood cells from other cellular elements, thereby concentrating the desired cells (especially epithelial cells). This can be accomplished by utilizing the Ficoll-Paque density gradient technique described here. The specimen is layered onto an undiluted Ficoll-Paque solution and centrifuged. Differential migration during centrifugation results in the formation of layers enriched in different cell types. This allows extraction of other cells in the sample from red blood cells. This method is not ideal for isolating white blood cells for microdissection as many of them separate with the red blood cells. See the Arcturus Engineering web site (<http://www.arctur.com>) for a protocol for isolating the buffy coat of blood.

Materials

Cytologic sample
Sterile saline (i.e., 0.9% w/v NaCl) or balanced salt solution
Ficoll-Paque (Pharmacia)
50-ml centrifuge tubes

Concentrate cellular components

1. Centrifuge the cytologic sample for 10 min at $350 \times g$, room temperature, in a 50-ml centrifuge tube.
2. Aspirate the supernatant with a pipet.
3. Resuspend the cell "button" in 5 to 10 ml sterile saline or balanced salt solution.

**Discovery of
Differentially
Expressed Genes**

25A.1.7

Separate cellular components

4. Add 20 ml Ficoll-Paque to a clean-50 ml centrifuge tube. Carefully pipet the cell suspension onto the Ficoll-Paque.

It is best not to mix the Ficoll-Paque with the specimen at this point.

5. Centrifuge 10 min at $350 \times g$, room temperature.

After centrifugation, the top and clearest layer contains any epithelial cells and some white blood cells. The middle layer is the Ficoll-Paque and the lowest layer is predominantly red blood cells and white blood cells.

6. Prepare the superficial cell layer as direct smears or cytopins (see Basic Protocols 3 and 4).

HEMATOXYLIN AND EOSIN STAINING

Histologic section and cytologic preparations must be stained so that the component cells can be adequately visualized for accurate identification; hematoxylin and eosin stain is commonly used for this purpose. With this stain, nuclei are black-blue and cell cytoplasm and most extracellular material are varying shades of pink. Although both hematoxylin and eosin staining solutions can be prepared from their basic components, the authors recommend purchasing prepared, ready-to-use stains.

Materials

Sample on a glass slide (see Basic Protocols 1 to 4)

70%, 95%, and 100% ethanol

Sterile, distilled, or RNase free water

Mayer's hematoxylin (Richard-Allan Scientific)

Bluing reagent (Richard-Allan Scientific)

Eosin Y

Xylene

1. *For frozen sections (optional):* Rapidly remove the sample on a glass slide from -80°C storage (see Basic Protocol 1) and immerse in or flood with 70% ethanol without allowing the slide to thaw and dry prior to contact with the ethanol. Allow the ethanol to remain in contact with the tissue for 30 sec.

Deparaffinized fixed sections (see Basic Protocol 2) as well as samples prepared by direct smear or cytopsin (see Basic Protocols 3 and 4) will already be in 70% alcohol and are ready to proceed through the following steps.

2. Allow the slide containing the tissue section to remain in the following solutions for the specified times in the specified sequence:

Sterile, distilled, or RNase-free water	10 sec
Mayer's hematoxylin	10 sec
Sterile, distilled, or RNase-free water	10 sec
Bluing reagent	15 to 30 sec
70% ethanol	15 to 30 sec
Eosin Y	15 to 30 sec
95% ethanol	30 sec
95% ethanol	30 sec
100% ethanol	30 sec
100% ethanol	30 sec to 1 min
Xylene	1 to 5 min

3. Allow the section to air dry completely and proceed to LCM (see Basic Protocol 6 and Alternate Protocol 2).

Poor LCM transfers will result if the tissue section is not fully dehydrated. This may result if the 100% ethanol becomes hydrated after repeated use. One way to check the 100% ethanol for water is to put a small amount into xylene. If there is water present, the xylene will become cloudy. The final xylene rinse also facilitates the efficiency of transfer with LCM. If a tissue section does not transfer well, repeating the dehydration with fresh 100% alcohol and/or a longer xylene rinse may help. While other staining protocols can be used, the slides should be dehydrated with graded alcohols and the final xylene step.

LASER CAPTURE MICRODISSECTION

The described procedure is for the PixCell I or II Laser Capture Microdissection System and assumes a general knowledge of the function of the components of the instrument and the software that accompanies the instrument. The general theory underlying the use of the instrument is discussed elsewhere (see Background Information). The procedure can be divided into three basic steps: slide positioning, microdissecting with the laser, and collecting the microdissected cells. Additional information about the Arcturus LCM software, including capturing and storing images, and additional instruction for LCM, can be found in the instrument users' manual and at the Arcturus Engineering web site (<http://www.arctur.com>), the National Institute of Environmental Health Sciences web site (<http://dir.niehs.nih.gov>), or from Arcturus technical support (650-962-3020).

Materials

- Glass slide with stained specimen (see Basic Protocol 5)
- Appropriate lysis buffer (e.g., DNA lysis buffer, protein lysis buffer; see recipes)
- PixCell I or II Laser Capture Microdissection System (Arcturus Engineering)
- Arcturus LCM software (Arcturus Engineering; optional)
- CapSure transfer film (Arcturus Engineering)
- 0.5-ml microcentrifuge tubes (Eppendorf)

NOTE: Wear gloves when microdissecting to avoid contamination of the LCM specimens. Clean the microscope stage and capping station before beginning the microdissection (e.g., use 95% ethanol wipes), to reduce the possibility of contamination.

Position slide (section) to be microdissected

1. Turn on the PixCell I or II Laser Capture Microdissection System. Open the Arcturus LCM software if it is to be used.

The Arcturus LCM software is not required for LCM as all adjustments of parameters can be made on the laser electronics box; however, it eases the use of the instrument and performs useful functions, such as counting the pulses of the laser ("shots") and allowing the procurement and archiving of images.

2. Place the glass slide with the stained section to be microdissected on the microscope stage. Move the joystick so that it is perpendicular to the tabletop to allow proper placement of the CapSure transfer film ("cap"). Focus the microscope to view the tissue or cells. Locate the area to be microdissected, moving the slide by hand rather than with the joystick, so that the joystick will be in proper alignment when the area to be microdissected is located.

Samples are usually stained in order to be visualized for LCM; however, LCM can be performed successfully without staining, but desired cells may not be identifiable.

The area selected should be located such that a portion of the slide covers the vacuum chuck hole and the slide spans the central hole in the stage.

BASIC PROTOCOL 6

Discovery of Differentially Expressed Genes

25A.1.9

3. Turn on the vacuum slide holder.

IMPORTANT NOTE: *The joystick should now be used to move the slide.*

4. Use the visualizer to more precisely locate the cells to be microdissected.

The light from the microscope will need to be increased when using the visualizer.

The area to be microdissected should be in the field of view.

The sections are not coverslipped; therefore, the area of interest may be difficult to visualize. All models of the PixCell System are equipped with a visualizer which acts to diffuse light and improves resolution; however, the visualizer is engaged differently on different models (see instrument user's guide).

Microdissect with the laser

5. Pick up a cap from the loaded cassette module on the right side of the microscope stage (see instrument users' guide for instructions on loading the caps into the cassette module) with the placement arm. Swing the placement arm toward the caps until the arm overrides the first cap in the cassette module. Ensure that the cassette module is engaged in the proper indent so that the first available cap is aligned with the arrow on the microscope stage. Lift the transport arm until the cap detaches from the base slide in the cassette module.

6. Without lowering the placement arm, swing the arm back toward the tissue section as far as possible, so that the arm is over the tissue. Make sure that the area to be microdissected is still in the microscopic field of view by looking through the microscope eyepieces or at the monitor. Gently lower the arm so that the cap contacts the tissue section.

If there are folds in the tissue, the cap may not make direct contact with the entire surface in the area to be microdissected, and transfer efficiency will be compromised; therefore, it is advisable to inspect the tissue before placing down the cap. If any tissue is mounded or folded, it is best not to place the cap over that area. Alternatively, the area of the tissue with folds can be scrapped off the slide using a sterile razor blade, leaving only flat portions of the tissue section. The tissue section must be dry and cannot be coverslipped for LCM transfer.

7. Enable the laser by turning the key on the laser electronics box and pushing the laser-enable button.

The laser-tracking beam should now be visible on the monitor, as well as the area to be microdissected. If it is not, try lowering the light from the microscope or raising the intensity of the tracking beam. If it is still not visible, check that the laser is enabled and that the joystick is perpendicular.

Avoid passing hands through the path of the laser when it is enabled.

8. Using the 20× objective, adjust the focus of the tissue by moving the slide via the joystick to an area of the slide without tissue. Adjust the laser spot size to 7.5 μm. Lower the light from the microscope until there is a black monitor screen, except for the tracking beam. Turn the laser focusing wheel until the tracking beam is a bright spot with a well-defined edge.

There should be no bright rings surrounding the central spot (Fig. 25A.1.1).

Always focus the laser with the 7.5-μm spot. Each tissue section and slide will need to be refocused. Once the 7.5-μm spot is focused for a particular slide, there is no need to refocus the 15-μm or 30-μm spots, as they are automatically calibrated.

9. Adjust the laser power and pulse duration settings for the particular spot size to be used as provided below:

Figure 25A.1.1 Focusing the Laser Beam. **(A)** Unfocused beam, the spot of light has concentric halos of light. **(B)** Focused beam, the spot of light has a sharp border without halos of light. **(C)** Unfocused beam, the spot of light has a blurred border. A 20 \times objective and 7.5- μm spot size is used in all three pictures.

Spot size	Power	Duration
7.5 μm	40 mW	450 μsec
15 μm	25 mW	1.5 msec
30 μm	20 mW	5 msec

Laser power and duration determine the spot size. The power and duration settings given above should provide a melted area that is similar in size to the tracking beam at each of the three settings, but may require adjustment. See the user's manual for more information.

- While the tracking beam is still located in an area without tissue, fire the laser by clicking the red button on the remote thumb switch to assess the effectiveness of the laser focus and settings.

Effective melting ("wetting") of the polymer on the lower surface of the cap is indicated by a circle with a well defined black outline (see Fig. 25A.1.2).

If the edges of the circle are not well delineated, check to make sure that the tissue section where the cap is placed is flat and refocus the beam. If this fails, increase the power and/or duration gradually and as little as possible (see Troubleshooting).

- Test the effectiveness of LCM in the tissue section by moving the tracking beam to the cells to be microdissected. After targeting the cells, fire the laser. Move the slide

Figure 25A.1.2 Polymer Melting After Laser Firing. **(A)** An adequate and effective melt has a sharp, delineated border. **(B)** The border of an inadequate melt is blurred and indistinct.

with the joystick to another group of cells and fire the laser again. Limit the number of pulses for this test to two or three.

The delineation of the circle may be more difficult to visualize on the tissue section, but the tissue in an area of proper “wetting” should become more sharply focused because the melted polymer acts as a coverslip. Lift the placement arm and inspect the area in which the laser was fired for removal of cells (see before and after photomicrographs in Fig. 25A.1.3).

If the LCM was successful, the area where the polymer was melted should no longer be occupied by tissue and should be empty, although a small amount of cellular and stromal material may remain. The great majority of the tissue that occupied those spots should now be attached to the cap. This can be checked by releasing the vacuum slide holder, moving the slide so that a clean area without tissue is in the microscopic field of view, lowering the cap to the slide, and scanning the surface of the cap. The microdissected tissue should be visible on the cap surface. If this is not the case, there are several explanations and potential remedies (see Troubleshooting).

Avoid lifting and lowering the cap repeatedly after firing the laser and capturing some tissue. It is difficult to replace the captured tissue in the exact spot from which it came. Consequently the captured tissue, and tissue that may nonspecifically stick to the cap, will be placed on the histologic section, resulting in a layering effect which can limit contact of the cap with the tissue and compromise the effectiveness of LCM; therefore, limit the number of shots used to test the adequacy of capture, and, if the test capture is successful, avoid lifting the cap again until the microdissection is complete.

Dense, dark or thick samples may occlude the tracking beam. If this occurs, increase the intensity of the tracking beam.

12. Once LCM is achieved successfully with the test pulses, proceed to microdissect the remainder of the desired cells.

Collect microdissected cells

13. After completing the intended microdissection, lift the placement arm. Assess the completeness of the capture by inspecting the microdissected tissue and the cap as described above.

Figure 25A.1.3 LCM of ductal carcinoma in situ. (A) The area of ductal carcinoma in situ prior to LCM. (B) The same focus after LCM. (C) The microdissected focus on the transfer film (cap).

14. Swing the placement arm with the cap towards the right to the unload platform and place the cap in the designated slot. Move the placement arm, without lifting it, to the left and place in a resting position.
15. Using the cap insertion tool, pick up the cap from the unload platform by sliding the insertion tool along the guide rail until the cap is engaged in the tool. Remove the cap from the unload platform by lifting the insertion tool.

The open end of the insertion tool should face the cap.

Because tissue and cells that were not selected for capture may nonspecifically stick to the surface of the cap, it is important to remove this unwanted tissue. This can be accomplished by using the CapSure Pads (Arcturus Engineering), which have a sticky surface. If using the CapSure Pad, place the pad on the microscope stage in the path of the placement arm prior to placing the cap on the unload platform. Move the placement arm over the pad, lower the cap, and raise the pad to contact the cap. Raise the placement arm and the cap while holding the pad in place with your hand. A less costly alternative to the CapSure Pad is to use the sticky surface of Post-It Notes (3M). The Post-It Notes can be used after the cap has been removed from the unload platform. Peel a fresh Post-It Note off the pad and lower the cap, loaded into the insertion tool, to contact the sticky surface of the Post-It Note. Repeat this 2 to 3 times.

16. Using the insertion tool, insert the cap into a 0.5-ml microcentrifuge tube containing an appropriate amount of lysis buffer (e.g., DNA or protein lysis buffer), usually between 50 and 100 μ l. Press down firmly and rotate the insertion tool to ensure an even seal.

The choice of lysis or digestion buffers is dependent on the analyte and the method of analysis. The recipes supplied in this unit (see Reagents and Solutions) provide examples of lysis buffers for DNA and protein that can be used for LCM samples. Other buffer recipes can be found in many of the references provided and at the BioProtocol web site (<http://www.bioprotocol.com>); however, it is best to customize the buffer to the methodology of the specific laboratory. The authors prefer to use Trizol (Life Technologies) or Stat-60 (Tel-Test) for cell lysis and RNA stabilization prior to RNA extraction and have not provided a recipe for an RNA lysis buffer; however, other buffers containing guanidine thiocyanate and 2-mercaptoethanol can also be used.

The caps fit well in standard 0.5-ml microcentrifuge tubes. When properly seated, the cap does not sit down fully in the tube, but should be seated evenly. Capped tubes will leak if the cap is pushed all the way down into the tube so that the top portion of the cap touches the lip of the microcentrifuge tube.

17. Invert the tube so that the lysis buffer contacts the cap surface. Flick the tube to move the lysis buffer to the cap surface, if necessary.

Place on ice or refrigerate until the microdissection session is over, if this will help to preserve the analyte in the chosen lysis buffer. This sample is now ready to be processed by appropriate methods for the analyte of interest.

ALTERNATE PROTOCOL 2

LASER CAPTURE MICRODISSECTION OF SINGLE OR A SMALL NUMBER OF CELLS

Arcturus Engineering has developed a line of related consumables that are specially designed for high-sensitivity capture and extraction of a single cell or a minimal number of cells. There are three key components of the system: a preparation strip that flattens the tissue section and removes loose debris, the high-sensitivity transfer cap (HS cap) that keeps the tissue surface area adjacent to the cells being captured out of contact with the sample, and a low-volume reaction chamber that fits onto the high-sensitivity transfer caps and accepts a low volume of lysis or digestion buffer while sealing out any nonselected material from the captured cells. The HS cap has a raised ridge on the contact surface so that only the ridge actually touches the tissue section. The surface coated with polymer only contacts the tissue in the area in which the laser is fired; thus, contamination by unwanted tissue is greatly reduced.

The basic steps of LCM as described (see Basic Protocol 6) are applicable to the use of the high-sensitivity consumables, with a few modifications. The modifications to the standard LCM protocol are described briefly below. These products can be purchased as a kit from Arcturus Engineering, which includes detailed instructions on their use.

Additional Materials (also see Basic Protocol 6)

- Preparation strips (Prep Strips; Arcturus Engineering)
- High-sensitivity transfer film (HS CapSure; Arcturus Engineering)
- Tweezers, clean
- Alignment tray designed for use with the high-sensitivity system
- Low-volume reaction chamber (ExtracSure; Arcturus Engineering)

NOTE: All pipetting steps should be performed using filtered aerosol-resistant pipet tips.

Position slide

1. Prior to placing the stained sample on the glass slide on the microscope stage, apply a preparation strip (Prep Strip) to the tissue section or sample to flatten the tissue and remove loose debris.

2. Position the slide as described in the basic LCM protocol (see Basic Protocol 6, steps 1 to 4).

Microdissect

3. Pick up a high-sensitivity transfer film (HS cap; e.g., HS CapSure) from the loaded cassette module on the right side of the microscope stage (see instrument user's guide for instructions on loading the caps into the cassette module) with the placement arm and position the HS cap on the tissue to be microdissected. Enable and focus the laser as previously described (see Basic Protocol 6, steps 5 to 8).
4. Begin at a starting power of 75 mW and a pulse duration of 1 msec and make adjustments to the spot size by changing the duration setting rather than the power.

These settings are those recommended for high-sensitivity LCM.

For the smallest spot size, keep the duration and power settings low but pulse multiple times at the same target to ensure capture and transfer.

The laser activates the transfer film, which then expands down into contact with the tissue. It is preferable to capture cells as close to the center of the cap as possible. Unlike basic LCM using the standard caps, the HS caps can be repositioned as often as needed to keep the targets toward the center of the cap, because the cap surface does not contact the tissue except at the area that the laser is fired. It is important to stay within the capture ring because areas outside the ring will be excluded from the low volume reaction tube.

5. Test the effectiveness as described (Basic Protocol 6, step 11).

Collect microdissected cells

6. After completing the intended microdissection, place the HS cap on the unload platform and pick up the HS cap with the cap insertion tool.
7. Remove the HS cap from the insertion tool using clean tweezers and place the HS cap into the alignment tray so that the captured sample is facing up.
8. Using clean tweezers, position the specialized low-volume reaction chamber over the cap.

The chamber has a port for insertion of the appropriate lysis buffer (e.g., DNA or protein lysis buffer), which should be facing up.
9. Push the chamber down onto the cap until it snaps into place.
10. Pipet 10 μ l desired buffer into the fill port. Cover the port with a 0.5-ml microcentrifuge tube or thin-walled PCR tube and press down to fit securely.
11. Proceed to extraction and analysis of the desired analyte.

TISSUE FIXATION AND PARAFFIN-EMBEDDING

If the researcher can choose a fixative, one which is alcohol based (e.g., 70% ethanol) is preferable for nucleic acid and protein recovery, and provides adequate morphologic detail for most LCM uses; however, alcohol-based fixatives have been reputed to confer a shrinkage artifact in histologic sections that is undesirable to diagnostic pathologists, as it results in tissue that is difficult to section and, at low dilutions, is inadequate for long-term storage of tissues (Vardaxis et al., 1997). On the other hand, Bostwick et al. (1994) successfully utilized an alcohol-based fixative in their pathology laboratory for one year without reporting these difficulties. Fixed tissue is typically embedded in paraffin to stiffen it so that thin histologic sections can be cut. Most paraffin used in pathology laboratories melts at $\sim 60^{\circ}\text{C}$, which may accelerate formaldehyde reactions and damage RNA, DNA, and proteins; therefore, waxes or paraffins that have a lower melting point can be used, but they make softer tissue blocks that are more difficult to cut and may

SUPPORT PROTOCOL

**Discovery of
Differentially
Expressed Genes**

25A.1.15

require refrigerated storage. Tissue processing, embedding, and sectioning are generally performed in a histology laboratory by histotechnologists and generally require some degree of training and skill. The processing steps provided are suggested for utilization by histology laboratories processing tissue for LCM (<http://www.arctur.com>); however, other processing sequences may also provide good LCM results.

Materials

Fresh tissue
Fixative of choice (e.g., 70% ethanol)
Neutral buffered formalin (NBF; Richard-Allan Scientific)
70%, 80%, 95% and 100% ethanol
Xylene
Embedding paraffin

Tissue cassettes
Automated tissue processor
Embedding mold (Tissue-Tek)
Embedding center (optional; Leica)

Fix tissue

1. Place fresh tissue in a volume of fixative that is $\geq 10\times$ the tissue volume, so that the fixative surrounds the tissue on all sides.

Unfixed tissue that floats should be covered by a layer of gauze or paper towel to ensure the tissue is under the fixative. Fixation can be carried out at room temperature or 4°C.

Fixation at 4°C slows down the autolytic process and can be useful for larger specimens.

2. Fix the tissue for an appropriate amount of time.

The time required for fixation is dependent on the size of the tissue and the speed with which the fixative penetrates the tissue. Formalin and 95% ethanol penetrate at a rate of ~ 1 mm/hr. Fixation time and tissue size should be adjusted as necessary.

For any fixative used, a fixing period of 16 to 24 hr is recommended to provide complete tissue fixation; however, a fixation period of < 6 hr provides better recovery of DNA than longer fixation times (<http://www.arctur.com>).

3. *Optional:* Trim tissue sections from larger fresh or fixed tissue specimens so that they are no more than 3 mm in thickness and no larger than the dimensions of the cassette used for tissue processing. Place one section in each cassette.

Again, 1-cm maximum dimension is ideal.

Process and embed tissue

4. After the tissue sections in the cassettes are fixed, place the cassettes in the first station of an automated tissue processor. Program and load the processor.

- 5a. *For routine overnight processing:* Perform the steps in Table 25A.1.1.

After processing, the tissue will be infiltrated with paraffin.

- 5b. *For accelerated processing:* Follow the steps in Table 25A.1.2.

No difference has been found in the LCM transfer efficiency of tissues processed either way.

6. Remove the tissue from the original cassette and embed the paraffin-infiltrated tissue in additional melted paraffin in an embedding mold. Allow to cool and harden.
7. Adhere the paraffin block to a cutting platform (chuck) and remove the paraffin block from the embedding mold. The paraffin block is now ready for sectioning (see Basic Protocol 2).

Also see Sheehan and Hrapchak (1987b).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

DNA lysis buffer

10 mM Tris·Cl, pH 8.0 (APPENDIX 2)

0.2% (v/v) Tween 20

100 µg/ml proteinase K

The authors use this lysis buffer for samples intended for PCR. Arcturus Engineering offers DNA extraction kits that were developed specifically for LCM specimens. The proteinase K should be stored at -20°C in aliquots, while the Tris·Cl and Tween 20 can be stored at -4°C . Once the proteinase K is thawed and added, the buffer should be used immediately.

**Discovery of
Differentially
Expressed Genes**

25A.1.17

Protein lysis buffer

10 mM Tris-Cl, pH 7.4 (APPENDIX 2)
0.1% Triton X-100
1.5 mM EDTA
10% (v/v) glycerol
Store several months at -4°C

This lysis buffer has been found to be useful for analysis of membrane-bound proteins (Simone et al., 2000). For cytoplasmic proteins, "T-Per" tissue protein extraction liquid reagent (Pierce Chemical) has been recommended (Simone et al., 2000). It has also been suggested that the addition of protease inhibitors, such as 4-(2-aminoethyl)-benzenesulfonyl fluoride (Boehringer Mannheim) to the buffer increases the yield of protein (Banks et al., 1999; Ornstein et al., 2000a).

COMMENTARY

Background Information

Technologic advances in gene sequencing and amplification techniques are allowing the identification of alterations in genes, proteins, and biochemicals that can explain the etiology and pathogenesis of many disease processes; however, the efficacy of these technologies depends on the identity and the purity of the cells being analyzed. Physical homogenization of tissues results in a mixture of many cell types—i.e., some are normal or minimally altered components, while others may be significantly diseased. Alterations detected in such homogenates cannot be localized to a particular cell type. Multiple mechanical methods for separating cells of interest from tissues have been described, especially as related to histologic sections (Sirivatanauksorn et al., 1999), but their methodology is time-consuming, extremely labor-intensive, and often imprecise. Laser Capture Microdissection (LCM) is one of the new generation of microdissection techniques that is relatively quick and precise.

LCM was conceived and first developed as a prototype research tool at the National Institute of Child Health and Human Development (NICHD) and the National Cancer Institute (NCI) of the National Institutes of Health (NIH). Arcturus Engineering and the NIH, working through a Cooperative Research and Development Agreement, developed LCM into a commercial laboratory instrument that is now utilized in many research laboratories. Other efficient microdissection techniques, such as laser pressure catapulting, have also been described (Bohm et al., 1997; Sirivatanauksorn et al., 1999).

With LCM, cells of interest are dissected from tissue sections or cytologic samples after microscopic identification with the aid of an ethylene vinyl acetate transfer film containing

a near-infrared absorbing dye. The transfer film coats a flat surface of an optically clear plastic cylinder, the "cap," with a diameter of 6 mm. The LCM system places the transfer film in contact with a histologic section and then directs an invisible infrared laser pulse onto the overlying polymer. The laser pulse is absorbed by and melts the transfer film causing it to flow around the targeted cells. The polymer rapidly cools and creates a bond between the transfer film and the targeted cells. The targeted cells can then be lifted from the section and utilized for RNA, DNA, or protein analysis (Fig. 25A.1.4). This targeting and capturing can be repeated many times on the same tissue section or cytologic sample. The temperature rise in the tissue created by the laser is limited to 90°C (Suarez-Quian et al., 1999) and is transient, lasting only a few milliseconds. Experimental results indicate that DNA, mRNA, and proteins are not degraded by the LCM process (Goldsworthy et al., 1999; Suarez-Quian et al., 1999).

Critical Parameters

LCM can be performed on solid tissues that have been either frozen or fixed under specified conditions, cytologic smears, or cytopsin preparations derived from animals or patient samples. The choice of specimen type depends on the type of tissue or cytologic specimen that is available, the physiologic or pathologic condition to be investigated, and the molecule to be analyzed (i.e., DNA, RNA, or protein). Solid tissues are typically sectioned for histologic examination, whereas cells from blood or cytologic samples, such as fine-needle aspirates, are prepared as direct smears or cytopsin. Frozen tissues have the benefit of being processed more rapidly for LCM than fixed tissue and are considered to be the most reliable source for

Figure 25A.1.4 LCM Instrument. Schematic of the operation of the PixCell Laser Capture Microdissection Instrument, indicating the location of the transfer arm, transfer film (“cap”), and the glass slide with the specimen to be microdissected. Also shown is a cross-section of the tissue specimen with overlying cap demonstrating the effect of laser firing. Reprinted with permission from Bonner et al. (1997).

molecular (i.e., DNA, RNA, and protein) recovery. Lengths of RNA and DNA of up to 800 base pairs have been recovered from sections prepared from frozen tissue (<http://www.arctur.com>; Dietmaier et al., 1999; Shibutani et al., 2000); however, histologic and cytologic detail are poor compared to fixed paraffin-embedded tissue and subtle diagnostic features may be difficult to discern. The most frequently utilized tissue fixative is neutral buffered formalin (NBF; i.e., 10% buffered formaldehyde) followed by paraffin embedding to allow histologic sectioning. This combination results in cross-linking and “breakage” of proteins, RNA, and DNA, which must be considered when utilizing tissues prepared in this manner.

Regardless of the preparation, cells or tissue are usually stained in order to be visualized for

LCM, although LCM can be performed successfully without staining. Hematoxylin and eosin (H&E) stain is the most commonly used stain for examination of histologic sections, and diagnostic histopathologic criteria are based on its use in veterinary and human pathology practice; therefore, it is frequently used for LCM even though hematoxylin may bind to nucleic acids causing adverse effects during PCR. Other stains such as methyl green and nuclear fast red have been recommended as alternatives, and literally hundreds of others exist in clinical practice and for research applications (Ohyama et al., 2000); however, H&E stained LCM samples have recently been shown to amplify equally as well as samples stained with methyl green, toluidine blue O, or azure B (Ehrig et al., 2001). This is likely due to the relatively small size of LCM samples,

which thus contributes only a small amount of hematoxylin to the PCR reaction mix. It is also recommended that the duration of staining with hematoxylin be minimized to decrease the concentration present. Eosin has been reported to interfere with PCR analysis utilizing the TaqMan instrument and can appear on electrophoretic gels when relatively large numbers of cells are captured for protein analysis (Banks et al., 1999; Ehrig et al., 2001). Consideration should be given to minimizing or eliminating its use when samples will be utilized for either of these assays. Specimens can also be stained immunohistochemically or with fluorescent labels prior to microdissection (Fend et al., 1999b; Murakami et al., 2000).

There are two alternative methods for specimen staining. One is to place the staining solutions into either Coplin jars or staining dishes and immerse the slides in the appropriate solutions. If this method is used, the stains should be changed frequently to prevent contamination by tissue fragments from other tissue samples or microorganisms found in the environment, and to avoid excessive dilution of the staining solutions. The second alternative, and the one that the authors prefer, is to keep the solutions in clean plastic squirt bottles and use a slide staining rack. The slide to be stained can then be placed on the staining rack and the solutions can be applied gently to the slide to cover the tissue or cells, allowed to remain the appropriate time, and then drained from the slide and replaced by the next solution. This reduces any possible contamination, minimizes dilution of solutions, and has the added advantage of using less reagents. For solutions requiring a duration of contact with the slide that is longer than 1 min (i.e., xylene), we utilize small Coplin jars. Thus, the best features of both systems may be used efficiently.

For a successful LCM transfer, the polymer film must be bonded to the targeted tissue so it forms a stronger bond than that between the tissue and the underlying glass slide; therefore, proper sample preparation is critical. It is important that the sample be well dehydrated so that the melted polymer can infiltrate intercellular spaces and create a tight bond. The final dehydration and xylene steps have been found to be absolutely crucial for successful LCM. Any moisture present in the sample during LCM will give less than optimal results. Ideally, samples should be microdissected shortly after dehydration; however, samples can be stored with desiccant after staining and dehydrated for later microdissection, although this is not rec-

ommended for recovery of RNA because of its lability. Additionally, the humidity in the laboratory will also affect the results, and protocols may need to be modified accordingly. Other factors that will affect this bond are presented below (see Troubleshooting).

Specimens, reagents, and materials for processing must be handled in a manner that will allow optimal preservation of the molecule to be analyzed; therefore, samples for RNA and DNA should be handled to minimize contamination from other tissues. Samples for RNA analysis should be processed rapidly, either as fresh-frozen material or briefly fixed in 95% ethanol. RNase-free reagents and materials should be utilized whenever possible. Also, the duration of the actual microdissection session on each stained frozen section should be limited to less than 30 min for optimal RNA preservation. Samples for protein analysis are also best processed as for RNA analysis, but reagents that include protease inhibitors can be used. DNA is more stable, and fixed or frozen tissues can be used, but samples should not be over-fixed in formalin, as DNA yield increases with prolonged fixation times (<6 hr is preferable for small samples).

Troubleshooting

If LCM fails to capture the cells (i.e., they are not released from the slide), the following steps are recommended.

1. Refocus the beam (see Basic Protocol 6).
2. Make sure the sections are flat. Wrinkles can be shaved off using sterile razor blades. Dip the section in xylene after saving the wrinkles to make sure that no contaminating debris remains on the section.
3. Change the cap. Not all caps perform equally well and the age of the caps is important. It is best not to use expired caps and to buy relatively small numbers of caps at a time so that the stock is relatively new.
4. Ensure thorough dehydration of the specimen. Place the slides in fresh xylene for 1 min or more and allow drying in a biologic safety hood for 1 to 5 min. If LCM is still not successful, pass the slides through 95% ethanol twice for 30 sec, absolute ethanol twice for 30 sec, and xylene for 1 to 5 min.
5. Process a new section and make sure that the frozen sections or cytologic specimens have not been allowed to dry on the slide prior to fixation. For formalin-fixed sections, do not bake or at least decrease the baking time.
6. Try a different brand or type of glass slide.

7. If still not successful, call the technical support at Acturus Engineering (650-962-3020). The authors also find that talking with other researchers working with LCM to be very useful.

If LCM is successful, but the cap contains contaminating debris, the following measures are recommended.

1. Make sure the slide is free of debris. It may be necessary to wash the slide in fresh changes of xylene.

2. Use a CapSure Pad or Post-It Note to remove any debris from the cap.

3. Use HS caps, which minimize contamination.

If the LCM was successful, but no RNA, DNA, or protein was identified at analysis, try the following.

1. Make sure optimum laboratory practices and conditions that are free of nucleases or proteinases have been observed.

2. Check the cap to see if the microdissected tissue has dissolved in the lysis buffer in the microcentrifuge tube.

3. Increase the number of microdissected cells.

4. An overnight incubation at 37°C can be used to lyse the cells from the cap when using DNA lysis solutions, if required. For RNA and proteins, inverting and gentle agitation should be used to dislodge the cells from the cap.

Anticipated Results

Many molecular analyses have been successfully performed on cells procured by LCM. These include genomic analyses such as loss of heterozygosity analysis, restriction fragment length polymorphism (RFLP) analysis, DNA methylation analysis, fluorescence in situ hybridization, and comparative genomic hybridization (Finkelstein et al., 1999; Guan et al., 1999; DiFrancesco et al., 2000; Jones et al., 2000; Shen et al., 2000; Slebos et al., 2000). Gene expression analysis has been accomplished from LCM samples utilizing reverse transcription PCR, construction of cDNA libraries, and differential hybridization on high-density-spotted nylon filters or glass microarrays (Peterson et al., 1998; Fend et al., 1999b; Kuecker et al., 1999; Luo et al., 1999; Sgroi et al., 1999; Garrett et al., 2000; Leethanakul et al., 2000; Ohyama et al., 2000). Successful proteomic analysis has been accomplished by coupling LCM with immunoblotting (UNIT 10.8), solid-phase sequential chemiluminescent immunometric assay, one-dimensional and two-dimensional polyacrylamide gel electrophore-

sis (PAGE; UNITS 10.2-10.4), protein chip surface enhanced laser desorption/ionization (SELDI) mass spectrometry, as well as matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry (Wright et al., 1999; Natkunam et al., 2000; Ohyama et al., 2000; Ornstein et al., 2000a,b; Palmer-Toy et al., 2000; Simone et al., 2000; also see UNIT 10.21). For all these assays, the expected results will depend on the quality of preservation of the analyte of interest within the sample and upon procurement of at least the minimum number of cells required for analysis.

The number of cells captured depends on tissue thickness and type, the size of the cells, and the size of the laser spot. The number of cells procured can be estimated by counting the number of cells per spot and multiplying by the number of pulses of the laser. The transfer efficiency of the capture should also be considered and can be assessed by viewing the captured tissue on the cap and estimating the percentage of spots that contain tissue.

The number of cells required depends on the assay and whether formalin-fixed, alcohol-fixed, or frozen samples are used. A single PCR reaction (DNA analysis) can be successfully performed with a single cell; however, results are more reliable with at least 10 to 20 cells from a 10- μ m-thick, formalin-fixed, paraffin-embedded section. Such small quantities of cells may not account for the significant heterogeneity that exists even within populations of the same cell type, which should be considered when determining the number of cells to be used. For RNA analysis, fresh-frozen tissues and cytologic specimens briefly fixed in alcohol are preferred. Only a small number of cells (i.e., <50) may be required for transcripts of high copy number per cell when utilizing RT-PCR; however, the authors prefer using ≥ 1000 cells for RT-PCR. cDNA arrays require significantly more RNA, but how much will depend on the type and size of array. It is estimated that a typical mammalian cell contains ~ 20 pg total RNA/cell; therefore, to achieve 5 μ g RNA, the lower limit for some expression arrays, will require the microdissection of 2.5×10^{11} cells, a daunting task. Thus, some authors have advocated amplification of RNA or resultant cDNA prior to hybridization with these larger arrays, even though this may introduce some degree of amplification bias (Luo et al., 1999; Ohyama et al., 2000). For protein analysis, using 50,000 cells for two-dimensional PAGE analysis has been a successful starting point. For western blot analysis, the number of cells

required is at least 2000 to 3000 (<http://www.arctur.com>). Some molecular assays may require modification in order to accommodate the relatively small amount of cells obtained by LCM.

Time Considerations

The time required for LCM is highly variable and depends on the method of tissue processing and staining, the number of cells to be microdissected, and the location and number of the desired cells in each section. H&E staining (see Basic Protocol 5) requires only 10 to 15 min. Microdissecting ~5000 cells, roughly equal to 1000 shots using a 30- μ m spot size, will require 15 to 30 min, provided all the cells required are present within a single tissue section or sample. If multiple sections or samples are required to procure an adequate number of cells, the time required for staining additional sections should be added. This also assumes that the samples are well prepared and microdissected efficiently, and that the cells of interest are easy to identify and locate. Some skill is also required in operating the joystick in combination with laser firing and in being able to identify the tissue and cell type of interest.

The time required for lysis of the cells from the cap depends on the buffer and the method of sample preparation. We have found frozen tissue will be completely removed from the cap by Stat-60 after ~5 min. Formalin-fixed paraffin-embedded tissue in buffers containing proteinase K requires significantly more time and may require an overnight incubation at 37°C.

Preparation of Single Cells from Solid Tissues for Analysis by PCR

The ability to amplify a few copies of DNA or RNA to analyzable quantities makes it technically possible to obtain detailed information regarding the DNA content and/or transcriptional pattern of a single cell (Mullis and Falona, 1987). Although in many cases, analysis at the level of the whole tissue can provide the required information, there are circumstances that necessitate acquiring data on individual cells of a particular type. A preparation of total DNA and RNA isolated from a tissue gives quantitative data but only an average profile, masking differences among individual cells. In situ analysis provides qualitative information on localization of abundant nucleic acids in specific cells, but is generally not quantitative. Thus, it can be desirable to apply quantitative assays to individual cells.

The acquisition of individual cells from blood and loosely associated tissues such as spleen is straightforward, since these organs are essentially cell suspensions. Solid tissues, however, are almost universally composed of tightly linked cells of multiple types, organized in a highly structured and functionally interactive manner (Gilbert, 1994). It is reasonable to expect that disruption of this environmental context rapidly alters the physiology of the once-partnered cells. Even in the case of easily dissociated tissues, the impact of manipulating the living tissue on the process under study must be considered. In addition, some adult cell types, most notably neurons, can be recovered only at low efficiency, with the majority bursting during the process (Pretlow and Pretlow, 1982).

This unit details a protocol for the separation of solid tissues into single-cell suspensions for subsequent analysis of nucleic acids and protein. This protocol was developed using mice, with the major focus being the analysis of the interaction of herpes simplex virus (HSV) with the neurons of the trigeminal ganglia (Sawtell, 1997). The balance between fixation and dissociation should be determined for the particular tissue of interest. It has been determined, however, that the dissociation protocol is directly useful for several other mouse tissues including liver, heart, skeletal muscle, lung, pancreas, brain, intestine, and reproductive organs. Kidney yields a combination of single cells and multicellular tubular structures. The adaptation of the method to other laboratory animals has not been fully explored. Again, the appropriate balance between fixation and dissociation would need to be determined for other species of interest. Using the approach of adjusting the volume of the fixative perfused through the animal to achieve this balance, the author's laboratory has determined that the method is directly useful for guinea pigs.

Tissues are fixed in situ by perfusion (see Basic Protocol 1), terminating cell processes and thus changes that would accompany dissociating the living tissue; their numbers can then be quantitated (see Support Protocol). Once separated, individual cells or groups of a particular cell type can then be analyzed using PCR strategies (see Basic Protocols 2 and 3; Fig. 25A.2.1). An alternative to fixing by perfusion (see Alternate Protocol 1) and a modification of the standard Percoll gradient separation to prepare *lacZ* expressing cells (see Alternate Protocol 2) are also provided. The method has broad potential and is particularly potent when the cell type of interest represents a minor population relative to other cells types in the tissue. The procedure can also be adapted to allow quantification of the number of cells within a tissue containing specific nucleic acid sequences, for example, a particular viral DNA or RNA sequence.

25A.2.1

Supplement 58

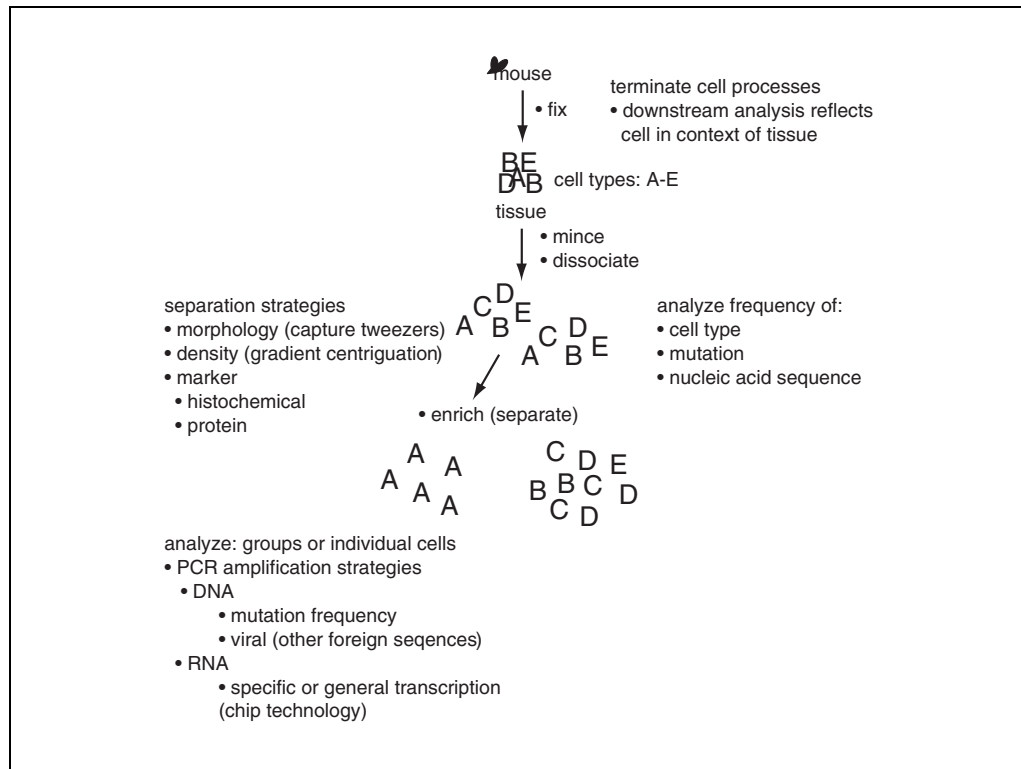

Figure 25A.2.1 Schematic representation of the preparation of single cells from solid tissue. Tissue is represented by the box in the center, and letters A to E represent different cell types within that tissue.

BASIC PROTOCOL 1

PERFUSION FIXATION AND ENRICHMENT OF SINGLE CELLS

In this protocol, the animal (here, a mouse) is perfused with Streck tissue fixative (STF), a noncrosslinking fixative. This fixative and the fixation conditions presented were determined empirically so that intracellular nucleic acids and proteins are preserved without interfering significantly with the ability of the dissociating enzymes to free the cells from the extracellular matrix. The fixed tissues of interest are dissected out, finely minced, and enzymatically separated using collagenase. The cell types of interest are then enriched using a suitable strategy.

At this point, any of a number of methods can be used to harvest the desired cell populations from the cell suspension. Percoll gradient separation is given here; however, the end application will strongly influence the procedure selected.

Materials

- Streck tissue fixative (STF; Streck Laboratories)
- Animal (e.g., mouse)
- Sodium pentobarbital
- 95% ethanol
- 0.25% (w/v) collagenase CLS I (Worthington) in Hank's balanced salt solution (HBSS; see recipe)
- Triple 0.2- μ m filtered nanopure (3 \times F) H₂O
- Percoll (Pharmacia): adjust to pH 6.0 with HCl
- Peristaltic pump (BRL CP-600 or equivalent) and appropriate tubing
- 15- and 50-ml conical tubes
- 27-G needle
- 80°C water bath

Dissecting microscope (optional)
Clean dissection tools (e.g., forceps, scalpel blades, hemostat, 25-G needles)
Glass slides: bake overnight (3 hr minimum) at 250°C
200- and 1000- μ l aerosol-resistant pipette tips
15-ml polystyrene conical tubes
9-in. Pasteur pipettes: bake overnight (3 hr minimum) at 250°C

Additional reagents and equipment for determining number of neurons recovered (see Support Protocol), and analyzing DNA or RNA from single-cell populations (see Basic Protocols 2 and 3)

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

NOTE: Depending upon the final application of the cells, all materials must be DNase- and RNase-free, and free of contaminating nucleic acids which could interfere with the interpretation of downstream PCR.

Perform perfusion fixation (as performed in mice)

1. Set up perfusion equipment by placing tubing from a peristaltic pump in the bottom of a ~50 ml conical tube containing 30- to 40-ml Streck tissue fixative (STF). Attach a 27-G needle to the other end (this will be inserted into the left ventricle). Run fixative through the line.
2. Place a 50-ml conical tube containing 50 ml STF in an 80°C water bath and equilibrate to temperature.

Heat facilitates the inactivation of nucleases.

3. While the fixative is heating, anesthetize the animal by intraperitoneal injection of 80 to 100 mg/kg sodium pentobarbital. As soon as deep reflexes are fully deadened—i.e., in mice, lack of corneal reflexes (i.e., no blinking response when touched with the tip of a gloved finger) and response to pinching rear paw very firmly—place the animal ventral surface up on absorbent paper and wet the chest and abdomen with 95% ethanol.

Isoflurane can be used as an alternative anesthetic.

4. Use forceps to lift the skin and, using a scalpel, make a T-shaped incision starting over the abdomen with the vertical- and horizontal-cut centers at the base of the sternum just below the diaphragm. Cut the diaphragm along the rib line and keep the chest cavity open by clamping the base of sternum with a small hemostat, rotating it upward toward the chest.

For additional information on animal handling, see Coligan et al. (2001), Chapter 1.

5. Insert the needle at the end of the pump tubing into the left ventricle and start the pump, adjusting the flow rate to ~6 ml/min. When the right atrium becomes dilated, pierce with sharp pointed forceps to provide outflow. First pump 15 to 20 ml room-temperature STF through the animal to remove blood from the vasculature, followed by 40 to 50 ml heated (80°C) fixative. Stop the pump when fixative has been depleted.

This procedure is not difficult but requires practice. The best indicator of a successful perfusion is paling of the liver. If the liver does not begin to pale rapidly, try repositioning the needle in the ventricle, adjusting its depth and angle.

Perfusion fixation is effective because the fixative is distributed to tissues and cells via the macro- and microvasculature. Coagulation of the blood in the vessels could occur upon contact with the heated fixative, thus it is important to first remove blood with room-temperature STF.

Dissociate tissue

6. Using a dissecting microscope (if possible), dissect the tissues of interest with “clean” dissection tools and finely mince on a nuclease-free (i.e., baked) glass slide using scalpel blades or needles (e.g., 25-G needles for ganglia).

The author uses disposable instruments (e.g., unused 25-G needles, unused scalpel blades) that are discarded after use (i.e., a single dissection), which prevents the possibility of any carryover; however, it should be adequate to clean instruments in detergent (e.g., liquinox), rinse, and soak in 3% hydrogen peroxide for 2 hr, then rinse in 3×F H₂O and bake overnight (3 hr minimum) at 250°C. Any procedure for cleaning potentially contaminated instruments should be confirmed to be effective.

Visualization of the mincing procedure under a dissecting microscope is helpful. Separate instruments must be used for each tissue unit if cross contamination will present a problem in the interpretation of downstream analyses.

7. Place minced tissue into 0.25% (w/v) collagenase CLS I in HBSS and incubate in a 1.5- or 2-ml microcentrifuge tube 5 to 10 min at 37°C.

The volume of collagenase used will depend upon the amount of tissue. Six fixed mouse trigeminal ganglia (TG) are routinely digested in 1.5 ml collagenase.

The investigator must screen batches of collagenase and select a batch that is free of DNase activity. If RNA will be analyzed, a batch free of RNase must be selected (see Critical Parameters and Troubleshooting, Collagenase)

8. After collagenase treatment, facilitate dissociation by gentle trituration, first using 1000- μ l, then 200- μ l (as the tissue dissociates into smaller pieces) aerosol-resistant pipet tips.

In the author's studies, dissociation of TG is generally complete within 30 min.

Depending on the application, the requirement for complete dissociation may be less critical. It is helpful to monitor progress of dissociation by viewing a drop of the suspension under the microscope.

9. Pellet dissociated tissue by microcentrifuging 5 min at 5000 rpm, room temperature. Resuspend gently in STF at room temperature. Heat resuspended cell suspension to 70°C for 10 min. Place on ice briefly, repellet, and resuspend in triple 0.2- μ m filtered nanopure (3×F) water.

At this point the integrity of the DNA, RNA, and/or protein (depending upon what will be analyzed), should be tested. DNA can be isolated using standard proteinase K/SDS digestion followed by phenol/chloroform extractions and ethanol precipitation (UNIT 2.1A). RNA can be isolated from the cells using commercially available reagents such as Ultraspec (Biotecx). When isolating RNA, cells should be homogenized using a tissue grinder to ensure complete disruption of the cell membrane. Protein should be prepared from cells by boiling in standard Laemmli cocktail (e.g., 0.125 M Tris·Cl/4% SDS/20% glycerol/10% 2-mercaptoethanol). Integrity of nucleic acid or protein is then determined by appropriate gel electrophoresis (Chapter 10). If information about the integrity of a specific nucleic acid or protein is desired, Southern (UNIT 2.9A), northern (UNIT 4.9), and/or immunoblotting (UNIT 10.8) can then be performed, probing the membrane with the relevant labeled nucleic acid probe or antibody. One should not necessarily expect that the integrity of these cells will be as great as that from tissue culture cells or fresh tissue, but it can be more than adequate to permit qualitative analysis by RT-PCR.

Figure 25A.2.2A.1 to D.1 shows several tissues, including cerebral cortex, trigeminal ganglia, liver, and diaphragm, after fixation and dissociation.

10. Determine the number of neurons recovered (see Support Protocol).

Figure 25A.2.2 Photomicrograph showing tissues after dissociation and density gradient centrifugation. Following perfusion fixation, several tissue types were removed, finely minced, and dissociated as described in this protocol. The total dissociated cell suspensions obtained from cerebral cortex (**A.1**), trigeminal ganglia (**B.1**), liver (**C.1**), and diaphragm (**D.1**) are shown. Following density gradient centrifugation, enriched populations of neurons were obtained from cerebral cortex (**A.2**, **A.3**) and trigeminal ganglia (**B.2**). Enriched populations of satellite and support cells isolated from trigeminal ganglia are shown in **B.3**. An example of “marker” based separation is shown in panels **E.1** to **E.3**. A mouse infected with a virus containing a β -galactosidase expression cassette was perfusion fixed and the trigeminal ganglia removed and stained histochemically for β -galactosidase activity using Xgal. The dark spots in panel E.1 are blue neurons, a result of the action of β -galactosidase on Xgal. The presence of this blue reaction product indicates that these neurons contain virus actively transcribing the β -galactosidase gene. The ganglia were then dissociated into single cell suspensions (E.2) and the blue neurons enriched by density gradient centrifugation (E.3). These neurons can be analyzed individually or in groups using PCR strategies.

11. Harvest desired cell populations by Percoll gradient centrifugation (steps 12 to 16) or by another suitable method.

The end application will strongly influence the procedure selected. The following steps enrich for neurons, but the protocol can also be used to enrich for other cell types.

Enrich for neurons by Percoll gradient

12. Prepare a discontinuous Percoll gradient as follows:
 - a. Mix Percoll and 3 \times F H₂O to make 40%, 50%, and 60% (v/v) Percoll solutions. Keep on ice.
 - b. Place the dissociated cell mixture on the bottom of a 15-ml polystyrene (for greater visibility) conical tube.
 - c. Using a baked 9-in. Pasteur pipette, layer 2.5 ml of 40% solution beneath the cell suspension, then carefully dispense the 50% solution under the 40% layer. Finally, carefully dispense the 60% solution beneath the 50% layer. Be sure to dispense all solutions from the tip of the pipette in a slow continuous stream.

13. Centrifuge the gradient in a benchtop centrifuge 10 min at 1800 rpm ($\sim 900 \times g$), 4°C.

The Percoll gradient resulting in the optimum separation of neurons from support cells was determined empirically.

14. Remove tube from the centrifuge and place in a stable rack, taking care not to disturb the gradient. Visually inspect the gradient. Carefully draw off the top myelin-containing layer to reduce contamination of cells banding lower on the gradient. A band of cells should be apparent at the 50%:60% interface. This band will contain highly enriched neurons.
15. Insert a baked 9-in. glass Pasteur pipette into the band of neurons and draw the banded cells into the pipette. Place the Percoll/cell mixture into a 15-ml polystyrene conical tube. Rinse by filling the tube with $3\times F$ H₂O and pelleting the cells by centrifuging in a benchtop centrifuge 10 min at 1800 rpm ($\sim 900 \times g$), 4°C.

A second gradient is not useful unless the first gradient has been overloaded.

16. Decant supernatant and resuspend the pellet in ~ 12 ml $3\times F$ H₂O. Repeat two additional times.
17. After the final rinse, decant the supernatant and resuspend the pellet in a small volume (e.g., 300 to 500 μ l) $3\times F$ H₂O. Transfer resuspended cells to a 1.5-ml centrifuge tube and examine one drop using a microscope. Determine number of neurons (see Support Protocol).

For examples of results, see Figure 25A.2.2, panels A.2 to C.2, A.3, and B.3.

Many factors will influence the separation of the cell suspension on the Percoll gradient. Thus, adjusting the gradient to give the separation desired may be required. Monitoring the distribution of cells throughout the gradient is helpful when beginning to determine optimum separation conditions.

18. Analyze DNA or RNA from single cell populations (see Basic Protocols 2 and 3).

SUPPORT PROTOCOL

DETERMINING NUMBER OF NEURONS RECOVERED

In the preceding method (see Basic Protocol 1), there are two steps (i.e., steps 10 and 17) at which evaluating the yields of the cell type of interest should be performed. The following procedure is presented for the evaluation of neurons but can be easily adapted for any cell type that can be distinguished on the basis of morphology or specific marker protein.

Materials

Cell pellet (see Basic Protocol 1)
Cresyl violet solution (see recipe)
95% and 100% ethanol
Xylene
Permount
Superfrost/Plus glass slides (Fisher) or equivalent with coverslips
Additional reagents and equipment for analyzing neuron-specific proteins (e.g., neurofilament 200 kDa peptide) by immunohistochemistry (Sawtell, 1997)

1. Resuspend cell pellet in a known volume of $3\times F$ H₂O. Mix tube well by flicking and inverting several times to ensure uniform distribution of cells. Dot five 1- μ l aliquots of the cell suspension onto a Superfrost/Plus glass slide or equivalent. Keep cell suspension thoroughly mixed during aliquoting. Dry slide thoroughly.

If more than one type of assessment is to be performed, multiple slides should be prepared.

2. Stain the slide with cresyl violet solution by overlaying the staining solution onto the slide for 5 min at room temperature, rinsing in deionized water, and dehydrating by dipping once in 95% ethanol and then twice in 100% ethanol. Clear the dehydrated slide in xylene and mount coverslip using Permount.
3. Identify neurons on the basis of morphology using a microscope. Count the number of neurons in each 1- μ l aliquot. Determine the average number of neurons per microliter and calculate the total number of neurons by multiplying the average number per microliter by the total number of microliters cell suspension.
4. Analyze an additional slide by immunohistochemistry for a neuron-specific protein, such as neurofilament 200 kDa peptide (detailed in Sawtell, 1997).

The number of neurons determined by morphology should be similar to that determined on the basis of neurofilament 200 kDa peptide staining.

NONPERFUSION FIXATION WITH STF SOLUTION

In some cases, perfusion fixation is not possible. The following procedure is an alternative to perfusion fixation for subsequent analysis of DNA.

Additional Materials (also see *Basic Protocol 1*)

Harvested tissue, fresh
HBSS (see recipe)

1. Finely mince freshly harvested tissue in a drop of STF on a glass slide.

The tube sizes and volumes given are appropriate for 30 to 40 mg of tissue. If larger amounts of tissue are used, tube sizes and volumes should be scaled up accordingly.

2. Transfer minced tissue to a 1.5 to 2-ml tube containing 1 ml STF and incubate for the desired time at room temperature.

The optimum fixation time must be determined empirically. In a preliminary experiment, divide minced tissue into several tubes and fix 5 to 15 min.

Fixation is carried out at room temperature so that subsequent dissociation is possible; therefore, this method is not recommended for separation of cells to be used for downstream analysis of RNA.

3. Following fixation, rinse minced tissue by microcentrifuging tissue 5 min at 5000 rpm, room temperature, then drawing off the supernatant and resuspending the pellet in HBSS. Repeat this process four times.
4. Treat the fixed minced tissue (Basic Protocol 1, steps 7 to 9). Examine the dissociation properties of the cells and the integrity of the nucleic acids and proteins. Select the fixation time yielding good separation and integrity.
5. Proceed as described for perfusion fixation (see Basic Protocol 1, steps 10 to 18).

PREPARATION OF *lacZ*-EXPRESSING CELLS FROM SOLID TISSUES

In this example, a procedure used in the author's laboratory, mice expressing an *E. coli* β -galactosidase expression cassette are perfusion fixed using a modification of the procedure described above (see Basic Protocol 1), to visualize *lacZ*-expressing cells.

Materials (also see *Basic Protocol 1*)

Glutaraldehyde
100 μ g/ml Xgal in Xgal buffer (see recipe)

**ALTERNATE
PROTOCOL 1**

**ALTERNATE
PROTOCOL 2**

**Discovery of
Differentially
Expressed Genes**

25A.2.7

1. Perfusion-fix the animal (see Basic Protocol 1, steps 1 to 4), except add 0.2% (w/v) glutaraldehyde to the STF and pump 20 ml of this solution through the animal at room temperature. Proceed with 80°C STF-only perfusion as described (see Basic Protocol 1, step 5).

This preserves β -galactosidase activity which does not remain active in STF alone. The author has utilized mice infected with a viral mutant containing a β -galactosidase expression cassette; however, mice containing a β -galactosidase transgene or mice in which a β -galactosidase cassette has been introduced using any gene transfer approach could also be analyzed in this way.

2. Remove tissue of interest and incubate in 100 μ g/ml Xgal in Xgal buffer at 37°C for 3 hr.

The time of incubation in the Xgal will depend on the strength of the promoter driving expression. The minimum amount of time for development should be used.

3. Inspect tissue and confirm presence of “marked” cells, then mince and dissociate the tissue (see Basic Protocol 1, steps 6 to 9).
4. Enrich cell population by Percoll gradient separation (see Basic Protocol 1, steps 10 to 17) or other suitable method.

Blue neurons are enriched in the bottom of the gradient, presumably because of increased density from the precipitated X-gal reaction product. This is shown in Fig. 25A.2.1E.1 to 3.

BASIC PROTOCOL 2

ANALYSIS OF SINGLE CELLS BY PCR

In the following section, a protocol for analyzing the dissociated enriched neurons by PCR to detect the HSV thymidine kinase gene is presented; however, this protocol can be applied to other cell types and nucleic acids as well. The goal in developing this assay was to provide a method for the quantitative assessment of the number of neurons containing the HSV genome. Because the frequency of the latent viral genome in the author’s experimental system was relatively high (20% to 30% of the total neurons in the ganglion), the analysis had to be performed on single neurons; however, depending on the frequency of the nucleic acid of interest in the cell pool being analyzed, it could be possible to perform the analysis on samples containing groups of known numbers of cells.

The primers and basic PCR conditions are essentially as reported by Katz and Coen (1990) and detailed in *UNIT 15.7*. Steps are included here for (1) aliquoting cells, (2) confirming the number of cells per tube being analyzed, and (3) eliminating any extracellular contaminating DNA. This step is critical to ensure that the DNA being amplified is actually intracellular. This is done by using DNase linked to beads. The bead cannot enter the cell, and thus the DNase is able to digest DNA in the fluid surrounding the cell, but does not destroy the DNA within the cell. In the next steps, which include a proteinase K treatment (to increase the permeability of the cell) and the PCR reaction itself, a two-part buffer system is utilized to minimize pipetting and insure maximum uniformity in the setup of samples by eliminating the need to pipet very small volumes.

Materials

- Enriched cell sample (see Basic Protocol 1 or Alternate Protocols 1 or 2)
- Triple 0.2- μ m filtered nanopure (3 \times F) H₂O
- Ponceau S solution (see recipe)
- Immobilized-DNase on PVP beads (Mobictec)
- DNase reaction buffer (see recipe)
- PCR/PK solution (see recipe)

DNA standards—e.g., cloned segments of HSV genome containing the gene being amplified (e.g., thymidine kinase)
PCR amplification solution (see recipe)
Taq DNA polymerase (Life Technologies)
200- μ l PCR tubes
Dissecting microscope
PCR Gene Amp 2400 (Perkin Elmer Cetus)
Gene screen plus nylon membrane (NEN Life Science Products)
Storage phosphor screen (Molecular Dynamics)
Imagequant software

Additional reagents and equipment for quantitating standards (UNIT 15.7; Sawtell and Thomson, 1992), PCR (UNIT 15.1), nondenaturing polyacrylamide gel electrophoresis (UNITS 2.5 & 2.7), UV-crosslinking DNA to filters (UNIT 2.9), hybridizing blots with oligonucleotides (UNITS 2.9A & 6.4), labeling oligonucleotides (UNITS 4.6, 4.8 & 15.7), and phosphorimaging (APPENDIX 3A)

Select single neurons

1. Dilute a portion of the enriched neuron sample with 3 \times F H₂O so that 1 μ l contains ~1 neuron. Add Ponceau S solution to a final volume of 1/200 and aliquot 1 μ l neuronal suspension into the bottom of a 200- μ l PCR tubes.

This dye allows easy visualization of neurons in the bottom of the PCR tube when viewed under a dissecting microscope, but does not interfere with subsequent analyses.

2. Examine each tube under a dissecting microscope and identify those containing a single neuron for use in step 3.

The number of tubes will depend upon the anticipated frequency of the DNA sequence being analyzed. In the authors studies, a typical analysis will include 200 single neuron samples.

Immobilized DNase treatment and PCR reaction

3. Resuspend immobilized-DNase on PVP beads in DNase reaction buffer so that 5 μ l contains ~100 beads. Add a 5- μ l aliquot to each PCR tube containing a single neuron. Mix gently. Incubate samples several hours or overnight at 37°C.

The purpose of the DNase treatment is to make sure that the DNA being measured is the DNA within the cell or cells in the PCR tube. While DNase treatment could be performed on cells en masse, one could not be sure that some cells were not broken during purification and aliquoting of cells.

Prior to use of the immobilized DNase, it is important to confirm that the DNase activity in the preparation is associated with the bead, and that no free DNase activity can be detected, as any free DNase could enter the cell and destroy the intracellular DNA. To test this, the immobilized DNase in activation buffer is pelleted gently (as detailed by the manufacturer) and an aliquot of the supernatant is drawn off and placed in a 1.5-ml microcentrifuge tube. The supernatant is then spiked with intact plasmid DNA of known size and incubated for ~1 hr at 37°C. Agarose gel electrophoresis (UNIT 2.5A) is then used to evaluate integrity of DNA incubated with and without supernatant. The supernatant-treated DNA should show no evidence of degradation.

When aliquoting cells at the single-cell level, many of the tubes contain no cells. Some of these samples, as well as samples spiked with HSV DNA, are utilized as controls to test the completeness of the DNase treatment (see Critical Parameters and Troubleshooting). The ability of the immobilized DNase to eliminate potential contamination should be determined by spiking a sample with the DNA sequence being amplified. It is important to spike the sample with an amount of DNA that would reflect anticipated levels of contamination. With proper technique, these levels should be extremely low and not present in every cell sample. The DNase step is an important safeguard, but not a solution for poor technique.

4. Place samples in a PCR Gene Amp 2400 or equivalent and heat to 94°C for 5 min to inactivate DNase. Reduce temperature to 50°C, add 34 µl PCR/PK solution to each sample, and incubate 3 hr.
5. Prepare standards and quantitate as described (UNIT 15.7; Sawtell and Thompson, 1992). Prepare standard dilutions representing 10,000, 1,000, 100, 10, and 0 HSV viral genomes in 6 µl.

Standards are treated identically to the cell samples with the exception of DNase treatment. To quantify other nucleic acids of interest, use appropriate standards and optimized PCR assays (UNIT 15.1).

6. Incubate samples and standards 7 min at 94°C to inactivate proteinase K.
7. Incubate at 63°C while adding 10 µl PCR amplification solution and 1.25 U *Taq* DNA polymerase per reaction (50 µl total).
8. Amplify using the following program parameters:

45 cycles:	30 sec	94°C	(denaturation)
	30 sec	55°C	(annealing)
	30 sec	72°C	(extension)
Final step:	7 min	72°C	(extension/hold).

PCR conditions should be optimized for the primer/target of interest as described in UNIT 15.1.

9. Electrophorese 5 µl each PCR product through a nondenaturing 12% polyacrylamide gel (UNITS 2.5A & 2.7), transfer to a Gene screen plus nylon membrane (UNIT 2.9A), and perform hybridization analysis (UNIT 2.9A & 6.4) using a ³²P-end-labeled oligonucleotide internal to the PCR primers (UNIT 15.7).
10. Expose blot to a storage phosphor screen (APPENDIX 3A) and analyze using Imagequant software.

BASIC PROTOCOL 3

ANALYSIS OF ENRICHED CELL POPULATIONS BY RT-PCR

Presented in this section is a protocol that can be adapted to examine either specific or general transcriptional patterns in groups of selected populations of cells harvested from solid tissues. The cells in the tissue are first stabilized by fixation, avoiding the transcriptional changes that would occur with the manipulation and dissociation of living cells. Using carefully screened reagents, it is possible to maintain the integrity of the RNA within the cells during the dissociation process so that RT-PCR analysis is possible (Sawtell, 1997). The goal of the author was to analyze the RNA contained within just a few cells using RT-PCR. In PCR analysis (see Basic Protocol 2), the integration of the pretreatment steps and the PCR reaction in a single assay tube was straightforward; however, in the case of RT-PCR, establishing the compatibility of all of the enzymatic steps required for the pretreatment, reverse transcription, and subsequent PCR without an extraction step was more challenging. The assay developed is presented below. This protocol has been successfully utilized to detect transcripts in samples of fewer than ten neurons. This approach has proven to be especially useful to examine cell type specific expression of transcripts within solid tissues. For example, the author used this approach to demonstrate that the expression of a novel stress-induced spliced form of a key transcription factor was restricted to the neurons in the trigeminal ganglion (unpub. observ.).

Primer selection will depend on the transcript of interest. The MacVector PCR primer selection program has proven to consistently yield primers that work well. If specific

transcripts are being analyzed, primers that span splice sites is a distinct advantage. If a nonspliced transcript is being amplified, it is imperative to include sufficient controls in which the reverse transcriptase has been omitted to rule out the possibility that DNA rather than RNA is being amplified. One limiting factor will be the length of product generated by the reverse transcription reaction. The author has had success using this direct fixed cell RT-PCR assay with primers to mouse genes that generate a 500-bp product.

Materials

Proteinase K solution (see recipe)
40 mM PMSF, fresh
RNase-free DNase I: 3 U RNase-free DNase I (Boehringer Mannheim)/25 mM DTT/ 2.5 U placental RNase inhibitor
8 pmols/ μ l reverse transcriptase primer
Reverse-transcription reaction mix (see recipe)
200 U/ μ l SuperScript II reverse transcriptase (Life Technologies)
PCR amplification solution (see recipe)
1.25 U *Taq* DNA polymerase (Life Technologies)
PCR tubes

Additional reagents and equipment for obtaining dissociated perfusion-fixed cells (see Basic Protocol 1) and PCR optimization (*UNIT 15.1*)

1. Obtain cells dissociated from perfusion fixed tissues as detailed above (see Basic Protocol 1) using solutions tested to be free of RNase activity.

At this point, immobilized RNase could be utilized to remove any contaminating RNA from the aliquoted cells, as detailed above (see Basic Protocol 2, step 3); however, the author has tested extensively for specific RNAs in the supernatant of washed, dissociated cells and has not detected extracellular RNA contamination. This could reflect the inability of the reverse transcription reaction to detect one or just a few template molecules. In contrast, HSV DNA could occasionally be detected in the supernatant; therefore, eliminating it was imperative.

2. Aliquot cells to be analyzed in a 1- μ l volume into PCR tubes. Add 4 μ l proteinase K solution and incubate 60 min at 50°C. After digestion, add 0.25 μ l freshly prepared 40 mM PMSF.

Preliminary analysis demonstrated the need for protease digestion of cellular proteins in isolated cells for complete DNase I digestion of genomic DNA; however, the high temperatures required for heat inactivation of this enzyme led to degradation of RNA, most likely through metal ion-catalyzed hydrolysis. Thus, following digestion with proteinase K, activity of this enzyme is selectively inhibited by adding freshly prepared PMSF.

3. Add 0.75 μ l RNase-free DNase I. Incubate 45 min at 37°C.
4. Inactivate DNase by incubating 15 min at 70°C. After this time, add 0.25 μ l of 8 pmol/ μ l (2 pmol total) reverse transcriptase primer and incubate an additional 10 min at 70°C.
5. Reduce temperature to 50°C and add 3.5 μ l reverse-transcription reaction mix, followed by an additional 0.25 μ l of 40 mM PMSF and 0.25 μ l of 200 U/ μ l (50 U) SuperScript II reverse transcriptase. Incubate 60 min at 50°C.

If the transcripts are to be detected are unspliced, samples are set up in multiples, half of which receive no reverse transcriptase. In additional controls, RNase is included with the DNase (step 3).

6. After 60 min, increase temperature to 70°C for 15 min. Add $\frac{1}{5}$ to $\frac{1}{2}$ of the cDNA sample to 47 μ l PCR reaction buffer and heat 5 min at 94°C.

7. Reduce the temperature to 5°C above the annealing temperature (*UNIT 15.1*) and add 1.25 U *Taq* DNA polymerase to each sample (50 µl total).
8. Analyze amplification products as described above (see Basic Protocol 2, steps 9 and 10)

The usefulness of the RT-PCR assay for quantification at the single-cell level has not been fully explored. Using primers to specific HSV genes, the reverse transcription reaction lacked the sensitivity required to detect the very low levels of these transcripts anticipated during viral latency. This may be due, in part, to the very high GC content of the HSV genome in general and the specific regions being reverse transcribed. Regardless, the assay can detect specific transcripts in small numbers of cells.

REAGENTS AND SOLUTIONS

Use 3×F H₂O in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Cresyl violet solution

Prepare the following in triple 0.2-µm filtered nanopure (3×F) H₂O:
0.5% (w/v) cresyl violet
10% (v/v) glacial acetic acid
Store up to 12 months at room temperature

DNase reaction buffer

Prepare the following in triple 0.2-µm filtered nanopure (3×F) H₂O:
20 mM Tris·Cl, pH 7.5 (*APPENDIX 2*)
5 mM MgCl₂
5 mM CaCl₂
Aliquot and store up to 12 months at –20°C

Hanks balanced salt solution (HBSS)

0.4 g/liter KCl
0.06 g/liter KH₂PO₄
8.00 g/liter NaCl
0.35 g/liter NaHCO₃
0.048 g/liter Na₂HPO₄
1.00 g/liter D-glucose
Sterilize by passing through three 0.2-µm filters
Aliquot and store up to 12 months at –20°C

PCR amplification solution

Prepare the following in triple 0.2-µm filtered nanopure (3×F) H₂O:
20 mM Tris·Cl, pH 8.4 (*APPENDIX 2*)
50 mM KCl
1.5 to 4.5 mM MgCl₂
5% (w/v) gelatin
200 µM each dNTP
25 to 50 pmols of each primer (*UNIT 15.7*; Katz et al., 1990)
Store up to 1 month at –20°C

While the buffer can be stored with primers and dNTPs, it is better to add them just before use. Buffer without primers or dNTPs can be stored up to 12 months at –20°C.

*The concentration of MgCl₂ will depend on specific primers utilized (*UNIT 15.1*) but will commonly range between 1.5 to 4.5 mM.*

PCR/PK solution

Prepare the following in triple 0.2- μ m filtered nanopure (3 \times F) H₂O:
20 mM Tris·Cl, pH 8.4 (*APPENDIX 2*)
50 mM KCl
1.4 to 4.5 mM MgCl₂
Aliquot and store up to 12 months at -20°C
Just before use, add 50 $\mu\text{g}/\text{ml}$ proteinase K

The concentration of MgCl₂ will depend on specific primers utilized (UNIT 15.1) but will commonly range between 1.5 to 4.5 mM.

Ponceau S solution

Prepare the following in triple 0.2- μ m filtered nanopure (3 \times F) H₂O:
0.5% (w/v) Ponceau S
1% (v/v) glacial acetic acid
Store in aliquots up to 12 months at room temperature.

Proteinase K solution

25 mM Tris·Cl, pH 8.4 (*APPENDIX 2*)
37 mM KCl
1.5 mM MgCl₂
0.3 μg proteinase K
Make fresh

Reverse-transcription reaction mix

93 mM Tris·Cl, pH 8.3 (*APPENDIX 2*)
140 mM KCl
5.5 mM MgCl₂
Store up to 12 months at -20°C
Just before use add DTT to 25 mM and dNTPs (*UNIT 3.4*) to 0.25 mM

Xgal buffer

Prepare the following in “clean” phosphate buffered saline, pH 7.4 (PBS;
APPENDIX 2):
5 mM K₃Fe(CN)₆ (potassium ferrocyanide)
5 mM K₄Fe(CN)₆·3H₂O (potassium ferricyanide)
2 mM MgCl₂
Aliquot and store up to 3 months at room temperature

COMMENTARY

Background Information

The concept of “cellular pathology” was put forth nearly 150 years ago by Virchow (1863) with the view that disturbances in structure and function of individual cells form the basis of disease. Current understanding of the interactive nature of the cells comprising an organism have substantiated this view. It is now clear that cells differentiate and function according to the summation of the molecular cues arising from many other cells in the organism (Gilbert, 1994). It follows that certain important aspects of the molecular behavior of individual cellular components can only be observed in the context of the organism.

Reported here is a strategy, contextual expression analysis (CXA), that combines the cell-specific information of in situ approaches with the analytical and quantitative potential of solution PCR (Sawtell, 1997). Cells are chemically stabilized in the context of the organism and subsequently isolated. PCR can then be utilized to gain insight into the molecular processes of a single cell among billions.

The enzymatic dissociation of living tissues has been widely used and refined for many specific tissue types (Pretlow and Pretlow, 1982). Inherent in this process are cellular molecular changes induced by disruption of context. In order to prevent these changes, tissues

are stabilized by chemical fixation prior to dissociation. Yields of even fragile adult cell types such as neurons are high. Distinct morphological features, such as brush borders of the intestinal epithelial cells as well as nuclear and cytoplasmic nucleic acid staining patterns are comparable to those in sectioned tissues (Sawtell, 1997). DNA and RNA isolated from dissociated tissues are reasonably intact. By immunohistochemical staining, the distribution of cytoskeletal proteins including actin and neurofilament 200 kDa peptide are similar in dissociated cells when compared to sectioned tissue (Sawtell, 1997).

The impetus for development of this protocol arose out of the need in the author's laboratory to identify the cell types and to quantify the number of cells in a specific solid tissue that harbored the latent HSV genome. It was also important to determine the number of viral genomes in each of those cells. The approach has proven extremely useful for this purpose (Sawtell, 1997; Thompson and Sawtell, 1997, 2000, 2001; Sawtell et al., 1998; Sawtell et al., 2001); however, this method should be widely useful for facilitating the analysis of rare cells or cellular events occurring in a complex multicellular environment.

Critical Parameters and Troubleshooting

In developing this procedure, several common fixation formulations were tested in combination with alternative digestive enzymes. For the most part, tissues either remained a solid mass or disintegrated into cellular debris; however, perfusion with STF followed by digestion with collagenase (i.e., Worthington CLSI) yielded single cell suspensions from peripheral and central nervous tissue, lung, liver, intestine, heart, pancreas, muscle, and reproductive tract. Nonetheless, optimizing the balance between fixation and dissociation for the specific tissue of interest is advisable.

Fixation

The volume of fixative perfused through the animal is critical and should be measured. The procedure can be modified for larger animals, such as guinea pigs, by increasing the volume of fixative utilized.

Several different types of fixatives were tested, including various formaldehyde based formulations. The fixative found to give the best results was Streck tissue fixative (STF). This is a noncrosslinking fixative containing diazolid-

inyl urea, 2-bromo-2-nitropropane-1,3-diol (bronopol), zinc sulfate, and sodium citrate. Why STF works in Basic Protocol 1 has not been explored; however, it is likely that absence of crosslinking in the fixed tissue is favorable for the subsequent enzymatic dissociation process.

Mincing

It is critically important to finely and uniformly mince the tissue. This allows greater and more uniform access of dissociating enzymes to the tissue.

Collagenase

The collagenase preparation used contains several collagenases, as well as caseinase, clostripain, and tryptic activities. This is a relatively crude preparation and there is lot-to-lot variation in this product. The author's laboratory has tested a number of purified enzymes with varying levels of success; however, none worked as well as the crude preparation. Batches of collagenase must be screened not only for optimum dissociation activity but also for DNase and RNase activity, depending upon final use of cells. This can be done easily by spiking an aliquot of the enzyme (5× strength) with DNA or RNA. The sample is then incubated at 37°C for 1 hr and examined by agarose gel electrophoresis for integrity of the nucleic acids. While many batches will be free of DNase, RNase-free collagenase is less common.

Contamination

Careful planning to prevent contamination control is necessary for the success of this procedure. *UNIT 15.7* discusses many of the relevant issues. It is critical that the results obtained from the PCR be related to the contents of the cell being analyzed and not contamination introduced at any point during the procedure. With all aspects of this procedure, the final use of the cells will determine the types of contamination that must be avoided. The most meticulous technique is required if downstream applications require intact RNA. The introduction of RNases at any point must be avoided.

Controls

Observe the tissue and cells of interest frequently during the dissociation process. Such observation will provide important information regarding the response of the dissociating tissue and cells to the process. Make estimates of the

number of cells expected and determine if recoveries are reasonable. There should be minimal cell loss with this method.

Examine the integrity of the nucleic acids and proteins by carrying out routine isolation and analytical procedures on the tissue after dissociation.

All standard PCR and RT-PCR controls should be included. Additional controls will be required, depending on the final application of the cells.

Anticipated Results

Single cell suspensions of tissues will be obtained. With proper attention to the quality of reagents used, specifically the collagenase, the nucleic acids within the cells will be intact. Keep in mind that the results obtained from downstream analyses will depend on the quality of the cells obtained from the dissociation step.

Time Considerations

The time required will depend on the skill level of the individual performing the task. For the skilled practitioner, mouse perfusion will require 10 to 15 min, dissection and mincing of tissue 5 to 15 min (depending on how many tissues are being dissected), tissue dissociation 30 to 45 min, rinsing and post-fixation 20 min, neuron counts ~1 hr (depending on how many slides are examined), separation of Percoll gradient and rinsing 1 hr, aliquoting individual cells one to several hours (depending on the number of tubes), PCR (including all pretreatments) 1.5 to 2 days (this is not a continuous effort), and gel electrophoresis, prehybridization, and hybridization 1 to 1.5 days (this also is not a continuous effort).

MOLECULAR METHODS FOR DISCOVERY OF DIFFERENTIALLY EXPRESSED GENES

SECTION B

Production of a Subtracted cDNA Library

UNIT 25B.1

PRODUCTION OF A SUBTRACTED LIBRARY

BASIC
PROTOCOL

For some experiments, a complete cDNA library (UNIT 5.8A) is unnecessary and instead, a subtracted cDNA library is useful. A subtracted cDNA library contains cDNA clones corresponding to mRNAs present in one cell or tissue type and not present in a second type. This cDNA library is used to isolate a set of cDNA clones corresponding to a class of mRNAs, or to aid in the isolation of a cDNA clone corresponding to a particular mRNA where the screening procedure for the cDNA clone is laborious because a specific DNA or antibody probe is unavailable. A technique known as differential screening is an alternative to creating subtracted libraries (see Commentary).

In this protocol, the tissue, library, RNA, or cDNA designated with a [+] contains the target or desired sequence(s), and that which is to be subtracted from the [+] is termed [-]. Since relatively few recombinants are obtained after subtraction, this protocol is for a cDNA library constructed in the λ gt10 vector or its equivalent, which allows a high cloning efficiency and permits elimination of nonrecombinants; however, the protocol can be used to produce subtracted cDNA libraries in any vector system.

[+] cDNA with *EcoRI* ends and [-] cDNA with blunt ends are prepared. The [-] cDNA is digested with *RsaI* and *AluI* to give small blunt-ended fragments. The [+] cDNA inserts are mixed with a 50-fold excess of fragmented [-] cDNA inserts, the DNAs in the mixture are heated to melt the double-stranded DNA, and the single-stranded insert DNA is allowed to hybridize. After hybridization, annealed cDNA inserts are ligated to λ gt10 arms, packaged, and transfected.

The only [+] cDNA likely to regenerate double-stranded fragments with an *EcoRI* site at each end are those sequences for which no complementary fragments were present in the [-] cDNA. The subsequent cloning step allows the selection and amplification of these fragments.

Materials

- [+] and [-] cDNA libraries (ATCC or Stratagene)
- TE buffer (APPENDIX 2)
- EcoRI* and 10 \times *EcoRI* buffer (UNIT 3.1)
- 0.5 M EDTA, pH 8.0 (APPENDIX 2)
- 10% sucrose solution (UNIT 5.3)
- 1.5% and 2% agarose gels (UNIT 2.5A)
- TBE buffer (APPENDIX 2)
- 95% and 70% ethanol
- S1 nuclease (Sigma; UNIT 3.12) and 10 \times S1 nuclease buffer (UNIT 3.4)
- 25:24:1 phenol/chloroform/isoamyl alcohol (UNIT 2.1A)
- 3 M sodium acetate, pH 5.2 (APPENDIX 2)
- AluI* and 10 \times *AluI* buffer (UNIT 3.1)
- RsaI* (UNIT 3.1)
- Deionized formamide (Fluka, IBI, or American Bioanalytical)
- 20 \times SSC (APPENDIX 2)
- 1 M NaPO₄, pH 7.0 (see recipe)

Supplement 55

10% sodium dodecyl sulfate (SDS)
10 mg/ml yeast tRNA
24:1 chloroform/isoamyl alcohol
Phosphatase λ gt10 arms (Stratagene)
10 \times T4 DNA ligase buffer (UNIT 3.4)
T4 DNA ligase (measured in cohesive-end units; New England Biolabs; UNIT 3.14)
E. coli C600/hflA (Table 1.4.5)
 λ phage packaging extracts (Stratagene)
Suspension medium (SM; UNIT 1.11)

SW-28 rotor and 38-ml centrifuge tubes (Beckman) or equivalent
0.4-ml microcentrifuge tube

Additional reagents and equipment for construction of recombinant DNA libraries (UNITS 5.5 & 5.6), large-scale DNA preps from plasmids (UNIT 1.7) or phage (UNIT 1.13), sucrose gradients (UNIT 5.3), agarose gel electrophoresis (UNIT 2.5A), production and growth/maintenance of λ phage libraries (UNITS 5.8, 25B.2, and 1.9-1.13), plating and titering libraries (UNITS 6.1 & 6.2), hybridization (UNIT 6.3), and radiolabeling probes (UNIT 3.4)

Prepare the insert DNA

1. Prepare or obtain cDNA libraries from the [+] and [-] cells or tissue sources.

A major advantage of this protocol is that a subtracted library may be prepared from existing libraries, which is highly recommended. Complementary DNA libraries from many species and tissue sources are widely available and considerable time may be saved by obtaining preexisting [+] and [-] libraries to be used in this protocol.

Alternatively, prepare $\geq 1 \mu\text{g}$ [+] cDNA with EcoRI ends and $10 \mu\text{g}$ [-] cDNA with blunt ends (stop the [-] cDNA synthesis before adding linkers) from poly(A)⁺ [+] and poly(A)⁺ [-] RNA, respectively (UNITS 5.5 & 5.6). If this is done, proceed to step 13.

The protocol assumes that the [+] and [-] libraries are bacteriophage λ libraries. If the vector for either is a plasmid, only 100 μg of each is needed (scale down steps 2 and 3 by $\frac{1}{10}$) and the inserts should be purified by agarose gel electrophoresis rather than by sucrose gradient centrifugation.

2. Perform large-scale (2 to 3 liters) DNA preps of both the [+] and [-] libraries to obtain >1 mg DNA from each library. Resuspend the DNA at 1 mg/ml in TE buffer.

Digest the DNA

3. Digest 1 mg of each library DNA in a 1.5-ml microcentrifuge tube as follow (final volume 1.167 ml):

1 ml library DNA (1 mg)
0.117 ml of 10 \times EcoRI buffer
0.05 ml EcoRI (1000 U).

Mix by shaking and incubate 5 hr at 37°C. Stop the reaction by adding 40 μl of 0.5 M EDTA, pH 8.0, and incubate 10 min at 65°C. During the digestion, prepare four 10% to 40% sucrose gradients in 38-ml SW-28 tubes (UNIT 5.3). Label two tubes [+] and two tubes [-].

Internal EcoRI sites present in the cDNA inserts will be cut. If this occurs, the partial-length cDNA clone obtained through this procedure can be used to generate a probe with which to screen the initial [+] library for a full-length clone. The advent of newer vectors (e.g., λ ZAP; see Fig. 1.10.8) with cloning sites for enzymes such as NotI will nearly eliminate this difficulty.

Run the sucrose gradients

4. Mix each digest with an equal volume of 10% sucrose solution and carefully layer the digested [+] library DNA onto the two 10% to 40% sucrose gradients labeled [+]. Split the sample between the two tubes evenly. Similarly, load the [-] DNA onto the two gradients labeled [-]. Centrifuge the gradients overnight (18 to 24 hr) at 122,000 × g (26,000 rpm in an SW-28 rotor), 20°C.

The insert fragments will remain near the top of the gradient while the phage arms will migrate half the length of the tube.

5. Harvest the gradients by gently removing 0.2-ml fractions from the top of the tube with a pipettor. Place each fraction into a separate, labeled microcentrifuge tube at 4°C.

Twenty fractions per gradient are sufficient, as the insert DNA is small and barely enters the gradient under these conditions. Save the remainder of the gradient until the fractions containing the inserts have been identified, just in case!

Recover the DNA

6. Identify the tubes containing the insert DNA by analyzing 20 µl of every other fraction on a 1.5% agarose gel made in TBE buffer.
7. Precipitate the insert DNA: add 0.3 ml TE buffer and 1.0 ml of 95% ethanol to each tube, mix, and place at -20°C for 2 hr or on dry ice for 15 min.

Because the sucrose gradient buffer contains 1 M NaCl, there is sufficient NaCl in the fractions for precipitation of the DNA. The sucrose in the gradient fractions must be diluted in order to successfully precipitate the DNA. A 2- to 3-fold dilution of these low-density fractions is adequate. A greater dilution of the higher density fractions is necessary in order to obtain high recoveries of DNA following ethanol precipitation.

8. Thaw and collect the DNA by microcentrifugation at high speed for 15 min. Aspirate the supernatant and save until DNA recovery has been checked. Add 0.5 ml of 70% ethanol to each tube. Recentrifuge, aspirate the ethanol supernatants, and dry the pellets.
9. Resuspend and pool the fractions containing insert DNA from the [+] library in TE such that the final concentration is 0.2 mg/ml. Store the DNA at -20°C.
10. Resuspend and pool the insert DNA from the [-] library in 100 µl TE buffer and place on ice. Save an aliquot of 400 ng of each [+] and [-] cDNA separately, to be used in evaluating the final library produced.

Expect recoveries of >10 to 15 µg of insert DNA from 1 mg of total library DNA. The aliquots of [+] and [-] DNA, alternatively, may be radiolabeled and used as probes for differential screening of the [+] library (see Commentary).

Remove EcoRI ends from [-] DNA

11. Remove the EcoRI ends from the [-] DNA by mixing in the following order (final volume 112 µl):

100 µl [-] insert DNA (10 to 15 µg)
11 µl 10× S1 nuclease buffer
1 µl 1:500 S1 nuclease (2 U).

Mix by vortexing, briefly microcentrifuge, and incubate 30 min at 37°C.

12. Stop the reaction by adding:

5 μ l 0.5 M EDTA, pH 8.0
200 μ l TE buffer
300 μ l phenol/chloroform/isoamyl alcohol.

Vortex. Microcentrifuge 1 min to separate the phases and transfer the upper, aqueous phase to a new tube. Add 30 μ l of 3 M sodium acetate, pH 5.2, and 700 μ l ethanol. Freeze, then collect the DNA by centrifugation as in steps 7 and 8. Resuspend the washed and dried pellet in 100 μ l TE buffer.

Digest the [–] DNA with AluI and RsaI

13. Digest the S1 nuclease–treated [–] insert DNA to small fragments with *AluI* and *RsaI* by adding in the following order (final volume 121 μ l):

100 μ l [–] insert DNA (10 to 15 μ g)
12 μ l 10 \times AluI buffer
5 μ l *AluI* (50 U)
4 μ l *RsaI* (60 U).

Mix by vortexing, briefly microcentrifuge, and incubate 3 hr at 37°C. Add 5 μ l of 0.5 M EDTA, pH 8.0, and incubate 10 min at 65°C to stop the reaction. Remove and save 5 μ l of the digest for evaluation by electrophoresis.

14. Add 200 μ l TE buffer and 300 μ l phenol/chloroform/isoamyl alcohol; extract and ethanol precipitate the DNA as in step 12. Resuspend the washed and dried pellet in TE buffer at 1.0 μ g/ μ l.
15. Check the 5- μ l aliquot from step 13 by running a 2% agarose minigel (in TBE buffer) and ethidium bromide–staining. The [–] DNA fragments should be between 50 and 200 bp in length.

Hybridize the DNA

16. Hybridize the [+] insert DNA with the [–] DNA fragments. Add in the following order to a 0.4-ml microcentrifuge tube (final volume 51 μ l):

25 μ l deionized formamide (50% vol/vol final)
10 μ l [–] DNA fragments (10 μ g)
1 μ l [+] insert DNA (0.2 μ g)
12.5 μ l 20 \times SSC (5 \times final)
0.5 μ l 1 M NaPO₄, pH 7.0 (10 mM final)
0.5 μ l 0.1 M EDTA, pH 8.0 (1 mM final)
0.5 μ l 10% SDS (0.1% final)
1.0 μ l 10 mg/ml yeast tRNA (0.2 mg/ml final).

Mix by vortexing, briefly microcentrifuge, and place tube in a bath of boiling water for 5 min. Briefly microcentrifuge again and incubate 18 to 24 hr at 37°C.

The boiling step melts the DNA strands. During the hybridization step, only [+] sequences not present in the [–] DNA will find their complementary strands and regenerate clonable, double-stranded fragments with EcoRI ends. A [+] sequence also present in the [–] DNA will hybridize with at least one of the AluI/RsaI [–] fragments, forming a partially single-stranded, partially double-stranded molecule without clonable ends.

17. Add 200 μ l TE buffer and transfer the mixture to a 1.5-ml microcentrifuge tube. Wash the hybridization tube with 250 μ l TE buffer and add it to the hybridization mix (the volume is now 500 μ l). Add 500 μ l phenol/chloroform/isoamyl alcohol, vortex, and microcentrifuge 1 min to separate the phases.

- Transfer the upper, aqueous phase to a new tube. Reextract this phase with 500 μ l chloroform/isoamyl alcohol as in step 17. Recover the aqueous phase and add 50 μ l of 3 M sodium acetate, pH 5.2, and 1 ml ethanol. Precipitate as in steps 7 and 8. Resuspend the washed and dried pellet in 12 μ l TE buffer.

Chloroform/isoamyl alcohol extraction ensures removal of SDS and formamide.

Ligate the DNA

- Ligate the insert DNA to λ gt10 (not λ gt11) phage arms by adding in the following order (final volume 25 μ l):

12 μ l insert DNA
10 μ l λ gt10 phosphatased phage arms (10 μ g)
2.5 μ l 10 \times ligase buffer
0.5 μ l T4 DNA ligase (200 U).

Mix by gently pipetting up and down and incubate overnight at 12 $^{\circ}$ to 15 $^{\circ}$ C.

Package and plate the library

- Start a fresh overnight culture of *E. coli* C600\lambda phage packaging extracts according to manufacturer's instructions.

The vector λ gt10 is used here because it permits selection of recombinants when grown on the appropriate host. Ten micrograms of bacteriophage λ vector is roughly an equimolar amount of EcoRI ends with respect to the input [+] DNA, the ends of which must be considered even though only a small fraction of the [+] insert DNA is clonable after the melting and hybridization steps. The recommended 10 μ g of vector and no less than 8 to 10 packaging extracts will ensure a library of good complexity.

- Add suspension medium (SM) to the packaging mixtures and pool them in a 5-ml polypropylene tube to a final volume of 2 ml. Add two drops of chloroform, shake by hand for 3 sec, and allow the chloroform to settle.
- Plate 0.2 ml packaged phage with 3 ml fresh C600^{\circ}C.
- The following morning, count the number of plaques on a representative plate and multiply by 10 to determine the total number of recombinants in the library.

Typically, 300 to 15,000 phage per library are obtained.

- Elute the plates with SM as in UNIT 25B.2 or directly select individual plaques for screening.

Evaluate the library

- Evaluate a newly prepared subtracted library as described in UNIT 5.8A (first support protocol).

The best approach is to amplify the library and differentially screen duplicate nitrocellulose filters from a single 150-mm plate of 20,000 to 40,000 recombinants. Hybridize one lift with a total [+] cDNA probe and the other with a total [-] cDNA probe. The total [+] and [-] cDNA probes are prepared by radiolabeling some of the [+] and [-] cDNA saved from step 10. Most clones should hybridize with the [+] probe and few with the [-] probe. Evaluation by screening the library with a probe for proteins such as actin or tubulin would not be appropriate, since the expected result is no hybridization (or only a few), which may occur for a variety of reasons.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

1 M NaPO₄, pH 7.0

A: 1 M Na₂HPO₄

B: 1 M NaH₂PO₄

Add B to A until pH = 7.0

COMMENTARY

Background Information

The practical consequence of creating a subtraction library is considerable enrichment of the target cDNA clones. For example, a subtracted cDNA library was used to isolate T cell antigen receptor cDNAs. By hybridizing T cell cDNA to B cell mRNA, and selecting the single-stranded cDNA molecules by hydroxylapatite column chromatography, the T cell antigen receptor cDNAs were significantly enriched. The cDNA was then hybridized back with the T cell mRNA from which it was derived and the double-stranded RNA-DNA hybrids were selected, carried through second-strand cDNA synthesis, and the resulting cDNA was cloned (Hedrick et al., 1984). Thus, a large percentage of the clones in the subtracted library were T cell-specific. All clones in the subtracted library would have been present in a library constructed from the T cell line without the subtraction step; the objective was to obtain a library so enriched that clones derived from it could be screened by random selection.

Two major disadvantages to the approach outlined above are that poly(A)⁺ RNA from both [+] and [-] source is required and the hybridizations, hydroxylapatite columns, and library production with a very small amount of cDNA are technically difficult. A conceptually different approach, termed deletion enrichment, has been undertaken in the construction of a genomic library enriched for Y chromosome-specific sequences (Lamar and Palmer, 1984). In this case, [+] DNA (male) and an excess of [-] DNA (female) fragments were mixed, denatured, hybridized, and [+] DNA that did not hybridize to [-] was selected by a cloning step. Production and selection of a library were accomplished simultaneously.

The subtracted cDNA library protocol described here is an adaptation of the deletion enrichment method to cDNA libraries and is recommended over the other because (1) it is conceptually and practically simple, involving only standard laboratory techniques; (2) it does not involve the handling of RNA, which can be

problematic; (3) it may be performed with DNA prepared from already existing libraries, eliminating the potential time and expense involved in the preparation of fresh tissue or cells; and (4) with slight modifications, either cDNA or genomic subtracted libraries may be prepared.

A disadvantage of this approach is that if no [+] or [-] cDNA libraries are available, they must first be made or cDNA must be synthesized, requiring an extra few days to a week. A second disadvantage of this or any other subtraction protocol is that clones containing reiterated sequences—e.g., an *Alu* repeat in the 3' untranslated region—would be eliminated from the library on that basis. Thus, the representation of a clone containing a reiterated sequence would be lower than expected, with only partial-length cDNAs present after subtraction.

A good alternative to creating a subtracted library is differential screening of a library known to contain the target clone(s). In one well-characterized experiment, duplicate lifts from a lymphoid tissue cDNA library were screened with total B cell cDNA and total T cell cDNA probes. B cell-specific clones were identified as plaques that hybridized with a B cell cDNA probe and not with a T cell probe (Tedder et al., 1988). A potential drawback to the differential screening approach is that rare sequences will have very low specific probe concentrations in the mixture and thus might not hybridize to the DNA from a target plaque in a reasonable period of time (e.g., overnight).

Critical Parameters

Because the *Eco*RI ends of [+] insert cDNA must remain intact through the sucrose gradient and hybridization steps, the nuclease inhibitor and bacteriostatic agent EDTA is present in both steps. In contrast, S1 nuclease digestion destroys the *Eco*RI ends of [-] cDNA, ensuring that all clones in the final library are derived from [+] cDNA. Restriction digestion of [-] DNA with *Alu*I and *Rsa*I increases the molar ratio of [-] to [+] DNA while not increasing the

mass of [−] cDNA, which can inhibit subsequent steps. The boiling step prior to hybridization is essential to melt the cDNA to its single-stranded form. The hybridization conditions favor the annealing of fragments >50 bp and a relatively long hybridization is required to permit reannealing of rare [+] cDNA. Hybridization buffer must be diluted at least 10-fold in order to successfully phenol extract, chloroform extract, and ethanol precipitate the DNA. A full 10 μg of phage vector arms must be added in the ligation reaction. This represents only an equimolar amount of *EcoRI* ends with respect to the number of ends from the [+] cDNA, and is by no means an excess.

A major advantage of this protocol is that it may be performed with reagents, enzymes, and supplies routinely available in a typical molecular biology laboratory. Sucrose for gradients should be molecular biology grade (DNase-free). λgt10 phosphatased arms and packaging extracts should be obtained commercially unless large volume use is anticipated, in which case “homemade” arms and extracts would be more economical.

Troubleshooting

The initial *EcoRI* digestion, the sucrose gradients, and the *AluI* and *RsaI* digestion of [−] DNA are monitored by minigel electrophoresis. If difficulties such as incomplete digestion or poor separation occur here, see the commentaries of *UNITS 3.1 & 5.3*. Poor recovery of DNA is usually not a problem, since at least 10 μg of DNA is present at each precipitation. Once beyond these steps, there is no method for evaluation short of determining the titer and composition of the subtracted library. Possible adverse outcomes include too few clones, too many clones, or no enrichment for [+] clones (see Anticipated Results).

When too few clones are obtained, check the λgt10 phage arms, packaging extracts, and host bacteria by cloning a test insert. If $>1 \times 10^7$ PFU/μg test insert are obtained, the problem may be that the *EcoRI* ends of the [+] cDNA have been destroyed or there is an inhibitor of one of the later steps present in the DNA. Evaluate these possibilities by cloning [+] DNA after the sucrose step and measuring the efficiency, and by cloning a test insert with and without post-hybridization DNA added to the test insert ligation.

If too many clones are obtained, the problem is usually contamination of one or more reagents with phage, non-*E. coli* C600/*hflA* bacterial host, or failure to denature the [+] or [−]

DNA prior to hybridization. Too many clones may also be obtained if the S1 nuclease digestion of [−] DNA did not work, which can be evaluated by cloning some of the [−] DNA directly. Alternatively, check the S1 nuclease step by digesting some M13 DNA under the same conditions and monitoring the reaction by agarose gel electrophoresis.

If the subtraction did not work, duplicate filters screened with [+] and [−] total cDNA probes as described in step 20 will have roughly equal numbers of positive clones. The most likely explanation is that the S1 nuclease digestion was incomplete. Check the S1 step by cloning 100 ng of the [−] DNA; $<10^3$ PFU/μg insert is expected.

Anticipated Results

The number of clones obtained depends on the similarity of sources of [+] and [−] cDNA. For a subtracted cDNA library prepared from B cell [+] and T cell [−] cDNA, 5500 recombinants were obtained, 15% of which were immunoglobulin clones. Because of the high level of similarity between B cells and T cells, this result probably represents a minimum number to be expected. Investigators using this protocol have reported 300 to 15,000 phage per library. Twenty to fifty percent of the clones in a well-constructed library will be [+] specific; most of the remainder will be abundant cDNAs present in both [+] and [−] cDNA. Five to ten percent of clones *not* [+] specific may have inserts that are not released by *EcoRI* and probably represent aberrant ligation of [−] fragments into the vector.

Time Considerations

Once [+] and [−] total library DNA is obtained, perform the *EcoRI* digestion during the day and run the sucrose gradient overnight. On the second day harvest the gradients, perform the S1 digestion of the [−] cDNA, and store the precipitated DNA overnight. On the third day, digest the [−] DNA with *AluI* and *RsaI* and set up the hybridization overnight. The fourth day, ligate the cDNA to the λgt10 vector overnight and start an overnight culture of host cells. Package and plate over the following night. The protocol may be interrupted at any ethanol precipitation overnight or over the weekend.

PCR-Based Subtractive cDNA Cloning

Subtractive cloning is a powerful technique that allows isolation and cloning of mRNAs differentially expressed in two cell populations. In the generalized subtraction scheme illustrated in Figure 25B.2.1, the cell types to be compared are the [+] or tracer cells and the [-] or driver cells, where mRNAs expressed in the tracer and not the driver are isolated. Briefly, tracer nucleic acid (cDNA or mRNA) from one cell population is allowed to hybridize with an excess of complementary driver nucleic acid from a second cell population to ensure that a high percentage of the tracer forms hybrids. Hybrids that form include sequences common to both cell populations. Hybrids between the tracer and driver, and all driver sequences, are removed in the subtraction step. The unhybridized fraction is enriched for sequences that are preferentially expressed in the tracer cell population.

The method described here (see Basic Protocol) uses double-stranded cDNA (ds cDNA) as both tracer and driver and is modified from protocols devised by Sive and St. John (1988) and Wang and Brown (1991; see Background Information and Fig. 25B.2.2). Reciprocal subtractions are performed between two cell populations, A and B: that is, genes preferentially expressed in A more than in B are isolated, as are genes expressed

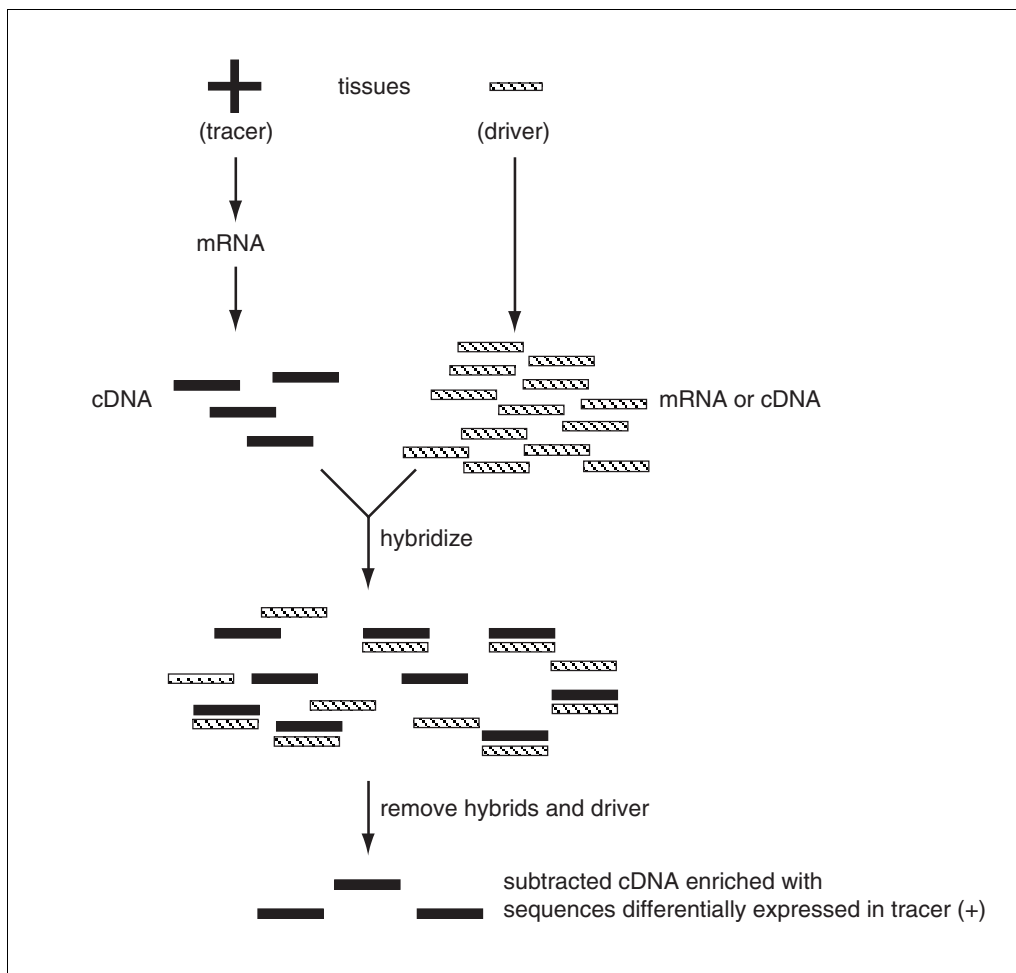

Figure 25B.2.1 Generalized subtraction scheme. Tracer cDNA from the + cell population is hybridized to >10-fold excess driver mRNA or cDNA from the - cell population. The resulting hybrids and excess driver are removed to enrich for cell type-specific sequences in the tracer. The subtraction may be repeated for further enrichment.

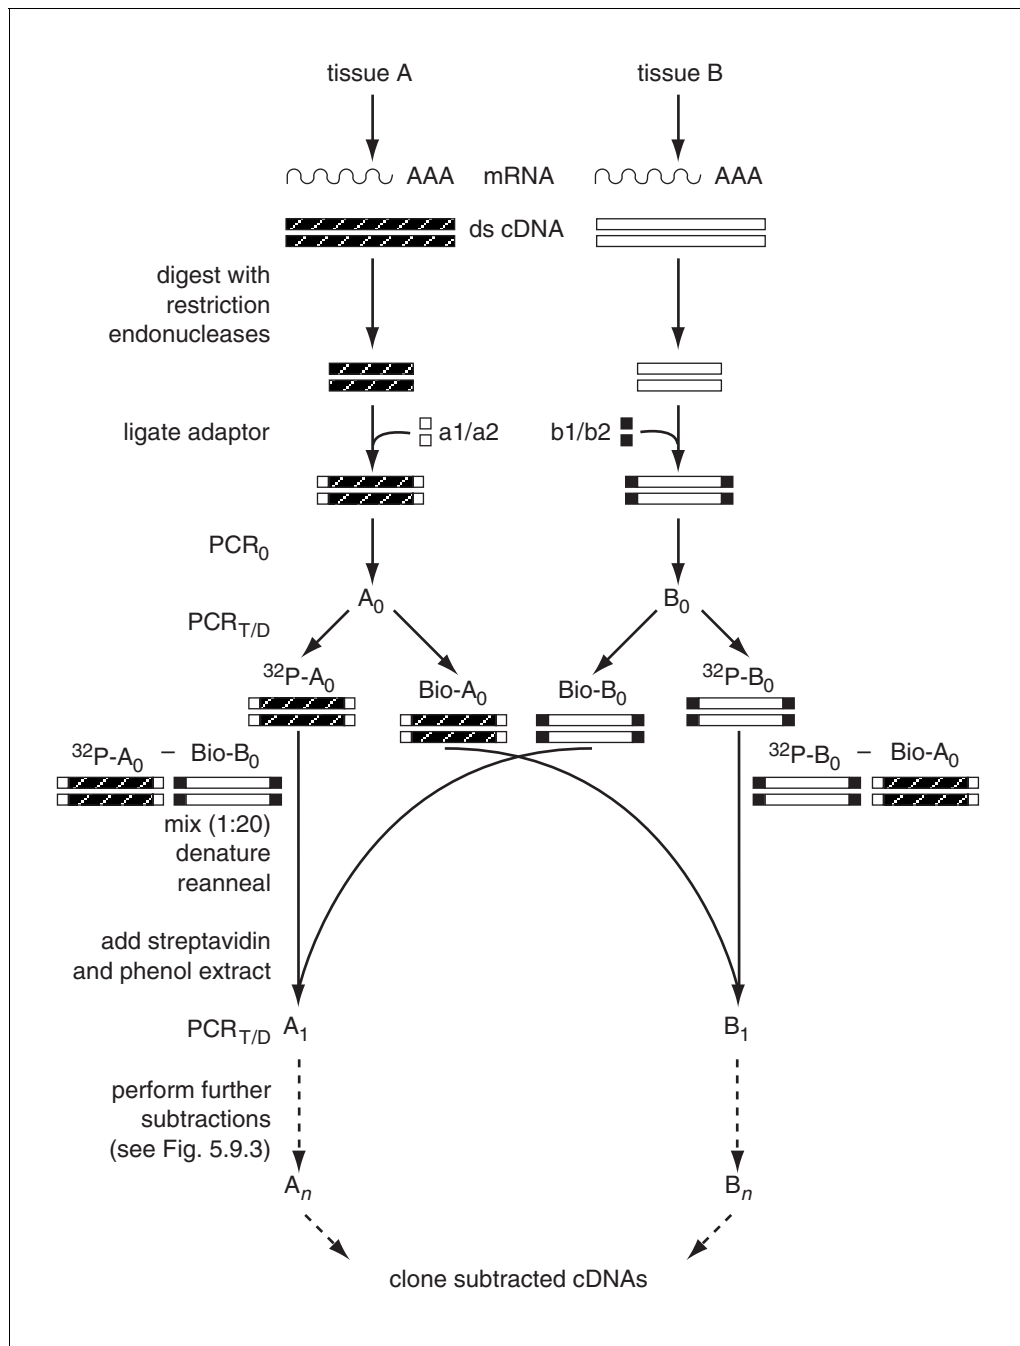

Figure 25B.2.2 Basic steps in PCR-based cDNA subtraction cloning. mRNAs purified from tissues A and B are used to synthesize double-stranded cDNA by standard methods. The resulting cDNAs are then digested with restriction endonucleases that have 4-bp recognition sequences. Two different sets of adaptors (a1/a2 and b1/b2) are ligated to the two sets of digested cDNA. The cDNAs are amplified with the appropriate primers (a1 or b1) to yield A_0 and B_0 . Two sets of subtractions are performed ($A_0 - B_0$ and $B_0 - A_0$). In each case the tracer is labeled with small amounts of [α - ^{32}P]dCTP, and the driver is labeled with bio-11-dUTP during PCR synthesis. Tracer and driver cDNAs are mixed at a ratio of 1:20, denatured, and allowed to reanneal. Driver/driver and tracer/driver hybrids are removed by treatment with streptavidin and extraction with phenol. This results in an enrichment of sequences found at greater abundance in tracer versus driver to yield A_1 and B_1 . Further subtractions are performed after another round of amplification using the appropriate cDNAs (see Fig. 5.9.3). When the subtractions are completed, the cDNAs are cloned into an appropriate vector for analysis.

preferentially in B more than in A. The method uses the polymerase chain reaction (PCR) to amplify cDNAs after each subtraction to prepare tracer and driver for the next subtraction. This makes it possible to begin with very small quantities of cells and, by performing repeated subtractions, achieve maximal enrichment of differentially expressed genes in both cell populations. The progress of subtraction is monitored by slot blot hybridization (see Support Protocol). Differentially expressed cDNA sequences are used to construct a subtracted cDNA library.

STRATEGIC CONSIDERATIONS

For this method ds cDNA, full-length (if possible) and prepared from cell types A and B using oligo(dT) as first-strand primer, is the starting material. The ds cDNA is digested by restriction endonucleases to obtain short cDNA fragments. This prevents preferential PCR amplification of naturally small cDNAs. Next, each of the two cDNA samples is ligated to different adapters and amplified by PCR to obtain a large amount of material.

In the first (and subsequent) PCR amplification step, both tracer and driver cDNAs are made for each cell type to allow subtractions in both directions. The first subtractions are A_0 tracer – B_0 driver and B_0 tracer – A_0 driver. Tracer cDNA is made partially radioactive so the success of subtractions can be monitored. Driver cDNA is biotinylated during PCR by incorporating bio-11-dUTP to provide a basis for separation of hybrids and driver. Tracer and driver are mixed, denatured, and allowed to reanneal at a driver cDNA/tracer cDNA ratio of 20:1 and a driver concentration of ≥ 2 mg/ml (or for a driver with fragment sizes of 200 bp, 15 μ mol/liter). In order to achieve this concentration, hybridizations are performed in small volumes (5 to 10 μ l). Subtractions are performed in driver excess to ensure that the reannealing rate is a function of the driver concentration only and to drive hybridization of tracer as close to completion as possible. Subtractions are performed either for a short period of time to remove sequences that are common to both A and B and abundant in both, or for much longer to remove rarer sequences that are common to both A and B (see Critical Parameters).

After annealing, tracer/driver and driver/driver hybrids are efficiently removed by addition of streptavidin (a protein that specifically and tightly binds biotin) and extraction with phenol. Biotinylated nucleic acid that has bound streptavidin is taken into the organic phase or remains at the interface (Sive and St. John, 1988). Unhybridized tracer or tracer hybrids are not removed by the streptavidin/phenol treatment because they are not biotinylated and so remain in the aqueous phase. This constitutes subtraction and enrichment for differentially expressed genes. cDNAs remaining after the first set of subtractions are termed A_1 and B_1 ; these are used for the next round of subtraction.

The subtraction sequence is shown in Figure 25B.2.3. The number of subtractions necessary depends primarily on the complexity of the cDNAs, where complexity refers to the total number of different cDNAs, or fragments of cDNA, from each cell type (Davidson, 1986). The complexity should not be confused with the number of differentially expressed cDNAs, which is only a subset of the total cDNA populations. The greater the complexity of the starting mRNA pool (or, in general, the greater the number of cell types contributing to the starting mRNA), the more subtractions will be required. Ideally, subtraction should be repeated until no more cDNA is removed after hybridization and/or until the subtracted cDNAs (A_n and B_n) do not cross-hybridize. In practice, with the scheme described here, this is usually between five and twenty subtractions.

Figure 25B.2.3 Sequence of subtractions. The order of subtractions performed is outlined here for the first five subtractions. The approximate timescale and the hybridization length for each subtraction is indicated along with the primary purpose for each subtraction. Subtractions alternate between a short (2-hr) subtraction with A_0 or B_0 as driver and a long subtraction (30- to 40-hr) with A_n or B_n as driver. A_0 and B_0 are not normalized, that is, they contain an excess of abundant mRNAs or cDNAs and are therefore used to ensure that abundant common sequences are removed. Conversely, $A_1 - A_n$ and $B_1 - B_n$ are enriched for rarer sequences and therefore remove rare common sequences more efficiently than does A_0 or B_0 . The progress of the subtractions is monitored by slot blot hybridization after every three to four subtractions. When the degree of enrichment is satisfactory (>20-fold differential; that is, when A_n hybridizes to itself better than to B_n >20-fold), then the subtracted cDNAs (A_n and B_n) are cloned into appropriate vectors for clonal analysis.

BASIC PROTOCOL

CONSTRUCTION OF SUBTRACTED cDNA LIBRARIES

This protocol describes preparation of libraries of subtracted cDNA clones that represent differentially expressed genes prepared from two cell populations. Each cDNA is ligated to a specific adapter and then the two sets of cDNAs are amplified by PCR to provide large amounts of starting material. Part of the starting material is radiolabeled to provide tracer cDNA to monitor subtraction efficiency; part is biotinylated to provide driver cDNA to facilitate removal of hybrids after annealing. Tracer cDNA from cell population A is hybridized to driver cDNA from population B and vice versa. Tracer/driver and driver/driver hybrids are removed by exposure to streptavidin and phenol extraction, leaving subtracted tracer cDNAs enriched for differentially expressed genes for each population. The sequences are enriched further by repeated rounds of amplification and hybridization. The progress of subtraction is monitored by slot blot hybridization (see Support Protocol). Finally, the subtracted cDNAs are ligated into vectors and used to create libraries that can be screened for individual differentially expressed genes.

PCR-Based Subtractive cDNA Cloning

25B.2.4

Materials

Double-stranded cDNA (ds cDNA) for cell types A and B (*UNIT 5.5*)
AluI and 10× *AluI* buffer (see recipe)
RsaI
10, 15, and 75 mM ATP
10 U/μl T4 polynucleotide kinase and 10× T4 polynucleotide kinase buffer (see recipe)
Oligonucleotide primers
3 μg/μl a1: 5'-TAG TCC GAA TTC AAG CAA GAG CAC A-3'
2.5 μg/μl a2: 5'-CTC TTG CTT GAA TTC GGA CTA-3'
3 μg/μl b1: 5'-ATG CTG GAT ATC TTG GTA CTC TTC A-3'
2.5 μg/μl b2: 5'-GAG TAC CAA GAT ATC CAG CAT-3'
10 U/μl T4 DNA ligase and 10× T4 DNA ligase buffer (see recipe)
40% (w/v) polyethylene glycol 8000 (PEG 8000)
25:24 (v/v) phenol/chloroform (made with buffered phenol; *UNIT 2.1*)
Chloroform
5 U/μl *Taq* DNA polymerase and 10× *Taq* DNA polymerase buffer (see recipe)
25 mM MgCl₂
10 mM 4dNTP mix (*UNIT 3.4*)
Mineral oil, PCR-grade, sterile
800 Ci/mmol [α -³²P]dCTP (10 Ci/μl)
Driver dNTP mix (see recipe)
Ethanol
1 and 5 M NaCl
HEPES buffer (see recipe)
2× hybridization buffer for subtractions (see recipe)
Streptavidin solution (see recipe)
EcoRI and 10× *EcoRI* buffer (see recipe) or *EcoRV* and 10× *EcoRV* buffer (see recipe)
pBluescript vector cut with *EcoRI*
pBluescript vector cut with *EcoRV*
Transformation-competent bacterial strain (*UNIT 1.8*)
Radiolabeled subtraction probes (see Support Protocol)
0.5-ml PCR tubes
Sephacryl S-300 spin columns (Pharmacia Biotech)
Beckman Accuspin FR centrifuge with swinging-bucket rotor or equivalent
Thermal cycler
Anion-exchange PCR spin columns (Qiagen)
1.5-ml microcentrifuge tubes, silanized (*APPENDIX 3B*)
Hand-held Geiger counter
Heating block
Additional reagents and equipment for restriction endonuclease digestion (*UNIT 3.1*), agarose gel electrophoresis (*UNIT 2.5A*), chromatography to remove oligonucleotide fragments (*UNIT 2.6*), phenol/chloroform extraction and ethanol precipitation (*UNIT 2.1A*), anion-exchange (Qiagen) column purification of oligonucleotides (*UNIT 2.1B*), spectrophotometric quantitation of nucleic acids (*APPENDIX 3D*), hybridization of slot blots (*UNIT 2.9B* & *2.10*; also see Support Protocol), bacterial transformation (*UNIT 1.8*), plating libraries (*UNIT 6.1*), preparing replica filters (*UNIT 6.2*), hybridizing replica filters (*UNIT 6.3*), preparing minipreps of plasmid DNA (*UNIT 1.6*), and sequencing plasmid DNA (*UNIT 7.4A* & *7.4B*)

Digest ds cDNA with restriction endonucleases

Double-stranded cDNA (ds cDNA) is digested with frequent-cutting restriction endonucleases into 200- to 600-bp fragments so PCR will not be biased towards smaller fragments.

1. For each set of ds cDNA (A and B) set up two digestions (*AluI* and *AluI* + *RsaI*) as follows:

30 ng ds cDNA
3 μ l 10 \times *AluI* buffer
10 U *AluI* or 10 U *AluI* + 10 U *RsaI*
H₂O to 30.0 μ l.

Incubate overnight at 37°C to ensure complete digestion.

Any other frequent-cutting restriction endonucleases may be used, but enzymes that generate blunt ends are preferable. If an enzyme does not generate blunt-ended DNA fragments, an additional filling-in or chewing-back step is required.

This protocol starts with double-stranded cDNA, full length if possible and primed with oligo(dT), from each cell type being compared (see UNIT 5.5). Commercially available cDNA-synthesis kits from several companies (e.g., Pharmacia Biotech or Life Technologies) work well, even with ≤ 100 ng poly(A)⁺ RNA. Silanized tubes and glycogen are used during ethanol precipitation to avoid loss of cDNA. Sephacryl S-400 columns (Pharmacia Biotech) can be used to purify the synthesized cDNA, which must be cuttable and clean enough for adapter ligation. Between 10 and 100 ng cDNA is a suitable quantity for this digestion.

2. Heat inactivate restriction endonucleases by incubating the reactions ≥ 10 min at 65°C.

Some restriction endonucleases are not susceptible to heat inactivation; phenol/chloroform extraction (UNIT 2.1A) is required to remove them.

Prepare adapters

The adapters are made by annealing kinased oligonucleotide primers a1 or b1 to unphosphorylated primers a2 or b2, respectively.

3. Kinase oligonucleotides a1 and b1 using the following reaction (25 μ l per reaction):

18.0 μ l H₂O
2.5 μ l 10 mM ATP
2.5 μ l 10 \times T4 polynucleotide kinase buffer
1.5 μ l 3 μ g/ μ l oligonucleotide a1 or oligonucleotide b1
0.5 μ l 10 U/ μ l T4 polynucleotide kinase.

Incubate 60 min at 37°C.

It is important that the ligated adapters do not contain or regenerate the restriction endonuclease recognition site in case the enzymes are not totally inactivated (see Critical Parameters).

4. Heat inactivate the kinase by incubating 20 min at 65°C.
5. Add 1.5 μ l of 2.5 μ g/ μ l oligonucleotide a2 or 2.5 μ g/ μ l oligonucleotide b2 to form a1/a2 or b1/b2 adapters. Mix and microcentrifuge briefly at maximum speed. Incubate 10 min at 45°C.

The adapters can be stored at -20°C at this stage.

Ligate adapters to cDNA

Adapters are ligated onto the cDNAs and excess adapters are removed.

6. Set up ligation reactions in 0.5-ml PCR tubes for each set of cDNAs using the appropriate adapter (130 μ l per reaction):

63 μ l H₂O
13 μ l 10 \times T4 DNA ligase buffer
30 μ l 40% PEG 8000
1 μ l 15 mM ATP
10 μ l *AluI*-digested cDNA
10 μ l *AluI/RsaI*-digested cDNA
2 μ l a1/a2 adapter *or* 2 μ l b1/b2 adapter
1 μ l 10 U/ μ l T4 DNA ligase.

Mix and incubate 2 hr at 16°C.

7. Incubate reactions >10 min on ice.
8. Prepare Sephacryl S-300 spin columns according to manufacturer's instructions.
9. Add 1 μ l of 75 mM ATP and 1 μ l T4 polynucleotide kinase to each ligation reaction. Incubate 30 min at 37°C.
10. Extract the ligation reaction with 1 vol of 25:24 phenol/chloroform, then with 1 vol chloroform.
11. Centrifuge the reaction mixture through a prepared Sephacryl S-300 spin column—i.e., 2 min at 400 \times *g* in a Beckman Accuspin FR with a swinging-bucket rotor, room temperature—to remove unligated adapters.

Approximately 130 μ l ligated cDNA will come through the column.

Ligated cDNAs may also be separated from unligated adapters by agarose gel electrophoresis (UNIT 2.5A) followed by electroelution (UNIT 2.6).

Amplify ligated cDNA

Ligated cDNA is amplified by PCR to obtain large amounts of cDNA (A₀, B₀).

12. Set up a PCR mixture for each of the two sets of cDNAs (50 μ l per reaction):

35 μ l H₂O
5 μ l 10 \times *Taq* DNA polymerase buffer
3 μ l 25 mM MgCl₂
1 μ l 10 mM 4dNTP mix
0.5 μ l 2.5 μ g/ μ l oligonucleotide a2 *or* oligonucleotide b2
5 μ l 0.2 ng/ μ l ligated A cDNA *or* B cDNA
0.5 μ l 5 U/ μ l *Taq* DNA polymerase.

Add a few drops of sterile PCR-grade mineral oil to cover the reaction.

13. Amplify the cDNA using the following PCR program:

30 cycles:	1 min	94°C (denaturation)
	1 min	50°C (annealing)
	2 min	72°C (extension)
	25 sec	72°C (autoextension)

If available, use the autoextension function of the thermal cycler (e.g., Perkin-Elmer 480). Alternatively, for thermal cyclers without autoextension, increase the extension time from 2 to 4 min.

This amplification should yield ~10 μ g A₀ and B₀ cDNAs.

The reaction product can be stored overnight at 4°C or longer at -80°C.

14. Analyze 5 to 10 μl of the amplified cDNAs by agarose gel electrophoresis (UNIT 2.5A) to determine the size ranges of amplified cDNAs.

The size of amplified cDNAs should be between 150 bp and 1.5 kb with most ~250 bp.

Prepare labeled tracer and driver DNAs

Radioactive tracer DNA is required for monitoring subtraction efficiency; biotinylated driver DNA is required for removing hybrids by streptavidin binding and phenol extraction.

15. For both sets of amplified cDNAs, set up the following tracer synthesis PCR (100 μl per reaction):

77 μl H₂O
10 μl 10 \times Taq DNA polymerase buffer
6 μl 25 mM MgCl₂
2 μl 10 mM 4dNTP mix
1 μl diluted [³²P]dCTP
1 μl 2.5 $\mu\text{g}/\mu\text{l}$ oligonucleotide a2 or b2
2 μl A₀ or B₀ cDNA (~0.4 μg)
1 μl 5 U/ μl Taq DNA polymerase.

Add a few drops of sterile PCR-grade mineral oil to cover the reaction.

The amount of cDNA used for these initial A₀ and B₀ tracer synthesis reactions is 400 ng; this may be decreased but use ≥ 40 ng for the first amplification. In subsequent amplifications, use 5 to 10 ng A_n or B_n cDNA.

These reactions yield ³²P-labeled tracer cDNA ([³²P]A₀ and [³²P]B₀ in the first round and [³²P]A_n and [³²P]B_n in subsequent rounds; see Fig. 25B.2.2).

16. For both sets of amplified cDNAs, set up three or four driver synthesis PCRs (100 μl per reaction):

73.3 μl H₂O
10 μl 10 \times Taq DNA polymerase buffer
6 μl 25 mM MgCl₂
6.7 μl driver dNTP mix
1 μl 2.5 $\mu\text{g}/\mu\text{l}$ oligonucleotide a2 or b2
2 μl A₀ or B₀ cDNA (1 to 5 ng)
1 μl 5 U/ μl Taq DNA polymerase.

Add a few drops of sterile PCR-grade mineral oil to cover the reaction.

The driver dNTP mix contains 0.5 mM bio-11-dUTP and 1.0 mM dTTP. In the authors' hands this ratio of bio-11-dUTP/dTTP gives the highest overall subtraction efficiency and still allows efficient base pairing.

These reactions yield biotinylated driver cDNA (Bio-A₀ and Bio-B₀ in the first round and Bio-A_n and Bio-B_n in subsequent rounds; see Fig. 25B.2.2).

17. Use the PCR amplification program described in step 13 for tracer and driver synthesis.

18. Purify amplified cDNAs away from unincorporated nucleotides, primer, and salts using a commercial anion-exchange PCR spin column (Qiagen) as directed by the manufacturer (UNIT 2.1B).

An alternate way to purify the PCR products is by agarose gel purification (UNIT 2.5A), but care must be taken to avoid contamination with other DNAs.

19. Determine the yields by spectrophotometric quantitation of nucleic acids (*APPENDIX 3D*).

Typical amplifications yield 12 to 16 μg ^{32}P -labeled cDNA per 100- μl tracer reaction and 7 to 10 μg biotinylated cDNA per 100- μl driver reaction.

The quality and size range of the purified cDNA should be checked using agarose gel electrophoresis (UNIT 2.5A) after every third PCR amplification before proceeding to the next subtraction step. The size range should not change significantly.

Anneal tracer and driver

This is a hybridization between ^{32}P -labeled tracer and biotinylated driver cDNAs.

20. Set up two hybridization reactions ($[^{32}\text{P}]\text{A}_n - \text{Bio-B}_n$ and $[^{32}\text{P}]\text{B}_n - \text{Bio-A}_n$). Ethanol precipitate 1 μg radiolabeled tracer and 20 μg biotinylated driver DNAs in a 1.5-ml silanized microcentrifuge tube without freezing. Air dry the pellet and when just dry, resuspend in 5 μl HEPES buffer by gentle pipetting. Monitor resuspension of the pellet with a hand-held Geiger counter.

A small radioactive pellet should be clearly visible. By not freezing during ethanol precipitation, the possibility of a large salt pellet is avoided.

Resuspension of the pellet sometimes requires a little patience; warming the tube to 60°C usually helps. Also check that none of the counts (i.e., cDNA) are stuck to the pipet tip, as this can greatly reduce the subtraction efficiency. The use of silanized pipet tips may help reduce sticking.

The pellet should not be resuspended in a larger volume because this will lower the concentration of driver, and hence the reannealing rate.

21. Transfer resuspended DNA to a 0.5-ml PCR tube. Add 5 μl of 68°C 2 \times hybridization buffer for subtractions. Mix by gentle pipetting and add a few drops of sterile PCR-grade mineral oil to cover the DNA solution. Microcentrifuge briefly at maximum speed.

If a pellet is visible, the DNA has come out of solution.

22. Incubate the two tubes 10 min at 95°C and cool slowly over 1 hr to 68°C. Continue incubation 2 hr at 68°C (short hybridization).

Either a thermal cycler or a heat block may be used for this step.

Subsequent hybridizations alternate between long (30- to 40-hr) hybridizations during which both rare and abundant common sequences form hybrids, and short (2-hr) hybridizations during which only abundant common sequences form hybrids.

Remove biotinylated annealed and single-stranded DNA

Tracer/driver and driver/driver hybrids and biotinylated single-stranded driver cDNA are removed by addition of streptavidin and extraction with phenol/chloroform.

23. Mix 7 μl of 1 M NaCl with 140 μl HEPES buffer and warm to 68°C. Add to the hybridization reaction to dilute the reaction. Mix and microcentrifuge briefly at maximum speed. Cool to room temperature.
24. Remove 5 μl from each tube and save (total pre-phenol extraction counts).
25. Add 15 μl streptavidin to each tube. Vortex and incubate 5 min at room temperature.
26. Extract each tube with an equal volume 25:24 phenol/chloroform. Retain the aqueous phases and transfer to new tubes.

27. Add 10 μ l streptavidin to each tube containing aqueous phase. Mix and incubate 5 min at room temperature.
28. Extract twice with phenol/chloroform and twice with chloroform. Measure the volume of the aqueous layer for each tube.

The volume for each reaction should be ~150 μ l.

The aqueous phase contains A_n and B_n cDNA.

29. Remove 5 μ l of the aqueous layer from each tube (total post-phenol extraction counts).

Use either scintillation or Cerenkov counts of the pre- and post-phenol extraction samples to determine efficiency of subtraction. The percent tracer cDNA removed is calculated by the following equation:

$$\% \text{ tracer removed} = 100 - (\text{total post-phenol counts} \times 100 / \text{total pre-phenol counts})$$

The subtracted material can be stored at -20°C .

Perform further subtractions

Further rounds of subtraction are performed using subtracted cDNAs from the previous round as template for PCR synthesis of tracer and driver cDNAs. Additional rounds of subtraction, with alternating short and long hybridization steps, continue enriching for the differentially expressed genes.

30. Repeat the subtractions (steps 15 to 29) using A_n or B_n tracer cDNA and the appropriate driver cDNA as determined by the subtraction strategy (see Fig. 25B.2.3). Use A_0 or B_0 drivers for short (2-hr) hybridizations and A_n or B_n drivers for long (30- to 40-hr) hybridizations. Monitor the progress of subtraction by slot blot hybridization (see Support Protocol).

Between five and twenty rounds of subtraction are usually sufficient to isolate cDNAs for differentially expressed genes.

Clone subtracted cDNAs

Subtracted cDNAs are ligated into a vector and cloned to permit screening of individual clones.

31. Amplify 5 μ l of the subtracted cDNAs (A_n and B_n) using the program described in step 13. Purify PCR products with a commercial anion-exchange PCR spin column (e.g., Qiagen; UNIT 2.1B).
32. Digest the cDNAs with the appropriate restriction endonucleases that cut within the adapters (e.g., *EcoRI* and *EcoRV* for the adapters used here).

Taq DNA polymerase may survive phenol/chloroform extraction, so it may help to purify the cDNAs by treating the amplified reaction with proteinase K, extracting with phenol/chloroform, and precipitating with ethanol before digestion.

Digestion may be omitted if blunt-ended ligations are to be performed. PCR amplification often results in the addition of an extra adenosine at the 3' end; this should be removed by Klenow treatment (UNIT 3.16) if blunt-ended ligations are to be performed. Alternatively, the subtracted cDNAs may be cloned into a T-vector (UNIT 15.4).

33. Purify digested cDNAs by phenol/chloroform extraction and ethanol precipitation.
34. Ligate the DNA into an appropriate vector (UNIT 3.16; e.g., pBluescript digested with *EcoRI* or *EcoRV*).

Any convenient vector may be used (see Critical Parameters and Troubleshooting). Using a vector with blue-white selection is useful because it allows immediate assessment of the proportion of the library that contains inserts.

35. Transform the vector into a transformation-competent bacterial strain (UNIT 1.8).

If the subtractions were done to (or nearly to) completion and most of the colonies contain inserts, then it should be possible to pick colonies at random and check for differential expression. Alternatively, use the following steps to assess the quality of the library.

Assess subtracted libraries

Replica filters of the library are probed to assess for percent differentially expressed clones and to provide an indication of the success of the subtractions.

36. Plate out the subtracted library (UNIT 6.1).

It is worth titrating the library first (UNIT 1.3) to obtain individual colonies. It is also important to determine the percentage of colonies that have inserts and the sizes of the inserts (UNIT 5.8). The insert size should be ~250 bp. If the insert size is >500 bp, consider the possibility that the inserts may be double inserts.

37. Prepare four replica lifts from each primary filter (UNIT 6.2).

38. Denature, neutralize, and cross-link the lifts according to the manufacturer's instructions (also see UNIT 6.2).

39. Use subtracted probes (see Support Protocol, step 5) to hybridize the replica filters.

Comparison of filters probed with A_n versus B_n identifies those clones that are probably differentially expressed in the starting A_0 and B_0 cDNAs and also indicates what proportion of the library contains differentially expressed genes. Further rounds of subtraction may be desirable if only a small number of the clones seem to be differentially expressed. The filter probed with a common abundant gene should give very few or no positive signals if the subtractions were done to completion. Finally, probing with a known differentially expressed gene(s) gives another indication of how well the subtractions have worked. If the library evaluation suggests that no further subtractions are needed, analyze individual clones in the library.

Sort through the library

The number of differentially represented clones from the subtracted library is assessed by sequencing and/or gridding.

40. Pick 50 to 100 differentially expressed clones from the library either randomly (if the library assessment indicates most of the clones are differentially expressed) or based on a differential hybridization screen using A_n and B_n as probes. Prepare a miniprep of plasmid DNA (UNIT 1.6).

41. Sequence the inserts in each of the plasmid DNAs (UNIT 7.4A & 7.4B) and group together clones containing the same sequences.

DNA sequence analysis software such as that from DNASTar is helpful.

If most of the clones analyzed initially are the same, they should be subtracted out to reveal rarer transcripts. This is done by pooling the identified clones and using them to make driver that is then used for subtraction with A_n or B_n tracer. Alternatively, the library can be plated out and the lifts probed with mixed probe from the sequenced clones (≤ 20 sequences/mixed probe). Clones that do not hybridize have not yet been sequenced and should be analyzed. If all the clones seem to be differentially expressed but a few are particularly prevalent, then another way to reveal rare transcripts is to normalize A_n and B_n (or self-subtract them—i.e., $A_n - A_n$ and $B_n - B_n$) for a short period of time. These procedures greatly reduce the work involved in sorting through the library.

42. Determine whether the clones are truly differentially expressed in the starting tissues by RNA expression analysis—e.g., northern blot hybridization (UNIT 4.9), RNase protection assay (UNIT 4.7), quantitative RT-PCR (UNIT 15.5), or in situ hybridization (UNITS 14.3 & 14.7).

**SUPPORT
PROTOCOL**

SLOT BLOT HYBRIDIZATION TO MONITOR SUBTRACTION

After every three to four subtractions, the progress of enrichment for differentially expressed genes is monitored by slot blot hybridization (also see UNITS 2.9B & 2.10).

Additional Materials (also see Basic Protocol)

cDNA from each subtraction (see Basic Protocol, step 28)
3 M NaOH
2 M ammonium acetate, pH 7.0
Probe dNTP mix (see recipe)
Sephadex G50/80 spin column (Pharmacia Biotech) in sterile 1-ml syringe
Additional reagents and equipment for slot blotting (UNIT 2.9B) and hybridization (UNIT 2.10)

1. Denature 1200 ng cDNA from each subtraction ($A_n - B_n$ and $B_n - A_n$) by adding 0.1 vol of 3 M NaOH to cDNA and heating 30 to 60 min at 65°C.
2. Neutralize the DNA by adding 1 vol of 2 M ammonium acetate, pH 7.0.
3. Spot duplicate 100-ng aliquots of denatured and neutralized cDNA from each subtraction onto each of six or more slot blots (UNIT 2.9B).
4. Use cDNA from A_n , B_n , A_0 , B_0 , a gene expressed at high levels in both A and B, and one or more genes expressed differentially by A or B (or a gene used to spike the reaction) to prepare radiolabeled subtraction probes. Prepare a PCR mixture for each probe (50 μ l per reaction):

17.5 μ l H₂O
5 μ l 10 \times *Taq* DNA polymerase buffer
3 μ l 25 mM MgCl₂
2 μ l probe dNTP mix
20 μ l [α -³²P]dCTP
1 μ l 2.5 μ g/ μ l primer a2, primer b2, primer specific for gene expressed in both A and B, *or* primer specific for gene expressed differentially in A or B
0.5 μ l 4 ng/ μ l subtracted A_n or B_n cDNA or appropriate gene template DNA
1 μ l 5 U/ μ l *Taq* DNA polymerase.

Add a few drops of sterile PCR-grade mineral oil to cover the reaction.

5. Amplify and label the probe using the following PCR program:

30 cycles	1 min	94°C (denaturation)
	1 min	50°C (annealing)
	2 min	72°C (extension)

This reaction yields a double-stranded probe; the probes should be denatured before hybridization.

6. Purify the probe by centrifuging it through a 1-ml Sephadex G50/80 spin column, 2 min at $170 \times g$, in a Beckman Accuspin FR with a swinging-bucket rotor, room temperature.
Expect ~50 μ l eluate after centrifugation.
7. Measure incorporation by counting a 1- μ l fraction of the eluate in a scintillation counter.
Routinely, incorporation is $\sim 10^6$ cpm/ μ l eluate.
8. Hybridize each slot blot with one of the above probes (UNIT 2.10).
9. Wash the blots to high stringency (UNIT 2.10).
10. Expose filters to X-ray film or a phosphoimaging plate (APPENDIX 3A).

The A_n and B_n hybridizations are the most important because they reveal the degree to which A_n and B_n cDNAs still cross-hybridize with B_n and A_n cDNAs, respectively. In general, further subtractions are desired if the differential is <20 -fold (that is, A_n hybridizes <20 -fold better to itself than to B_n and vice versa). Probing the subtracted cDNAs with a highly expressed gene or with a differentially expressed gene gives another indication of how well the subtractions are advancing. Common abundant genes should become less abundant with increasing rounds of subtraction, and the known differentially expressed gene should become enriched in one series of cDNAs and depleted in the other. The A_0 and B_0 probes usually represent the common abundant genes and therefore behave accordingly; that is, they hybridize more strongly to cDNA from earlier rounds of subtraction and less so to later rounds. When the evaluation suggests that no more subtractions are required, then the A_n and B_n cDNAs should be cloned into an appropriate vector.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

AluI buffer, 10 \times

- 100 mM Bis-Tris propane (1,3-bis[tris(hydroxymethyl)methylamino]propane)·Cl, pH 7.0
- 100 mM MgCl₂
- 10 mM dithiothreitol (DTT; APPENDIX 2)
- Store up to 6 months at -20°C

Driver dNTP mix

- 1.5 mM each dATP, dCTP, and dGTP
- 1.0 mM dTTP
- 0.5 mM bio-11-dUTP (Enzo Diagnostics)
- Store up to 3 month at -20°C

EcoRI buffer, 10 \times

- 1 M Tris·Cl, pH 7.5 (APPENDIX 2)
- 500 mM NaCl (APPENDIX 2)
- 100 mM MgCl₂ (APPENDIX 2)
- 0.25% (v/v) Triton X-100
- Store at -20°C

EcoRV buffer, 10 \times

- 100 mM Tris·Cl, pH 7.9 (APPENDIX 2)
- 500 mM NaCl (APPENDIX 2)
- 100 mM MgCl₂ (APPENDIX 2)
- 10 mM dithiothreitol (DTT; APPENDIX 2)
- Store up to 6 months at -20°C

HEPES buffer

100 mM HEPES (*N*-2-hydroxyethylpiperazine-*N*-2-ethanesulfonic acid), pH 7.3
1 mM EDTA (*APPENDIX 2*)
Store at -20°C

Hybridization buffer for subtractions, 2 \times

50 mM HEPES, pH 7.3
10 mM EDTA (*APPENDIX 2*)
0.2% (w/v) SDS
1.5 M NaCl (*APPENDIX 2*)
Store up to 3 months at -20°C
To avoid cloudiness, add NaCl last and warm to 68 $^{\circ}\text{C}$

Probe dNTP mix

0.5 mM each dATP, dGTP, and dTTP
0.1 mM dCTP
Store up to 3 months at -20°C

Streptavidin solution

2 $\mu\text{g}/\mu\text{l}$ streptavidin
0.15 M NaCl (*APPENDIX 2*)
HEPES buffer (see recipe)
Store up to 6 months at -20°C

T4 DNA ligase buffer, 10 \times

500 mM Tris \cdot Cl, pH 7.8 (*APPENDIX 2*)
100 mM MgCl_2 (*APPENDIX 2*)
100 mM dithiothreitol (DTT; *APPENDIX 2*)
10 mM ATP
250 $\mu\text{g}/\text{ml}$ BSA
Store up to 6 months at -20°C

T4 polynucleotide kinase buffer, 10 \times

700 mM Tris \cdot Cl, pH 7.6 (*APPENDIX 2*)
100 mM MgCl_2 (*APPENDIX 2*)
50 mM dithiothreitol (DTT; *APPENDIX 2*)
Store up to 6 months at -20°C

Taq DNA polymerase buffer, 10 \times

100 mM Tris \cdot Cl, pH 9.0 (*APPENDIX 2*)
500 mM KCl (*APPENDIX 2*)
1% (v/v) Triton X-1000
Store at -20°C

COMMENTARY**Background Information**

Early subtractive cloning involved one or two rounds of hybridization using cDNA as tracer and mRNA as driver. cDNA/mRNA hybrids were removed by binding to hydroxylapatite columns maintained at 68°C . This scheme has two major limitations that prevented subtractive cloning from becoming a routine and frequently used technique. The first was that hydroxylapatite columns are cumbersome, making it difficult to separate

single-stranded sequences from the hybrids. This problem has been largely overcome through the use of biotinylated driver sequences in combination with streptavidin treatment and phenol extractions (Sive and St. John, 1988; Sive et al., 1989), or streptavidin-conjugated magnetic beads (Uhlen, 1989; Straus and Ausubel, 1990).

A second problem with the original technique was the rapid decrease in the amount of cDNA present, making it very difficult to per-

form multiple rounds of subtraction or to clone the minute amounts of cDNA left after subtraction. Several different approaches have been used to tackle this second problem. One solution has been to construct directional phagemid libraries that can be converted into a single-stranded library; after the subtractions are performed, the remaining single-stranded plasmids are transformed into bacteria for amplification (Duguid et al., 1988; Rubenstein et al., 1990). The subtracted library can be used in further rounds of subtractions; however, the method is laborious and care must be taken to avoid contamination with the double-stranded (ds) forms of the phagemid. Contaminating ds phagemid DNA will not be subtracted away and will transform bacteria much more efficiently than single-stranded DNAs do, thus reducing the overall subtraction effect. Other methods have used cDNA attached to oligo(dT)-Latex in combination with the polymerase chain reaction (PCR). This allows the driver to be reused (Hara et al., 1993).

An alternative solution described in this protocol regenerates the cDNAs by PCR (Duguid and Dinauer, 1989; Wang and Brown, 1991). A problem with PCR is that it amplifies smaller fragments better than larger fragments and therefore selects for smaller mRNAs. Wang and Brown (1991) overcame this difficulty by cutting the original cDNAs to smaller sizes before PCR. This approach allows multiple rounds of subtractions and has allowed isolation of many genes that are differentially expressed in metamorphosis-stage *Xenopus* embryos after thyroid hormone treatment (Buckbinder and Brown, 1992). With the modified protocol detailed here, the authors have isolated many genes that delineate the early events of neural induction and anteroposterior patterning in *Xenopus* (Patel et al., unpub. observ.). The method described here is very sensitive and can isolate genes that are as little as 2- to 3-fold differentially expressed.

In the scheme described here, two cDNA populations are cross-subtracted—that is, A tracer is subtracted with B driver and B tracer with A driver. This allows isolation of genes expressed preferentially in A and genes expressed preferentially in B. Cross-subtraction has two other effects. The first is to increase the concentration of rare sequences relative to the concentration of abundant common sequences in the driver, because the latter rapidly hybridize (at low C_0t) and are removed by subtraction. This is termed normalization, as it normalizes or equalizes the concentrations of what were

initially rare and abundant common cDNAs. In practice, it is not possible to reach a truly equalized representation of sequences, but the starting concentrations of different cDNAs can vary 10,000-fold, and after normalization this can be reduced to ~10-fold (Patanjali et al., 1991; Soares et al., 1994). Normalizing the driver makes it much more efficient at removing rare common sequences than an unnormalized driver. Normalizing the driver is essential when starting with tissues that have high mRNA complexity. It is, of course, also important that some of the subtractions be performed with a driver that still contains high levels of abundant common sequences (that is, the starting cDNA population, A_0 or B_0); otherwise these abundant sequences will never be removed.

Normalization could also be achieved by subtracting the driver against itself (self-subtraction). The reason cross-subtractions are used instead is that they provide a second benefit. One of the problems with any efficient subtraction scheme is that it may remove sequences expressed only a few-fold higher in one cell population than the other, and therefore allow isolation of only those sequences that are not expressed at all in the driver. Sequences expressed with ≤ 10 -fold differential may be of great interest and can be isolated by cross-subtractions. Suppose that sequence G is present at a ratio of 1:5 in A_0/B_0 , the starting cDNAs. If B_0 is subtracted with A_0 , and vice versa, G will be removed somewhat from the resulting B_1 ; however, after the reciprocal $A_0 - B_0$ subtraction, relatively more G will be removed from the resulting A_1 than it was from B_1 because the driver (B_0) had a higher concentration of G than A_0 did. Thus, the ratio of G in A_1/B_1 will decrease, perhaps to 1:10. This enhanced relative difference in the level of G between A_1 and B_1 will be enhanced even more in subsequent cross-subtractions, to ultimately allow isolation of G as a differentially expressed clone. One problem here is that cross-subtracting can result in false positives (genes that are differentially represented in the final A_n and B_n cDNA populations, but not in the starting A_0 and B_0 cDNAs). This is a particular problem if the efficiencies of the two subtraction series ($A - B$ versus $B - A$) are different, but it can easily be checked after subtraction by asking whether a clone is differentially represented in the A_0 and B_0 starting cDNAs.

This protocol includes two modifications to the Wang and Brown (1991) method that the authors feel improve it. First, bio-11-dUTP is

incorporated into the driver as a means of biotinylating (Patel and Sive, unpub. observ.) in place of the photobiotinylation originally described (Sive and St. John, 1988) for two reasons. Incorporation of biotin during PCR amplification is extremely simple and does not require additional photobiotinylation steps. Substituting 30% of the dTTP with bio-11-dUTP in the amplification of driver nucleic acid gives maximal subtraction efficiency. With lower substitution, subtraction efficiency decreases, presumably because the density of biotin is not great enough; with greater substitution, subtraction efficiency also decreases, presumably because the biotin interferes with base-pairing (Patel and Sive, unpub. observ.). Photobiotinylated nucleic acid is rather insoluble in aqueous solutions due to a long hydrocarbon linker arm; photobiotinylated driver sometimes precipitates out of the hybridization mix. Nucleic acids with biotinylated nucleotides incorporated during PCR seem as soluble as unmodified nucleic acids and precipitation in the hybridization mix does not occur, at least in the authors' hands. Another method for incorporating biotinylated nucleotides is to use biotinylated primers for PCR (Rosenberg et al., 1994). Second, this protocol uses different adapters on the driver and tracer cDNAs. The original protocol (Wang and Brown, 1991) used the same adapters for both tracer and driver to ensure that all sequences in tracer and driver amplified to the same extent; however, this also

meant an increased risk of driver carry-over into the next round of subtraction; such carried-over driver would be amplified along with the subtracted cDNA and would decrease subtraction efficiency. Using the different primers given here, the authors have observed essentially equivalent PCR efficiency for the two cDNA pools.

Several other methods have been used to isolate genes that are differentially expressed between two or more cell populations (see Table 25B.2.1)—random sampling (in which clones are randomly selected from a cDNA library), differential hybridization (in which probes made from the mRNAs of the two tissues being compared are used to screen a cDNA library, and clones that hybridize to one probe but not to the other are isolated), and differential display (*UNIT 25B.3*; in which partially random primers are used to amplify a subset of mRNAs expressed in a given cell type; these are then separated on an acrylamide gel and the bands between different samples compared). Of all the procedures, subtractive cloning is probably the most sensitive, and it is the method of choice to isolate as complete a set of differentially expressed genes as possible. The other methods allow isolation of a small number of differentially expressed genes and may be sufficient to obtain useful markers. Random sampling of a cDNA library is useful only if the two tissues to be compared contain a widely different spectrum of mRNAs.

Table 25B.2.1 A Comparison of Differential Screening Methods

Method	Advantages	Disadvantages
Subtractive cloning	Targets rare mRNAs (<0.001%) Targets complete set of differentially expressed RNAs Requires little starting material Nonisogenic tissues can be compared	Can generally only compare two tissues at one time Procedure can be long
Differential display	Requires little starting material Can compare more than two tissues or treatments at one time Procedure is relatively short	Targets only a subset of the differentially expressed genes Generally targets medium-abundant mRNAs Can yield many false positives
Differential hybridization	Procedure is relatively easy	Targets relatively abundant mRNAs (~0.1%)
Random sampling	Simple procedure; only cDNA libraries are required	Only useful for comparing very different tissues

Critical Parameters and Troubleshooting

Some of the more common problems that arise with this procedure and their solutions are listed in Table 25B.2.2.

RNA preparation

It is essential to start with a clean preparation of RNA that is free of any salts or other substances that may inhibit reverse transcription. The RNA should not be contaminated with

even trace amounts of genomic DNA. In fact, all RNA preparations should be treated with RNase-free DNase, then checked for contaminating genomic DNA by PCR using primers for specific genes. Contaminating DNA alters the representation of the various mRNAs during the subtractions to create false positives.

Purity of oligonucleotides

The quality of the primers is crucial to the success of the procedure. It is worth purifying

Table 25B.2.2 Troubleshooting Guide for Subtractive cDNA Cloning

Problem	Probable cause(s)	Remedy
No amplified cDNAs visible on agarose gel	Failure of adapters to ligate to cDNA due to: Kinasing of wrong primer Inactive ligation buffers and/or enzymes Inhibitors in cDNA	Kinase correct primer Test and replace as necessary Repurify cDNA by phenol/chloroform extraction and ethanol precipitation using glycogen as carrier
	Failure of PCR amplification due to inactive amplification buffer and/or enzymes	Test and replace as necessary
Median size range of amplified cDNAs >500 bp in A ₀ and/or B ₀	Incomplete digestion of cDNA before amplification due to: Inhibitors in ds cDNA	Purify ds cDNA by phenol/chloroform extraction and ethanol precipitation using glycogen as carrier
	Inactive restriction buffers or enzyme	Test and replace as necessary
Low subtraction efficiency	Loss of DNA during ethanol precipitation or resuspension Incomplete resuspension of DNA before hybridization	Repeat with careful monitoring using hand-held Geiger counter Avoid complete drying of DNA pellet before resuspension Warm sample to 60°C to aid resuspension
No or few colonies after cloning into vector	Incomplete digestion of DNA	Repurify DNA; treat with proteinase K, phenol/chloroform extract, ethanol precipitate, and wash with 70% ethanol
	Inactive enzymes or buffers Poor ligation efficiency	Test and replace as necessary Repurify DNA; test and replace enzymes or buffers
	Low transformation efficiency	Test and replace competent cells
No or few differentially expressed genes	Contamination of RNA or cDNA with (genomic) DNA before ligation of adaptors	Restart with fresh RNA and treat it with DNase before reverse transcription

the primers to ensure they are full length and free of any salts or other inhibitors. The synthesized primers can be gel purified, although the authors prefer to use Nensorb Prep columns (Du Pont NEN). To use these columns, the 5'-trityl group on the primer must not be removed (see UNIT 2.11 for more information about the synthesis of oligonucleotides).

Primer design

The two different adapters used during this protocol are created by annealing a 21-mer and a 25-mer oligonucleotide. The sequences of four primers that these authors have used successfully are listed in the Basic Protocol. These primers contain sites for *EcoRI* or *EcoRV*; however, different restriction endonuclease sites or other special features for particular vectors may be desirable, so this section outlines some considerations in primer design.

First, restriction endonucleases generally require at least four bases next to their recognition sequences to work efficiently. Second, primers should contain minimal secondary structure to maximize annealing to the target sequence. Third, there should be no similarity between the primers that make up one set of adapters and those that make up the second set. This is extremely important for the success of the subtractions, and it is essential to check for any cross-annealing by testing whether a primer from one set of adapters can amplify cDNA (or a test DNA fragment) ligated to the other adapter. Fourth, in order to perform the PCR amplifications for the two sets of cDNAs (A and B) at the same time, it is important that the primers have similar melting temperatures (T_m). Fifth, the T_m should not be so high that it approaches the hybridization temperature of 68°C, so the GC content should be kept <50%, and the primers should not be excessively long (>50 bases). Standard oligonucleotide software (e.g., Oligo, Primerselect) is helpful for designing primers. Primer sequences should also be checked against a database such as GenBank for any similarities to sequences in known genes.

Restriction digestion of cDNAs

It is very important that the cDNAs of both the tracer and driver sides be cut to completion before adapter ligation. If, for example, A cDNA has not digested as well as B cDNA, PCR may be biased for smaller fragments in A but not B, resulting in false positives at the end of the procedure. The A_0 and B_0 populations

should be checked on a gel to ensure that the size ranges of amplified cDNAs are the same.

Monitoring subtractions

It is necessary to monitor efficiency of the subtractions to determine when to stop subtracting. In many cases a problem can be easily resolved on the spot rather than being discovered at the end of the subtractions so that it is necessary to start all over again. Subtraction efficiency can be monitored in the following ways. First, the cumulative percentage removal of tracer counts after the phenol extractions at each subtraction should be determined to provide an immediate and fairly accurate way of determining whether a particular subtraction has been successful and whether the subtraction should be repeated. Second, the degree to which A_n and B_n cross hybridize can be monitored by slot blotting cDNAs from each step of subtraction and probing the blots with the last set of subtracted cDNAs (A_n and B_n). Subtractions are generally stopped when a probe made from A_n hybridizes to the A_n cDNA pool ~20-fold better than it does to the B_n pool, and vice versa. Third, the removal or enrichment of a known differentially expressed gene in A_0 through A_n can be monitored by slot blot hybridization. If no such gene is available, then the original tracer may be spiked with some DNA such as β -galactosidase, which can be removed at the end. Fourth, if the subtractions are working, common abundant sequences should be progressively removed with each subtraction.

Anticipated Results

The end result of the procedure is the isolation of fragments of differentially expressed genes. The actual number of such genes obtained depends on the tissues being compared. Hence, if the two starting tissues are of very similar complexity, only a few genes may be obtained. On the other hand, if the tissues being compared contain a mixture of cell types and are very different, it is easily possible to obtain hundreds of differentially expressed genes. Abundant transcripts will be represented more frequently than rare transcripts. Additionally, each original transcript may be represented by multiple clones because the original cDNA was digested into fragments before subtraction. In theory, because the restriction endonucleases (*AluI* and *RsaI*) have 4-bp recognition sequences, digestion should produce approximately four 250-bp fragments per kilobase

original mRNA. In practice, digestion yields one to two fragments per gene. If the subtractions have been performed exhaustively, then theoretically every clone in the subtracted library should be differentially expressed. Furthermore, it should be possible to isolate genes that are 2- to 3-fold differentially expressed between two given tissues and whose abundance is as little as 5 copies mRNA/cell; however, the isolation of rare differentially expressed genes is dependent on the complexity of the starting tissues.

Time Considerations

A time schedule for this procedure is presented in Table 25B.2.3. This schedule is approximate and assumes that the procedure starts with double-stranded cDNA (see Fig. 25B.2.3).

Differential Display of mRNA by PCR

UNIT 25B.3

**BASIC
PROTOCOL**

This unit describes differential display to identify mRNA species for differentially expressed genes. DNA sequences corresponding to these mRNAs can be recovered, cloned, sequenced, and used for hybridization or library screening probes. This approach combines both the power of polymerase chain reaction (PCR) amplification and the high resolution of denaturing polyacrylamide gel electrophoresis for separation of amplified cDNA products. The basic principle is to reverse transcribe and systematically amplify the 3' termini of mRNAs with a set of anchored oligo(dT) primers and an arbitrary decamer. Figure 25B.3.1 illustrates the general strategy of differential display. Specifically, an RNA sample is reverse transcribed with each of the four sets of degenerate anchored oligo(dT) primers ($T_{12}MN$), where M can be G, A, or C and N is G, A, T, and C. Each primer set is dictated by the 3' base (N), with degeneracy in the penultimate (M) position. For example, the primer set where N = G consists of:

5'-TTTTTTTTTTTTGG-3'
5'-TTTTTTTTTTTTAG-3'
5'-TTTTTTTTTTTTCG-3'

The resulting cDNA population is PCR-amplified using the degenerate primer set, an arbitrary decamer, and radioactive nucleotide. The radioactively labeled PCR products that represent a subpopulation of mRNAs defined by the given primer set are separated on a denaturing polyacrylamide gel. By changing primer combinations, most of the RNA species in a cell may be represented. Side-by-side comparison of RNA samples from different cells allows the identification and cloning of differentially expressed genes.

Materials

Total cellular human RNA (UNIT 4.2) or poly(A)⁺ RNA (UNIT 4.5)
1 U/μl human placental RNase inhibitor
10 U/μl DNase I (RNase-free)
0.1 M Tris·Cl, pH 8.3 (APPENDIX 2)
0.5 M KCl
15 mM MgCl₂
3:1 (v/v) phenol/chloroform
3 M sodium acetate, pH 5.2 (APPENDIX 2)
100%, 70%, and 85% ethanol
Diethylpyrocarbonate (DEPC)-treated H₂O (UNIT 4.1)
10 μM each degenerate anchored oligo(dT) primer set 5'-T₁₂MN-3' (e.g., GenHunter): T₁₂MG, T₁₂MA, T₁₂MT, and T₁₂MC (M represents G, A, or C)
5× MoMuLV reverse transcriptase buffer (UNIT 15.6)
0.1 M dithiothreitol (DTT; APPENDIX 2)
250 μM and 25 μM 4dNTP mixes (UNIT 3.4)
200 U/μl Moloney murine leukemia virus (MoMuLV) reverse transcriptase
10× PCR amplification buffer (make as in UNIT 15.1, with 15 mM MgCl₂, but use only 0.1 mg/ml gelatin; store at -20°C)
10 μCi/μl [α -³²P]dATP (>2000 Ci/mmol)
2 μM arbitrary decamer (see Critical Parameters; e.g., GenHunter or Operon Technologies)
5 U/μl Taq DNA polymerase
Mineral oil
Formamide loading buffer (see recipe)
10 mg/ml glycogen (DNA-free)

Supplement 56

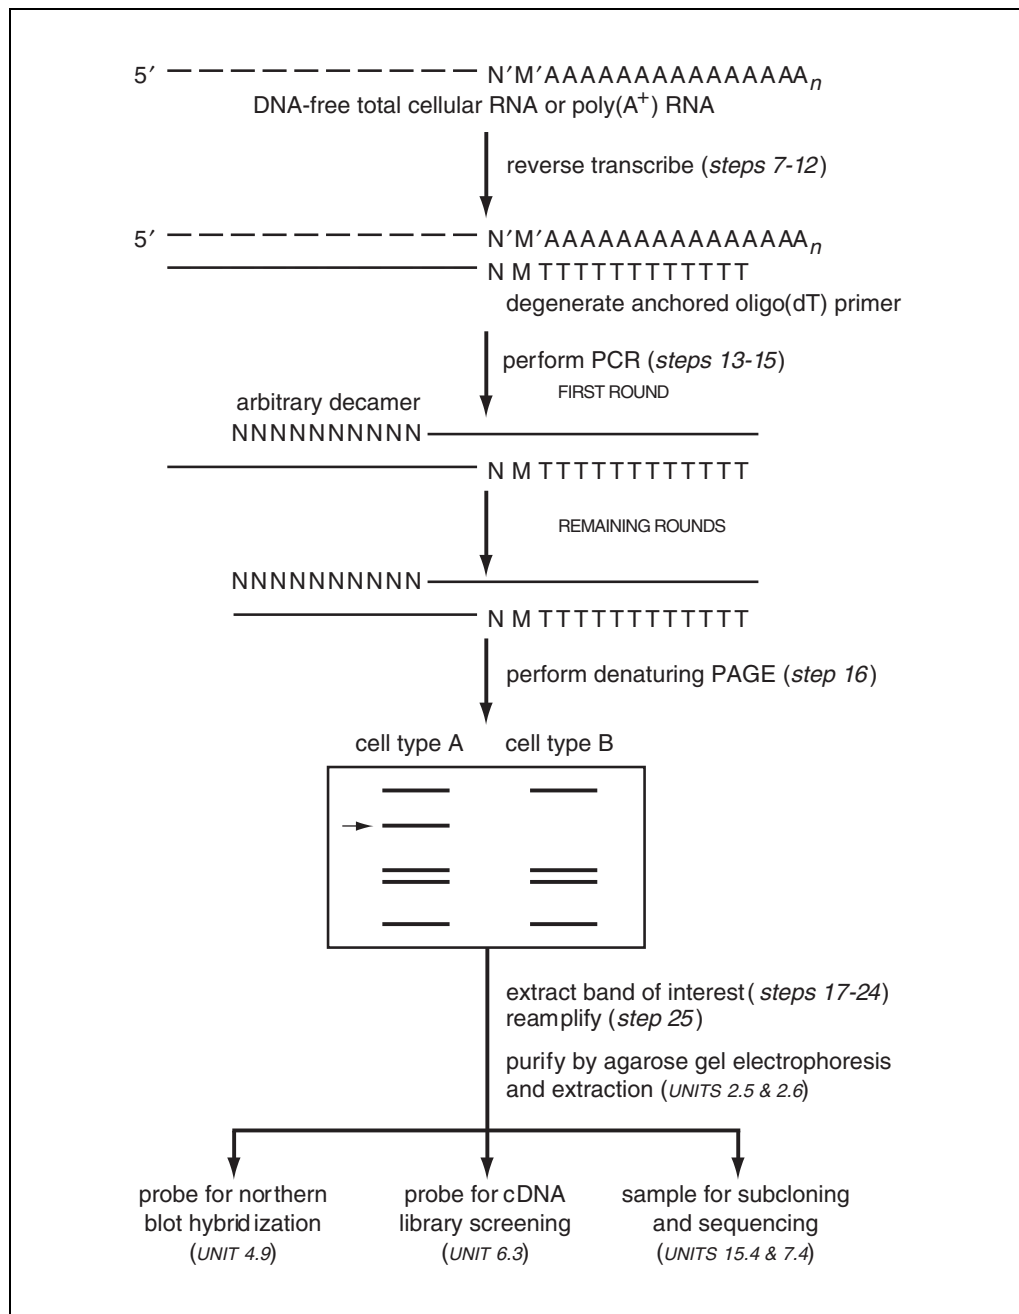

Figure 25B.3.1 Schematic representation of differential display. Diagram of gel represents results with a single primer set for two cell types, A and B. Dashed line, RNA; solid line, DNA; T₁₂MN, degenerate oligo(dT) primer; M indicates A, C, or G (degenerate); N can be A, C, G or T.

65°, 95°, 80°, and 100°C water baths

Thermal cycler

Whatman 3MM filter paper

Additional reagents and equipment for preparing total (UNIT 4.2) or poly(A)⁺ (UNIT 4.5) RNA, quantitating RNA (APPENDIX 3D), PCR (UNIT 15.1), agarose-formaldehyde gel electrophoresis (UNIT 4.9), denaturing PAGE (UNIT 7.6), autoradiography (APPENDIX 3A), agarose gel electrophoresis (UNIT 2.5A), purifying DNA from agarose gels (UNIT 2.6), analysis of RNA by northern blot analysis (UNIT 4.9), screening libraries using oligonucleotide probes (UNIT 6.3), cloning PCR products (UNIT 15.4), and dideoxy DNA sequencing (UNIT 7.4)

CAUTION: This procedure should be performed only by personnel trained in the proper use of ^{33}P isotope and in NRC licensed sites. Standard precautions to prevent excessive exposure and radioactive contamination of personnel and equipment should be followed at all times.

NOTE: Experiments involving RNA require careful technique to prevent RNA degradation (UNIT 4.1).

Remove chromosomal DNA contamination from RNA

1. Digest DNA from total cellular RNA or poly(A)⁺ RNA by mixing:

- 50 μg RNA
- 10 μl 1 U/ μl human placental RNase inhibitor
- 1 μl 10 U/ μl RNase-free DNase I
- 5 μl 0.1 M Tris·Cl, pH 8.3
- 5 μl 0.5 M KCl
- 5 μl 15 mM MgCl_2
- H_2O to 50 μl .

Incubate 30 min at 37°C.

When performing differential display, it is essential that the RNA sample be free from any genomic DNA contamination. RNA preparations isolated by various methods are often found to be contaminated with trace amounts of chromosomal DNA that results in reverse transcription-independent DNA amplification. Amounts from 15 to 100 μg of total RNA can be cleaned with this procedure.

2. Add 50 μl phenol/chloroform (3:1), vortex, and microcentrifuge 2 min at maximum speed to separate phases.

This step serves to inactivate DNase I before cDNA synthesis during reverse transcription, so vigorous mixing is important to allow complete extraction of DNase I.

3. Transfer upper phase to a clean microcentrifuge tube and add 5 μl of 3 M sodium acetate and 200 μl of 100% ethanol. Incubate 30 min at -70°C to precipitate RNA.
4. Microcentrifuge 10 min at high speed. Remove supernatant and wash pellet (precipitated RNA) once with 500 μl of 70% ethanol.
5. Dissolve RNA pellet in 20 μl DEPC-treated water and quantitate the RNA concentration accurately by measuring the A_{260} with a spectrophotometer (APPENDIX 3D).

DNA-free RNA should be stored at a concentration $>1 \mu\text{g}/\mu\text{l}$. It should not be diluted to the working concentration until immediately before reverse transcription. Diluted RNA should not be reused for differential display as diluted RNA is very unstable during storage and repeated freezing and thawing.

6. Check the integrity of the RNA to be used for differential display by performing agarose/formaldehyde gel electrophoresis (UNIT 4.9) on 3 μg of cleaned RNA. Store DNA-free RNA at -80°C until used for differential display.

For undegraded total RNA, the 28S and 18S ribosomal RNAs should be clearly visible by ethidium bromide staining.

Reverse transcribe RNA

7. For each RNA sample, label four microcentrifuge tubes G, A, T, and C—one tube for each degenerate anchored oligo(dT) primer set.
8. Dilute 1 μg DNA-free RNA (step 5) to 0.1 $\mu\text{g}/\mu\text{l}$ in DEPC-treated water and place on ice.

9. Set up reverse transcription of DNA-free total RNA *or* poly(A)⁺ RNA with each of four different degenerate anchored oligo-dT primer sets (5'-T₁₂MN-3': T₁₂MG, T₁₂MA, T₁₂MT, and T₁₂MC, where M is G, A or C) as follows:

4 μl 5× MoMuLV reverse transcriptase buffer (1× final)
2 μl 0.1 M DTT (10 mM final)
1.6 μl 250 μM 4dNTP mix (20 μM final)
0.2 μg total RNA *or* 0.1 μg poly(A)⁺ RNA
2 μl of one 10 μM degenerate anchored oligo(dT) primer set (T₁₂MN;
1 μM final)
Adjust volume to 19 μl with DEPC-treated H₂O.

There will be four reactions for each RNA sample, each made with one degenerate primer set.

10. Incubate tube 5 min at 65°C to denature the mRNA secondary structure and incubate 10 min at 37°C to allow primer annealing.
11. Add 1 μl of 200 U/μl MoMuLV reverse transcriptase to each tube, mix well, and incubate 50 min at 37°C.
12. Incubate 5 min at 95°C to inactivate the reverse transcriptase and microcentrifuge briefly at high speed to collect condensate. Place tube on ice for immediate PCR amplification *or* store at -20°C for later use (stable at least 6 months).

Perform PCR amplification

13. Prepare a 20-μl reaction mix for each primer set as follows:

10 μl H₂O
2 μl 10× amplification buffer (1× final)
1.6 μl 25 μM 4dNTP mix (2 μM final)
0.2 μl [α -³³P]dATP
2 μl 2 μM arbitrary decamer (0.2 μM final)
2 μl 10 μM degenerate anchored oligo(dT) primer set (T₁₂MN; 1 μM final)
2 μl cDNA (step 12)
0.2 μl 5 U/μl *Taq* DNA polymerase.

*To avoid pipetting errors, prepare enough PCR reaction mix without the arbitrary decamer for 5 to 10 reactions and aliquot 18 μl to each tube. Then add the arbitrary decamer. Otherwise it is difficult to pipet accurately 0.2 μl of *Taq* DNA polymerase.*

14. Pipet up and down to mix well and overlay with 25 μl mineral oil.
15. Carry out PCR in a thermal cycler using the following amplification cycles:

40 cycles:	30 sec	94°C (denaturation)
	2 min	40°C (annealing)
	30 sec	72°C (extension)
1 cycle:	5 min	72°C (extension)
Final step:	indefinitely	4°C (hold).

The 2-min incubation at 40°C is to allow sufficient time for the short primers to anneal and start extension. The short extension period at 72°C is intended to amplify only short (<600-bp) DNA products to be separated on a denaturing polyacrylamide gel.

PCR products may be stored at 4°C until used.

16. Mix 3.5 μl PCR product with 2 μl formamide loading buffer and incubate 2 min at 80°C. Load sample onto a 6% denaturing polyacrylamide gel (UNIT 7.6). Run the gel ~3 hr at 60 W until xylene cyanol runs to within 10 cm of the bottom.

Flush out the urea from the gel wells with a syringe and needle just before loading samples to obtain high-resolution differential-display cDNA patterns.

Recover differentially displayed amplified DNAs

17. Carefully remove one of the glass gel plates. Place a piece of Whatman 3MM filter paper over the gel without trapping air bubbles between filter paper and gel. Dry the gel ~1 hr at room temperature without fixing it in methanol/acetic acid.

Fixing the gel with methanol/acetic acid will make it difficult to reamplify recovered DNA because DNA is labile at acidic pH, especially at the high temperature at which the gel is normally dried.

The dried gel should be handled with gloves to prevent DNA contamination. Always store the dried gel between two sheets of clean Whatman 3MM filter paper.

18. Use either radioactive ink or needle punches to mark X-ray film and dried gel to orient them. Expose the film 24 to 48 hr at room temperature (APPENDIX 3A).
19. Develop the film, align film with gel, and indicate DNA bands of interest (those differentially displayed in different lanes) either by marking beneath the film with a clean pencil or by cutting through the film.

Typical results of differential display are shown in Figure 25B.3.2.

20. Cut out gel slice and attached Whatman 3MM filter paper with a razor blade and place in a microcentrifuge tube. Add 100 μ l H₂O and incubate 10 min at room temperature.

If more than one band is differentially expressed, extract and reamplify each one separately.

21. Cap tube tightly and boil 15 min.

Place a lid-lock on the tube to prevent it from opening while boiling.

22. Microcentrifuge 2 min at high speed to pellet gel slice and paper debris. Decant supernatant into clean tube.
23. Add 10 μ l of 3 M sodium acetate (to give 0.3 M final) and 5 μ l of 10 mg/ml glycogen (as a carrier) to supernatant. Add 400 μ l of 100% ethanol and incubate 30 min at -70° C. Microcentrifuge 10 min at high speed, 4° C.

Glycogen is soluble at ethanol concentrations <85%.

24. Rinse pellet with 500 μ l of 85% ethanol, air-dry, and dissolve the DNA in 10 μ l H₂O.

Reamplify DNA

25. Reamplify 4 μ l of the eluted DNA in a 40- μ l reaction volume using the same degenerate anchored oligo(dT) primer set and PCR conditions as in steps 13 through 15, *except* add 3.2 μ l of 250 μ M 4dNTP mix (20 μ M final) instead of 1.6 μ l of 25 μ M 4dNTP mix and omit isotope. Save the remaining recovered DNA at -20° C for future reamplification (stable indefinitely).
26. Electrophorese 30 μ l of each PCR sample on a 1.5% agarose gel and stain with 0.5 μ g/ml ethidium bromide (UNIT 2.5A). Store the remaining PCR samples at -20° C (stable for years).

Most amplified DNAs should be visible after the first reamplification. Fragment molecular weights should be checked after reamplification to ensure that they are consistent with those on the denaturing polyacrylamide gel. If a DNA is not visible after the first reamplification, 4 μ l of 1/100 dilution (in water) of the first reamplification sample may be used for a second 40-cycle amplification.

27. Extract the desired reamplified DNA band from the agarose gel (*UNIT 2.6*) and use it as a probe for northern blot analysis (*UNIT 6.3*) and cDNA library screening (*UNIT 6.3*).
Store extracted DNA at -20°C (stable for years) if it is not to be used immediately.
28. Characterize remaining PCR sample (from step 26) by subcloning (*UNIT 15.4*) and sequencing (*UNIT 7.4*).

Figure 25B.3.2 Reproducibility and multiple display of mRNAs from normal versus ras/p53 mutant transformed cells. **(A)** RNA samples from normal rat embryo fibroblasts REF (R) and its ras/p53 doubly transformed derivative T101-4 cells (T) were reverse transcribed and amplified in duplicate with T12MA and OPA17 primers (left four lanes). In a separate experiment, RNA samples from REF (R), T101-4 (T), and another ras/p53 temperature-sensitive mutant transformed cell line A1-5 grown at nonpermissive temperature (A) and shifted to permissive temperature for 24 hr (A₃₂) were reverse transcribed and amplified in duplicate with T12MA and OPA17 primers (right eight lanes). An arrowhead indicates a reproducible difference between normal and transformed cells. **(B)** Northern blot analysis of this reamplified cDNA probe (named as clone J). 20 mg of total RNA from REF, T101-4, and A1-5 cells were analyzed. 36B4 was used as a probe for RNA loading control.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Formamide loading buffer

- 95% (v/v) formamide
 - 0.09% (w/v) bromphenol blue
 - 0.09% (w/v) xylene cyanol FF
- Store at 4°C

COMMENTARY

Background Information

Current methods to distinguish mRNAs in comparative studies rely largely on differential or subtractive hybridization techniques (Hedrick et al., 1984; Lee et al., 1991). Several important genes implicated in tumorigenesis have been isolated using these methods (Steege et al., 1988). Although subtraction is quite sensitive and can detect fairly rare mRNAs (see UNIT 25B.1), the method recovers genes incompletely and selects for genes in only one direction at a time during a two-way comparison between a pair of cells. The process is also laborious and time-consuming.

The differential display technique was developed with the goal of identifying differentially expressed genes, detecting individual mRNA species that are changed in different sets of mammalian cells, then recovering and cloning the cDNA (Liang and Pardee, 1993; Liang et al., 1993). This method utilizes polymerase chain reaction (PCR) amplification and denaturing polyacrylamide gel electrophoresis, two of the most commonly used molecular biological methods, and provides a sensitive, straightforward, and flexible approach to detect genes that are differentially expressed at the mRNA level.

In differential display, each RNA sample is first reverse transcribed with a degenerate anchored oligo(dT) primer set that anneals at the start of the poly(A) tails of mRNAs. Each degenerate anchored oligo(dT) primer set (e.g., T₁₂MA) will, in theory, reverse transcribe one-fourth of the total mRNA population. In combination with a decamer oligonucleotide of arbitrary sequence, which in theory can hybridize to any mRNA, cDNA fragments representing the 3' termini of mRNAs defined by both primers are amplified. Thus, this procedure allows amplification of an mRNA subpopulation without knowledge of sequence information. If any given arbitrary decamer does not actually sample all mRNAs, different de-

camers can be used to permit sampling of differential mRNA populations.

Differential display can be used for many purposes. One is to provide a picture of mRNA composition of cells by displaying subsets of mRNAs as short DNA bands. This mRNA fingerprinting is useful in the same way as are two-dimensional protein gels, for example, for observing alterations in gene expression. Secondly, these DNAs can be quickly reamplified, cloned, sequenced, and compared with sequences in data banks. Finally, reamplified cDNAs can be used as probes for northern or Southern blot hybridization and to isolate genes from genomic or cDNA libraries for further molecular characterization.

Investigations of expression genetics (Sager, 1997) has gained in preeminence. The differential display procedure is being successfully employed by many research groups to identify numerous expressed genes. Related publications have increased exponentially, and currently there are ~2000. For a cross section of results see Liang et al. (1994). Thus, differential display is a viable method for the identification of novel gene targets.

Critical Parameters and Troubleshooting

The most important, powerful application of differential display is to identify and clone differentially expressed genes in various biological systems. Because the method is based on reverse transcription-PCR (RT-PCR; UNIT 15.5), critical parameters relevant to that procedure generally apply for this protocol.

Utilization of this technique has encountered the problem of isolation of “false-positive” transcripts—i.e., PCR products that appear to be differentially expressed but which cannot be verified when subsequent northern analysis is performed using the same RNA source. PCR is highly sensitive to minor variations in experimental procedures and is noto-

riously difficult to make quantitative. In the authors' experience, success with differential display is dependent to a large degree on experimental design, great care in achieving consistency, the use of core reagent mixes, and duplicate assays, among other things.

Many modifications of the original protocol have been described, the implementation of which have resulted in enhanced fidelity and overall utility of this evolving technique.

Isolation of RNAs that are undegraded and that are free of contaminating DNA is necessary to select optimally for expressed genes (see Quality of RNA, below). A considerable number of articles propose modifications in choice of primers for both reverse transcriptase and PCR steps. Single base oligo(dT)-anchored primers reduce the number of reactions and redundancy (Liang et al., 1994). A recent study proposes primer sequences based on frequencies of gene sequences (Pesole et al., 1998). Longer arbitrary primers seem to enhance the reproducibility of the differential display patterns (Liang et al., 1994; Zhao et al., 1995). Labelling the PCR products with [³⁵S]- or [³³P]deoxynucleotides has safety advantages over [³²P] (Trentmann, 1995). Bands may be visualized nonradioactively with silver staining or fluorescence. Improved methods for cloning differential display products have also been proposed (Comes et al., 1997; Wybranietz and Laurer, 1998).

One band on a sequencing gel often contains more than one cDNA, and the contaminating band can generate a false northern signal if its mRNA is very plentiful. For avoiding false positives, cloning strategies (Zhao et al., 1996), restriction cutting (Prasher and Weissman, 1996), nested PCR reamplification (Zhang et al., 1996; Martin et al., 1998), and single-strand conformation polymorphism gels (Miele et al., 1998) can help to avoid this problem.

Direct sequencing of differentially expressed cDNAs has been reported (Wang and Feurstein, 1995). Dot blot grids are being developed to evaluate the differential display products (Martin et al., 1998).

Recently, other methods have been developed for studying expression genetics. These include representational difference analysis (Lisitsyn, 1995), serial analysis of gene expression (SAGE; Zhang et al., 1997), and dot blot analysis (Wodicka, 1997), by which differential mRNA expression is examined with high throughput mass cDNA library screening on dot blots placed on chips, together with powerful computational analysis of sequences. This

technique will in time provide massive amounts of information, although it is relatively laborious and requires special facilities.

Quality of RNA

The quality of RNA is determined by two criteria. First is the integrity of the RNA; second is the degree of chromosomal DNA contamination. The integrity of total RNA can be easily verified by agarose/formaldehyde gel electrophoresis, whereas the integrity of poly(A)⁺ RNA must be checked by northern blot hybridization using a cDNA probe for an mRNA with known molecular weight. Contamination by chromosomal DNA can be checked by performing differential display omitting the reverse transcription step. Under the PCR conditions used for differential display (i.e., low dNTP concentrations), RNA amplification is dependent on reverse transcription. Because total RNA isolated with various methods is generally found to be contaminated with DNA, it is recommended that, as a good practice, RNA samples be treated with DNase I before being used for differential display.

Design of arbitrary decamers

Generally any arbitrary decamer can be used as long it does not contain palindromic sequences and has a G+C content of 50% to 70%. The original decamer chosen for this application was from the mouse thymidine kinase gene (Liang and Pardee, 1993), but it has been used successfully to detect multiple mRNAs in cells of various species. Because the arbitrary decamers have been shown to contain up to 4-bp mismatches with the original cDNA templates and these mismatches are often clustered at the 5' end of the primers (Liang et al., 1993), the arbitrary decamers can be designed in such a way that the 3' sequences are maximally randomized while the 5' bases (up to four bases) are fixed. The G+C content of the arbitrary decamers can be increased or decreased to reflect the G+C content of the genome of the organism from which the mRNA is isolated.

False-positive difference

The intrinsic problem encountered with differential display, as with any method based on PCR, is that it is highly sensitive to minor variations. True differences in expression must be differentiated from the "noise" that is the major source of false-positive differences. If a pair of RNA samples is to be compared, the displayed (DNA) pattern differences must be reproducible. An advantage of differential dis-

play is the ability to simultaneously compare more than two relevant RNA samples (e.g., from different cell types or stages of development); multiple display thus has a built-in internal control for distinguishing “noise” from true differences. This also facilitates isolation of genes that really give useful results for the system under study.

Size of DNA probe

Short DNA probes (<150 bp) have been found to be hard to label and often fail to produce any signals in northern blot hybridizations. Therefore, it is advised that only DNA bands >150 bp be further characterized by northern blot analysis and that smaller bands be ignored.

Anticipated Results

This method should produce reproducible amplified DNA patterns. The reproducible DNA bands representing differentially expressed genes should be readily reamplifiable and usable as probes for northern blot analysis or cDNA library screening.

Time Considerations

The whole procedure from RNA to DNA samples ready to use as probes can be performed within three days. Treating RNA with DNase I and checking its integrity by gel electrophoresis takes ~2 hr. Reverse transcription takes ≤2 hr. Setting up 40 PCR samples requires 1 to 2 hr. PCR amplification requires ~4 hr but can be performed overnight. Preparing, running, and drying the denaturing polyacrylamide gel takes 1 day. Autoradiography can be as brief as overnight. Recovery, reamplification of DNA, and extraction of reamplified DNA from an agarose gel can easily fit into the third day. Northern blot analysis requires an additional 2 days.

Restriction-Mediated Differential Display (RMDD)

Restriction-mediated differential display (RMDD) can be applied to identify differentially expressed (i.e., up- or down-regulated) genes in many eukaryotic cells or tissues by comparison of band patterns obtained from two or more different RNA preparations. As opposed to early differential display or other RNA-fingerprinting protocols based on arbitrarily primed PCR, RMDD provides very robust and reproducible results which are largely independent of the exact amount of input material or of the exact cycling conditions, respectively. Two different PCR strategies for fragment amplification, depending on the complexity of the material under investigation as well as the appropriate choice of the restriction enzyme or enzymes used, are discussed (see Strategic Planning). The first protocol describes oligo(dT)-primed conversion of total RNA into double-stranded cDNA, which is cleaved with a frequently cutting restriction enzyme, ligated to linker molecules (thus creating the “RMDD library”), and amplified with labeled selective 3'-elongated oligonucleotide primers to generate subpools of amplified fragments which represent the 3'-ends of the cDNA molecules (see Basic Protocol and Fig. 25.B4.1). A protocol outlining two-phase PCR is given as an alternative to the amplification steps used in the Basic Protocol (see Alternate Protocol). This protocol is usually chosen if the RNA samples to be analyzed are particularly complex. The final protocol describes nonradioactive fragment analysis through the use of biotinylated primers and direct-blotting electrophoresis (see Support Protocol).

NOTE: 5'-labeled primers are indicated by an asterisk (*). The label can be a radioactive isotope (e.g., ³²P) or a nonradioactive label such as biotin or digoxigenin. In the latter case, labels should be attached via a sufficiently long spacer to the oligonucleotide (e.g., tetraethylene glycol from Eurogentec) to ensure maximum detection sensitivity.

NOTE: The technology described in this unit is protected by certain patent rights (US 5,876,932; EP 0 743 367; JP 96/308598). Commercial application of RMDD (including in-house research projects of any company) thus requires a license. No license is required for academic use.

STRATEGIC PLANNING

The “RMDD library” contains a mixture of restriction fragments of all cDNA molecules obtained from the respective biological sample. It has been estimated that a single cell type contains ~10,000 different mRNA molecules, resulting in 10,000 different cDNA species. For successful gel display of the fragments derived from the 3' ends of these cDNA molecules, a strategy must be provided to subdivide this rather complex fragment mixture into a number of subpools, each containing a sufficiently low number (i.e., ≤50 to 100) of different fragment species. This can be easily achieved by fragment amplification employing oligonucleotide primers each carrying one additional “selective” base at the 3'-end. Theoretically, such a selective base allows primer extension by a polymerase only if it perfectly matches the corresponding base on the other strand. Combining selective primers directed against the ligated linker and against the sequence introduced by the cDNA primer thus allows subdivision of fragments into nonoverlapping subpools. The RMDD protocol (see Basic Protocol and Alternate Protocol) involves two subsequent rounds of amplification, the first employing selective primers extended by one base each and the second employing primers extended by one more base, providing a total number of $12 \times 16 = 192$ reactions to be performed for complete coverage of all generated 3'-end fragments. Two rounds are chosen, since the discrimination of a polymerase against extension of primers distinguished by a mismatch at the second last position is much less pronounced than the discrimination against extension of terminal mismatches, prohibiting use of primers carrying two selective bases at their 3'-end in a single round of PCR. However, in practice, a certain extent of “bleedthrough” can still be observed (i.e., amplification of fragments with a given selective primer, which theoretically should not take place due to a 3'-terminal mismatch of the annealed primer).

If mRNA complexity is not too high (e.g., material obtained from cell cultures or “simple” tissues of low complexity), this “bleedthrough” usually does not cause any problems; nevertheless, when working with highly complex samples (e.g., RNA isolated from mammalian brain), bleedthrough may render band patterns too crowded for reliable isolation of particular bands of interest. To reduce bleedthrough, both first and second amplification reactions can be performed in a “two-phase” manner (see the Alternate Protocol). The first phase, performed at extremely low concentrations of dNTPs (i.e., 2 μM each), involves 10 (first amplification) or 15 (second amplification) cycles and defines which products will be amplified to a detectable level. This phase exploits the fact that mismatch extension can be significantly reduced at low dNTP levels. For the second phase, dNTP concentrations are raised to “normal” levels (i.e., 200 μM each), which, after an additional 10 cycles, allows for accumulation of the desired amount of product.

The choice of the restriction enzyme used for RMDD depends on the particular organism to be analyzed, since average fragment size may vary due to differences in codon usage and G/C content. To obtain cDNA 3'-fragments in a size range optimal for gel display (i.e., most of the fragments having a size between 100 and 700 bp), an appropriate enzyme

has to be employed—e.g., *Mbo*I, as described in this protocol (see Basic Protocol)—which has proven satisfactory with RNA isolated from man, rat, mouse, corn, and *Arabidopsis*. Should another enzyme be chosen, linker and linker primer sequences will have to be modified accordingly, and the same holds true if, for the sake of more complete coverage of the transcriptome, experiments are repeated with a second enzyme. Computer analysis has demonstrated that in man and rodents roughly 80% to 85% of all transcripts contain a recognition site for *Mbo*I (unpub. observ.); therefore, 15% to 20% of transcripts would be inaccessible to analysis using this particular enzyme. Accordingly, if nearly complete coverage of transcripts is desired, a second-pass RMDD analysis might be performed with a second frequently cutting enzyme. Performing RMDD with a second enzyme, assuming both enzymes recognize 80% of cDNAs each, would provide a total coverage of 96% of all transcripts.

RMDD LIBRARY PREPARATION AND TWO-ROUND AMPLIFICATION

This protocol describes conversion of total RNA to labeled PCR products, which are ready to be displayed by gel electrophoresis.

Materials

50 µg total RNA (UNITS 4.1 & 4.2)
RNase-free water
10 µM cDNA primer CP29V: 5'-ACC TAC GTG CAG ATT TTT TTT TTT TTT TX₁-3' (X₁ = A, C, or G; equimolar amounts of all three species; see UNIT 2.11 for oligonucleotide synthesis)
100 mM RNase-free DTT (Life Technologies)
5× SuperScript buffer (Life Technologies)
10 mM RNase-free and standard dNTPs
40 U/µl RNase inhibitor (e.g., RNasin)
200 U/µl SuperScript II reverse transcriptase (Life Technologies)
5× second-strand buffer II (UNIT 5.5)
1.5 U/µl RNase H
10 U/µl *E. coli* DNA polymerase I
Phenol equilibrated with TE buffer, pH 8.0 (UNIT 2.1A)
Chloroform
20 mg/ml glycogen
28% PEG 8000/3.6 mM MgCl₂ (see recipe)
70% and 100% ethanol
10× universal buffer (Stratagene)
4 U/µl *Mbo*I restriction endonuclease (Stratagene)
3 M sodium acetate, pH 5.2 (APPENDIX 2)
10 mM ATP
0.5 µg/µl *Mbo*I-linker ML2025 (see recipe)
T4 DNA ligase and 10× buffer (Roche)
1× and 0.25× TE buffer, pH 8.0 (APPENDIX 2)
4 µM primer CP28X₁: 5'-ACC TAC GTG CAG ATT TTT TTT TTT TTT TX₁-3' (X₁ = A, C, or G; see UNIT 2.11 for oligonucleotide synthesis)
4 µM primer ML19Y₁: 5'-TGC TAA GTC TCG CGA GAT CY₁-3' (Y₁ = A, C, G, or T; see UNIT 2.11 for oligonucleotide synthesis)
10× PCR buffer (see recipe)
20 mM MgCl₂ (APPENDIX 2)
RediLoad (Research Genetics)
5 U/µl *Taq* DNA polymerase
100-bp DNA size ladder (e.g., Life Technologies)

**BASIC
PROTOCOL**

Expressed Genes**

25B.4.3

1.5% agarose gel (UNIT 2.5A)

4 μM primer CP28X₁X₂: 5'-ACC TAC GTG CAG ATT TTT TTT TTT TTT T
X₁X₂-3' (X₂ = A, C, G, or T; see UNIT 2.11 for oligonucleotide synthesis)

4 μM labeled primer *ML18Y₁Y₂: 5'-*GCT AAG TCT CGC GAG ATC Y₁Y₂-3'
(Y₂ = A, C, G, or T; see UNIT 2.11 for oligonucleotide synthesis)

Formamide buffer: 5 mM EDTA/0.1% bromophenol blue in 99% deionized formamide

22°, 37°, 42°, 65° and 75°C water bath, heat blocks, or equivalent

Thermal cycler with heated lid

96-well PCR plates (e.g., MJ Research)

Additional reagents and equipment for ethanol precipitation and phenol/chloroform extraction of DNA (UNIT 2.1A), and pouring and running (UNIT 2.5A) agarose and 6% polyacrylamide gels (UNIT 7.6)

Synthesize first-strand cDNA

1. Ethanol precipitate 50 μg total RNA (UNIT 2.1A) and dissolve in 15.5 μl RNase-free water. Add 1.5 μl of 10 μM cDNA primer CP29V, denature 5 min at 65°C (e.g., in a heat block), and cool down on ice.

It is not necessary to isolate poly(A+) RNA. Band patterns obtained with mRNA are virtually identical to those obtained with total RNA. On the other hand, mRNA isolation is a potential source of variation and should therefore be avoided.

DEPC treatment will not usually be required for RNase-free water.

2. Assemble components for first-strand synthesis on ice (29.1 μl total):

17.0 μl freshly denatured RNA with cDNA primer

3.0 μl 100 mM RNase-free DTT

6.0 μl 5 \times SuperScript buffer

1.5 μl 10 mM RNase-free dNTPs

0.6 μl 40 U/ μl RNase inhibitor (e.g., RNasin)

1.0 μl 200 U/ μl SuperScript II reverse transcriptase.

Mix well and incubate 1 hr at 42°C. Stop reaction by placing on ice.

Incubation is best done in a water bath or thermal cycler. Hot air ovens do not guarantee sufficiently quick heating of samples.

To check for possible RNA degradation in the course of first-strand synthesis due to RNase contamination, 0.5 to 1 μl of the first-strand synthesis reaction can be analyzed on a 1% standard agarose gel (UNIT 2.5A; no special RNA gel is required), watching for undegraded ribosomal RNA bands.

Synthesize second-strand cDNA

3. Assemble on ice the following components (207.2 μl total) for second-strand synthesis:

48 μl 5 \times second-strand buffer II

3.6 μl 10 mM dNTPs

148.4 μl H₂O

1.2 μl 1.5 U/ μl RNase H

6.0 μl 10 U/ μl *E. coli* DNA polymerase I.

4. Combine first-strand and second-strand synthesis reactions. Mix and incubate for 2 hr at 22°C. After completion of second-strand synthesis, inactivate DNA polymerase by heating for 20 min to 75°C.

Purify cDNA

5. Extract with 100 μ l phenol equilibrated with TE buffer, pH 8.0. Extract again with 100 μ l chloroform.

UNIT 2.1A describes the procedures for phenol-chloroform extraction of DNA.

CAUTION: Phenol and chloroform are severe health hazards. See UNIT 2.1A for precautions.

6. For size-selective PEG precipitation, carefully mix:

200 μ l phenol/chloroform-extracted ds cDNA
1.0 μ l 20 mg/ml glycogen
200 μ l 28% PEG 8000/3.6 mM MgCl₂.

Let the reaction (401 μ l total) stand at room temperature for 5 min, then microcentrifuge for 15 min at maximum speed, 10°C. Wash pellet carefully with 70% ethanol.

This precipitation step removes unincorporated cDNA primer as well as small (i.e., below ~100 nt) nucleic acid molecules. Since size-selective PEG precipitations are susceptible to minor concentration changes, it is imperative to adhere to the following guidelines:

1. *Make sure to pipet exactly 200 μ l ds cDNA. Vapor pressure of chloroform dissolved in the aqueous phase tends to displace liquid from the pipet tip, making accurate pipetting difficult. One way to overcome this problem is to repeatedly (5 to 10 times) withdraw and expel again ~50 to 100 μ l of the chloroform-saturated aqueous phase before pipetting the required 200 μ l, thus allowing the pipet to saturate with chloroform vapor.*

2. *The 28% PEG/3.6 mM MgCl₂ solution is rather viscous. Pipet slowly and carefully, again being sure to accurately transfer the required volume.*

3. *Mix carefully by first repeatedly inverting the tube, then vigorously vortexing. Due to viscosity, complete and homogeneous mixing takes a while.*

During addition of PEG solution, a white glycogen precipitate usually forms. This becomes invisible again in the course of mixing.

When washing the pellet with ethanol, detachment from the tube wall does no harm since the pellet is too large to be easily lost.

Perform restriction digest

7. Dissolve the pellet on ice in the following solution (96 μ l total):

15.0 μ l 10 \times universal buffer
81.0 μ l H₂O.

Instead of the Universal buffer supplied by Stratagene, any buffer supplied with the restriction enzyme can be used. In this case, adhere to the manufacturer's recommendations concerning dilution of buffer stock.

8. Add 4.0 μ l of 4 U/ μ l MboI and incubate 1 hr at 37°C. Inactivate the enzyme by heating 20 min at 65°C.

The choice of restriction enzyme is discussed elsewhere in this unit (see Strategic Planning).

9. Extract with 50 μ l phenol buffered with TE buffer, pH 8.0, then with 50 μ l chloroform. Add 1 μ l glycogen and 10 μ l 3 M sodium acetate, pH 5.2, followed by 2.5 vol 100% ethanol. Microcentrifuge 20 min at maximum speed and wash pellet with 70% ethanol. Air dry pellet briefly (5 to 10 min). Do not apply heat and/or vacuum, since overdrying DNA pellets might make resuspending them difficult.

Perform linker ligation

10. Dissolve pellet in ligation mix (20 μ l total), consisting of the following components:

- 1.2 μ l 10 \times ligation buffer
- 2.0 μ l 10 mM ATP
- 8.0 μ l 0.5 μ g/ μ l *Mbo*I-linker ML2025
- 7.8 μ l H₂O
- 1.0 μ l 1 U/ μ l T4 DNA ligase.

Ligate overnight at 16°C or over the weekend at 4°C.

11. Add 90 μ l water, mix, and extract with 50 μ l phenol buffered with TE buffer, pH 8.0, then with 50 μ l chloroform. For removal of unligated linkers, assemble a second PEG precipitation reaction (201 μ l total):

- 100 μ l phenol-extracted ligation products
- 1.0 μ l glycogen
- 100 μ l 28% PEG/3.6 mM MgCl₂.

Let stand at room temperature 5 min, then microcentrifuge 15 min at maximum speed, 10°C. Wash pellet carefully with 70% ethanol and resuspend in 40 μ l TE buffer, pH 8.0.

For precautions, see step 6.

Perform first-round amplification of 3'-cDNA fragments

12. Set up first-round amplification reactions by combining 1 μ l of each of the three 4 μ M CP28X₁ (X₁ = A, C, or G) primers with 1 μ l of each of the four 4 μ M ML19Y₁ (Y₁ = A, C, G, or T) primers in separate tubes on ice (12 reactions total). Assemble a master mix with all remaining components (recipe is for 1 reaction):

- 2.0 μ l template (PEG-precipitated ligation products)
- 2.0 μ l 10 \times PCR buffer
- 1.5 μ l 20 mM MgCl₂
- 0.4 μ l 10 mM dNTPs
- 2.0 μ l RediLoad
- 9.9 μ l H₂O
- 0.2 μ l 5 U/ μ l Taq DNA polymerase.

Assemble reactions and place the tubes in the wells of a thermocycler preheated to 90°C.

13. Apply the following cycling program:

- | | | |
|---------------|--------------|-------------------------|
| Initial step: | 1 min | 94°C (denaturation) |
| 25 cycles: | 20 sec | 94°C (denaturation) |
| | 30 sec | 65°C (primer annealing) |
| | 4 min | 72°C (primer extension) |
| Final step: | indefinitely | 10°C (hold/extension). |

14. Load 10 μ l of each reaction onto a 1.5% agarose gel and check for successful amplification by agarose gel electrophoresis (UNIT 2.5A). Include a 100-bp ladder as a size marker.

PCR conditions are adjusted in such a way that the amount of primers limits the amount of product. The long extension time ensures that differently sized products are simultaneously amplified essentially without a bias against the longer ones. Agarose gel electrophoresis should yield smears between ~100 bp and ~700 bp with very few (if any) discrete bands being visible. Most importantly, reactions obtained with the same primer combina-

tion, but from different RNA samples to be compared, should look essentially indistinguishable. If appearance and/or amount of material should visibly differ, probably one of the enzymatic steps prior to amplification was performed at too low an efficiency (see Troubleshooting and Table 25.B4.1).

15. Dilute reactions 1:100 with 0.25× TE buffer, pH 8.0.

Diluted reactions can be indefinitely stored at –20°C.

Perform second-round amplification of 3'-cDNA fragments

16. Set up second-round amplification mix by combining in 96-well plates each of the 12 CP28X₁X₂ primers with each of the 16^{*}ML18Y₁Y₂ primers (192 different reactions per sample; 20 µl each):

2.0 µl template (diluted first-round PCR)
2.0 µl 10 × PCR buffer
1.5 µl 20 mM MgCl₂
0.4 µl 10 mM standard dNTPs
2.0 µl 4 µM primer CP28X₁X₂ (X₂ = A, C, G, or T)
2.0 µl 4 µM labeled primer ^{*}ML18Y₁Y₂ (Y₂ = A, C, G, or T)
2.0 µl RediLoad
7.9 µl H₂O
0.2 µl 5 U/µl *Taq* DNA polymerase.

Make sure that for every reaction, X₁ and Y₁ of the second-round amplification are identical to X₁ and Y₁ of the first-round amplification. PCR can be conveniently performed in two 96-well plates per RNA sample.

It is highly preferable to use a thermocycler equipped with a hot top, obviating the need to cover reactions with oil.

Use of labeled primers instead of incorporating labeled nucleotides has the advantage that (1) only one of two complementary strands is visualized, thus limiting complexity of band patterns (usually, two complementary strands of equal length show slightly different mobility in polyacrylamide gels), and (2) label intensity does not increase with fragment length. In addition, if biotin is used as a label, incorporation of an undefined number of biotin molecules (it is not possible to replace all nucleotides of a given type by enzymatic incorporation of the biotinylated analog) into the amplified strands leads to pronounced smearing of the obtained bands due to the incremental mobility shift caused by each of the biotin groups in a DNA molecule.

17. Apply the cycle program of step 13, but for only 20 cycles. Check for successful amplification by agarose gel electrophoresis (also see step 13).

Reactions obtained with the same primer combination but from different RNA samples should again look essentially indistinguishable, whereas reactions obtained with different primer combinations usually look distinct. Other than with first-round PCR products, usually a small number of discrete bands (e.g., 1 to 5) can be observed.

18. Transfer 5 µl of each reaction into a fresh microtiter plate containing 5 µl formamide buffer per well and mix. Denature 2 min at 75°C.

Nonradioactively labeled PCR products in formamide buffer can be stored for several months at –20°C. When radioactive labeling is chosen, storage time is limited by decay of the incorporated isotope.

Label nucleotides

- 19a. *For radioactive labeling:* Load 1 to 2 µl sample into the slots of a denaturing 6% polyacrylamide gel and run as described in UNIT 25B.3, starting at Basic Protocol, step 16, of that unit.

19b. *For nonradioactive labeling and use of direct blotting electrophoresis:* See Support Protocol, below.

**ALTERNATE
PROTOCOL**

AMPLIFICATION BY TWO-PHASE PCR

Alternatively, the amplification steps (see Basic Protocol, steps 12 to 17) can be replaced by a two-phase PCR (see Strategic Planning). This procedure decreases the “bleedthrough” sometimes observed between different PCRs obtained from the same sample by “illegitimate priming” (i.e., priming with a mismatch at the primer’s 3′-ultimate base). The approach is to perform the first 10 to 15 cycles of each PCR at an extremely low nucleotide concentration (2 μ M each), which increases the bias of *Taq* polymerase against mismatch extension. After these initial cycles are finished and the product composition in each reaction has been defined, reactions are supplemented with nucleotides to a final concentration of 200 μ M each, thus allowing sufficient amounts of amplification products to be generated. The drawback is the increase in hands-on time required for pipetting.

Additional Materials (also see Basic Protocol)

0.1 mM dNTPs (freshly diluted from 10 mM dNTPs)

Perform first-round low-concentration amplification

1. Synthesize ds cDNA (see Basic Protocol, steps 1 to 11).
2. Set up first-round 2- μ M amplification reactions (12 different reactions per sample, 20 μ l each):

2.0 μ l template (PEG-precipitated ligation products; see Basic Protocol, step 11)
2.0 μ l 10 \times PCR buffer
1.5 μ l 20 mM MgCl₂
0.4 μ l 0.1 mM dNTPs (freshly diluted from 10 mM dNTPs)
2.0 μ l 4 μ M primer CP28X₁ (X₁ = A, C, or G)
2.0 μ l 4 μ M primer ML19Y₁ (Y₁ = A, C, G, or T)
9.9 μ l H₂O
5 U/ μ l 0.2 μ l *Taq* DNA polymerase.

Again, all PCR mixtures should be prepared as master mixes.

3. Carry through the same program as described (see Basic Protocol, step 13), except for 15 rather than 25 cycles.

Perform first-round normal-concentration amplification

4. Transfer reaction tubes to ice. To each tube add 20 μ l of 200 μ M amplification mix, prepared as follows:

2.0 μ l 10 \times PCR buffer
1.5 μ l 20 mM MgCl₂
0.8 μ l 10 mM dNTPs
4.0 μ l RediLoad
11.5 μ l H₂O
0.2 μ l 5 U/ μ l *Taq* DNA polymerase.

5. Repeat the program cycle as described (see Basic Protocol, step 13), performing the remaining cycles (i.e., 16 to 25).

6. Check products by agarose gel electrophoresis (see Basic Protocol, step 14 and *UNIT 2.5A*).
7. Dilute reactions 1:100 with 0.25× TE buffer.

Perform second-round low-concentration amplification

8. Using 96-well microtiter plates, set up second-round 2 μM amplification reactions (192 different reactions per sample; 20 μl each):

2.0 μl template (diluted first-round PCR)
 2.0 μl 10× PCR buffer
 1.5 μl 20 mM MgCl₂
 0.4 μl 0.1 mM dNTPs
 4.0 μl 4 μM primer CP28X₁X₂ (X₂ = A, C, G, or T)
 4.0 μl 4 μM labeled primer *ML18Y₁Y₂ (Y₂ = A, C, G, or T)
 5.9 μl H₂O
 5 U/μl 0.2 μl *Taq* DNA polymerase.

9. Transfer plates to the preheated wells of a thermal cycler and cycle as described above (see Basic Protocol, step 13), except for only 10 rather than 25 cycles.

Perform second-round normal-concentration amplification

10. Cool reaction tubes on ice and add 20 μl of 200 μM amplification mix (step 4) to each tube.
11. Repeat the program (see Basic Protocol, step 13), this time using 20 cycles (i.e., add 10 more cycles).
12. Check products by agarose gel electrophoresis (see Basic Protocol, step 14 and *UNIT 2.5A*).

Agarose gel electrophoresis can be skipped if radioactive label is used. In the latter case, adhere to the usual precautions for working with radioisotopes (APPENDIX 1F) and handle samples at a dedicated workspace only.

DIRECT BLOTTING ELECTROPHORESIS

The authors have found direct blotting electrophoresis (DBE) to be an extremely helpful technique to get high-quality display results from amplified RMDD products and to simplify physical access to bands of interest. In contrast with standard fragment analysis (see Chapter 2) based on radioactive labeling, it is not necessary, for the sake of optimal resolution of different size ranges, to perform “short” and “long” runs of each sample. In DBE, all fragments, including the largest ones, pass the whole length of the gel before being transferred to the blotting membrane, providing unsurpassed resolution of bands in the size range relevant for RMDD. Working with nonradioactive materials provides considerable convenience, and stained bands can be directly cut out of the blotting membrane for recovery and analysis.

Additional Materials (also see *Basic Protocol*)

TBE electrophoresis buffer (*APPENDIX 2*) standard and degassed (i.e., stirred under vacuum 20 min)
 Maleic buffer, pH 7.5 (see recipe)
 1.5% blocking reagent (see recipe)
 Streptavidin-alkaline phosphatase conjugate (Roche Molecular Biochemicals)
 Reaction buffer, pH 9.5 (see recipe)
 NBT/BCIP in 67% (v/v) DMSO (Roche Molecular Biochemicals)

25B.4.9

Primers (see *UNIT 2.11* for oligonucleotide synthesis):

CP28: 5'-ACC TAC GTG CAG ATT TTT TTT TTT TTT T-3'

ML18: 5'-GCT AAG TCT CGC GAG ATC-3'

GATC 1500 Direct Blotting Electrophoresis System (GATC Biotech AG)

Direct blotting membrane (GATC Biotech AG)

10-ml syringe and 25-G needle

32-well sharkstooth comb

GELoader tips (Eppendorf) with capillary-like part cut away

Stratalinker (Stratagene)

Developing drum (e.g., GATC tube; GATC Biotech AG)

Adhesive tape

Rolling incubator accepting 18 × 35-cm tubes and capable of revolving at ~20 rpm

2-mm-thick polyethylene wrap (e.g., Neolab, Heidelberg, FRG) or material from a thick hybridization bag

T-A cloning system (e.g., Invitrogen; optional)

Additional reagents and materials for casting denaturing polyacrylamide gels (*UNIT 2.12*), agarose gel electrophoresis (*UNIT 2.5A*), and molecular cloning of PCR products (*UNIT 15.7*).

NOTE: For details concerning use of the GATC 1500 Direct Blotting Electrophoresis apparatus, consult the manufacturer's instructions.

Prepare the gel

1. Cast a denaturing 4.5% polyacrylamide gel (*UNIT 2.12*). Attach a 40- to 45-cm long piece of blotting membrane to the conveyor belt of the direct blotting electrophoresis system. Mount the gel on the apparatus and fill with the appropriate amount of TBE electrophoresis buffer, using degassed buffer in the lower chamber. Move the leading edge of the membrane 1 cm past the lower edge of the gel. Connect apparatus to a high-voltage power supply.

When choosing the direct blotting technique, all fragments, including the largest ones, pass through the whole length of the gel. Thus, a lower acrylamide concentration (i.e., 4.5% instead of 6%) is used as compared to the concentration used for standard sequencing gels.

2. Prerun (i.e., with no sample) the gel for 30 min with the power supply set to 2000 V and 30 W as limiting parameters.

Electrophorese samples and transfer to the membrane

3. Rinse gel slot with TBE buffer using a 10-ml syringe and 25-G needle, and insert a 32-well sharkstooth comb. Using GELoader tips with the capillary-like part cut away, load 1 to 1.5 μ l denatured reaction (see Basic Protocol, step 18) per well, being sure to load the whole gel within ~10 min.

Although 48-well combs are available as well, no satisfactory results could be obtained with them in the authors' laboratory.

Do not use the first and the last slot of a gel, since the corresponding lanes easily run off the membrane due to imprecise membrane alignment prior to the run.

4. Start electrophoresis with the same parameters used for prerunning. After 45 to 50 min, start the conveyor belt with an initial speed of 16 cm/hr, linearly decreasing to 10 cm/hr.

The continuous decrease in conveyor belt speed (i.e., in the blotting membrane feed rate) compensates for the nonlinear mobility of differently sized DNA molecules. The chosen parameters yield an approximate equidistant spacing of bands of different size (e.g., the

distance between a 100- and a 150-bp band is roughly the same as the distance between a 400- and a 450-bp band).

At the end of the run, the conveyor belt and membrane are wound up to the back roller. The membrane can be left wound up for drying overnight. Alternatively, it can be removed and hung up in a dust-free space.

If a size marker is desired, biotinylated Sequamark 10-bp ladder (Research Genetics) turns out to be optimal. This marker provides an accurate and easily identifiable standard for DNA fragments up to 500 bp; however, 5- to 10-fold concentration of the marker by precipitation is necessary to obtain sufficient sensitivity.

5. Air-dry the membrane overnight and fix by gentle UV irradiation in a Stratalinker with a UV dosage of $\sim 10,000 \mu\text{J}/\text{cm}^2$ (i.e., $\sim 1/10$ the “auto-cross-link” dosage).

For later recovery of bands of interest, it is important not to overfix membranes.

Rinse membrane and block nonspecific binding

6. Insert membrane into a suitable developing drum (e.g., GATC tube), fix with some adhesive tape, and rinse with 100 ml water while rotating 5 min on a suitable rolling incubator.

Any roller that accepts a tube 18 cm in diameter \times 35 cm long and is able to revolve at ~ 20 rpm will do.

7. Replace water with 150 ml maleic buffer, pH 7.5, and equilibrate membrane by rotating another 5 min. Pour buffer into a beaker and store for later use.
8. Incubate 40 to 50 min in a rolling incubator with 80 ml of 1.5% blocking reagent.

Label bands with streptavidin-alkaline phosphatase

9. Discard buffer and add 20 ml of 1.5% blocking reagent and 2 to 4 μl streptavidin-alkaline phosphatase conjugate. Incubate membrane 30 min in a rolling incubator.
10. Pour off buffer completely and wash 5 min, using the 150 ml maleic buffer set aside in step 7. Replace with 150 ml fresh maleic buffer and wash 10 min. Replace with another 150 ml maleic buffer and wash 15 min.
11. Replace with 150 ml reaction buffer, pH 9.5, and equilibrate membrane 5 min.

Develop color

12. For color development, pour off buffer and add 20 ml reaction buffer containing 400 μl NBT/BCIP stock solution. Develop under slow rotation for 2 to 3 hr.

CAUTION: NBT is a suspected carcinogen. Moreover, the DMSO in the concentrated stock solution might mediate penetrance of dissolved substances through the skin, and is itself hazardous. Wear gloves, replace contaminated gloves immediately, and carefully avoid any skin contact. Dispose of according to institutional regulations (also see APPENDIX 1H).

13. Pour off developing solution and perform three 10-min rinses with 150 ml water each.
14. Put the wet membrane between two sheets of 2-mm-thick polyethylene wrap or material from a thick hybridization bag. Inspect wet membranes visually for bands appearing significantly stronger or weaker in one lane as compared to adjacent corresponding lanes.

Polyethylene wrap is also called “tubular film” and must be thick, as thinner material makes handling of the wrapped membranes much more difficult and might not be a sufficient barrier against water vapor, allowing the membranes to dry. The material from a hybridization bag should also work, provided it is thick enough.

It is important that, after color development, membrane pieces carrying DNA to be reamplified never dry, as otherwise reamplification by PCR may become impossible.

For documentation, scanning of the wrapped wet membranes has proved to yield the most satisfactory results.

Isolate and reamplify sample band

15. Cut out “differential” bands with a scalpel and transfer to microcentrifuge tubes each containing 20 μl TE buffer, pH 8.0. Make sure that membrane pieces do not become dry during this procedure. Using the scalpel tip, immediately submerge bands in the buffer. Rinse scalpel carefully before excising the next band.

If excision is not intended to occur immediately, wet membranes can be stored 1 to 2 days at 4°C; however, during prolonged storage, wet membranes tend to become blotched. It is therefore advisable to dry membranes after at most one week. To avoid fading after drying, membranes should be kept dark (indefinitely) at room temperature.

16. For band reamplification, transfer half of the respective piece of membrane into a PCR tube containing 30 μl of the following mixture:

4.0 μl buffer from the tube in which the band was stored
3.0 μl 10 \times PCR buffer
2.25 μl 20 mM MgCl_2
0.6 μl 10 mM dNTPs
13.85 μl H_2O
3.0 μl 4 μM CP28
3.0 μl 4 μM ML18
0.3 μl 5 U/ μl *Taq* DNA polymerase.

17. Amplify under the following conditions:

Initial step:	1 min	94°C (denaturation)
20 or 25 cycles:	20 sec	94°C (denaturation)
	20 sec	65°C (annealing)
	2 min	72°C (extension)
Final step:	indefinitely	10°C (hold).

Amplification takes place for 20 cycles (strong bands) or 25 cycles (weak bands), respectively.

Do not use biotinylated primers for band reamplification. 5'-modification of oligonucleotide primers will interfere with cloning.

18. Check products by agarose gel electrophoresis (UNIT 2.5A).

Clone products

19. Clone reamplification products as described in UNIT 15.7 or by using one of the commercially available T-A cloning systems.

In the authors' laboratory, 4 to 5 clones per band are usually sequenced. Depending on band intensity, all clones may be identical, or there may be more than one sort of insert. In the latter case, choose the most frequently occurring insert for further processing.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Blocking reagent, 1.5%

Prepare stock solution by suspending blocking reagent (Roche Molecular Biochemicals) to 10% (w/v) in maleic buffer, pH 7.5 (see recipe) and autoclaving. Store frozen up to 1 year at -20°C . Immediately before use, dilute 1.5 parts (v/v) of the 10% stock with 8.5 parts (v/v) of maleic buffer.

Maleic buffer, pH 7.5

100 mM maleic acid

150 mM NaCl

200 mM NaOH

Store indefinitely at room temperature

MboI-linker ML2025

Combine:

150 μl 100 pmol/ μl ML20: 5'-TCA CAT GCT AAG TCT CGC GA-3' (see UNIT 2.11)

150 μl 100 pmol/ μl LM25: 5'-GAT CTC GCG AGA CTT AGC ATG TGA C-3' (see UNIT 2.11)

55 μl 10 \times ligation buffer

195 μl H₂O.

Mix and place in a 90°C heating block. Shut off the heating block and let cool down slowly to room temperature. The linker (~ 0.5 $\mu\text{g}/\mu\text{l}$) is now ready for use and should be stored frozen up to 1 to 2 years at -20°C .

Alternatively, a thermocycler programmed to a low cooling rate (e.g., $0.02^{\circ}\text{C}/\text{sec}$) can be used as opposed to a heating block.

PCR buffer, 10 \times

670 mM Tris·Cl, pH 8.8 (APPENDIX 2)

170 mM (NH₄)₂SO₄

1% (v/v) Tween 20

Store up to 2 years at -20°C

PEG 8000, 50%

Add exactly 10 g of PEG 8000 (Promega) to 10 g water in a 50-ml conical tube (e.g., Becton Dickinson). Close the tube and attach to the rotor of a hybridization oven with the heat turned off. Rotate at room temperature 12 hr to overnight until all flakes are completely dissolved. Store up to 1 to 2 years at -20°C .

After thawing, shake vigorously until no more "schlieren" can be observed. Wait ~ 10 to 15 min until all air bubbles introduced by shaking have come to the surface before slowly and carefully withdrawing the desired volume.

It is important to adhere to the exact 1:1 weight ratio of PEG and water.

PEG 8000, 28%/MgCl₂, 3.6 mM

Carefully mix 5.6 ml 50% PEG 8000 (see recipe) with 3.68 ml water and 720 μl of 50 mM MgCl₂ (APPENDIX 2). Store up to 2 years at -20°C .

Reaction buffer

100 mM NaCl

5 mM Tris hydrochloride

90 mM Tris base

Store up to 1 year at room temperature

COMMENTARY

Background Information

Identification of differentially expressed genes is currently one of the most promising approaches toward understanding fundamental life processes. However, due to the high complexity of mRNA composition in a living cell, as well as the broad range of relative frequencies of particular transcripts and the fact that subtle changes in the expression level of a gene can have profound biological effects, performing a sensitive, reliable, and relatively complete comparative expression analysis has remained a nontrivial task up to the present.

Probably the first methods for isolation of differentially expressed genes that found widespread acceptance were the fingerprinting techniques of differential display (e.g., Liang and Pardee, 1992; see also *UNIT 25.B3*) and RNA arbitrarily primed PCR (Welsh et al., 1992). These methods relied on the generation of arbitrarily primed amplification products, each representing a particular transcript, which were radiolabeled and separated by polyacrylamide gel electrophoresis. Resulting band patterns originating from different samples were then compared. An indisputable strength of display technology, as opposed to subtractive hybridization experiments (*UNIT 25.B2*), is the option to directly compare any desired number of different samples with each other. Moreover, no prior knowledge about the RNA to be analyzed is required, rendering these methods suitable for analysis of RNA from any source. Nevertheless, in some hands, the application of these protocols was not always satisfactory (Debouck, 1995), due to insufficient reproducibility (Malhotra et al., 1998), a high rate of isolating false positive clones (Poirier et al., 1997), a biased representation favoring abundant transcripts (Ledakis et al., 1998), and contamination of workspaces through closed tube walls by volatile sulfur compounds (Trentmann, 1995). The use of longer primers (i.e., 20-mers; Zhao et al., 1995) improved reproducibility, but not other problems.

To address these issues, arbitrarily primed PCR was replaced by amplification of linker ligated restriction fragments (Fischer, 1995; Fischer et al., 1995; Prashar and Weissman, 1996). With this approach, it is possible to generate and display exactly one fragment per cDNA, thereby clearly increasing the sensitivity of the analysis. Spiking experiments demonstrated that, following the RMDD protocol as described above, an mRNA species at a

relative concentration of 1:100,000 will usually be identifiable by a specific band. This holds true for the radioactive as well as for the non-radioactive version of the protocol—i.e., the authors could not detect any differences in the sensitivity of RMDD regardless of whether biotin or ^{33}P was used for labeling, which is due to the fact that sensitivity is not limited by the amount of amplification product used for display, but by a slight background smear which cannot be avoided when separating complex mixtures of PCR products by gel electrophoresis.

It is important to note that, due to the use of nonphosphorylated linkers, only one of the two linker strands is covalently attached to the cDNA restriction fragments upon ligation. The opposite linker strand is melted off during the initial denaturation step and can no longer serve as a primer binding site. Thus, amplification can take place only when extension of a non-linker primer (i.e., the “downstream” primer which is essentially identical to the cDNA primer) has taken place, incorporating the reverse complement of the covalently attached linker strand. As a consequence, only cDNA 3'-ends are amplified to a detectable level, whereas “internal” cDNA fragments flanked by linkers at both ends remain unamplified.

Another problem that had to be solved was band identification. “Classic” protocols rely on cutting out invisible radioactive bands from dried gels after superimposing the gel and its corresponding autoradiogram (Liang and Pardee, 1992). In addition to the uncertainty of cutting invisible bands, which may easily lead to missing the desired band, tiny splinters of the radioactive gel, which becomes quite brittle after drying, might be inhaled. On the other hand, nonradioactive in-gel detection of DNA by silver staining turned out to lack sufficient sensitivity, and also significantly reduced the dynamic range of display patterns (A. Fischer, unpub. observ.). Attempts to bypass the physical fragment isolation step by defining fragment signatures and performing database searches after fluorescent gel display on an automatic DNA sequencer (A. Fischer, unpub. observ.; Shimkets et al., 1999; Sutcliffe et al., 2000) are hampered by the unpredictable influence of base composition on the electrophoretic mobility of a DNA strand, which introduces considerable inaccuracies when fragment sizes are to be determined, and are unsuitable for organisms less well characterized molecularly

Table 25B.4.1 Troubleshooting Guide for RMDD

Problem	Possible cause	Solution
Low amount of first-round PCR product	RNase contamination	Take care to use only RNase-free solutions. Make sure RNA is not contaminated by remaining traces of RNase. Check integrity of ribosomal bands after cDNA first-strand synthesis.
	RNA preparation contaminated by inhibitors of cDNA synthesis	Use only RNA that is as pure as possible. Usually, standard purification protocols (e.g., the “classic” guanidinium method, <i>UNIT 4.2</i> , or more modern, commercially available RNA purification columns), if not overloaded, yield RNA of sufficient purity. Should problems persist, in very tenacious cases purification of RNA by CsCl density gradient centrifugation (<i>UNIT 4.2</i>) might be considered.
	Incomplete PEG precipitation	Be sure to exactly balance the amounts of DNA solution and of PEG solution.
	Inefficient ligation	Check activity of ligase or use a fresh batch. Make sure linkers fit to the fragment ends generated by the employed restriction enzyme.
Agarose gel appearance of first-round PCR products obtained with identical primer combinations between samples	Very low amounts of template DNA lead to stochastic effects in early PCR cycles (“Monte Carlo effect”; Karrer et al., 1995)	See “low amount of PCR product”
Fuzzy bands on DBE membrane	Glass plates accumulated too much silane	Immerse glass plates for 1 hr in 0.5 M NaOH
	Edges of glass plates not exactly parallel	Make sure plates are carefully aligned immediately after pouring gel
Low signal intensity after color development	Biotin label of blotted DNA not sufficiently accessible	Use biotinylated PCR primers distinguished by a TEG spacer
	Insufficient amounts of second-round PCR primers	Check primer concentration. Since primers are used at limiting concentration, inaccuracies upon determination of concentration may hamper generation of sufficient PCR product.
White vertical stripes interrupt band pattern on membrane	Air bubbles accumulated at the lower edge of the gel	Degas running buffer for lower chamber by stirring 20 min under vacuum. Insert glass plates slightly inclined.
Band reamplification fails	UV fixation too strong	Apply $\sim 1/10$ the UV dose usually chosen for fixing DNA blots (recommended dose is 10,000 $\mu\text{J}/\text{cm}^2$)
	Membrane has become dry before reamplification	Keep wet membrane between two sheets of thick polyethylene wrap until bands are cut out. After cutting out bands, immediately submerge in buffer.
False positive clones (no regulation detectable)	Reamplification product contained more than one DNA species	Sequence more than one clone per band. If several inserts are identified, choose the most frequently occurring one.

than man or mouse. Attempts to use such an approach for analysis of rat RNA resulted in an unacceptably low hit rate (i.e., <10%) of correctly identified fragments (A. Fischer, unpub. observ.). Thus, although the RMDD technique could be very well performed using ^{32}P or ^{33}P as a label, the authors developed a protocol using nonradioactive detection of biotinylated amplification products. These are transferred to a membrane by use of direct blotting electrophoresis (DBE; Beck and Pohl, 1984); visible bands are rendered directly accessible by simply cutting them out of the stained membrane, eliminating one of the most common sources of false positives. Besides providing convenient access to “differential” bands, DBE proved superior in terms of resolution power, yielding nearly equally spaced bands in the range between 100 and 1000 base pairs.

After generating a library of cDNA-derived restriction fragments ligated to linkers, sufficient resolution and sensitivity of detection for the thousands of 3'-cDNA fragments generated has to be achieved. Towards this end, RMDD primers elongated at their 3'-ends are used for amplification, each only allowing the amplification of a defined subset of fragments. Using extensions of two nucleotides on each side, 16 linker primers and 12 reverse primers (the first extension nucleotide by definition cannot be a T) are synthesized. Thus, during the subsequent PCR step, the original set of fragments is divided into $16 \times 12 = 192$ subsets, which fits exactly in two 96-well PCR plates and renders the method suitable for automation. Each of these subsets then contains an estimated 50 to 100 fragments, which can be easily resolved by denaturing polyacrylamide electrophoresis.

Critical Parameters

During efforts to identify critical steps contributing to the robustness of the RMDD protocol, the amount of amplifiable material left after enzymatic processing of input RNA was identified as a major factor causing instability of band patterns, probably due to random fluctuations during early PCR cycles (Karrer et al., 1995). The authors' RMDD protocol was therefore optimized to minimize losses during sample preparation. Toward this end, an important step was replacing spin-column chromatography for removal of unincorporated linker molecules with size-selective polyethylene glycol precipitation, allowing almost 100% recovery of the desired DNA species and reduction of the protocol to as few steps as possible. In its

current version, RMDD yields highly reproducible band patterns, independent of moderate variations of the amount of input material, in the range of at least down to 10 μg total RNA; however, it is essential that the analyzed RNA be of high purity. Otherwise, due to inhibition of enzymatic steps, the amount of linker-ligated template fragments effectively entering amplification might become too low to guarantee stable PCR results.

One should also be aware that RMDD analysis only covers those transcripts that carry a recognition site for the restriction enzyme used in an “amplifiable” distance from the poly(A) tail. For a more detailed discussion of this issue, see Strategic Planning.

Troubleshooting

For solutions to problems that may arise during these protocols, see Table 25.B4.1.

Anticipated Results

After corresponding PCRs (distinguished by identical primer extensions) from different RNA samples are run side by side on the gel, resulting band patterns are visually compared. A typical RMDD pattern shows, in each lane, bands of different sizes and intensities, each representing one particular cDNA. Patterns obtained from similar samples should very closely resemble each other, with only very few (if any) differences. Within these patterns, band intensities correlate with the original relative frequencies of the template cDNAs. This is due to the fact that in complex PCR reactions (i.e., with more than one amplification product) entry into plateau phase of amplification freezes the different amounts of synthesized products (McClelland and Welsh, 1994); therefore, if a particular cDNA is present at different amounts in the two samples, the resulting bands will show different intensities on the RMDD membrane. Differences in expression levels at least down to 2-fold will be detectable. In one instance, a band that was shown by quantitative PCR to represent a gene down-regulated 1.4-fold was isolated in the authors' laboratory. This is especially significant as the “gold standard” in transcription profiling is usually set at 2-fold up- or down-regulation; therefore, the fact that RMDD allows isolation of transcripts regulated to a lower degree, which still can be of the highest biological relevance (e.g., gradients in developmental biology), clearly contributes to its usefulness.

Time Considerations

When starting with up to six samples of precipitated RNA, the protocol, including second-round amplification with a subset of all primer combinations, can be performed within two days, including an overnight ligation step. The remaining set of second-round amplifications can be done at a rate of four to six 96-well plates per day and person. Alternatively, employment of a robotic pipetting station might be considered. Choosing the DBE variant, two membranes per day per DBE machine can be prepared, each providing space for 30 reactions. It should be noted that buffer capacity allows for using each DBE gel twice, provided that the second run starts immediately after the first run without idle electrophoresis in between. One person can then operate three to four machines per day and produce 6 to 8 membranes. In such a medium-scale setup, gels are prepared in the evening, and, with edges carefully wrapped in plastic wrap with some wetted pieces of paper towel enclosed, allowed to polymerize overnight. In the morning, gels are mounted and electrophoresis is started. During electrophoresis, the membranes of the day before are developed, the glass plates of the previous runs cleaned, and the gels for the next day are prepared.

AFLP-Based Transcript Profiling

UNIT 25B.5

BASIC
PROTOCOL

In recent years, several techniques have been developed to analyze the transcriptome—i.e., the entirety of transcripts present in a cell, tissue, or organ. These procedures include methods based on hybridization to microarrays of known expressed sequence tag (EST)-sequences (Schena et al., 1995; De Risi et al., 1997), sequence-based approaches like SAGE (Velculescu et al., 1995; UNIT 25B.6) and random EST sequencing (Adams et al., 1991), and protocols based on display of cDNA fragment patterns on high-resolution gels (Liang and Pardee, 1992; UNITS 25B.3 & 25B.4). In the last category is transcript profiling based on amplified fragment length polymorphism (AFLP)-fingerprinting of double-stranded cDNA (Zabeau and Vos, 1993; Vos et al., 1995; Bachem et al., 1996). The protocol, illustrated in Figures 25B.5.1 and 25B.5.2, includes the following steps: (1) the isolation of poly(A)⁺ RNA from total RNA (UNIT 4.2), (2) the synthesis of a double-stranded (ds) cDNA library, (3) the preparation of template fragments by digestion of the cDNA library with a combination of two restriction enzymes and the ligation of adapters to the fragment ends, (4) the selective amplification of specific subsets of fragments, and (5) the electrophoretic analysis of these amplification products on standard denaturing polyacrylamide gels. The protocol given in this unit describes all steps in the procedure, except the isolation of total RNA; however, any of the presently used methods is acceptable (e.g., UNIT 4.2). The restriction enzyme combination (EC) used in this protocol is *TaqI*-*MseI*. This EC will target the majority of the mRNAs, and both *MseI* and *TaqI* are reliable and inexpensive. Other combinations of two 4-base cutters may also work well

Figure 25B.5.1 Principle of the AFLP-based transcript profiling technique. The poly(A)⁺ RNA is indicated at the top with the poly(A) tail at the 3' end. The ds cDNA is shown as a double line; restriction enzyme sites with 5' overhangs are indicated. The ds *TaqI* and *MseI* adapters are depicted as small black and gray boxes respectively, attached to the protruding ends of the restriction fragments. At the bottom the "X's" illustrate the poor amplification of the *MseI*-*MseI* fragments.

Differentially
Expressed Genes

25B.5.1

Supplement 57

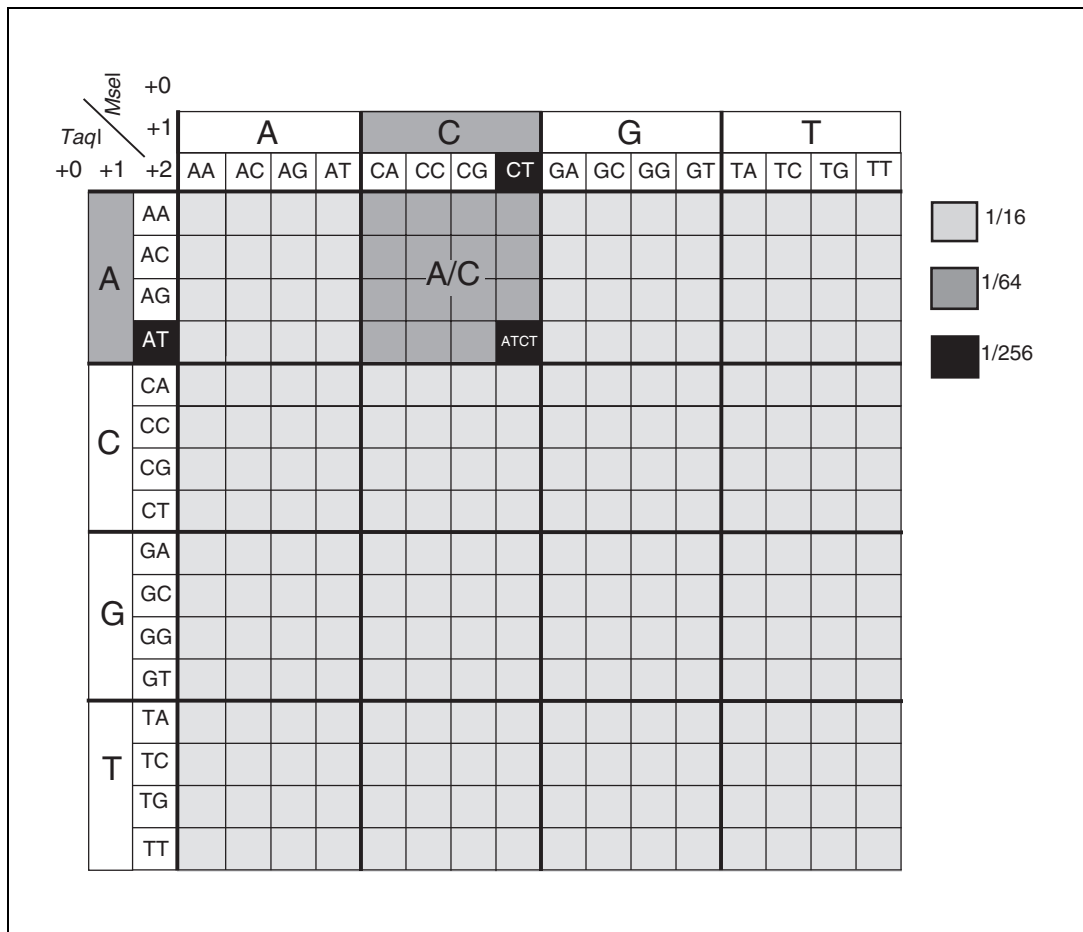

Figure 25B.5.2 Illustration of the selective amplification principle. The smallest squares indicate subsets of the transcript fragment population amplified with four selective nucleotides, two for *TaqI* and two for *MseI*, and exemplified by the black square amplified with *TaqI*-AT and *MseI*-CT. The 16 larger squares, composed of 16 of the smallest squares, indicate the transcript fragment subsets amplified using two selective nucleotides, exemplified by the dark gray square of *TaqI*-A and *MseI*-C. The total transcript fragment population is depicted by the full square, composed of 256 of the smallest squares.

but require the use of adaptors and primers that match the recognition sequences of the corresponding enzymes (see Reagents and Solutions). Restriction enzymes that cut less frequently in the cDNA are not advised since these enzymes target only a small subset of the mRNAs.

To generate specific subsets of fragments, three PCR steps are used, which minimizes mismatch amplification. When all combinations of PCR primers are used at each step, as prescribed in the protocol, this generates an expression profile consisting of 256 “fingerprints” (Fig. 25B.5.2). (One can modify the protocol to use only certain primer combinations, but this will yield fewer fingerprints and less information.) The first PCR step entails no selective nucleotides on each primer (i.e., nonselective preamplification +0/+0). The second step entails one selective nucleotide at each primer (selective preamplification +1/+1; 16 combinations). The third step entails two selective nucleotides at each primer (selective amplification +2/+2; 256 combinations).

NOTE: All solutions and materials coming into contact with RNA must be RNase free, and proper techniques should be used accordingly (see APPENDIX 2).

NOTE: AFLP is a registered trademark of Keygene N.V. and is protected by patents and patent applications of Keygene N.V.

Materials

Total RNA (*UNIT 4.2* or equivalent)
5'-biotinylated oligo-dT₂₅ (5-biotin-dT₂₅)
1× and 2× binding buffer (see recipe)
H₂O: Milli-Q purified (i.e., water deionized by passage through a five-stage Milli-Q Plus system; Millipore) or double-distilled
Streptavidin-coated magnetic beads (Dynal)
Wash buffer (see recipe)
2 mM EDTA, pH 7.5
5× first-strand buffer (see recipe)
5× second-strand buffer (see recipe)
0.1 M DTT (*APPENDIX 2*)
5 and 10 mM (each) mixture of all 4 dNTPs (Pharmacia or *UNIT 3.4*)
SuperScript II (Life Technologies)
E. coli DNA ligase (Life Technologies)
E. coli DNA polymerase I (Pharmacia Biotech)
RNase H (Pharmacia Biotech)
2× and 1× STEX (see recipe)
10 mM Tris·Cl, pH 8.0/0.1 mM EDTA (*APPENDIX 2*)
TaqI restriction endonuclease (New England Biolabs; *UNIT 3.1*)
5× RL buffer (see recipe)
MseI restriction endonuclease (New England Biolabs; *UNIT 3.1*)
50 pmol/μl *TaqI* adapter top and bottom strands (see recipe for oligonucleotides and double-stranded adapters)
50 pmol/μl *MseI* adapter top and bottom strands (see recipe for oligonucleotides and double-stranded adapters)
10 mM ATP (Pharmacia)
T4 DNA ligase (Pharmacia)
8 pmol/μl AFLP + 0 (nonselective) primers (see recipe for oligonucleotides and double-stranded adapters): *TaqI* + 0 and *MseI* + 0 primers
10× PCR buffer (see recipe)
AmpliTaq DNA polymerase (Perkin-Elmer; *UNIT 3.5*)
10 μCi/μl (~2000 Ci/mmol) [³³P-γ]ATP (Amersham)
10× T4 polynucleotide kinase buffer (see recipe)
T4 polynucleotide kinase (Pharmacia; *UNIT 3.4*)
8 pmol/μl AFLP +1 and + 2 (selective) primers (see recipe for oligonucleotides and double-stranded adapters): *TaqI* + 1 and + 2 and *MseI* + 1 and + 2 primers
AmpliTaq-Gold polymerase (Perkin-Elmer)
Loading dye (see recipe)
Repel silane (Pharmacia)
Bind silane solution, fresh: Combine 30 μl bind silane (Pharmacia Biotech) and 30 μl glacial acetic acid in 10 ml ethanol
4.5% denaturing polyacrylamide gels (see recipe)
1× TBE (see recipe)
Molecular weight standard (e.g., SequaMark 10-base ladder; Research Genetics; optional)
10% acetic acid
Microcentrifuge tubes, RNase free
Magnetic plate chamber (MPC; Dynal)
PE-9600 thermal cycler (Perkin Elmer) and PCR microtiter plate

Sequencing gel system (e.g., BioRad 38 × 50 × 0.04–cm SequiGen sequencing gel system)

PhosphorImager (Fujix BAS 2000, Molecular Dynamics STORM 824)

Additional reagents and equipment for agarose gel electrophoresis (UNIT 2.5A), analysis by denaturing polyacrylamide gel electrophoresis (UNIT 2.12), and detection of DNA by autoradiography or phosphor imaging (APPENDIX 3A)

NOTE: Suppliers and brands are generally not very critical, however in case of problems it is advised to use the suggested suppliers for at least the reverse transcriptase (SuperScript II) and *Taq* polymerases (AmpliTaq and AmpliTaq-Gold).

NOTE: When preparing AFLP amplifications, it is advisable to work with mixes of reagents as much as possible. Working with mixes facilitates assembly and is also important for the reliability and reproducibility of the reactions. In practice, the assembly of the mixes depends on the experiment—i.e., which components remain constant in a series of reactions: the template-DNA or the primer combinations (e.g., one sample with many primer combinations, many samples with one primer combination).

Isolate poly(A)⁺ RNA

1. Combine 200 μg total RNA, 600 ng 5'-biotinylated oligo-dT₂₅ (5-biotin-dT₂₅), and 300 μl 2× binding buffer in an RNase-free microcentrifuge tube. Adjust the volume to 600 μl with water. Incubate 5 min at 70°C, followed by 15 to 20 min at room temperature.

Sufficient poly(A)⁺ RNA to perform the subsequent steps (i.e., cDNA synthesis and template preparation in duplicate) is yielded from 200 μg total RNA.

2. Wash 150 μl streptavidin-coated magnetic beads with 0.5 ml of 1× binding buffer (see step 4 below for technique or use microcentrifuge). Resuspend the beads in 50 μl of the same buffer.

Mix the magnetic beads solution well before use to obtain a homogeneous suspension. Do not let the magnetic beads dry for a long period of time, as drying may lower their capacity (see Dynal, 1995).

3. Add these prewashed beads to the RNA-containing mixture (step 1) and incubate 30 min at room temperature with gentle agitation.
4. Place the microcentrifuge tube in the magnetic plate chamber (MPC) for ~30 sec and then remove as much of the supernatant as possible without disturbing the beads. Remove the tube from the MPC, add 0.5 ml wash buffer, and mix thoroughly. Repeat two more times, removing the supernatant after the final wash.

Do not allow the beads to dry out.

5. Elute poly(A)⁺ RNA by resuspending the beads in 20 μl of 2 mM EDTA and incubating 5 min at 70°C. Collect the beads with the MPC as in step 4 and transfer the supernatant to a new RNase-free microcentrifuge tube as quickly as possible without transferring any beads. Repeat once to obtain ~40 μl of poly(A)⁺ RNA solution.

For long-term storage, add 0.1 vol 2 M sodium acetate, pH 5.5 and mix. Add 3 vol 100% ethanol and store indefinitely at -20°C (UNIT 2.1A). To recover, microcentrifuge 5 min at maximum speed, remove supernatant, dry in a rotary evaporator, and resuspend in the original volume of double-distilled water or buffer.

6. Check the yield (on average ~2 μg) and quality of the isolated poly(A)⁺ RNA by performing agarose gel electrophoresis alongside molecular weight markers (UNIT

2.5A) using 5 μ l of the poly(A)⁺ RNA solution, which should appear as a faint smear from ~10 kb down (i.e., lower molecular weight) with trace rRNA bands.

It is not necessary to eliminate the rRNA contamination by extracting the mRNA from the eluate a second time.

Synthesize the ds cDNA

7. For first-strand cDNA synthesis, combine the following:

- 10 μ l poly(A)⁺ RNA (~0.5 μ g)
- 0.5 μ l 700 ng/ μ l 5-biotin-dT₂₅ (reverse transcription primer)
- 2 μ l H₂O
- 4 μ l of 5 \times first-strand buffer
- 2 μ l 0.1 M DTT
- 1 μ l 10 mM dNTPs
- 0.5 μ l of 200 U/ μ l SuperScript II (add last).

Incubate 2 hr at 42°C.

8. For second-strand synthesis, combine the following:

- 20 μ l first-strand cDNA synthesis mixture (from step 7)
- 16 μ l 5 \times second-strand buffer
- 1.5 μ l 10 mM dNTPs
- 3 μ l 0.1 M DTT
- 7.5 U *E. coli* DNA ligase
- 25 U *E. coli* DNA polymerase I
- 0.8 U RNase H
- H₂O to 80 μ l.

Incubate 1 hr at 12°C followed by 1 hr at 22°C.

The quality and yield of the resulting ds cDNA can be checked by agarose gel electrophoresis (UNIT 2.5A).

9. Wash 25 μ l streptavidin-coated beads with 100 μ l of 2 \times STEEX (see step 4 for technique). Resuspend in 80 μ l of 2 \times STEEX.

10. Add the bead suspension to the cDNA mixture and incubate 30 min at room temperature with gentle agitation.

Purification of a large number of samples using beads can be performed in 96-well format. Incubation at room temperature is done in 96-well plates with caps. Subsequently, samples are transferred to fresh microtiter plates.

11. Collect beads with the MPC (step 4), wash once with 100 μ l of 1 \times STEEX, and transfer to a fresh microcentrifuge tube. Wash twice more with 1 \times STEEX and resuspend final bead pellet in 50 μ l H₂O or 10 mM Tris-Cl, pH 8.0/0.1 mM EDTA.

Generally, 250 to 500 ng ds cDNA will be obtained from the 500 ng of input (single-stranded) poly(A)⁺ RNA.

10 mM Tris-Cl, pH 8.0/0.1 mM EDTA is also known as T₁₀E_{0.1} buffer and has a lower EDTA concentration than the TE buffer described in APPENDIX 2 of this manual.

The ds cDNA is attached to the beads and is taken into subsequent steps while attached to the beads.

Prepare the AFLP cDNA template fragments using *TaqI* and *MseI*

12. Mix the following:

20 μ l cDNA preparation (generally 100 to 200 ng cDNA)
10 U *TaqI* restriction endonuclease
8 μ l 5 \times RL buffer
Adjust volume to 40 μ l with H₂O.

Incubate 1 hr at 65°C.

13. Add the following:

10 U *MseI* restriction endonuclease enzyme
2 μ l 5 \times RL buffer
Adjust the volume to 50 μ l with H₂O.

Incubate 1 hr at 37°C.

14. Prepare the *TaqI* adapter by combining 8.5 μ g (1500 pmol) top and 8 μ g (1500 pmol) bottom strands. Adjust volume to 30 μ l with water.

*This results in a solution of 50 pmol/ μ l of double-stranded *TaqI*-adapter.*

15. Prepare the *MseI* adapter by combining 8.0 μ g (1500 pmol) of the top strand and 8.0 μ g (1500 pmol) of the bottom strand. Adjust volume to 30 μ l with water.

*This results in a solution of 50 pmol/ μ l of ds *MseI* adapter.*

*The *TaqI* and *MseI* adapters both have double-stranded parts of 14 base pairs; it appears unnecessary to perform a specific denaturation-renaturation procedure to anneal the two strands of the adapters. Note that the base-pair adjacent to the restriction site overhang is such that the recognition site is not restored upon ligation (see Background Information). Absence of 5'-phosphates prevents self-ligation of adapters.*

16. To the cDNA fragments digested with *TaqI* and *MseI* (steps 12 and 13), add 1 μ l of each adapter (50 pmol each; steps 14 and 15), 1 μ l of 10 mM ATP, 2 μ l of 5 \times RL-buffer, 1 U of T4 DNA ligase, and 10 μ l water. Incubate 2 hr at 37°C.

The cDNA is incubated for 2 hr with restriction enzymes (steps 12 and 13) followed by an additional incubation of 2 hr in the presence of DNA ligase. It is not advisable to perform the restriction digestion and ligation simultaneously. This may affect the efficiency of the DNA restriction. Longer incubation times are also not recommended, because this may affect the quality of the transcript fingerprints. After digestion and ligation of adapters, the cDNA is stored at -20°C or immediately used for the subsequent steps.

Perform nonselective preamplification of the template fragments

17. Dilute a small aliquot (2 to 5 μ l) of the template mixture (step 16) 10-fold with Tris·Cl, pH 8.0/0.1 mM EDTA. Prepare the following preamplification reactions:

5.0 μ l 1:10 diluted template mixture
1.5 μ l 8 pmol/ μ l each AFLP + 0 (nonselective) primer
2.0 μ l 5 mM dNTPs (0.2 mM final concentration of each dNTP)
5 μ l 10 \times PCR buffer
1 U AmpliTaq DNA polymerase
Adjust volume to 50 μ l with H₂O.

18. Amplify using the following temperature cycle profile on a PE-9600 thermal cycler:

20 cycles:	30 sec	94°C	(denaturation)
	60 sec	56°C	(annealing)
	60 sec	72°C	(extension).

The purpose of the nonselective preamplification reaction is to generate more starting material for the subsequent selective AFLP reactions. This is one of the advantages of the AFLP technique. Once the template-DNA is made, new starting material for selective amplifications can always be made by nonselective amplification of the template DNA, and hence, new RNA isolation will never have to be done again.

Note that the adapter strands are not phosphorylated and that, therefore, the strand which represents the primer-target is not ligated to the template DNA. Thus, a “hot-start” should never be performed (UNIT 15.1); however, during the initial heating step, Taq polymerase should elongate the staggered ends of the template replacing the adapter strands.

19. Check the preamplification by running 10 μ l of the reaction mixture on an agarose gel alongside molecular weight markers (UNIT 2.5A), which should give a visible smear of products in the size range of 50 to 500 base pairs.

Perform selective preamplification reactions using TaqI+I and MseI primers

20. Dilute 2 μ l nonselective preamplified cDNA fragments (i.e., +0/+0) 1:500 in Tris·Cl, pH 8.0/0.1 mM EDTA.
21. Prepare selective preamplification (+1/+1) reactions in a microtiter plate for a PE-9600 thermocycler in the following way:

- a. Dispense 5 μ l of 1:500 nonselective preamplification cDNA fragments into each well of the first two columns (1 and 2) of the microtiter plate.
- b. Dispense 1.5 μ l of 8 pmol/ μ l TaqI+A primer into each of wells A1 to D1, 1.5 μ l of 8 pmol/ μ l TaqI+C primer into each of wells E1 to H1, 1.5 μ l of 8 pmol/ μ l TaqI+G primer into each of wells A2 to D2, and 1.5 μ l of 8 pmol/ μ l TaqI+T primer into each of wells E2 to H2.
- c. Dispense 1.5 μ l of 8 pmol/ μ l MseI+A primer into each of wells A1, A2, E1, and E2; 1.5 μ l of 8 pmol/ μ l MseI+C primer into each of wells B1, B2, F1, and F2; 1.65 μ l of 8 pmol/ μ l MseI+G primer into wells C1, C2, G1, and G2; and 1.4 μ l of 8 pmol/ μ l MseI+T primer into each of wells D1, D2, H1, and H2.
- d. Prepare dNTP/polymerase mix by combining 32 μ l 5 mM dNTPs, 80 μ l of 10 \times PCR buffer, 16 U AmpliTaq-Gold polymerase, and adjust the volume to 672 μ l with water.
- e. Dispense 42 μ l dNTP/polymerase mix into each well of the first two columns.

The procedure above can be adjusted when more samples are processed at the same time (i.e., 3 samples occupy 48 wells of the microtiter plate and three times more TaqI+I primers, MseI+I primers, and dNTP/polymerase mix will be needed).

An individual reaction can be prepared by combining 5 μ l of 1:500 nonselective preamplification product, 1.5 μ l of 8 pmol/ μ l TaqI+I primer (12 pmol), 1.5 μ l of 8 pmol/ μ l MseI+I primer (12 pmol), 2 μ l of 5 mM dNTP, 5 μ l 10 \times PCR buffer, and 1 U AmpliTaq-Gold polymerase. The volume is adjusted to 50 μ l with water.

22. Perform AFLP amplification with the following “touch-down” temperature cycle program:

13 cycles:	30 sec	94°C	(denaturation)
	30 sec	65°–0.7°C/cycle	(annealing)
	60 sec	72°C	(extension)
23 cycles:	30 sec	94°C	(denaturation)
	30 sec	56°C	(annealing)
	60 sec	72°C	(extension).

The initial annealing step is performed at 65°C, decreasing by 0.7°C each cycle.

A stepwise amplification procedure is used to minimize mismatch amplification. A single additional selective nucleotide (one on each primer) is added per selective AFLP amplification. The most useful expression profiles consist of the 256 fingerprints obtained with all combinations of the *TaqI*+2 and *MseI*+2 primers. This implicates a series of 3 consecutive PCRs, the first with no selective nucleotides (nonselective preamplification +0/+0), the second with one selective nucleotide at both the *TaqI* and *MseI* primer (selective preamplification +1/+1), and the third with two selective nucleotides at each primer (final selective amplification +2/+2).

Similar to the nonselective preamplification, it is advisable to check 10 μl of the reaction mixtures on an agarose gel.

Label selective *TaqI* + 2 primers

23. Prepare the following phosphorylation reaction mixture:

- 2.0 μl 10 $\mu\text{Ci}/\mu\text{l}$ (~2000 Ci/mmol) [^{33}P - γ]ATP
- 1.0 μl 10 \times T4 polynucleotide kinase buffer
- 4 U T4 polynucleotide kinase
- Adjust volume to 8 μl with water.

24. To phosphorylate 16 pmol selective *TaqI*+2 primer (the amount required for 20 AFLP reactions; i.e., the amount required to perform all 16 +2/+2 reactions for a given *TaqI*+2 primer in the complete set of 256 primer combinations), combine 2.0 μl of 8 pmol/ μl selective primer (+2) and 8.0 μl phosphorylation reaction mix (step 23), yielding labeled primer at a concentration of 12.6 pmol/ μl and a final volume of 10.0 μl . Incubate 60 min at 37°C, followed by 10 min at 70°C to inactivate the kinase.

^{33}P -labeled primers are preferred because they give a better resolution of the PCR products on polyacrylamide gels. Also, the reaction products are less prone to degradation due to autoradiolysis.

*Only the *TaqI* primers should be labeled. Labeling both the *TaqI* and *MseI* primers causes each of the two strands of the AFLP fragments to be visualized on the gels, often causing "doublets" when these two strands migrate differently on the gel.*

Perform selective AFLP amplification using labeled *TaqI* + 2 and *MseI* + 2 primers

25. Dilute 2 μl of each selective preamplification product (+1/+1; step 22) 500-fold with Tris-Cl, pH 8.0/0.1 M EDTA. Prepare selective amplification (+2/+2) reactions in a microtiter plate for a PE-9600 thermocycler in the following way:

- a. Dispense 2 μl of 1:500 preamplification mixture *TaqI*+A/*MseI*+C in the first two columns of the microtiter plate.
- b. Dispense 0.5 μl labeled *TaqI*+AA primer into each of wells A1 to D1; 0.5 μl labeled *TaqI*+AC primer into each of wells E1 to H1; 0.5 μl labeled *TaqI*+AG primer into each of wells A2 to D2, and 0.5 μl labeled *TaqI*+AT primer into each of wells E2 to H2.
- c. Dispense 0.6 μl unlabeled *MseI*+CA primer into each of wells A1, A2, E1, and E2; 0.6 μl unlabeled *MseI*+CC primer into each of wells B1, B2, F1, and F2; 0.6 μl unlabeled *MseI*+CA primer into each of wells A1, A2, E1, and E2; 0.6 μl unlabeled *MseI*+CG primer into each of wells C1, C2, G1, and G2; and 0.6 μl unlabeled *MseI*+CT primer into each of wells D1, D2, H1, and H2.
- d. Prepare dNTP/polymerase mixture by combining 12.8 μl of 5 mM dNTPs, 32 μl of 10 \times PCR buffer, 6.4 U AmpliTaq-Gold polymerase, and adjusting the volume to 270.4 μl .
- e. Dispense 16.9 μl dNTP/polymerase mixture in the first two columns of the microtiter plate.

An individual reaction can be prepared by combining 2 μ l of 1:500 selective preamplification reaction product, 0.5 μ l of 1.6 pmol/ μ l (5 ng) labeled selective TaqI+2 primer, 0.6 μ l of 8 pmol/ μ l (30 ng) unlabeled selective MseI+2 primer, 0.8 μ l of 5 mM dNTPs, 2.0 μ l of 10 \times PCR buffer, and 0.4 U AmpliTaq-Gold polymerase. The volume is adjusted to 20 μ l with water.

26. Amplify the material using the “touch-down” PCR program specified in step 22.

Generally, a number of AFLP reactions will be performed in parallel and the indicated quantities of the reaction mixes should be adjusted accordingly.

Analyze amplification products by standard PAGE

27. Mix the AFLP reactions with an equal volume (20 μ l) of loading dye. Denature the AFLP reaction products by heating at 90°C for 3 min and then quickly cooling on ice.

CAUTION: Formamide is harmful—perform this step under a fume hood.

28. Treat the back plate of the sequencing gel system with 2 ml repel silane, and the front plate with 10 ml bind silane solution. Prepare 4.5% denaturing polyacrylamide gels (~100 ml).

The authors use the BioRad SequiGen sequencing gel system (38 \times 50 \times 0.04-cm), for which the parameters given in this protocol are optimized; however, other sequencing gel systems should also work well.

29. Using 1 \times TBE as the running buffer, prerun gels 0.5 hr just before loading the samples under appropriate conditions to heat the gel to ~55°C (e.g., 110-W limit for the BioRad system). Use a gel thermometer to monitor temperature.

Maintaining this temperature throughout the electrophoresis is crucial for good quality fingerprints.

30. Load either 3 μ l (for 48-lane gels) or 1.5 μ l (for 96-lane gels) of sample into each well and analyze at ~55°C. Include a molecular weight standard (e.g., SequaMark 10-base ladder) if desired.

31. After electrophoresis, disassemble the gel cassette. Fix the gel, which will stick to the front glass plate because of the silane treatments, by soaking in 10% acetic acid for 30 min. Rinse thoroughly with water and dry 10 to 20 hr at room temperature in a fume hood, or for a shorter time period at an elevated temperature (e.g., using an incubator).

CAUTION: Radioactive materials require special handling. See APPENDIX 1F and the institutional Radiation Safety Office for guidelines concerning proper handling and disposal.

Gel is dry when it is no longer “sticky.”

32. Visualize gel-fractionated cDNA AFLP fragments by autoradiography or using a phosphorimager (APPENDIX 3A).

Exposure times are reduced at least 2.5-fold using phosphorimaging technology.

REAGENTS AND SOLUTIONS

Use Milli-Q purified or double-distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Binding buffer, 2×, 1×

20 mM Tris·Cl, pH 7.5 (APPENDIX 2)

150 mM LiCl

1 mM EDTA (APPENDIX 2)

Store up to 6 months at room temperature

Dilute to 1× with Milli-Q-purified or double-distilled H₂O

Denaturing polyacrylamide gel, 4.5%

Prepare 4.5% (v/v) Sequagel ready-for-use gel mix (19:1 acrylamide/methylene bisacryl; National Diagnostics) in 7.5 M urea (Life Technologies)/0.5× TBE (see recipe) at a total volume of ~100 ml. Add 500 µl of 10% ammonium persulfate (APS), freshly made just before use, and 100 µl of TEMED (*N,N,N',N'*-tetramethylethylenediamine) immediately before casting the gel. Cast the gel according to the instructions of the gel system manufacturer, using either two 24-well (for 48-lane gels) or 48-well (for 96-lane gels) sharktooth combs to create the gel slots.

These gels are essentially normal sequencing gels (Vos and Kuiper, 1998; UNIT 7.6), with the exception that a lower percentage of polyacrylamide is used. Ready made solutions should also work well.

First-strand buffer, 5×

250 mM Tris·Cl pH 8.3 (APPENDIX 2)

15 mM MgCl₂

375 mM KCl

Store up to 6 months at -20°C

Oligonucleotides and double-stranded adapters

Adapters:

TaqI adapter top strand: 5'-CTCGTAGACTGCGTACA-3'

TaqI adapter bottom strand: 3'-CATCTGACGCATGTGC-5'

MseI adapter top strand: 5'-GACGATGAGTCCTGAG-3'

MseI adapter bottom strand: 3'-GCTACTCAGGACTCAT-5'

Nonselective primers (AFLP + 0):

TaqI + 0 primer: 5'-CTCGTAGACTGCGTACACGA-3'

MseI + 0 primer: 5'-GACGATGAGTCCTGAGTAA-3'

Selective primers (AFLP +1 and +2):

TaqI + 1 primer: 5'-GTAGACTGCGTACACGAN-3'

TaqI + 2 primer: 5'-GTAGACTGCGTACACGANN-3'

MseI + 1 primer: 5'-GATGAGTCCTGAGTAAN-3'

MseI + 2 primer: 5'-GATGAGTCCTGAGTAANN-3'

N is any nucleotide; therefore, there are a total of 1 "+ 0," 4 "+ 1," and 16 "+ 2" primers for each restriction endonuclease.

Loading dye

98% formamide, deionized and filtered (Merck)

10 mM EDTA, pH 8.0 (APPENDIX 2)

5 mM spermidine·3HCl (Sigma)

Trace amounts (i.e., ~0.5 mg/ml) of bromphenol blue and xylene cyanol

Store in small (500 µl) aliquots up to 6 months at -20°C.

PCR buffer, 10×

100 mM Tris·Cl, pH 8.3 (APPENDIX 2)
15 mM MgCl₂
500 mM KCl
Store up to 6 months at room temperature

RL buffer, 5×

50 mM Tris acetate, pH 7.5
50 mM magnesium acetate
250 mM potassium acetate
25 mM DTT
Store in small aliquots (up to 500 μl) and store up to 6 months at -20°C

Second-strand buffer, 5×

100 mM Tris·Cl, pH 7.0 (APPENDIX 2)
20 mM MgCl₂
450 mM KCl
750 μM NAD⁺
50 mM (NH₄)₂SO₄
Store in small aliquots up to 6 months at -20°C

STEX, 2×, 1×

20 mM Tris·Cl, pH 8.0 (APPENDIX 2)
2000 mM NaCl (APPENDIX 2)
2 mM EDTA (APPENDIX 2)
0.2 % (v/v) Triton X-100
Store up to 6 months at room temperature
Dilute to 1× with Milli-Q-purified or double-distilled H₂O

T4 polynucleotide kinase buffer, 10×

250 mM Tris·Cl, pH 7.5 (APPENDIX 2)
100 mM MgCl₂
50 mM DTT
Make small aliquots and store up to 6 months at -20°C

TBE, 1×

Prepare a 10× stock:
1 M Tris base
1 M boric acid
20 mM EDTA, pH 8.3
Store up to 6 months at room temperature
Dilute to 1× with water

Wash buffer

10 mM Tris·Cl, pH 7.5 (APPENDIX 2)
150 mM LiCl
1 mM EDTA
Store up to 6 months at room temperature

COMMENTARY

Background Information

At present, a variety of technologies are available for high-throughput analysis of mRNA populations in cells, tissues, and organs. These can be divided into three major classes: (1) methods based on hybridization of labeled cDNA to transcript sequences on microarrays (Skena et al., 1995; De Risi et al., 1997), (2) methods based on high-throughput sequencing of small identifier (“signature”) sequences corresponding to specific transcripts (UNIT 25B.6; Velculescu et al., 1995; Brenner et al., 2000), and (3) methods based on display of cDNA fragment patterns on high-resolution gels such as AFLP (UNITS 25B.3 & 25B.4; Liang and Pardee, 1992; the current unit).

Hybridization to microarrays of known transcript sequences is an attractive method for high-throughput transcript analysis (Skena et al., 1995; De Risi et al., 1997). The amount of data that can be obtained with this technology cannot be matched easily by any other presently known transcript analysis method. The fast growing number of gene and whole genome sequences creates a valuable resource for probe design for microarrays. One of the most attractive applications of the technology to date is the comparative analysis of gene expression between two samples for which the cDNA is differentially labeled (Welsh et al., 2001). Cross hybridization may pose a problem using microarrays, primarily because gene families are quite predominant in higher organisms; however, the use of multiple oligonucleotide probes of individual genes alleviates this problem, enabling the design of highly discriminative oligonucleotide sets (Wodicka et al., 1997).

A second category of transcript analysis technologies is represented by the SAGE technology (Serial Analysis of Gene Expression) first described by Velculescu et al. (1995; UNIT 25B.6) and the Massive Parallel Signature Sequencing (MPSS) technology first described by Brenner et al. (2000). These technologies generate small identifier or signature sequences specific for each transcript in a particular cell or tissue type, and are very well suited for transcript discovery in known genomic sequences. Gene prediction from genomic sequences is still far from perfect today, and the whole genome sequences of complex organisms suggest that the transcript repertoire may be quite complicated. The MPSS technology is commercialized by Lynx Therapeutics. SAGE

technology is described elsewhere in this book (UNIT 25B.6).

Differential display (DD) technology as first described by Liang and Pardee (1992; UNIT 25B.3) uses one random primer and an anchored oligo-d(T) primer for amplification of cDNA fragments, which are displayed on denaturing polyacrylamide gels (i.e., sequencing gels). The major difference between DD and the AFLP cDNA technology described in this unit is that AFLP cDNA profiling allows a systematic display of cDNA fragments, with each primer combination displaying a different subset of the cDNAs (Durrant et al., 2000; Van der Biezen et al., 2000; Breyne and Zabeau, 2001; Din et al., 2001; Qin et al., 2001). This, and the smaller fragments generated by AFLP, generally yield sharper and more discrete banding patterns. Another alternative to DD is restriction enzyme analysis of differentially expressed sequences. This technology makes use of restriction enzyme cleavage sites in the cDNA and yields sharp, discrete bands like AFLP (UNIT 25B.4; Fischer et al., 1995; Prashar and Weismann, 1996).

The AFLP technique allows the selective amplification of subsets of genomic restriction fragments or cDNAs, which can subsequently be displayed on DNA sequencing gels. One of the characteristics of the AFLP technique is that the reaction proceeds until the primer is depleted from the reaction mixture (Vos et al., 1995). This is different from a standard PCR, where the amplification process is inhibited in the final stage of the reaction due to competition between fragment-to-fragment, reannealing, and primer-to-template annealing. This difference is probably caused by the fact that the concentration of individual AFLP fragments is much lower compared to standard PCR due to many fragments competing for the same primer set. This characteristic of the AFLP technique is of great importance for the quantitative amplification and display of transcript fragments.

Another important characteristic of the AFLP technique is the preferential amplification of *TaqI-MseI* fragments compared to the *TaqI-TaqI* fragments and *MseI-MseI* fragments that will also result from template preparation. It is the authors' belief that the *TaqI-TaqI* fragments and *MseI-MseI* fragments amplify less efficiently because they contain inverted repeats at the fragment ends after adapter ligation. As a result, intramolecular self ligation of *TaqI-TaqI* fragments and *MseI-MseI* fragments will

Figure 25B.5.3 Schematic of primer design.

compete with primer annealing during AFLP amplification. This hypothesis is supported by the observation that amplification of *MseI*-*MseI* fragments is efficient when two different *MseI* adapters are used for template preparation and two corresponding *MseI* primers are used for amplification (P. Vos, unpub. observ.).

In the protocol outlined in this chapter, double-stranded cDNA is restriction digested with *TaqI* and *MseI*, and adapters for these two restriction endonucleases are ligated to the resulting restriction fragments. Adapters create a target site for the AFLP primers in the subsequent amplification reactions. The adapter ligation is performed in a way that the original *TaqI* and *MseI* sites are not restored. After adapter ligation the *TaqI*-*MseI* restriction fragments have from 5' to 3' a universal sequence at the *TaqI* end (*TaqI* adapter + remnant of *TaqI* site), the original sequence between the *TaqI* and *MseI* recognition sequence, and a second (different from *TaqI*) universal sequence at the *MseI* end (*MseI* adapter + remnant of *MseI* site; Figure 25B.5.3). The primer design matches the newly created fragment ends. The use of the restriction endonuclease combination *TaqI*-*MseI* and primers containing four selective nucleotides (two selective bases for *TaqI* and two selective bases for *MseI*) divides the mixture of transcript fragments into 256 different fragment subsets. Each fragment subset will be amplified by a specific combination of *TaqI* and *MseI* primers (i.e., a primer combination), and will display a small amount (i.e., ~1/256) of the transcript fragments in a specific sample. From various experiments it is known that an AFLP fragment will be detected if at least 1/1000 part of the AFLP primer is incorporated in the AFLP

fragment (P. Vos unpub. observ.; P. Stanssens unpub. observ.); therefore, the detection sensitivity of the protocol described in this unit will generally be quite high. However, it should be noted that the detection sensitivity may vary from one primer combination to another as a result of the specific subset of transcript fragments that will be amplified within each primer combination.

In conclusion, the use of cDNA AFLP is an attractive technology for gene expression analysis and transcript discovery, particularly in organisms for which little or no sequence information is available. The technology is complementary to microarray based transcript imaging techniques that rely on prior characterization of the gene sequences.

Critical Parameters and Troubleshooting

AFLP analysis of genomic DNA is a very robust technology that has been used by numerous laboratories around the world for the past five years. Very few technical problems are generally encountered (Vos et al., 1995; Vos and Kuiper, 1998); however, the quality of the poly(A)⁺ RNA and resulting ds cDNA is critical to its success. The authors advise that the protocols for poly(A)⁺ RNA isolation from total RNA and the synthesis of ds cDNA be strictly followed.

Despite the robustness of AFLP, there are several theoretical and technical reasons why specific transcripts might not be displayed. These include (1) low transcript abundance, (2) the absence of relevant restriction enzyme sites in the transcript, and (3) features of the transcript that prevent efficient reverse transcrip-

Figure 25B.5.4 cDNA fingerprint of *Aspergillus niger* that displays a very typical result for AFLP technology. Samples A1 to A3 represent three different samples which have been taken independently through the procedure of RNA isolation, cDNA synthesis, template preparation, and cDNA-AFLP reactions (notice the reproducibility). The same is true of samples B1 to B3; however, these samples were induced differently than the “A” sample sets and therefore a number of differentially expressed cDNAs are detected between the two samples. Fingerprints on the right represent +2/+2 fingerprints, and on the left corresponding +1/+2 fingerprints. The figure clearly shows that the cDNA fragments in the +2/+2 fingerprints are a subset of the cDNA fragments in the +1/+2 fingerprint.

tion (e.g., secondary structure). In the authors’ experience the major cause for this is deviation from the protocol as outlined above. Annotations to the steps highlight important considerations.

The quality of the sequence gels can simply be verified by adding a “sequence ladder” to the gel. Gels that work well for sequencing will be good for AFLP profiling as well.

Anticipated Results

All experiments carried out according to the protocol outlined above will give satisfactory

results. Typical transcript profiles show 50 to 100 cDNA AFLP fragments per lane (i.e., sample). The profiles should change completely when a different primer combination is used, with virtually none of the fragments being the same. Transcript profiles from the same individual will vary according to the tissue that is inspected and the conditions that are used (e.g., developmental stages, environmental factors, pathogenic infections). Figure 25B.5.4 displays an example of a typical experiment with the transcript profiles of various organisms.

Table 25B.5.1 Typical AFLP Experiment Time Course

Day 1	Poly(A) ⁺ RNA isolation and synthesis of ds cDNA
Day 2	AFLP cDNA template preparation and nonselective preamplification reactions
Day 3	Selective amplification, gel electrophoresis and overnight exposure of the gels to X-ray films or phosphoimaging screens
Day 4	Analysis of results

Time Considerations

Starting from total RNA, the following time considerations are expected for up to 96 samples:

1. Isolating poly(A)⁺ RNA: 1 to 2 hr depending on the number of samples.
2. Synthesizing ds cDNA from the poly(A)⁺ RNA: 5 to 6 hr.
3. Preparing the AFLP cDNA templates from the ds cDNA: 5 to 6 hr.
4. Nonselective preamplification: 3 to 4 hr (up to 96 samples).
5. Selective amplification: 3 to 4 hr (up to 96 samples).
6. Gel electrophoresis (up to 4 × 96 samples), 6 to 8 hr.

The procedure may be interrupted after each of above steps. A typical experiment time course starting from poly(A)⁺ RNA is given in Table 25B.5.1.

Serial Analysis of Gene Expression (SAGE)

UNIT 25B.6

This unit provides a protocol for performing serial analysis of gene expression (SAGE). SAGE involves the generation of short fragments of DNA, or tags, from a defined point in the sequence of all cDNAs in the sample analyzed. This short tag, because of its presence in a defined point in the sequence, is typically sufficient to uniquely identify every transcript in the sample. SAGE allows one to generate a comprehensive profile of gene expression in any sample desired from as few as 100,000 cells or as little as 1 µg total RNA. SAGE also allows an investigator to readily and reliably compare data to those produced by other laboratories, making the SAGE data set increasingly useful as more data are generated and shared.

Serial analysis of gene expression (SAGE), as described in the main method (see Basic Protocol 1), involves the generation of an oligonucleotide library, with each 14-bp SAGE tag representative of a discrete cDNA. Sometimes, the gene that the SAGE tag represents cannot be readily identified. Thus, a second method (see Basic Protocol 2) describes reverse cloning the 3' end of the cognate cDNA for an unknown SAGE tag. Three additional protocols for verifying cDNA by PCR (see Support Protocol 1), optimizing ditag PCR (see Support Protocol 2), and annealing linkers (see Support Protocol 3), are also given.

MicroSAGE

SAGE library construction involves anchoring mRNA molecules via their poly(A) tails to magnetic beads. (MicroSAGE, which is described here, differs from conventional SAGE in that this anchoring at the 3' end takes place prior to cDNA synthesis rather than after cDNA synthesis.) cDNA synthesis is then conducted, and the cDNAs are cleaved with *Nla*III to completion. This results in the loss of all cDNA sequence 5' to the cleavage site, and ensures that only the 3'-most *Nla*III site is exposed at the 3' end of the cDNA. The cDNA sample is then divided into two equal pools and two sets of linkers (which contain a *Bsm*FI site, PCR primer sites, and modified 3' bases to prevent ligation to each other) are then added by ligation. *Bsm*FI is a type IIS restriction enzyme, with a cut site 15 bp 3' of the recognition site. The resulting cDNAs are then digested with *Bsm*FI, which results in the release of the linker, the *Nla*III site, and 10 to 11 bp 3' of the *Nla*III site. The resulting "tags" are then blunt-ended with the Klenow fragment of DNA polymerase I, and the two separate pools of tags are ligated together via blunt-end ligation to form "ditags." These are then amplified via the PCR primer sites incorporated into the linkers and then recleaved with *Nla*III. These cleaved ditags are purified and ligated together to form concatemers of tags, which are then subcloned into plasmid vectors to create a SAGE library. Individual clones are then sequenced, and analyzed via SAGE analysis software. SAGE software identifies and discards any sets of duplicate ditags (i.e., a given combination of any two individual tags) to control for PCR amplification bias. It can also be used to prepare a tag report, listing all tags and their abundance in a given library, or a tag comparison file, listing the tag abundances in a number of different libraries.

An overview of the microSAGE protocol is shown in Figure 25B.6.1.

Materials

Dynabeads mRNA DIRECT kit (Dynal Biotech):

Dynabeads oligo (dT)₂₅

Lysis/binding buffer

Washing buffer A: add 1 µl 20 mg/ml molecular-biology-grade glycogen (Roche Diagnostics) per milliliter

Washing buffer B

Cells or tissue of interest

SuperScript Choice System cDNA synthesis kit (Life Technologies):

5× first-strand buffer

DEPC-treated double-distilled water (DEPC ddH₂O)

1× first-strand buffer: dilute from 5× stock in DEPC ddH₂O

0.1 M DTT

10 mM dNTP

200 U/µl SuperScript II reverse transcriptase

5× second-strand buffer

10 U/µl *E. coli* DNA ligase

10 U/µl *E. coli* DNA polymerase I

2 U/µl *E. coli* RNase H

1× and 5× T4 DNA ligase buffer

1 U/µl T4 DNA ligase (UNIT 3.14)

0.5 M EDTA, pH 8.0 (APPENDIX 2)

1× BW buffer (see recipe)/2× BSA (New England Biolabs)/0.1% (w/v) SDS

1× BW buffer/2× BSA

1× NEBuffer 4 (New England Biolabs)/2× BSA

LoTE buffer (see recipe)

100× BSA (New England Biolabs)

10 U/µl NlaIII and 10× NEBuffer 4 (New England Biolabs; UNIT 3.1): store at -80°C

1× BW buffer/2× BSA/1% (v/v) Tween 20

Annealed linkers (see Support Protocol 3):
 5 U/μl (high-concentration) T4 DNA ligase (Life Technologies; *UNIT 3.14*)
 2 U/μl *BsmFI* (New England Biolabs; *UNIT 3.1*)
 PC8 (see recipe)
 SeeDNA (Amersham Pharmacia Biotech)
 3:1 solution of 20 mg/ml glycogen/SeeDNA (optional)
 3 M sodium acetate (*APPENDIX 2*)
 70% and 100% ethanol
 Klenow fragment of DNA polymerase I and 10× buffer (Amersham Pharmacia Biotech; *UNIT 3.5*) or Roche Buffer H
 3 mM Tris·Cl, pH 7.5 (*APPENDIX 2*)
 10× SAGE PCR amplification buffer (see recipe)
 DMSO (Sigma)
 PCR primers (see recipe):
 350 ng/μl primers 1 and 2
 350 ng/μl M13 forward and reverse primers
 5 U/μl Platinum *Taq* DNA polymerase (Life Technologies; *UNIT 3.5*)
 20 mg/ml glycogen (Roche Diagnostics)
 7.5 M ammonium acetate (Sigma)
 Dry ice/methanol bath
 5× loading buffer (*UNIT 2.7*)
 20% (w/v) polyacrylamide/TBE minigels (Novex)
 20-bp DNA ladder (GenSura)
 10,000× SYBR Green I (Roche Diagnostics)
 1× TBE (*APPENDIX 2*)
 1-kb DNA ladder
 pZErO-1 plasmid (Invitrogen)
SphI and NEBuffer 2 (New England Biolabs; *UNIT 3.1*)
 TE buffer, pH 8.0 (*APPENDIX 2*)
 SOC medium (*UNIT 1.8*)
 0.01 ng/μl pUC19 control DNA
 DH10B Electromax competent cells, −70°C (Life Technologies)
 LB medium (*UNIT 1.1*; optional)
 LB plates with 100 μg/ml ampicillin (*UNIT 1.1*)
 10-cm zeocin-containing low-salt LB plate (see recipe)
 10:1 U/μl *Taq/Pfu* polymerase (Stratagene)
 Exonuclease I (USB)
 Shrimp alkaline phosphatase (USB)
 50 mM Tris·Cl, pH 8.0 (*APPENDIX 2*)
 0.5-, 1.5-, 2.0-ml RNase-free No-stick siliconized microcentrifuge tubes (Ambion)
 Magnetic rack for 1.5-ml microcentrifuge tubes (DynaL Biotech)
 Tissue homogenizer (e.g., Polytron PT1200, Brinkmann Instruments)
 23-G needles and 1-ml syringes
 200-μl aerosol-barrier pipet tips
 16° and 65°C water baths, heat blocks, or equivalent
 96-well PCR plates
 50-ml conical tubes
 Tabletop centrifuge with swinging-bucket rotor
 Gel-loading tips
 UV box and SYBR green or UV filter
 0.5-ml microcentrifuge tubes with ~0.5-mm holes in the bottom: pierce from the inside out with a 21-G needle

Spin-X centrifuge-tube filters (Costar)
Long wavelength UV source
0.1-mm disposable micro-electroporation cuvettes (BioRad)
Bio-Rad gene pulser electroporator or equivalent
15-ml culture tubes

Additional reagents and equipment for determining integrity of cDNA by PCR (see Support Protocol 1), optimizing ditag PCR conditions (see Support Protocol 2), agarose gel electrophoresis (UNIT 2.5A), ethanol precipitation (UNIT 2.1A), and direct sequencing of PCR products (UNIT 15.2)

NOTE: Prepare Dynabeads, washing solutions, and 5× first-strand mix before thawing and collecting cells.

Prepare mRNA and synthesize cDNA

1. Thoroughly resuspend Dynabeads oligo (dT)₂₅, transfer 100 µl to a 1.5-ml RNase-free siliconized No-stick microcentrifuge tube, and place on a magnetic rack. After ~30 sec remove supernatant.

This volume of beads is much more than needed, but permits easy handling.

When removing the supernatant, always place the pipet tip at the opposite side of the tube, push the pipet tip to the bottom, and pipet very slowly, so as not to disturb the beads.

2. Resuspend beads in 500 µl lysis/binding buffer by “flicking” the tube or by gently vortexing. Leave beads in buffer until ready to add them to the cell lysate (step 4).

In this and all subsequent washing steps, add solution to the tube while keeping it on the magnetic rack in order to minimize “drying out” of the beads. Next, close the cap, remove the tube from the magnet, and resuspend the beads. Place back on the magnetic rack for ~30 sec to collect beads at the bottom before removing wash.

3. Lyse 100,000 to 1,000,000 cells (or 2 to 10 mg tissue) in 1 ml lysis/binding buffer in a 2-ml microcentrifuge tube with a tissue homogenizer for 1 min.

Before using the homogenizer, clean it thoroughly, rinse with 100% ethanol, and pulse in 1 liter DEPC ddH₂O.

If necessary, remove any cellular debris that remains following homogenization by microcentrifuging 1 min at maximum speed.

4. Immediately shear genomic DNA by pressing lysed cells through a 23-G needle attached to a 1-ml syringe into the tube containing prewashed Dynabeads (step 2), from which the buffer has been removed. Incubate 3 to 5 min at room temperature with constant agitation by hand.

Alternatively, total RNA previously isolated and stored at –80°C may be used. Total RNA (1 to 10 µg in 500 µl of lysis/binding buffer) may be added and incubated 3 to 5 min, room temperature, with constant agitation by hand. It is best to run some of the RNA on a denaturing gel to check for degradation. Visualization of sharp 28S and 18S ribosomal bands should be seen.

5. Place the tube on a magnetic rack for 2 min, then remove the supernatant.

This supernatant can be used for a genomic DNA prep if desired.

6. Wash beads by pipetting up and down several times with a 200-µl aerosol-barrier pipet tip in the following sequence:

Twice with 1 ml washing buffer A
Once with 1 ml washing buffer B
Four times with 1× first-strand buffer.

Pipetting the beads is more efficient than flicking the tubes.

7. Resuspend beads in the following first-strand synthesis mix:

54 μ l DEPC ddH₂O
18 μ l 5 \times first-strand buffer
9 μ l 0.1 M DTT
4.5 μ l 10 mM dNTP.

Heat tube 2 min at 37°C, then add 3 μ l of 200 U/ μ l SuperScript II reverse transcriptase. Incubate 1 hr at 37°C, mixing beads every 10 min by hand. Terminate reaction by placing tube on ice.

8. Add the following components of the second-strand synthesis to the first-strand reaction in the order shown on ice:

227 μ l ddH₂O, prechilled
150 μ l 5 \times second-strand buffer
15 μ l 10 mM dNTP
3 μ l 10 U/ μ l *E. coli* DNA ligase
12 μ l 10 U/ μ l *E. coli* DNA polymerase I
3 μ l 2 U/ μ l *E. coli* RNase H.

Incubate 2 hr at 16°C, mixing beads every 10 min by hand.

9. After incubation, place tubes on ice and terminate reaction by adding 100 μ l of 0.5 M EDTA, pH 8.0.

10. Wash beads one time with 0.5 ml of 1 \times BW buffer/2 \times BSA/0.1% (w/v) SDS.

The BSA appears to reduce the stickiness of the beads and improves the efficiency of the washes and the quality of the library. Extra washes with SDS can cause beads to clump severely.

11. Wash beads three times, each in 500 μ l of 1 \times BW buffer/2 \times BSA. Resuspend beads in 500 μ l of 1 \times BW buffer/2 \times BSA and heat 20 min at 75°C.

This heating step is crucial as it inactivates the nuclease activity of Poll.

12. Wash three times in 500 μ l of 1 \times BW buffer/2 \times BSA. Wash twice with 200 μ l of 1 \times NEBuffer 4/2 \times BSA, transferring to new tubes after the first wash in NEBuffer 4/BSA and saving 5 μ l of the last bead suspension.

13. Check the integrity of cDNA by PCR with primers for genes known to be in the cDNA being used for library construction using the saved 5- μ l aliquot (see Support Protocol 1).

Cleave cDNA with anchoring enzyme (NlaIII) and ligate linkers to cDNA

14. Resuspend beads in following mix:

171 μ l LoTE buffer
4 μ l 100 \times BSA
20 μ l 10 \times NEBuffer 4
5 μ l 10 U/ μ l *NlaIII*.

Incubate 1 hr at 37°C.

15. After incubation, place on a magnetic rack ~30 sec, then wash beads with the following solutions by pipetting up and down several times with a 200- μ l aerosol-barrier pipet tip:

Twice with 500 μ l 1 \times BW/2 \times BSA/1% Tween 20
Four times with 500 μ l 1 \times BW/2 \times BSA
Twice with 1 \times T4 DNA ligase buffer.

After final resuspension in ligase buffer, transfer 100 μ l of each sample into two new 1.5-ml siliconized microcentrifuge tubes.

16. Remove last wash and resuspend beads with the following:

- 5 μ l LoTE buffer (both tubes)
- 2 μ l 5 \times T4 DNA ligase buffer (both tubes)
- 3 μ l 2 ng/ μ l annealed linkers 1A and 1B (only in tube 1)
- 3 μ l 2 ng/ μ l annealed linkers 2A and 2B (only in tube 2).

17. Heat tubes 2 min at 50°C then let sit for 5 to 15 min at room temperature. Add 1 μ l of 5 U/ μ l (high-concentration) T4 DNA ligase to each tube and incubate 2 hr at 16°C. Mix beads intermittently.

Release cDNA-tags using tagging enzyme BsmFI

18. After ligation, place on a magnetic rack ~30 sec, then wash each sample two times with 500 μ l of 1 \times BW/2 \times BSA/0.1% SDS each, pooling tube 1 and tube 2 together after first wash in order to minimize loss in subsequent steps.

19. Wash four times with 500 μ l of 1 \times BW/2 \times BSA each and twice with 200 μ l of 1 \times NEBuffer 4/2 \times BSA (transfer to new tubes after first wash in NEBuffer 4/BSA).

20. Preheat the following mix 2 min at 65°C:

- 170 μ l LoTE buffer
- 20 μ l 10 \times NEBuffer 4
- 4 μ l 100 \times BSA
- 2 μ l 2 U/ μ l *BsmFI*.

Resuspend beads in the mixture and incubate 1 hr at 65°C, mixing intermittently.

21. After incubation, microcentrifuge 2 min at maximum speed, then transfer supernatant to a new 1.5-ml microcentrifuge tube. Wash beads once with 40 μ l LoTE buffer, then resuspend to a final volume of 240 μ l with LoTE buffer.

IMPORTANT NOTE: From this point on, do not use siliconized tubes.

22. Extract with 240 μ l PC8 and ethanol precipitate with SeeDNA using the following procedure:

- a. Add 4 μ l SeeDNA. Alternatively, use 4 μ l of a 3:1 solution of 20 mg/ml glycogen/SeeDNA mix.
- b. Add 0.1 vol of 3 M sodium acetate (24 μ l) and mix briefly.
- c. Add 2 vol of 100% ethanol (480 μ l) and vortex briefly.
- d. Incubate 2 min at room temperature.
- e. Microcentrifuge 5 min at maximum speed.
- f. Wash two times with 70% ethanol and microcentrifuge again after last wash. Carefully remove residual liquid with a pipet tip and resuspend pellet in 10 μ l LoTE buffer.

SeeDNA is a brightly colored carrier molecule that allows easy visualization and maximal recovery of alcohol-precipitated DNA or RNA. The glycogen/SeeDNA mixture may be used to reduce cost.

One may pause the protocol here and store the pellet overnight at -20°C.

Perform blunt-end digestion on released tags

23. Add the following mix to tags:

- 30.5 μl ddH₂O
- 5 μl 10 \times Klenow buffer (or Roche Buffer H)
- 2.5 μl 10 mM dNTPs
- 1 μl 100 \times BSA
- 1 μl Klenow fragment of DNA polymerase I.

Incubate 30 min at 37°C then add 190 μl LoTE buffer (240 μl final volume).

24. Extract with an equal volume of PC8 (240 μl). Transfer 200 μl into a ligase “+” tube and the remaining 40 μl into a ligase “-” tube.
25. Ethanol precipitate with 2 μl SeeDNA, 0.1 vol of 3 M sodium acetate, and 2 vol of 100% ethanol. Wash two times with 70% ethanol and centrifuge again after last wash. Carefully remove residual liquid with a pipet tip and air-dry 5 to 10 min. Resuspend pellet in 2 μl LoTE buffer.

Do not overdry because DNA will be lost.

Ligate tags to form ditags

26. Prepare 2 \times ligase “+” mix as follows:

- 2.5 μl 3 mM Tris·Cl, pH 7.5
- 3.0 μl 5 \times T4 DNA ligase buffer
- 2.0 μl 5 U/ μl (high-concentration) T4 DNA ligase.

Prepare a 2 \times ligase “-” mix with 4.5 μl of 3 mM Tris·Cl, pH 7.5 and 3.0 μl of 5 \times T4 DNA ligase buffer. Add 2 μl of appropriate mix to +/- ligase samples and incubate in a thermal cycler overnight (8 to 12 hr) at 16°C.

The sample may dry out in a water bath (in 4°C cold room), thus incubation in a PCR machine/thermal cycler is preferable.

27. After ligation, add 98 μl LoTE buffer, optimize PCR conditions (see Support Protocol 2), and proceed to large-scale PCR amplification.

Samples may be stored >1 year at -20°C.

Perform large-scale PCR amplification of ditags

28. Prepare a reaction mastermix for large-scale PCR (two to three 96-well PCR plates containing 50 μl reaction per well) using the following recipe for one reaction as a guide:

- 5 μl 10 \times SAGE PCR amplification buffer
- 3 μl DMSO
- 4.0 to 10 μl 10 mM dNTPs
- 1 μl 350 ng/ μl PCR primer 1
- 1 μl 350 ng/ μl PCR primer 2
- Adjust volume to 49 μl with ddH₂O
- 0.7 μl 5 U/ μl Platinum *Taq* DNA polymerase.

Aliquot 49 μl of reaction mix to each well, then add 1 μl template at appropriate dilution (see Support Protocol 2).

The authors usually use a 300-reaction PCR premix that is dispensed into 96-well plates at 50- μl per well.

The volume of dNTPs to use is determined through optimization (see Support Protocol 2).

Platinum Taq DNA polymerase is used because it allows for a room-temperature hot start reaction (the Taq DNA polymerase is complexed with an anti-Taq antibody that denatures when heated to 94°C).

29. Carry out the amplifications in a thermal cycler with the following parameters:

1 cycle:	2 min	94°C	(denaturation)
26 to 32 cycles:	30 sec	94°C	(denaturation)
	1 min	55°C	(annealing)
	1 min	70°C	(extension)
1 cycle:	5 min	70°C	(final product extension).

The number of cycles to use is determined through optimization (see Support Protocol 2).

If a thermal cycler with heated lid is not available, oil can be used to prevent evaporation (see UNIT 15.1).

The ligase “–” sample should be amplified for 35 cycles.

Do not substitute conventional hot-start PCR for use of Platinum Taq DNA polymerase. The authors have found that yields are much lower if this is done. There is no need to refrigerate the PCR mix while setting up the reactions.

Isolate ditags

30. Pool PCR reactions into a 50-ml conical tube, adjusting volume to 11.5 ml with LoTE buffer, then extract with an equal volume of PC8.

31. Precipitate with ethanol as follows:

11.5 ml samples
10 µl SeeDNA
100 µl 20 mg/ml glycogen
5.1 ml 7.5 M ammonium acetate
38.3 ml 100% ethanol.

Place in a dry ice/methanol bath for 15 min. Thaw 2 min at room temperature to fully melt the solution.

32. Vortex briefly and centrifuge 30 min in a tabletop centrifuge with swinging-bucket rotor at $\sim 3000 \times g$ (4000 rpm), room temperature.

33. Wash with 5 ml of 70% ethanol, vortex, and centrifuge an additional 5 min at $\sim 3000 \times g$, room temperature.

34. Resuspend pellet in 216 µl LoTE buffer and add 54 µl of 5× loading buffer (270 µl total).

35. Using gel-loading pipet tips, load 10 µl sample into each of 27 lanes on each of three prepoored 20% polyacrylamide/TBE minigels. Include 10 µl of a 20-bp ladder on each gel as a marker.

It is critical not to overload the gel wells, as this can lead to linker contamination and poor separation of products.

36. Electrophorese 90 min at 160 V.

The optimal distance for electrophoresis is ~ 1 cm above the bottom of the gel. The idea is to obtain maximum separation of the 102- (ditags) and 80-bp bands (linker-linker dimers) without allowing product to get too close to the edge of the gel. Depending on the apparatus and batch of TBE buffer, varying the electrophoresis time might be necessary.

37. Stain 15 min in a foil-wrapped container on a platform shaker using 2 to 5 μl of 10,000 \times SYBR Green I in 50 ml of 1 \times TBE buffer. Visualize on a UV box using a SYBR green or UV filter.

Alternatively, use long-wavelength UV. Amplified ditags should run at 102 bp while a background band (linker-linker dimers) runs at \sim 80 bp.

38. Cut out only amplified ditags from the gel, and place three cut-out bands in 0.5-ml microcentrifuge tubes (nine tubes total) which have an \sim 0.5-mm diameter hole in the bottom.

39. Place the 0.5-ml microcentrifuge tubes in 2.0-ml siliconized microcentrifuge tubes and microcentrifuge 4 min at maximum speed.

This serves to break up the acrylamide gel into small fragments at the bottom of the 2.0-ml microcentrifuge tube.

40. Discard 0.5-ml microcentrifuge tubes. Add 250 μl LoTE buffer and 50 μl of 7.5 M ammonium acetate to each 2.0-ml microcentrifuge tube.

At this point, the 2.0-ml microcentrifuge tubes can remain overnight at 4°C.

41. Vortex each tube, and incubate 15 min at 65°C. Add 5 μl LoTE buffer to the membrane of each of 18 Spin-X centrifuge-tube filters.

42. Transfer contents of each tube to two Spin-X centrifuge tube filters (i.e., nine tubes transferred to 18 Spin-X centrifuge tube filters). Microcentrifuge each SpinX filter for 5 min at maximum speed. Consolidate sets of two eluates (300 μl total) and transfer to 1.5-ml microcentrifuge tubes.

Sometimes, purified 102-bp bands do not recut well with NlaIII, which seems to be related to imperfect purification from the gel. If this is a problem, run 300 μl eluate through a Qiaquick gel extraction protocol (Qiagen). Bring the volume of the extract back up to 300 μl to proceed.

43. Ethanol precipitate eluates by adding the following:

300 μl sample
0.5 μl SeeDNA
1.5 μl glycogen
133 μl 7.5 M ammonium acetate
1000 μl 100% ethanol.

Vortex and place in a dry ice/methanol bath for 15 min. Warm 2 min at room temperature until solution has melted, then microcentrifuge 15 min at 4°C.

44. Microcentrifuge 15 min at maximum speed. Wash two times with 75% ethanol. Resuspend each DNA tube in 10 μl LoTE buffer. Pool samples into one microcentrifuge tube (90 μl total).

The total amount of DNA at this stage should be 10 to 20 μg .

45. Digest PCR products with NlaIII by adding the following:

90 μl PCR products in LoTE buffer
226 μl LoTE buffer
40 μl 10 \times NEBuffer 4
4 μl 100 \times BSA
40 μl 10 U/ μl NlaIII.

Incubate 1 hr at 37°C.

Purify the ditags

46. Extract with an equal volume of PC8. Pool aqueous phases and transfer into 1.5-ml microcentrifuge tubes. Ethanol precipitate in dry ice as follows:

200 μ l sample
66 μ l 7.5 M ammonium acetate
3 μ l SeeDNA
825 μ l 100% ethanol.

Vortex and place in dry ice/methanol bath for 15 min.

47. Warm 2 min at room temperature until solution has melted, then microcentrifuge 15 min at 4°C.
48. Wash once with cold 75% ethanol, removing ethanol traces with a gel-loading pipet tip. Resuspend pellet in 40 μ l LoTE buffer. On ice, add 10 μ l of 5 \times loading buffer (50 μ l total).
49. Load this sample into four lanes of a 20% polyacrylamide/TBE gel, load the 20-bp ladder into a separate lane, and run ~2.5 hr at 160 V. Stain as described in step 37.

Optimal electrophoresis time may vary somewhat. Be careful not to run the gel too long.

50. Cut out the 24- to 26-bp band from four lanes under long-wavelength UV illumination, and place two cut-out bands in each of two 0.5-ml microcentrifuge tubes which have an ~0.5-mm diameter hole in the bottom.
51. Microcentrifuge as described in step 39.
52. Discard the 0.5-ml microcentrifuge tubes. Add 250 μ l LoTE buffer and 50 μ l of 7.5 M ammonium acetate to each of the 2.0-ml microcentrifuge tubes. Vortex the tubes, and incubate 1 hr at 37°C.

IMPORTANT NOTE: Do not incubate at 65°C. This will cause the 26-bp ditags to denature. Longer incubations (even overnight) can be performed, but do not appear to result in significantly higher yields.

53. Use four Spin-X centrifuge-tube filters to isolate eluate as described in step 42. Ethanol precipitate in three tubes (200 μ l each) with the following:

200 μ l sample
66 μ l 7.5 M ammonium acetate
2 μ l SeeDNA
3 μ l glycogen
825 μ l 100% ethanol.

Incubate 10 min in a dry ice/methanol bath, then microcentrifuge 15 min at 4°C.

54. Wash two times with cold 75% ethanol each. Resuspend each DNA sample on ice in 2.5 μ l cold LoTE buffer and pool (7.5 μ l total).

It is critical to keep the purified ditags on ice until the ligation buffer is added. High A and T content ditags can denature at room temperature, even in LoTE buffer.

Ligate ditags to form concatemers

55. Mix the following:

7 μ l pooled purified ditags
2 μ l 5 \times T4 DNA ligase buffer
1 μ l 5 U/ μ l (high-concentration) T4 DNA ligase.

Incubate 1 to 3 hr at 16°C.

Do not ligate overnight, as this will result in long concatemers that are difficult to clone. The authors usually ligate for 2 hr with good results.

The length of ligation time depends on the quantity and purity of the ditags. Typically, several hundred nanograms of ditags are isolated and produce large concatemers when the ligation reaction is performed for 1 to 3 hr at 16°C (lower quantities or less-pure ditags will require longer ligations).

56. After completing ligation, add 2.5 μ l of 5 \times loading buffer to the ligation reaction. Heat samples 5 min at 65°C and immediately place on ice.

The heating step melts annealed sticky ends and is critical for obtaining a good yield of clonable concatemers.

57. Separate concatemers on a 10% to 12% polyacrylamide/TBE gel (UNIT 2.7). Load 1-kb DNA marker in first lane, leave one empty lane, and then load the entire concatenated sample into the third well. Run samples 45 min at 200 V.

58. Stain and visualize as described in step 37. Isolate regions of interest.

Concatemers will form a smear on the gel with a range from ~100 bp to several kilobases.

The authors usually isolate regions 600 to 1200 bp and 1200 to 2500 bp. These size ranges clone efficiently and yield ample sequencing information.

59. Place each gel piece into 0.5-ml microcentrifuge tubes which have an ~0.5-mm-diameter hole in the bottom.

60. Microcentrifuge as described in step 39.

61. Discard the 0.5-ml microcentrifuge tubes. Add 300 μ l LoTE buffer to the gel pieces in the 2.0-ml microcentrifuge tubes. Vortex each tube, and incubate 15 min at 65°C.

If desired, this incubation can be extended to overnight, but yields are not significantly increased.

Note that ammonium acetate is not required for high-molecular-weight molecules.

62. Add 5 μ l LoTE to the membrane of each four Spin-X microcentrifuge-tube filters. Transfer contents of each tube to two Spin-X microcentrifuge-tube filters (four total). Microcentrifuge each Spin-X tube 5 min at maximum speed.

63. Pool eluates from two Spin-X centrifuge tube filters into one 1.5-ml microcentrifuge tube and ethanol precipitate by adding the following:

300 μ l eluate
2 μ l SeeDNA
133 μ l 7.5 M ammonium acetate
1000 μ l 100% ethanol.

Glycogen can be substituted for SeeDNA, but the authors obtained better results when only SeeDNA was used.

64. Microcentrifuge 15 min at maximum speed. Wash two times with 70% ethanol and air dry 5 min. Resuspend purified concatemer DNA in 6 μ l LoTE buffer.

Ligate the concatemers into vector

65. Digest 1 μ g pZER0-1 plasmid with *Sph*I in a total volume of 10 μ l by adding the following:

1 μ l pZER0-1 plasmid
7 μ l ddH₂O
1 μ l 10 \times NEBuffer 2
1 μ l 10 U/ μ l *Sph*I.

Incubate 15 to 30 min at 37°C, then heat inactivate 10 min at 65°C. Do not digest >30 min.

Concatemers can be cloned and sequenced in a vector of choice. The authors currently clone concatemers into a SphI-cleaved pZErO-1.

66. Check for complete digestion on an agarose gel (UNIT 2.5A). Dilute the cut vector with 90 µl TE buffer, pH 8.0, then extract with equal volume of PC8. Ethanol precipitate (UNIT 2.1A), wash two times with 70% ethanol, and resuspend in 40 µl water or TE buffer (~25 ng/µl of vector).

The authors recommend using the linearized DNA immediately, but it may be stored for up to 2 weeks at -20°C with decreased ligation efficiency. Ligation efficiency varies beyond 2-week storage. A 2-to-5 fold increase in background is observed upon prolonged storage, due to self-ligation—i.e., no insert.

67. Mix the following ligation reaction and set up a duplicate reaction for a control with no concatemer:

6 µl purified concatemer (step 64; none in control)
1.5 µl dH₂O (7.5 µl in control)
1 µl 25 ng/µl pZErO plasmid cut with *SphI*
1 µl 10× T4 DNA ligase buffer
1.0 µl 1 U/µl T4 DNA ligase.

Incubate 2 hr at 16°C.

Consider using 3 µl concatemers and save the rest for backup.

*The manufacturer of pZErO plasmid warns that there is increased background at incubations >1 hr, which may result in breakthrough by spontaneous mutations in the *ccdB* death gene.*

68. Bring sample volume to 200 µl with LoTE buffer. Extract with an equal volume PC8, then ethanol precipitate by mixing the following:

200 µl sample
133 µl 7.5 M ammonium acetate
2 µl SeeDNA
777 µl 100% ethanol.

69. Wash four times with 70% ethanol. Microcentrifuge briefly at maximum speed, remove 70% ethanol, and air dry 5 min. Resuspend in 10 µl LoTE buffer.

Excess salt can cause arcing during electroporation and kill the cells.

Transfect DNA by electroporation

70. Place an appropriate number of 0.1-mm microelectroporation cuvettes and 1.5-ml microcentrifuge tubes on ice.

71. Place 1 ml SOC medium in an appropriate number of 15-ml culture tubes at room temperature.

72. Add 1 µl DNA from step 69 to 1.5-ml microcentrifuge tubes on ice. To determine transformation efficiency, add 1 µl of 0.01 ng/µl pUC19 control DNA to a tube labelled “control.”

Use 1 µl of the DNA for this transfection. The remainder of the sample is stored at -20°C.

73. Remove DH10B Electromax competent cells from -70°C and thaw on wet ice. When cells are thawed, mix cells by tapping gently.

74. Add 40 μl competent cells to each chilled 1.5-ml microcentrifuge tube containing DNA. Refreeze any unused cells in a dry ice/methanol bath for 5 min before returning to -70°C .
75. Pipet 40 μl of the cell/DNA mixture into a prechilled disposable microelectroporation cuvette (step 70). Perform electroporation with the Bio-Rad gene pulser electroporator at 100 Ω /25 μF /1.8 kV.
76. Transfer electroporated cells into a 15-ml culture tube and immediately add 1.0 ml SOC medium at room temperature. Shake 15 min at 225 rpm, 37°C .

The incubation time is short because, in theory, the postelectroporation incubation period is required for expression of the antibiotic resistance gene, hence increasing transformation efficiency. However, given that the doubling time of the bacteria is ~ 20 min, it is possible that the transformed bacteria may double during the incubation period, potentially skewing the library's representation of tags. With 15 min incubation prior to plating, the authors found the transformation efficiency to be 1.0×10^{10} cfu/ μg pUC19, respectable when compared with the 1-hr incubation recommended by the manufacturer that resulted in 1.5×10^{10} cfu/ μg pUC19.

77. Spread 100 μl of a 1:100 dilution of control cells (pUC19) in SOC or LB medium on LB plates containing 100 $\mu\text{g}/\text{ml}$ ampicillin.
78. Plate $\frac{1}{10}$ transfected bacteria onto each of ten 10-cm zeocin-containing low-salt LB plates. Incubate and analyze 12 to 16 hr later.

Insert-containing clones should have hundreds to thousands of colonies while no-insert control plates should have zero to tens of colonies.

Save all ten plates for each concatemer ligation reaction since, if insert size appears appropriate, these may be used for sequencing described below.

Check insert size by PCR

79. Prepare a reaction mastermix using the following recipe for one reaction as a guide:

2.5 μl 10 \times SAGE PCR amplification buffer
 1.25 μl DMSO
 1.25 μl 10 mM dNTP
 0.5 μl 350 ng/ μl M13 forward PCR primer
 0.5 μl 350 ng/ μl M13 reverse PCR primer
 18.5 μl ddH₂O
 0.5 μl 10:1 U/ μl *Taq:Pfu* DNA polymerase.

Pipet 25 μl master mix to wells of 96-well PCR plates.

*Any thermostable polymerase can be used (with the appropriate buffer), but the *Taq:Pfu* mixture works well.*

80. For each reaction, use a sterile toothpick or pipet tip to gently touch colony and then dip tip with a twirl into PCR mix.
81. Carry out the amplifications in a thermal cycler with the following parameters:

1 cycle:	2 min	95°C	(denaturation)
25 cycles:	30 sec	95°C	(denaturation)
	1 min	56°C	(annealing)
	2 min	72°C	(extension)
1 cycle:	5 min	70°C	(final product extension).

*For *Taq* DNA polymerase-based PCR amplifications, an extension time of 0.5 to 1.0 min/kb of template amplified is sufficient, but in contrast, *Pfu*-based PCR amplifications require a minimum extension time of 1 to 2 min/kb of amplified template to achieve similar target synthesis.*

82. Analyze on a 1.5% agarose gel at ~150 V (UNIT 2.5A).

For large-scale screening, use multichannel pipettors with an Owl Centipede 50-well horizontal electrophoresis system. The tips of the multichannel pipettors fit into every second well of the 50-slot comb used on the Owl Centipede rigs. Consequently, to maintain a sequential loading order for each 96-well plate, the authors prepare a separate 96-well loading plate with sample loading dye.

The authors typically get 85% to 95% of clones with inserts, of which >95% are >400 bp long. Libraries of this quality can be sequenced directly without gel screening and sorting.

Purify template and sequence amplification product

83. Use 2 μ l PCR product (the exact amount will depend on the sequencing protocol and should be optimized) for clean-up using the following:

0.1 μ l exonuclease I
0.1 μ l shrimp alkaline phosphatase
1.8 μ l 50 mM Tris·Cl, pH 8.0.

Add 2 μ l clean-up mix to 2 μ l DNA.

The exonuclease I degrades unincorporated primers while the alkaline phosphatase degrades unincorporated free nucleotides.

84. Perform reactions in 96-well plates on a thermal cycler, incubating 15 min at 37°C, then 15 min at 80°C. Add ddH₂O to 15 μ l. Sequence PCR products directly (UNIT 15.2).

Use as little as 2 μ l of diluted product for the sequencing reaction—optimize according to protocol. The authors run reactions on an ABI 3700 96 capillary machine, though any sequencing system may be used.

85. Download SAGE analysis software from SAGEnet (see Internet Resources) and follow easy-to-use instructions.

SUPPORT PROTOCOL 1

VERIFYING cDNA PRODUCTION BY PCR ANALYSIS

The PCR primers used to test efficiency of the reverse-transcription will depend on the species and tissue type from which the library is constructed. Working in mouse, the authors typically test a ubiquitously-expressed mRNA (RPS17) and a more tissue-restricted mRNA. Design primers to be 18 to 22 bp in length and have a T_m of 55° to 60°C. T_m for the two primers should not differ by more than 1° to 2°C. The PCR product should be 300 to 700 bp in length, with a 5' end not more than 1 kb from the 3' end of the mRNA. The following describes the authors' method; however, conditions will have to be optimized for each primer set (see UNIT 15.1).

Materials (also see Basic Protocol 1)

350 ng/ μ l 5' and 3' primers (e.g., Integrated DNA Technology)
Bead suspension (see Basic Protocol 1, step 13)

Additional reagents and equipment for agarose gel electrophoresis (UNIT 2.5A)

1. Prepare the following PCR mixture:

5 μ l 10 \times SAGE PCR buffer
3 μ l DMSO
4 μ l 10 mM dNTP mix
0.5 μ l 350 ng/ μ l 5' primer
0.5 μ l 350 ng/ μ l 3' primer
31.3 μ l ddH₂O
0.7 μ l 5 U/ μ l *Taq* DNA polymerase
5 μ l bead suspension.

It is possible to test smaller aliquots of bead suspension depending on the abundance of the template.

2. Perform PCR using the following program:

Initial step:	2 min	95°C	(denaturation)
30 cycles:	30 sec	95°C	(denaturation)
	1 min	53°–58°C	(annealing)
	1 min	72°C	(extension)
Final step:	5 min	70°C	(final extension).

Annealing temperature should be 2° to 3°C lower than the lowest predicted T_m for the primers.

3. Analyze 5 µl of each PCR product on a 1.5% agarose gel in TAE buffer and visualize bands by ethidium bromide staining (UNIT 2.5A).

OPTIMIZING DITAG PCR AMPLIFICATION

The following protocol gives a method for optimizing ditag PCR by varying template concentration, nucleotide concentration, and number of cycles. The optimal template concentration to use is the one which gives a high yield of the 102-bp band with the least concentration of template. A clear plateau in yield should be seen with high concentrations of template. The optimal concentration of nucleotide is simply that which gives the highest yield of the 102-bp band. If none of the PCR reactions give high yields of the 102-bp band, repeat the protocol, but run one tube for 30 cycles and one for 32 cycles. The authors have found that the optimal concentration of nucleotide can vary from batch to batch and supplier to supplier, so repeated optimization may be required.

See Basic Protocol 1 for materials.

1. Prepare serial dilutions of LoTE diluted ditag reaction (see Basic Protocol 1, step 27) at 1:3, 1:9, 1:27, 1:81, and 1:243 in LoTE buffer using 10 µl reaction and 20 µl LoTE buffer (30 µl total) at each step.
2. Prepare the following PCR reaction mixture:
 - 5 µl 10× SAGE PCR amplification buffer
 - 3 µl DMSO
 - 1 µl 350 ng/µl PCR primer 1
 - 1 µl 350 ng/µl PCR primer 2
 - 28.3 µl ddH₂O
 - 0.7 µl 5 U/µl Platinum *Taq* DNA polymerase.
3. Prepare six tubes each containing 1 µl of either stock (see Basic Protocol 1, step 27) or diluted ditag reaction (1:3, 1:9, 1:27, 1:81, or 1:243). In duplicate, add 4, 7, or 10 µl of 10 mM dNTP mix (i.e., prepare two tubes of each dilution and nucleotide concentration pair). Add sufficient double-distilled water to bring the total volume to 11 µl.
4. Perform PCR as described (see Basic Protocol 1, step 29), using 26 cycles for one of the duplicate tubes and 28 for the other.
5. Remove 10 µl from each reaction and run on a prepoured 20% polyacrylamide/TBE gel, using a 20-bp ladder as a marker (10 µl of 1:5 dilution of the marker stock solution; see Basic Protocol 1, steps 35 and 36). Stain gel and visualize as described (see Basic Protocol 1, step 37).

SUPPORT PROTOCOL 2

Discovery of
Differentially
Expressed Genes

25B.6.15

The amplified ditags should be 102 bp in size. A background band of equal or lower intensity (due to linker-linker dimers) occurs at ~80 bp. All other background bands should be of substantially lower intensity.

The ligase “-” samples should not contain any amplified product of the size of the ditags even at 35 cycles.

**BASIC
PROTOCOL 2**

REVERSE CLONING UNKNOWN SAGE TAGS (rSAGE)

SAGE is a technique that allows a generally unbiased evaluation of cellular mRNAs on a genome-wide scale, thus providing a generally more quantitative analysis than subtractive cloning or microarray approaches. Furthermore, the sequencing of 14-bp SAGE tags has a significantly higher throughput than conventional expressed sequence tag (EST) approaches; however, the cDNA that a SAGE tag represents may not be readily identifiable due to the lack of an appropriate anchored cDNA sequence or multiple potential tag to gene matches. This protocol describes an approach, reverse-SAGE (rSAGE), by which the native 3' sequence can be cloned from cDNA utilizing a variation of the original SAGE protocol and PCR primers based upon sequences in the SAGE tag. The advantage of this protocol is that the unknown gene is cloned using 3' cDNA fragments that are the most 3' sequences containing the anchoring enzyme recognition sequence. This approach provides increased specificity of cloning the appropriate cognate cDNA from an anonymous SAGE tag.

Figure 25B.6.2 summarizes this procedure. The starting material is total RNA that expresses the target gene, and as a result, the anonymous SAGE tag. Double-stranded cDNA is synthesized by mRNA priming with a biotinylated poly-dT oligonucleotide that also encodes an M13 forward priming site and an *Asc*I restriction site. The anchoring

Figure 25B.6.2 Steps of an rSAGE experiment.

enzyme, *Nla*III, is used to cleave the cDNA and produce 3' cDNA fragments with *Nla*III cohesive overhangs. These 3' cDNA fragments are captured onto magnetic streptavidin Dynabeads and subsequently purified. The *Nla*III overhangs are then ligated with annealed linkers, 2A/2B, that encode a priming site for PCR primer 2, which is used for subsequent amplification. The cDNA is then released from the Dynabeads by digestion with *Asc*I restriction endonuclease. The resulting cDNA library is then amplified using PCR primer 2 and M13 forward primer (M13F). A specific rSAGE PCR product is then generated using a SAGE tag-specific primer with M13F. The SAGE tag-specific PCR product is then agarose gel purified and subsequently TA cloned into a sequencing vector.

Materials

SuperScript Choice System cDNA synthesis kit (Life Technologies):

- DEPC ddH₂O
- 5× first-strand buffer
- 0.1 M DTT
- 10 mM dNTP
- 200 U/μl SuperScript II reverse transcriptase
- 5× second-strand buffer
- 10 U/μl *E. coli* DNA ligase
- 10 U/μl *E. coli* DNA polymerase I
- 2 U/μl *E. coli* RNase H
- 5 U/μl T4 DNA polymerase
- 1× and 5× T4 DNA ligase buffer
- 1 μg/μl gel-purified BRS1 primer (see recipe)
- 0.5 M EDTA, pH 7.5 (*APPENDIX 2*)
- PC8 (see recipe)
- SeeDNA (Amersham Pharmacia Biotech)
- 7.5 M ammonium acetate (Sigma)
- 70% and 100% ethanol
- LoTE buffer (see recipe)
- 100× BSA (New England Biolabs)
- 10 U/μl *Nla*III (*UNIT 3.1*) and 10× NEBuffer 4 (New England Biolabs)
- Streptavidin Dynabeads (Dynal)
- 1× BW buffer (see recipe)
- Annealed linkers (see Support Protocol 1)
- 5 U/μl (high-concentration) T4 DNA ligase (Life Technologies; *UNIT 3.14*)
- 1× BW buffer/1× BSA
- 1× NEBuffer 4/1× BSA
- 100× BSA
- 10 U/μl *Asc*I (New England Biolabs; *UNIT 3.1*)
- 10× SAGE PCR buffer (see recipe)
- DMSO
- PCR primers (see recipe):
 - 350 ng/μl M13 forward primer
 - 350 ng/μl primer 2
- 5 U/μl Platinum Taq DNA polymerase (Life Technologies; *UNIT 3.5*)
- 4% to 20% TBE acrylamide gel (Novex)
- 1-kb ladder
- 1× SYBR green I (Roche Diagnostics) in TBE buffer (*APPENDIX 2*)
- 5 M betaine: prepare monohydrate salt (Sigma) in PCR-grade ddH₂O
- SAGE tag-specific primer (see recipe)

Qiaquick gel-extraction kit (Qiagen):

Qiaquick columns

EB Buffer

TOPO TA Cloning Kit with pCR2.1 vector (Invitrogen) *or*

TOPO TA Cloning Kit for Sequencing with pCR4-TOPO vector (Invitrogen)

16°, 50°, and 70°C water baths, heat blocks, or equivalent

1.5-ml No-stick siliconized microcentrifuge tubes (Ambion)

Magnetic rack for 1.5-ml microcentrifuge tubes (Dyna)

1.5-ml nonsiliconized nuclease-free microcentrifuge tubes

Additional reagents and equipment for preparing total RNA (UNIT 4.2) agarose-gel electrophoresis (UNIT 2.5A) and sequencing (UNIT 7.4A)

Synthesize cDNA

1. Prepare total RNA in DEPC ddH₂O using standard methods (e.g., UNIT 4.2).

Trizol (Sigma) is the preferred method in the authors' laboratory. The same RNA with which the original SAGE library was generated would be ideal (see Basic Protocol 1, steps 3 and 4).

It is advisable to also generate a control rSAGE library that will not express the genes of interest. As PCR cloning from the rSAGE library might generate more than one clonable band, PCR of a control rSAGE library would allow the researcher to discriminate and identify the likely rSAGE product representing the gene of interest.

2. Add 2 µl of 1 µg/µl gel-purified BRS1 primer to a nonsiliconized 1.5-ml microcentrifuge tube. Add 6 µl total RNA (5 to 10 µg total) and mix.
3. Heat mixture to 70°C for 10 min and quick chill on ice. Microcentrifuge briefly at room temperature. Prepare first-strand-synthesis mix as shown below:

8 µl BRS1 primer/RNA
4 µl 5× first-strand buffer
2 µl of 0.1 M DTT
1 µl of 10 mM dNTP.

4. Mix gently by vortexing and microcentrifuge briefly at room temperature. Incubate 2 min at 37°C, then add 5 µl of 200 U/µl SuperScript II reverse transcriptase and mix well. Incubate an additional 1 hr at 37°C.
5. After incubation, place tube on ice to terminate the reaction. Add the components of the second-strand-synthesis mixture to the first-strand reaction on ice in the order shown:

93 µl DEPC ddH₂O, 4°C
30 µl 5× second-strand buffer
3 µl 10 mM dNTP
1 µl 10 U/µl *E. coli* DNA ligase
4 µl 10 U/µl *E. coli* DNA polymerase I
1 µl 2 U/µl *E. coli* RNase H.

Vortex gently to mix.

6. Incubate 2 hr at 16°C. Intermittently mix by gentle flicking. Add 2 µl 5 U/µl T4 DNA polymerase and incubate 5 min at 16°C. Place tubes on ice and terminate reaction by adding 10 µl of 0.5 M EDTA, pH 7.5.

T4 DNA polymerase is used in the reverse-SAGE protocol to fill in 5' overhangs generated after second-strand synthesis.

7. Add 150 μl PC8 and vortex thoroughly. Microcentrifuge 5 min at maximum speed, room temperature. Remove and save aqueous layer ($\sim 150 \mu\text{l}$).

Unlike microSAGE, the reverse-SAGE protocol synthesizes DNA onto unbound biotinylated oligonucleotides, making purification (i.e., phenol-chloroform extraction followed by ethanol precipitation) easier. As a result, the heat denaturation and multiple wash steps in the SAGE protocol are unnecessary.

8. Ethanol precipitate aqueous layer in a fresh standard 1.5-ml microcentrifuge tube by adding the following reagents:

2 μl SeeDNA
70 μl 7.5 M ammonium acetate
500 μl 100% ethanol.

Vortex thoroughly, then microcentrifuge 20 min at maximum speed, 4°C. Wash pellet in 70% ethanol.

9. Resuspend in 20 μl LoTE buffer.

Samples may be stored at 4°C up to a week or frozen at -20°C for months. However, it is best to leave at 4°C overnight and resume the protocol the following day.

Cleave cDNA with anchoring enzyme (*NlaIII*) and ligate linkers

10. Cleave cDNA with the anchoring enzyme (*NlaIII*) using the following mixture:

20 μl cDNA (step 9)
148 μl H₂O
2 μl 100 \times BSA
20 μl 10 \times NEBuffer 4
10 μl 10 U/ μl *NlaIII*.

Mix and incubate 1 hr at 37°C.

It is best to proceed with prewashing the streptavidin-Dynabeads (step 11) during this incubation such that the beads will be ready for use in the subsequent steps.

11. Thoroughly resuspend Streptavidin Dynabeads, exercising care to avoid excessive vortexing as streptavidin may be sheared off the magnetic beads. Transfer 200 μl beads to a No-stick siliconized 1.5-ml microcentrifuge tube and place in a magnetic rack. After ~ 1 min remove supernatant. Wash beads twice in 200 μl of 1 \times BW then let stand in 200 μl of 1 \times BW until ready for use (up to several hours).

All manipulations with Dynabeads are done using siliconized microcentrifuge tubes to avoid loss of yield due to products sticking to tube walls. All other manipulations, especially ethanol precipitations, should be done in standard microcentrifuge tubes.

Dynabead washes are executed in the same fashion as done in the primary method (see Basic Protocol 1, step 2). Briefly, the beads are placed in the magnet 1 to 2 min. While the siliconized tube is still in the magnet, the buffer is gently pipetted off. The tube is then taken off the magnet and fresh buffer/wash is added to the tube and the beads are resuspended by agitation by hand or gentle vortexing. It is critical that the Dynabeads are not allowed to dry between the wash steps.

12. Ethanol precipitate cDNA from step 10 as described in step 8. Resuspend cDNA pellet in 200 μl of 1 \times BW.
13. Remove 1 \times BW from Dynabeads (step 11) and replace with 200 μl cDNA in BW. Mix gently by pipetting the mixture up and down. Incubate 15 min at room temperature with intermittent agitation by hand. Wash three times with 200 μl of 1 \times BW. Add 200 μl of 1 \times T4 DNA ligase buffer.

14. Prepare the following mix:

2 μ l 200 ng/ μ l linkers 2A and 2B (annealed)
28 μ l LoTE
8 μ l 5 \times T4 DNA ligase buffer.

Remove 1 \times ligase buffer from the Dynabeads by pipetting and add the above mixture.

15. Mix bead slurry bound with cDNA gently, but well. Heat the tube 2 min at 50°C then incubate 15 min at room temperature.

16. Add 2 μ l of 5 U/ μ l (high-concentration) T4 DNA ligase and incubate 2 hr at 16°C. Mix beads intermittently during ligation.

It is best to use annealed linkers 2A/2B that are <1 month old.

Release cDNA with *AscI*

17. After ligation, wash beads four times with 1 \times BW/1 \times BSA. Wash in 1 \times NEBuffer 4/1 \times BSA and proceed immediately to the next step.

18. Resuspend the beads by adding the following components:

85 μ l LoTE buffer
10 μ l 10 \times NEBuffer 4
2 μ l 100 \times BSA
2 μ l 10 U/ μ l *AscI*.

Mix contents gently, but well using a pipette.

19. Incubate 1 hr at 37°C, agitating intermittently by hand every 15 min.

20. After digestion, collect supernatant carefully with a magnet. Place supernatant into a fresh nonsiliconized microcentrifuge tube. Add 50 μ l LoTE to sample. Extract with PC8 as described in step 7.

21. High-concentration ethanol precipitate by combining the following:

150 μ l sample
2 μ l SeeDNA
70 μ l 7.5 M ammonium acetate
500 μ l 100% ethanol.

Microcentrifuge 20 min at full speed, room temperature. Wash with 70% ethanol and resuspend in 25 μ l LoTE.

This is the concentrated rSAGE product, which may be stored indefinitely at -20°C. Avoid repeated freeze-thaw.

Amplify rSAGE-library dilutions by PCR

22. Make several dilutions of rSAGE product in LoTE.

Usually 1 μ l of 1:25, 1:50, and 1:100 dilutions are recommended for PCR. Due to frequent variations in yield, this can vary widely. These dilutions are good starting point, however.

23. Prepare the following PCR reaction:

1 μ l rSAGE dilution
5 μ l 10 \times SAGE PCR buffer
3 μ l DMSO
3 μ l 10 mM dNTPs

1 μ l 350 ug/ μ l M13 forward primer
 1 μ l 350 ug/ μ l primer 2
 36 μ l ddH₂O
 1 μ l 5 U/ μ l Platinum *Taq* DNA polymerase.

Repeat for all dilutions.

24. Use the following PCR cycling conditions:

Initial step:	2 min	94°C	(denaturation)
25 cycles:	45 sec	94°C	(denaturation)
	1 min	57°C	(annealing)
	1 min	70°C	(extension)
1 cycle:	5 min	70°C	(fill-in)
Final step:	indefinite	4°C	(hold).

25. Analyze 10 μ l of each PCR product on a 4% to 20% Novex TBE acrylamide gel along with 1-kb ladder. Stain with 1 \times SYBR Green I in TBE buffer for 30 min and visualize under UV light.

A smear predominantly in the 200 to 500 bp range should be observed. Choose the highest rSAGE dilution that gives reliable results. The authors usually use the amplified 1:50 dilution of the rSAGE product. Amplified rSAGE libraries may be stored at -20°C for months.

PCR amplify using SAGE tag-specific primer and M13F primer

26. Prepare the following PCR mixture per reaction:

1 μ l amplified rSAGE library (step 24)
 5 μ l 10 \times SAGE PCR buffer
 2.5 μ l DMSO
 3 μ l 10 mM dNTPs
 10 μ l 5 M betaine
 1 μ l 350 ug/ μ l M13 forward primer
 1 μ l 350 ug/ μ l SAGE tag-specific primer
 25.5 μ l H₂O
 1 μ l 5 U/ μ l Platinum *Taq*.

See Critical Parameters and Troubleshooting for a discussion of SAGE tag-specific primers.

27. Amplify under the following PCR cycling conditions:

Initial step:	2 min	93°C	(denaturation)
1 cycle:	30 sec	93°C	(begin touchdown)
	1 min	60°C	
	1 min	70°C	
15 cycles:	30 sec	93°C	(touchdown cycles)
	1 min	60° - 1°C/cycle	
	1 min	70°C	
30 cycles:	30 sec	93°C	(amplification cycles)
	1 min	44°C	
	1 min	70°C	
1 cycle:	5 min	70°C	(fill-in)
Final step:	indefinite	4°C	(hold).

These PCR cycling conditions are only guidelines that happen to work well for most SAGE tag-specific primers. A prolonged touchdown is pivotal for the specificity of priming.

Optimal annealing temperatures may vary depending upon the nucleotide makeup of the SAGE tag-specific primer. Therefore, the touchdown annealing temperature should begin at least 10°C above the predicted oligonucleotide melting point (T_m). Over the 15 touchdown cycles, the annealing temperature should, by -1°C increments, settle upon the predicted SAGE-tag-specific primer's annealing temperature, where the rest of the 30 amplification cycles will proceed. It is not advisable to go below an annealing temperature of 40°C, regardless of how low the oligonucleotide T_m might be. Despite the apparent numerous amplification cycles used in this prolonged touchdown approach, the Taq polymerase remains very much active, mostly attributable to the protective effects of high-concentration betaine. See Critical Parameters and Troubleshooting for further discussion.

28. Visualize 5 µl of the PCR products on a 1.5% TBE agarose gel (UNIT 2.5A).

The expected amplicons are usually between 100 to 400 bp, sometimes larger or smaller. Sometimes multiple bands may be amplified. If a control rSAGE amplified library was constructed, the band that is more intense in the experimental rSAGE library should be selected for further characterization. Often, multiple closely sized bands are amplification products of the same cDNA, attributable to variable oligo-dT priming along the poly-A tract during reverse transcription.

29. Load 25 µl of PCR products into a 1.5% TBE agarose gel and electrophorese until individual bands can be resolved (UNIT 2.5A). Carefully excise the amplicon in the smallest agarose piece possible without sacrificing yield and place into a preweighed microcentrifuge tube.

30. Purify PCR product using the Qiaquick gel-extraction kit according to manufacturer's instructions (Qiagen). Elute Qiaquick columns with 30 µl EB Buffer. Proceed immediately to cloning using 4 µl eluant and the TOPO TA Cloning Kit or Cloning Kit for Sequencing per manufacturer's instructions.

If the only goal for the rSAGE procedure is to sequence the cDNA fragment, then the standard TA cloning vector pCR2.1 (Invitrogen) should suffice. However, if there are future plans for in vitro transcription of the cloned cDNAs, then it is advisable to use the TA cloning vector pCR4-TOPO (Invitrogen), which has both T7 and T3 RNA polymerase recognition sequences flanking the multiple cloning site.

IMPORTANT NOTE: After TOPO TA cloning, do not use the M13 forward primer for subsequent colony PCR or cycle sequencing, as the M13 forward site will be embedded in the cloned cDNA. The M13 forward primer will not discriminate between M13 forward sites in the cDNA clone and the vector.

31. Sequence TA cloning products using conventional methods (e.g., UNIT 7.4A).

SUPPORT PROTOCOL 3

PHOSPHORYLATING AND ANNEALING LINKERS

It is critical that the linkers be both annealed into double-stranded products and efficiently phosphorylated prior to ligation onto *Nla*III-digested cDNAs during SAGE-library construction. Even if linkers are ordered prephosphorylated, it is critical to test the efficiency of linker phosphorylation by self-ligation prior to SAGE library construction so as not to lose precious time and material. The following protocol details linker phosphorylation, annealing, and self ligation.

Additional Materials (also see Basic Protocol 1)

- Linkers 1A, 1B, 2A, and 2B (see recipe)
- 10× kinase buffer (New England Biolabs)
- 10 mM ATP
- 10 U/µl T4 polynucleotide kinase (New England Biolabs; UNIT 3.10)

Phosphorylate linkers

1. If linkers 1B and 2B are not already phosphorylated on their 5' ends, prepare the following mixture:

9 μ l 350 ng/ μ l linker 1B or 2B
6 μ l LoTE buffer
2 μ l 10 \times kinase buffer
2 μ l 10 mM ATP
1 μ l 10 U/ μ l T4 polynucleotide kinase.

Incubate 30 min at 37°C, then heat inactivate 15 min at 65°C.

Anneal linkers

2. Add 9 μ l of 350 ng/ μ l linker 1A to 20 μ l phosphorylated linker 1B.
3. Add 9 μ l of 350 ng/ μ l linker 2A to 20 μ l phosphorylated linker 2B.
4. Perform the following incubations on each linker pair:

2 min at 95°C
10 min at 65°C
10 min at 37°C
20 min at room temperature.

5. Dilute to 2 ng/ μ l with LoTE prior to use in SAGE-library construction.

Perform and check ligation

6. Prepare the following ligation reaction:

0.5 μ l annealed undiluted 350 ng/ml linker 1A + phosphorylated linker 1B
(step 4)
0.5 μ l annealed undiluted 350 ng/ml linker 2A + phosphorylated linker 2B
(step 4)
7 μ l H₂O
1 μ l 10 \times T4 DNA ligase buffer
1 μ l 5 U/ μ l (high-concentration) T4 DNA ligase buffer.

Incubate 4 hr at 16°C.

All linkers, whether ordered prephosphorylated or phosphorylated in house, should be checked for self-ligation.

7. Analyze product on a prepoured 20% polyacrylamide/TBE gel. Visualize as described (see Basic Protocol 1, step 37).

Phosphorylated linkers should allow linker-linker dimers (80 to 100 bp) to form after ligation, while nonphosphorylated linkers will prevent self-ligation. Only linker pairs that self-ligate >70% should be used in further steps.

REAGENTS AND SOLUTIONS

Use double-distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

BRS1 primer

5'-Biotin-CCGGGCGCGCCGTAAAACGACGGCCAG(T)₁₉-3'

Order HPLC purified from a trusted supplier. The authors recommend using Integrated DNA Technologies (IDT).

BW buffer, 1×

For 2× stock:

10 mM Tris·Cl, pH 7.5 (APPENDIX 2)

1 mM EDTA

2.0 M NaCl

Store up to 1 year at room temperature

Dilute to 1× with H₂O just before use

Linkers

Linker 1A: 5' TTTGGATTTGCTGGTGCAGTACA ACTAGGCTTAATAGGGA-CATG 3'

Linker 1B: 5' TCCCTATTAAGCCTAGTTGTACTGCACCAGCAAATCC[amino mod C7] 3'

Linker 2A: 5' TTTCTGCTCGAATTCAAGCTTCTAACGATGTACGGGGA-CATG 3'

Linker 2B: 5' TCCCCGTACATCGTTAGAAGCTTGAATTCGAGCAG[amino mod C7] 3'

The authors recommend using Integrated DNA Technologies for ordering oligonucleotides.

LoTE buffer

3 mM Tris·Cl, pH 7.5 (APPENDIX 2)

0.2 mM EDTA, pH 7.5

Store up to 1 year at room temperature

PC8

480 ml phenol, warmed to 65°C

320 ml 0.5 M Tris·Cl, pH 8.0 (APPENDIX 2)

640 ml chloroform

Add in sequence and place at 4°C. After 2 to 3 hr, shake again. After an additional 2 to 3 hr, aspirate aqueous layer. Store up to 1 year in aliquots at -20°C or 6 months at 4°C.

Commercially available 1:1 (v/v) phenol:chloroform mix can also be substituted, as long as the pH is preset to 8.0.

PCR primers

Primer 1: 5' GGATTTGCTGGTGCAGTACA 3'

Primer 2: 5' CTGCTCGAATTCAAGCTTCT 3'

M13 forward: 5' GTAAAACGACGGCCAGT 3'

M13 reverse: 5' GGAAACAGCTATGACCATG 3'

The authors recommend using Integrated DNA Technologies for ordering oligonucleotides.

SAGE PCR buffer, 10×

166 mM ammonium sulfate

670 mM Tris·Cl, pH 8.8 (APPENDIX 2)

67 mM MgCl₂

100 mM 2-mercaptoethanol

Dispense into aliquots and store up to 1 year at -20°C.

SAGE tag-specific primer

5'-GACATGXXXXXXXXXX-(10-bp SAGE tag)-3'

If the SAGE-tag-specific primer has a calculated annealing temperature below 40° C, incorporate additional bases further 5' on linker 2A (see recipe for linkers) to increase the oligonucleotide melting temperature. The full linker 2A-SAGE tag sequence is as follows:

5'-TTTCTGCTCGAATTCAAGCTTCTAACGATGTACGGGGACATGXXXXXXXXXX-(10-bp SAGE tag)-3'

The SAGE 2000 software has the ability to extract an additional base for an 11-base tag. This may be helpful, as any additional sequence-specific bases may yield a more specific product.

Zeocin-containing low-salt LB plates

For 1 liter:

10 g tryptone

5 g yeast extract

5 g NaCl

Adjust the pH to 7.5 and add 15 g bactoagar. Autoclave solution and allow to cool before adding zeocin to 100 mg/ml.

COMMENTARY

Background Information

Serial analysis of gene expression (SAGE) was first developed in 1995 (Velculescu et al., 1995), and has since been used to generate a large variety of data from normal and cancerous human tissue (Zhang et al., 1997), yeast (Velculescu et al., 1997), mouse (Virlon et al., 1999), rat (Klimaschewski et al., 2000), and even (with modifications) human oocytes (Neilson et al., 2000).

SAGE is a powerful method for providing genome-wide gene-expression data. In much the same fashion as EST libraries, SAGE utilizes cDNA “tags” which are sequenced and quantified. The 14-bp SAGE tags differ from ESTs essentially by size, allowing subsequent concatenation and high-throughput sequencing in much greater volumes. The location of the anchoring enzyme site is essentially sufficient to uniquely identify the cognate cDNA or gene. The original protocol required relatively large amounts of starting material (2 to 5 µg of polyA mRNA) and was technically quite challenging, frequently giving variable results even in experienced hands. Major improvements were made to the protocol by a number of groups (Virlon et al., 1999; Datson et al., 1999; St. Croix et al., 2000), which collectively gave rise to a version of the protocol known as microSAGE (see Basic Protocol 1), owing to the fact that over 1000-fold less starting material could be readily used for library construction. The critical modifications appear to have been anchoring the mRNA to magnetic beads prior to cDNA synthesis (rather than after cDNA synthesis via incorporation of a biotinylated oligo(dT) primer as in the original protocol) and optimization of the quantities of reagents used, in particular, the quantities of linkers. Additional improvements, such as heating the ditag concatemers prior to gel purification (Angelastro et al., 1999), have resulted in SAGE libraries with substantially higher insert frequency and larger insert size than in the original protocol. These technical improve-

ments, coupled with the drop in the cost of DNA sequencing, have combined to allow the generation of over 3.5 million human SAGE tags alone, many of which are publicly available for analysis (<http://www.ncbi.nlm.nih.gov/SAGE>).

SAGE analysis has a number of unique advantages over hybridization-based measures of global gene expression, such as microarray analysis (Chapter 22), or approaches such as subtractive hybridization (UNITS 25B.1 & 25B.2) and differential display methodologies (UNITS 25B.3-25B.5). Since very few mRNAs lack *Nla*III sites, SAGE generates a tag for virtually every cellular mRNA, providing a level of coverage unequaled by any microarray yet available for humans or mice. For these same reasons, SAGE can also serve as a tool for gene discovery and transcript annotation even in species with fully sequenced genomes. The sensitivity of SAGE is limited only by the number of tags that one has the desire or resource to sequence and, with larger numbers of tags sequenced, it becomes possible to determine relatively small (<2-fold) changes in gene expression between samples. Since individual SAGE tag levels are expressed as a percentage of total tags, it is straightforward to compare tag levels among libraries generated by other labs. As more SAGE libraries are generated and made public, these data sets can be used to generate a large-scale atlas of gene expression that is of great use to the whole scientific community. Such a resource is already available for human normal and malignant tissues at NCBI (<http://www.ncbi.nlm.nih.gov/SAGE>), and libraries from other species are available from various sources (see Internet Resources for a partial list).

The main drawbacks of SAGE analysis are the time and expense required to generate sufficient numbers of tags to examine expression of low and moderate-abundance mRNAs. The price of sequencing has dropped considerably

Table 25B.6.1 Troubleshooting for SAGE Reactions

Problem	Possible cause	Solution
<i>MicroSAGE</i>		
No PCR product with control primers following cDNA synthesis	Dynabeads inactive	Store Dynabeads at 4°C only; do not freeze
	Reverse transcriptase inactive	Replace reverse transcriptase
	RNA degraded prior to homogenization	Minimize delay between tissue harvesting and homogenization
Ditag PCR product is slightly shorter (running at ~90 bp) and will not redigest with <i>Nla</i> III	Cells insufficiently lysed	Homogenize tissue thoroughly. Use homogenization by Polytron only.
	Failure to completely remove <i>E. coli</i> DNA polymerase I following second strand cDNA synthesis	Do not omit or shorten SDS washes or 75°C heat inactivation step
PCR product in no-ligase control at 100 bp	Contamination of reagent by ditags from a previously constructed SAGE library	Use separate aliquots of LoTE buffer, ammonium acetate, and PC8 for each large-scale ditag purification. Use aerosol pipet tips.
Ditag yield low (100-bp band <80-bp band)	Ratio of linkers to cDNA too high	Reduce amount of linkers in ligation
	cDNA synthesis inefficient	See advice in steps 1-11
Ditags do not cut with <i>Nla</i> III following purification	PCR conditions not optimized	Titrate dNTP concentration and number of amplification cycles
	Quantity of starting material too low	Increase amount of starting material
Ditags do not cut with <i>Nla</i> III following purification	<i>Nla</i> III inactive	Store enzyme in aliquots at -80°C. Do not reuse thawed aliquots.
	Ditags insufficiently pure	Run Qiaquick gel extraction on eluate (see step 44)
Ditag concatemers not generated efficiently	Insufficient quantity of purified ditags used in ligation	Increase quantity of cDNA used for large-scale ditag prep and/or increase number of cycles of amplification
	Ditags used in ligation are insufficiently pure	Run preparative gel longer to more efficiently separate 100- and 80-bp bands
Ditag concatemers most concentrated at high molecular weight (3kb) and do not clone efficiently	Concatemer ligation not heated properly	Heat at 65°C and chill on ice immediately
Concatemers have a high (5%) frequency of duplicate ditags	Too many cycles of PCR used to reamplify ditags	Reduce number of cycles used. Increase amount of starting material when making cDNA

continued

Table 25B.6.1 Troubleshooting for SAGE Reactions, continued

Problem	Possible cause	Solution
<i>rSAGE procedure</i>		
No SAGE tag-specific PCR product	Degraded RNA	Use fresh RNA
	Error in generation of rSAGE amplified library	Reconstruct rSAGE library
	Poor tag specific primer design	Redesign primer (see Critical Parameters and Troubleshooting)
Multiple SAGE tag-specific PCR products	Low abundance transcript	Increase the number of amplification cycles
	Multiple splice variants or multiple gene identities for a given SAGE tag	Clone all PCR amplicons
Poor sequence quality	Nonspecific priming	Construct a control rSAGE library and select amplicons not present in control library
	Use of M13 forward primer for cycle sequencing	Start the PCR touchdown cycles at a higher temperature
		Use another universal primer on the pCR vector for sequencing—e.g., M13 reverse, T3, T7

in the past few years, but real costs still remain around \$0.25/tag. For researchers simply hoping to identify a handful of differentially expressed genes in their sample of interest, subtractive hybridization (UNIT 25B.1), differential display methodologies (UNITS 25B.3-25B.5), or even the use of commercially available microarray technology may prove more cost-effective. An additional drawback of SAGE is the requirement that a large body of cDNA/EST sequence must be available from the organism being studied in order to match SAGE tags to the specific mRNAs. This effectively limits the use of SAGE to model organisms. Another drawback of the method is the occasional failure of a SAGE tag to match a predicted gene or to be long enough to easily isolate a full-length cDNA clone. While this happens at relatively low frequency for high abundance transcripts in model organisms, it can limit the interpretation of the data in some cases.

As a result, several approaches, most of which are variations of conventional RT-PCR, have been developed to identify these unknown or anonymous SAGE tags. There has been marked improvements in strategies used to identify unknown SAGE tags by reverse-cloning cDNA fragments, collectively called reverse SAGE (rSAGE; see Basic Protocol 2). First, the cloning process is similar to the original SAGE

protocol; therefore, only cDNA pieces which are 3' to the most 3' anchoring enzyme site are used as templates for subsequent PCR amplification and subcloning (Polyak et al., 1997; also see Internet Resources, SAGEnet). Second, the use of betaine allows for a prolonged PCR touchdown that results in more specific priming.

Critical Parameters and Troubleshooting

MicroSAGE

The two key determinants of a successful SAGE library are quantity and purity of ditags. To ensure obtaining many ditags, carefully optimize the starting reaction and scale up the number of PCR reactions as desired. For certain low-yield preparations, the authors have gone as high as 700 PCR reactions of 50 μ l to generate the starting material. For purity, ensure that the 102-bp and the 80-bp bands are well separated, and be very careful not to extract any of the 80-bp band. Run the gel as long as possible and do not overload the wells (no more than 10 μ l per well, despite the large number of gels this will require). Do the same for the 26-bp cut ditag band (avoiding the 40-bp linker band).

One other problem that has been encountered occasionally is contamination of reagents fol-

lowing construction of libraries, which will result in 102-bp bands in the no-ligase control in the initial optimization PCR reactions. To avoid this, be very careful to avoid splashes and not reuse tips during the scale-up or initial purification of the 102-bp band. Make separate aliquots of LoTE buffer, PC8, ammonium acetate, and ethanol for each library during these steps to reduce the likelihood of contamination. Use aerosol-barrier tips wherever possible.

A final common cause of experimental failure is low-quality reagents. Wherever possible, order supplies from the sources specified in the protocol. The authors have most frequently observed problems with the *Nla*III enzyme and the linkers. Always store *Nla*III in aliquots at -80°C , do not reuse aliquots, and try to have the enzyme shipped on dry ice if possible. The authors order linkers prekinased, but always check via self-ligation to ensure that a sufficiently large fraction of the linkers is properly phosphorylated.

rSAGE

For the rSAGE procedure, much depends on the quality of RNA used in the sample. It would be best to use the same batch of RNA that was originally used to construct the SAGE library. As most interesting SAGE tags are those that are expressed in abundance in one RNA sample and not in another, it is advisable to make a reverse-SAGE library of such a control tissue. It is not uncommon to generate multiple PCR bands from a tag-specific rSAGE amplification. Identifying a PCR product that is specific to the experimental rSAGE library and not present (or less apparent) in the control would help in the cloning and identification process.

The most technically challenging aspect of reverse-cloning SAGE tags is the PCR of a specific cDNA with the tag-specific primer. The rSAGE-amplified library used as a template for this PCR reaction consists solely of 3'-cDNA ends which have the linker2-SAGE tag on the 5' end and an oligo dT-M13 forward sequence on the 3' end. The PCR of a specific product is difficult when the reverse primer (M13 Forward) anneals to all templates, and the forward primer (SAGE-tag specific) shares the same sequences on the 5' end. Specificity is conferred only by the last 10 bases on the forward primer, representing the unique 10-base SAGE tag. One may also choose to incorporate an additional SAGE-tag base, information that the SAGE 2000 software can extract from the raw data. The SAGE tag-specific PCR is executed with a prolonged touchdown using an automatic hot-

start *Taq* polymerase (i.e., Platinum *Taq*; Invitrogen). As a 15-cycle touchdown requires 46 denaturing cycles, betaine is used as a *Taq* polymerase protectant. The authors strongly advise against switching to a proofreading DNA polymerase, such as *Pfu* or *Vent*, in the PCR reactions. Proofreading enzymes have significant 3'-5' exonuclease activity which may digest the 3' end of the SAGE tag-specific primer. Even one-base differences may reduce the specificity of the PCR product.

Designing of SAGE tag-specific primers is a matter of much debate. Only the 3'-most ten bases of the oligonucleotide contains tag-specific sequences, and the rest of the primer at the 5' end consists of linker sequences which are shared by all the cDNAs in the amplified rSAGE library. As a result, the authors empirically use CACATG-XXXXXXXXXX as a guideline for primer design where the Xs refer to the specific sequence in the SAGE tag of interest. Only six bases are nonspecific, and the relatively low annealing temperatures allow for an extended touchdown starting at a temperature that is well above the oligonucleotide melting point. However, if the rSAGE-specific primer has an annealing temperature which is too low, there is a risk of the primers melting off the template before the extension cycle. Therefore, if the calculated T_m of the SAGE tag specific primer is below 40°C , it is advisable to incorporate more of the linker sequence to raise the melting temperature of the oligo.

In the rare case that the SAGE tag in question lies immediately 5' to the polyA tail, reverse-SAGE may yield no additional information, and the PCR product may be too small to adequately visualize on a 1.5% agarose gel.

Additional troubleshooting guidelines are presented in Table 25B.6.1.

Anticipated Results

If Basic Protocol 1 is followed closely, libraries containing >85% inserts with an average size of 30 to 50 tags (450 to 750 bp) should be routinely generated. This should enable one to obtain a SAGE data set of 50,000 tags after ~2000 individual sequencing reactions.

If the above guidelines for rSAGE (see Basic Protocol 2) are followed, one should be able to clone the cDNA, usually 75 to 400 bp, from which a given SAGE tag is generated. This cDNA fragment would stretch from the 3'-most anchoring-enzyme site to the poly-A tail. The additional sequence data can be used to BLAST genome databases (UNIT 19.3) or be used to generate primers for 5' RACE (UNIT 15.6). The cloned

fragment may also be used for northern analyses (UNIT 4.9) or in-situ hybridizations (UNIT 14.3).

Time Considerations

MicroSAGE

The time typically taken for RNA preparation through *Bsm*FI digestion is 10 to 14 hr. Blunt-ending and ditag-ditag ligation take 2 to 3 hr. Ditag amplification and PCR optimization take 2 to 3 hr and large-scale ditag amplification and purification take 6 to 8 hr/day for 2 days. Ditag digestion and purification take 6 to 8 hr. Concatemer formation, purification, and subcloning take 6 to 8 hr. Template cleanup and transformation take 4 to 6 hr. PCR of library clones and gel analysis take 4 to 5 hr.

If a high-quality SAGE library is produced, it will require ~2000 sequencing reactions to obtain 50,000 tags. This will take anywhere from an additional 1 week to 3 months, depending on the resources and sequencing capacity.

rSAGE

Generating purified double-stranded cDNA typically takes 4.5 hr. Cleaving the cDNA with the anchoring enzyme (*Nla*III), magnetic bead purification, ligating linkers to cDNA, and release of 3' cDNA fragments from magnetic beads with *Asc*I typically takes 6 to 8 hr. PCR generation of amplified rSAGE libraries takes 2.5 to 3.5 hr. SAGE tag-specific PCR takes 3.5 to 4.5 hr. TOPO-TA cloning and subsequent sequencing is user-dependent.

Representational Difference Analysis

UNIT 25B.7

This unit provides a protocol for performing representational difference analysis (RDA); a technique that couples subtractive hybridization to PCR-mediated kinetic enrichment for the detection of differences between two complex genomes. RDA requires the generation of representations from two pools of nearly identical DNA varying only in polymorphisms, deletions/amplifications, rearrangements, or exogenous pathogens. A representation or subset of the genome is used rather than the entire genome, since the full complexity of genomic DNA is unfavorable for hybridization to proceed to completion. In its original formulation by Lisitsyn and colleagues (1993), 2% to 15% of the genome is included in the representation, the percentage being dependent on the frequency of restriction endonuclease sites and the efficiency of PCR amplification of these restriction-generated fragments. While RDA was first developed for genomic DNA, subsequent modifications have been devised to look for differences in transcript expression.

RDA starts with the digestion of two comparison samples of DNA (see Basic Protocol 1) or cDNA (see Basic Protocol 2) with a frequently cutting restriction enzyme. Some consideration should be given to which of the two genomes is designated tester and which is designated driver. In principle, the tester should contain DNA restriction fragments not found in the driver. Specific linkers are ligated to DNA restriction fragments from each pool and amplicons are generated by PCR. Linkers are then removed from both samples and a new linker is added only to size-selected tester amplicons. These tester amplicons are mixed and melted with a large excess of driver amplicons lacking linkers. Hybridization between complementary single strands is allowed to proceed, resulting in the generation of three species of double-stranded DNA fragments: (1) both strands derived from driver DNA (lacking linkers on either strand), (2) hybrids with one strand from driver (no linker) and one from tester (with linker), and (3) both strands from tester DNA (linkers on both strands). Excess driver will soak up DNA fragments common to both samples (i.e., tester:driver), and only the DNA fragments unique to the tester (i.e., the tester:tester population) will be exponentially amplified and kinetically enriched when linker-specific primers are used. Iterative rounds of subtractive/kinetic enrichment against driver amplicons is performed until distinct difference products can be cloned.

GENOMIC REPRESENTATIONAL DIFFERENCE ANALYSIS

This protocol describes RDA for genomic DNA derived from tissues or cells. Modifications for performing cDNA RDA are discussed below (see Basic Protocol 2).

Materials

- Tester and driver DNA samples
- Phenol (Amresco; UNIT 2.1A)
- Phenol:chloroform:isoamyl alcohol (Amresco; UNIT 2.1A)
- 20 µg/µl glycogen
- TE buffer, pH 8.0 (APPENDIX 2)
- Primers/oligomers, HPLC purified (Table 25B.7.1)
- 400 U/µl T4 DNA ligase and 10× buffer (New England BioLabs; UNIT 3.14)
- 5× RDA PCR buffer (see recipe)
- dNTP chase solution: 4 mM (each) dGTP, dATP, dTTP, dCTP; store at -20°C
- 5 U/µl *Taq* DNA polymerase (Invitrogen; UNIT 3.5)
- Mineral oil
- Isopropanol
- 10 M ammonium acetate (APPENDIX 2)

^aR primers are used only in making representations of the tester and driver DNAs. The O and E primers are used in odd and even iterations of the subtractive/enrichment process. These were previously designated J and N in the original protocol (Lisitsyn et al., 1993).

^bUnderscores indicate restriction sites that are variable, but limited to those comprising restriction sites (i.e., can be changed to accommodate other enzymes). Nucleotides shown in bold outline invariant core sequences of the primers. Nucleotides which are neither bold nor underscored are completely variable.

100% ethanol, ice cold

70% ethanol, room temperature

3 M sodium acetate, pH 5.2 (APPENDIX 2)

EE × 3 hybridization buffer (see recipe)

5 M NaCl

5 µg/µl glycogen in TE buffer (see APPENDIX 2 for TE buffer)

10 U/µl mung bean nuclease and 10× buffer (New England BioLabs; UNIT 3.12)

50 mM Tris·Cl, pH 8.9 (APPENDIX 2)

Thermal Cycler (Perkin-Elmer Model 480 preferred)

24-mm GF/C glass microfibre filters (Whatman)

Dialysis tubing, 6,000 to 8,000 MWCO (Spectra/Pore)

Flat blunt forceps

18-G needle

Additional reagents and equipment for restriction digestion (UNIT 3.1), agarose gel electrophoresis (UNIT 2.5A), ethanol and isopropanol precipitation (UNIT 2.1A), and quantifying DNA by absorbance spectroscopy (APPENDIX 3D), gel isolation (UNIT 2.6), and sequencing (UNIT 7.1).

NOTE: Use de-ionized, distilled water in all recipes and protocol steps, and ensure that the water is RNase/DNase free. Since minute amounts of contaminating DNA may be detected by RDA, use barrier pipet tips throughout the protocol.

Prepare amplicons and representation: Enzyme restriction of tester and driver DNA

1. Using 10 U enzyme per microgram DNA and a total volume of 200 μ l (each), separately digest 5 μ g tester and driver DNA samples with the restriction enzyme chosen for representation (UNIT 3.1). Analyze 40 μ l (1 μ g) of each reaction by electrophoresis on a 1% agarose gel (UNIT 2.5A) to confirm complete digestion. Bring volume of remaining digest to 400 μ l each with water.

This step provides three to four times the DNA needed for the preparation of amplicons; therefore, if the amount of starting DNA is a limiting factor, as little as 1 to 2 μ g DNA can be used.

BglII, BamHI, and HindIII are the enzymes which were used in the original RDA publication by Lisitsyn and colleagues (1993). Oligomer/primers compatible with each of these enzymes are listed in Table 25B.7.1. These enzymes with corresponding oligomers have been extensively and successfully used in RDA applications; however, other enzymes may be used by adapting the restriction sites adjacent to the core sequences. In particular, four-base cutters may be more appropriate for less complex genomes.

2. Extract digested tester and driver with 1 vol phenol (400 μ l each) followed by 1 vol phenol:chloroform:isoamyl alcohol (400 μ l each). Ethanol precipitate DNA (UNIT 2.1A), adding 20 μ g glycogen and microcentrifuging at 4°C to increase recovery. Dry pellets and resuspend at 0.1 μ g/ μ l in TE buffer, pH 8.0, instead of water in the final step. Confirm DNA concentration by comparison to dilution of known standards by agarose gel electrophoresis (UNIT 2.5A).
3. Resuspend HPLC-purified primers/oligomers in water at 62 pmol/ μ l, an OD₂₆₀ of 6 or 12 AU/ml for 12- and 24-mers, respectively (APPENDIX 3D).

HPLC purification of oligomers is critical for minimizing false positive RDA bands (O'Neill and Sinclair, 1997).

Ligate adapters onto driver and tester DNA

4. Mix the following in thermal cycler tubes colored differently for tester and driver DNA:

2 μ l water
3 μ l 10 \times ligase buffer
7.5 μ l 12-mer (R primer)
7.5 μ l 24-mer (R primer)
10.0 μ l (1 μ g) driver or tester DNA digest
30 μ l total volume.

The use of tubes of different colors throughout the protocol helps distinguish between driver and tester samples to avoid confusion and cross-contamination of DNA.

5. Place tubes in a thermal cycler at 55°C. Program the thermal cycler to decrease the temperature to 4°C over 1 hr.

Slow annealing allows the 12- and 24-mers to form a temporary bridging complex with cohesive ends complementary to the restriction sites on the ends of the digested DNAs.

The Perkin-Elmer Model 480 is preferred because of its larger tube capacity, but any 96-well thermal cycler may also be used.

6. Add 1 μl of 400 U/ μl T4 DNA ligase, mix by gentle pipetting, and incubate 12 to 16 hr at 14°C.

This step results in ligation of the 24-mers onto the 5' ends of the DNAs. The temperature used is below the T_m of the four base duplexes formed by the overhanging ends.

7. Transfer ligation product to 1.5-ml microcentrifuge tubes matching the colors used above (step 4). Dilute adapter-ligated tester and driver DNA to 1 ng/ μl by adding 970 μl TE buffer.

PCR-amplify driver and tester amplicons

8. Prepare two tubes of PCR mix for preparation of tester amplicon and twelve tubes for driver amplicon, each containing:

240 μl water
80 μl 5 \times RDA PCR buffer
32 μl dNTP Chase solution
8 μl 24-mer oligonucleotide (R primer)
360 μl total volume.

9. Add 40 μl diluted adapter-ligated tester or driver DNA (40 ng) to corresponding PCR tubes (two for tester and twelve for driver) and place tubes in a thermal cycler 1 to 2 min at 72°C.
10. Fill-in 3'-recessed ends of the ligated adapters by adding 3 μl of 5 U/ μl (15 U) *Taq* DNA polymerase to each tube, mix by pipetting, and overlay with 110 μl mineral oil. Incubate 5 min at 72°C.

If using a 96-well PCR machine, double the number of tubes and halve the amount of PCR mixture for each tube such that four tubes of tester and twenty-four tubes of driver amplicon are made. With the 96-well PCR machine, no mineral oil is required. Do not let the tubes cool below 72°C in steps 9 or 10.

11. Perform the following two-step PCR program:

20 cycles:	1 min	95°C	(denaturation)
	3 min	72°C	(extension)
Final step:	10 min	72°C	(extension).

Quantitate amplicons and remove linkers

12. Pipet off as much mineral oil as possible. Combine the contents of both tester PCR tubes into a single 1.5-ml microcentrifuge tube. Combine driver tubes pairwise into single microcentrifuge tubes (i.e., six driver tubes total).

For the 96-well PCR format, combine the contents of four PCR tubes into a single 1.5-ml microcentrifuge tube.

13. Extract each tube with 1 vol phenol followed by 1 vol phenol:chloroform:isoamyl alcohol, isopropanol precipitate with 20 μg glycogen, and dry the pellets (*UNIT 2.1A*).
14. Resuspend driver and tester amplicons in TE buffer at a concentration between 0.2 to 0.4 $\mu\text{g}/\mu\text{l}$ (expecting ~ 15 μg of DNA from each 0.5-ml PCR tube). Pool driver DNA into a single tube. Confirm concentrations of driver and tester DNA by agarose gel electrophoresis (*UNIT 2.5A*) against DNA standards.

Enough of the driver amplicon needs to be prepared to provide sufficient amounts of DNA such that all rounds of hybridization use aliquots that are identical and derived from the same source. Calculate the total amount of driver DNA needed for the experiment (~ 40 $\mu\text{g}/\text{round}$) and if necessary, scale up driver amplicon production or perform additional driver amplicon amplifications and pool.

15. Digest 150 µg driver DNA and 15 µg tester DNA with initially chosen restriction endonuclease (step 1) in volumes of 400 µl to remove the adapters.
16. Repeat step 2 and resuspend in 125 µl TE buffer.

Expect the concentration of tester to be ~0.1 µg/µl and that of driver to be ~1 µg/µl.
17. Dilute 2 µl resuspended driver amplicon digest with 18 µl water to an expected concentration of 0.1 µg/µl. Load 0.2, 0.4, and 0.6 µg driver and tester amplicon digests and compare with DNA standards by 2% agarose gel electrophoresis (UNIT 2.5A). Using electrophoresis results as a guide, perform final dilution with TE buffer such that the driver amplicon digest concentration is 0.5 µg/µl and the tester amplicon digest concentration is 50 ng/µl.

Change adapters on tester amplicon

18. Load 5 µg (100 µl) tester amplicon DNA digest on a 1% agarose gel (UNIT 2.5A). Electrophorese at appropriate voltage until DNA in the range from 150 to 1500 bp can be resolved.
19. With a clean razor blade, cut two full thickness slits in the running lanes, one at 150 and another at 1500 bp.
20. Soak small pieces of 24-mm GF/C glass microfibre filter and 6,000- to 8,000-MWCO dialysis tubing in water. Make a two-layer barrier of filter and dialysis tubing and cut into rectangles slightly higher and wider than the agarose lane. Using a blunt flat forceps, insert the filter/dialysis tubing barrier into each of the slits with the filters facing the loading wells.

Be sure that the entire running lane is blocked by both the filter as well as the dialysis tubing.
21. Resume electrophoresis until DNA between 150 and 1500 bp has migrated onto the filter/dialysis tubing. Stop the electrophoresis and carefully remove the DNA embedded filter/dialysis tubing from the 150-bp slit.

DNA larger than 1500 bp should be blocked from migrating past the filter/dialysis membrane in the 1500-bp slit.

In the author's hands, this method gives better recovery than gel isolation and elution.
22. Cut the lid off a 0.5-ml PCR tube and puncture a hole in the bottom with an 18-G needle so that DNA can elute. Make a collecting apparatus comprised of the PCR tube placed inside a 1.5-ml microcentrifuge tube.
23. Place the filter/dialysis membrane into the PCR tube of the collecting apparatus. Microcentrifuge the collecting apparatus 5 min at 8,000 rpm, room temperature.
24. Discard the PCR tube and filter/dialysis tubing. Bring up volume of collected liquid to 400 µl with water and extract with 1 vol phenol followed by 1 vol phenol:chloroform:isoamyl alcohol. Ethanol precipitate DNA with 20 µg glycogen and dry the pellet as described (step 2).
25. Dissolve the DNA pellet in 30 µl TE buffer, check DNA concentration by agarose gel electrophoresis against DNA standards (UNIT 2.5A), and adjust the concentration to 0.1 µg/µl.
26. Ligate 1 µg purified tester amplicon DNA digest to primer set O, as described in steps 4 to 6 above.

The R set of primers used to make the driver amplicons is never used in subsequent subtractive/kinetic enrichment rounds to prevent driver amplification as a result of uncleaved primers.

27. Dilute the pellet to a concentration of 10 ng/μl by adding 70 μl TE buffer

If using HindIII, dilute the pellet to 25 ng/μl by adding 10 μl TE buffer.

Perform subtractive/kinetic enrichment

28. In a microcentrifuge tube, combine driver and tester by mixing 80 μl driver amplicon DNA digest (0.5 μg/μl) and 40 μl diluted tester amplicon ligate (0.4 μg for representations made with most six cutters or 1 μg for *HindIII* representation).

The first hybridization is done at a tester:driver ratio of ~1:100.

29. Extract once with 120 μl phenol:chloroform:isoamyl alcohol.
30. Ethanol precipitate DNA with ammonium acetate as follows:
- Add 30 μl of 10 M ammonium acetate and mix by pipetting.
 - Add 300 μl (2 vol) ice-cold 100% ethanol.
 - Add 1 μl (20 μg) glycogen and mix by inverting.
 - Chill 10 min at -70°C.
 - Microcentrifuge 20 min at 13,000 rpm, room temperature.
 - Carefully remove the supernatant.
 - Wash the pellet with 1 ml room-temperature 70% ethanol.
 - Dry pellet.
31. Add 4 μl EE × 3 hybridization buffer to the pellet. Resuspend by pipetting, incubate 5 min at 37°C, vortex 2 min, and then microcentrifuge at maximum speed to collect the sample at the bottom.
32. Transfer resuspended DNA to a PCR tube. In another PCR tube, add 1 μl of 5 M NaCl. Place both tubes in a thermal cycler preheated to 95°C and incubate 1 min. Centrifuge the tubes briefly to collect the contents at the bottom and immediately transfer the denatured DNA to the tube containing NaCl. Mix well by pipetting and overlay with 35 μl mineral oil.
33. Incubate the tube containing DNA and NaCl in the thermal cycler for an additional 4 min at 95°C to ensure that all DNA species are denatured.
34. Set the thermal cycler to hold >20 hr at 67°C. Incubate at least 18, but not more than 48 hr, to allow the DNAs to hybridize to complementary strands.

As a result of the vast excess of driver, the majority of fragments common to both the driver and tester populations will rapidly form driver:driver or tester:driver complexes. The fragments unique (or at a relatively higher quantity) in the tester will require a significantly longer period of time to completely hybridize and form tester:tester complexes.

Perform selective amplification

35. Remove as much of the mineral oil as possible without losing the hybridizing mixture. Dilute the DNA stepwise to a concentration of 0.1 μg/μl by first adding 8 μl of 5 μg/μl glycogen in TE buffer and mixing by pipetting, then adding 23 μl TE buffer and again mixing by pipetting, and finally adding 364 μl TE buffer and vortexing.
36. To fill-in the adapter ends, make two tubes of PCR mix (not containing 24-mer):

235 μl water
80 μl 5× RDA PCR buffer
32 μl dNTP chase solution
347 μl total volume.

Add 40 μ l diluted hybridized DNA (4 μ g) to each tube. Place tubes in thermal cycler set at 72°C.

This reforms priming sites at both ends of tester:tester complexes necessary for exponential amplification of difference products.

37. Add 3 μ l *Taq* DNA polymerase, mix by pipetting, and incubate an additional 5 min.

38. Add 10 μ l 24-mer primer (O primer set), mix by pipetting, and overlay with mineral oil.

If using a 96-well thermal cycler, double the number of tubes and halve the PCR recipe in each tube. In this case, addition of mineral oil is not necessary.

39. Perform the following two-step PCR program:

10 cycles:	1 min	95°C	(denaturation)
	3 min	72°C	(extension)
Final step:	10 min	72°C	(extension).

For the OBgl 24 primer, a lower annealing temperature of 70°C is required.

40. Remove as much mineral oil as possible and combine the contents of the PCR tubes in a microcentrifuge tube. Extract and isopropanol precipitate as described (step 13), but dissolve the pellet in 40 μ l water and do not pool DNA.

41. Digest single-stranded templates with mung bean nuclease (MBN) by mixing:

- 14 μ l water
- 4 μ l 10 \times mung bean nuclease buffer
- 20 μ l amplified difference product
- 2 μ l 10 U/ μ l mung bean nuclease (MBN)
- 40 μ l total volume.

Incubate at 30°C for 30 min.

42. Add 160 μ l of 50 mM Tris·Cl, pH 8.9. Inactivate MBN by incubating 5 min at 98°C.

43. Prepare two tubes of PCR mix (360 μ l) containing the O 24-mer primer as in step 8. Add 40 μ l MBN-treated difference product in each tube and place in a thermal cycler set at 72°C.

For OBgl 24-mer use an annealing temperature of 70°C.

44. Add 3 μ l of 5 U/ μ l (15 U) *Taq* DNA polymerase to each tube, mix by pipetting, overlay with 110 μ l mineral oil, and incubate 5 min at 72°C.

Again, double the number of PCR tubes and halve the given recipe placed in each tube if using a 96-well PCR machine.

45. Perform the following two-step PCR program:

20 cycles:	1 min	95°C	(denaturation)
	3 min	72°C	(extension)
Final step:	10 min	72°C	(extension).

For the OBgl 24 primer, a lower annealing temperature of 70°C is required.

46. Run 10 μ l amplified product on a 2% agarose gel with DNA concentration standards (UNIT 2.5A). If necessary to improve the yield, perform 1 to 3 more cycles after addition of 3 μ l fresh *Taq* DNA polymerase.

The quantity of DNA should be between 0.1 to 0.3 µg.

In subsequent iterations of this step, discrete products should be observed. Alternatively, the results of the agarose gel may suggest strategies for interventional troubleshooting (see Commentary). For example, a high background may indicate either primer hydrolysis or the need for increasing the stringency of the preceding hybridization step (i.e., decreasing tester relative to driver).

Change adapter on the difference product

47. Combine the contents of the two PCR tubes in one microcentrifuge tube (four tubes for the 96-well format). Extract and isopropanol precipitate as described in step 13.
48. Dissolve the pellet in 80 µl TE buffer. Determine DNA concentration by 2% agarose gel electrophoresis (UNIT 2.5A), and adjust to 0.1 µg/µl.
49. Digest 5 µg difference product (50 µl) with 10 U/µg chosen restriction enzyme (step 1) in a total volume of 200 µl. Bring volume of digested product up to 400 µl with water.
50. Extract and ethanol precipitate as described (step 2).
51. Resuspend DNA pellet at 0.1 µg/µl in TE buffer. Take 10 µl (1 µg) DNA solution and directly ligate to primer set E in a volume of 30 µl as described in steps 4 to 6.

Changing primer sets between each round of RDA ensures that selective subtractive/kinetic enrichment of unique tester DNA restriction fragments will occur from newly ligated primer and not from uncleaved primer carried over from the previous rounds.

52. Dilute the ligated difference product to 1.25 ng/µl with TE buffer.

For HindIII representation, dilute to 2.5 ng/µl with TE buffer.

Always ligate 1 µg tester, then serially dilute the ligation product to a concentration such that 40 µl will give the appropriate amount of tester for the selected tester:driver hybridization ratio.

Perform subsequent subtractive/kinetic enrichment steps

53. For a second subtractive/kinetic enrichment, mix 40 µl (50 ng) adapter-ligated difference product (100 ng for *HindIII* representation) and 80 µl (40 µg) of driver amplicon DNA digest. Proceed through subtractive/kinetic enrichment exactly as outlined in steps 28 to 51 except substitute E for O primers/oligomers and dilute the ligated difference product to 2.5 pg/µl (10 pg/µl for *HindIII* representation).

*The second hybridization is done at a tester:driver ratio of 1:800 (1:400 for *HindIII* representations).*

54. For a third subtractive/kinetic enrichment, mix 40 µl (100 pg) difference product from the second subtractive/kinetic enrichment (400 pg for *HindIII* representation) and 80 µl (40 µg) driver amplicon DNA digest. Proceed exactly as outlined in steps 28 to 51 using O primers/oligomers.

*The third hybridization is done at a tester:driver ratio of 1:400,000 (1:200,000 for *HindIII* representations).*

55. *For HindIII:* Use 5 pg difference product from the third subtractive/kinetic enrichment (tester:driver ratio of 1:8,000,000). Again, proceed through steps 27 to 51 of the protocol, except substitute E for O primers/oligomers, and use 27 cycles in the final PCR of the selective amplification (step 44).

For HindIII representation sometimes this fourth subtractive/kinetic enrichment is needed.

56. Clone products following gel isolation (UNIT 2.6) or use shotgun cloning and subsequent sequencing (UNIT 7.1).

cDNA REPRESENTATIONAL DIFFERENCE ANALYSIS

cDNA RDA works under the same principles as RDA of genomic DNA, and requires only minor modification from the procedure described above (see Basic Protocol 1). Two RDAs may be performed at the same time with the testers and drivers reversed in order to detect both induced as well as suppressed transcripts. There are two other modifications to Basic Protocol 1. The first is the substitution of *DpnII* or its isoschizomer *Sau3AI*, as the restriction endonuclease. *DpnII* is a four-base recognition enzyme that is compatible with the *BglII* and *BamHI* primers listed in Table 25B.7.1. The second is the use of different ratios of tester to driver in the sequential hybridizations. For cDNA RDA, the ratios of 1:10, 1:100, 1:500, and 1:25000 may be used (see Table 25B.7.2 for ranges of tester:driver ratios; Pastorian et al., 2000).

Table 25B.7.2 Tester:Driver Hybridization Stringencies for cDNA RDA

Subtractive/kinetic enrichment	Range of tester:driver ratios
Round 1	1:10–1:50
Round 2	1:100–1:500
Round 3	1:1000–1:5,000
Round 4	1:10,000–1:50,000

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

***EE* × 3 hybridization buffer**

30 mM 4-(2-hydroxyethyl)-1-piperazinepropanesulfonic acid (EPPS), pH 8.0 at 20°C
3 mM EDTA
Store up to 6 months at room temperature.

***RDA PCR buffer*, 5×**

335 mM Tris·Cl, pH 8.8 at 25°C (APPENDIX 2)
20 mM MgCl₂
80 mM (NH₄)₂SO₄
50 mM 2-mercaptoethanol
0.5 mg/ml BSA
Store up to 6 months at –20°C.

COMMENTARY**Background Information**

Representational difference analysis (RDA) was first described in 1993 and has been used to detect polymorphisms between individuals, positional synteny between species, and genetic lesions in neoplasms (Lisitsyn et al., 1993; Lisitsyn and Wigler, 1995; Lowrey et al., 2000). In addition to finding genomic alterations, RDA has been successfully used to identify exogenous sequences from DNA-based infectious agents (Chang et al., 1994). While RDA

was original applied to genomic DNA, the versatility of the technique allowed minor modifications in the protocol for the examination of differences in gene expression (Hubank and Schatz, 1994; Bakin and Curran, 1999; Reick et al., 2001; Shields et al., 2001) as well as the identification of new RNA viruses (Nishizawa et al., 1997; Birkenmeyer et al., 1998).

RDA has advantages and limitations when compared to other techniques used to detect

differences in genomic content. The first generation technique of subtractive hybridization requires large amounts of starting DNA and is inefficient, usually allowing only a 1:100-fold enrichment of target sequences. This is due to the complexity of eukaryotic genomes in which hybridization of complementary sequences cannot go to completion. Therefore, only very long or abundant sequences can be isolated. RDA circumvents this problem by the incorporation of a simplification step in which only a representation of the genome is used in the analysis. The simplification process is based on restriction endonuclease digestion of the genome and is accomplished by selective amplification of digested DNA fragments with lengths amenable to PCR followed by physical size selection. This simplification is key to successful RDA, but its disadvantage is that not all of the potential differences between two genomes will be found.

Many techniques are available for scanning differential gene expression, whether to ascertain changes that occur in development and differentiation, or that are associated with disease phenotypes. These include differential display, (*UNIT 25B.3*) cDNA array, serial analysis of gene expression (SAGE; *UNIT 25B.6*), and rapid analysis of gene expression (RAGE). In a novel combination of two techniques, RDA is performed first to generate products used as hybridization probes which are then applied to cDNA microarrays (Geng et al., 1998). Consideration must be given to the strengths and weakness of each tool in individual applications. The main advantages of using RDA are that the analysis is not limited to known sequences, it is efficient, and it is affordable for even small laboratories.

Critical Parameters and Troubleshooting

General considerations

DNA RDA is dependent on the generation of different DNA restriction fragments between driver and tester after restriction endonuclease digestion. Furthermore, the extra DNA fragment(s) must be found in the tester and not the driver, and must be within the size range for standard PCR amplification. Therefore, if the targeted genetic change does not result in a unique DNA fragment after digestion, then the change cannot be detected. In the case of DNA RDA, it is critical that the two samples to be compared are extracted from tissues or cells of

nearly identical genetic background. To look for polymorphism, tissues from closely related individuals of the same gender may be used. To look for genetic changes associated with a neoplastic phenotype, tumor and normal tissue from the same individual is appropriately matched, unless the genetic change is germline. Although translocations may be identified whether the neoplastic tissue is used as the driver or tester, deletions require the neoplastic DNA to be used as driver. When the nature of the genetic change is not known, it is reasonable to perform two RDA with the samples switched from their designation as driver or tester.

Several issues arise when hunting for a microbial agent. The agent's genome must be large enough to offer a DNA fragment which when digested is big enough to PCR, and the genome must go through a DNA stage in its life cycle. RNA viruses must be pursued using cDNA RDA. Optimally, samples are acquired in a sterile manner and are free from contaminating organisms. In particular, epithelial or mucosal surfaces should be dissected off prior to DNA extraction. Diseases primarily involving such tissues are difficult to analyze by RDA unless existing microbial flora is matched. Lastly, the infected tissue should always be used as the tester, keeping in mind that the infection may be disseminated. In a related cautionary, when working with cell lines, ensure that no mycoplasma infection is present in cultures and that transformed cell lines are not generated by viral infections (i.e., herpesviruses, papillomaviruses, or adenoviruses).

The use of PCR in RDA necessitates implementation of procedures that guard against DNA contamination. If RDA is performed repetitively, all work areas and surfaces should be monitored regularly for occult adapter-ligated products. This can be done with swipe tests followed by PCR with the O and E 24-mers. PCR preparation, amplification, and analysis should be isolated from each other if possible, dedicated micropipettors should be used, and reagents should aliquoted and changed frequently.

Amplicon preparation

In both DNA and cDNA RDA, the quality of the starting material is important. Tissues or cells used to generate tester and driver DNA should be subjected to the same harvesting, storage, and DNA extraction conditions. Use methods for DNA preparation which give relatively pure DNA to ensure complete digestion.

The amount, the completion of digestion, as well as the integrity of DNA should be assessed by agarose gel electrophoresis to confirm that smears of tester and driver DNA in the initial steps prior to hybridization are comparable in both intensity and size distribution. Agarose gel electrophoresis is the preferred method for evaluating products in the protocol, since this method allows not only concentration determination, but also visualization of DNA integrity. When preparing cDNA, any standard protocol or kit may be used; however, be aware that some reverse transcriptases may contain minute amounts of contaminating vector which can give false positive results. To ensure the highest quality full-length cDNA, poly(A) RNA should be immediately subjected to reverse transcription and second-strand cDNA synthesis with no intermediate storage or precipitations.

If the amount of amplicon generated is suboptimal, several more cycles of PCR may be performed with the addition of new *Taq* DNA polymerase; however, PCR-introduced distortions of representations can be expected to be more pronounced at higher cycle numbers.

Subtractive/kinetic enrichment

In every round of subtractive hybridization, the amount of driver DNA remains constant. The amounts of tester (the product from the previous round) will diminish round by round to ultimately yield only the difference product or the differentially expressed targets. For DNA RDA, increasing stringency occurs with successive tester:driver ratios of 1:100, 1:800, 1:400,000, and 1:8,000,000. The tester:driver hybridization ratios may be modified, particularly when performing cDNA RDA to detect rare transcripts or smaller fold differences in expression between tester and driver. If no DNA products appear as bands by agarose gel electrophoresis in the later rounds of RDA, it may help to start either the particular hybridization round or the entire RDA again with a less stringent tester:driver hybridization ratio (relatively more tester DNA). If too much background smearing occurs in later rounds of RDA and primer problems have been ruled out (see below), then a more stringent tester:driver hybridization ratio in the preceding round may help.

No difference products

RDA requires the generation of restriction fragments between 200 to 1000 bp to ensure optimal PCR amplification. Because of this simplification step, a particular restriction strat-

egy may fail to find sought after differences. Therefore, if no difference products are isolated after iterative rounds of kinetic/subtractive enrichment, alternate restriction endonucleases may be tried. The placement in the tester sample of an internal control with known restriction characteristics at the beginning of an RDA experiment can be used; however, to prevent preferential amplification of the internal control, the internal standard should be spiked at sufficiently low concentrations (<1:100,000 on a weight basis).

Too many difference products or high background

HPLC purification of oligomers is critical for minimizing false positive RDA bands (O'Neill and Sinclair, 1997). Additionally, repeated thawing and freezing of primers in aqueous solution results in increased primer hydrolysis and contributes to mispriming during PCR amplification. This may result in increased false positives, increased rounds required to isolate true difference products, and excessive background smearing. Primers can be stored in lyophilized aliquots to circumvent this problem.

Anticipated Results

The RDA protocol selectively enriches for unique DNA sequences in the tester DNA sample. Upon completion of RDA, enriched populations of DNA can be visualized on agarose gel electrophoresis as a few or several distinct bands that range usually from between 150 to 800 bp. Although a significant background smear with only poorly identifiable bands may be seen at the end of the first round of kinetic/subtractive enrichment, successive rounds of enrichment should result in sharper bands with clean backgrounds. Even if discrete bands appear in the first or second rounds of RDA, three or more rounds are typically required to minimize background amplimers or stochastically amplified false positives. Authentic bands can then be cloned by a variety of different approaches. Sequence analysis of clones should reveal authentic endonuclease restriction sites at the termini of the inserts. It is not unusual to identify more than one discrete DNA fragment from each band; however, the majority of the clones should contain a single true positive difference product.

Time Considerations

Preparation of amplicons and representations requires 4 days. Each round of DNA

kinetic/subtractive enrichment also requires 4 days. If three rounds are performed, an RDA experiment exclusive of DNA and cDNA preparation or subsequent cloning can be completed in 16 days. Four rounds require 20 days. With some consideration for life's distractions, an RDA experiment can be performed in 4 weeks.

Acknowledgments

The contributor would like to thank Nikolai A. Lisitsyn, Michael Wigler, and Craig V. Byus for providing detailed laboratory protocols for RDA, Roy Bohenzky and Patrick S. Moore for helpful discussion, and Patrick S. Moore for review of the protocol.

Gene Expression Analysis of a Single or Few Cells

UNIT 25B.8

The need to analyze rare or even single cells is based on the dynamic nature of tissue differentiation and regeneration, the initiation and propagation of disease processes in multicellular organisms, and the functional diversity of individual cells. Gene transcription is the most important regulatory mechanism by which a phenotype and functional state of a cell is determined. Therefore, qualitative and quantitative assessment of mRNA abundance is not only a first step into the nature of biological processes but is easier to investigate in a comprehensive way than protein expression when small cell numbers are used.

In this unit, a protocol that allows a semi-quantitative analysis of gene expression of a single cell and a quantitative representation of expressed genes from >10 to 30 cells is described. This unit concentrates on the amplification procedure (see Basic Protocol 1) and less on the cDNA array hybridization. However, a basic protocol (see Basic Protocol 2) for array hybridization on nylon filters is provided because such filters are available in every laboratory without the need of additional expensive equipment. As tissue samples contain many different cell types in variable amounts, their analysis often requires microdissection of the tissue to isolate the specific cell types. Therefore, additional information on how to isolate mRNA from very small tissue samples such as biopsies and laser-microdissected material from cryosections (see Alternate Protocols 1 and 2) is given. Finally, a simple procedure to prepare the data for statistical analysis is also provided (see Basic Protocol 3).

STRATEGIC PLANNING

This unit deals with the handling of minute amounts of mRNA. Therefore, two “natural foes,” contamination and RNA degrading enzymes (RNases; see *UNIT 4.1* for additional details), will be encountered. Contamination can be reduced by working under a laminar-flow clean bench that has never been exposed to PCR-amplified DNA or cloned DNA, and that is preferably located in a room apart from laboratories where DNA is handled. It is recommended to always use filter tips for solutions and to take care not to contaminate pipets or other devices with DNA from other rooms. Unfortunately, contamination might still occur since many enzymes (in particular, reverse transcriptase) contain traces of bacterial DNA/RNA that will be co-amplified with the desired single-cell mRNA. For many assays, this bacterial DNA will not interfere, but may be a potential source of trouble. Degradation of RNA by RNases can be avoided by the use of powder-free gloves (changing them frequently) and being cautious when preparing buffers. RNase inhibitors are not added because they are frequently derived from human placenta and might therefore be contaminated with human nucleic acids. Working quickly and placing probes on ice is also recommended.

GLOBAL AMPLIFICATION OF SINGLE-CELL cDNA

This PCR-based protocol has been developed for maximal sensitivity of transcript detection. This raises the concern of exponential-error transmission, which will be discussed in detail along with the means that have been undertaken to reduce this error. However, one has to be aware that by using this method an exact quantification of the transcripts from a single cell is not possible; rather, semi-quantitative results are obtained.

Differentially
Expressed Genes**

25B.8.1

paramagnetic oligo-dT beads. While the mRNA is bound to the beads, reaction buffers can easily be changed without loss of mRNA or cDNA. This allows using optimal (i.e., high) concentrations of cDNA primers and nucleotides during cDNA synthesis without interference with the subsequent tailing reaction. To avoid loss of transcripts, do not contaminate the reaction with RNases because the mRNA holds the newly synthesized cDNA to the bead. After cDNA synthesis and before starting the tailing reaction, the unbound cDNA synthesis primers and unincorporated dNTPs have to be washed out. Tailing is performed in a KH_2PO_4 buffer that, unlike the provided potassium-cacodylate buffers, does not inhibit the subsequent PCR reaction, which is set up in the same reaction tube without discarding the tailing buffer.

Random primers were originally used because they reduced the length of an amplicon and allowed amplification of 5'-sequences. These random primers, combined with oligo-dT primers, slightly improve the results when single cells are used (CFL5 primer mix). However, when higher cell numbers (>100) are used, it appears that random primers alone work at least as well as the combination. For single cells, a random octamer increases the average fragment length, compared to a random hexamer, by ~100 to 200 bp. Due to the increasing number of commercially available oligo arrays that are restricted to the 3'-end, it might be advantageous to use oligo dT primers alone. The authors' first experiments indicate that the CFL5CT₍₂₄₎ primer should be used in this instance.

Materials

Oligo dT kit (Dynal) including:

Dynabeads Oligo (dT)₂₅

Washing buffer containing LiDS

Lysis buffer

Phosphate-buffered saline (PBS; APPENDIX 2)

5× RT buffer (Life Technologies)

0.1 M DTT (Life Technologies)

10% (v/v) Igepal

cDNA synthesis primers:

For mRNA amplification for ≥100 cells:

CFL5C6: 5'-(CCC)₅ GTC TAG ANN NNN N-3' (200 μM)

For single cells and 5' and 3' coverage:

CFI5C8: 5'-(CCC)₅ GTC TAG ANN NNN NNN-3' (200 μM)

CFI5CT: 5'-(CCC)₅ GTC TAG ATT TTT TTT TTT TTT TVN-3' (100 μM)

CFL5 primer mix: 1 vol CFI5c8 (200 μM) + 1 vol CFI5cT (100 μM)

For the use of 3'-restricted oligo arrays:

CFI5CT₍₂₄₎: 5'-(CCC)₅ GTC TAG ATT (T)₂₂ VN-3'

10 mM and 200 μM dNTPs

Reverse transcriptase (Superscript II; Life Technologies)

Igepal wash buffer (see recipe)

Tween 20 wash buffer (see recipe)

40 mM MgCl_2

2 mM dGTP

200 mM KH_2PO_4

Tailing wash buffer (see recipe)

Mineral oil

Terminal deoxynucleotide transferase (TdT; Amersham Pharmacia Biotech)

Expand Long Template (ELT) PCR system (Roche Diagnostics) including:

10× ELT buffer 1 (17.5 mM MgCl_2)

3.5 U/μl DNA polymerase mix

20% (v/v) formamide
 PCR primer, CP2: 5'- TCA-GAA-TTC-ATG-CCC-CCC-CCC-CCC-3' (24 μ M)
 1 \times PCR buffer (Sigma)
 Primers for β -actin: 5'- CTA CGT CGC CCT GGA CTT CGA GC-3' and 5'-GAT GGA GCC GCC GAT CCA CAC GG-3'
 Primers for EF-1 α : 5'- GCA GTG CAC ACA CAG AGG TGT A-3' and 5'- CTA CCG CTA GGA GGC TGA GCA A-3'
 0.75 U *Taq* DNA polymerase (Sigma)
 Magnet separation apparatus for 0.2-ml tubes (Dynal)
 0.2-ml PCR tubes
 15- to 50-ml tubes
 Roller-bottle apparatus or other rotisserie-type rotator
 Thermal cycler
 Hybridization oven or other rotator with temperature control
 Additional reagents and equipment for agarose gel electrophoresis (UNIT 2.5A)

Lyse cells and isolate mRNA

1. Wash beads two times in an equal volume of washing buffer containing LiDS using the magnet.

Dynal beads are supplied as a solution and have to be washed using the magnet prior to use. Resuspend beads in adequate volume of lysis buffer to which the cells or tissue biopsies are added.

The beads must completely adhere to the side of the tube at the site of the magnet before the supernatant is removed to avoid loss of beads. This wash procedure can take several minutes. Do not forget to prepare beads for the negative control.

2. Resuspend beads in an equal volume of lysis buffer. The amounts of lysis buffer and beads depend on the cell number. Table 25B.8.1 suggests the volumes of lysis buffer and beads to use for specific numbers of cells.

3. Pick cells in 1 \times PBS (APPENDIX 2) in the smallest possible volume. Pick single cells in a 1- to 2- μ l volume and add to the beads in lysis buffer in a 0.2-ml PCR tube.

Individual cells can be isolated from suspensions using a 2- μ l automatic pipettor and an inverted microscope.

Cell numbers >3000 in one reaction tube should be avoided because the released genomic DNA will clump the beads and prevent successful isolation of mRNA. When more cells are used, either use up to 500 μ l of lysis buffer with 50 μ l of beads, use aliquots, or isolate total RNA first by classical protocols (e.g., UNIT 4.1) and add the RNA (1 to 10 μ g total RNA) to the beads.

4. Place the 0.2-ml PCR tubes in a 15- to 50-ml tube and rotate the lysate for 30 min at 4° to 20°C (room temperature) in a roller-bottle apparatus.

Rotation ensures that the beads remain suspended.

If desired, freeze the sample after this step at -80°C. The authors have stored samples for up to 12 months without any negative effect. On continuation, resuspend the beads after thawing and rotate for 5 min.

Table 25B.8.1 Volumes of Beads and Lysis Buffer for Given Numbers of Cells

No. of cells	Oligo dT beads	Lysis buffer
1–10	10 μ l	10 μ l
11–50	30 μ l	30 μ l
51–300	50 μ l	50 μ l
>300–3000	50 μ l	50–200 μ l

^aAll solution volumes are indicated in microliters.

Synthesize cDNA

5. Prepare cDNA synthesis mix I and II (see Table 25B.8.2) on ice while the beads are rotating. Add the reverse transcriptase to mix II just before use.

Never use a reverse transcriptase with RNase H activity.

6. Add an equal volume of Igepal wash buffer to the cell lysate containing the mRNA bound to the beads and place tube in the magnet. Remove supernatant after the beads have completely adhered to the tube at the site of the magnet. Resuspend beads carefully in 20 μ l Tween 20 wash buffer. Transfer to a fresh 0.2-ml tube, place in the magnet, and remove the supernatant after complete adhesion of beads to the magnet.

The multiple washing steps as well as the change of the reaction tube serve to remove the LiDS-containing buffer, since even small traces of LiDS can inhibit reverse transcription. It is very important to allow complete adhesion of the magnetic beads to the tube wall at the site of the magnet to avoid loss of cDNA. Note that collection of the supernatant and storage at -20°C may be desired because it contains the genomic DNA that can be used for additional analyses at a later time.

7. Resuspend beads in cDNA synthesis mix I and allow primers to anneal for 2 min on the bench at room temperature, then add mix II (remember to add the RT in mix II). Immediately start cDNA synthesis by placing the tubes in a hybridization oven for 45 to 60 min at 44°C with rotation.

It is important to rotate so that the beads remain suspended.

The authors tape the 0.2-ml sample tubes to pre-heated hybridization bottles.

8. Prepare tailing mix (see Table 25B.8.3).
9. Place tubes in the magnet and remove supernatant. Wash beads one time in 20 μ l tailing wash buffer. Pre-heat thermal cycler to 94°C .

After cDNA synthesis and before starting the tailing reaction, the unbound cDNA synthesis primers and unincorporated dNTPs have to be washed off. Therefore, meticulously remove all of the cDNA synthesis solutions by carefully pipetting, because dNTPs and primers will interfere with the tailing reaction.

Table 25B.8.3 Tailing Mix^a

No. of samples	1	2	3	4	5	6	7	8	9	10

^aAll solution volumes are indicated in microliters.

Tail cDNA

- Resuspend beads in tailing mix and add 40 μl mineral oil on the surface. Place the 0.2-ml tubes in the preheated thermal cycler and denature RNA-DNA hybrids for 5 min at 94°C. Immediately chill on ice.

This step serves to generate single-stranded cDNA, which is tailed with high efficiency in contrast to RNA-DNA hybrids. (After denaturation, the cDNA is no longer bound to the magnetic beads but is now found in the supernatant.) The following tailing and PCR procedure will take place with the beads in the tube.

- Add 10 to 15 U TdT, mix thoroughly, and start tailing in a thermal cycler programmed for 60 min at 37°C, then 22°C indefinitely.

Tailing is complete after 1 hr, but can be extended overnight at 22°C, whenever necessary.

- Inactivate TdT by incubating cDNA at 70°C for 5 min.

Amplify by PCR

- Prepare PCR mix I and II on ice (see Table 25B.8.4).
- After inactivation of TdT, add PCR mix I to the aqueous phase under the mineral oil. Incubate for 30 sec at 78°C.
- Add 5.5 μl mix II, then carry out the amplifications in a thermal cycler with the following parameters:

1 cycle:	30 sec	78°C
19 cycles:	15 sec	94°C
	30 sec	65°C
	2 min	68°C

continued

20 cycles:	15 sec	94°C
	30 sec	65°C
	2.5 min + 10 sec/cycle	68°C
1 cycle:	7 min	68°C
	indefinitely	4°C.

The separation of mix I and II serves for the hot-start procedure. Add the largest solution volume first, which consists of buffer and water. After 78°C has been reached, add the primers, nucleotides, and enzymes. Taq long template is one of several available mixtures of a highly processive DNA polymerase (Taq-polymerase) and a proof-reading enzyme with 3'-5' exonuclease activity (Pwo-polymerase). The exonuclease activity would degrade the single-stranded CP2 primer in absence of dNTP, which consequently has to be included in mix II. The reason for the hot start is to avoid unspecific priming and extension of the CP2 primers (that bound to the single-stranded cDNA at low temperatures) until 94°C is reached. The longer extension time in cycles 20 to 39 is due to the increased amount of product.

16. Store sample at -20°C.

Evaluate global amplification and validate genes

17. Check 3 to 5 µl of the primary PCR on a 1.5 % agarose gel for the presence of a smear in the range of 300 to 2000 bp.

18. Test amplification success by performing gene-specific PCR on at least two house-keeping genes.

For human cells, use the primers for β-actin and EF-1α (see Materials) in the conditions outlined below (see step 19). For other species, choose/design primers specific to house-keeping genes of those species.

To test amplification success, perform gene-specific PCRs for selected genes. Each gene-specific PCR should be individually optimized. For most transcripts, best results will be obtained after dilution of the primary amplifications in water (1:10). As the length of the amplified cDNA is usually <1000 bp, choosing primers that amplify sequences of 150 to 200 bp is recommended, as this size range produces the best results.

19. Make up a PCR reaction containing 2.5 ng of each cDNA in a 25-µl reaction containing 1× PCR buffer (Sigma), 200 µM dNTPs, 0.4 µM of each primer (β-actin or EF-1α), and 0.75 U Taq polymerase. Carry out the amplifications in a thermal cycler with the following parameters:

1 cycle:	2 min	94°C
	30 sec	58°C
	2 min	72°C
14 cycles:	40 sec	94°C
	30 sec	58°C
	20 sec	72°C
15-45 cycles:	40 sec	94°C
	30 sec	58°C
	30 sec	72°C
1 cycle:	40 sec	94°C
	30 sec	58°C
	2 min	72°C
	indefinitely	4°C.

The number of cycles in the main part of the amplification can be 15 to 45, depending on the transcript abundance.

20. Run PCR products on a 2% agarose gel containing 0.5 µg/ml ethidium bromide.

EXTRACTION OF mRNA FROM SMALL TISSUE BIOPSIES

This protocol is used to isolate and amplify mRNA from small biopsies that are obtained during diagnostic clinical procedures and do not undergo laser microdissection (*UNIT 25A.1*). The fresh biopsy is immediately snap-frozen in liquid nitrogen and stored in liquid nitrogen or at -80°C until lysis and mRNA preparation is performed.

Additional Materials (also see *Basic Protocol 1*)

Biopsy sample
Liquid nitrogen
Dry ice
Mortar and pestle

1. Use only a small piece of the biopsy sample with a size of 1 to 1.5 mm in diameter.
2. Using a mortar and pestle, crush the frozen tissue sample in liquid nitrogen.

Prior to using the mortar and pestle, destroy all nucleic acids by UV irradiation. Expose the internal surface of the mortar to UV light in a transilluminator or hold it close to a UV light source (254-nm wavelength) for 10 to 15 min. For the pestle, in order to expose the whole surface, it will be necessary to turn it, as only DNA lying in the direct path of the light will be destroyed by the UV irradiation (also see APPENDIX 3F for sterile technique).

Thawing of the sample must be avoided under all circumstances! Therefore, place the mortar on dry ice and frequently pour liquid nitrogen over the sample.

3. Add the powdered sample directly to 50 μl of prepared Dynal beads (see *Basic Protocol 1*, steps 1 and 2) and rotate lysate as in *Basic Protocol 1*, step 4.
4. Proceed with global amplification in *Basic Protocol 1*, steps 5 through 20.

EXTRACTION OF mRNA FROM MICRODISSECTED SAMPLES

Laser microdissection is the cleanest way to isolate selected morphologically defined cell groups from tissue sections. However, it is also possible to scratch the tissue area with a glass needle of which the tip is then broken into the lysis buffer. The authors use the PALM Laser-MicroBeam System (PALM) that first cuts the selected area by a laser beam and then catapults it into the lid of the reaction tube (see Fig. 25B.8.2). Other laser microdissection systems (see *UNIT 25A.1*) should work equally as well, as long as the isolation does not change the composition of the lysis buffer. The combination with *Basic Protocol 1* (Global Amplification) and *Basic Protocol 2* (Non-Radioactive Gene Expression Analysis on Nylon Arrays) enables quick analysis of global gene expression from 30 to 200 cells from 5- μm sections.

Materials (also see *Basic Protocol 1*)

Resectioned tissue snap-frozen in liquid nitrogen and stored at -80°C (see *Alternate Protocol 1*)
OCT embedding compound (Tissue-Tek, Miles; also see *UNIT 25A.1*)
Mayer's hematoxylin solution (Sigma)
70%, 95%, and 100% ethanol
Lysis buffer from Oligo dT kit (see *Basic Protocol 1*)
Cryostat
Slides for the PALM Laser-MicroBeam System (PALM)
PALM Laser-MicroBeam System (PALM)

Figure 25B.8.2 Isolation of small tissue samples by laser microdissection and catapulting using the PALM system.

1. Embed the tumor sample in OCT embedding medium (*UNIT 25A.1*) and cut the sample to 5- μ m thick slices on slides for the PALM Laser-MicroBeam System using a cryostat.
2. Place the slides in Mayer's hematoxylin solution for 45 sec, in water for 5 min, and in distilled water for 1 min.
3. Dehydrate sections in 70%, 95%, and 100% ethanol for 60 sec in each concentration.
4. Dry stained tissue sections overnight at room temperature.

The slides are ready for the Laser-MicroBeam System.

For the PALM Laser-MicroBeam System, the sections have to be completely dried, otherwise the heat generated by the laser beam will be transmitted, boil the tissue, and destroy the mRNA. If using a different microdissection system, individually establish the conditions and parameters.

5. To catch the catapulted tissue area in the lid of a PCR reaction tube, pipet 5 μ l lysis buffer on the inner wall of the lid.
6. Centrifuge the lysed tissue (mRNA and DNA) at maximum speed and proceed with mRNA isolation and global amplification (see Basic Protocol 1).

NON-RADIOACTIVE GENE EXPRESSION ANALYSIS ON NYLON ARRAYS

This protocol allows one to assay the expression of many genes whose mRNAs are represented in the amplification in Basic Protocol 1 without expensive equipment. It also assesses the complexity of sequences within the amplification, which can be helpful before proceeding to more detailed analyses. Test filters may be self-prepared by spotting 5 to 50 ng of each cDNA sequence (each should have a length of 300 to 700 bp) in 1 to 2 μ l of 0.1 M NaOH on a positively charged nylon membrane. There are also several commercially available products. See Chapter 22 for methods to prepare and assay arrays on glass slides.

**BASIC
PROTOCOL 2**

**Discovery of
Differentially
Expressed Genes**

25B.8.9

Materials

Expand Long Template (ELT) PCR system (Roche Diagnostics) including:
10× ELT buffer 1 (17.5 mM MgCl₂)
3.5 U/μl DNA polymerase mix
1/7 dNTP mix (see recipe)
20% formamide
CP2 primer: 5'-TCA-GAA-TTC-ATG-CCC-CCC-CCC-CCC-3' (24 μM)
Digoxigenin-11-dUTP (Dig-UTP), alkali labile (Roche Diagnostics)
Sample
DIG Easy Hyb solution (Roche Diagnostics)
E. coli DNA
DNase I
Labeled probe
Herring sperm DNA (Invitrogen)
20× SSC
10% SDS
Development buffer 1 (see recipe)
Development buffer 2 (see recipe)
DIG Luminescent Detection Kit (Roche Diagnostics) containing:
Blocking reagent
750 U/ml anti-digoxigenin-AP (Fab fragment) antibody
11.6 mg/ml CSPD
Tween 20 (Sigma)
Development buffer 3 (see recipe)
Thermal cycler
Nylon membrane containing an array of cDNAs (either self-prepared or commercially available)
Hybridization tubes
Hybridization oven or other rotator with temperature control
1.5-ml microcentrifuge tubes
Acetate sheets
Whatman 3MM filter paper
Biomax ML film (Kodak)

Label amplifications with Dig-UTP

1. Prepare PCR master mix as in Table 25B.8.5. Pipet 49-μl aliquots in sterile PCR tubes, add 1 μl from the sample (i.e., from the PCR product obtained in Basic Protocol 1, step 15) and program the thermal cycler with the following parameters:

1 cycle:	2 min	94°C
	4 min	68°C
10 cycles:	15 sec	94°C
	4 min	68°C
2 cycles:	15 sec	94°C
	4 min + 10 sec/cycle	68°C
1 cycle:	7 min	68°C
2. Determine the concentration of the amplified DNA (see UNIT 2.6, Support Protocol).
3. Prehybridize nylon array by placing the nylon membrane containing the cDNA array in a small hybridization tube, add 6 ml DIG Easy Hyb solution supplemented with 100 μg/ml *E. coli* DNA that has been digested with DNase I to a size of 100 to 1000 bp, and prehybridize for at least 6 hr at 45°C.

^aAll solution volumes are indicated in microliters.

Be aware that several commercial membranes are heavily contaminated with bacterial and/or plasmid DNA. The additional DNA in the hybridization solution serves not only to block all non-specific binding of labeled probe but also any amplified bacterial/plasmid DNA contaminating the enzyme preparations used to generate probes. All enzyme preparations contain traces of bacterial RNA/DNA that will be amplified by the highly sensitive amplification protocol and sometimes hybridize to bacterial/plasmid DNA on the filters. Therefore, even with the additional DNA, some poor arrays might not be usable. Always test the quality of the arrays by labeling and hybridizing a probe that has been amplified by the protocol in the absence of cellular RNA (negative control), in which contaminating DNA from the enzymes can be expected to be present as in the cell samples.

Note that although some favor the opposite nomenclature for array hybridizations, the authors use the term “probe” to refer to the labeled DNA in solution.

Add probe to membrane

- Mix in a 1.5-ml microcentrifuge tube, 1 ml DIG Easy Hyb solution, 6 μg of the labeled probe from step 1, and 100 μg of herring sperm DNA. Denature 5 min at 94°C and immediately add to the prehybridization solution in the hybridization tube. Incubate with slow rotation at least 36 hr at 45°C.

It is important that the nylon membrane be completely covered with the hybridization solution before rotating. Otherwise, high non-specific backgrounds will result due to the drying of the membrane during hybridization. Therefore, adjust the amount of hybridization solution to add to the prehybridization accordingly.

Additionally, do not pour the concentrated probe directly onto the filter. This will result in high background.

Wash the membrane

- Remove the hybridization solution and wash the membrane in the bottle and in the hybridization oven at 68°C using the following regimen:

- 1 min in 2× SSC + 0.1% SDS
- 1 min in 1× SSC + 0.1% SDS
- 15 min in 0.5× SSC + 0.1% SDS
- 30 min in 0.1× SSC + 0.1% SDS (two times)

Warm all solutions to 68°C prior to use in a water bath.

The hybridization mix can be stored at –20°C and re-used for additional filters. Before re-using the hybridization mix, denature the solution for 10 min at 80°C.

- Wash the membrane in development buffer 1 for a few seconds at room temperature, then block in 25 ml development buffer 2 for 30 min with gentle agitation.

7. Dilute 2.5 μ l anti-digoxigenin-AP (Fab fragment) antibody directly into the 25 ml development buffer 2 and incubate for an additional 30 min at room temperature.
8. Pour off development buffer 2 and wash two times, 15 min each, in development buffer 1 containing 0.3% Tween 20 at room temperature.

This step will remove the unbound antibody.

Detect binding with chemiluminescent substrate

9. Prepare 50 ml of development buffer 3 and prepare 1 ml of chemiluminescent substrate by mixing 10 μ l CSPD with 990 μ l development buffer 3. Equilibrate the membrane for a few seconds in the remaining development buffer 3.
10. Place the membrane between two acetate sheets. Lift the top sheet of plastic and add 1 ml of the chemiluminescent substrate (from step 9), scattering the drops over the surface of the membrane. Carefully lower the top sheet of plastic without producing any bubbles.
11. Incubate on the bench 5 min at room temperature. Remove the membrane from the plastic sheets and place on a sheet of Whatman 3MM paper for a few seconds to remove excessive chemiluminescent substrate, then put the membrane back between two clean, dry acetate sheets.

It is important to remove any excess moisture from the membrane. This avoids the development of background during film exposures up to 60 min. However, the membrane should not completely dry out because this would exclude any further use.

12. Incubate 15 min at 37°C and place the membrane on film to be exposed.

The 37°C-incubation allows the alkaline phosphatase reaction to reach a steady state quickly. The authors recommend 15 min for the first exposure, then adjust the time according to the signal strength.

BASIC PROTOCOL 3

DATA ANALYSIS OF HYBRIDIZED cDNA ARRAYS

There are several ways to analyze and normalize the data obtained by gene-expression profiling with cDNA arrays. This protocol describes a method to measure differences of signal intensities of differentially expressed genes and to normalize the signal intensities to several housekeeping genes. See *UNIT 22.3* for other information regarding data analysis.

Materials

- Photographic step tablet (Kodak)
- Transparency scanner that can be calibrated (e.g., SNAPSCAN, Agfa)
- Labscan software or equivalent (Scanwise v. 1.2.1, Agfa)
- Array Vision software or equivalent (Clontech)
- Excel software or equivalent (Microsoft)
- SPSS software or equivalent (SPSS)

Perform intensity calibration of the scanner

1. Define the known density values from the photographic step tablet.

To analyze the signal intensity on the X-ray film, it is important to measure its optical density. Signal intensity is usually measured in units, which do not necessarily represent the same “real-world” values in different images. It is important to calibrate a scanner before measuring the optical density of the signals. Therefore, by indicating raw intensity values in an image and defining their corresponding optical density, the system can be provided with the information it needs to convert its measurements to real-world quantities.

2. Scan the photographic step tablet in the grayscale mode values that have been entered.

The Kodak No. 2 Photographic Step Tablet Standard values are provided as optical density values, starting at 0.05 and proceeding at 0.15-OD increments to 3.05 OD units. At least four calibration points are necessary to compute a calibration curve.

3. Compute a calibration curve.

At least three different curve models are available. The linear option calculates the curve with the formula: $y = ax + b$; the quadratic option with the formula: $y = ax^2 + b$; and the log linear option with the formula: $y = a \log ((255 - x)/255) + b$. The authors recommend the log linear option.

Scan the developed films

4. Scan the grayscale of the developed films in the transmission mode with a resolution of at least 600 dpi.
5. Save files as MD GEL (*.gel), MCID (*.im), BRS (*.img), TIFF (*.tif), TIFF5 (*.tif), Fujix Bas Series (*.inf), Bio-Rad PA (*.img), Packard (*.tif), or MD Dataset (*.ds).

Other data formats cannot be imported by the array vision software.

Analyze with software

6. Define a template according to the grid of the cDNA arrays that were used.
7. Import the scanned films as a data file into arrays vision.
8. Align the grid to the corresponding spots on the cDNA array.
9. Normalize the signals to the housekeeping genes present on the cDNA array.

The average of the signals of the housekeeping genes is set to a value of one and the background to a value of zero.

10. Sample the template.
11. Export the gained data to MS Excel and/or SPSS for further statistical analysis.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Development buffer 1

100 mM maleic acid
150 mM NaCl, pH 7.5
Autoclave and store up to 6 months at room temperature

Development buffer 2

100 mM maleic acid
150 mM NaCl, pH 7.5
1% blocking reagent (DIG Luminescent Detection Kit, Roche Diagnostics)
Store up to 12 months at -20°C

Development buffer 3

100 mM Tris-Cl, pH 9.5 (APPENDIX 2)
100 mM NaCl
Prepare fresh just prior to use.

dNTP mix, 1/7

10 mM dCTP
10 mM dGTP
10 mM dATP
8.4 mM dTTP
Store up to 12 months at -20°C

Igepal wash buffer

50 mM Tris·Cl, pH 8 (*APPENDIX 2*)
75 mM KCl
10 mM DTT
0.25% (v/v) Igepal CA-630 (Sigma)
Store up to 12 months at -20°C

Tailing wash buffer

50 mM potassium phosphate, pH 7 (*APPENDIX 2*)
1 mM DTT
0.25% (v/v) Igepal CA-630 (Sigma)
Store up to 12 months at -20°C

Tween 20 wash buffer

50 mM Tris·Cl, pH 8 (*APPENDIX 2*)
75 mM KCl
10 mM DTT
0.5% (v/v) Tween 20
Store up to 12 months at -20°C

COMMENTARY

Background Information

Overview of amplification methods for small amounts of mRNA

With the completion of the human genome project and the introduction of technologies such as DNA microarrays and laser microdissection, many fields in biology and medicine await the application of comprehensive gene expression analyses of specific cell types isolated from defined tissues. The first protocols for the amplification of single cell mRNA were introduced in the late 1980s and early 1990s (Belyavsky et al., 1989; Brady and Iscove, 1993) and their development as well as their technical differences and application have been recently reviewed (Brady, 2000). All protocols are based on either of two principal approaches—linear amplification by T7 RNA polymerase or PCR amplification. Both procedures have advantages and disadvantages, and the one used depends on the experimental situation.

As a general rule, PCR-based methods are easier to handle and less time consuming, although there are concerns about the quantitative reliability of measurements obtained after

exponential amplification (Brail et al., 1999). The linear amplification achieved by T7 RNA polymerase, also referred to as the Eberwine protocol (Eberwine et al., 1992; Kacharina et al., 1999), has the advantage that a failure to amplify a given transcript will not be exponentially transmitted. On the other hand, there are several publications using PCR-based protocols showing that the relative abundance of transcripts is preserved even after 50 cycles. T7 RNA polymerase-based methods have been applied to cDNA and oligonucleotide arrays, but so far, the least number of cells that could be used successfully was ~1000 (Luo et al., 1999).

The methods provided in this unit are PCR approaches, and therefore are inherently prone to exponentially propagate initial amplification errors. The authors' primary intention was to obtain a qualitative representation of a single-cell transcriptome rather than preserving the numerical ratios of transcript abundance (Klein et al., 2002). Having established the method for single cells, the authors saw that quantitative differential analysis of gene expression with higher cell numbers (100 to 1000 cells) works quite well (Zohlnhofer et al., 2001a,b). This

seems to result from the fact that all experimental steps were optimized individually and in combination, that the number of steps was kept to a minimum, which led to high-complexity transcriptomes when the amplicons derived from single cells were hybridized onto cDNA arrays. Three points seemed to be particularly important. First, random primers reduce the length of primary transcript and enable subsequent amplification within the optimal range for PCR. Second, a poly-G tail provides a much better primer binding site than a poly A or poly T tail. Third, a poly-C containing PCR primer (binding to the poly G tail) should not be combined with any other primer sequence. Therefore, the flanking region of the cDNA synthesis primer has to be a poly-C track and a single PCR primer is used. A high annealing temperature and the addition of 3% formamide provide highly specific and optimal conditions for such sequences.

Reproducibility on a single-cell level is very difficult to assess, as two individual cells cannot be assumed to be identical and in the same functional stage. To exclude intercellular variation, the cDNA of an individual cell was divided prior to amplification, and then the variation of the resulting expression patterns (which was presumably introduced by the different methodological steps) was tested. Although random priming during cDNA synthesis, labeling, and hybridization add to the total variation, overall congruence of the two halves from one cell after global PCR was remarkably high for strong and intermediate signals. The weaker the signal, the more likely it was lost in one of the two halves (Klein et al., 2002). Therefore, when single cells are analyzed, the lack of a signal is more difficult to interpret and the authors recommend using independent methods such as real-time PCR or antibody staining.

Oligo arrays have become increasingly available from commercial suppliers (Affymetrix, Clontech, Qiagen, MWG-Biotech). Most of the sequences on these arrays are selected from the 3' end of a transcript. In those cases where the 5'-3' ratio is included into the bioinformatic evaluation (Affymetrix), one should not include the random primers, as the ratio will be shifted to the 5' end. Here, initial results indicate that the CFI5CT₍₂₄₎ alone results in more quantitative results (if using the Affymetrix system, do not forget to include the T7 promoter into the oligo in the order: 5'-poly-C-flank, T7 promoter, dT₍₂₄₎-3'). In addition, if enough cells are available that allow division of the sample, it is

advisable to determine the number of cycles needed to reach the plateau of the PCR reaction. Quantification is more precise during the linear phase of PCR, i.e., just before the plateau is reached. This can be done by setting up and running the PCR with half of the cDNA, and then running a gel of 3- μ l aliquots that are taken during the PCR at various cycle numbers between 20 and 40 cycles (e.g., cycle 20, 24, 28, etc.). Then, the PCR may be set up with the other half of the cDNA, programming the thermal cycler for the ideal number of cycles.

Critical Parameters

For best results, adhere to the following rules.

High-quality enzymes are critical for amplification success. In particular, terminal deoxynucleotide transferase (TdT) and RNaseH-deficient reverse transcriptase (RT) need to be selected carefully. TdT is delivered either in cacodylate-containing or KH₂PO₄-containing storage buffers. Avoid cacodylate-containing buffers unless they can be highly diluted. Reverse transcriptase is sometimes contaminated with bacterial DNA. Therefore, check different batches of a manufacturer.

Always work under sterile conditions with filter tips and avoid RNase contamination. It is also of great importance to protect the reactions from any nucleic acid contamination because DNA/RNA molecules present in the tube will be amplified as well (reverse transcriptase also uses DNA as a template).

Always work on ice.

During all wash steps using the magnet, check that no beads are aspirated with the supernatant.

Do not allow the beads to dry out. This preserves the binding of the mRNA to the beads.

Working with more than eight samples at once is not recommended, since it increases the duration of the procedure and consequently favors RNA degradation.

Clumped beads typically result from genomic DNA. Refer to Table 25B.8.1 to adjust the bead volume to the cell number.

Perform the hot-start procedure quickly, since keeping a single-stranded cDNA at 78°C for extended times can destroy the template.

Troubleshooting

Global amplification

There is no way to check the individual steps prior to PCR amplification. Before hybridizing a sample to an array, test amplification success

Table 25B.8.6 General Troubleshooting Guide

Cause/problem	Possible solution
<i>Negative PCRs or no primary product</i>	
Inactive reagents	Because all steps are critical, be sure that all reagents have been properly stored and handled. Primers should be dispensed into aliquots prior to use in order to prevent repeated freeze/thaw cycles; do not store diluted dNTP or dGTP too long; check expiration dates of enzymes; check tailing buffer and TdT storage buffer for absence of cacodylate; formamide must be deionized. High-quality enzymes and primers are most essential.
Gene-specific PCR	Most gene-specific PCRs will work with the primary PCR products as template, but be prepared to re-test the annealing temperature for the CP2-amplified cDNA. Sometimes, gene-specific PCR works better on 1:10 to 1:1000 diluted template than on undiluted amplicons.
<i>No or weak signals on cDNA arrays</i>	
Degraded Dig-UTP	Digoxigenin is alkali-labile. Therefore, check pH of all solutions after hybridization.
Film exposure	Be sure to expose the hybridized/exposed side of the filter. Re-expose cDNA array, prolong exposure time, correct orientation of coated film.
Hybridization temperature	Control the hybridization temperature. Some hybridization buffers work at 68°C, others at 45°C, depending on the content of DNA-denaturing substances.
Denaturation of DNA	Both probe and target have to be single stranded. Check denaturation and the protocol for array preparation.
<i>Suspiciously identical results with different probes on cDNA arrays</i>	
Co-amplification, labeling, and hybridization of bacterial/plasmid DNA with cellular cDNA	<p>Control the quality of the array by hybridizing labeled <i>E. coli</i> and plasmid DNA to the array; use arrays of which the cDNAs have been amplified by insert-specific PCR or oligonucleotide arrays</p> <p>Check for possible sources of contamination in the sample; test different batches of reverse transcriptase</p> <p>If contamination is unavoidable, label the negative control and add increasing amounts of blocking DNA (i.e., <i>E. coli</i> or DNA of the most frequently used plasmids used to generate the array) until the filters are clean</p>
<i>High background of cDNA arrays</i>	
Probe concentration	Check concentration of added probe. Concentrations >1.5 µg/ml can result in high background
Addition of probe	Never add undiluted probe to the array. Direct contact with the nylon membrane will result in dark areas/spots. Dilute the labeled probe in ~1 ml hybridization buffer and be careful not to pour it directly onto the filter.
Restringency washes	Unbound or unspecifically bound probe must be entirely washed out. Check SSC concentrations and washing temperatures.
Alkaline phosphatase	Alkaline phosphatase is expressed by bacteria. Check/autoclave buffers used for developing the filters.
Filters	Nylon membranes can be stripped and re-hybridized up to six to eight times. Repeated use, however, will increase background every time.
Precipitated Fab fragments, degraded anti-digoxigenin-alkaline phosphatase	Spin down antibody solution prior to use and use the supernatant only

by gene-specific PCRs for housekeeping genes and one less abundant, but more or less consistently expressed, gene of the investigated cells. In addition, it is advisable to run a gel with 5 μ l of the primary PCR. It should show a smear ranging from 200 to 2000 bp without bands. A sample without the addition of cellular mRNA should also be checked since contamination can be detected this way. If a smear (originating from DNA contamination in the enzyme preparations) is at all present, in the negative control, it should be smaller (100 to 300 bp) and less intense. Note that individual bands sometimes result from concatamerization of the primers and do not necessarily indicate contamination.

Gene expression analysis on nylon arrays

Roche Diagnostics provides an excellent manual with the digoxigenin hybridization kit. All relevant information for non-radioactive array analysis can be found there.

A general troubleshooting guide is presented in Table 25B.8.6.

Anticipated Results

After PCR amplification, the DNA content of the sample should be measured by following the Support Protocol in *UNIT 2.6* or by optical density, an ethidium bromide plate compared with a standard, or alternative methods like Nucleic dotMetric (Genotech). The anticipated amount of cDNA is between 100 and 300 ng/ μ l.

Before hybridization, amplification success is tested by checking the primary product and by gene-specific PCR as described. Running a gel with the primary PCR product, a smear ranging from 100 to 2000 bp without bands should be observed. Using single cells sometimes results in a smaller range. A sample without cellular mRNA should be included throughout the whole experiment as a negative control. From this sample, there should be no apparent smear; however, sometimes smears can be observed when the reagents, especially enzyme preparations, contain nucleic acids. Controlling the primary amplification by gene-specific PCRs for two housekeeping genes and one constantly but less abundantly expressed gene is recommended. The negative control must be negative for all gene-specific PCRs. Gene-expression analysis on nylon arrays should result in films with low background and ~20% to 40% positive hybridization signals for >10 to 20 cells. Positive signals from single cells should range from 5% to 25% of spotted cDNAs, depending on activation stage. The housekeep-

ing genes spotted on each filter should yield strong positive signals. The negative-control spots show no signal unless sample and array are contaminated with bacterial/plasmid-derived DNA.

Time Considerations

Global amplification of cellular cDNA

The time needed depends on the incubation/reaction times and the number of samples (washing >7 samples using the magnet is time consuming). It takes ~45 to 60 min for cell lysis, mRNA capture to the beads, and washing steps. At this point, the mRNA on the beads can be frozen and stored at -80°C . The subsequent cDNA synthesis, tailing reaction, and PCR amplification must be performed without interruption. cDNA synthesis including the wash steps will take ~1.5 hr and the tailing reaction will take an additional 1.5 hr. The PCR will take 3 to 4 hr and can be run overnight.

Non-radioactive gene expression analysis on nylon arrays

It takes ~30 min to set up the labeling PCR and the PCR itself will take ~1.5 hr. Pre-hybridization of samples requires at least 6 hr when cDNA arrays are used. Hybridize the labeled probe over 2 nights when few cells were used; cDNA from higher cell numbers might be hybridized for 1 night. Non-radioactive development of filters will require ~3 hr. The exposure time of the film has to be individually evaluated, but usually two films developed at 15 and 60 min are sufficient.

Data analysis of hybridized cDNA arrays

Scanning of the films will take ~10 min per film and data analysis by array vision will take 30 to 60 min per film.

CHAPTER 26

Gene Silencing

INTRODUCTION

The phenomenon of gene silencing mediated by short double-stranded RNA molecules was only discovered a few years ago, and many of the underlying molecular mechanisms involved remain to be elucidated. Nevertheless, a variety of techniques have been developed that exploit the use of short interfering RNAs (siRNAs) to study gene function in a variety of eukaryotic hosts. siRNAs were discovered in the course of experiments that involved the use of antisense RNA molecules to specifically knock down the expression of a particular target gene. Now it appears that siRNA-mediated gene silencing is an important component of the eukaryotic immune response to viral infection that has been highly conserved in evolution. Short double-stranded RNA molecules also appear to play an important role in gene regulation in plants, animals, and fungi. This high level of evolutionary conservation presumably explains the broad applicability of RNA interference technology (referred to as RNAi) to modulate gene expression in both readily manipulable genetic hosts such as *Caenorhabditis elegans*, *Drosophila melanogaster*, and *Arabidopsis thaliana*, as well as in mammalian tissue culture cells.

RNAi technology has a particularly important role in genome-wide studies of gene function. Given the genome sequence of a target eukaryotic organism, RNAi libraries corresponding to every open reading frame in a genome can be generated, thereby allowing genome-wide screens of gene function. This approach is particularly powerful for *C. elegans* and *D. melanogaster*. In *C. elegans*, RNAi can be accomplished by the relatively straightforward approach of constructing an *E. coli*-based plasmid vector that directs the synthesis of a dsRNA molecule and then simply feeding this plasmid-containing *E. coli* strain to *C. elegans*. Thus, genome-wide *C. elegans* RNAi libraries are being generated which can be systematically fed to *C. elegans*, one clone at a time. Given a particular phenotype, many *C. elegans* genes affecting the phenotype can be readily identified. In *D. melanogaster*, genome-wide RNAi analysis can be carried out by exposing tissue culture cells to short ds RNAs. In contrast, identifying genes that correspond to a particular *C. elegans* or *D. melanogaster* mutant generated by traditional forward genetic approaches is often an arduous process, involving time-intensive map-based cloning strategies.

This chapter begins with an overview of the brief history of RNAi techniques and the underlying science concerning the role of siRNAs in pathogen defense and gene regulation (UNIT 26.1). The overview is followed by a set of protocols for carrying out RNAi in different hosts. The chapter currently has protocols for mammalian cells (UNIT 26.2), *C. elegans* (UNIT 26.3), *D. melanogaster* (UNIT 26.5) and for cloning small endogenous RNA (UNIT 26.4); in future supplements, we anticipate including RNAi protocols for plants and perhaps other hosts as well. Each of these protocols is highly species-specific, focusing on the most efficient methods for delivering dsRNA molecules to a particular host. As more is understood about the underlying molecular machinery involved in mediating RNAi, we anticipate that much more efficient RNAi protocols will be developed. We will therefore update the protocols to keep them current with new advances in this rapidly evolving field.

Frederick M. Ausubel

Overview of RNA Interference and Related Processes

HISTORY

The history of RNA interference (RNAi) has unfolded rapidly since 1997 with a series of discoveries from plants, fungi, and animals. Initially, the interest was directed towards development of gene silencing technology that could be applied in research, medical therapy, and crop improvement. However, as the underlying mechanism was revealed, it became apparent that RNAi manifests a novel system of genetic regulation that was only hinted at by previous data.

A starting point for this history is the 1980s when plant researchers encountered two unexpected complications with antisense technology. First, most of the plant lines with an antisense transgene did not exhibit suppression of the corresponding endogenous gene (Smith et al., 1988). Second, some of the control lines with the sense constructs exhibited coordinate suppression (cosuppression) of the transgene and the homologous endogenous gene (Napoli et al., 1990; Smith et al., 1990; van der Krol et al., 1990).

From the initial findings, it was not clear whether the antisense and cosuppression mechanisms were related, although both involved a block at the post-transcriptional level (Kooter and Mol, 1993). One school of thought was that sense transgenes were transcribed into antisense RNA by adjacent plant promoters (Grierson et al., 1991). Other views invoked different sense and antisense mechanisms. The antisense mechanisms would be a simple block on the target RNA, whereas sense suppression would be mediated through a system that could detect gene over-expression or transgene transcripts that were structurally aberrant (Jorgensen, 1995).

At about the same time, there was a similar controversy in the *Caenorhabditis elegans* field. Gene expression could be specifically suppressed by direct injection of antisense RNA; however, the process was inefficient because large amounts of antisense RNA had to be injected (Fire et al., 1991). Additionally, there was a remarkable resonance of the plant “antisense versus cosuppression” mystery, because injected sense RNA was as potent as antisense RNA (Guo and Kemphues, 1995).

An inspired analysis of the *C. elegans* phenomenon provided the key to understanding

these unexpected findings. It revealed that RNAi in injected *C. elegans* was mediated by a small amount of double-stranded (ds) RNA that contaminated the sense and antisense RNA preparations (Montgomery et al., 1998). Subsequently, it was established in plants that if dsRNA was produced, suppression of endogenous gene expression was more efficient than with sense or antisense transgenes (Waterhouse et al., 1998; Chuang and Meyerowitz, 2000). Inverted repeat transgenes were particularly efficient, but simultaneous expression of sense and antisense RNA was also effective (Waterhouse et al., 1998).

A second important discovery followed from the search for the specificity determinant of cosuppression in plants. It was reasoned that, as cosuppression is nucleotide sequence-specific and acts at the RNA level, there should be antisense RNA corresponding to the target species. Presumably this antisense RNA would guide the degradation of the cosuppressed RNA. An initial unsuccessful search for this antisense RNA focused on RNA of >100 nucleotides length. However, when the hunt was redirected to small RNAs, an antisense species of ~25 nucleotides length was discovered (Hamilton and Baulcombe, 1999). These short RNAs also corresponded to the sense strand of the cosuppression target and it seemed likely that they were derived from a dsRNA precursor. This link with RNAi was subsequently confirmed when short RNAs were associated with RNAi in *Drosophila melanogaster* (Hammond et al., 2000). The *D. melanogaster* work also confirmed the prediction that the short RNAs guide a ribonuclease complex (RISC) to its target RNA.

The discovery that short RNAs play a key role in RNAi-mediated suppression of gene expression precipitated an avalanche of discoveries that are relevant to the application of RNAi and cosuppression, as well as to understanding of the natural roles of these processes. For example, the short RNAs have been characterized in detail and are now known to exist in a double-stranded form, with two-nucleotide overhangs at each 3' end, and are known as siRNAs (Elbashir et al., 2001a). Several different proteins have been identified that are associated with siRNAs in ribonucleoproteins (Caudy et al., 2002; Mourelatos et al., 2002).

Contributed by David Baulcombe

Current Protocols in Molecular Biology (2003) 26.1.1-26.1.6
Copyright © 2003 by John Wiley & Sons, Inc.

At least some of these proteins are part of RISC (Hammond et al., 2001). It is also now understood how dsRNA is processed into the siRNAs. The processing enzyme is known as Dicer and is a member of the RNase III family with dsRNA binding regions and a conserved PAZ domain shared with members of the piwi, argonaute and zwiille family (Bernstein et al., 2001), from which it takes its name. ATP is required at several stages in the processing of dsRNA and assembly of RISC (Nykanen et al., 2001). In some instances an RNA-dependent RNA polymerase is also involved (Cogoni and Macino, 1999; Dalmay et al., 2000; Mourrain et al., 2000). It converts a single-stranded RNA into a double-stranded siRNA precursor.

NATURAL ROLES OF RNAi AND RELATED PROCESSES

In plants, a natural role of RNAi and cosuppression is as an antiviral defense system (Voinnet, 2001). Viruses produce a dsRNA replication intermediate that is the substrate for Dicer and that leads to production of siRNA. The accumulation of siRNA guides RISC to the single-stranded viral RNA so that a feedback system is established in which there is an equilibrium between the level of RISC and the rate of virus accumulation. Accordingly, viruses produce suppressor proteins of RNAi as a counter-defense system (Voinnet, 2001). It is thought that if a suppressor is weak then virus accumulation would be transient, whereas a strong suppressor would permit prolonged accumulation to a high level. An antiviral role in insects is also likely as a nodavirus encodes a protein with suppressor activity (Li et al., 2002). At present it is not known whether the mechanism has an antiviral role in vertebrates; however, the recent findings that siRNAs have antiviral activity in mammalian cells are certainly consistent with that possibility (Novina et al., 2002).

The RNAi mechanism may also provide protection against transposons or other genome perturbations. Thus, in plants and protozoans there are endogenous short RNAs from retroelements (Hamilton et al., 2002), while in *C. elegans* mutations that affect RNAi may also cause genome instability (Ketting et al., 1999). Presumably, retroelement double-stranded RNA is processed by Dicer into short RNAs that prevent expression and mobilization of the corresponding genomic elements.

Many of the proteins required for RNAi are conserved in animals, plants, and fungi

(Zamore, 2001). It is therefore likely that the mechanism evolved in primitive eukaryotes as a defense system against viruses and selfish DNA, as in modern plants. However, it seems that the RNAi mechanisms have been recruited during evolution of modern eukaryotes into other aspects of genetic regulation. Thus, in fungi, proteins similar to those required for RNAi are required for transcriptional silencing of unpaired DNA or of centromeric genes (Shiu et al., 2001; Volpe et al., 2002). In *Tetrahymena*, a PAZ-domain protein and short RNAs that may be similar to siRNAs are implicated in control of genome rearrangement during differentiation of the transcriptionally active macronucleus (Mochizuki et al., 2002). It is not known at present whether RISC is involved in these effects at the genome level. The alternative possibility is that a separate complex recruits short RNAs and targets DNA rather than RNA.

Additional roles of RNAi-related mechanisms are implied from the identification of microRNAs (miRNAs) in plants and animals (Lagos-Quintana et al., 2001; Lau et al., 2001; Lee and Ambros, 2001; Reinhart et al., 2002; Rhoades et al., 2002). These miRNAs are similar to siRNAs in that they are produced by Dicer-like enzymes and are a similar length. They may also be recruited into RISC and mediate targeted RNA degradation or translational arrest. Other effects on, for example RNA processing, are also possible (Mishra and Handa, 1998). However, unlike siRNAs that are from transposons, transgenes, or viruses, the miRNAs are transcribed from endogenous DNA. A typical dsRNA precursor of miRNA is the transcript of inverted-repeat DNA in regions between conventional genes.

The likely role of miRNAs is in the control of mRNA translation or stability. Thus, the first miRNAs to be described were *lin4* and *let7* RNAs in *C. elegans* (Ruvkun, 2001). They mediate temporal control over translation of *lin14* and *lin41* mRNAs during *C. elegans* development. More recently, an miRNA in *Arabidopsis* (*miR171*) has been identified that apparently regulates site-specific cleavage of a transcription factor mRNA (Llave et al., 2002a).

At the time of writing this overview, *lin4*, *let7*, and *miR171* were unusual in that their mRNA targets had been identified. With *miR171*, this was relatively straightforward because it is perfectly matched to the target mRNA (Llave et al., 2002a). Other plant miRNAs may have fewer than three mismatches and putative targets have been identified by computational analysis of genome sequence

(Rhoades et al., 2002); however, these targets have not been verified. In contrast, for most animal miRNAs, the putative miRNA targets cannot be easily identified because the mismatch is greater than in plants. A strategy for miRNA target identification is a major outstanding challenge.

STRATEGIES FOR RNAi AND COSUPPRESSION IN PLANTS AND ANIMALS

RNAi and cosuppression are promising new approaches to genetic analysis and manipulation. It should be possible, for example, to infer the function of an uncharacterized gene, to correct dominant genetic defects, and to develop antiviral strategies using this approach. RNAi and related procedures may have several advantages over alternative strategies or may provide solutions to currently intractable problems. For example, if a gene of interest is a member of a multigene family, it may not be possible to infer function from standard genetic knockout strategies. The expression of functionally redundant gene family members may compensate for the mutant gene. However, because the RNAi-based procedures are nucleotide-sequence rather than genetic-locus specific, they allow suppression of many similar family members with a single manipulation.

Despite the relative novelty of RNAi and cosuppression technologies, there are already many different procedures that can be used, depending on the organism and the function of the target RNA. The most cumbersome of these involve transformation of the organism to produce a dsRNA precursor of an siRNA. This approach has been used in plants and animals (Wesley et al., 2001; Giordano et al., 2002; Paddison et al., 2002; Sui et al., 2002) and has the advantage that the phenotype is stable through several generations.

More direct approaches do not require stable transformation and are particularly amenable to high-throughput applications, including genome-wide surveys of gene function. It is possible, for example, to transfect with dsRNA or siRNA targeted at a gene of interest (Elbashir et al., 2001b; Harborth et al., 2001). If chemically synthesized siRNAs are used, this approach is relatively expensive. However siRNA produced in vitro by enzymatic cleavage of dsRNA may be a less expensive alternative (Yang et al., 2002).

Direct introduction of dsRNA or siRNA is effective in cultured cells. Surprisingly, however, direct introduction of siRNA or dsRNA

to intact multicellular animals can also result in RNAi. With *C. elegans*, for example, it is necessary only to feed animals on *E. coli* that is transformed to produce the dsRNA (Timmons and Fire, 1998). Thus, by producing a set of *E. coli* strains with dsRNA targeted against each gene, it was possible to generate a resource that will greatly facilitate characterization of the *C. elegans* genome (Kamath et al., 2003). Short dsRNA or siRNA could also be used in adult mice to target transgene expression in the liver (McCaffrey et al., 2002).

In plants, RNAi can be achieved in transgenic plants expressing the dsRNA of the target. An alternative strategy involves infecting plants with virus vectors carrying endogenous gene fragments. The corresponding host RNA is suppressed in the infected plant and the symptoms resemble a loss of function mutant phenotype. This approach has been refined on the model plant *Nicotiana benthamiana* and has been used to investigate genes involved in cell wall biosynthesis and disease resistance (Burton et al., 2000; Peart et al., 2002a,b). The potential of virus-mediated RNAi has not been fully explored in animals or animal cells.

DETECTION AND CHARACTERIZATION OF siRNAs AND miRNAs

A direct procedure for detection of siRNA and miRNA is northern blotting. The procedures are similar to the standard protocol for detection of mRNA, but are modified to account for the small size of these RNAs. Thus, the RNA is fractionated by electrophoresis on a polyacrylamide gel instead of agarose and electroblotted onto a nylon membrane. The stringency of the hybridization is also reduced. Probes can be labeled cDNA, cRNA, or oligonucleotides (Hamilton and Baulcombe, 1999).

Depending on its abundance, the short RNA may be detectable in total RNA preparations. However, for rare species it is necessary to enrich for short RNA by selective precipitation or enrichment for short RNA protein complexes (Mourelatos et al., 2002). Alternatively, for rare short RNAs, RNase protection can be used instead of northern blotting. However the cost of the increased sensitivity is the loss of size resolution—i.e., rather than appearing as a discrete-sized species, the RNase protection reveals the short RNA as a smear (Sijen et al., 2001).

There are several procedures for cloning of cDNA corresponding to siRNA or miRNA

(Djikeng et al., 2001; Lagos-Quintana et al., 2001; Llave et al., 2002b). These procedures all involve addition of adaptors to the termini of the short RNA using RNA ligase followed by reverse transcription and PCR amplification. The various protocols employ different strategies to avoid circularization or concatemerization of the reaction intermediates. However, some of the protocols do allow for concatemerization of the PCR products prior to cloning so that a single sequence reaction will be informative about several short RNA species.

Norwich, United Kingdom

For many years, the specific and efficient modulation of mammalian gene expression has been a very difficult and labor-intensive task. Particularly promising technologies for controlling gene expression are antisense oligonucleotides and ribozymes. In the case of antisense technology, there are a number of examples in which reasonably strong down-regulation of specific target genes was obtained. In most cases, however, a tedious and costly process of target-sequence optimization has been necessary to obtain satisfactory results.

The recent discovery of gene-specific silencing in mammalian cells mediated by ~20- to 25-nucleotide double-stranded RNA, better known as short interfering RNA (siRNA), allows researchers to circumvent many problems of the traditional antisense protocols. Paying attention to a few rules of oligoribonucleotide design and determining an efficient cell transfection procedure for a particular cell line are the remaining obstacles. RNA interference works in a wide variety of cell types and target sequence identification is straightforward. In most cases, it is sufficient to design one to five different siRNA molecules for each target gene.

The induction of siRNA-mediated RNA interference (RNAi) in mammalian cells can be achieved by microinjection of siRNA, transfection of siRNA using cationic lipids, electroporation of siRNA, transfection of plasmids containing siRNA expression cassettes, or infection of cells by recombinant viruses that express siRNA. This unit contains a method for siRNA transfection (see Basic Protocol) and an alternative for electroporating siRNA (see Alternate Protocol). In addition, procedures for annealing siRNA strands (see Support Protocol 1) and for cotransfecting modified reporter genes with siRNA (see Support Protocol 2) are also provided. Besides a specific experimental siRNA, all experiments have to include at least one control siRNA unrelated to the target mRNA to evaluate nonspecific or toxic effects.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

NOTE: All solutions and materials coming into contact with RNA must be RNase free, and proper techniques should be used accordingly (see UNIT 4.1 and APPENDIX 2).

LIPOSOME-MEDIATED TRANSFECTION OF MAMMALIAN CELLS WITH siRNA

BASIC PROTOCOL

The liposome transfection of mammalian cells with siRNA shares some similarity with DNA transfection protocols (see UNIT 9.4 for additional information). Similar considerations apply for siRNA and DNA transfection protocols, although special transfection reagents were developed in order to achieve optimal transfection efficiencies with siRNA. For some cell lines, specific DNA transfection reagents such as Lipofectamine PLUS (Invitrogen) appear to work the best.

Materials

- Mammalian cells to be transfected (e.g., HeLa-S3)
- Complete medium (APPENDIX 3F)
- 20 μM annealed siRNA (see Support Protocol 1)

Gene Silencing

26.2.1

Supplement 62

Serum-free medium (*APPENDIX 3F*)

Lipofectamine PLUS (Invitrogen)

12-well culture dishes (2-cm diameter)

1.5-ml polypropylene tubes

Additional reagents and equipment for mammalian cell tissue culture, including trypsinization (*APPENDIX 3F*)

NOTE: Lipofectamine PLUS is used in this protocol as it works well for HeLa-3 cells. Other transfection reagents can also be used by following manufacturer's instructions. Lipofectamine PLUS consists of two reagents, the transfection reagent itself (Lipofectamine) and an enhancer (PLUS).

Culture cells

1. Cultivate the mammalian cells to be transfected to late log phase in complete medium (*APPENDIX 3F*).
2. Trypsinize and count cells (*APPENDIX 3F*). Transfer to appropriate tubes and centrifuge 5 min at $300 \times g$, room temperature. Discard supernatant and wash once with complete medium. Resuspend in complete medium.
3. Seed 1 ml containing 1×10^5 cells in each well of a 12-well tissue culture plate and incubate ~24 hr.
4. Replace the medium with 500 μ l fresh medium 4 hr before the start of transfection and return to the incubator.

Perform transfection

5. For each well, mix 1.25 μ l of 20 μ M annealed siRNA with 43.75 μ l serum-free medium in a 1.5-ml polypropylene tube. Thoroughly vortex PLUS enhancer component of Lipofectamine PLUS reagent and add 5 μ l to each well.
6. In a second 1.5-ml reaction tube, dilute 2.5 μ l Lipofectamine component in 47.5 μ l serum-free medium.
7. Incubate the two tubes for 15 min at room temperature.
8. Add the Lipofectamine solution (step 6) to the tube containing the siRNA/PLUS mixture (step 5; 100 μ l total) and mix gently. Incubate 15 min at room temperature.
9. Remove the complete medium from each well and replace it with 400 μ l serum-free medium.
10. Add all of the siRNA transfection mix (100 μ l) from step 8.
Using this protocol as written (i.e., 20 μ M siRNA stock), the final concentration of siRNA is 50 nM. The best siRNA concentration varies depending on cell line or target gene and is likely between 1 to 100 nM. If the siRNA concentration is too high, Lipofectamine PLUS can have toxic effects on some cell types.
11. Incubate 2.5 hr, remove the transfection medium, and replace it with 1 ml complete medium.
12. Incubate 16 to 48 hr and analyze RNA by Northern blot (*UNIT 4.9*) or RNase protection assay (*UNIT 4.7*). Alternatively, determine resulting protein levels by immunoblot (*UNIT 10.8*).

In most cases a decrease in target RNA level is accompanied by simultaneous depletion of the corresponding protein in cell extracts. However, some proteins may have a half life of many hours in vivo and thus, the time course of RNA and protein degradation are not the same. In those, cases the cells have to be harvested at different time points. For example RNA preparation can be done after 48 hr, whereas protein extracts have to be prepared after 72 or 96 hr.

ELECTROPORATION OF MAMMALIAN CELLS WITH siRNA

ALTERNATE PROTOCOL

Many mammalian cell types can be easily and efficiently electroporated under very mild conditions resulting in cell survival rates >90%. Particularly with suspension cells, siRNA delivery by electroporation is superior to liposome-mediated transfection. Tests with fluorescently labeled siRNA and subsequent analysis by fluorescence-activated cell sorting indicate that up to 100% of Kasumi-1 cells can be transfected (Heidenreich et al., 2002). An additional advantage is that the electroporation protocol needs no particular transfection reagents and requires only a few steps.

An increasing number of laboratories are now discovering the advantages of using electroporation for siRNA transfection instead of liposome-based methods. However, very high electroporation efficiencies are only observed for particular cell lines. Suspension cells, as for example Kasumi-1 or other hematopoietic cells, are good candidates for this method. These suspension cells seem to work well with electroporation and are often difficult to transfect with liposome-forming reagents. Nonetheless, exceptions are observed among suspension cells and there is no general advantage to electroporate adherent cells.

Additional Materials (also see Basic Protocol)

4-mm electroporation cuvettes (e.g., Equibio ECU104)
Square-wave electroporator (e.g., Fischer EPI 2500)
Culture vessel

1. Cultivate, trypsinize, and wash mammalian cells as described (see Basic Protocol, steps 1 and 2). Resuspend in complete medium at a final concentration of $1\text{--}2 \times 10^7$ cells/ml.
2. Transfer 100 to 800 μl cell suspension into a 4-mm electroporation cuvette at room temperature. Add 20 μM annealed siRNA to a final concentration of 100 to 200 nM. Mix well by flicking the cuvette.
3. Place cuvette into the holder of a square-wave electroporator and electroporate at the desired voltage and time setting.

For hematopoietic cell lines such as BAF3, K562, or Kasumi-1, settings of 300 to 350 V and 10 msec are recommended. To establish the electroporation conditions, the authors routinely electroporate 10^6 cells in 100 μl medium containing 200 nM of the corresponding siRNA for a constant time of 10 msec and varying voltages ranging from 300 to 400 V. Some electroporation systems offer more variables (e.g., voltage, pulse time, resistance, impedance). The settings have to be determined for each cell line empirically. See UNIT 9.3 for more detail.

4. Remove cuvette from holder and incubate 15 min at room temperature.
5. Return the electroporated cells to a culture vessel and dilute the cell suspension to the desired cell density.

For electroporated Kasumi-1 cells, a cell density of $5 \times 10^5/\text{ml}$ is appropriate. For hematopoietic suspension cells, transfection rates of up to 100% can be obtained with a fluorescently labeled siRNA; however, for fibroblast cell lines such as NIH3T3, the authors observed rather poor transfection rates.

6. Analyze RNA (UNITS 4.7 & 4.9), protein expression (UNIT 10.8), and consequences of target gene depletion.

Decreases in RNA levels are visible within 16 hr after electroporation. Reduction of protein levels and the consequences of the protein depletion depend on the half-life of the targeted protein. In the case of electroporated Kasumi-1 cells, the authors observe ~70% reduction of endogenous gene expression.

Gene Silencing

26.2.3

ANNEALING EQUIMOLAR siRNA

A detailed discussion of how to design and where to obtain siRNA is given in the Commentary section of this unit (see Critical Parameters).

Materials

siRNA sense and antisense strands (see Critical Parameters)

Annealing buffer: 100 mM NaCl in 20 mM sodium phosphate buffer, pH 6.8 (see APPENDIX 2 for buffer)

Additional reagents and equipment for nondenaturing polyacrylamide gel electrophoresis (UNIT 2.7) and ethidium bromide staining (UNIT 4.9)

1. Combine equimolar amounts of sense and antisense strands and adjust the siRNA concentration to 20 μ M (double stranded) in a final volume of 100 to 500 μ l annealing buffer.
2. Heat a glass beaker containing 500 ml water to 90°C on a magnetic stirrer with adjustable temperature. Place tightly capped 1.5-ml reaction tubes containing the RNA in a flotation device and transfer to the water bath. After 3 min switch the heating element off.
3. Allow the water bath to slowly cool to room temperature (~3 hr) to permit the siRNA to anneal.
4. Load ~1.5 μ g of both single-stranded and double-stranded siRNA on a 10% nondenaturing polyacrylamide gel (UNIT 2.7). Visualize by ethidium bromide staining as described for northern hybridization of RNA (UNIT 4.9).

Samples of properly annealed siRNA run slower compared to sense and antisense strands and show no signs of remaining single-stranded RNA. This is apparent on an ethidium bromide-stained gel when the fluorescent signal from the single-stranded species is below the detection limit during illumination by UV light. It is important to remember, however, that ethidium bromide interaction with single-stranded RNA is weak compared to double-stranded RNA which can cause underestimation of single-stranded RNA quantities. Also bear in mind that even properly annealed siRNA tends to dissociate during the acrylamide-gel run and minute amounts of smeared single-stranded RNA will always be detectable with other staining procedures (e.g., "stains all" dye) that visualize single- and double-stranded RNA with the same efficiency. In the authors' hands, the more common ethidium bromide staining procedure is sufficient for estimating success.

5. Store the siRNA stock solutions up to several years at -80°C.

Smaller samples of siRNA can be stored at -20°C for at least 6 months and repeated freezing/thawing cycles do not decrease their quality. Do not keep solutions of highly diluted siRNA for more than an hour, as the double-stranded molecules tend to dissociate. The stability of siRNA at room temperature depends on its sequence and the composition of the solvent (e. g. serum-free medium). Keep in mind that not only RNases are harmful to RNA. In addition, the pH and salt composition of the solvent may accelerate RNA decay in solution. Generating fresh siRNA dilutions for a new experiment is rather simple and more convenient than determining the shelf life of individual siRNAs empirically.

LIPOSOME-MEDIATED COTRANSFECTION OF REPORTER GENES WITH siRNA

Developing an efficient siRNA protocol for silencing an endogenous gene in a particular cell line can be a very tedious task. In case of failure it is impossible to tell whether the designed siRNA does not work, the transfection method was inefficient, or the target RNA or protein level was monitored within the wrong time window. In addition, the expression level of the target gene can be very low. In the cases where these problems are encountered, the cotransfection of plasmid-encoded reporter genes together with siRNA allows an

estimation of RNAi efficiency in a particular cell line via the silencing of the reporter gene. The overall transfection efficiency is no longer a limiting factor as the reporter plasmids and siRNA are obviously part of the same liposome complexes and therefore, reach the same cells. In addition, the evaluation of almost any target sequence of an endogenous gene or viral gene for siRNA design is simplified by fusing it to a reporter gene.

Presented here as an example is a reporter system consisting of a generated recombinant transcript containing a short sequence derived from a human hepatitis C virus (HCV) genome ligated to the open reading frame of the firefly luciferase gene. This example was chosen as human HCV is very difficult to study in cell culture and thus the use of models and reporter systems is prevalent, meaning that the system is well defined. The widely used reporters β -galactosidase or green fluorescent protein (gfp) tolerate even longer gene fusions. The artificial sequence context and the high expression level obviously does not represent the situation of an endogenous gene; however, the detection of siRNA activity of the reporter is comparatively easy and reproducible, and thus should give an idea of overall RNAi efficiency in the cell line used.

Additional Materials (also see *Basic Protocol*)

Reference plasmid expressing β -galactosidase (e.g., pCMV beta, Clontech)

Plasmid expressing reporter gene fusion (e.g. HCV-Luciferase in pcDNA3.1+, Invitrogen)

TE buffer (*APPENDIX 2*)

5 μ M annealed siRNA (see Support Protocol 1)

GenePORTER 2 kit (Gene Therapy Systems):

DNA diluent B

GenePORTER 2 Reagent (liposome transfection reagent)

Annealing buffer: 100 mM NaCl in 20 mM sodium phosphate buffer, pH 6.8 (see *APPENDIX 2* for buffer)

96-well culture dishes

Additional reagents and equipment for β -galactosidase and firefly luciferase assays (*UNIT 9.7B*)

1. Prepare cells as described (see *Basic Protocol*, steps 1 and 2).

In the present example, the liver cancer cell line HuH-7 was cultivated in DMEM/10% FBS.

2. Seed an appropriate number of wells in a 96-well dish with 100 μ l containing 2×10^4 cells. Incubate ~24 hr.
3. Mix 3 μ g reference plasmid expressing β -galactosidase with 1 μ g of the plasmid carrying the reporter gene fusion. Adjust the total DNA concentration to 375 ng/ μ l with water or TE.
4. Mix the following solutions in reaction tubes for the identical transfection of three wells:

Tube A:

2 μ l 375 ng/ μ l plasmid mix

6.6 μ l 5 μ M annealed siRNA

16.4 μ l DNA diluent B

Tube B:

6 μ l GenePORTER reagent

19 μ l serum-free medium.

Incubate both tubes 5 min at room temperature. Add contents of tube B to tube A and incubate an additional 5 min at room temperature.

5. As a negative control, prepare one transfection mix with the relevant plasmids, but replace the 5 μ M siRNA with 6.6 μ l annealing buffer.
6. Add 16 μ l transfection mix to each cell culture well (step 2) and mix gently by pipetting.

Each well receives 250 ng plasmid and ~100 nM siRNA.

7. Analyze the enzyme activity of β -galactosidase and firefly luciferase after 16 to 48 hr incubation.

Use the protocols of UNIT 9.7B or commercially available kits to determine enzymatic activities.

COMMENTARY

Background Information

The recent demonstration of gene-specific silencing in mammalian cells by ~20- to 25-nucleotide dsRNA, better known as siRNA, has had a very stimulating effect on cell biology research. siRNA leads to a strong reduction of either cellular or viral gene expression (Elbashir et al., 2001; Novina et al., 2002). A straightforward approach combines synthetic siRNA with transfection technologies for transferring the molecules into the cells. This results in a transient decrease in expression of the target gene for 3 to 5 days. The integration of siRNA expression cassettes in the host genome may lead to a sustained suppression of target gene expression, but is more time consuming to establish.

The practical uses of siRNA applications are very appealing; however, the mechanism of RNA interference in mammalian cells is poorly understood. Parallel work that is being carried out in plants, *D. melanogaster*, and *C. elegans* allows some understanding of the underlying mechanisms of RNA interference in mammalian systems (Hannon, 2002; Sharp, 2001; Zamore, 2001).

In *Drosophila*, extended stretches of dsRNA are recognized by dicer, an RNase III-like nuclease. Dicer cleaves the dsRNA into smaller pieces of an average ~22 nucleotides in length. The short double-stranded RNAs are then bound by a multiprotein complex, RISC (RNA-induced silencing complex). The RISC complex is able to find homologous sequences among RNA or mRNAs and possesses helicase and nuclease activity. RISC uses the dsRNA as a guide for the identification of complementarity between dsRNA and target RNA. The identified target RNA is a substrate for endonucleolytic cleavage leading to its further degradation by exo- and endonucleases (see Fig. 26.2.1). This pathway may represent a cellular

defense mechanism against viral infection or transposon replication. The discovery of microRNAs (miRNA) in *C. elegans* suggests that RNA interference is also involved in the regulation of developmental genes (Schwarz and Zamore, 2002). For more information about RNA interference, as well as dicer and RISC, refer to UNIT 26.1.

In contrast to long double-stranded RNAs, which cause a general arrest of translation by activating protein kinase R and RNase L, siRNAs induce neither of these activities due to their small size (Caplen et al., 2001). Thus, the application of siRNAs is suitable for sequence-specific inhibition of single genes.

Critical Parameters

siRNA design

siRNAs are double-stranded RNAs of 21 to 25 nucleotides with overhangs of 2 to 3 nucleotides at both 3' ends (Elbashir et al., 2001). The sense strand is identical to the target mRNA, while the antisense strand is complementary to both the sense strand and the mRNA. Figure 26.2.2 shows several siRNA molecules that trigger strong effects in mammalian RNAi studies. Although the overall structural features of potent siRNA molecules have been identified, certain details have to be considered in order to optimize their inhibitory effect. The important features to consider, as discussed below, are (1) selecting the best target site, (2) length of the double-stranded region, (3) overhang on either 3' end, and (4) tolerance for chemical modifications.

Target-site selection

In contrast to the inhibitory effects of antisense oligonucleotides or ribozymes, the RNA interference process is not merely a matter of base pairing and annealing between

Figure 26.2.1 A model for RNA interference in mammalian cells. Long double-stranded RNAs are processed by dicer. RISC induces a target-site-specific cleavage of RNA using siRNA and dicer products as a guide. See text for more details.

target sites and the complementary antisense molecule. The basic mechanisms of RNA interference are not yet completely understood. For this reason, it is not possible to predict the sequence preference of the multienzyme complexes that are involved in the gene silencing process of mammalian cells. In spite of the limited available information, recommendations for a particular sequence motif for siRNA design are sometimes found in the literature or in technical notes of commercial siRNA suppliers.

Target sites on mRNA, noncoding RNA (e.g., rRNA), or viral RNA are also subject to RNA interference. The cognate sequence of an siRNA is either located on the untranslated 5' region of an mRNA, the open reading frame, or the 3' end of the message; however, the efficiency of individual target sites on a given RNA may vary considerably without obvious

reasons (Holen et al., 2002). A potential for stable secondary structures decreases the value of a given sequence as an siRNA target site, but is not necessarily incompatible with RNA interference. Sequences within introns should not be used as siRNA target sites as the gene silencing machinery works only in the cell cytoplasm and not in the nucleus (Zeng and Cullen, 2002).

Since siRNAs are rather short molecules, the anticipated target site may be present in more than one mammalian mRNA. At least two or three mismatches between the prospective siRNA sequence and an mRNA are necessary to completely prevent siRNA-mediated RNA cleavage. A BLAST search (*UNIT 19.3*) of the siRNA sequence against a mouse or human gene bank is highly recommended. Both mRNA and genomic sequences should be checked.

Figure 26.2.2 Examples of synthetic siRNA and their target gene. Efficient siRNA have double-stranded regions of 19 to 21 nucleotides and 2-nucleotide overhangs at the 3' end on both strands. A substitution of ribouridine bases by deoxythymidine at the 3' prime ends may stabilize the siRNA in solution, but is not necessary for efficient gene silencing in mammalian cells. The two targets of the siRNA shown at the top of the figure are lamin A/C (Elbashir et al., 2001) and firefly luciferase (Hohjoh, 2002), respectively. The two siRNAs shown at the bottom of the figure both have chloramphenicol acetyl transferase (Caplen et al., 2001) as their target.

Length of double-stranded region and overhang

siRNAs may be designed as symmetrical molecules with the sense and antisense strands having the same length. The double-stranded region may vary between 19 and 21 nucleotides. An overhang of two nucleotides in length at the 3' end of either strand is beneficial (Caplen et al., 2001; Elbashir et al., 2001; Hohjoh, 2002). Unless data about the best G+C content of the siRNA are generated, it is prudent to avoid extreme values. Therefore, the G+C content of the double-stranded region should be between 40% to 55%. Figure 26.2.2 shows some examples of siRNA that were applied in mammalian RNA interference experiments that led to strong gene silencing effects.

Tolerance for modifications of the RNA strands

Natural siRNAs are products of nuclease activities that process long double-stranded RNA. As a result, ribonucleotides are the only constituents of endogenous dicer products. However, the RNA interference machinery tolerates certain chemical modifications in synthetic siRNAs—e.g., substituting the two-nucleotide 3'-end overhang ribouridines with deoxythymidines does not interfere with siRNA

activity and probably protects the RNA against nuclease attack. The coupling of fluorophores allows the detection of siRNA by fluorescence microscopy or fluorescence-activated cell sorting. Customized siRNA with fluorophores are commercially available (e.g., Ambion, Dharmacon Research, Eurogentec). Care must be taken not to alter too many of the ribonucleotides. In particular, the core of the siRNA double-stranded region has to maintain its ribonucleotide character.

The sense strand is more tolerant of modifications without losing RNAi efficiency than the antisense strand. A covalent modification of the 3' hydroxy group at either end of the double strand or the 5' end of the sense strand is acceptable; however, blocking of the antisense 5' end destroys siRNA activity. This position has to be either a 5' hydroxyl or a phosphate group (Chiu and Rana, 2002; Martinez et al., 2002).

How to get siRNA

The World Wide Web offers many tools for selecting manufacturers of siRNA molecules or accessories (see Internet Resources). siRNA can be obtained by chemical synthesis or in vitro transcription. In addition, siRNA can be generated by intracellular expression.

Figure 26.2.3 Model for plasmid-derived synthesis of siRNA in vivo. An RNA polymerase III promoter drives the expression of short hairpin-like RNA with a proposed 19-nucleotide duplex. The complementary sense and antisense sequence of the final siRNA are linked by a loop of 8 to 10 nucleotides (A). This hairpin RNA is probably subject to intracellular processing. The remaining double-stranded molecules (B) possess sequence homology with the target gene and perform like functional siRNA (Brummelkamp et al., 2002).

Many companies with expertise in DNA oligonucleotide production now offer customized solid-phase synthesis of RNA. RNA synthesis is more difficult and less efficient than DNA synthesis; therefore, additional purification steps of the RNA strands are recommended to obtain reproducible results. RNA purification by gel electrophoresis or HPLC and the annealing of both strands are offered by all manufacturers. Dharmacon Research synthesizes RNA with a proprietary technology that results in RNA strands of considerably higher purity and better yield than most other sources. In this case, additional purification steps are usually not necessary.

Whereas experiments with antisense DNA oligonucleotides may need up to 2 μ g DNA for transfecting cells in a single well, 50 to 100 ng siRNA are sufficient to inhibit gene expression with the same or even better efficiency. Thus, a synthesis with yields ranging from 50 to 1000 nmol provides enough material for large sets of experiments. The possibility to receive ready-to-use molecules and the option for introducing chemical modifications make synthetic siRNA an attractive choice.

Ambion offers an in vitro transcription kit for siRNA synthesis. The customer has to design some DNA oligonucleotides for cloning into an RNA expression cassette. The transcription of this unit leads to RNA strands that are hybridized and further trimmed by nucleases. This is a rather inexpensive way of getting functional siRNA and allows the probing of many different target sites at moderate costs.

A totally different approach is the intracellular synthesis of siRNA (see Fig. 26.2.3). In this case, a plasmid contains an expression cassette for the synthesis of a short-hairpin RNA molecule. An RNA polymerase III promoter, either U6 or H1, drives the expression of the RNA. This single-stranded RNA contains two stretches of complementary sequences that refold into a double-stranded region and a connecting loop, which is probably subjected to further processing (Brummelkamp et al., 2002; Paddison et al., 2002; Sui et al., 2002). Due to the constitutive expression of the siRNA, a sustained inhibition of target gene expression is achievable. The silencing plasmid can also be used for the generation of stable cell lines. Gene-silencing plasmids are commer-

cially available (e.g., Ambion or Imgenex) and come with detailed protocols for the proper setup of a hairpin-like RNA. As an alternative to hairpin RNA expression cassettes, sense and antisense strands can be expressed separately and will hybridize inside the cell to form siRNA (Lee et al., 2002).

Gene silencing by *in vivo* expression of siRNA circumvents the need for highly efficient siRNA transfection protocols. However, transient expression demands a high yield of transfected cells. The generation of permanent cell lines is a very elegant way of inhibiting target gene expression, but siRNA efficiency in gene silencing has to be verified before starting cell line selection. In addition, siRNA can be generated by intracellular expression using vectors like pSUPER (Fig. 26.2.3).

Preparation of siRNA samples

All commercial manufacturers offer synthesized siRNA in a highly purified form at a defined concentration with annealed strands. Some researchers might prefer to order individual strands or synthesize the RNA in-house. Gel purification under denaturing conditions is similar for short RNA and DNA (see *UNIT 2.12* for useful instructions for preparative denaturing polyacrylamide gel electrophoresis). After RNA purification, it is necessary to determine the concentration as accurately as possible by ultraviolet spectroscopy at 260 nm (*APPENDIX 3D*). The molar extinction coefficient of each RNA sequence has to be calculated individually, due to the limited size of 21 to 23 nucleotides. An easy-to-use program for this purpose is the biopolymer calculator. This program for computing molecular properties of RNA strands is accessible at <http://paris.chem.yale.edu/extinct.html>.

Cell transfection

There is no “gold standard” for transfecting siRNA. The best method for transferring synthetic siRNA into a given mammalian cell line has to be found empirically. High transfection efficiencies are of crucial importance for gene silencing experiments.

MacManus and Sharp (2002) summarized some of the published transfection methods in mammalian gene silencing experiments. As long as popular laboratory cell lines such as HeLa or NIH 3T3 are used, the development of siRNA transfection procedures is simple; however, this is not true for other cell lines (e.g., hepatic star cells, neuronal cells). Here, determining optimal conditions can be a tedious process.

Some companies offer siRNA and transfection kits as a package. Using a modified siRNA carrying a fluorescent marker allows the determination of transfection efficiency by fluorescence microscopy or fluorescent-activated cell sorting. Most protocols involve the use of transfection kits with either polycationic or lipid compounds which build vesicles upon contact with the siRNA. Some manufacturers offer reagents optimized for siRNA (e.g., Mirus, Invitrogen, Gene Therapy Systems); however, some cell types are more efficiently transfected by standard DNA transfection kits. Methods based on calcium phosphate complexes are not the best choice for siRNA, but the successful use of adapted protocols have also been reported (Paddison et al., 2002).

A very convenient way to render mammalian cells permeable for siRNA is electroporation. For optimum results, electric settings and siRNA concentrations have to be tested. Generally, higher siRNA concentrations are needed for electroporation as compared to lipofection in order to achieve good transfection and inhibition efficiencies.

The transfection of siRNA expression plasmids is not different from standard DNA transfection. Chapter 9 presents several units containing protocols for the successful introduction of DNA into mammalian cells and ways to select stable cell lines that contain the siRNA plasmid integrated into the genome. Methods based on calcium phosphate complexes (e.g., *UNIT 9.1*), however, are rarely used for transfecting siRNA. This is because the calcium phosphate transfection protocol often demands higher amounts of siRNA than liposome-based protocols. In addition, the authors have observed that the skills and experience of the experimenter influence the outcome of a calcium phosphate transfection protocol to a considerable extent. Nevertheless, a careful optimization of transfection conditions and siRNA concentration may result in good silencing efficiencies in certain cell lines (Paddison et al., 2002).

Troubleshooting

A guide to some of the common problems in RNAi experiments, along with their possible causes and solutions, is presented in Table 26.2.1.

Anticipated Results

Support Protocol 2 was developed for the testing of a fusion reporter gene between a short hepatitis C virus (HCV) sequence (Kolykhalov et al., 1996) and firefly luciferase. This recom-

Table 26.2.1 Troubleshooting RNA Silencing

Problem	Possible cause	Solution
No gene silencing	siRNA was not properly annealed	Repeat annealing and check on nondenaturing gel (<i>UNIT 2.7</i>)
	siRNA was degraded	Discard and use a new siRNA batch
	Low transfection efficiency	Try other transfection methods and use fluorescent siRNA for verifying transfection efficiency
		Vary siRNA concentration in the experiment
	siRNA was targeting an intron sequence	Choose a new sequence outside the intron region
	Target site was inaccessible	Try a different sequence with new siRNA
	Target site and siRNA sequence differed	Check whether the sequence information about the target site is true for the particular cell line
	Wrong time window	Analyze target gene at different time intervals
	Forbidden modification	Determine if chemical modification inactivated the siRNA
Gene silencing observed with negative control siRNA	siRNA concentrations were too high	Try lower siRNA concentrations
	siRNA affected more than one gene	Repeat BLAST search
	siRNA were toxic for the cells	Try other transfection reagents and reduce siRNA concentration

binant gene was generated by PCR and cloned into a standard mammalian expression vector. The vector was cotransfected with a β -galactosidase reference plasmid and one of three types of siRNA into the liver cell line HuH-7 (#JCRB0403, Health Science Research Resources Bank, <http://www.jhsf.or.jp>). The β -galactosidase plasmid permits correction for transfection efficiency and cell lysis differences. HCV1+2 siRNA targeted the HCV sequence, LUC1+2 was directed against a sequence within the firefly luciferase open reading frame, and C1+2 served as negative control and was not complementary either to luciferase or to β -galactosidase. Figures 26.2.4 and 26.2.5 show the luciferase reporter gene, the siRNAs used in this experiment, and the results obtained. About 48 hr after the transfection, the cells were lysed and the luciferase and β -galactosidase activities were quantitated with chemoluminescence enzyme assays (see *UNIT 9.7B*). The relative ratio between firefly luciferase and β -galactosidase was then calculated. The value for the expression of reporter plasmids in the absence of siRNA was set to 1. In the presence of specific siRNAs HCV1+2 and

LUC1+2, the expression level of the firefly gene was reduced by a factor of 5 compared to the no-siRNA control. The nonspecific control siRNA C1+2 had no inhibitory effect on the luciferase gene. Instead, a slight increase of reporter gene activity was observed. (This phenomenon is frequently observed, but at this time, a reasonable explanation for this behavior does not exist.) However, higher concentrations of negative control siRNA may lead to a nonspecific inhibitory effect. Therefore, it is necessary to determine an optimum siRNA concentration with strong inhibitory effects of the specific siRNA and only moderate or no effects for the negative siRNA control.

The siRNA-mediated inhibition of the HCV-luciferase fusion gene led to an 80% reduction. Repeating the same experiment in HeLa-S3 cells led to 95% reduction.

The HCV1+2 siRNA was as effective as LUC1+2, although the HCV target sequence possessed three particular features that are not in favor of efficient inhibition. First, the HCV sequence has a predicted tendency to fold into a stem-loop structure. Second, the HCV sequence lies upstream of the open reading frame

Gene Silencing

26.2.11

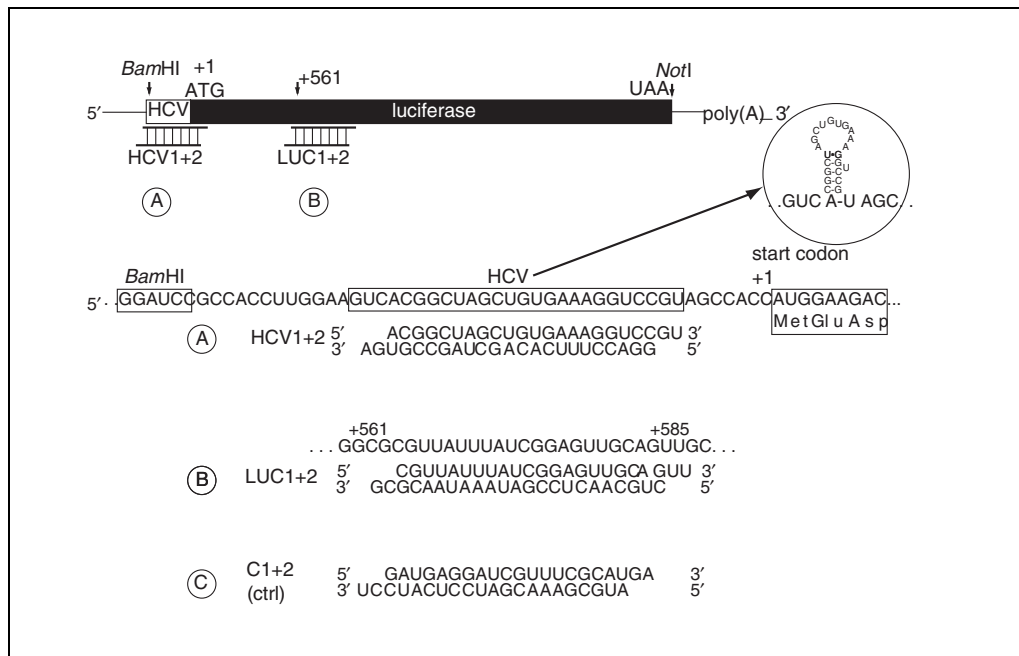

Figure 26.2.4 A recombinant fusion gene serves as a reporter system for siRNA efficiency in mammalian cells. A 26-nucleotide hepatitis C virus sequence is placed upstream of the firefly luciferase open reading frame. The viral sequence possesses the ability to form a stem-loop structure. Two siRNAs were designed to target the mRNA. HCV1+2 (A) is directed against the hepatitis C region, whereas LUC1+2 (B) is targeting the open reading frame of the fusion gene. The siRNA C1+2 (C) is not related to the reporter mRNA and serves as a negative control.

Figure 26.2.5 In liver cells, the reporter gene is expressed at a 5-fold lower level in presence of HCV1+2 and LUC1+2 compared to control siRNA or absence of siRNA. Note the slight stimulation of reporter gene activity by C1+2. Refer to Figure 26.2.4 for siRNA sequences.

start codon within the 5' untranslated region. Third, the target sequence is next to the ribosome-binding site and may compete with protein complexes for target-site binding. Nevertheless, for unknown reasons, it worked.

Time Considerations

A complete RNAi experiment can be completed within 3 days, but may last up to several weeks. Usually, the transfection of siRNA starts with seeding cells at day 1. This takes about 1 hr. On day 2, the lipofection protocol (see Basic Protocol) includes the pipetting of siRNA dilutions and the preincubation with a transfection reagent, which needs 1 hr of hands-on work. An additional 20 min to 1 hr are necessary to add the siRNA complexes to the cells. Approximately 4 hr are required for annealing the siRNA strands (see Support Protocol 1), and both annealing and electrophoresis can be performed in a single day.

For the cell electroporation protocol (see Alternate Protocol), the whole process of handling the cells, including centrifugation, electroporation, and final transfer into a culture vessel, takes <1 hr.

After transfecting synthetic siRNA, maximum effects on target gene expression are detectable after 16 hr incubation. On day 3, the harvest of transfected cells and preparation of extracts need about 2 hr for total RNA or protein.

Depending on the gene of interest, the cell line used, or the gene product, the incubation time may need to be extended to 72 hr. The authors recommend combined analyses of target RNA and protein abundance. As the half-life of proteins is generally longer than that of their corresponding mRNAs, an efficient inhibition of mRNA expression does not immediately result in a reduction of protein levels.

The expression of siRNA *in vivo* from a plasmid vector leads to a sustained inhibition of the target genes. A decrease of RNA or protein levels is still detectable after several days or weeks.

Phenotypical changes of the cells (e.g., the induction of apoptosis) may immediately follow the gene silencing effects or may need additional hours or days before becoming obvious.

The nematode worm *C. elegans* is a useful genetic model system for a variety of reasons (see Wood, 1988; Hope, 1999). Embryonic development, from fertilization to hatching, occurs in just 12 hours at room temperature, resulting in a first-stage larva with just over 550 cells. Newly hatched larvae progress through four larval molts to reach adulthood in ~3 days, and adult hermaphrodites produce ~300 self-progeny over the next three days. Both larval and adult worms have remarkably simple anatomies which consists of an inner tube comprised of the pharynx and intestine, surrounded by a hydrostatic, fluid-filled body cavity and by an outer tube that consists of the musculature, hypodermis, and ultimately a collagenous cuticle. Remarkably, the diverse tissues that comprise the adult are specified by a total of only ~1000 somatic cells. Due to the highly stereotyped cell division patterns, the origins and fates of each cell in the embryo and adult is known. Consequently, perturbations of the developmental program can be traced to changes in the fates of individual cells.

The ability to generate mutants in *C. elegans* has made this species a powerful model genetic organism. Despite being the first metazoan with a completely sequenced genome (The *C. elegans* Sequencing Consortium, 1998), conventional methods of gene knock-out/replacement by homologous recombination remain elusive. Current methods for generating deletion mutants, while valuable, are laborious and time consuming (Jansen et al., 1997; Liu et al., 1999). Since its discovery, RNA interference (RNAi) has become an important tool for *C. elegans* research and the scientific community in general. RNAi has provided a potent, specific, rapid, and simple method for determining the null phenotype of genes in *C. elegans*, and has been the basis of several genome-wide screens (Fraser et al., 2000; Gonczy et al., 2000; Piano et al., 2000; Maeda et al., 2001; Ashrafi et al., 2003; Kamath et al., 2003). RNAi is an excellent way to examine genetic interactions. For example, the dsRNA of interest can be delivered to a battery of candidate mutants that may represent sensitized genetic backgrounds. Thus, if RNAi into wild-type animals fails to give a phenotype, one may nevertheless detect suppression or enhancement of phenotypes in such strains.

In *C. elegans*, RNAi can be induced by delivering dsRNA to animals in any of four ways: microinjection (see Basic Protocol 1 and Alternate Protocol), feeding (see Basic Protocol 2), soaking (see Basic Protocol 3), or promoter-driven expression (Tabara et al., 1999; Tavernarakis et al., 2000). Most needs can be met by at least one delivery method. Microinjection of dsRNA, while technically challenging, is nevertheless the method of choice for RNAi experiments. Indeed, while other less difficult methods, such as feeding or soaking animals in dsRNA, should be used in parallel, injection should be attempted before drawing any conclusions about the function (or lack of function) of a gene of interest. It is also possible to simultaneously inhibit two or more genes at one time by coinjecting dsRNAs within a mixture. Therefore, microinjection of dsRNA is an excellent way to assay members of a gene family for overlapping or redundant functions.

Animals exposed to dsRNA by feeding or soaking are more amenable to biochemical analyses, since these procedures may easily be scaled up. The feeding and soaking protocols can also be performed in microtiter format allowing for large numbers of RNAi experiments to be performed simultaneously (Fraser et al., 2000; Maeda et al., 2001). In promoter-driven RNAi, dsRNA is produced in vivo from a transgene (Tabara et al., 1999). This is perhaps the most technically demanding and time-consuming procedure, since it requires the generation of a transgenic line. In principal, however, the transgene can be

integrated, resulting in a stable line in which the gene of interest may be silenced in a constitutive or regulated fashion, depending on the promoter used to drive dsRNA synthesis.

In the microinjection and soaking protocols, *in vitro* preparations of dsRNA are delivered mechanically by microinjection or passively by soaking. In the feeding protocol, dsRNA is expressed in *E. coli* and ingested by animals. The protocols provided in this unit are meant to guide the complete novice at worm culture in the selection and application of these RNAi delivery methods. Towards that end, protocols are also provided for transferring and propagating (see Support Protocol 1) as well as sexing and mating (see Support Protocol 2) *C. elegans*. References for more in depth discussion of these topics as well as *C. elegans* in general are provided at the end of the unit (see Key References).

NOTE: All solutions and equipment coming into contact with organisms must be sterile, and proper sterile technique should be used accordingly.

BASIC PROTOCOL 1

MICROINJECTING WORMS WITH dsRNA

To perform RNAi by microinjection, one will need to have access to a microscope equipped with a micromanipulator for holding and maneuvering the microinjection needle. Injections need not be performed at high magnification, and differential interference contrast microscopy (Nomarski optics) is not necessary. Therefore, even if expertise in *C. elegans* microinjection is unavailable, it should be possible to master dsRNA microinjection with only a few hours of practice. Microscopes suitable for this purpose will be found in a range of laboratories.

In this procedure, healthy L4 or adult hermaphrodites are immobilized under halocarbon oil on a dry agarose pad and microinjected with dsRNA, causing the body of the animal to noticeably inflate with the dsRNA solution. Injected animals are removed from the pad using a mouth pipet and a small amount of sterile M9 buffer, and then placed onto a *C. elegans* culture dish. After a period of recovery, animals that have moved (i.e., are alive) are transferred to individual plates and allowed to lay eggs for several days. The injected animals and their progeny are examined/scored for phenotypes resulting from gene silencing. In a successful RNAi by microinjection experiment, one should aim to recover ten viable injected hermaphrodites to obtain a high degree of confidence in the results.

In addition to the standard equipment for manipulating worms (e.g., stereomicroscope, platinum wire pick, media; Hope, 1999), this procedure requires microinjection equipment, including an inverted microscope equipped with a 10× objective, micromanipulator, N₂ gas, and microinjection assembly to regulate the pressure and flow of the microinjection solution. The procedure described here utilizes a Nikon inverted microscope equipped with 10× objectives, gliding stage, and Narishige MN151 micromanipulator with fine z-axis adjustments, as well as a Tritech microinjector system for pressurizing the microinjection needle. Injections are normally carried out using the 10× objective for a total magnification of 100×. As noted above, it should be possible, with some practice, to perform microinjections with a range of different microinjection systems.

IMPORTANT NOTE: The experimenter should become familiar with the microinjection setup before proceeding with the experiment.

Materials

- 0.1 to 1 $\mu\text{g}/\mu\text{l}$ dsRNA
 - Halocarbon oil Series 700 (Halocarbon Products)
 - L4 to young-adult staged *C. elegans* (e.g., strain N2; CGC)
 - M9 buffer (see recipe)
 - NGM plates seeded with *E. coli* (see recipe)
 - Loading capillary (see recipe)
 - Microinjection needle (see recipe)
 - Inverted microscope with micromanipulator and microinjection assembly with N_2 gas supply (e.g., TRITECH Research Microinjector System)
 - Agarose microinjection pads (see recipe)
 - 30-mm Petri dish lid
 - Dissecting microscope
 - Platinum wire pick flattened at the end
- Additional reagents and materials for transferring and propagating *C. elegans* (see Support Protocol 1)

Load and mount the microinjection needle

1. Pellet insoluble material that may clog the microinjection needle by centrifuging the 0.1 to 1 $\mu\text{g}/\mu\text{l}$ dsRNA solution 5 min at $10,000 \times g$, 20°C .
2. Touch the drawn-out end of the Pasteur pipet portion of the loading capillary to the dsRNA solution, allowing a small volume to be drawn into the pipet. Deposit the RNA solution just behind the drawn-out tip of the needle by threading the loading pipet all the way into the needle and gently blowing through the mouth pipet (Fig. 26.3.1).

Needles can be loaded and stored up to several hours inside a humidifying chamber constructed from a Petri dish containing a wet piece of filter paper. It is often prudent to load two needles for each microinjection solution and store one in the humidifying chamber as a backup in case of problems.

3. Attach the loaded microinjection needle to the microinjection assembly, sliding the tubing over the back end of the needle (Fig. 26.3.2).

The tubing should fit snugly over the needle making a tight seal. If the seal is not tight enough, the N_2 gas will escape around the needle when pressure is applied and the dsRNA solution will not flow from the needle.

4. Turn on the light source of an inverted microscope. Mount the loaded needle onto the micromanipulator and roughly align the tip of the needle into the center of the light beam.

The needle should be positioned such that it has a downward angle of $\sim 15^\circ$ to 20° .

Prepare worms for microinjection

5. Working at a dissecting microscope, prepare a microinjection pad by placing a small ($\sim 10\text{-}\mu\text{l}$) drop of halocarbon oil Series 700 on the glass surface of the coverslip adjacent to the region coated with dry agarose. Place the microinjection pad onto an inverted 30-mm Petri dish lid resting on the stage of a dissecting microscope.

This will hold the microinjection pad at approximately the same height as the worms on a small plate, so that minimal focusing will be required while transferring worms to the microinjection pad.

6. Briefly flame a platinum wire pick that has been flattened at the end for picking up worms.

Figure 26.3.1 Loading the microinjection needle.

Figure 26.3.2 Attaching the microinjection needle to the microinjection assembly via tubing.

7. Touch the pick to the surface of the halocarbon oil on the pad. Using this viscous oil drop on the end of the wire, pick up several L4- to young adult-staged *C. elegans* for microinjection. Transfer the worms to a dry portion of the pad by gently touching the underside of the pick to the agarose surface of the pad and sliding the pick along to gently push the worm down to the surface of the pad, making a mental note of the configuration of the animals.

Pick up the worms by gently touching the oil-coated undersurface of the pick to the top of the worm on the Petri dish. When the pick is raised, the worm should be transferred from the plate to the underside of the pick by surface tension. Move to another worm and repeat the procedure.

Beginners should start with two or three worms, but experts will pick up as many as twenty worms on the same pick. If possible, choose worms that are either off the E. coli lawn or are on a thin area.

It is not necessary to place the worms in a row, or even to separate the worms from one another, but it is helpful if the majority of the worms are angled with the long axis of their bodies oriented in the same general direction.

8. Go back to the oil drop with the pick and obtain additional oil to spread over the worms as necessary, making sure that all of the worms are completely covered.
9. If the worms are not sticking to the microinjection pad, gently pat the worms along the length of the body to encourage them to stick to the agarose pad.

IMPORTANT NOTE: *Once the animals have been transferred to the microinjection pad, work as quickly as possible to prevent the animals from drying out.*

Use pads that are thoroughly dry to immobilize the worms. If necessary, rebake pads 1 hr in a 50°C oven. Check to make sure that the agarose side of the pad is facing up. The worms will not stick to bare glass.

Inject the dsRNA into worms

10. Place the microinjection pad with immobilized worms onto the stage of the inverted microscope and focus on the worms.
11. Move the tip of the microinjection needle into the center of the field of view, being careful to keep the needle above the worms (Fig. 26.3.3A). Maintain this needle position and only move the needle into or out of the focal plane (i.e., toward or away from the microinjection pad) using the z-axis control knob on the micromanipulator.
12. Orient the pad so that the general body axis of the animals parallels the orientation of the needle (Fig. 26.3.3).

If the needle is perpendicular to the body axis of the animal, it may completely penetrate the animal or cause it to roll over during the microinjection procedure.

13. Using the 10× objective, choose a worm at one end of the cluster of worms and position the worm directly under the needle tip by moving the stage.

Keep in mind the configuration of worms placed on the pad (step 7). Move from one end of the cluster to the other systematically.

Some investigators prefer to move the stage by hand, while others prefer to use the stage dials. Try both and use whichever method is more comfortable.

14. Focus carefully and lower the needle directly down on top of the first animal's body. With the needle pressing against the body of the animal (creating an indentation), push on the stage to gently move the worm into the needle tip (Fig. 26.3.3B to D).
15. Once the needle penetrates the cuticle, apply pressure to the needle and allow the dsRNA solution to flow into the animal.

With an ideal microinjection, the flow of the solution from the needle tip will be easily observable in both directions (i.e. towards the mouth and anus; Fig. 26.3.3E to G) and a slight increase in size near the point of injection may even be observed. If the animal rapidly increases in both diameter and length, then too much solution is being injected, and the animal may not survive. Decrease the duration of the pulse and, if necessary, give several quick pulses to deliver the dsRNA into the animal.

16. Remove the needle from the worm by pulling back on the sliding stage (Fig. 26.3.3H). Raise the needle slightly using the z-axis knob on the micromanipulator and move to the next worm.

Figure 26.3.3 Overview of the microinjection technique. **(A)** The injection needle enters the field of view from the left of the image and is oriented above and roughly parallel to the body axis of the worm. **(B to D)** The needle is lowered until the tip touches the worm forming a slight indentation. The worm is pushed against the needle until the tip of the needle penetrates the cuticle. **(E to G)** The dsRNA solution is injected into the body cavity of the worm and flows in both directions away from the tip (indicated by the bars and arrows). **(H)** The needle is then backed out of the worm by moving the worm away from the needle.

- Repeat steps 13 to 16 until all of the worms are injected. Carefully remove the pad from the microinjection microscope and transfer to a dissecting microscope.

Recover injected animals for phenotype analysis

- Recover the animals by placing a small drop of M9 buffer directly under the halocarbon oil so that it contacts the worms and gently floats them off of the agarose.

The loading capillary can be used for this purpose. Simply break off the very thin drawn-out end of the loading capillary, creating an opening just slightly larger in diameter than a worm. Using the capillary, blow M9 against the worms to loosen them from the pad and suck each worm up into the capillary.

Generally, it is wise to transfer worms in small groups, approximately five animals at a time, as occasionally worms become stuck to the glass inside the capillary.

- Deposit the worms on a fresh NGM plate seeded with *E. coli*, and allow the worms to recover (i.e., incubate at 20°C) overnight (see Support Protocol 1).

Healthy worms that survive the microinjection should begin to move vigorously in the M9 buffer or shortly after transfer to the NGM plate.

- Transfer each injected animal to a fresh NGM plate (day 1) and incubate an additional 24 hr at 20°C (see Support Protocol 1). Transfer the injected animals to a fresh NGM plate once more (day 2).

- Monitor the injected animals and their progeny for phenotypes (see Hope, 1999; Wood, 1988).

Embryos that are still present on day 1 plates 24 hr after removing the adult indicates that the microinjected dsRNA produces an embryonic lethal phenotype. However, always be sure to compare the injected animals and their progeny to uninjected or control-injected animals.

*In some cases, postembryonic phenotypes can easily be determined by comparing the progeny of injected animals to the progeny of uninjected or control injected animals. These may include phenotypes such as uncoordinated (*Unc*), slow growth (*Gro*), sterility (*Ste*), larval lethal (*Lvl*), larval arrest (*Lva*), lethality (*Let*; any stage), egg-laying defective (*Egl*), high incidence of males (*Him*), dumpy (*Dpy*), small (*Sma*), long (*Lon*), blister (*Bli*), protruding vulva (*Pvl*), multivulva (*Muv*), and body morphology defects (*Bmd*).*

MICROINJECTION INTO *unc-42 rde-1* ANIMALS CROSSED TO N2 MALES TO EXAMINE ZYGOTIC RNAi PHENOTYPES

ALTERNATE PROTOCOL

If RNAi by microinjection (see Basic Protocol 1) results in embryonic arrest, this could reflect a maternal function for the targeted gene. To look specifically for zygotic activity of a targeted gene, it is possible to inject dsRNA into an RNAi-deficient (*rde* mutant) strain that has been mated to a wild-type N2 male (Fig. 26.3.4). In this scenario, maternal activity of the targeted gene will be unaffected since RNAi is not functional in the *rde* mutant hermaphrodite. However, wild-type males that successfully mate with the *rde* mutant hermaphrodite will provide RNAi activity in the cross progeny, thereby silencing zygotic expression of the targeted gene. To facilitate the identification of *rde*⁺ cross progeny, an *rde* mutant that is marked with a recessive visible mutation—e.g., uncoordinated (*Unc*)—is mated to N2 males, injected with dsRNA, and the non-*Unc* cross progeny examined for phenotypes resulting from loss of zygotic activity of the targeted gene.

Gene Silencing

26.3.7

Figure 26.3.4 Schematic of the zygotic RNAi procedure.

Additional Materials (also see Basic Protocol 1)

Male N2 *C. elegans* (CGC)
unc-42 rde-1 C. elegans (WM36; CGC)
 Mating plates (see recipe)

Additional reagents and equipment for transferring and propagating (see Support Protocol 1), and mating *C. elegans*

1. Mate wild-type (N2) *C. elegans* males with an *unc-42 rde-1* mutant strain overnight (see Support Protocol 2; Hope, 1999).
2. Inject dsRNA into the mated Unc hermaphrodites (see Basic Protocol 1).
3. Transfer (see Support Protocol 1) each injected hermaphrodite to individual mating plates with males to recover (i.e., incubate at 20°C) overnight and to continue mating (see Support Protocol 2).
4. Transfer the hermaphrodite alone to a fresh NGM plate and score non-Unc cross progeny for RNAi phenotypes as described above.

**BASIC
 PROTOCOL 2**

FEEDING WORMS dsRNA

RNAi can be induced by cultivating worms on bacteria expressing dsRNA (Timmons et al., 2001). First, a cDNA corresponding to the gene of interest is cloned into a bacterial expression vector between opposing phage T7 polymerase promoter sites. The feeding vector is then transformed into the *E. coli* HT115 strain carrying the DE3 lysogen (*UNIT 1.8*), providing IPTG inducible expression of the phage T7 RNA polymerase. The HT115(DE3) strain also lacks the RNase III gene and is therefore deficient in degrading dsRNA. The RNAi food is prepared and seeded onto worm plates. Animals are placed onto the RNAi food and both the hermaphrodite and progeny are examined and scored for phenotypes.

Figure 26.3.5 Multiple cloning site of the double T7 RNAi feeding vector L4440. Opposing phage T7 promoters flank the multiple cloning site of L4440. The restriction sites shown are present exclusively in the MCS with the unique sites indicated in bold.

To simultaneously target two genes by feeding, the authors have found it best to fuse two cDNA fragments, one from each gene, into a single feeding vector. Mixing of two *E. coli* strains will also work, but is more prone to error caused by unequal mixing or RNA expression in the two different feeding strains. Do not attempt to feed animals that were previously injected with dsRNA; for unknown reasons the microinjection of dsRNA (even nonspecific dsRNA) will suppress bacterial RNAi.

This protocol can be easily performed on large populations to examine strains at a biochemical level that have been depleted for a particular gene product. The procedure can also be performed in microtiter format using 12 or 24 well plates (Fraser et al., 2000).

Materials

cDNA

L4440 double T7 RNAi feeding vector (Fig. 26.3.5; A. Fire, <http://www.ciwemb.edu>)

E. coli RNAi feeding strain HT115 (CGC)

Terrific broth (TB; UNIT 1.1) containing 50 µg/ml each ampicillin and tetracycline (UNIT 1.4)

TB containing 50 µg/ml ampicillin

M9 buffer (see recipe)

M9/15% glycerol (see recipe)

NGM/amp/IPTG plates (see recipe)

Gravid/young adult, L1 larvae, or L4 larvae *C. elegans* of appropriate strain(s) (e.g., N2, CGC)

NGM/amp/IPTG plates (see recipe) seeded with HT115 containing empty L4440 RNAi feeding vector

Additional reagents and equipment for subcloning DNA fragments (UNIT 3.16), transforming *E. coli* (UNIT 1.8), growing *E. coli* (UNIT 1.2), and transferring and propagating *C. elegans* (see Support Protocol 1)

NOTE: Perform each RNAi experiment in triplicate.

Prepare the RNAi feeding strain

1. Clone a cDNA for the gene of interest into L4440 double T7 RNAi feeding vector (UNIT 3.16).

Avoid introns—the presence of introns in the feeding construct may reduce the efficiency of interference.

As alternatives to L4440, NEB offers Litmus 28i and 38i.

2. Transform the RNAi feeding construct into the *E. coli* feeding strain HT115 (UNIT 1.8).
3. Pick a colony and inoculate 2 ml terrific broth (TB) containing 50 µg/ml each ampicillin and tetracycline, and grow overnight at 37°C (UNIT 1.2).
4. Seed the starter culture into 1 liter TB containing 50 µg/ml ampicillin and incubate with shaking at 37°C for 8 to 16 hr (UNIT 1.2).

Tetracycline in this culture is unnecessary and, in fact, may reduce the efficiency of RNAi (Kamath et al., 2001).

Cultures can be scaled down; however, excess food from large cultures can be stored at –80°C, indefinitely.

Harvest the bacteria

- 5a. *For centrifugation:* Centrifuge bacteria 10 min at 800 × g, 4°C. Resuspend the bacterial pellets in M9 buffer (use 25 ml for each liter of culture) and transfer to a 50-ml conical tube.

Harvest food by centrifugation if food is needed urgently.

If time permits, allow the bacteria to precipitate passively to reduce the likelihood of contaminating the dsRNA food.

- 5b. *For passive precipitation:* Replace TB medium with M9 buffer as follows:
 - a. Allow bacteria to settle to the bottom of the culture flask overnight at 4°C. Carefully aspirate as much of the medium from the flask as possible without disturbing the bacteria, which forms a soft layer at the bottom of the flask. Swirl the flask to suspend the bacteria in the remaining volume of TB and pour into a 50-ml conical tube.
 - b. Pellet the bacteria in a clinical centrifuge 10 min at 800 × g (4500 rpm), 20°C. Remove broth by aspiration.

These pellets tend to be soft and pouring off the medium could result in loss of the bacterial pellet.
 - c. Wash the bacteria in 5 pellet volumes M9 buffer by vortexing until the clumps are dissolved.
6. Pellet the bacteria in a clinical centrifuge 10 min at 800 × g (4500 rpm), 20°C.

- 7a. *For immediate/short term use:* Resuspend washed bacteria in 5 pellet volumes of M9 buffer. Store up to 1 month at 4°C.

RNAi food is ready to use after resuspension in either buffer.

- 7b. *For storage:* Resuspend washed bacteria in M9/15% glycerol. Store in 10-ml aliquots indefinitely at –70°C.

8. Seed an appropriate number of NGM/amp/IPTG plates with one drop (~100 µl) each RNAi food.

9. Allow plates to dry overnight at room temperature.

This also allows induction of dsRNA production and consistently produces the most penetrant RNAi phenotypes by feeding.

Seeded plates can be stored in a sealed container up to several weeks at 4°C. Warm the RNAi plates to room temperature prior to use.

Cultivate worms on RNAi food and analyze phenotypes

- 10a. *Test for embryonic and post-embryonic phenotypes:* Place single gravid adult *C. elegans* onto NGM/amp/IPTG plates. As a control, place single gravid adults onto HT115(DE3) containing the empty L4440 RNAi feeding vector. After 24 hr, transfer each RNAi-fed or control-fed adult to a fresh plate of the same type and count the number of progeny (eggs and larvae) on each plate.

By placing gravid adults onto RNAi plates, one can assess the ability of the RNAi to produce embryonic as well as postembryonic phenotypes on the same plate.

- 10b. *Test for embryonic lethal phenotypes:* Place single L4 animals onto NGM/amp/IPTG (RNAi) and control—i.e., seeded with HT115(DE3) containing the empty L4440 RNAi feeding vector—plates. After 24 hr, transfer each adult to a fresh plate of the same type onto which it was seeded (i.e. RNAi or control) and count the number of progeny (eggs and larvae) on each plate.

- 10c. *Test for postembryonic phenotypes:* Place 20 newly hatched L1 larvae onto RNAi and control plates.

11. Examine the plates each day to determine whether the RNAi food produces any embryonic and/or postembryonic phenotypes.

Embryos that are still present on RNAi plates 24 hr after removing the adult indicates that the RNAi produces an embryonic lethal phenotype. However, always be sure to compare RNAi plates to control plates.

In some cases, postembryonic phenotypes can easily be determined by comparing the RNAi-fed progeny with the control-fed progeny.

SOAKING WORMS IN dsRNA

Soaking worms in dsRNA solution can also induce RNAi (Tabara et al., 1998). In this simple procedure, L4-stage animals are placed in soaking solution containing dsRNA corresponding to the gene to be silenced. Animals are soaked for up to 24 hr and recovered on Petri dishes. The exposed animals and their progeny are then examined for phenotypes.

The soaking procedure is capable of being scaled up or performed in microtiter format (Maeda et al., 2001). Another variation of the procedure is to soak L1-stage animals to examine postembryonic phenotypes.

Materials

dsRNA

Nonspecific dsRNA—i.e., dsRNA that is nonhomologous to any *C. elegans* sequence and which is comparable in length to the experimental dsRNA (e.g., *gfp*; optional)

Soaking solution (see recipe)

C. elegans (e.g., N2, CGC)

M9 buffer (see recipe)

NGM plates (see recipe) with and without seeded *E. coli* OP50 (see recipe)

65°C water bath
0.2- and 2.0-ml microcentrifuge tubes
5-ml glass pipet

Additional reagents and equipment for ethanol precipitation (*UNIT 2.1A*)

1. Ethanol precipitate (*UNIT 2.1A*) an appropriate amount of dsRNA sample and, if available, nonspecific dsRNA. Dissolve the pellet in soaking solution to a final concentration of 0.5 to 5.0 mg/ml.

It may be necessary to try several different concentrations of dsRNA to determine the concentration required to generate a phenotype.

2. Denature the RNA by heating 15 min at 65°C. Anneal the dsRNA by cooling the sample to room temperature for ~15 to 30 min.
3. Pipet 5 μ l sample dsRNA into an appropriately labeled 0.2-ml microcentrifuge tube. Do the same for the nonspecific dsRNA control, or if this is not available, use soaking solution alone.

It may also be useful to set up a positive control (i.e., a dsRNA proven to demonstrate a phenotype) to determine that the procedure is working as expected.

4. Using a 5-ml glass pipet, rinse a healthy mixed-stage population of *C. elegans* with 2 ml M9 buffer and transfer to a 2.0-ml microcentrifuge tube.
5. Pellet the animals by microcentrifuging 30 sec at 800 \times g, 20°C. Remove M9 buffer with a 1-ml pipet tip and wash again.
6. Transfer the worms to an unseeded NGM plate and let them crawl around for 5 to 10 min at 20°C to allow complete digestion of bacteria in the gut.
- 7a. *To test for embryonic lethal phenotypes:* Pick and transfer five to ten L4-stage animals to each sample or control tube (step 3). Incubate 24 hr at 20°C. Recover the soaked worms by plating them onto an NGM plate seeded with *E. coli* OP50, transfer each worm to an individual plate, and incubate 24 hr at 20°C. Transfer each worm to a fresh plate and count the number of progeny.
- 7b. *To test for postembryonic phenotypes:* Place 20 newly hatched L1 larvae into each sample or control tube and incubate 24 hr at 20°C. Recover soaked worms by plating them onto an NGM plate seeded with *E. coli* OP50. When the L1-soaked animals reach L4 stage, transfer each animal to an individual plate.
8. Monitor the treated animals and their progeny for mutant phenotypes resulting from dsRNA treatment.

SUPPORT PROTOCOL 1

PICKING AND PROPAGATING *C. ELEGANS*

C. elegans can be transferred from one plate to another using a worm pick—a short piece of platinum wire with one end flattened and the other end mounted to a Pasteur pipet. Platinum wire heats and cools rapidly and can and should be flamed before and after every pick to avoid contamination.

Label the bottom half of an NGM plate (see recipe) with the appropriate strain name and the date. Working under a dissecting microscope, pick up a dab of *E. coli* OP50 food (see recipe) on the underside of the flattened end of the worm pick. Gently touch the food on the bottom of the pick to the top of a worm. The worm should stick to the food on the worm pick by surface tension. Quickly transfer the worm to a new NGM plate, gently touching the worm to the plate and allowing the worm to swim off of the worm pick.

For those unfamiliar with *C. elegans*, propagating worms may be difficult at first, but with practice picking and maintaining worms will be routine. See Support Protocol 2, Hope (1999), and Wood (1988) for additional details on propagating, staging, cleaning, synchronizing, and mating *C. elegans*.

SEXING AND MATING *C. ELEGANS*

C. elegans comes in two sexes, hermaphrodite and male, which are determined by the number of X chromosomes. Males can be distinguished from hermaphrodites physically by the lack of hermaphrodite sex organs (e.g., vulva and uterus containing developing embryos) and by the tail, which has a barbed appearance under the dissecting microscope. Hermaphrodites (XX) produce both sperm and oocytes and can reproduce by self-fertilization. Hermaphrodites can also be cross-fertilized by *C. elegans* males (XO), which produce sperm only. If a *C. elegans* male successfully mates with a hermaphrodite, the majority of the progeny will be cross-progeny because male sperm outcompetes hermaphrodite sperm. As such, one half of the cross-progeny will be male and the other half will be hermaphrodites. For a detailed description of hermaphrodites and males and their identification, refer to Wood (1988) and Riddle et al. (1997).

Because *C. elegans* males are rare, try to set up a cross when a male is found. Males arise by spontaneous X chromosome nondisjunction at a frequency of ~0.1% (Riddle et al., 1997). This frequency can occasionally be increased by heat-shock treatment of L4 hermaphrodites at 30°C for 4 hr. Once a male stock is obtained, the population should be maintained by periodically setting up crosses.

Genetic crosses in *C. elegans* are typically set up between a phenotypically wild-type male and a hermaphrodite that is homozygous for a visible mutation—e.g., uncoordinated (Unc). This allows cross-progeny (non-Unc) to be easily distinguished from self-progeny (Unc). Multiple (e.g., ten) young healthy males and multiple (e.g., five) L4 or young adult hermaphrodites should be chosen when crossing *C. elegans* strains.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Agarose microinjection pads

Prepare injection pads by sandwiching a couple of drops of melted 2% (w/v) agarose between two 22 × 50-mm glass coverslips. Once the agarose hardens (<1 min), pop off one of the coverslips. Dry the agarose pad onto the remaining coverslip by baking at 50°C for 1 hr. A large number of microinjection pads can be made at one time and stored indefinitely at room temperature in a closed container (e.g., a Petri dish or empty coverslip box) to prevent dust from accumulating on the surface.

Baking dries the agarose to the coverslip. One of the coverslips must be removed before baking. The popped off coverslip can then be reused for another microinjection pad.

***E. coli* OP50 food**

Inoculate (UNIT 1.2) 100 ml of L broth (UNIT 6.12) with a single colony of OP50 (CGC) using sterile technique. Incubate the culture overnight at 37°C with shaking. Store the liquid culture at 4°C for several weeks

*The uracil auxotrophic *E. coli* OP50 strain is typically used as a food source for *C. elegans*, as the limited growth of *E. coli* OP50 on NGM plates provides easier observation of the worms.*

Loading capillary

The loading capillary consists of a drawn-out Pasteur pipet connected via tubing to a mouth pipet. The diameter of the drawn-out end of the Pasteur pipet must be less than that of the inner diameter of the nondrawn-out portion of the microinjection needle (see recipe) to facilitate loading.

M9 buffer with and without 15% glycerol

3.0 g monobasic potassium phosphate (KH₂PO₄)
6.0 g dibasic sodium phosphate (Na₂HPO₄)
5.0 g NaCl
1 ml 1 M magnesium sulfate (MgSO₄)
Add 150 ml glycerol (15%) if appropriate
Adjust volume to 1 liter with H₂O
If using glycerol, prepare 100-ml aliquots
Sterilize by autoclaving
Store up to 2 months at 20°C

Mating plates

Flame the end of a Pasteur pipet until it is rounded and nearly closed. Using the Pasteur pipet, withdraw some *E. coli* OP50 food (see recipe) from an overnight culture. Touch the rounded tip of the Pasteur pipet to the center of a 30-mm NGM plate (see recipe), dispensing a very small droplet of the *E. coli* OP50 food. Incubate the plates at room temperature 2 to 3 hr and store at 4°C in a sealed container for several weeks.

Mating plates are NGM plates seeded with a very thin and small (~5 mm) spot of E. coli OP50 in the center.

Alternatively, a small dab of E. coli OP50 food can be transferred from a dry seeded plate to an unseeded 30-mm NGM plate just prior to setting up a cross.

See UNIT 1.2 for more information regarding culture of E. coli.

Microinjection needles

The ideal microinjection needle (i.e., borosilicate glass capillaries, World Precision Instruments) should taper to a sharp and stiff point and can be pulled using 1.2- or 1-mm capillary blanks and a wide variety of needle-pulling devices (e.g., Narishige PN-30). After pulling the first two needles, examine them under a dissecting microscope. The needles should taper gradually and steadily to a very sharp point. Using one of the first two needles, gently touch the other needle just behind the tip while watching through the dissecting scope. If the needle tips bend easily without breaking then it is probably not stiff enough for penetrating the cuticle of the worm. A common problem is a needle that is hair-like at the tip. To correct this problem, reduce the heat setting on the needle puller. It may also be necessary to adjust the pull strength. Get advice from someone experienced in pulling capillaries if problems persist. Most needles will be closed at the tip after pulling and thus, it will be necessary to gently break the needle tip prior to microinjection. Alternatively, the needle tips can be etched with acid (Mello and Fire, 1995).

NGM plates or NGM/amp/IPTG plates

Prepare the following in a 2-liter Erlenmeyer flask:
3.0 g NaCl
17 g Agar
2.5 g Bacto-peptone
975 ml H₂O

Add a stir bar and sterilize by autoclaving. Cool to ~55°C and add 25 ml of 1 M potassium phosphate buffer, pH 6 (see recipe), 1 ml of 1 M CaCl₂, 1 ml of 5 mg/ml cholesterol in 100% ethanol, and 1 ml of 1 M MgSO₄. For NGM/amp/IPTG plates, also add 50 µg/ml ampicillin and 1 mM (final) IPTG (UNIT 1.4). Dispense into Petri dishes (~3 ml per 30-mm plate). Dry the plates at room temperature for 1 to 2 days before seeding with OP50. Store up to 1 month at 4°C in a sealed container.

NGM plates seeded with OP50

Seed each NGM plate (see recipe) with one drop (~100 µl) of *E. coli* OP50 food (see recipe). Allow the *E. coli* OP50 drop to dry into the plate and to grow overnight at room temperature or for 8 hr at 37°C (UNIT 1.2). Store seeded plates in a sealed container for several weeks at 4°C.

Potassium phosphate buffer, 1 M, pH 6.0

108.3 g monobasic potassium phosphate (KH₂PO₄)

35.6 g dibasic potassium phosphate (K₂HPO₄)

Adjust volume to 1 liter with H₂O

Adjust pH to 6.0 if necessary

Store up to 2 months at 20°C

Soaking buffer, 10×

1.55 g dibasic sodium phosphate (Na₂HPO₄)

0.75 g monobasic potassium phosphate (KH₂PO₄)

0.12 g NaCl

0.25 g ammonium chloride (NH₄Cl)

0.5 g gelatin

Adjust volume to 100 ml with H₂O

Sterilize by autoclaving

Store up to 2 months at 20°C

Soaking solution

0.5 ml 10× soaking buffer (see recipe)

15 µl 1 M spermidine (Sigma)

4.5 ml H₂O

Use immediately

COMMENTARY

Background Information

RNA interference (RNAi) is a form of sequence-specific, post-transcriptional gene silencing (PTGS) that is triggered by the introduction of dsRNA (UNIT 26.1; Fire et al., 1998). RNAi is related to a number of gene silencing phenomena in a variety of organisms. Genetic and biochemical studies are revealing a conserved set of factors required for silencing and demonstrating that the underlying mechanisms of these silencing phenomena are remarkably conserved (for reviews, see UNIT 26.1 and Hannon, 2002). The specificity and potency of RNAi has provided researchers with an efficient means of inactivating gene expression in model organisms where conventional gene replacement techniques are unavailable, such as *C. elegans*, *Drosophila*, fungi, plants, and try-

panosomes (Bosher and Labouesse, 2000). The ability to perform RNAi in human cells (Elbashir et al., 2001) has rapidly transformed basic research and holds promise as a therapy for human disease.

RNAi can inhibit gene function in worms injected with dsRNA (see Basic Protocol 1 and Alternate Protocol; Fire et al., 1998), soaked in solution containing dsRNA (see Basic Protocol 3; Tabara et al., 1998), fed bacteria expressing dsRNA (see Basic Protocol 2; Timmons et al., 2001), or engineered to express dsRNA in vivo (Tabara et al., 1999). Interference by dsRNA is sequence-specific and potent (Fire et al., 1998). Worms that are injected in the gut with ~60,000 dsRNA molecules targeting the muscle-specific *unc-22* gene exhibit an *unc-22*(-) twitching phenotype (Fire et al., 1998). Moreover, F1

progeny of injected worms also exhibit a severe twitching phenotype. These findings indicate that dsRNA, or a secondary silencing factor, is transported from one tissue to another and that interference can be inherited. The specific, potent, systemic, and heritable features of RNAi make this an ideal method for assaying the function of genes in *C. elegans*.

Not only does the ability to induce RNAi by a variety of methods allow researchers of different skill levels to apply the technique, it also allows them to characterize gene function under a variety of conditions. Typically, investigators determine whether a particular gene has an RNAi phenotype first by microinjection, simply because the preparation of dsRNA is straightforward and takes less time to prepare than RNAi food and plates (see Time Considerations). However, this does not necessarily mean that RNAi by microinjection is superior to other methods. While some genes are indeed silenced more effectively by microinjection than by feeding, the converse is also true (Kamath et al., 2001), and other genes are equally sensitive to both methods (Kamath et al., 2003; unpub. observ.). Therefore, if microinjection does not work, feeding and/or soaking should be attempted. For RNAi by feeding, Kamath et al. (2003) have generated a library of 16,757 RNAi bacterial feeding clones, representing 86% of the 19,427 predicted *C. elegans* genes.

Due to the requirement of a balancer chromosome for viability, a null mutation in an essential gene limits the ability to perform biochemistry or applications that require large populations. The ability to silence a gene in large populations of *C. elegans* using RNAi by feeding or soaking should make *C. elegans* more amenable to such applications.

RNAi is also a simple way to examine genetic interactions between genes. Sequential microinjection, microinjection or soaking with multiple dsRNAs simultaneously, exposure of mutant strains to dsRNA, as well as feeding constructs containing more than one insert have all been successfully used to determine whether two genes interact (Grishok et al., 2001; Bei et al., 2002; Dudley et al., 2002).

Despite its success, RNAi in *C. elegans* does have its limitations. RNAi does not work for every gene. In particular, pharyngeal, vulval, sperm, and neuronal genes are often difficult to silence (Fire et al., 1998). The reasons for this is not known, but could be due to inefficient transport or maintenance of trigger dsRNA, or secondary signals to these tissues. In some

cases, efficient silencing can be triggered for refractory genes by driving the expression of hairpin dsRNA from a transgene (Tavernarakis et al., 2000).

A large amount of RNAi data is being generated in *C. elegans*. The data can be accessed and searched from Wormbase (<http://www.wormbase.org>) to determine whether a particular gene exhibits an RNAi phenotype or to identify genes that show a particular phenotype. In general, the quality of the data is good, but keep in mind that a negative result does not necessarily mean that a particular gene does not exhibit an RNAi phenotype. It simply means that under the conditions tested no phenotype was observed. Investigators should try the experiment by additional methods before accepting a negative RNAi result.

A common problem with all RNAi methods is the possibility of inadvertently silencing related genes. Generally, this only occurs when a few segments of perfect nucleotide identity of at least 25 nucleotides exist within the gene. As a standard control for this problem in RNAi studies, it is always important to identify related genes in the genome and assay each of these for similar or overlapping phenotypes.

Although RNAi can be inherited (Fire et al., 1998; Grishok et al., 2000), in most instances—e.g., using BLAST (*UNIT 19.3*) or a similar search program—it is not permanent. While this may be considered as a benefit to some, to the classical geneticist this is a drawback. In order to produce a phenotype, the investigator must repeat the experiment from start to finish. Variability is typically not a problem, but a range of phenotypes is possible, so great care must be taken when assaying the animals. Because the feeding strategy (see Basic Protocol 2) requires less actual worm manipulation, it may be the more consistent protocol, provided care is taken when preparing the dsRNA food and media. When possible, it is a good idea to confirm RNAi phenotypes by obtaining a genetic mutant. Genetic mutants remain the gold standard in *C. elegans* research.

Critical Parameters

Target selection

There are few hard and fast rules for determining the region of a gene to target. Since introns and untranslated regions are not efficient targets of the RNAi machinery (Montgomery et al., 1998), the dsRNA should be designed to target the coding region of the mature mRNA. Although 500 to 1000 bp is

sufficient, if feasible, target the entire coding region of the gene of interest or several different regions. The sensitivity of worms to RNAi targeting different regions of a particular gene can be determined in a relatively short period of time by microinjection.

As mentioned above, care should be taken when performing RNAi on members of a gene family. Experiments should be designed such that the targeted region of a gene of interest does not overlap with the other member(s) of the gene family. This may be difficult if extensive homology exists, but in most cases this should not be a problem. Use BLAST (UNIT 19.3) to identify related sequences in *C. elegans* and to determine whether there is significant identity to complicate the analysis. If there is significant identity between two sequences, attempt to find and target regions that are divergent.

Obtaining cDNA clones

The laboratory of Yuji Kohara (ykohara@lab.nig.ac.jp) has generated a library of cDNAs expressed in *C. elegans*. In addition, they have generated sequence tags for a large number of these clones and assigned them to the corresponding genes. If a cDNA for a particular gene has been identified, the clone or yk (for Yuji Kohara) number will be listed at the bottom of the Gene Report Web page at Wormbase (<http://www.wormbase.org>; see Internet Resources) under the subheading Reagents: Matching cDNAs. The cDNA clones are made available to the *C. elegans* community and are provided as a small aliquot of Lambda ZAP II bacteriophage. A kit provided by Stratagene can be used to amplify the phage and to excise the pBluescript SK(-) phagemid. Each insert is flanked by the phage T3 and T7 RNA polymerase promoters, which can be used to synthesize sense and antisense RNA strands in vitro (UNIT 3.8). If a yk clone is not available, a cDNA can be generated by RT-PCR from total worm RNA or polyA-selected mRNA using sequence-specific oligonucleotides and cloned into an appropriate expression vector (e.g., pBluescript).

Transcription templates can also be generated by PCR from genomic DNA using oligonucleotides with 5' tails containing phage T7 RNA polymerase promoter sequences. In this case, try to identify and amplify the longest contiguous stretch of exon sequence possible, minimizing the inclusion of introns. The resultant PCR product will contain a portion of the gene of interest flanked by opposing T7 promoter sites. Using such a template, both sense

and antisense strands of RNA can be produced simultaneously in a single in vitro transcription reaction.

When generating clones for RNAi by feeding, inserts should be exon rich. The authors have had success with a variety of feeding constructs, targeting sequences from 300 to 2400 nt long. The optimal length of the targeted region for RNAi by feeding is likely to be gene specific and should be determined empirically; however, the parameters discussed above represent a good starting point.

dsRNA preparation

Sense and antisense RNA strands are prepared using standard protocols and kits, and then annealed to make dsRNA. Several companies now provide high yield in vitro transcription kits. The Megascript Kit from Ambion is outstanding and the instruction manual provides a lot of useful information, from designing oligonucleotides containing phage promoters to troubleshooting transcription reactions.

Efficient RNAi will be achieved for many genes over a very broad range of concentrations (0.01 to 5 mg/ml). Initially, higher concentrations (i.e., 1 mg/ml) are preferred because some genes are less sensitive to RNAi than others for unknown reasons. A small percentage (<5%) of nonspecific embryonic lethality among progeny of the injected animals is sometimes observed; however, there are no other noticeable side effects from injecting high dsRNA concentrations.

At very low concentrations of dsRNA, one may be able to induce hypomorphic phenotypes. Mixing two different RNAi feeding strains has been shown to dramatically reduce the penetrance of mutant phenotypes observed with one feeding strain alone (Kamath et al., 2001). These authors also found that a 1:1 mixture of *unc-37* RNAi food and normal OP50 (which does not express the dsRNA) completely abolished the embryonic lethality induced by *unc-37* RNAi; however, 100% of the progeny displayed hypomorphic postembryonic phenotypes, which was also observed when the RNAi food was induced with very low levels of IPTG. Therefore, adjusting the levels of dsRNA delivered to the animals can alter the penetrance and spectra of RNAi phenotypes.

Silencing multiple genes simultaneously

As discussed above, care should be taken when designing RNAi experiments so that simultaneous silencing of related genes does not

Table 26.3.1 Troubleshooting Guide for *C. elegans* RNAi Studies

Problem	Possible cause	Solution
<i>RNAi by microinjection</i>		
dsRNA solution does not flow from the needle	Needle is closed	Etch or break the needles after pulling to open
	Needle is clogged	Break the tip of the needle to restore flow Use a new needle Centrifuge dsRNA solution prior to use
Worms do not stick to agarose injection pad	Agarose is not dry enough	Bake agarose pads at least 1 hr at 50°C
No RNAi phenotype observed	dsRNA is degraded	Prepare fresh dsRNA and analyze on 1% agarose gel to check quality (<i>UNIT 2.5A</i>) Perform positive control for RNAi by injection
	Target gene is refractory to RNAi	Try another region of the gene Attempt to achieve RNAi by feeding or soaking
<i>RNAi by feeding</i>		
No RNAi phenotype observed	dsRNA production is not induced	Test the plates by performing a positive control for RNAi Prepare fresh NGM/Amp/IPTG plates
	RNAi food is contaminated	Prepare fresh RNAi food. Be sure to include both ampicillin and tetracycline in the starter culture to prevent contamination with another bacterial species. Perform all food preparation carefully.
<i>RNAi by soaking</i>		
No RNAi phenotype observed	dsRNA is degraded	Prepare fresh dsRNA and soaking solution

occur inadvertently. Nevertheless, there may be instances when it is desirable to silence multiple genes simultaneously. For instance, two related genes that function redundantly in a particular process may show no phenotype or produce an incompletely penetrant phenotype when silenced individually by RNAi. On the other hand, simultaneous RNAi targeting of both genes may dramatically produce a completely penetrant phenotype (Grishok et al., 2001). As mentioned above, RNAi is also a simple and rapid method for examining genetic interactions. In principle, each of the dsRNA delivery methods is amenable to simultaneous RNAi; however, microinjection is the most widely used technique for this purpose. Simultaneous RNAi by feeding also works, although it is somewhat limited relative to microinjection. As mentioned above, mixing two different RNAi feeding strains together dramatically reduces the penetrance of RNAi, but by engineering the

feeding vector to contain two inserts, the authors have been able to silence two genes simultaneously by double RNAi feeding without an apparent reduction in the penetrance of RNAi relative to either single RNAi food. The combined inserts so far have not exceeded 1.5 kb in length, so presumably additional genes could be targeted, for example in a triple RNAi feeding construct.

Troubleshooting

Table 26.3.1 presents a guide to some of the common problems of achieving RNAi in *C. elegans*, as well as their causes and solutions.

Anticipated Results

Regardless of the delivery method, if RNAi produces a phenotype, the animals will typically be affected for one generation—i.e., the F1 progeny of animals exposed to dsRNA. However, for RNAi by feeding, as long as the

animals are cultivated on RNAi food, they are exposed to dsRNA and the phenotype will persist. Investigators have observed persistent RNAi by microinjection into the F2 generation, although the penetrance is reduced.

In a typical RNAi microinjection experiment, early embryos developing within the uterus may be unaffected, but may carry the silencing signal into the subsequent generation. These unaffected and carrier progeny will be laid on the initial recovery plate after microinjection. After transferring an injected animal from the recovery plate to a fresh plate (~16 hr), the remaining portion of the brood should be completely affected by the RNAi.

For uncharacterized genes, it is difficult to know what to expect from an RNAi experiment; however, if the expression pattern or localization is known (e.g., from *in situ* hybridization), then an estimated guess can be made about the type of phenotype for which to look. For example, if *in situ* analysis indicates that the gene product is expressed in the germline, one might expect to see an embryonic-lethal phenotype or postembryonic-sterile phenotype. For a gene product expressed in muscle cells, one might expect defects in motility. *In situ* expression data can be searched from Wormbase or from the Nematode Expression Pattern Database (NEXTDB; see Internet Resources).

It is recommended that the novice enlist the aid of individuals with expertise in *C. elegans* biology when phenotyping animals.

Time Considerations

RNAi by microinjection

A complete microinjection experiment from injecting animals to scoring phenotypes will take 3 to 6 days. On day 0, the novice should expect to spend about 1 to 2 hr at the injection microscope performing microinjection. With practice, this time can be shortened to ~15 min for each dsRNA and strain. The amount of time to transfer animals to individual NGM plates on days 1 and 2 will vary depending on the number of worms to transfer (5 to 30 min). Expect to spend several hours counting progeny and analyzing phenotypes.

RNAi by feeding

Growth, preparation, and induction of the RNAi food will take 2 to 4 days. The remainder of the feeding experiment will take 3 to 6 days to complete. As for microinjection, plan to

spend several hours counting progeny and analyzing phenotypes.

RNAi by soaking

The amount of time it will take to perform the entire soaking procedure will be similar to that of microinjection.

Cloning of Small RNA Molecules

In the past few years, it has become evident that double-stranded RNA–derived small RNAs are key regulators of gene expression in plants, animals, and most fungi. These small RNAs are involved in a variety of gene silencing processes that are now referred to as RNA silencing. The most well known of these phenomena is RNA interference (RNAi), which leads to sequence-specific degradation of mRNAs that are identical in sequence to the initiator dsRNA. The guide RNAs in RNAi are called small interfering RNAs (siRNAs), which form ribonucleoprotein complexes that mediate target mRNA cleavage.

Another group of small RNAs, the microRNAs (miRNAs), represent evolutionarily conserved small RNAs that are derived from gene products that code for short double-stranded RNA precursors. The two groups of small RNAs, miRNAs and siRNAs, share common features including their biogenesis. In plants, miRNAs act predominantly as siRNAs by guiding degradation of target mRNAs that show near perfect complementarity to the miRNAs. In contrast, animal miRNAs are believed to bind to partially complementary repetitive sequence elements within the 3′-untranslated region of the target mRNAs and repress translation. Artificial targets in animal cells fully complementary to endogenous miRNAs are subjected to degradation.

The most recent class of characterized small RNAs appears to be involved in initiating or maintaining heterochromatin and has been referred to as heterochromatic siRNAs (hsRNAs). Finally, there is emerging evidence for small RNAs participating in directed elimination of DNA sequences during macronuclei differentiation in *Tetrahymena thermophila*.

Because of their important roles in gene regulation, it is of significant interest to characterize the small regulatory RNAs of an organism at the cellular level. Cloning and sequencing of small RNAs from cultured cells or tissues is the most straightforward approach, but it is a technically demanding protocol. If only a given gene or sequence is to be characterized, northern blotting or nuclease-protection techniques may be employed.

This unit provides a detailed stepwise protocol for cloning small RNAs from tissues or cultured cells. Cloning is most successful when starting with 200 to 1000 μg of total RNA. A flowchart of the process is shown in Figure 26.4.1.

Small RNAs of the desired size range (19 to 24 nt in mammals, 19 to 29 nt in *Drosophila* or plants) are gel-isolated from total RNA and subjected to sequential 3′- and 5′-adapter ligation. The oligonucleotide adapters are needed for priming reverse transcription and for defining the orientation of the cloned small RNA. There are two protocols for adapter ligation; the Basic Protocol for ligation uses exclusively commercial reagents, while the Alternate Protocol requires a short chemical synthesis of an adenylated 3′-adapter oligonucleotide. If many ligation reactions are anticipated, the Alternate Protocol should be followed in order to save time.

CLONING OF SHORT RNA MOLECULES

In this basic adapter ligation protocol, the small RNAs are first dephosphorylated prior to ligation of the 3′ adapter to prevent circularization of the small RNAs. A 5′-phosphorylated 3′-adapter oligonucleotide with a blocked 3′-hydroxyl group is attached to the small RNAs. The ligation product is separated from excess 3′ adapter and is subsequently 5′ phosphorylated and subjected to 5′-adapter ligation. The Alternate Protocol uses an

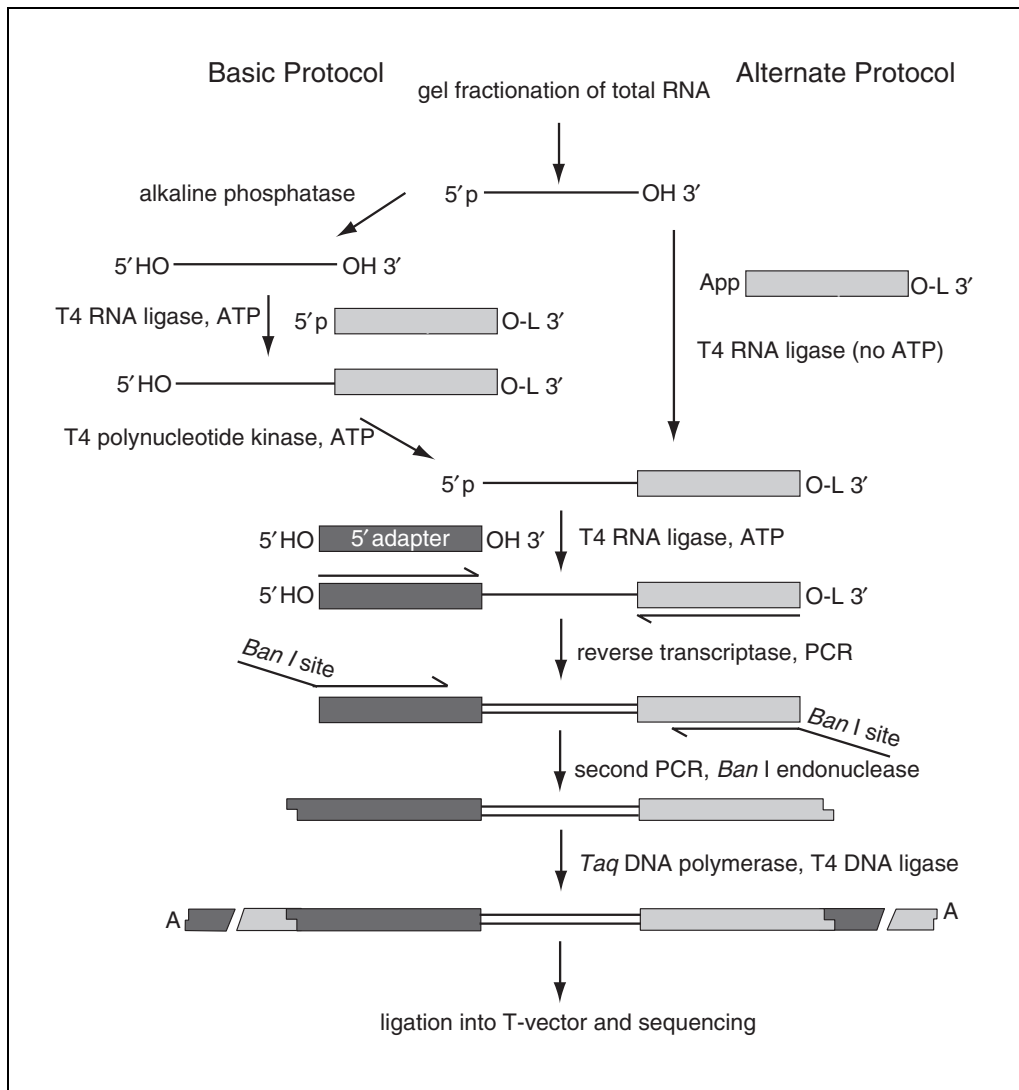

Figure 26.4.1 Schematic drawing of the Basic and Alternate Protocols small RNA cloning steps.

adenylated 3' adapter in the first ligation step in the absence of ATP, therefore bypassing the need to dephosphorylate the small RNAs to prevent circularization during T4 RNA ligation. The ligation product is joined to the 5' adapter without any further 5' phosphorylation.

The final ligation products are reverse transcribed into cDNA and then PCR amplified. To enable directional concatamerization, an additional PCR reaction is performed to introduce non-palindromic *Ban I* restriction sites at both ends of the PCR product. The *Ban I*-digested PCR products are then concatamerized using T4 DNA ligase and subsequently ligated into a commercial TOPO-TA cloning vector. Individual colonies are screened for inserts by PCR. The insert-containing PCR products are purified and submitted for sequencing. The RNA sequences are extracted manually or by using appropriately developed software tools.

Materials

- 200 to 1000 µg of total RNA isolated from cultured cells or tissues (UNIT 4.2)
- Denaturing solution (UNIT 4.2)
- Tris-buffered water-saturated phenol (UNIT 4.2), pH 7.8
- Deionized formamide

Gel-loading solution (see recipe)
 10-well 15% denaturing gel (15 × 7 × 0.15–cm, 50-ml gel volume, see *UNIT 2.12*)
 Radiolabeled RNA size markers
 0.5× TBE (*APPENDIX 2*)
 0.3 M, 0.4 M, and 5 M NaCl (RNase-free)
 Absolute ethanol
 RNase-free water
 10× phosphatase buffer (New England Biolabs)
 20 U/μl alkaline phosphatase (CIP; New England Biolabs)
 25:24:1 (v/v/v) phenol/chloroform/isoamyl alcohol
 Chloroform
 100 μM non-radioactive 5′-phosphorylated 3′-adapter oligonucleotide (see *UNIT 3.10*
 and Table 26.4.1; Fig. 26.4.2A,B)
 10 μM ³²P-labeled 3′-adapter oligonucleotide (see *UNIT 3.10*)
 10× RNA ligation buffer (see recipe)
 50% (v/v) aqueous dimethyl sulfoxide (DMSO)
 20 U/μl T4 RNA ligase (New England Biolabs)
 20-well 15% acrylamide gel (15 × 17 × 0.08–cm, 30-ml gel volume, see *UNIT 2.12*;
 see recipe)
 10× PNK buffer (New England Biolabs)
 100 mM ATP, pH 7.0
 10 U/μl T4 polynucleotide kinase (New England Biolabs)
 100 μM reverse transcription (RT) primer (see Table 26.4.1)
 0.1 M DTT
 5× first-strand buffer
 10× dNTP solution (dATP, dCTP, dGTP, dTTP, 2 mM each, pH 7.5)
 200 U/μl reverse transcriptase (Superscript II, RNase H(-) M-MLV reverse
 transcriptase, Invitrogen)
 150 mM KOH/20 mM Tris base
 150 mM HCl
 10× PCR buffer
 100 μM first PCR 5′ primer and first PCR 3′ primer (see Table 26.4.1)
 5 U/μl *Taq* polymerase
 2% (w/v) standard agarose gel (*UNIT 2.5A*)
 25-bp DNA ladder (Invitrogen)
 100 μM second PCR 5′ primer and second PCR 3′ primer (see Table 26.4.1)
 20 U/μl *Ban* I restriction endonuclease and 10× NEB buffer 4 (New England
 Biolabs)
 2000 U/μl T4 DNA ligase and 10× DNA ligation buffer (New England Biolabs)
 100-bp DNA ladder (New England Biolabs)
 2% (w/v) NuSieve (low-melt) agarose gel (Cambrex)
 10× TAE (*APPENDIX 2*)
 TOPO-TA cloning kit with TOP10 cells and pCR2.1 vector (Invitrogen)
 100 μM primer M13 (–20) F (see Table 26.4.1)
 100 μM primer M13 R (see Table 26.4.1)
 QIAquick PCR purification kit (Qiagen)
 Homogenizer
 Spectrophotometer and 1-cm quartz cuvette
 Plastic wrap
 Phosphorimaging screen and phosphorimager (see *APPENDIX 3A*)
 1.5-ml siliconized Eppendorf-style reaction tubes (Bio Plas)
 Eppendorf or Speed-Vac concentrator

Figure 26.4.2 Structure of special reagents. **(A, B)** Structure of two alternative 3' blocks of the 3' adapter oligonucleotide after chemical synthesis and deprotection. Commercial DNA/RNA synthesis product providers use similar reagents. The C-7 linker in **(A)** was purchased from Chemgenes as 3'-TFA MODIFIER C-7 ICAA CPG and used for chemical DNA/RNA synthesis in house. The 3' blocking group after deprotection is shown in **(B)**, used during the authors' cloning experiments in 2001. The reagent used for the synthesis was dimethoxytrityl-dimethylbenzyl-succinyl-aminopropyl CPG and was a gift from Brian Sproat. Again, this 3'-modifier group was coupled to CPG for chemical DNA/RNA synthesis. **(C, D)** Reagents for the Alternate Protocol. **C**, ImpA; **D**, 3'-adenylated 3'-adapter oligonucleotide.

500- μ l PCR tubes
Thermal cycler
360-nm UV transilluminator
96-well thermocycler-compatible microtiter plates

Additional reagents and equipment for RNA extraction (UNIT 4.2), cloning and purification (Chapter 1)

Isolate total RNA

1. Extract total RNA according to the Basic Protocol of UNIT 4.2, except for the following modifications:

- a. Prepare an RNA extraction solution by pre-mixing one volume of denaturing solution with one volume acidic water-saturated phenol.
- b. In a homogenizer, pour 4 ml extraction solution (from step a, instead of the denaturing solution) per gram of tissue or cell directly onto the liquid nitrogen frozen powdered tissue or cell pellet. Follow the standard RNA isolation protocol (UNIT 4.2), but do not add any additional phenol after this homogenization step.

Do not resuspend the RNA pellet in 75% aqueous ethanol. Short RNAs are soluble to some extent in 75% ethanol in the absence of salt and a detached pellet is easily lost. The purpose of the recommended resuspension of the RNA pellet is mostly to remove residual salt. If an ethanol wash step is performed, carefully rinse the tube walls with 75% ethanol without perturbing the pellet and centrifuge immediately.

2. Dissolve the RNA pellet from 1 g of tissue in 200 μ l deionized formamide. Estimate the concentration of the total RNA after diluting with water and measuring the absorbance (A_{260}) of the RNA solution in a 1-cm quartz cuvette.

The RNA is dissolved in deionized formamide rather than water for more effective denaturation prior to gel loading.

The concentration (c) of total RNA (in μ g/ μ l) is calculated according to:

$$c = A_{260} \times f \times 0.04 \mu\text{g}/\mu\text{l}$$

where, f is the dilution factor. The yield of total RNA is ~1 mg per gram of tissue or cells and the concentration is ~5 μ g/ μ l.

Commercial RNA isolation kits with ion-exchange columns should not be used because they are not designed to isolate small RNAs.

Aqueous LiCl precipitation, which is frequently used to precipitate long RNA transcripts, must be avoided because small RNAs and tRNAs do not precipitate.

Gel-purify small RNA from total RNA

3. Dilute 600 μ g of sample RNA with gel-loading solution to a final volume of 200 μ l. Denature the RNA solution by incubating the tube for 30 sec at 90°C. Load the RNA solution in two center wells of a 10-well 15% denaturing gel (15 \times 7 \times 0.15-cm, 50 ml gel volume, see UNIT 2.12).
4. Load a cocktail of radiolabeled RNA size markers. Apply the size marker cocktail in a similar volume as the RNA sample onto the gel to ensure similar gel running behavior. To avoid spillover of marker (and subsequent cloning of marker RNA), leave one well empty between sample and size markers.

Size markers are radiolabeled individually in a 10- μ l reaction at 1 μ M concentration by T4 polynucleotide kinase using γ -³²P-ATP as described in UNIT 3.10. After gel purification of the markers, dissolve each of the marker oligoribonucleotides in 20 μ l of formamide. Use 1- μ l aliquots to prepare the size marker cocktail.

5. Run the gel for 1 to 1.5 hr at 30 W using 0.5× TBE buffer until the bromophenol blue dye of the gel-loading solution is 2 to 3 cm from the bottom of the gel.

Do not run the gel further than necessary for the separation of the size markers, because the recovery of small RNAs is more efficient if the small RNAs are concentrated in a narrow band.

6. Dismantle the gel and wrap the gel in plastic wrap (e.g., Saran wrap) to protect it from the environment. Expose the wrapped gel to a phosphorimaging screen for ~30 min (see APPENDIX 3A).

To facilitate the alignment of the gel to the phosphorimager printout, implanting three tiny radioactive gel pieces asymmetrically near the borders of the gel after removal of one of the glass plates is recommended. Radioactive gel pieces can be collected from the gel that was used to purify the size markers after initial ³²P-labeling.

7. Print out a 100%-scaled image of the gel, position the gel on top of the printout, and align to the size marker lanes. Excise the bands defined by the mobility of the RNA size markers.

8. Excise the radioactive band containing the size markers and elute the marker RNAs to run as a control. Run the control RNAs in parallel with the RNA sample for the adapter ligation steps.

The eluted markers will be used to control for RNA recovery and are subsequently needed for controlling the ligation reactions and to produce new size markers for the adapter ligation products.

9. Cut each gel slice into small pieces and transfer to a pre-weighed 1.5-ml siliconized tube. Determine the weight of the gel slices. Add 2 to 3 vol RNase-free 0.3 M NaCl and elute the small RNAs from the gel by incubating the tube at 4°C, overnight, under constant agitation (e.g., on a rocker in the cold room).

It is extremely important to carry out all RNA elution or reaction steps in siliconized reaction tubes. The walls of regular, untreated reaction tubes otherwise absorb the tiny amounts of small RNA and adapter ligation products.

10. Collect the supernatant and precipitate the small RNAs at –20°C, overnight, by adding 3 to 4 vol absolute ethanol.

Dephosphorylate small RNAs

11. Collect the small RNA pellet after ethanol precipitation in a tabletop centrifuge for 10 min at maximum speed (16,000 × g), 4°C. Remove the supernatant and collect the residual liquid at the bottom of the tube by an additional 10-sec centrifugation. Remove the residual liquid completely using a small pipet tip without disturbing the pellet.

The additional centrifugation is needed to collect all residual liquid and prevents NaCl contamination of the pellet.

12. Dry the tube for 2 min under vacuum using the Eppendorf or Speed-Vac concentrator and dissolve the pellet in 27 μl RNase-free water (dissolve the pellet in 10 μl RNase-free water for the Alternate Protocol).

All RNA precipitations in subsequent steps shall be performed similarly, but the volumes in which the pellets are dissolved may vary.

13. Add 3 μl of 10× phosphatase buffer and 0.5 μl of 20 U/μl alkaline phosphatase. Incubate the reaction mixture 30 min at 50°C.

14. Add 45.5 μ l RNase-free water and 4.5 μ l of 5 M NaCl and perform two 100- μ l 25:24:1 phenol/chloroform/isoamyl alcohol extractions followed by a final 100- μ l chloroform extraction (the upper phase always contains the RNA).
15. Precipitate the dephosphorylated RNA by adding 3 to 4 vol absolute ethanol and incubating on ice for at least 1 hr.

The precipitation may also be carried out at -20°C overnight.

Washing RNA pellets is not recommended because small pellets are frequently lost. Salt contamination is avoided by complete removal of the precipitant solution by a second short centrifugation step rather than washing the pellet.

When an RNA pellet is dissolved in a small volume of water, it is best to add the water on top of the pellet and leave the tube undisturbed for 15 min at room temperature. If the tube is vortexed too quickly after adding water, the partly dissolved pellet may be displaced to the side of the tube where it will not dissolve completely.

It is preferable to adjust RNA solutions to a 0.3 M NaCl concentration before gel elution or phenol/chloroform/isoamyl alcohol extraction while the precise volume of the solution is still known. Changes in the volume of the aqueous solution during extraction or elution due to incomplete recovery of the input solution makes it difficult to precisely adjust the NaCl concentration; imprecise NaCl concentration may affect the RNA precipitation.

Ligate phosphorylated 3' adapter to dephosphorylated small RNAs

16. Collect the RNA pellet as described in step 11. Dissolve the sample pellet and the marker pellet in 10 μ l RNase-free water.
17. Add 1 μ l of 100 μ M non-radioactive 5'-phosphorylated 3'-adapter oligonucleotide (see UNIT 3.10 and Table 26.4.1), 1 μ l of 10 μ M ^{32}P -labeled 3'-adapter oligonucleotide (see UNIT 3.10), 2 μ l of 10 \times ligation buffer, and 6 μ l of 50% aqueous DMSO.
18. Denature the RNA by incubating the tube for 30 sec at 90°C . Place the tube immediately on ice for 20 sec.
19. Add 1 μ l of T4 RNA ligase, mix gently, and incubate for 1 hr at 37°C .

Table 26.4.1 Oligonucleotides and Their Corresponding Sequences^a

Oligonucleotide	Sequence ^a
19-nt RNA marker	r(CGUACGCGGAAUACUUCGA)
24-nt RNA marker	r(CGUACGCGGAAUACUUCGAAAUGU)

2nd PCR 3' primer	GACTAGCTTGGTGCCGAATTCGCGGTAAA
2nd PCR 5' primer	GAGCCAACAGGCACCGAATTCCTCACTAAA
M13 -20 F primer	GTAAAACGACGGCCAG
M13 R primer	CAGGAAACAGCTATGAC

^aA, C, G, T, DNA residues; rA, rC, rG, rU, RNA residues; L, 3' hydroxyl blocking group. 3'-Adapter oligonucleotides with C3- or C7-amino modifiers as blocking groups can be purchased from commercial DNA/RNA synthesis companies.

20. Add 1 vol of gel-loading solution and load the sample in 2 wells of a 20-well 15% acrylamide gel (15 × 17 × 0.08–cm, 30-ml gel volume). Load the ligated marker sample next to the sample, but not directly adjacent to avoid contamination.
21. Run the gel for ~1 hr at 28 W using 0.5× TBE buffer until the bromophenol blue dye is ~2 cm from the bottom of the gel.
22. Dismantle and wrap the gel in plastic wrap to protect it from the environment. Record the position of the marker and the ligation products by phosphorimaging as described in steps 6 and 7.
23. Excise the ligation product band as well as the ligated size markers and elute the ligation products from the gel slices overnight at 4°C using 300 µl of 0.3 M NaCl in siliconized tubes.
24. Precipitate the RNA by addition of 3 to 4 vol absolute ethanol as described in step 14.

It is not always possible to detect the ligation product for the sample lane, especially when starting with a small amount of RNA. If a ligation band is not detected in the sample lane, refer to the marker ligation products and cut out a band of corresponding mobility.

Perform 5' phosphorylation of the ligation product

25. Collect the RNA pellet as described in step 4. Dissolve the pellet in 10 µl RNase-free water.
26. Add 2 µl of 10× PNK buffer, 0.4 µl of 100 mM ATP, 7.1 µl RNase-free water, and 0.5 µl of T4 polynucleotide kinase, and incubate for 30 min at 37°C.
27. Stop the reaction by adding 37 µl RNase-free water and 3 µl of 5 M NaCl. Perform one 50-µl 25:24:1 phenol/chloroform/isoamyl alcohol extraction followed by a 50-µl chloroform extraction. Precipitate the RNA by adding 3 to 4 vol absolute ethanol, and then incubate at least 1 hr on ice.

Ligate the 5' adapter

28. Collect the RNA pellet as described in step 11. Dissolve the pellet in 10 µl RNase-free water.
29. Add 1 µl of 100 µM 5' adapter oligonucleotide (see Table 26.4.1), 2 µl of 10× RNA ligation buffer, and 6 µl of 50% aqueous DMSO.
30. Denature the RNA by incubating the tube for 30 sec at 90°C. Place the tube immediately on ice for 20 sec.
31. Add 1 µl of T4 RNA ligase, mix gently, and incubate for 1 hr at 37°C.
32. Add 1 vol of gel-loading solution and load the sample in 2 wells of a 20-well 15% acrylamide gel (15 × 17 × 0.08–cm, 30-ml gel volume). Load the 5' adapter–ligated marker sample next to the sample, but not directly adjacent to avoid contamination.
33. Run the gel for ~1 hr at 28 W using 0.5× TBE buffer until the bromophenol blue dye is ~2 cm from the bottom of the gel. Image the gel as described in steps 6 and 7, and excise the new ligation product.
34. Elute the ligation product from the gel slices in 300 µl of 0.3 M NaCl in siliconized tubes overnight at 4°C. Add 1 µl of 100 µM reverse transcription (RT) primer (see Table 26.4.1) during the elution as a carrier to facilitate the recovery of the ligation product.

35. Precipitate the RNA and RT primer by addition of 3 to 4 vol absolute ethanol as described in step 15.

Perform reverse transcription of the final ligation product

36. Collect the RNA/RT primer pellet as described in step 11. Dissolve the pellet in 5.6 μ l RNase-free water.
37. Denature the RNA by incubating the tube for 30 sec at 90°C.
38. Add 1.5 μ l of 0.1 M DTT, 3 μ l of 5 \times first-strand buffer, 4.2 μ l of 10 \times dNTP, and incubate 3 min at 50°C. Add 0.75 μ l of reverse transcriptase and incubate 30 min at 42°C.
39. To hydrolyze the RNA, add 40 μ l of 150 mM KOH/20 mM Tris base and incubate 10 min at 90°C.
40. Neutralize the solution by adding ~40 μ l of 150 mM HCl to obtain a pH between 7.0 and 9.5.

Near the end point of titration, monitor the pH by spotting 1 μ l of the neutralized DNA solution on pH indicator paper. Be aware that HCl is volatile and KOH solutions absorb carbon dioxide so that the pH of these solutions change over time. Prior to neutralization, test the concentration of the KOH/Tris base and HCl solutions by combining equal volumes and monitoring the pH. If the pH is not within the recommended range, the pH of the subsequent PCR reaction will be affected, therefore, risking failed amplification.

Perform first PCR amplification of the cDNA

41. Combine 10 μ l of the cDNA sample from the previous step with 10 μ l of 10 \times dNTP, 10 μ l of 10 \times PCR buffer, 1 μ l of 100 μ M first PCR 5' primer (see Table 26.4.1), 1 μ l of 100 μ M first PCR 3' primer (see Table 26.4.1), 67 μ l water, and 1 μ l of *Taq* polymerase.
42. Run a PCR using the following parameters:

20 cycles:	45 sec	94°C
	1 min, 25 sec	50°C
	1 min	72°C.

43. Run 6 μ l of the PCR product on a 2% standard agarose gel containing ethidium bromide (see UNIT 2.5A). Use a 25-bp DNA ladder as a size marker, the size of the PCR product should be ~70 bp.

At this point, a double-band ~50 and 70 bp is sometimes detected on the gel. The 50-bp band is likely derived from traces of ligation product of directly joined 3' and 5' adapter oligonucleotides without a small RNA insert. The larger PCR product can be purified away from this contaminant using a 3% low-melt NuSieve agarose gel in 1 \times TAE buffer. Excise the 70-bp band, and isolate the DNA from the gel as described in step 55. Dissolve the pelleted DNA in 50 μ l of 1 \times PCR buffer.

Perform second PCR amplification to enable concatamerization

44. Combine 1 μ l of the first PCR solution with 50 μ l of 10 \times dNTP, 50 μ l of 10 \times PCR buffer, 5 μ l of 100 μ M second PCR 5' primer (see Table 26.4.1), 5 μ l of 100 μ M second PCR 3' primer (see Table 26.4.1), 384 μ l water, and 5 μ l *Taq* polymerase. For PCR, divide the reaction mixture between five 500- μ l PCR tubes.
45. Run 10 cycles of PCR as described in step 42 and examine 6 μ l of the PCR reaction as described in step 43.

46. If the PCR product is detectable, combine all the PCR reactions in one 1.5-ml Eppendorf tube, add 30 μ l of 5 M NaCl, and perform one 500- μ l 25:24:1 phenol/chloroform/isoamyl alcohol extraction followed by a 500- μ l chloroform extraction. Precipitate the DNA by adding 2 vol absolute ethanol and incubate at least 1 hr on ice.

Avoid denaturation of the second PCR product at any time during the subsequent step. The PCR product consists of a pool of distinct small sequences flanked by constant primer sequences. Denaturation and renaturation of the pool sequences may result in imperfect rehybridization and formation of DNA duplexes with internal bulges. Bulged DNA duplexes are poor substrates for the subsequent restriction endonuclease digestion or later steps.

If the PCR product is not detectable after 10 cycles, run 2 or 3 additional cycles. Do not amplify the DNA outside the exponential amplification range because it may result in the formation of bulged DNA duplexes due to re-annealing of imperfect complement strands of denatured PCR products. The optimal number of PCR cycles can be determined in a pilot experiment. If a pilot experiment is included, prepare two times the volume of the PCR reaction. Use one half for the pilot experiment while keeping the other on ice. Remove small samples between 8 and 12 PCR cycles at end of each elongation step and compare the intensity of the PCR products by running the samples on a 2% agarose gel containing ethidium bromide.

Digest second PCR product with Ban I

47. Microcentrifuge the DNA pellet 10 min at maximum speed (16,000 \times g), 4°C. Remove the supernatant completely but do not allow the pellet to dry. Dissolve the pellet in 190 μ l of 1 \times Ban I buffer. Keep 2 μ l of undigested material for further gel analysis.

To avoid DNA denaturation, do not allow the pellet to dry and resuspend the pellet in buffer rather than in water.

48. Add 10 μ l of 20 U/ μ l Ban I endonuclease and incubate for 3 hr at 37°C. Verify that the restriction digestion is complete by running 2 μ l of the digested sample and 2 μ l of the undigested sample on a 2% standard agarose gel as described in step 43.
49. Stop the reaction by adding 12 μ l of 5 M NaCl and perform a 200- μ l 25:24:1 phenol/chloroform/isoamyl alcohol extraction and one 200- μ l chloroform extraction. Precipitate the DNA by adding 2 vol absolute ethanol and incubating for at least 1 hr on ice.

Concatamerize Ban I restriction enzyme–digested DNA

50. Collect the DNA pellet as described in step 47. Dissolve the pellet in 90 μ l of 1.1 \times T4 DNA ligation buffer.
51. Add 3 μ l of 100 μ M second PCR 5' primer and 3 μ l of 100 μ M second PCR 3' primer (see Table 26.4.1). Incubate 10 min at 65°C.

This step is important to prevent religation of the 12-bp Ban I–digested fragments in the concatamerization step. At 65°C, the 12-bp fragments, not long DNA, are denatured and upon cooling will hybridize in a competitive manner to the excess PCR primers. If religation of the 12-bp Ban I–digested fragment occurs, the concatamerization step will not work.

52. Add 4 μ l of T4 DNA ligase and incubate 5 hr at 22°C.
53. Analyze 2 μ l of the reaction to check for complete concatamerization on a 2% agarose gel. Also load a 100-bp DNA ladder as a size marker.

The concatamerization product appears as a fuzzy ladder ranging in size from 60 bp (the monomer) to 1 kb.

54. Purify 50 μ l of the concatamerization products on a 2% NuSieve low-melt agarose gel containing ethidium bromide in 1 \times TAE running buffer. Load 10 to 15 μ l of sample per well of a 60-ml gel. Run the gel for ~45 min at 80 V until the marker bands are sufficiently resolved.

To avoid melting of the NuSieve gel at a high current, limit the voltage for electrophoresis to 80 V. Use TAE buffer rather than TBE gel running buffer when extracting DNA from low-melting agarose to avoid possible borate precipitates during ethanol-precipitation of the DNA.

55. Visualize the DNA in the gel using a 360-nm UV transilluminator. Excise the DNA band between 400 and 800 bp with a razor blade or scalpel and transfer the gel slices into a pre-weighed 1.5-ml reaction tube.

If the gel slices weigh >250 mg, split the agarose band into two tubes.

56. Add at least 1 vol 0.4 M NaCl to obtain a final volume of 500 μ l. Incubate the tube 10 min at 70°C to melt the gel slices and add 500 μ l of 70°C-preheated, buffered water-saturated phenol, pH 7.8. Vortex the solutions vigorously and immediately separate the phases by microcentrifuging 5 min at maximum speed, room temperature.

The agarose should accumulate at the interphase.

57. Collect the aqueous upper phase and extract the aqueous phase once again with 500 μ l of 25:24:1 phenol/chloroform/isoamyl alcohol and then with 500 μ l chloroform. Precipitate the DNA by adding 2 vol absolute ethanol and incubating for at least 1 hr on ice.

It is important not to transfer any solidified agarose with the aqueous phase during phenol extraction. Be careful to perform centrifugation steps at room temperature and not in a refrigerated centrifuge to avoid rapid solidification of the agarose and entrapment of DNA within the agarose.

Instead of a phenol extraction, the DNA may be electroeluted from the agarose gel (see UNIT 2.6, Basic Protocol 1). Avoid commercial DNA isolation kits that denature the DNA during isolation (see annotation to step 46).

Tail the ends of concatamers for T-vector ligation

58. Collect the DNA pellet as described in step 47. Dissolve the pellet in 15 μ l of a PCR mix containing 1 \times dNTPs, 1 \times PCR buffer, and 0.15 μ l *Taq* polymerase.
59. Incubate the reaction mixture for 30 min at 72°C for enzymatic 3' tailing.
60. Perform TOPO TA cloning with a pCR2.1-TOPO vector as described by the manufacturer (Invitrogen; also see Chapter 1).

Screen colonies for concatamer inserts by PCR

61. Fill the desired number of wells of a 96-well thermocycler-compatible microtiter plate with 50 μ l of a PCR solution containing 5 μ l of 10 \times PCR buffer, 5 μ l of 10 \times dNTPs, 0.5 μ l of 100 μ M primer M13 (–20) F, 0.5 μ l of 100 μ M primer M13 R (see Table 26.4.1), and 0.5 μ l *Taq* polymerase.
62. Transfer individual white colonies to the wells of the microtiter plate filled with the PCR mixture. Pick the white colonies from the agar plate using a pipet tip and resuspend the colony by pipetting up and down. Run 25 cycles of PCR as described in step 42.
63. Analyze 6 μ l of the PCR products on a 2% standard agarose gel, using the 100-bp DNA ladder as a size marker.

64. Purify the remaining PCR with the QIAquick PCR purification kit according to the manufacturer's instructions. Submit the purified PCR product for automated sequencing using M13 (-20) F or M13 R primers.

**ALTERNATE
PROTOCOL**

**CLONING OF SMALL RNA USING THE ADENYLATED 3'-ADAPTER
OLIGODEOXYNUCLEOTIDE**

This protocol is adapted from the protocol of Lau et al. (2001), which is available on the Bartel laboratory Web site at <http://web.wi.mit.edu/bartel/pub>. An adenylylated 3'-adapter oligodeoxynucleotide can be joined directly to the isolated small RNAs without prior 5' dephosphorylation in the absence of ATP (Lau et al., 2001). Without ATP, circularization of the 5' phosphorylated small RNAs cannot occur. Although the ligation reaction with adenylylated adapters is simple, it requires chemical synthesis of the 5' phosphorimidazolide of adenosine (ImpA, Fig. 26.4.2C) followed by chemical adenylation of the 5' phosphate of the 3'-adapter oligodeoxynucleotide using ImpA.

The chemical synthesis reactions in this procedure have been adapted from Mukaiyama and Hashimoto (1971) and Lohrmann and Orgel (1978).

Additional Materials (also see *Basic Protocol*)

- Adenosine 5'-monophosphoric acid (5' AMP)
- Dimethylformamide (DMF)
- Triphenylphosphine
- 2,2'-Pipyridyldisulfide
- Imidazole
- Triethylamine
- Sodium perchlorate
- Acetone
- Anhydrous ethyl ether
- Thin layer chromatography (TLC) cellulose plates with a 254-nm fluorescence indicator (cellulose-F TLC; Merck)
- 10% (v/v) saturated (NH₄)₂ SO₄
- 80% ethanol
- 1 M MgCl₂
- 5× adenylylation buffer (ATP-free; see recipe)
- 1.25 mM phosphorylated 3'-adapter oligodeoxynucleotide (see *UNIT 3.10*)
- 10 μM ³²P-labeled 3'-adapter oligonucleotide (see *UNIT 3.10*)
- 30-ml Corex tubes
- Sorvall centrifuge with SS34 rotor (or equivalent)
- Vacuum drying oven
- Glass capillaries
- 254-nm UV light
- 13-ml polypropylene tube, 95 × 16.8-mm (Sarstedt)

NOTE: All reagents can be purchased from Sigma and should be at least 99% pure.

Synthesize ImpA

1. Dissolve 174 mg (0.5 mmol) of 5' AMP in 15 ml DMF. Keep a 50-μl aliquot for TLC analysis.
2. Dissolve 262 mg (1 mmol) of triphenylphosphine, 220 mg (1 mmol) of 2,2'-dipyridyldisulfide, and 170 mg (2.5 mmol) of imidazole in 15 ml DMF and 0.9 ml (2.5 mmol) of triethylamine.

3. Add the AMP solution (from step 1) dropwise to a vigorously stirred triphenylphosphine-containing solution (from step 2). Stir for another 1.5 hr at room temperature.

Initially, a precipitate appears, then the mixture will turn yellow-green and the precipitate eventually dissolves.

Purify ImpA

4. Precipitate the ImpA by adding the reaction mixture dropwise into a vigorously stirred solution of 1.1 g (9 mmol) sodium perchlorate, 115 ml acetone, and 55 ml anhydrous ethyl ether.
5. Let the precipitate settle to the bottom of the beaker for 1 hr and decant ~150 ml of the supernatant without perturbing the precipitate.

A large glass pipet connected to a pipetting aid may also be used to aspirate off the supernatant.

6. Once the volume has been reduced to ~20 ml, resuspend the precipitate with the residual supernatant and transfer the suspension to 30-ml Corex tubes. Transfer the residual precipitate by rinsing the beaker with small volumes (5 ml) of acetone. Collect the precipitate by centrifuging 10 min at $3000 \times g$ (5000 rpm with a Sorvall SS34 rotor), room temperature.
7. Remove the supernatant and wash the pellet two times by resuspending it with 10 ml acetone and then centrifuge 5 min at $3000 \times g$ (5000 rpm with a Sorvall SS34 rotor), room temperature.
8. Resuspend the pellet in 10 ml anhydrous ethyl ether and centrifuge 20 min at $3000 \times g$ (5000 rpm with a Sorvall SS34 rotor), room temperature. Dry the pellet overnight in a vacuum oven at 40°C.
9. Store the dried powder up to 3 weeks at -20°C protected from humidity.

The yield of ImpA is ~80 mg. The molecular weight of ImpA is 412.3 g/mol.

Perform quality control of synthesized ImpA

10. Soak cellulose-F TLC plates in 10% saturated aqueous $(\text{NH}_4)_2\text{SO}_4$ and dry the TLC plates in open air for 1 hr or blow dry.
11. Dissolve 1 mg ImpA in 50 μl water and spot the sample on pre-treated TLC plates with aliquots of the AMP solution and triphenylphosphine solution from steps 1 and 2, respectively, using glass capillaries. Develop the TLC by using 80% ethanol and visualize the spots under 254-nm UV light.

The AMP should have the lowest retention factor ($R_f = 0.26$), ImpA should run faster ($R_f = 0.4$), and the components of the triphenylphosphine solution all run near the solvent front.

Perform adenylation of 3' adapter oligodeoxynucleotide

12. Dissolve 9 mg of ImpA in 420 μl of water, add 14 μl of 1 M MgCl_2 , and 80 μl of 1.25 mM phosphorylated 3'-adapter oligodeoxynucleotide (see UNIT 3.10).

The final concentrations for the chemical adenylation reaction are 200 μM phosphorylated 3'-adapter oligodeoxynucleotide (see Table 26.4.1), 50 mM ImpA (mol. wt. 412.3 g/mol), and 25 mM MgCl_2 .

13. Incubate the reaction mixture for 3 hr at 50°C. For adenylation of 5'-radiolabeled 3'-adapter oligodeoxynucleotide, reduce the reaction volume four-fold and use 5 µl of 10 µM ³²P-labeled 3'-adapter oligonucleotide (see UNIT 3.10).
14. Stop the reaction by adding 1 vol of gel-loading solution. Prepare two 20% acrylamide gels (15 × 17 × 0.15-cm, 50-ml gel volume) using a 6-well comb. Load 125 µl per well and run the gels for ~1 to 1.5 hr at 28 W using 0.5× TBE buffer until the bromophenol blue dye reaches the bottom of the gel.
15. Dismantle the gels and wrap them in plastic wrap. Place them onto a fluorescence indicator-coated silica gel plate and visualize the oligodeoxynucleotides by 254-nm UV-shadowing (see UNIT 2.12).

The adenylated oligonucleotide migrates slower and above the unreacted oligodeoxynucleotide. The yield is ~10% to 20%.

16. Excise the reaction product and elute the adenylated oligonucleotide from the gel slices overnight at 4°C (see Basic Protocol, steps 7 to 10).

If the radioactive adenylation product is not detectable by UV shadowing, use phosphorimaging to detect the bands.

To accommodate the large volume of gel slices, it is recommended to elute and precipitate the non-radioactive adenylation product in 13-ml polypropylene tubes.

17. Precipitate the adenylated oligodeoxynucleotide by adding 3 vol absolute ethanol and incubating for at least 1 hr on ice.
18. Collect the pellet as described in Basic Protocol, steps 11 and 12. When using 13-ml polypropylene tubes, centrifuge 20 min at 17,000 × g (12,000 rpm with an SS34 rotor). Dissolve the pellet in 20 µl of water and determine the concentration by UV.

Ligate adenylated 3' adapter to small RNAs

19. Dissolve the small RNA pellet from Basic Protocol, step 11, in 10 µl water. Add 4 µl of 5× adenylate ligation buffer (ATP-free), 4 µl of 200 µM adenylated 3'-adapter oligodeoxynucleotide, and 1 µl radiolabeled adenylated 3'-adapter oligodeoxynucleotide.
20. Denature the RNA by incubating the tube 30 sec at 90°C. Place the tube immediately on ice for 20 sec.
21. Add 1 µl of T4 RNA ligase, mix gently, and incubate 1 hr at 37°C.
22. Add 1 vol gel-loading solution and load the sample in 2 wells of a 20-well 15% acrylamide gel (15 × 17 × 0.08-cm, 30-ml gel volume). Load the ligated marker sample next to the sample, but not directly adjacent to avoid contamination. Run the gel for ~1 hr at 28 W in 0.5× TBE buffer until the bromophenol blue dye is ~2 cm from the bottom of the gel.
23. Dismantle the gel and wrap the gel in plastic wrap to protect it from the environment. Record the position of the marker and the ligation products by phosphorimaging as described in Basic Protocol, steps 6 and 7. Excise the ligation product band as well as the ligated size markers. Elute the ligation products from the gel slices overnight at 4°C in 300 µl of 0.3 M NaCl in siliconized tubes.
24. Precipitate the RNA by adding 3 to 4 vol absolute ethanol as described in Basic Protocol, step 10 and proceed with Basic Protocol, step 28.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Acrylamide gel solution, 15% or 20%

1× TBE (APPENDIX 2)
7.5 M urea
15% or 20% 19:1 acrylamide/bisacrylamide
Store up to 1 year at 4°C

Adenylate ligation buffer, 5×

16.5 mM DTT
41.5% glycerol
250 mM HEPES-KOH, pH 8.3
50 mM MgCl₂
50 µg/ml acetylated bovine serum albumin (Ac-BSA, Sigma)
Store up to 1 year at –20°C

Gel-loading solution

0.1 ml 0.5 M EDTA, pH 8 (APPENDIX 2)
5 mg bromophenol blue
Bring up to 9.9 ml with deionized formamide
Store up to 1 year at room temperature

RNA ligation buffer, 10×

0.1 M MgCl₂
0.1 M 2-mercaptoethanol
0.5 M Tris·Cl, pH 7.6 (APPENDIX 2)
1 mg/ml acetylated bovine serum albumin (Ac-BSA, Sigma)
2 mM ATP
Store up to 1 year at –20°C

COMMENTARY

Background Information

The first glimpse on the importance of small RNAs was given by the identification of the *lin-4* gene product (Lee et al., 1993). Mutations of this gene caused developmental defects in the nematode *Caenorhabditis elegans*. Several years later, a second 22-nt RNA, the *let-7* gene product, was also found to regulate development in *C. elegans* (Reinhart et al., 2000). These RNAs were therefore called small temporal RNAs (stRNAs) and were regarded as specific to nematode development until it was realized that *let-7* RNA was conserved in all animals with a bilateral symmetrical axis (Pasquinelli et al., 2000). Around the same time, it was also discovered that dsRNA-triggered RNA interference was guided by 21- and 22-nt small interfering RNAs (siRNAs) that mediate the target RNA degradation (Hamilton and Baulcombe, 1999; Elbashir et al., 2001). These discoveries indicated the need for the development

of methods to characterize small RNA profiles of eukaryotic cells.

The RNA cloning protocol (see Basic Protocol) was originally developed to study Dicer ribonuclease III-dependent processing patterns of long dsRNAs (30 to 500 bp) to the siRNAs in cytoplasmic lysates prepared from *D. melanogaster* embryos (Tuschl et al., 1999; Elbashir et al., 2001). When analyzing the cloned sequences, high levels of cellular 21-nt RNAs were identified. These endogenous RNAs were derived from numerous cellular genes coding for short hairpin RNAs, which represented the dsRNA precursors of miRNAs (Lagos-Quintana et al., 2001). The authors' original cloning protocol was gradually improved, incorporating modifications from the protocol used in David Bartel's laboratory (Lau et al., 2001; available at <http://web.wi.mit.edu/bartel/pub/>). The protocol is now routinely used to characterize the miRNA profile of dif-

Figure 26.4.3 Example of a concatamer sequence after cloning of small RNAs from *Drosophila* embryos. The lowercase letters represent the vector sequence and the uppercase letters represent concatamer sequence. Constant sequences of the adapter oligonucleotides are highlighted (dark gray, 3' adapter and light gray, 5' adapter). The *Ban* I restriction site is underlined.

ferent cell lines or tissues and requires between 1 and 2 weeks beginning with the isolation of total RNA until obtaining the sequence information (Lagos-Quintana et al., 2002, 2003).

Critical Parameters and Troubleshooting

One of the critical starting points of this protocol is high quality of the total RNA preparation. If the RNA has been prepared from cells that were not healthy or contained a high fraction of apoptotic cells, the cloning procedure will identify mostly ribosomal RNA and tRNA degradation products. It is therefore recommended to harvest the cells during their exponential growth phase. Some tissues, like pancreas or small intestine, are rich in nucleases and intrinsically difficult to handle. It is recommended that the quality of the RNA preparation be carefully examined before making the decision to start a lengthy cloning protocol. High-

quality total RNA shows defined 18S and 28S rRNA bands by agarose gel electrophoresis. Alternatively, a more modern RNA LabChip technique may be used for analyzing the quality of the total RNA. LabChip technologies (e.g., Agilent 2100 Bioanalyzer) were developed for quality control of total RNA to be used for gene profile analysis on DNA arrays.

Another difficulty is the handling of extremely low amounts of RNA products making it necessary to use surface-treated, siliconized reaction tubes. Extreme care is needed to avoid nuclease contamination throughout the protocol.

Drosophila or plant small RNAs are composed of two distinct classes of ~21 and 25 nt in length. The longer species of small RNAs has not been detected in mammals, probably because only one Dicer RNase III exists in mammals while the other species contains multiple Dicer RNase III homologs. If the longer

species of small RNA is also to be isolated, it is recommended that a 30-nt RNA size marker be included. *Drosophila* is also special because its rRNA contains an abundant 30-nt 2S rRNA not found in most other organisms. The 2S rRNA is readily detected by UV-shadowing and care has to be taken to avoid excising the small RNA band with an overlap to the 2S rRNA band.

Finally, although it is feasible to analyze the cloned sequences by hand, it is recommended that the assistance of an experienced bioinformatics specialist be sought to develop adequate analysis and archiving tools. The small RNA fractions often contain substantial amounts of degradation products of other abundant non-coding RNAs such as rRNAs, tRNAs, snRNAs, and snoRNAs, as well as messenger RNAs. A guideline to the annotation of newly identified miRNA genes has been published (Ambros et al., 2003) and a repository for miRNAs can be found at <http://www.sanger.ac.uk/Software/Rfam/index.shtml>.

Anticipated Results

Each clone carrying an insert of a concatamerized PCR product should yield 4 to 8 small RNA sequences. An example of the raw data obtained after sequencing is shown in Figure 26.4.3.

Time Considerations

The Basic Protocol is a multi-step procedure, similar to an organic synthesis of a complex molecule. If any of the many steps fails, the final product will never be obtained. See Figure 26.4.1 for a flow chart of all steps.

Isolation of total RNA, radiolabeling, and gel purification of all oligonucleotides require 1 day. Gel-purification of small RNAs from total RNA requires 1 day with an overnight elution from the gel. Dephosphorylation of small RNAs and ligation of phosphorylated 3' adapter to dephosphorylated small RNAs require 1 day with an overnight elution from the gel. 5' phosphorylation of the ligation product and ligation of the 5' adapter takes 1 day with an overnight elution from the gel. Reverse transcription of the final ligation product, PCR amplification of the cDNA, and second PCR amplification to enable concatamerization all require 1 day. *Ban* I restriction digestion of the second PCR product and concatamerization of *Ban* I restriction-digested DNA require 1 day. Tailing of the ends of concatamers for T-vector ligation and TOPO/TA cloning take 1 day. PCR screening of colonies for concatamer inserts and sequencing of positive clones require 1 day.

The protocol can be safely interrupted at every ethanol precipitation step and the ethanol solution can be stored at -20°C for several days prior to collecting the pellet.

RNA Interference in Cultured *Drosophila* Cells

UNIT 26.5

RNA interference (RNAi) resulting in the ablation of specific proteins in *Drosophila* cell culture is a valuable tool for dissecting signal transduction pathways and elucidating the cellular functions of proteins. Since the early 1960s, several *Drosophila* cell lines representing different cell lineages have been propagated (Table 26.5.1; Schneider, 1972). Because many signal transduction pathways and the functions of conserved proteins have been maintained from *Drosophila* to mammals, the ablation of protein expression in these cell lines makes it possible to study conserved biochemical processes in a relatively simple environment. Furthermore, because *Drosophila* is amenable both to gene ablation studies and RNAi analyses, results obtained from cell culture studies can be confirmed in the whole organism. Finally, the use of double-stranded RNA (dsRNA) technology in *Drosophila* cell culture is simple, highly reproducible, and efficient. Transfection is unnecessary, because dsRNA is naturally internalized by the cells, thereby circumventing the problems associated with transfection protocols, such as variable efficiency and toxicity. The gene silencing effect is also sustainable through many cell divisions, provided the protein of interest is not necessary for viability (Clemens et al., 2000).

The ablation of protein expression in *Drosophila* cell culture is achieved by exposing the cells to dsRNA ranging from 300 to 700 bp. The efficacy of this process is best measured by immunoblot using antibodies directed against the target protein of interest. However, in the absence of available antibodies, Northern, RT-PCR, or RNase protection analyses can be employed to measure the amount of mRNA remaining. This unit contains a technique for treatment of *Drosophila* cell lines with dsRNA (see Basic Protocol). In addition, an efficient method for generating dsRNA synthesis templates that harbor T7 RNA polymerase promoters on their 5'-ends is described (see Support Protocol 1) and the procedure used for dsRNA synthesis is also provided (see Support Protocol 2).

NOTE: Care must be taken to use only RNase-free solutions and materials. Gloves should be worn to prevent RNase contamination.

TREATMENT OF *DROSOPHILA* CELLS WITH dsRNA

The advantage of using *Drosophila* cells for protein ablation studies is underscored by their ability to take up dsRNA without the use of transfection reagents. This ability is manifested by all of the *Drosophila* cell lines listed in Table 26.5.1. Furthermore, *Drosophila* cells do not require a CO₂ incubator and some can be grown in suspension cultures as well as in the more traditional tissue culture flasks. Note that although the protocol described below is optimized for S2 cells, no major modifications are necessary when using other cell lines.

Materials

Drosophila cells (e.g., S2 cells; Table 26.5.1)
S2 growth medium (see recipe)
Schneider's *Drosophila* medium (Life Technologies)
dsRNA (see Support Protocol 2)
6-well tissue culture dishes

Additional reagents and equipment for counting cells (APPENDIX 3F), assaying RNA depletion—i.e., Northern blot (UNIT 4.9), RNase protection assay (UNIT 4.7), or RT-PCR (UNIT 15.5)—and immunoblotting (UNIT 10.8)

**BASIC
PROTOCOL**

Gene Silencing

26.5.1

Table 26.5.1 *Drosophila* Cell Lines

Line	Origin	Reference	Characteristics
S2	Oregon R, dissociated embryos	Schneider (1972)	Round, semi-adherent, phagocytic, granular cytoplasm
S2-R+	Oregon R, dissociated embryos	Yanagawa et al. (1998)	Flat, adherent, phagocytic, hemocyte-like gene expression
Kc	F2 ebony × sepia, dissociated embryos	Echalier and Ohanessian (1969)	Round, clump in sheets, semiadherent, phagocytic, hemocyte-like gene expression
BG2-c6	Third instar larvae, central nervous system	Ui-Tei et al. (1994)	Semiadherent, neuronal-like processes
Clone 8	Third instar larvae, wing imaginal disc	Peel et al. (1990)	Columnar epithelial, adherent

Culture cells

1. Propagate S2 cells in S2 growth medium containing antibiotics. Passage cells at a 1:20 dilution into a new flask once they achieve a cell density $>6 \times 10^6$ cells/ml.

S2 cells that are attached to the flask are easily displaced by trituration. These cells grow well as long as they are not subcultured to a very low density (i.e., $<1 \times 10^5$ cells/ml). They are also sensitive to different sources of FBS. Life Technologies FBS designated for neuronal cells consistently produces good results; however, each new lot should be tested to ensure growth of S2 cells.

2. Count the cells (APPENDIX 3F). Pellet a sufficient number for each experimental condition (i.e., 1×10^6 cells) and an untreated control by centrifuging 10 min at $500 \times g$, 20°C. Resuspend in Schneider's *Drosophila* medium to a density of 1×10^6 cells/ml.

No serum or antibiotics should be present in the medium.

3. Seed 1 ml cells into each well of a 6-well tissue culture dish.

Plating S2 cells in serum-free media will cause them to adhere tightly to the dish.

Treat with dsRNA

4. Add 15 µg double-stranded (ds)RNA (see Support Protocol 2) and hand mix the plates ~10 sec.
5. Incubate 30 to 60 min at room temperature.
6. Add 2 ml S2 growth medium to each well.
7. Incubate the cells 2 to 6 days at room temperature to allow turnover of the targeted protein.
8. Measure depletion of the target RNA after 24 to 48 hr by Northern blot (UNIT 4.9), RNase protection assay (UNIT 4.7), or RT-PCR (UNIT 15.5).
9. If possible, measure ablation of protein expression by immunoblot analysis (UNIT 10.8).

The time course of elimination depends upon protein half-life.

PREPARATION OF PCR TEMPLATES

cDNA is used to generate a 300- to 700-bp PCR template that harbors a T7 RNA polymerase consensus binding site (5'-TTAATACGACTCACTATAGGGGAGA-3') at its 5'-termini. A discussion of where to obtain the cDNA of interest is provided in the Commentary section of this unit (see Critical Parameters). The PCR template may include coding, 5'-, or 3'-untranslated sequences. If starting with genomic DNA, care should be taken not to incorporate intervening sequences into the PCR product.

Materials

cDNA encoding the protein targeted for ablation (see Critical Parameters)
DNA polymerase, 1× buffer, and Mg²⁺ stock (if required): Applied Biosystems
Ampli*Taq* Gold (UNIT 3.5) or NEB Vent DNA polymerase
10 mM (each) dNTPs (dATP, dCTP, dGTP, dTTP; UNIT 15.1)
High Pure PCR Purification kit (Roche Molecular Biochemicals)
DEPC-treated H₂O (UNIT 4.1)

Additional reagents and equipment for purification of DNA (UNITS 2.1A & 2.1B;
optional), and agarose gel electrophoresis and ethidium bromide staining (UNIT
2.5A)

1. Design two oligonucleotides, forward and reverse, each containing the T7 RNA polymerase consensus binding sequence at their 5'-termini.

The melting temperature of these oligonucleotides should be between 52° and 58°C. A rough estimate of the melting temperature can be calculated by using 4°C for each C/G base pair and 2°C for each A/T base pair. See the Commentaries of UNITS 2.10 & 15.2 for additional discussions of melting temperature calculations.

2. Set up a typical 100-μl PCR reaction as follows:

100 ng cDNA encoding targeted protein
250 ng each oligonucleotide primer
1× polymerase buffer
0.2 mM dNTPs from a 10 mM stock
5 U DNA polymerase (e.g., Ampli*Taq* Gold or Vent)
Mg²⁺ stock (if required)
H₂O to 100 μl.

The optimal Mg²⁺ concentration must be empirically determined for individual PCR reactions (see UNIT 15.1).

3. Purify the completed PCR reaction using the High Pure PCR Product Purification kit according to manufacturer's instructions or using the procedures described in UNITS 2.1A & 2.1B.
4. Elute the PCR product from the column with 50 μl DEPC-treated H₂O.
The DNA must be at a concentration of ≥125 ng/μl to proceed to the RNA synthesis step (see Support Protocol 2).
5. Visualize the PCR product by agarose gel electrophoresis and ethidium bromide staining to determine both its size and purity (UNIT 2.5A).

PREPARATION OF DOUBLE-STRANDED RNA

The Ambion MEGAscript T7 kit is used to synthesize dsRNA from the PCR template generated above. One 20-μl reaction typically yields between 50 to 100 μg of dsRNA 700 bp in length. Properly stored, this dsRNA preparation will remain efficacious for at least two years.

Materials

MEGAscript T7 kit (Ambion):
T7 enzyme mix
10× T7 reaction buffer
75 mM ATP, CTP, GTP, and UTP solutions
Nuclease-free H₂O
DNA, purified (see Support Protocol 1)
DEPC-treated H₂O (UNIT 4.1)
3 M ammonium acetate, pH 4.0
100% ethanol

Additional reagents and equipment for determining nucleic acid concentration (APPENDIX 3D) and visualization of dsRNA by agarose gel electrophoresis and ethidium bromide staining (UNIT 2.5A)

1. With the exception of the enzyme mix, thaw the components of the MEGAscript T7 kit at room temperature.
2. Determine the concentration of purified DNA (APPENDIX 3D). Calculate the volume DNA required to yield 1 μg (y). Determine the amount of DEPC-water required to prepare a 20-μl reaction:

Vol. DEPC-treated water (x) = 8 μl – vol. DNA to yield 1 μg (y).

3. Prepare the following reaction, adding the components in order:

x μl DEPC-treated H₂O
2 μl 10× T7 reaction buffer
2 μl each ATP, GTP, CTP, and UTP solution
y μl DNA template (1 μg DNA)
2 μl enzyme mix.

Hand mix the tube gently. Incubate the reaction 2 to 6 hr at 37°C.

4. Add an equal volume (i.e., 20 μl) nuclease-free H₂O. Precipitate the RNA by adding 1/10 vol of 3 M ammonium acetate, pH 4.0, and 2.5 vol of 100% ethanol, and incubating ≥15 min at –20°C.

Template removal is unnecessary (see Critical Parameters).

5. Pellet the RNA by microcentrifuging 15 min at maximum speed, 4°C. Remove the supernatant and air dry the pellet 15 min.
6. Resuspend the RNA pellet in 50 μl DEPC-treated H₂O and determine the concentration (APPENDIX 3D).
7. *Optional:* Anneal the RNA strands by incubating 30 min at 65°C in a beaker of water. Remove beaker from heat to the bench top and allow to cool slowly (i.e., ~60 min) to room temperature.
8. Dilute the sample to a final concentration of 3 μg/μl.

Preparations are stable for a minimum of 24 months at –20°C with no loss of efficacy.

9. Visualize the dsRNA on a 1% agarose gel to check the integrity and size (UNIT 2.5A).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see *APPENDIX 2*; for suppliers, see *APPENDIX 4*.

S2 growth medium

Prepare Schneider's *Drosophila* medium (Life Technologies) containing 10% (v/v) FBS for neuronal cells (Life Technologies), 50 U/ml penicillin (*UNIT 1.4*), and 50 mg/ml streptomycin (*UNIT 1.4*). Store up to 2 months at 4°C.

Each new lot of FBS should be tested to ensure growth of *S2* cells.

COMMENTARY

Background Information

Double-stranded RNA (dsRNA)-mediated interference (RNAi) of gene expression has become a widely used method for reducing or ablating the synthesis of specific proteins in a variety of systems, ranging from whole animals (i.e., *C. elegans* and *Drosophila melanogaster*) to mammalian and insect cell cultures (*UNIT 25.1*; Fire et al., 1998; Kennerdell and Carthew, 1998; Ngo et al., 1998; Alvarado and Newmark, 1999). Discovery of this phenomenon originated from antisense RNA experiments, where it was noted that both sense and antisense RNAs were effective at producing the desired reduction of protein expression (Montgomery and Fire, 1998). These studies paved the way for the discovery that if complimentary strands of a specific RNA were combined, producing dsRNA, interference of protein expression was facilitated (Fire et al., 1998).

RNAi was originally used for performing reverse genetic studies in *C. elegans* (Fire et al., 1998); however, this technique was soon adopted for studies in *Drosophila* (Kennerdell and Carthew, 1998; Misquitta and Paterson, 1999) and, with some major modifications, mammalian cells (Caplen et al., 2001; Elbashir et al., 2001a). Detailed descriptions of experiments in mammalian cells and worms are found in *UNITS 26.2 & 26.3*, respectively. In *Drosophila*, injection of embryos with dsRNAs before the syncytial blastoderm stage successfully mimics previously characterized loss-of-function embryonic mutations (Kennerdell and Carthew, 1998; Misquitta and Paterson, 1999). Because embryos at this developmental stage have no cell membranes, the dsRNAs are free to diffuse throughout the embryo and become incorporated into newly forming cells. The RNAi effect persists throughout development and can be observed in the adult at low penetrance. However, unlike the case for *C. elegans*, the effect is not transmissible to progeny.

Studies in *Drosophila* cell-free systems have led to a better understanding of the mechanism of action of RNAi (Tuschl et al., 1999; Zamore et al., 2000; Elbashir et al., 2001b). Briefly, dsRNA molecules are recognized by dicer, an RNaseIII-like nuclease. Dicer cleaves the dsRNAs into ~22-bp pieces that are subsequently bound by a multiprotein complex, the RNA-induced silencing complex (RISC; Bernstein et al., 2001; Ketting et al., 2001; Knight and Bass, 2001). The RISC complex possesses helicase and nuclease activity and targets homologous sequences in mRNAs for nucleolytic attack, thereby destroying them. For more information about dicer and RISC, refer to *UNIT 26.1*.

Critical Parameters

Since dsRNA >300 bp (preferably 500 to 700 bp) is used for *Drosophila* RNAi, the selection of the dsRNA sequence is not as critical as for mammalian RNAi. Presumably, the 300-bp dsRNA will be processed into many different 22-bp pieces, several of which may be good templates for directing the attack by the RISC complex. The authors commonly prepare dsRNA from coding sequences, although 5'- and 3'-nontranslated sequences also work. However, if starting from genomic DNA, care should be taken to avoid the inclusion of intervening sequences.

Obtaining cDNA clones

Although templates for dsRNA synthesis can be generated by PCR from genomic sequences or by RT-PCR from mRNA, the authors prefer to start with ESTs (*UNIT 19.3*) provided by The Berkeley *Drosophila* Genome Project (BDGP). The BDGP has released two sets of cDNAs comprising most if not all of the predicted protein products in *Drosophila melanogaster*. These clones can be obtained from the BDGP or from Open Biosystems as bacterial stocks (see Internet Resources).

dsRNA preparation

The authors use the T7 MEGAscript kit from Ambion. They feel it is a superior product and have found the technical resources provided by Ambion to be superb. The authors find it unnecessary to remove the DNA template nor do they use any kits to clean up the reaction prior to use. However, precipitation of the dsRNA and resuspension in nuclease-free water is recommended. When treated in this manner, the dsRNA can be stored >24 months at -20°C with no loss of efficacy. It can also withstand several cycles of freezing and thawing.

Troubleshooting

Since the dsRNA used in *Drosophila* cell culture is ideally ~500 to 700 bp, target selection is not an issue. Also, since *Drosophila* cells take up the dsRNA without the need for transfection reagents, all the caveats associated with transfection are avoided. The most common problems encountered in the authors' laboratory are (1) the lack of commercial antibodies available to check the level of protein expression after dsRNA treatment and (2) that primary neuronal cultures are recalcitrant to RNAi. The first problem requires that one either produce antibodies against the protein of interest (UNIT 11.12) or determine the level of the specific mRNA remaining by Northern analysis (UNIT 4.9), RNase protection (UNIT 4.7), or RT-PCR (UNIT 15.5). It should be noted that disappearance of the requisite mRNA does not guarantee ablation of the protein, as the half-life of the protein must be taken into consideration. The second problem has not been resolved at the time of this writing.

Anticipated Results

Protein expression is generally decreased by at least 95% by 72 hr after treatment, and the effect can persist up to two weeks. Addition of more dsRNA can extend this effect indefinitely, provided that the protein of interest is not necessary to the growth and survival of the cells.

Time Considerations

S2 cells can be plated and treated in ~1 hr. The expression of the protein can then be measured after 48 to 72 hr. Routinely, the authors' experiments take 3 days, but proteins with longer half-lives may require longer incubation times.

RNA silencing in plants is routinely used for assignment of gene function. It is increasingly popular because it is often quicker than genetic approaches. In plants, as in other organisms, silencing requires production of small interfering RNA (siRNA) corresponding to the target gene. Most investigators achieve this by constructing stable transgenic plants in which the transgene constructs generate double-stranded (ds) RNA, either directly or indirectly (Basic Protocol 1). The dsRNA is then processed to siRNA *in vivo* by the endogenous enzyme Dicer. Viruses can also be used to deliver the silencer sequences using a transient silencing protocol (Basic Protocol 2). Both of these basic protocols use *Agrobacterium tumefaciens* to deliver transgene constructs into plant hosts. This unit discusses practical aspects of various approaches to RNA silencing in plants. Related practical issues are also addressed elsewhere (Lu et al., 2003b). Basic Protocol 3 in this unit describes protein overexpression using viral proteins that suppress silencing.

CONSTRUCTING STABLE TRANSGENIC PLANTS THAT EXPRESS dsRNA

BASIC PROTOCOL 1

This protocol describes the application of RNAi in transgenic *Arabidopsis* plants, a typical application of RNAi technology. Introduction of dsRNA into plants by binary vectors carrying inverted cDNA repeats has been widely used to generate stable RNAi lines (i.e., stable transgenic plants) to study the functions of specific genes (Waterhouse et al., 1998; Chuang and Meyerowitz, 2000; Dalmay et al., 2000; Wesley et al., 2001; Beclin et al., 2002; Chen et al., 2003; Guo et al., 2003). Several vector systems are available to clone inverted cDNA repeats so that they can subsequently be used for *Agrobacterium tumefaciens*-mediated transformation (Table 26.6.1). As can be gleaned from Table 26.6.1, both constitutive and inducible promoters can be used. In addition, there are different methods to clone the inverted repeat (restriction enzymes or the "Gateway" recombination system). Different vectors make use of various introns inserted between the inverted repeats to serve as stuffer sequences.

In this protocol, the pHANNIBAL system is used as an example to describe the cloning of the RNAi construct and transformation of the construct into plants (Wesley et al., 2001). The pHANNIBAL vector contains a strong constitutive cauliflower mosaic virus 35S (CaMV 35S) promoter, two sets of multiple cloning sites flanking an intron from the pyruvate orthophosphate dikinase (*PDK*) gene, and the *A. tumefaciens* octopine synthase (*OCS*) terminator (Fig. 26.6.1). Sense and antisense cDNA fragments from target genes of interest are cloned into the two multiple cloning sites to form an inverted repeat. The cassette can be released by cutting at the flanking *NotI* sites and cloned into the unique *NotI* site of the *A. tumefaciens* binary vector pART27 (Gleave, 1992). The pART27 plasmid carries both the right and left T-DNA borders to integrate the flanking sequence into the plant genome and the *NPTII* gene under the control of the nopaline synthase (*NOS*) promoter and terminator to permit selection of transgenic plants using kanamycin. The resulting RNAi construct in pART27 is introduced into *A. tumefaciens* strain GV3101, which is then used to transform *Arabidopsis* plants using the floral dip method (Clough and Bent, 1998). Transgenic plants carrying the RNAi are identified by selection using kanamycin. Finally, target-gene expression is analyzed by RT-PCR (reverse transcription PCR) and northern blotting and/or immunoblotting to identify transgenic plants that exhibit an appropriate reduction in target-gene expression.

Gene Silencing

Hellsgate	CaMV 35S	<i>kan</i>	attP, attR	PDK intron	http://www.pi.csiro.au/tech_licensing_bioll/Main_tech_licensing_biol.htm Wesley et al. (2001) <i>Agrobacterium</i> binary plasmid vectors suitable for high-throughput applications using BP and LR. Clonase enzymes available from Invitrogen, with detailed descriptions and methods for using the Gateway cloning system from Invitrogen (http://www.invitrogen.com).
Hannibal/Kannibal	CaMV 35S	<i>kan</i>	Two-step ligation	PDK intron	http://www.pi.csiro.au/tech_licensing_bioll/Main_tech_licensing_biol.htm Wesley et al. (2001) Intermediate vectors for assembly of an inverted repeat unit in a CaMV 35S expression cassette. The cassette can be transferred into <i>Agrobacterium</i> binary plasmid vectors using flanking <i>NotI</i> sites.
pX7-RNAi	G10-90 estradiol inducible	<i>hyg</i>	Two-step ligation	<i>Arabidopsis</i> actin intron 11	Guo et al. (2003) An <i>Agrobacterium</i> binary plasmid vector. The RNAi construct is introduced into the expression cassette of a G10-90 promoter that is inactivated by an insert that can be removed by the estradiol activation of Cre recombinase. The estradiol can be applied to the whole plant to give permanent activation of the RNAi construct. It can also give localized activation of silencing when applied to specific parts of the plant.
alcR -RNAi	<i>alc</i>	<i>kan</i>	Multistep ligation	GA20 intron	Chen et al. (2003) The alcR system was developed for alcohol-inducible protein expression and has also been used for RNAi. The RNAi constructs were assembled by sequential addition of the inverted repeat arms to the stuffer sequence followed by transfer into the <i>alc</i> expression cassette and introduction into the <i>Agrobacterium</i> binary plasmid vector. Such a system could be used with any plant transformation vector. Continued expression of the induced RNAi sequence may require repeat application of the alcohol inducer. Acetaldehyde may give better induction (Junker et al., 2003).

^aAbbreviations: *alc*, an alcohol-inducible promoter; attP and attR, recombination sites for integration of foreign sequence with commercially available recombinase preparations; *basta*, selection for resistance to the herbicide Basta; CaMV 35S, a strong constitutive promoter used widely in plant transformation; CHS, chalcone synthase; GUS, β -glucuronidase; *hyg*, hygromycin selection; *kan*, kanamycin selection; PDK, pyruvate orthophosphate dikinase.

Figure 26.6.1 Vectors and cloning strategies for RNAi in transgenic plants. A target gene fragment is amplified with two sets of primers with added restriction sites and directionally cloned into two multiple cloning sites in the intermediate vector pHANNIBAL (Wesley et al., 2001). The expression of the inverted repeat of the target gene, which is separated by an intron sequence, is driven by the CaMV 35S promoter and terminated by the octopine synthase (OCS) terminator. The RNAi expression cassette is released by *NotI* and cloned into the same site of the binary vector pART27 (Gleave, 1992).

Materials

Template DNA: cDNA clone of target gene
Restriction enzymes: e.g., *KpnI*, *EcoRI*, *XhoI*, *XbaI*, *BamHI*, *HindIII*, *ClaI*, or *NotI*
(see Fig. 26.6.1)
Intermediate vector pHANNIBAL (Wesley et al., 2001) and binary vector pART27
(Gleave, 1992)
Agrobacterium tumefaciens strain GV3101 with pSa-rep (Hellens et al., 2000)
YEP medium (see recipe): with no supplements, with 50 mg/liter gentamicin, and
with 50 mg/liter gentamicin plus 50 mg/liter spectinomycin
0.15 M NaCl (autoclave and store at room temperature)
20 mM CaCl₂ (filter sterilize; store at 4°C) supplemented with 15% (v/v) glycerol
(autoclave and store at room temperature)
Liquid nitrogen
YEP plates (see recipe) supplemented with 50 mg/liter gentamicin and 50 mg/liter
spectinomycin
Arabidopsis thaliana ecotype *Columbia* (Col-0) seeds (Lehle Seeds)
0.1% (w/v) phytoagar (Caisson Laboratories; autoclave and store at room
temperature)
Arabidopsis infiltration medium (see recipe)
Silwet L-77 (Lehle Seeds)
70% ethanol containing 0.1% (v/v) Triton X-100
95% or 100% ethanol
Arabidopsis transgenic plant selection plates (see recipe) and wild-type control
plates (omit kanamycin)

100-ml and 2-liter Erlenmeyer flasks
28°C shaking incubator
High-speed refrigerated centrifuge and rotors
Equipment for growing *Arabidopsis thaliana* (Lehle Seeds):
Potting soil
3 × 5-in. plastic pots
Nylon screens
Clear covers
Environmentally controlled 22°C growth chambers and growth rooms for
Arabidopsis
22°C incubator allowing control over light/dark cycles

Rubber bands or tape
Covers of pipet-tip box or deep petri dishes as containers for *Agrobacterium*
solution
Plastic wrap (e.g., Saran wrap)
Coin envelopes for seed drying and storage
15-ml tubes
100-mm diameter filter papers, sterilized by autoclaving

Additional reagents and equipment for PCR (UNIT 15.1), restriction enzyme
digestion (UNIT 3.1), agarose gel electrophoresis (UNIT 2.5A), DNA purification
from agarose gels (UNIT 2.6), use of T4 DNA ligase (UNIT 3.14), transformation of
E. coli (UNIT 1.8), plasmid DNA minipreps (UNIT 1.6), dephosphorylation of DNA
with alkaline phosphatase (UNIT 3.10), culture of bacteria (UNIT 1.2), plant RNA
preparation (UNIT 4.3), RT-PCR (UNITS 15.5 & 15.8), northern blotting (UNIT 4.9), and
immunoblotting (UNIT 10.8)

Construct RNAi vectors for plant transformation

1. Design and synthesize two sets of primers that will amplify a region of the target gene and add appropriate restriction sites for cloning (Fig. 26.6.1).

UNIT 15.1 discusses general principles of primer design and software programs for that purpose.

The first set of primers should contain restriction sites for KpnI, EcoRI, or XhoI at the 5' end. For example, to clone the amplified cDNA into pHANNIBAL in the sense direction, the 5' primer might include a XhoI site and the 3' primer a KpnI site. The second set of primers should contain restriction sites for XbaI, BamHI, HindIII, or ClaI at the 5' end. To clone the amplified cDNA in the antisense direction, the 5' primer might include an XbaI site and the 3' primer a ClaI site. Other enzyme combinations can be selected according to the restriction sites present in the cDNA. The order of the cloning of sense or antisense fragments can also be reversed if necessary.

The authors always add 3 bp at the 5' end of the primers (before the restriction site) to facilitate restriction enzyme digestion.

2. Perform PCR to amplify the template cDNA corresponding to the target gene (UNIT 15.1).
3. Digest the PCR products with appropriate restriction enzymes (e.g., XhoI and KpnI for sense fragment; ClaI and XbaI for the antisense fragment; UNIT 3.1).
4. Perform agarose gel electrophoresis (UNIT 2.5A) on the digested PCR products. Recover the sense and antisense DNA fragments from the agarose gel (UNIT 2.6).
5. Digest the vector pHANNIBAL with one set of restriction enzymes (e.g., XhoI and KpnI). Perform agarose gel electrophoresis on the digested DNA. Recover the digested vector DNA from the agarose gel.
6. Ligate the appropriate digested cDNA fragment (in this case, the sense fragment) to the vector using T4 DNA ligase (UNIT 3.14).
7. Transform the ligation mixture into competent *E. coli* cells (UNIT 1.8).
8. Prepare minipreps of plasmid DNA (UNIT 1.6) and identify the plasmids that contain the correct insertion by restriction digestion and agarose gel electrophoresis.
9. Repeat steps 5 to 8 for the antisense cDNA fragment by digesting the plasmid DNA from step 8 that contains the correct insertion with the second set of restriction enzymes (ClaI and XbaI).
10. Digest pART27 binary vector with NotI, then treat with calf alkaline phosphatase (CIP; UNIT 3.10) to prevent self-ligation.
11. Release the RNAi cassette from the pHANNIBAL vector by digestion with NotI and clone it into the NotI site of binary vector pART27 using T4 DNA ligase.
12. Prepare minipreps of RNAi plasmid DNA.

Transform *A. tumefaciens*

13. In a 100-ml flask, inoculate a single colony of *A. tumefaciens* strain GV3101 with pSa-rep into 20 ml YEP medium supplemented with 50 mg/liter gentamicin. Incubate at 28°C overnight with shaking.

UNIT 1.2 describes basic bacterial culture techniques.

14. In a 2-liter Erlenmeyer flask, inoculate 500 ml YEP supplemented with 50 mg/liter gentamicin with 20 ml of overnight culture. Incubate at 28°C until an OD₆₀₀ of ~0.5 is obtained (which will take ~4 hr).

15. Collect cells by centrifuging 5 min at $3000 \times g$, 4°C . Remove supernatant and resuspend cells in 100 ml of 0.15 M NaCl.
16. Centrifuge 5 min at $3000 \times g$, 4°C . Remove supernatant and resuspend pellet in 10 ml ice-cold 20 mM CaCl_2 supplemented with 15% glycerol.
17. Add 1 to 2 μl of RNAi plasmid DNA (200 to 500 mg) to 200 μl of competent *A. tumefaciens* cells in a 1.5-ml microcentrifuge tube and incubate on ice for 30 min.
At this time the cells that are not needed can be frozen as 200- μl aliquots in liquid nitrogen and stored in a -80°C freezer for future use.
18. Freeze cells in liquid nitrogen for 1 min, then thaw the frozen mixture in a 37°C water bath for 1 min.
19. Add 1 ml YEP medium and incubate at 28°C for 2 hr with gentle shaking.
20. Collect cells by microcentrifuging briefly at maximum speed. Remove supernatant and resuspend cells in 100 μl YEP medium.
21. Plate the cells onto YEP plates containing 50 mg/liter gentamicin and 50 mg/liter spectinomycin and incubate at 28°C for 2 to 3 days.
22. Prepare 2-ml overnight cultures of *A. tumefaciens* from five to ten single colonies in YEP medium containing gentamicin and spectinomycin. Prepare plasmid DNA minipreps from the 2-ml overnight cultures and perform PCR (UNIT 15.1) with the primers made in step 1 to confirm that the cells contain the construct.

Grow Arabidopsis plants for transformation

23. Add ~ 200 seeds of *Arabidopsis* (ecotype Col-0) to 50 ml of 0.1% phytoagar and vernalize for 1 to 2 days at 4°C .
24. Put soil into 3×5 -in. pots and wet the soil with water (prepare 2 to 4 pots for each construct to be transformed). Put 10 to 15 of the vernalized seeds into each pot using a plastic pipet. Cover the pots with nylon screen and secure with rubber bands or tape. Cover the pots with a clear cover to keep the humidity high.
25. Grow seedlings for ~ 5 days until the first leaves appear. Remove the clear cover and grow the plants in a greenhouse or growth room at 22°C with a 16 hr light/8 hr dark cycle for ~ 4 weeks.
26. Water the plants every 5 days or as needed; when the plants start to flower, remove the emerging primary inflorescence to encourage growth of multiple secondary inflorescences.

The plants will be ready for transformation ~ 1 week after the removal of the primary inflorescence. The presence of unopened flower buds indicates the optimal time for transformation.

Transform Arabidopsis plants

27. Inoculate a single colony of *A. tumefaciens* carrying the RNAi construct into 100 ml YEP medium supplemented with 50 mg/liter gentamicin and 50 mg/liter spectinomycin. Grow for 2 days at 28°C with shaking at 200 rpm.
28. Harvest cells by centrifuging 10 min at $3000 \times g$, room temperature. Resuspend the cells in 200 ml *Arabidopsis* infiltration medium. Add 40 μl Silwet L-77 (0.02% final concentration) and mix well.
29. Pour the *A. tumefaciens* culture into a deep petri dish or the cover of a pipet-tip box. Invert the plants (inflorescences with flower buds) into the solution and incubate for 15 min at room temperature.

30. Remove plants from the *A. tumefaciens* suspension. Loosely cover plants with Saran wrap to maintain humidity and return to 22°C. Remove wrap after 24 hr. Grow plants an additional 4 weeks or until seeds are dry.
31. Harvest the seeds from each pot separately and keep them in a coin envelope for 1 week before selection.

These seeds are the first generation of transformants (T1).

Select RNAi transgenic plants

32. Sterilize 200 to 500 mg harvested T1 seeds by incubating in a 15-ml tube with 10 ml of 70% ethanol containing 0.1% Triton X-100 for 10 min with shaking. Rinse the seeds three times, each time with 10 ml of 95% or 100% ethanol. Transfer the seeds to sterilized filter papers placed in a sterile hood and let the seeds dry for 15 to 30 min.
33. Sprinkle ~20 mg of seeds (~1000 seeds) evenly onto one *Arabidopsis* transgenic plant selection plate. Seal plate with tape. Keep at 4°C for 1 to 2 days. Transfer plates to an incubator with light/dark cycles (16 hr/day) at 22°C.
34. Distinguish transgenic seedlings (green) from nontransgenic seedlings (yellow) about 2 weeks after germination. Transfer the transgenic plants to soil. Grow plants for 4 more weeks, then harvest the T2 seeds.

Characterize RNAi transgenic plants

35. Germinate 20 to 50 T2 transgenic plant lines on *Arabidopsis* transgenic plant selection plates. Also include a wild-type control plate without kanamycin.

The authors usually sterilize about 200 seeds for each line and put them in one 100 × 20-mm plate containing 25 ml of the phytoagar-containing selection medium.

36. Grow the T2 seedlings on plates for 2 to 3 weeks under light (16 hr/day). Collect 200 mg transgenic tissue (about 50 whole seedlings) and prepare total RNA (UNIT 4.3).
37. Synthesize cDNA from 2 µg RNA using RT-PCR (UNIT 15.5). Perform quantitative RT-PCR (UNIT 15.8) to quantify the expression of the target gene in wild-type control and RNAi transgenic lines.

It will be necessary to optimize the PCR cycle numbers to quantify the expression of the target gene.

38. Confirm transgenic lines with reduced target gene expression (identified by RT-PCR) by northern blotting (UNIT 4.9).

Target-gene expression can be detected by a regular northern blot (UNIT 4.9), or the presence of siRNA in the RNAi transgenic lines can be detected by a northern blot transferred from a 15% denaturing polyacrylamide gel (also described in UNIT 4.9).

39. If antibodies against the target protein are available, perform an immunoblot to confirm that the protein level of the target gene is reduced (UNIT 10.8).

VIRUS-INDUCED GENE SILENCING

This protocol describes the use of a tobacco rattle virus (TRV) vector for virus-induced gene silencing (VIGS). TRV has a bipartite RNA genome. One of the components (RNA1) encodes the RNA replication enzymes and the other component (RNA2) encodes the coat protein. In the system described here, RNA2 is engineered such that a nucleic acid sequence corresponding to the target gene of interest can be replicated as part of the viral genome. The engineered RNA2 containing the RNAi construct is then cloned into an *A. tumefaciens* binary vector. RNA1 is cloned separately into another *A. tumefaciens*

binary vector. The two different *A. tumefaciens* strains carrying the RNA1 and RNA2 constructs are then coinfecting into a target plant (*Nicotiana benthamiana*) that is highly susceptible to *A. tumefaciens*, allowing a high level of transient expression of genes on the binary vectors that are transferred from *A. tumefaciens* to the plant cells. This transient expression system is referred to as "agroinfection." VIGS develops over a period of 1 to 3 weeks following *A. tumefaciens* infection, as virus particles are produced.

It is possible to circumvent the use of *A. tumefaciens* for the inoculation; viral cDNA can be inoculated directly or it can be transcribed in vitro into infectious RNA. However, these latter procedures require isolation and repeated handling of the viral cDNA, and produce a lower inoculation efficiency than *Agrobacterium*.

In the VIGS protocol described below, it is useful to include an empty TRV2 vector as a control. The symptoms on the infected plant are slight stunting and very mild mosaicism. A useful positive control for silencing is the TRV2 vector with an insert from the endogenous *N. benthamiana* genes encoding phytoene desaturase (PDS) or magnesium chelatase. The silencing symptoms develop over 1 to 3 weeks as photobleaching (PDS) or yellow chlorosis (magnesium chelatase). It is important that the plants do not experience temperature stress above 28°C (for *N. benthamiana*).

CAUTION: Plants infected with virus vectors should be grown under appropriate containment conditions according to regulations determined by the appropriate regulatory authority and with the approval of the relevant institutional biosafety committee.

Materials

- A. tumefaciens* binary vector pTRV: TRV RNA2 vector construct (e.g., pTV00 based on TRV strain PPK20; Ratcliff et al., 2001); freely available to academic scientists from the Baulcombe laboratory (<http://www.sainsbury-laboratory.ac.uk/dcb/>)
- SOB medium (see recipe)
- 10% (v/v) glycerol, ice cold
- L medium and plates (see recipe) supplemented with 50 µg/ml kanamycin, 5 µg/ml tetracycline, and 50 µg/ml rifampicin
- A. tumefaciens* strain C58C1 carrying pBINTRA6 (GeneBank accession no. AF314165; Ratcliff et al., 2001); freely available to academic scientists from the Baulcombe laboratory (<http://www.sainsbury-laboratory.ac.uk/dcb/>)
- SOB medium (see recipe) supplemented with 50 µg/ml kanamycin, 5 µg/ml tetracycline, and 50 µg/ml rifampicin
- 10 mM MgCl₂ with 100 µM acetosyringone (3',5'-dimethoxy-4'-hydroxyacetophenone; Acros Organics) and 1 mM MES, pH 5.6
- Nicotiana benthamiana* seedlings (5 cm high, 2 weeks old)
- 2-liter Erlenmeyer flasks
- 250-ml centrifuge bottles
- Electroporator (Cell-Porator and Voltage Booster; Invitrogen) and 0.15-cm cuvettes, prechilled
- Culture tubes
- 1-ml syringes
- 20° to 24°C greenhouse or growth chamber
- Additional reagents and equipment for constructing RNAi vector and transforming *A. tumefaciens* (see Basic Protocol 1), electroporation (optional; UNIT 1.8), alkaline lysis minipreps (UNIT 1.6), PCR (UNIT 15.1), and restriction enzyme digestion (UNIT 3.1)

Construct RNAi cDNA viral vectors

1. Engineer an inverted cDNA RNAi construct in *A. tumefaciens* binary vector pTRV (see Basic Protocol 1, steps 1 to 12, but use the pTRV binary vector).

The TRV vector pTV00 has a SmaI site for insertion of blunt-ended cDNA fragments from any target gene. The fragments can be derived by suitable restriction enzyme digestion of the cloned DNA or by PCR amplification of genomic DNA or cDNA with primers that include restriction sites that leave blunt-ended DNA. The primers are designed with at least three nucleotides outside the restriction site to facilitate digestion. The ligation reaction is carried out with a two-fold molar excess of RNAi insert to TRV vector.

Transform *A. tumefaciens* with pTRV (RNA2)

Transform *A. tumefaciens* strain GV3101 with pTRV DNA by electroporation (steps 3 to 6 below) or by the CaCl₂ method (see Basic Protocol 1, steps 13 to 20). After either transformation method, proceed to selection of transformed cells as in step 7 below.

2. Add 1.0 ml of an overnight culture of *A. tumefaciens* strain GV3101 with pSa-rep to 500 ml of SOB medium in a 2-liter flask and incubate for 5 to 6 hr at 28°C with vigorous shaking.
3. When the OD₅₅₀ reaches 0.7, chill the culture on ice for 30 min, then transfer to 250-ml centrifuge bottles and centrifuge 15 min at 2600 × *g*, 4°C. Remove supernatant, then wash four times, each time by adding 250 ml 10% glycerol, centrifuging as before, and removing the supernatant. Resuspend cells in a final volume of 1.0 ml in ice-cold 10% glycerol. Use electrocompetent cells immediately or store at –70°C.
4. To a 40-μl aliquot of electrocompetent cells, add 50 ng of the engineered TRV RNA2 vector cDNA.
5. Electroporate (UNIT 1.8) using prechilled 0.15-cm cuvettes in a Cell-Porator with Voltage Booster according to conditions recommended by the manufacturer (capacitance, 330 μF; resistance, 4000 Ω; voltage, 380 V; impedance, low Ω; charge rate, fast).
6. Transfer the electroporated cells to 0.5 ml SOB medium and incubate at 28°C for 1 hr with gentle shaking (100 rpm).
7. Plate out the transformed cells on L plates supplemented with 50 μg/ml kanamycin, 5 μg/ml tetracycline, and 50 μg/ml rifampicin.
8. Prepare a 5-ml overnight culture in L medium supplemented as above.
9. Isolate plasmid DNA from *Agrobacterium* using the alkaline lysis miniprep method (UNIT 1.6). Characterize the DNA by PCR (UNIT 15.1) or restriction enzyme digestion (UNIT 3.1) to confirm the identity of the plasmid DNA in the transformed *A. tumefaciens*.

*For the restriction digestion approach, it may be necessary to reamplify the isolated DNA in *E. coli* strain DH5α because the yield from *A. tumefaciens* is low. Transform *E. coli* by calcium chloride or electroporation (UNIT 1.8) and isolate plasmid DNA by alkaline lysis miniprep (UNIT 1.6).*

Inoculate plants

10. Prepare separate 10-ml *A. tumefaciens* cultures containing pBINTRA6 (C58C1) and the TRV RNA2 vector cDNA (GV3101:pSa-rep) in SOB medium with 50 μg/ml kanamycin, 5 μg/ml tetracycline, and 50 μg/ml rifampicin. Grow overnight at 28°C.

pBINTRA6 is an RNAi Ti plasmid clone of TRV.

11. Centrifuge the cultures 20 min at 2600 × *g*, room temperature, and remove the supernatants. Resuspend each pellet individually in 10 ml of 10 mM MgCl₂ with 100 μM acetosyringone and 1 mM MES, pH 5.6.

- Mix the two suspensions in a 1:1 ratio and infiltrate the liquid into leaves of *N. benthamiana* seedlings by transferring aliquots to a 1-ml syringe and pressing the tip of the syringe against the lower surface of the leaves.

Infiltrate two to three leaves per plant. Apply as much suspension as necessary to fill most of the leaf, ~200 μ l depending on the size of the leaf. The leaf appears water-soaked in the infiltrated zone.

- Maintain the plants at 20° to 24°C in a greenhouse or growth chamber under 8 hr dark/16 hr light cycles and monitor the development of viral symptoms.

The viral symptoms appear after about 10 days and reflect the phenotype of the silenced target gene. They will vary from mild mosaic to death of the plant depending on the function of the gene that is targeted by silencing.

SUPPRESSION OF SILENCING FOR PROTEIN OVEREXPRESSION

Transient gene expression is a fast, flexible, and reproducible approach to high-level expression of useful proteins. In plants, recombinant strains of *Agrobacterium tumefaciens* can be used for transient expression of genes that have been inserted into the T-DNA region of the bacterial Ti plasmid. A bacterial culture is vacuum-infiltrated into leaves, and, upon T-DNA transfer, there is ectopic expression of the gene of interest in the plant cells. Ectopic protein expression continues for 2 or 3 days, but then ceases because of post-transcriptional gene silencing (PTGS). Virus-encoded suppressors of silencing can be used to extend the time of ectopic protein expression and to increase the level of protein-produced viral-encoded suppressor of gene silencing (Johansen and Carrington, 2001; Voinnet et al., 2003). This protocol uses the p19 silencing suppressor protein of tomato bushy stunt virus. Coexpression of p19 enhances the expression of foreign protein by up to 50-fold, so that protein purification can be achieved from as little as 100 mg of infiltrated leaf material (Voinnet et al., 2003). Silencing suppressor-enhanced expression systems have potential value in industrial production and as a research tool for isolation and biochemical characterization of a broad range of proteins, without the need for the time-consuming regeneration of stably transformed plants.

Materials

- pBin61 binary plasmid vector with *Xba*I and *Sma*I restriction sites in the CaMV 35S expression cassette (Bendahmane et al., 2000); freely available to academic scientists from the Baulcombe laboratory (<http://www.sainsbury-laboratory.ac.uk/dcb/>)
- Restriction enzymes: *Sma*I and *Xba*I
- cDNA of full open reading frame to be overexpressed
- E. coli* strain DH5 α
- L plates (see recipe) supplemented with 50 μ g/ml kanamycin
- A. tumefaciens* strain C58C1:pCH32
- L plates (see recipe) supplemented with 50 μ g/ml kanamycin, 5 μ g/ml tetracycline, and 50 μ g/ml rifampicin
- A. tumefaciens* strain C58C1:pCH32:p35S-p19 (or C58C1:pCH32:p35S-pHC-Pro) harboring expression plasmids of the p19 (or HC-pro) viral suppressors of silencing (Voinnet et al., 2003); freely available to academic scientists from the Baulcombe laboratory (<http://www.sainsbury-laboratory.ac.uk/dcb/>)
- L medium (see recipe) supplemented with 50 μ g/ml kanamycin and 5 μ g/ml tetracycline
- 10 mM MgCl₂ with 100 μ M acetosyringone (3',5'-dimethoxy-4'-hydroxyacetophenone; Acros Organics) and 1 mM MES, pH 5.6
- Nicotiana benthamiana* seedlings (5 cm high, 2 weeks old)

28°C shaking incubator
Culture tubes
1-ml syringes
20°C to 25°C greenhouse or growth chamber allowing control of light/dark cycles
Additional reagents and equipment for restriction digestion (*UNIT 3.1*), use of T4 DNA ligase (*UNIT 3.14*), transformation of *E. coli* (*UNIT 1.8*), transformation of *A. tumefaciens* (see Basic Protocol 1 or 2), and growth of bacteria (*UNIT 1.2*)

Construct overexpression clone

1. Perform a restriction digest (*UNIT 3.1*) of pBin61 using sites that cleave in the CaMV 35S expression cassette (*Sma*I, *Xba*I). Using T4 DNA ligase (*UNIT 3.14*), ligate to cDNA of the full open reading frame to be overexpressed.
2. Transform the ligation mix into *E. coli* strain DH5 α (*UNIT 1.8*) and select for transformants on L plates with 50 μ g/ml kanamycin. Confirm the clone construction by sequence analysis or restriction digestion of the cloned DNA.
3. Transform into *A. tumefaciens* strain C58C1:pCH32 using the methods described Basic Protocol 1 or 2. Plate out transformants on L plates supplemented with 50 μ g/ml kanamycin, 5 μ g/ml tetracycline, and 50 μ g/ml rifampicin.

Overexpress protein

4. Prepare separate 10-ml overnight cultures of *A. tumefaciens* strains C58C1:pCH32:p35S-p19 (or C58C1:pCH32:p35S-pHC-Pro) and C58C1:pCH32:pBin61 (protein X) in L medium supplemented with 50 μ g/ml kanamycin and 5 μ g/ml tetracycline. Grow overnight at 28°C.

UNIT 1.2 describes basic bacterial culture techniques.

5. Centrifuge the cultures 20 min at 2600 \times g, room temperature, and remove the supernatants. Resuspend each pellet individually in 10 ml of 10 mM MgCl₂ with 100 μ M acetosyringone and 1 mM MES, pH 5.6.
6. Adjust the OD₆₀₀ of each culture to 0.5 with the same solution used in step 5 and mix the suspensions in a 1:1 ratio.
7. Infiltrate the liquid into leaves of *N. benthamiana* seedlings (3 to 4 leaves per plant) by transferring aliquots to a 1-ml syringe and pressing the tip of the syringe against the lower surface of the leaves.
8. Maintain the plants at 20° to 25°C in a greenhouse or growth chamber under 8 hr dark/16 hr light cycles. Monitor protein expression over a period of up to 10 days post-infiltration in the infiltrated regions of the leaves.

The temperature should not be allowed to increase over 28°C. Expression of foreign proteins will normally be highest at 5 to 7 days post-infiltration. Signs of protein expression are entirely dependant upon the protein being expressed.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see *APPENDIX 2*; for suppliers, see *APPENDIX 4*.

***Arabidopsis* infiltration medium**

$\frac{1}{2} \times$ Murishige & Skoog (MS) macro and micronutrients (Caisson Laboratories)
10 μ g/liter benzylaminopurine (Sigma; add 10 μ l of a 1 mg/ml stock per liter medium)
0.02% (v/v) Silwet L-77 (Lehle Seeds)
Adjust pH to 5.7 with 1 M KOH
Prepare fresh (no need to sterilize)

Arabidopsis transgenic plant selection plates

$\frac{1}{2}$ × Murishige & Skoog (MS) macro and micronutrients (Caisson Laboratories)
1% (w/v) sucrose
0.8% (w/v) phytoagar (Caisson Laboratories)
Adjust pH to 5.7 with 1 M KOH

Autoclave, cool to 55°C, and add kanamycin to 50 mg/liter (omit for wild-type control plates). Pour into 150 × 15–mm or 100 × 20–mm petri dishes, depending on the steps in which they are to be used. Store up to 2 to 3 months at 4°C.

L medium and plates

For liquid medium:

10 g Bacto tryptone
5 g Bacto yeast extract
5 g NaCl
1 g D-glucose
H₂O to 1 liter
Autoclave
Cool to 55°C

Add appropriate antibiotics from filter-sterilized stocks
Store up to 3 months at room temperature

For plates: Prepare medium as described above, but add 1% (w/v) agar (e.g., Difco) before autoclaving. After partially cooling, and antibiotics, pour medium into plates, and allow to harden. Store up to 1 month at 4°C.

SOB medium

2% (w/v) Bacto tryptone (Difco)
0.5% (w/v) Bacto yeast extract (Difco)
10 mM NaCl
2.5 mM KCl
Store up to 2 to 3 months at room temperature
Immediately before use, add antibiotics as needed from 50 mg/ml filter-sterilized stocks

YEP medium and plates

For liquid medium:

10 g Bacto yeast extract (Difco)
10 g Bacto peptone (Difco)
5 g NaCl
H₂O to 1 liter
Adjust pH to 7.0 using 1 M NaOH
Autoclave
Cool to 55°C

Add appropriate antibiotics from filter-sterilized 50 mg/ml stocks (store stocks at –20°C)

For plates: Prepare medium as above, but add 1.5% (w/v) agar (e.g., Difco) before autoclaving. After partially cooling, and antibiotics, pour medium into plates, and allow to harden. Wrap plates in Parafilm and store up to 2 to 3 months at 4°C.

COMMENTARY

Background Information

Silencing in transgenic plants

The first reports of RNA silencing in transgenic plants involved sense or antisense transgenes. In a small proportion of the lines produced with any one construct, there was coordinate silencing of both the transgene and the endogenous gene manifested as a loss of gene function (Napoli et al., 1990; van der Krol et al., 1990). It is now known that silencing in these lines occurs because an RNA-dependent RNA polymerase (RdRP) converts the single-stranded transcript of the transgene into a dsRNA, which is then processed by a Dicer into siRNA (Dalmay et al., 2000; Beclin et al., 2002). However, it is not yet understood why there is silencing in only a subset of the lines. One of the proposed explanations implicates an RNA threshold; in non-silencing lines, the transgene RNA would be present below a threshold level that is required for activation of silencing (Lindbo et al., 1993).

An alternative explanation of silencing variation invokes a qualitative difference in the transcripts of different lines; silencing lines would be those producing aberrant RNAs that are good templates for the RdRP (English et al., 1996). There has been extensive discussion about the features that define an aberrant RNA but, as yet, no definitive information. A likely scenario is that endogenous mRNAs are associated with proteins that interfere with the RdRP. According to this idea, the transgene RNAs might have a modified ribonucleoprotein (RNP) structure that allows the RdRP to produce dsRNA. The modified RNP might arise, for example, if the transgene RNAs are incomplete at the 3' end and, consequently, lack a poly(A)-binding protein or other component of the RNP.

Until these threshold and aberrant RNA models have been tested, there will be no rational criteria for design of sense or antisense constructs giving consistent silencing. However, the requirement for an RdRP step can be circumvented by use of dsRNA constructs (Dalmay et al., 2000; Beclin et al., 2002). These constructs have inverted repeat modules in the transcribed region, separated by a short stuffer sequence, and they are coupled to either constitutive (Waterhouse et al., 1998; Chuang and Meyerowitz, 2000) or inducible (Chen et al., 2003; Guo et al., 2003) promoters. The inducible promoters have to be used if silencing of the target genes

would prevent regeneration of the transgenic plant.

Versions of the dsRNA constructs have different types of stuffer sequence between the inverted repeats. In some of the vectors, this stuffer is an intron, whereas in others it is a sequence of noncoding DNA without known biological activity. There is one report that the silencing efficiency is increased if the stuffer sequence is an intron (Smith et al., 2000). However, it has not been ruled out that there is a sequence-specific influence of the linker sequence that is unrelated to intron processing.

Constructs using the earliest generation of dsRNA vectors can be assembled using conventional restriction enzymes and ligation. More recent vectors can be assembled without restriction enzymes, using *in vitro* attP and attR recombinase systems (<http://www.invitrogen.com/>; Wesley et al., 2001). These newer vectors are useful for high-throughput applications in which hundreds or even thousands of sequences are to be targeted as part of a survey of gene function. Table 26.6.1 summarizes the features of the dsRNA vectors and indicates the source of additional information, including access procedures.

In most applications, the silencer constructs will be used as transgenes that are integrated into the genome of a plant. Although the silencing phenotype will typically be apparent in most of the transgenic lines (Chuang and Meyerowitz, 2000; Smith et al., 2000; Wesley et al., 2001), there may be some between-line variation with respect to the degree of silencing. If complete loss of function in the target gene leads to death or growth arrest, the intermediate phenotypes that are due to partial silencing may be informative.

There are some instances when the silencer constructs can be introduced directly into cells where the target gene is expressed. This approach does not require integration of the silencer construct into the genome, and is best illustrated by experiments in barley in which the silencing target encodes a component of the disease-resistance signal-transduction pathway (Schweizer et al., 2000). The silencer was an inverted-repeat construct, as described above, introduced into a cell by bombardment with DNA-coated gold particles. The silencing phenotype that developed over a few days was manifested as growth of a pathogen in cells of a pathogen-resistant plant. The cells in the bombarded tissue that received the silencer DNA

were identified by coexpression of a reporter gene together with the silencer construct.

Transient silencing can be adapted to plants other than barley by modification of the conditions for particle bombardment. Alternatively, it may be possible to use *A. tumefaciens* to deliver the silencer constructs in a procedure that is normally used for transient protein overexpression (Hamilton et al., 2002). *A. tumefaciens* cells carrying the silencer construct are grown in liquid culture and harvested, and the resuspended cells are then infiltrated into leaves. The silencer construct transfers from the *A. tumefaciens* cells into the plant cells and, after 1 or 2 days, there is accumulation of the corresponding siRNA species.

The direct introduction of silencer constructs, as opposed to stable transgenesis, has the advantage of speed. However, methods employing the former approach are only appropriate when the target gene displays a phenotype in cells located in regions of the plant where they can be bombarded with DNA-coated gold particles or infiltrated with liquid cultures of *A. tumefaciens*. These transient silencing systems are also only appropriate when the RNA silencing target encodes an unstable protein. Stable proteins would persist after the onset of silencing, and there may not be a silencing phenotype even with reduced levels of the target RNA.

Virus-induced silencing

An alternative to stable or transient transformation for delivery of silencer constructs is virus-induced gene silencing (VIGS; Baulcombe, 1999; Basic Protocol 2). A sequence tag corresponding to the silencing target is inserted into the vector, and the gene-silencing phenotype is manifested in the infected regions of the plant. With RNA virus vectors, it seems likely that the dsRNA is the viral replication intermediate and that it is processed into the siRNA that targets mRNA degradation. It is less clear how DNA geminivirus vectors generate this dsRNA. It could be that there is read-through transcription on both strands of the circular DNA to generate overlapping RNAs. Alternatively, the geminiviral RNA could be copied by the RdRP, as described above for transgenes.

VIGS was developed as an RNA-silencing approach for essential genes because it would not be possible to generate transformed plants in which such genes were silenced. However, in infected plants, it would be possible to infer the function of such genes from the characteristics of VIGS-induced growth arrest. For

example, if the target gene were essential for cell division, the growth arrest would be most apparent in the meristems and along the veins. If the target gene were required for cell expansion, these zones of cell division would be unaffected, but the elongation zones of stems and the areas between veins in the leaves would exhibit growth arrest. VIGS was also designed for high-throughput applications because it does not require the time-consuming and labor-intensive procedures for plant transformation.

The advantages of VIGS for the analysis of gene function are illustrated by its use in a survey of nearly 5000 cDNAs (Lu et al., 2003a). One of the findings from this survey was that HSP90 proteins are required for disease resistance; this is an example of how silencing can be used to investigate multigene families. Repeated genes are often not amenable to mutation studies because of functional redundancy. A second advantage of VIGS can be inferred from the stunting or growth-arrest silencing symptoms in many of the infected plants (Lu et al., 2003a). These growth-arrested plants would most likely have a lethal phenotype when silenced with a constitutive promoter transgene or in null mutants.

The most widely used VIGS vectors are tobacco rattle virus (TRV) and potato virus X (PVX). TRV is effective on *N. benthamiana*, tomato, *Arabidopsis*, and other related species (Dalmay et al., 2000; Ratcliff et al., 2001; Liu et al., 2002), whereas PVX induces strong silencing only on *N. benthamiana* and *N. clevelandii* (Ruiz et al., 1998). The first VIGS vector was tobacco mosaic virus (TMV; Kumagai et al., 1995), but it has not been widely used because it induces strong symptoms in infected plants. However, a TMV-based system has been developed that, unlike TRV and PVX, gives good VIGS on the model plant *N. tabacum* (Gossele et al., 2002). Barley stripe mosaic virus (BSMV) has been used as a VIGS vector on barley (Holzberg et al., 2002), and geminivirus vectors are effective with *N. benthamiana* (Kjemtrup et al., 1998) and *Arabidopsis* (Turnage et al., 2002). For reasons that are not fully understood, VIGS is more effective in *N. benthamiana* and related species than in other hosts. Table 26.6.2 summarizes the features of various virus vectors and indicates references or Web sites that can be used for additional information. The vectors described use simple inserts, but the silencing effect can be enhanced if the insert is in an inverted repeat configuration (Lacomme et al., 2003).

Table 26.6.2 Vectors for VIGS

Virus	Assembly strategy	Host plants	Inoculation method	Reference	Web site
PVX (pGR106-7) ^a	Ligation	<i>N. benthamiana</i>	<i>Agrobacterium</i>	Lu et al. (2003a)	http://www.sainsbury-laboratory.ac.uk
TRV (pTV00) ^b	Ligation	<i>N. benthamiana</i> , <i>Arabidopsis</i>	<i>Agrobacterium</i> or manual inoculation of partially purified virions	Ratcliff et al. (2001)	http://www.sainsbury-laboratory.ac.uk
TRV ^c	Ligation, attP	<i>N. benthamiana</i> , tomato	<i>Agrobacterium</i>	Liu et al. (2002)	http://plantfunctionalgenomics.yale.edu/Dinesh/research/NSF/VIGSindex.html
SVISS: chimeric TMV/STMV ^d	Ligation	<i>N. benthamiana</i> , <i>N. tabacum</i> ,	Manual inoculation of in vitro transcripts	Gossele et al. (2002)	—
Tomato golden mosaic geminivirus ^e	Ligation	<i>N. benthamiana</i>	Bombardment of infectious DNA	Peele et al. (2001)	—
Cabbage leaf curl geminivirus ^f	Ligation	<i>Arabidopsis</i>	Bombardment of infectious DNA	Turnage et al. (2002)	—

^aThe PVX vector system was developed originally for protein overexpression and was then adapted for silencing. Earlier versions of the vector were transcribed in vitro to produce infectious RNA or were inoculated directly as cDNA. *Agrobacterium* inoculation is now preferred because the vector constructs do not need to be isolated and purified. In some respects PVX is easier to use than TRV because its genome has only a single component, and a toothpick inoculation procedure can be used that does not require a liquid culture. A toothpick is dipped into a small colony of the *Agrobacterium* vector clone and then pushed into a leaf or petiole of the plant to be inoculated. However, PVX symptoms are more severe than those of TRV and may interfere with the silencing phenotype. The reference describes the use of this system in a forward screen of genes required for disease resistance.

^bThis vector has largely superseded PVX for *N. benthamiana* because silencing is more persistent and viral symptoms are milder. It has also been used in *Arabidopsis*, but *Agrobacterium* inoculation is not effective. The most effective strategy at present requires an inoculum of partially purified virions and, even so, a typical experiment has several plants that do not become infected.

^cThe two TRV vector systems in this table were produced in separate laboratories from the same strain of virus, PPK20. The Dinesh-Kumar version (Liu et al., 2002) is effective on tomato and *Solanum* species and generates more severe symptoms on *N. benthamiana*. This version has been adapted to clone construction using the attP recombinase system.

^dSVISS is unlike the PVX and TRV vectors in that it is effective on *N. tabacum*.

^eIf the target genes are expressed in dividing or meristematic cells, this may be the most appropriate vector. The host range has not been fully explored.

^fThis vector is probably better than TRV for *Arabidopsis*.

VIGS is effective only in the parts of the plant that are invaded by the virus. Consequently, it cannot be used for analysis of embryo and seedling characteristics or, normally, of genes expressed in fruit and seeds, because these parts of the plant are often not infected. An additional limitation of VIGS is the need for large-scale facilities for growing plants under physical containment of genetically modified plant pathogens. In the future, it may be possible to miniaturize the procedures so that plants are inoculated as they germinate and the VIGS symptoms are assayed in seedlings. Such developments will facilitate containment by reducing the time course and scale of VIGS experiments. It may also be possible to develop biological containment systems so that there will be a reduced requirement for phys-

ical containment. Such systems could involve use of a deleted vector that would be competent to survive only on a transgenic host plant that complements the missing viral gene.

Critical Parameters

RNAi construct

Sense/antisense arms ranging from 98 to 853 base pairs have been found to give efficient silencing (Wesley et al., 2001), indicating that the length of the arm sequence can be flexible. Sequences derived from ORFs (open reading frames), 5'-UTRs (untranslated regions), and 3'-UTRs did not result in significant differences in silencing (Wesley et al., 2001). However, use of highly conserved sequences in the RNAi construct can knock down the target

gene as well as its close homologs (Yin et al., 2005). According to the authors' experience, genes with sequence identity of over 80% in the inverted repeat can be silenced, although the silencing efficiency is somewhat reduced compared to that achieved with the completely matched gene. Therefore, a highly conserved region from a gene family can be used to knock down several members of the gene family simultaneously. On the other hand, if one needs to reduce the expression of a specific family member, it is important to use a unique sequence in the RNAi construct that is not conserved among the homologs.

The pHANNIBAL system uses the strong and constitutive CaMV 35S promoter, so the target gene should be silenced in most cell types throughout development. If the target gene is essential for plant growth, or if it is necessary to assess gene function in different tissues/organs or different developmental stages, several vectors with inducible promoters are also available (Chen et al., 2003; Guo et al., 2003).

Plant transformation

The floral dip method (Clough and Bent, 1998) is a very simple and efficient way to make transgenic *Arabidopsis* plants. The most important parameter is to have healthy plants with many unopened flower buds for transformation. Healthy plants can be obtained by watering plants regularly and maintaining adequate light and optimal temperatures (22°C) in the growth room. The removal of the primary inflorescence leads to many secondary inflorescences, which is also very important to get many flower buds for transformation.

VIGS

VIGS has been used for silencing of many genes in *N. benthamiana*, and has been particularly effective as a tool for the analysis of defense-related genes. In test experiments, phytoene desaturase could be silenced with inserts that were as short as 23 nucleotides (Thomas et al., 2001). However, the silencing was less extensive and more transient than with larger sequence elements, and an insert of 150 to 500 nucleotides is recommended. Larger inserts can be used, but they are genetically unstable in the virus vector and do not cause enhancement of the silencing phenotype.

If the insert is from a region that is unique to the target gene, the silencing phenotype will be highly gene-specific. However, gene families may be targeted if the insert includes regions that are similar in related genes or other members of the gene family. Until now, there has

not been a systematic analysis of the sequence similarity needed for cross-silencing of related genes, and it is recommended that sequences be chosen that are more than 90% identical to the intended target.

Anticipated Results

Plant transformation

For *Arabidopsis*, the authors routinely achieve a 0.5% to 2% transformation frequency among the progeny of the transformed line after the floral dip protocol.

Gene silencing

The pHANNIBAL vector system yields gene silencing in over 90% of the independent transgenic lines, with at least 20% reduction in target gene expression (Wesley et al., 2001). To study the loss-of-function phenotype of *BES1* and its close family members, Yin et al. (2005) cloned an inverted repeat of about 900 bp coding region from the *BES1* gene using the pHANNIBAL system and made transgenic plants. About 25% of the transgenic lines showed more than 50% reduction in the expression of both *BES1* and its closest homolog, *BZRI*, and displayed an expected dwarf phenotype.

VIGS

All plants should become infected using these methods described with all or most showing symptoms of VIGS. The VIGS symptoms appear several days post-inoculation (dpi) and become extensive throughout the infected plant by 1 to 2 weeks. At later times, they may fade. The absence of a phenotype does not necessarily rule out involvement of the target gene in the trait of interest. VIGS is never complete and it is always possible that a silencing phenotype was not observed because the target gene function was supported by the residual low level of mRNA in the virus vector-infected plants. In some instances, the silencing may not be a direct consequence of loss of target gene function; there may be pleiotropic effects of target gene silencing. A final consideration applies to genes with an embryonic-lethal silencing phenotype in transgenic silencing approaches. It would be difficult to recover such plants, particularly if the transgenic silencing constructs employed a constitutive promoter. In a VIGS assay, such genes would induce symptoms with severe effects on growth and development.

Troubleshooting

Troubleshooting for common molecular biology techniques can be found in other

sections of this book. Potential troubles specific for this protocol are discussed here.

No or very few transgenic plants are recovered on selective media

If no transgenic plants are identified, check if the right antibiotics were used. A more common problem is that low numbers of transgenic plants are identified. In this case, grow new batches of flowering plants under more optimal conditions for transformation. Growing wild-type plants every 1 to 2 weeks will ensure that there are always plants available for transformation. Addition of 5% (w/v) sucrose to the infiltration medium can also increase the transformation efficiency.

No transgenic plants show a clear reduction in target gene expression

If an RT-PCR method is used to screen the RNAi transgenic lines, the parameters for PCR, especially the cycle numbers, need to be optimized. Reactions using 20, 22, 24, 26, 28, and 30 cycles should be tested to determine the right cycle number for a specific gene. Since RNAi lines usually knock down but do not knock out target gene expression, a small reduction in target gene expression may not be quantifiable by RT-PCR. In such a case, either real-time PCR or northern blotting should be performed to detect if there is a small reduction in target gene expression. Since the expression of a transgene is dependant on the position of its insertion in the genome (position effect), it may sometimes be necessary to screen a large number of transgenic lines to identify the few lines in which the target gene is significantly silenced. In addition, as described in Critical Parameters, a silenced transgenic plant may not be recovered if a gene is critical for plant growth and development. If this is the case, the use of inducible promoters in the RNAi construct can be helpful (Chen et al., 2003; Guo et al., 2003).

VIGS: Plants do not have a silencing phenotype

The precise timing of the maximum VIGS is highly dependent on environmental conditions: any stress to the plant would interfere with the *Agrobacterium* inoculation and/or spread of the virus in the infected plant. It is therefore advisable to measure the abundance of the intended target RNA or protein to confirm directly that its expression has been silenced. It is also useful to set up tests with well-characterized vector constructs to monitor the progress of the VIGS in parallel infected plants. The phytoene desaturase vectors

are useful for this purpose because they produce photobleaching symptoms that are very obvious. However, it may also be appropriate to use vectors that are targeted against genes involved in the trait of interest. For example, to identify genes required for disease resistance, it would be appropriate to establish the progression of VIGS using a control vector that targets a known defense-related gene.

VIGS: Plants do not have the expected silencing phenotype

The VIGS phenotype might not reflect loss of function in the target gene if there is sequence similarity between the insert and an unknown mRNA. Routine use of a second, nonoverlapping insert from the same target gene can rule out this artifact. If the target gene has been correctly identified, this second insert would reproduce the original VIGS phenotype. If the target gene is a member of a multigene family, it is necessary to target conserved and nonconserved regions to determine whether the silencing phenotype was influenced by one or several family members.

Time Considerations

Transgenic plants

It takes 2 to 4 weeks to make the RNAi construct (three cloning steps) and to transform the final construct into to *Agrobacterium*. Because it takes 4 to 5 weeks before the *Arabidopsis* plants are ready for transformation, several batches of *Arabidopsis* seeds should be planted before the cloning process is started. After *Arabidopsis* transformation, it will take 4 to 5 additional weeks to harvest T1 seeds and to identify T1 transgenic plants. Another 8 weeks are needed to obtain T2 seeds for further analysis. In the next 8 weeks, the T2 seedlings or plants can be analyzed, during which homozygous transgenic lines in the T3 generation can be identified to confirm the results from the T2 plants. Even when working efficiently, the entire process takes at least 6 months from start to finish.

VIGS

VIGS symptoms appear within 7 to 10 days post-inoculation and persist for at least 3 weeks.

CHAPTER 27

RNA-Protein Interactions

INTRODUCTION

This chapter is concerned with the analysis of RNA-protein interactions. The techniques in this chapter are analogous to those used to analyze protein-DNA interactions (Chapter 12), but the specific methods are different primarily due to the significant structural and biochemical differences between RNA and DNA and to the nature of the proteins and protein complexes that interact with these different nucleic acids.

UNIT 27.1 describes a method for fractionating and isolating RNA-protein complexes based on agarose gel electrophoresis. This method is simple, has excellent resolving power particularly for large complexes, and it minimizes disruption of the complexes. *UNIT 27.2* describes a UV cross-linking approach to identify RNA-binding proteins. The Basic Protocol involves UV cross-linking to uniformly labeled RNA, and treatment with RNase to generate proteins attached to a short oligoribonucleotide. The resulting material is analyzed by standard or two-dimensional electrophoresis, with the interacting proteins labeled by the crosslinked RNA. A modified version of this procedure incorporates immunoprecipitation, thereby allowing one to determine if a known protein is associated with a given RNA. *UNIT 27.3* describes purification of functional RNA-protein complexes using a combination of gel filtration and affinity chromatography. It is based on the specific binding of the MS2 protein to a defined RNA-hairpin structure, and is generally useful for isolating RNA-protein complexes assembled *in vitro*. Subsequent units will be concerned with specific biochemical assays for RNA-protein interactions.

Kevin Struhl

Agarose Gel Separation/Isolation of RNA-Protein Complexes

UNIT 27.1

ELECTROPHORETIC ISOLATION OF RNA-PROTEIN COMPLEXES

BASIC
PROTOCOL

Several methods are commonly used for detecting or separating RNA-protein complexes, including density-gradient sedimentation (Grabowski et al., 1985), vertical native polyacrylamide gels (Konarska and Sharp, 1986), and gel filtration (Reed, 1990). Native horizontal agarose minigels can be used for this purpose as well. Among the advantages of the agarose gel method are its simplicity, resolving power, and ability to detect complexes that are disrupted by other techniques. In addition, the use of low-melting-point agarose for fractionation readily allows for identification of the RNA species in each complex detected on the native gel.

Materials

DNA encoding desired sequence for RNA transcription (UNITS 1.5-1.7)

Reaction mixture (e.g., HeLa cell nuclear extracts, UNIT 27.3)

10× sample loading dye or 10× heparin loading dye (see recipes)

Low-melting-point agarose (Life Technologies)

0.5× TBE electrophoresis buffer (APPENDIX 2)

Gel-fixing solution: 10% acetic acid/10% methanol

Additional reagents and equipment for preparing ³²P-labeled RNA transcripts (UNIT 27.3), electrophoresis using agarose minigels (UNIT 2.5A), and autoradiography (APPENDIX 3A)

NOTE: Extreme caution should be taken to avoid RNase contamination. The experimenter should always wear gloves, and all the tubes and tips that come into contact with the sample should be certified RNase free; however, DEPC treatment (UNIT 4.1) of solutions and apparatus is not necessary.

Assembly of RNA-protein complexes

1. Prepare a ³²P-labeled RNA transcript from DNA encoding the desired sequence as described (UNIT 27.3).
2. Incubate the ³²P-labeled RNA transcript of interest in a 25- μ l reaction mixture under conditions that allow formation of RNA-protein complexes.

For example, spliceosomal complexes are assembled by incubation in HeLa cell nuclear extracts under splicing conditions (UNIT 27.3).

3. Gently mix (do not vortex) the samples with 2.5 μ l of 10× sample loading dye or 10× heparin loading dye and place on ice.

Electrophorese RNA-protein complexes on agarose gels

4. Prepare a 7 \times 8-cm horizontal low-melting-point-agarose minigel in 0.5× TBE electrophoresis buffer in a horizontal agarose minigel apparatus (UNIT 2.5A).

A thickness of ~0.5 cm is recommended (i.e., 25 ml melted agarose for a 7 \times 8-cm gel).

The optimal gel percentage should be determined for the RNA-protein complex of interest—e.g., 1.5% agarose is used for resolving spliceosomal complexes.

5. Load 10 μ l RNA-protein complex sample (step 2) in each well.

The remaining portion of each sample can be used for analysis of the RNA on a denaturing polyacrylamide gel (UNIT 2.12).

Supplement 63

6. Run the gel at 70 V in 0.5× TBE at either room temperature or 4°C.

The resolution varies depending on temperature and must be determined for each complex. The length of time for running the gel must also be determined empirically for each type of RNA-protein complex. For the spliceosome, the 1.5% gel is run until the bromphenol blue dye reaches the bottom.

Detect RNA-protein complexes

7. Incubate the agarose gel in gel-fixing solution for 15 min.
8. Dry the gel ~1 hr under vacuum at 80°C.
9. Visualize the complexes using a phosphorimager (*APPENDIX 3A*).

For instructions regarding elution of the RNA from the gel, which can be important if multiple complexes are observed on the gel, see Support Protocol.

SUPPORT PROTOCOL

ELUTION OF RNA FROM GEL-FIXED RNA-PROTEIN COMPLEXES

If several RNA-protein complexes are detected on the native gel, it may be important to determine the identity of the RNA species in each complex. For example, in the case of the spliceosome, complexes can be resolved that contain the unspliced pre-mRNA, the excised intron, or the spliced mRNA. To do this, follow the subsequent procedure.

Materials

Gel containing bands of interest (see Basic Protocol)
2× PK buffer (see recipe)
Proteinase K
RNase-free phenol, pH 5.2
20 mg/ml glycogen, molecular-biology grade
100% ethanol
Formamide loading dye (see recipe)

Additional reagents and equipment for autoradiography (*APPENDIX 3A*)

1. Excise the bands of interest from the gel using a clean razor blade. Melt the bands by heating 5 min at 70°C.
2. Mix with an equal volume of 2× PK buffer. Add proteinase K to a final concentration of 0.25 mg/ml. Mix and incubate 10 min at 37°C.
3. Extract the samples with an equal volume of RNase-free phenol, pH 5.2. Add 1/10 vol of 20 mg/ml molecular-biology-grade glycogen (2 mg/ml final) to the aqueous phase, mix, and then add 3 vol of 100% ethanol to precipitate RNA.
4. Add 10 µl formamide loading dye to the RNA pellets and incubate 5 min at 70°C.
5. Run the RNA samples on a denaturing polyacrylamide gel (*UNIT 2.12*). Visualize the RNA species by autoradiography (*APPENDIX 3A*).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Formamide loading dye

80% formamide
10 mM EDTA
0.1% (w/v) bromphenol blue
0.1% (w/v) xylene cyanol
Store up to 1 year at -20°C

Heparin loading dye, 10×

Prepare the following in 1× TBE electrophoresis buffer (*APPENDIX 2*):

6.5 mg/ml heparin sulfate

40% (v/v) glycerol

0.5% (w/v) bromphenol blue

0.5% (w/v) xylene cyanol

Store up to one month at -20°C

PK buffer, 2×

20 mM Tris-Cl, pH 8.0 (*APPENDIX 2*)

300 mM NaCl

25 mM EDTA

2% (w/v) SDS

Store up to one year at -20°C

Sample loading dye, 10×

Prepare the following in 1× TBE electrophoresis buffer (*APPENDIX 2*)

40% (v/v) glycerol

0.5% (w/v) bromphenol blue

0.5% (w/v) xylene cyanol

Store up to 1 year at -20°C

COMMENTARY

Background Information

Electrophoresis of RNA-protein complexes on horizontal native agarose minigels was developed as a simple and rapid method for the separation of spliceosomal complexes (Das et al., 2000). In addition, the method allowed for the detection of spliceosomal complexes that are too labile to be detected by any previously developed method (Chau and Reed, 1999; Luo and Reed, 1999; Das et al., 2000). The ATP-independent E complex was identified as the earliest discrete functional spliceosomal complex using gel filtration, but could not be detected by any of the native gel systems (Reed, 1990; Michaud and Reed, 1991). However, the E complex is readily detected on native agarose minigels. The advantage of the agarose gel over gel filtration for studies of the E complex is that multiple samples can be analyzed side-by-side on the same gel. The A, B, and C spliceosomal complexes assemble sequentially after the E complex and require ATP for their assembly. In the absence of heparin, these complexes comigrate as a large complex on agarose minigels, but can be resolved when heparin loading dye is used (Das and Reed, 1999). The yeast and mammalian A, B, and C complexes, as well as the yeast E complex, can be resolved on native polyacrylamide gels (Konarska et al., 1985; Konarska and Sharp, 1986; Pikielny et al., 1986; Seraphin and Rosbash, 1989). However, these gels are more difficult to pour than the

agarose gels and often do not allow as high a level of resolution. In addition, it is much simpler to cut out complexes and identify the RNA species in the complexes using the low-melting-point native agarose gels. Finally, the spliced mRNP complex, which promotes export of mRNA, was identified as a large heparin-sensitive complex on native agarose gels (Luo and Reed, 1999). This complex, like the E complex, can be detected by gel filtration, but not by any other native-gel method. Using the spliceosomal complexes as a precedent, the native low-melting-point-agarose gels may be a good choice for analysis of other types of RNA-protein complexes.

Critical Parameters

There are several parameters that can be tested to obtain the highest possible resolution of RNA-protein complexes by native agarose gel electrophoresis. The percentage of the gel, the length of time the gel is run, the voltage for running the gel, the sample concentration, and the temperature for running the gel can all be varied to optimize the results.

Troubleshooting

With some RNA-protein complexes, a portion of the sample becomes stuck in the well of the gel. This problem can sometimes be overcome by running the gel 30 min at low voltage and then increasing the voltage for the rest of

Figure 27.1.1 Detection of the earliest functional spliceosomal complex (the E complex), on a 1.5% native agarose minigel. E complex assembly requires incubation at 30°C and assembles in the absence of ATP. ³²P-labeled pre-mRNA containing one intron was incubated on ice or at 30°C for the times indicated (i.e., 0 or 40 min) in HeLa cell nuclear extracts in the absence of ATP. Aliquots of samples were gently mixed with sample loading dye (no heparin) and then loaded on the gel. The positions of the E complex and the nonspecific H complex are shown.

Figure 27.1.2 Resolution of the ATP-dependent spliceosomal complexes on a 2% native agarose minigel. ³²P-labeled pre-mRNA containing an AG to GG mutation at the 3' splice site (which allows assembly of the A, B, and C spliceosomal complexes, but not splicing) was incubated in nuclear extract in the presence of ATP. **(A)** At the time points indicated (i.e., 0, 8, 25, or 40 min), heparin loading dye was added to the samples before loading on a 2% agarose gel. The positions of spliceosomal complexes and nonspecific H complex are shown. **(B)** The RNA species in each complex—i.e., H (nonspecific complex), A, B, or C—was identified by excising the complexes from the agarose gel, preparing RNA, and fractionating it on an 8% denaturing gel. An aliquot of a splicing reaction incubated for 40 min was run as a marker (M). The pre-mRNA and splicing intermediates (lariat-exon 2 and exon 1) are indicated.

the running time. The sample or a portion of it may also become stuck in the well if the reaction is too concentrated. Try diluting the reaction 5- to 10-fold with 0.5× TBE electrophoresis buffer. Another strategy for eliminating the material in the well is to use the heparin loading dye. Previous studies using native polyacrylamide gels have shown that heparin dissociates nonspecific interactions and allows samples to enter the well completely. The disadvantage of heparin treatment is that it disrupts many RNA-protein complexes. The heparin can be titrated to find an optimal amount that allows sample entry without disrupting the complex of interest.

Anticipated Results

Two figures are shown to illustrate results obtained on native agarose gels when samples are treated without (Fig. 27.1.1) or with (Fig. 27.1.2) heparin.

Time Considerations

Preparation of ³²P-labeled RNA takes ~1 to 2 hr. Assembly of the RNA-protein complex varies according to the complex of interest. Separation of large RNA-protein complexes on a native agarose gel takes ~3 to 4 hr. Fixing and drying the gel takes 1.5 hr. Exposure on the phosphor imager cassette can take from 30 min to overnight depending on the efficiency of complex assembly and the specific activity of the radiolabeled RNA.

Identification of RNA Binding Proteins by UV Cross-Linking

UNIT 27.2

UV cross-linking is a standard method used to detect RNA-binding proteins. This method takes advantage of the ability of a photoreactive group, upon UV irradiation, to trigger the formation of a covalent bond between the RNA and closely interacting proteins. In this assay, proteins and a ^{32}P -radiolabeled RNA substrate are incubated to allow complex formation. The reaction mixture is then UV-irradiated, followed by treatment with RNase. This produces a protein attached to a short oligoribonucleotide. These protein-oligoribonucleotide products are analyzed by standard SDS-PAGE (UNIT 10.2A) or two-dimensional gel electrophoresis (UNITS 10.3 & 10.4), followed by phosphorimaging (APPENDIX 3A). Combined with immunoblotting (UNIT 10.8), immunoprecipitation (UNIT 10.16), and/or mass spectrometry (UNITS 10.21 & 10.22), the proteins can often be identified. Site-specific labeling of the RNA with ^{32}P increases the power of the UV-cross-linking assay because the RNA-protein interaction site can be defined on the RNA.

The following protocol demonstrates this method using the spliceosomal complex as an example.

CAUTION: Radioactive materials require special handling. See APPENDIX 1F and the institutional Radiation Safety Office for guidelines concerning proper handling and disposal.

NOTE: Extreme caution should be taken to avoid RNase contamination. The experimenter should always wear gloves and all the tubes and tips that come into contact with the sample should be certified RNase free; however, DEPC treatment (UNIT 4.1) of solutions and apparatuses is not necessary.

UV CROSS-LINKING USING A UNIFORMLY LABELED RADIOACTIVE RNA

BASIC
PROTOCOL

Materials

Linearized (UNIT 3.1) DNA template for transcription of the RNA of interest
200 mM and 2 M DTT (American Bioanalytical)
0.1% (v/v) Triton X-100 (Sigma)
1 mM NTPs (UNIT 3.4)
6.7 mM G(5')ppp(5')G cap (NEB)
RNasin (Amersham Pharmacia Biotech)
High specificity ^{32}P -labeled nucleotides (NEN):
10 Ci/ μl [α - ^{32}P]UTP (3000 Ci/mmol)
10 Ci/ μl [α - ^{32}P]ATP (3000 Ci/mmol)
10 Ci/ μl [α - ^{32}P]GTP (3000 Ci/mmol)
10 Ci/ μl [α - ^{32}P]CTP (3000 Ci/mmol)
50 U/ μl T7 or 20 U/ μl SP6 RNA polymerase (NEB)
5 \times transcription buffer (see recipe)
5 mg/ml DNase I (Amersham Pharmacia Biotech)
RNA phenol (American Bioanalytical)
5 M ammonium acetate
20 mg/ml glycogen, molecular-biology grade (Amersham Pharmacia Biotech)
70% and 100% ethanol
12.5 mM ATP
80 mM MgCl_2

RNA-Protein
Interactions

27.2.1

Supplement 63

0.5 M creatine phosphate (prepare from di-Tris salt)
 Splicing dilution buffer (see recipe)
 HeLa cell nuclear extract (UNIT 27.3; store at -80°C)
 Sephacryl S-500 high resolution resin (Amersham Pharmacia Biotech)
 1 \times gel-filtration column buffer (see recipe)
 10 mg/ml protease-free RNase A (Amersham Pharmacia Biotech)
 100 U/ μl RNase T1 (Boehringer Mannheim)
 20% (w/v) SDS
 Acetone
 2 \times protein-gel sample buffer (see recipe) or 2 \times SDS sample buffer (UNIT 10.2A)
 30 $^{\circ}$, 37 $^{\circ}$, 40 $^{\circ}$ (for SP6 transcripts), 65 $^{\circ}$, and 100 $^{\circ}\text{C}$ water baths
 1.5-cm-diameter \times 50-cm-long column (89-ml bed volume)
 Microcentrifuge tubes with caps removed
 254-nm UV light source (e.g., Sylvania G15T8 lamp)

Additional reagents and equipment for packing gel filtration columns (UNIT 10.9),
 1-D SDS-PAGE (UNIT 10.2A) or 2-D SDS PAGE (UNITS 10.3 & 10.4), and
 autoradiography (APPENDIX 3A)

Prepare the high specificity radioactive RNA

1. Prepare a transcription mixture by combining the following:

2 μl linearized DNA template for transcription of the RNA of interest
 5 μl 200 mM DTT
 10 μl 0.1% (v/v) Triton X-100
 10 μl 1 mM NTPs
 12.5 μl of 6.7 mM G(5')ppp(5')G cap
 2 μl RNasin
 5 μl 10 Ci/ μl [α - ^{32}P]UTP
 5 μl 10 Ci/ μl [α - ^{32}P]ATP
 5 μl 10 Ci/ μl [α - ^{32}P]GTP
 5 μl 10 Ci/ μl [α - ^{32}P]CTP
 20 μl 5 \times transcription buffer (i.e., T7 or SP6 RNA polymerase buffer)
 4 μl 50 U/ μl T7 or 20 U/ μl SP6 RNA polymerase
 14.5 μl H₂O (i.e., adjust to 100 μl final).

The size of the reaction can be modified based on the desired quantity of the transcript.

The radioactive NTPs and the quantities of each radioactive NTP should be chosen based on the desired specific activity of the RNA and the RNA sequence at the protein binding site (if known). As many as 10 to 20 nucleotides can be protected from RNase digestion by the cross-linked protein and therefore remain covalently attached to the RNA. This short RNA fragment is ultimately used to detect the protein after SDS-PAGE.

- 2a. For T7 RNA polymerase: Incubate 90 min at 37 $^{\circ}\text{C}$
- 2b. For SP6 RNA polymerase: Incubate 90 min in a 40 $^{\circ}\text{C}$ water bath.
3. Add 1 μl of 5 mg/ml DNase I. Incubate 10 min in a 37 $^{\circ}\text{C}$ water bath.
4. Adjust the final volume to 200 μl with water and mix the reaction. Remove 2 μl for Cerenkov counting, labeling the tube "cpm before."
5. Extract reaction with an equal volume of RNA phenol.
6. Transfer the aqueous phase to a new microcentrifuge tube. Add 200 μl of 5 M ammonium acetate and 2.5 μl of 20 mg/ml molecular-biology-grade glycogen to the tube. Vortex to mix.

7. Add 1 ml of 100% ethanol to the tube. Vortex to mix.
8. Microcentrifuge 15 min at 14,000 rpm. Discard the radioactive supernatant and wash the pellet with 1 ml of 70% ethanol.
9. Air dry the pellet and then resuspend in 200 μ l water.
10. Transfer 2 μ l RNA to a tube labeled “cpm after” for Cerenkov counting to determine the percentage of label that was incorporated:

$$\text{Percent incorporation} = \text{cpm}_{\text{after}} / \text{cpm}_{\text{before}} \times 100$$

Normal incorporation is 50% to 80%. A 100% incorporation will yield ~13 μ g RNA for this 100- μ l reaction—i.e., RNA amount (ng) = 13 \times percent incorporation \times 100. This in vitro transcription assay can be scaled to any size desired.

11. Dilute the RNA with water to 10 ng/ μ l.

The RNA solution can be stored at -20°C for up to one month. Note, however, that RNA labeled to high specific activity degrades more rapidly due to radiolysis.

Site-specifically labeled RNA is used to determine the site where a protein cross-links.

Prepare the nucleoprotein complexes

12. Prepare the following splicing mixture on ice:

2 μ l (20 ng) ^{32}P -labeled pre-mRNA
 1 μ l 12.5 mM ATP
 1 μ l 80 mM MgCl_2
 1 μ l 0.5 M creatine phosphate
 5 μ l water
 7.5 μ l splicing dilution buffer
 7.5 μ l HeLa nuclear extract

The reaction can be scaled to any volume desired.

It is advisable to thaw the HeLa cell nuclear extract on ice while preparing the other reagents, as it is very labile.

13. Mix gently by pipetting up and down a few times. Incubate 5 min to 1.5 hr at 30°C to form the complexes of interest.

Splicing is a dynamic process that involves the formation of a series of spliceosomal complexes. By controlling the time of incubation, it is possible to accumulate different complexes. For example, under the conditions described above, the A complex is the main complex at 15-min time point, while the B and C complexes become dominant at 45 min. At 90 min, the spliced mRNP is the main species. Similar principles also apply to other nucleoprotein complexes.

14. Pack a 1.5-cm-diameter \times 50-cm-long (89-ml bed volume) column with Sephacryl S-500 high resolution resin as described (UNIT 10.9). Place in a cold room (4°C) and equilibrate with 1 \times gel-filtration column buffer, 4°C .

15. Carefully load the assembly reaction onto the column.

The maximum loading volume of the reaction is 2.5 ml.

16. Collect 1-ml fractions, eluting at a flow rate of 0.1 ml/min, 4°C .

17. Transfer 25- μ l aliquots of fractions 21 to 80 to microcentrifuge tubes with the caps removed and analyze by Cerenkov counting.

Figure 27.2.1 Isolation of spliceosomes and H complex by gel filtration. A representative gel filtration profile using a Sephacryl S500 column is shown. Peaks: V, void volume; S, spliceosomes; H, H complex; F, free counts.

18. Create an elution profile of cpm versus fraction number. Use the fractions corresponding to the desired nucleoprotein complexes for subsequent studies (see Fig. 27.2.1).

The protocol described above is for spliceosomal complexes. This protocol can also be used for preparation of other RNA-protein complexes. In this case, some parameters should be changed accordingly, including the amount of RNA used in the assembly reaction, the protein extract, the time of incubation, and the gel filtration profile.

19. Transfer 50 to 200 μl of the column fraction containing the desired ribonucleoprotein complex to a new microcentrifuge tube.

Partial purification of the nucleoprotein complexes by gel filtration is very beneficial for UV cross-linking analysis. It can greatly reduce the free nucleotides and non-specific proteins, thus increasing the cross-linking efficiency and also dramatically decreasing the background.

Cross-link the ribonucleoprotein complexes with UV light and digest the unprotected RNA

20. Place the uncovered tube containing the reaction mixture on ice, directly underneath the bulb (~5-cm from the surface) of a 254-nm UV light source. Irradiate 5 to 30 min.

The experimental setup for UV cross-linking is similar to the one described in UNIT 12.5 (Fig. 12.5.1), except that the tube containing the ribonucleoprotein complexes should be uncovered and placed on ice.

If the sample contains high levels of ATP, the time of UV exposure should be increased because ATP absorbs UV light and thus significantly reduces cross-linking efficiency.

21. Add 3 μl of 10 mg/ml protease-free RNase A and/or 3 μl of 100 U/ μl RNase T1 (see below) to each 300 μl irradiated column fraction. Incubate at 37°C for 30 min.

RNase A and RNase T1 have different cleavage specificities. RNase A digests at the 3' side of U or C nucleotides, whereas RNase T1 digests after G nucleotides. Either one of these RNases can be used based on the nucleotide sequence around the binding site of interest (if known). RNase T1 is a suspension in ammonium sulfate. Before adding it to the reaction, transfer the desired amount of RNase T1 suspension (3 μl for each 300- μl reaction) to a microcentrifuge tube. Spin at 14,000 rpm for 5 min in a microcentrifuge. Discard the supernatant. Add the irradiated reaction to the RNase T1 pellet. The activity of RNase T1 requires Mg^{2+} . If the irradiated reaction contains EDTA, MgCl_2 must be added so that 1 to 3 mM of free Mg^{2+} is present in the reaction.

Electrophorese and visualize the cross-linked proteins by phosphorimaging

22. Add 30 μ l of 20% (w/v) SDS, and 3 μ l of 2 M DTT to each 300 μ l reaction. Mix and incubate the reaction 5 min in a 65°C water bath.
23. Add 2 μ l of 20 mg/ml glycogen. Mix well.
24. Add 1.2 ml acetone and vortex to mix. Incubate the mixture 10 min at room temperature to allow efficient precipitation.
25. Centrifuge in a microcentrifuge 15 min at 14,000 rpm. Discard the supernatant and air dry the pellet.
26. Resuspend the pellet in 20 μ l of 2 \times protein-gel sample buffer or 2 \times SDS sample buffer. Incubate the samples 5 min in a boiling (100°C) water bath.
27. Electrophorese the sample through a standard SDS-PAGE gel of appropriate percentage (UNIT 10.2A) or 2-D gel (UNITS 10.3 & 10.4).

A prestained protein molecular weight marker should be included in the standard SDS-PAGE gel to determine the molecular weight of each cross-linked protein. Two-dimensional gel analysis (UNITS 10.3 & 10.4) is often used to identify these proteins, which offers further separation of the target protein from other comigrating proteins. A gel slice corresponding to a radioactively labeled protein can be subjected to mass spectrometry to reveal the identity of this protein. Please note, however, a small UV cross-linking reaction normally does not yield enough material for mass spectrometry analysis (UNITS 10.2 & 10.22). In order to increase the quantity of the target protein, crude protein extract is often mixed in with the cross-linked sample prior to electrophoresis.

28. After running the gel, cut away the region that migrates with the dye front.

The bulk of digested nucleic acid products runs with the dye front and is highly radioactive. If these products are not cut away, they can obscure signals from the cross-linked proteins migrating toward the bottom of the gel.

29. Dry the gel and place on a phosphorimaging screen. Expose overnight to visualize cross-linked proteins (APPENDIX 3A).

IMMUNOPRECIPITATION OF UV-CROSS-LINKED PROTEINS

The most obvious advantage of combining UV cross-linking, 2-D gel electrophoresis (UNITS 10.3 & 10.4), and mass spectrometry (UNITS 10.21 & 10.22) is that all proteins that bind to the RNA, either known or unknown, can be identified. However, a large amount of material is often needed to achieve this goal. In this protocol, an alternate method to determine whether a known protein is directly associated with an RNA is described. This protocol is similar to the main method (see Basic Protocol), except that after the UV-cross-linking and RNase digestion, the mixture is subjected to immunoprecipitation before electrophoresis.

Additional Materials (also see Basic Protocol)

- Protein A- or protein G-Sepharose CL-4B (Amersham Pharmacia Biotech)
- 1 \times PBS, pH 7.4 (APPENDIX 2)
- Antibody against the protein of interest
- IP100 buffer (see recipe)
- SDS
- Triton X-100
- IP150/1 M urea (see recipe)

ALTERNATE PROTOCOL

RNA-Protein Interactions

27.2.5

Couple the antibody to the beads

1. Combine 20 μ l protein A- or protein G-Sepharose CL-4B with 1 ml of 1 \times PBS, pH 7.4. Invert the tube several times. Microcentrifuge briefly at maximum speed to collect the beads in the bottom of the tube.

Protein A-Sepharose CL-4B beads are often used to couple polyclonal antibodies. Protein G-Sepharose CL-4B beads, on the other hand, are normally used with monoclonal antibodies.

2. Discard the supernatant. Add 500 μ l PBS and 20 μ l antibody against the protein of interest to the beads. Rotate 1 hr at room temperature or overnight at 4°C.

The amount of antibody used in each immunoprecipitation varies based on the quality of the antibody and the efficiency of the immunoprecipitation.

3. Microcentrifuge briefly at maximum speed to collect the beads in the bottom of the tube. Discard the supernatant. Add 1 ml PBS and invert the tube several times. Place the tube on ice to let the beads settle to the bottom.
4. Repeat step 3 four times to wash the beads. Resuspend the beads in 100 μ l IP100 buffer.

Immunoprecipitate cross-linked proteins under denaturing conditions

5. Assemble the nucleoprotein complex, partially purify the complex by gel filtration, UV-cross-link, and digest the RNA with RNase as described above (see Basic Protocol, steps 1 to 21).
6. Add SDS to 0.5% (w/v) and Triton X-100 to 1.5% (v/v). Boil the sample for 3 min.
7. Dilute the sample 10-fold with IP100 buffer. Combine the diluted sample with 20 μ l precoupled protein A- or protein G-Sepharose CL-4B (step 4). Rotate 2 to 4 hr at 4°C.
8. Wash the beads twice with IP150/1 M urea and once with IP100 as described in step 3.
9. Remove all of the buffer from the beads. Add 40 μ l of 2 \times protein-gel sample buffer or 2 \times SDS sample buffer to the beads. Boil the samples for 5 min to elute the bound proteins.
10. Electrophorese the sample through a standard SDS-PAGE of appropriate percentage (UNIT 10.2A).
11. Dry the gel and place on a phosphorimaging screen. Expose overnight to visualize cross-linked proteins (APPENDIX 3A).

The denaturing conditions used in this immunoprecipitation disrupts most of the protein-protein interactions in the ribonucleoprotein complex. Thus, only the protein recognized by the antibody is pulled down. If the radioactively labeled protein analyzed by SDS PAGE is of the correct size, it is very likely that this protein is directly associated with the RNA.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Gel-filtration column buffer, 1 \times

20 mM Tris-Cl, pH 7.6 (APPENDIX 2)
60 mM KCl
0.1% (v/v) Triton X-100
0.2 mM PMSF
0.2% (w/v) sodium azide
Store up to 3 months at 4°C

IP100 buffer

100 mM NaCl
2 mM MgCl₂
50 mM Tris·Cl, pH 7.6 (APPENDIX 2)
0.05% (v/v) NP-40
0.5 mM DTT
Store up to 3 months at 4°C

IP150/1 M urea

150 mM NaCl
2 mM MgCl₂
50 mM Tris, pH 7.6 (APPENDIX 2)
0.05% (v/v) NP-40
0.5 mM DTT
1 M urea
Store up to 3 months at 4°C

Protein-gel sample buffer, 2×

125 mM Tris·Cl, pH 7.6 (APPENDIX 2)
20% (v/v) glycerol
4% (w/v) SDS
0.008% (w/v) bromphenol blue
20 mM DTT
Store up to 1 year –20°C

Splicing dilution buffer

20 mM Tris·Cl, pH 7.6 (APPENDIX 2)
100 mM KCl
Store up to 1 year –20°C

Transcription buffer, 5×

200 mM Tris·Cl, pH 7.6 (APPENDIX 2)
30 mM MgCl₂
10 mM spermidine
Store up to 1 year –20°C

COMMENTARY**Background Information**

Cross-linking proteins to RNA with UV light is a powerful tool to identify proteins that directly bind to a particular RNA. The basis for this assay is that UV irradiation of RNA produces purine and pyrimidine free radicals. If a protein is in close proximity to the free radical (e.g., due to binding), a covalent bond can be formed, thus cross-linking the protein to the RNA. When the RNA is radioactively labeled at or close to the binding site, this label is carried with the protein, rendering it easily detectable by phosphorimaging.

In general, UV cross-linking is relatively inefficient and the formation of a photo-induced product is strongly dependent upon structural parameters, such as the proximity of reactive amino acids and bases. When a normal

RNA molecule is used in this reaction, short-wavelength UV light (254 nm) and extensive irradiation is often required, especially for those proteins that interact with the RNA weakly; however, short wavelength UV light can be damaging to the protein. To circumvent this problem, a nucleotide analog which contains a more susceptible photoreactive group is often used for the UV cross-linking assay. Depending on the nature of the photoreactive group, different long-wavelength UV lights can be chosen. Over the years, many of these analogs have been developed. They can be divided into two main categories. Analogs in the first category contain cross-linking groups directly on the nucleotide base and function essentially as zero A probes—e.g., 4-thio-UTP (Tanner et al., 1988), 5-aido-UTP (Woody et al., 1988),

5-bromo-UTP (Hanna, 1989), and 8-aido-ATP (Woody et al., 1984). Analogs in the second category contain a flexible linker between the photoreactive group and the base—e.g., 5-APAS-UTP (Hanna et al., 1989), 5-APAS-CTP (Hanna et al., 1993), and 8-APAS-ATP (Costas et al., 2000). With these analogs, proteins that are not in direct contact with the RNA can also be detected. The correct analog should be chosen based on the purpose of the experiment.

RNA containing a single ^{32}P -labeled nucleotide allows identification of proteins bound to or at the proximity of this nucleotide. Site-specific labeling of RNAs has been described in *UNIT 3.4*.

UV cross-linking between protein and nucleotides was first discovered in 1972 when Markowitz and co-workers found that UV irradiation induced the formation of protein-DNA complexes that were resistant to very stringent conditions. Since then, UV cross-linking has been used routinely to study both protein-DNA and protein-RNA interactions. Marcinovits and Molnar (1982) used UV cross-linking to study RNA-protein interactions in the 30S subunits of rat liver hnRNP. Xiang and Lee (1989) identified proteins cross-linked to RNA in the 40S ribosomal subunits of *Saccharomyces cerevisiae*. Leibold and Munro (1988) found a cytoplasmic protein bound to the 5' UTR of ferritin mRNAs. Kwon and Hecht (1991) studied translational regulation of mouse protamine 2 mRNA by analyzing proteins that cross-link to the 3' UTR of the mRNA. Ping and coworkers (1997) examined the dynamics of RNA-protein interactions in the HIV-1 Rev-RRE complex. In the pre-mRNA splicing field, this technique has also been proven to be a powerful strategy for identifying specific sites on the RNA where proteins associate within spliceosomal complexes (Reed and Chiara, 1999 and references therein). In particular, site-specific ^{32}P labeling and RNA-protein cross-linking studies have led to models for how the dynamic spliceosome assembles. For example, studies in both mammalian and yeast systems showed that a U5 snRNP protein (U5²²⁰) cross-links to a region upstream of the 5' splice site prior to the first catalytic step of splicing, and also to a region downstream of the 3' splice site after the first catalytic step, leading to the model that U5²²⁰ plays a role in aligning the 5' and 3' exons for ligation (Wyatt et al., 1992; Uman and Guthrie, 1995; Teigelkamp et al., 1995; Chiara et al., 1997). Site-specific labeling and UV cross-linking studies have also revealed that different SR proteins are arranged

in the specific 5' to 3' order on a splicing enhancer (Lynch and Maniatis, 1996).

While the UV cross-linking assay is broadly used to understand RNA-protein interactions, several key parameters in this assay, including site-specific labeling (Moore and Sharp, 1992), choices of radiolabeled nucleotide (Hartley et al., 2002), and inclusion of a photoreactive group (Costas et al., 2000), have also been intensively studied. This assay is being further developed to suit the needs of research in the RNA field.

Critical Parameters and Troubleshooting

Many critical parameters in this assay can be easily optimized, including choice of radioactive NTPs, photoreactive group substitution, conditions for assembly of the ribonucleoprotein complex, choice of gel filtration column, and time of UV irradiation. Some protein-RNA complexes are particularly sensitive to RNase, especially when the protein does not directly protect the RNA. Thus, the amount of RNase and time of incubation can be titrated down to potentially obtain a positive result.

Anticipated Results

When the RNA is body-labeled with one radioactive nucleotide (uridine is often used in this case), the specific activity of the RNA will be $\sim 6 \times 10^3$ cpm/ng. When all four radioactive nucleotides are used, the RNA will be 2.4×10^4 cpm/ng. If the RNA is site-specifically labeled at one site, one can normally obtain RNA at 3×10^3 cpm/ng.

During complex assembly in a crude protein extract, a considerable amount of the RNA can be degraded into oligonucleotides or even free nucleotides. The longer the incubation time, the more degradation will occur.

Figure 27.2.1 represents a typical gel filtration column profile of spliceosomal complexes. Spliceosomes fractionate as a large complex, whereas the nonspecific H complex, which contains mostly hnRNP proteins, runs as a small complex. Both of these complexes can be separated from most of the nuclear proteins, which co-migrate with the free ^{32}P -labeled nucleotides. When this assay is used to study other RNA-protein complexes, the column profile should be determined by analyzing the RNA species in each column fraction.

Figure 27.2.2 shows the general outcome of UV cross-linking results when different parameters are chosen in this protocol. If a body-labeled RNA is used and UV irradiation is

Figure 27.2.2 General outcome of autoradiograms of typical UV cross-linking experiments when different parameters (as indicated) are chosen in this protocol. Lane 1, marker; lane 2, body-labeled RNA, lane 3, site-specific-labeled RNA, lane 4, gel-filtered site-specific-labeled RNA; lane 5, gel-filtered and immunoprecipitated site-specific-labeled RNA.

carried out directly with the assembly reaction (when a crude protein extract is used for the complex assembly), multiple bands of radiolabeled proteins will appear on the gel (lane 2). If a site-specifically labeled RNA is used under similar conditions, the number of radiolabeled proteins will be fewer (lane 3); however, most of these bands are still due to nonspecific association. If a site-specific-labeled RNA is used, combined with partial purification of the ribonucleoprotein complex by gel filtration prior to UV irradiation, a much higher specificity can be achieved (lane 4). The proteins that are radiolabeled are most likely directly associated with the RNA around the labeled nucleotide. To directly ask the question of whether a protein binds to a particular site on the RNA, RNA specifically labeled at this site is often used. Immunoprecipitation with an antibody against the protein is then carried out after UV irradiation and RNase digestion. If the protein does bind to the RNA at this site, only a single band at the correct size of the protein should be detected (lane 5).

Time Considerations

In vitro transcription to prepare the radiolabeled RNA takes 1 to 2 hr. Assembly of the ribonucleoprotein complex takes 1 to 3 hr depending upon the time of incubation. Isolating the complex by gel filtration takes 14 hr. However, most of this time is not labor intensive. UV cross-linking and RNase digestion takes 30 min to 1 hr. SDS-PAGE takes 2 to 3 hr. Phosphorimaging takes between 12 hr to 3 days, depending upon the specific activity of the RNA, the efficiency of cross-linking, and the extent of RNase digestion.

Using the alternative (see Alternate Protocol), coupling the antibody to the beads takes 1 to 2 hr. Immunoprecipitation takes 3 to 5 hr.

It is advisable to make a schedule ahead of time. Transcription can be done separately from the other steps since the RNA can be stored at -20°C . If the assembly reaction is carried out in the afternoon, the gel filtration can be finished overnight. UV cross-linking, RNase digestion and the subsequent steps can be finished within the next day.

Purification of Functional RNA-Protein Complexes Using MS2-MBP

UNIT 27.3

**BASIC
PROTOCOL**

This protocol describes the use of MS2-MBP to purify functional RNA-protein complexes, a method also known as maltose-binding protein (MBP)-affinity purification. This approach combines gel filtration and an affinity-chromatography strategy using the bacteriophage MS2 coat protein, which binds to a specific RNA-hairpin structure. The experimental design is illustrated in Figure 27.3.1. This method has been used to isolate human spliceosomes (complexes composed of pre-mRNA, small nuclear RNAs, and proteins which are responsible for the removal of introns from pre-mRNA) assembled on a well-characterized model pre-mRNA. However, the method can be adapted to isolating other RNA-protein complexes assembled *in vitro*. For the isolation, three MS2 coat protein-binding sites (hairpins) are inserted into the RNA of interest by constructing the appropriate clone. For isolation of the spliceosome, these hairpins are inserted at the 3' end of exon 2 (Fig. 27.3.1A). A fusion protein containing the MS2 coat protein and maltose-binding protein (MS2-MBP) is bound to the hairpins (Fig. 27.3.1B). This RNA/MS2-MBP complex is then assembled into spliceosomal complexes by incubation in HeLa nuclear extracts under splicing conditions (Fig. 27.3.1C). Spliceosomes are partially purified by Sephacryl S-500 gel filtration chromatography (Fig. 27.3.1D) and then affinity selected by binding to amylose resin (Fig. 27.3.1E). After washing, spliceosomes are eluted under gentle conditions using maltose elution buffer (Fig. 27.3.1F).

Materials

E. coli strain (e.g., DH5 α) containing plasmid expressing MS2-MBP fusion protein
(UNIT 16.6)

Plasmid DNA encoding desired RNA and MS2 binding sites

Buffer A: 10 mM sodium phosphate buffer, pH 7.0 (APPENDIX 2), filtered and degassed

Buffer B: 10 mM sodium phosphate buffer, pH 7.0 (APPENDIX 2)/1 M NaCl, filtered and degassed

Dialysis buffer: 10% (v/v) glycerol in PBS (see APPENDIX 2 for PBS)

[³²P]UTP (sp. act., 800 Ci/mmol; UNIT 3.4)

Splicing dilution buffer (see recipe)

1.5% agarose gel (UNIT 2.5A)

12.5 mM ATP

80 mM MgCl₂

0.5 M creatine phosphate

10 mg/ml HeLa cell nuclear extract (UNIT 12.1)

Gel filtration buffer (see recipe)

Amylose resin (New England Biolabs)

Phosphate-buffered saline (PBS; APPENDIX 2)

Maltose elution buffer (see recipe)

HiTrap Heparin HP column (Amersham Biosciences) and FPLC system (UNIT 10.10) with gradient maker

Dialysis cassettes (MWCO 10,000; Pierce)

Centricon-50 centrifugal concentrator (Amicon)

50-ml polypropylene tubes (e.g., Falcon)

Packed 1.5/50 cm Sephacryl S-500 HR column and a gel-filtration system (UNIT 10.9)

**RNA-Protein
Interactions**

End-over-end rotator

Additional reagents and equipment for purification of MS2-MBP protein from *E. coli* (UNIT 16.6), dialysis (APPENDIX 3C), preparation of radiolabeled RNA (UNIT 14.3, Support Protocol 1), mobility-shift RNA-binding assay (UNIT 12.2), agarose gel electrophoresis (UNIT 2.5A), and gel-filtration chromatography (UNIT 10.9)

NOTE: All of the reagents should be RNase free (UNIT 4.1) and all procedures involving RNA-protein complex isolation should be carried out at 4°C or on ice.

Prepare MS2-MBP fusion protein and RNA substrate

1. Express and purify MS2-MBP protein as described in UNIT 16.6.

The MS2-MBP protein purified by this step binds E. coli nucleic acid and will not bind substrate RNA well. Thus, further purification of MS2-MBP via an FPLC heparin column (see step 2) is recommended.

2. Apply the MS2-MBP protein to a HiTrap Heparin column on an FPLC system per the manufacturer's recommendations.
3. Elute the MS2-MBP by a linear gradient of 0 M NaCl (buffer A) to 1 M NaCl (buffer B) in 10 mM sodium phosphate buffer, pH 7.0. Reload the flowthrough onto the column two to three times to increase the binding efficiency and final yield of MS2-MBP.

The nucleic acid will be eluted at about 100 mM NaCl and the MS2-MBP will be eluted at around 300 mM NaCl.

4. Pool the peak fractions containing MS2-MBP in a dialysis cassette (MWCO 10,000) and dialyze against dialysis buffer for 2 hr at 4°C (also see APPENDIX 3C).
5. Concentrate the protein, if necessary, using a Centricon-50 centrifugal concentrator.

The typical final concentration of MS2-MBP is 5 mg/ml. The protein can be stored at -80°C for future use.

6. Transcribe RNA substrates from the plasmid DNA bearing desired sequences and MS2 binding sites using a T7, T3, or Sp6 RNA polymerase transcription system as described in UNIT 14.3, Support Protocol 1, except label the RNA substrate with ³²P instead of ³⁵S by substituting [³²P]UTP for [³⁵S]UTP in the protocol.

The typical concentration of the RNA products is 0.2 mg/ml. The products can be stored at -80°C.

Carry out an MS2-MBP/RNA binding assay

7. Perform a binding assay similar to that described in UNIT 12.2 to check the binding efficiency of purified MS2-MBP to the substrate RNA and to optimize the molar ratio of MS2-MBP to the RNA substrate. For spliceosome purification, mix a 100-fold molar excess of MS2-MBP protein (from step 4 or 5) with pre-mRNA (i.e., the labeled RNA from step 6), or, for other complexes, prepare a series of dilutions of the MS2-MBP or the RNA, in splicing dilution buffer and incubate 30 min on ice. Assay for binding by monitoring samples on a 1.5% agarose gel.

The MS2-MBP/RNA complex will migrate more slowly than the unbound RNAs. Thus, it is recommended that the binding reaction be performed in a series of dilutions of MS2-MBP or RNA to find out the best ratio of MS2-MBP to RNA so that all of the RNA is bound by MS2-MBP.

Assembly of the RNA-protein complexes

The following steps are carried out to form spliceosomes in a 2.4-ml splicing reaction. Other RNA-protein complexes should be prepared on a large scale using appropriate cell extracts and conditions.

8. Combine 10 μl of 0.2 mg/ml radiolabeled RNA substrate (step 6) and 20 μl of 5 mg/ml MS2-MBP (step 4 or 5) in a 1.5-ml microcentrifuge tube and incubate for 30 min on ice.

The mol. wt. of the RNA used for spliceosome purification is ~132 kD; the mol. wt. for MS2-MBP is ~60 kD.

9. Add 172 μl of splicing dilution buffer to the tube, mix, and keep on ice for another 20 min.
10. Transfer the above reaction to a 50-ml polypropylene test tube and add the following reagents:

720 μl splicing dilution buffer
480 μl H₂O
96 μl 12.5 mM ATP
96 μl 80 mM MgCl₂
96 μl 0.5 M creatine phosphate
720 μl 10 mg/ml HeLa cell nuclear extract.

Gently mix the reactions and incubate at 30°C for the appropriate time.

The time is dependent upon the complex to be assembled. A pilot experiment is recommended to determine the optimal incubation time. For spliceosomal C complex formation, 40 min of incubation is necessary.

Purify the RNA-protein complexes

11. Load the mixture onto a 1.5/50 cm Sephacryl S-500 gel filtration column that has been equilibrated in gel-filtration buffer (UNIT 10.9).

This column is appropriate for the spliceosome; for other complexes it may be necessary to test a few columns to find one that gives optimal separation of the RNA-protein complex.

12. Separate the protein complex by gel filtration (UNIT 10.9, Basic Protocol 2) at a flow rate of 1.0 ml/min, collecting the first 80 1.0-ml fractions.

The gel-filtration step takes about 14 hr. Thus, it is recommended that the complexes be assembled in the afternoon and the gel filtration be run overnight.

13. While the column fractions are still in the cold room, remove 25 μl from each fraction starting at no. 25 and continuing through no. 80. Determine the cpm in each fraction by Cerenkov counting. Draw a graph of the spliceosome separation using, e.g., Excel or Cricket with the fraction number as the x axis and cpm as the y axis and determine the peak of the spliceosome as shown in Figure 27.3.1D.

The distribution of RNAs and proteins after gel filtration can be analyzed by denaturing polyacrylamide gel to check RNAs and SDS-PAGE to check proteins (UNIT 10.2A).

14. Pool fractions from the desired peak(s) containing the RNA-protein complexes.
15. Wash amylose resin in PBS by mixing 1 vol beads with 10 vol of PBS. Prepare a 50% (v/v) suspension of the amylose resin in PBS. Add 30 to 60 μl of the suspension per ml of pooled fractions (the actual bead volume will be ~15 to 30 μl /ml fractions). Incubate 4 hr to overnight at 4°C with rotation on an end-over-end rotator.

16. Centrifuge 3 min at $2000 \times g$, 4°C , in a tabletop centrifuge, then carefully remove the supernatant.
17. Wash the amylose resin (now containing the spliceosome complex) by adding 10 ml of gel-filtration buffer and rotating the tubes 10 to 20 times. Spin down the resin as described in step 16 and discard the supernatant. Repeat this washing step 3 to 5 times. Finally, transfer the washed amylose resin to a new 1.5-ml microcentrifuge tube.
18. Carefully remove all liquid from the amylose resin. Add 300 μl maltose elution buffer and rotate 30 to 60 min at 4°C .

If it is necessary to keep the complex highly concentrated, a smaller volume of maltose elution buffer can be used, but the elution efficiency will be lower.

19. Centrifuge the resin as in step 16. Retain the supernatant, which contains the purified spliceosomes.
20. Repeat the elution (steps 17 to 19) as desired to recover more complexes.

Typically, 75% of the complexes will be eluted in the first elution followed by 15% in the second elution.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.

Gel filtration buffer

20 mM HEPES, pH 7.9
60 mM NaCl
0.1% (v/v) Triton X-100
0.01% (w/v) NaN_3
Store up to 2 months at 4°C

Maltose elution buffer

20 mM HEPES, pH 7.9
60 mM NaCl
10 mM 2-mercaptoethanol
12 mM maltose
1 mM PMSF (optional)
Store up to 1 week at 4°C

Splicing dilution buffer

20 mM HEPES, pH 7.9
100 mM KCl
Store up to 1 year at -20°C

COMMENTARY

Background Information

Biological machines composed of proteins and RNAs play essential biological roles. For example, the spliceosome, which is composed of pre-mRNA, five small nuclear RNAs (snRNAs), and ~145 proteins, is responsible for the removal of introns from pre-mRNA, an essential step in eukaryotic gene expression. Over the past 20 years, a great deal of progress

has been made in identifying spliceosomal components and critical RNA-RNA, RNA-protein, and protein-protein interactions. However, much less is known about the precise timing of these interactions during spliceosome assembly. In addition, little is understood about the factors that mediate the dynamics. Progress in understanding the mechanisms of pre-mRNA splicing has been hampered, in part,

because it has not been possible to isolate spliceosomes that are both highly purified and functional. Thus, it is difficult to establish the functional significance of many of the factors present in the spliceosomes.

The previously used biotin/avidin spliceosome purification method (Reed, 1990; Bennett et al., 1992) is inefficient, and requires high salt (250 mM), which dissociates some of the spliceosomal components. In addition, the bound complexes cannot be released from the affinity resin in an intact form. The MBP-MS2 method overcomes these problems, allowing efficient isolation of functional complexes in a highly pure form.

Other affinity tags were screened for their suitability for spliceosome purification. These studies revealed either high background (protein A tag) or low binding (GST or histidine tag). In contrast, significant levels of binding and low background were obtained with the maltose-binding protein (MBP). MBP affinity offers the added advantage of mild elution conditions, requiring only maltose. The MBP is fused to bacteriophage R17/MS2 coat protein, which binds to a specific hairpin RNA (Carey et al., 1983; Bardwell and Wickens, 1990; LeCuyer et al., 1995; Graveley and Maniatis, 1998). Thus, after engineering the hairpin structures into RNA, the RNA-protein complexes can be affinity-selected via MS2-MBP. A gel-filtration step that had been previously established to separate spliceosomes (Reed, 1990) was combined with MS2-MBP affinity selection. This dramatically improved the specificity of the spliceosome purification and indicated promise for isolation of other types of RNA-protein complexes. In addition, the number of MS2 binding sites and the ratio of MS2-MBP to RNA were both optimized to increase the efficiency of complex formation and purification (Zhou et al., 2002a).

Using the MS2-MBP purification method, highly purified and functional spliceosomal complexes were obtained (Das et al., 2000; Zhou et al., 2002b), the protein components were identified by mass spectrometry, and the structure of complexes were visualized by electron microscopy (Zhou et al., 2002a,b). The spliced mRNP complex that functions in nucleocytoplasmic export has also been isolated, and it retains its export activity (Zhou et al., 2000).

Critical Parameters

The efficacy of formation of the RNA-protein complex of interest is a major factor in determining the final yield of the purified com-

plexes. In the case of spliceosome purification, nuclear extract is of great importance. High-quality nuclear extract allows higher efficiency of spliceosome assembly and less RNA degradation. Another important factor is the quality of the MS2-MBP protein. Purification of MS2-MBP via a heparin column is critical for improving the binding efficiency of MS2-MBP to RNA and the final yield of the complexes. The last critical parameter is the negative control of the experiment. Generally, a similar RNA with a mutation in a critical functional site should be used in the same purification procedure to identify nonspecifically bound proteins.

Troubleshooting

The most common problem is low yield of purified RNA-protein complexes in the elution. This can be caused by insufficient binding of MS2-MBP to the RNA, inefficient binding of RNA-protein complexes to the amylose resin, poor elution, or simply inefficient formation of RNA-protein complexes. Any degradation of the RNAs or proteins will reduce or eliminate the yield as well. Thus, it is critical to perform stepwise assays to make sure that every step is working. For example, the MS2-MBP protein should be checked by SDS-PAGE to make sure it is purified and intact. A mobility gel-shift assay is necessary to optimize the binding of MS2-MBP to RNA. The RNA integrity should be monitored from the beginning of preparation of RNA, after RNA is bound by MS2-MBP, after RNA/protein complex formation, and during gel filtration and binding to the amylose beads. It is suggested that an aliquot of the reaction be saved at every step for RNA and protein quality assurance. The binding efficiency of the complex to the amylose beads and the elution efficiency of the complex can be monitored by comparing total radioactivity before and after the binding or elution.

Anticipated Results

In the case of spliceosome purification, typically about 30% of the spliceosomes will bind to the amylose resin and 80% of them will be eluted. The limiting factor in most instances is the efficiency of spliceosome assembly, which mainly depends on the quality of the nuclear extract and the sequences of the pre-mRNA substrate.

Time Considerations

Purification of MS2-MBP and preparation of substrate RNA takes one day. Assembly and purification of spliceosomes will take another

day. The time-consuming part of this protocol is the gel-filtration step, which takes ~14 hr, and it is best to schedule it to run overnight.

RNA Immunoprecipitation for Determining RNA-Protein Associations In Vivo

UNIT 27.4

Chromatin immunoprecipitation (ChIP; UNIT 21.3) is a powerful and widely applied technique for detecting the association of individual proteins with specific genomic regions in vivo. RNA immunoprecipitation (RIP) is very similar, but, as the name implies, this latter method focuses on protein-RNA interactions. In RIP (as in ChIP), live cells are treated with formaldehyde to generate protein-protein, protein-DNA, and protein-RNA cross-links between molecules in close proximity. A whole-cell extract is prepared in the presence of RNase inhibitors to maintain the integrity of RNA, and the cross-linked nucleic acids are sheared by sonication to reduce average fragment size to ~500 bases. The extract is then treated with DNase I to remove DNA, and the resulting material is immunoprecipitated with an antibody against the protein of interest. RNA sequences that directly or indirectly cross-link with a given protein are selectively enriched in the immunoprecipitated sample. Reversal of the formaldehyde cross-linking by heating permits the recovery and quantitative analysis of the immunoprecipitated RNA by reverse transcription (RT) PCR analysis. The amounts of a specific RNA sequence in control and immunoprecipitated samples are determined individually by quantitative RT-PCR. The fold enrichment of certain RNA sequences (e.g., presumed binding sites) relative to other sequences (e.g., presumed nonbinding sites) provides quantitative information about the relative level of association of a given protein with different regions. Protein association with specific RNA regions can be assayed under a variety of conditions (e.g., environmental change or cell-cycle status) and/or in wild-type versus mutant strains. Furthermore, as formaldehyde inactivates cellular enzymes essentially immediately upon addition to cells, RIP provides snapshots of protein-RNA interactions at a particular time point, and is therefore useful for kinetic analysis of events occurring on RNA in vivo. In addition, like ChIP, RIP can theoretically be combined with microarray technology to identify the location of specific proteins on a “genome”-wide basis (see Commentary). This unit describes the RIP protocol for cells of the baker’s yeast *Saccharomyces cerevisiae* (see Basic Protocol). It is also applicable to other organisms, although some organism-specific modifications related to cell lysis and sonication will probably be necessary.

RNA IMMUNOPRECIPITATION IN YEAST CELLS

In this RIP protocol, *Saccharomyces cerevisiae* cells are cross-linked with formaldehyde, then harvested and sonicated to release and minimize the length of nucleic acid molecules. DNA is removed by treatment with DNase I, and the RNA is protected by the addition of RNase inhibitor throughout. The protein-RNA molecules are then immunoprecipitated and purified, the cross-links are reversed, and the resulting RNA is analyzed by RT-PCR.

Materials

- Saccharomyces cerevisiae* cells to be studied (see Chapter 13)
- 37% formaldehyde (store up to 1 year at room temperature)
- 2 M glycine, sterilized by autoclaving
- Tris-buffered saline (TBS; APPENDIX 2), ice cold
- FA lysis buffer (see recipe), ice cold and room temperature
- 40 U/ μ l RNasin (Promega)
- ~0.5-mm-diameter silica-zirconia (preferably BioSpec) or glass beads
- Ice/salt mixture in beaker for cooling
- MgCl₂

**BASIC
PROTOCOL**

**RNA-Protein
Interactions**

27.4.1

CaCl₂
 20 mg/ml RNase-free DNase I (Sigma)
 0.5 M EDTA (*APPENDIX 2*)
 Primary antibody against protein or epitope of interest
 50% (v/v) protein A–Sepharose beads (Amersham Biosciences or equivalent) in
 FA lysis buffer containing 1 mg/ml BSA
 FA lysis buffer (see recipe) containing 1 mg/ml BSA
 FA500 (see recipe)
 LiCl wash solution (see recipe)
 TE/100 mM NaCl (see recipe)
 ChIP elution buffer (see recipe)
 5 M NaCl, sterilized by autoclaving
 20 mg/ml proteinase K (Roche) in TBS/50% glycerol (store up to 1 year at –20°C)
 Acid-equilibrated 5:1 phenol/chloroform, pH 4.7 (Sigma, cat. no. P1944)
 Phase Lock Gel, Heavy (Eppendorf)
 3 M sodium acetate, pH 5.5 (*APPENDIX 2*)
 Glycogen
 Absolute ethanol, ice cold
 70% ethanol
 TE buffer, pH 7.5 (*APPENDIX 2*)
 Titan One-Tube RT-PCR kit (Roche)
 6% acrylamide/bisacrylamide (19:1) nondenaturing PAGE gel prepared in TBE
 buffer (see *UNIT 2.7*)
 SYBR Green (Molecular Probes)
 500-ml Erlenmeyer flask
 Platform rocker
 50-ml centrifuge tubes
 Refrigerated centrifuge
 1.5-ml (nonstick) microcentrifuge tubes, certified RNase-free
 FastPrep benchtop cell disruptor (Qbiogene)
 Hypodermic needle
 2-ml microcentrifuge tubes
 15-ml conical polypropylene centrifuge tubes, disposable (e.g., Falcon)
 Sonicator with microtip probe (e.g., Branson Sonifier 250) End-over-end rotator
 Spin-X microcentrifuge tube filters (Corning, available, e.g., from Sigma)
 42° (optional) and 65°C water baths
 Thermal cycler
 Additional reagents and equipment for growth of *Saccharomyces cerevisiae*
 cultures (*UNITS 13.1 & 13.2*), determining chromatin fragment size (*UNIT 21.3*),
 phenol/chloroform extraction and ethanol precipitation (*UNIT 2.1A*), primer design
 for ChIP experiments (*UNIT 21.3*), oligonucleotide synthesis (*UNIT 2.11*), PCR (*UNITS*
 15.1 & 15.7), nondenaturing polyacrylamide gel electrophoresis (*UNIT 2.7*), and
 agarose gel electrophoresis and ethidium bromide staining of gels (*UNIT 2.5A*)

NOTE: Remember that this procedure is concerned with detecting RNA; therefore, great care has to be taken to avoid its degradation during handling. After harvesting of cells, use RNase-free tubes as indicated, pipet tips with aerosol-barrier filters, and solutions prepared with nuclease-free water (Ambion). Keep samples on ice.

Cross-link protein-RNA complexes in vivo

1. In a 500-ml Erlenmeyer flask, grow 100 ml of yeast cell culture (*UNIT 13.2*) to mid-logarithmic phase in the appropriate medium (*UNIT 13.1*). Measure the cell density (*UNIT 13.2*) before formaldehyde fixation.

A concentration of $0.5\text{--}2 \times 10^7$ yeast cells/ml is usually adequate. The total volume of culture can be reduced (50 ml is a reasonable minimum) or increased depending on need. Typically, 2 to 10 ml of yeast culture ($0.2\text{--}1 \times 10^8$ cells) are used for an individual immunoprecipitation. A larger volume permits multiple immunoprecipitations from the same cells, which is particularly useful for experiments involving the analysis of multiple factors or for carrying out independent immunoprecipitations involving the same factor for data reproducibility.

2. Add 2.7 ml of 37% formaldehyde (for a final concentration of 1%). Cross-link by incubating 15 to 20 min at room temperature, occasionally swirling the flask or shaking slowly on a platform rocker.

CAUTION: Keep cultures covered or work in a fume hood to avoid noxious formaldehyde fumes.

3. Add 10 ml of sterile 2 M glycine (for a final concentration of ~ 0.2 M) and incubate an additional 5 min at room temperature.

Glycine stops the cross-linking by reacting with formaldehyde.

Harvest cells

4. Transfer cells to a 50-ml centrifuge tube and centrifuge 5 min at $2500 \times g$, 4°C . Discard supernatant into a chemical waste container and resuspend pellet in 50 ml ice-cold TBS. Repeat once.
5. Centrifuge cells a third time for 5 min at $2500 \times g$, 4°C , and discard supernatant. Supplement FA lysis buffer with RNase inhibitor by adding 1 μl of 40 U/ μl RNasin to 1 ml ice-cold FA lysis buffer. Resuspend cells in 0.5 ml of this solution and transfer to a nonstick, RNase-free microcentrifuge tube.

Lyse cells

6. Microcentrifuge cell suspension 10 sec at maximum speed, 4°C , and discard the supernatant. Resuspend the cell pellet in 400 μl ml ice-cold FA lysis buffer containing RNase inhibitor (see step 5). Add 400 μl of dry, solid silica-zirconia or glass beads.

The cells can remain on ice for a few hours while other samples are being collected, so that all samples may be processed as a group from this point onward. Alternatively, the cells may be frozen in liquid nitrogen or a dry ice/ethanol bath and stored up to several months at -80°C . This is particularly helpful if multiple samples are being generated during a time-course experiment. If cells are frozen, they must be thawed on ice before continuing with the procedure.

7. Lyse cells by applying a FastPrep cell disruptor four to five times for 30 sec each at speed 5.5 (total breakage time 2 to 3 min), removing the sample, and incubating 1 min in an ice-water bath after each treatment.

Alternatively, cell extracts can be prepared using a Mini Bead Beater (BioSpec) or by vortexing, as described in UNIT 21.3.

8. Puncture a hole in the bottom of the tube with a hypodermic needle, place the tube into a 2-ml microcentrifuge tube, and microcentrifuge 1 min at 5000 rpm.
9. Transfer liquid to a 15-ml conical polypropylene centrifuge tube and add 1 ml FA lysis buffer containing RNase inhibitor (see step 5).

Shear nucleic acids

10. Place the tube in an ice/salt mix in a beaker to maintain temperature. Holding the microtip of a Branson Digital Sonifier near the bottom of the tube to prevent foaming, sonicate the sample for one or two cycles at 50% amplitude for 15 sec. Keep the sample immersed in an ice/salt bath between and during sonications; leave the samples in the ice/salt bath to cool for at least 2 min after each sonication cycle.

Take great care that the sample does not get too hot, as this may reduce the efficiency of subsequent steps.

If a different sonication device is used, empirically determine the conditions necessary to achieve the desired level of DNA shearing.

11. Add the following to 500 μl of the sonicated extract:

MgCl₂ to 25 mM final
CaCl₂ to 5 mM final
3 μl of 40 U/ μl RNasin
6 μl of 20 mg/ml RNase-free DNase I.

Incubate at 37°C for 15 min.

12. Stop the reaction by adding 20 μl of 0.5 M EDTA (for a final concentration of 20 mM). Microcentrifuge 5 min at maximum speed and retain the supernatant. Store in aliquots (stable for many weeks) at -70°C .

These steps remove DNA so that the subsequent precipitation and detection steps focus on protein associated with RNA only. The resulting supernatant constitutes the input sample for the subsequent immunoprecipitation. The frozen aliquots are stable for many weeks when stored at -70°C and are suitable for immunoprecipitation.

13. Check RNA fragment size by electrophoresis on a polyacrylamide gel (see UNIT 21.3 for checking fragment size).

RNA pieces should be between 100 to 1000 bases, with an average length of 300 to 500 bases. It is important to shear RNA down to an average length of 400 to 500 bases. Longer fragments will increase the background and decrease the resolution of the region where the protein associates.

Immunoprecipitate

14. Dilute extract equivalent to $0.2\text{--}1 \times 10^8$ cells (typically 50 to 100 μl of the extract from step 12) to 250 μl with FA lysis buffer containing RNasin. To this diluted extract, add 1 to 5 μl primary antibody against the protein or epitope of interest and incubate overnight on an end-over-end rotator at 4°C.

The actual amount and concentration of the individual antibody has to be empirically determined and can vary considerably. The immunoprecipitation conditions can be varied (e.g., with respect to time, temperature, salt concentration, and/or presence of detergents) if necessary.

15. Microcentrifuge 15 min at maximum speed, 4°C, then transfer the supernatant to a new tube.

16. Add 20 μl of a $0.5\times$ slurry of protein A–Sepharose beads (equilibrated in FA lysis buffer containing 1 mg/ml BSA and 40 U/ μl RNasin). Incubate 1 to 2 hr at 4°C.

Protein A–Sepharose beads are used here because they work well with most monoclonal antibodies derived from mouse and polyclonal sera derived from rabbit. In some cases, the use of other beads (e.g., protein G–Sepharose) may improve binding of some antibodies, including rat IgG.

Wash beads

17. Microcentrifuge 2 min at 3000 rpm, 4°C, and remove supernatant. Resuspend beads in 700 μl FA lysis buffer, room temperature, and transfer mixture into a Spin-X centrifuge tube filter.

The use of Spin-X filters aids in the recovery of the beads after washes and results in better uniformity between different samples. The procedure is also substantially faster with the filters, particularly when multiple samples are processed simultaneously. Alternatively,

conventional microcentrifuge tubes can be used for the washes, and the supernatant can be carefully aspirated after each spin.

18. Place the filter into a 1.5-ml microcentrifuge tube. Mix sample 3 min on an end-over-end rotator, then microcentrifuge 2 min at 3000 rpm, room temperature, and discard the flow-through liquid at the bottom of the tube.
19. Add 700 μ l FA lysis buffer, room temperature, to the beads in the filter and repeat the procedures described in step 18 for a second wash.
20. Wash beads successively, each time using the technique described in step 18, with the following solutions:
 - 0.7 ml FA lysis buffer
 - 1 ml FA500
 - 0.7 ml LiCl wash
 - 0.7 ml TE/100 mM NaCl.

For some polyclonal antibodies, the more stringent washes in this step result in a cleaner signal, while gentle washes alone frequently lead to an unacceptably high background. For other antibodies, repeated washes with FA lysis buffer alone, which are gentler, might be more appropriate.

Elute protein-RNA from beads

21. Place filter unit containing the beads into a new 1.5-ml microcentrifuge tube and add 75 μ l of ChIP elution buffer as described above. Gently pipet up and down two or three times in order to dislodge beads from the filter. Incubate 10 min in a 37°C water bath.

A water bath is used instead of other heating apparatus in order to improve heat transfer.

22. Microcentrifuge beads 2 min at 3000 rpm, room temperature. Transfer eluate to another tube. Repeat elution with another 75 μ l of ChIP elution buffer. Pool eluates and discard filter with beads.

Reverse cross-links and purify RNA

23. Add 6 μ l of 5 M NaCl (for final concentration of \sim 200 mM) together with 20 μ g proteinase K (from 20 mg/ml stock). Incubate at 42°C for 1 hr (optional), then at 65°C for 1 hr.

The incubation at 42°C allows for proteinase K digestion of cross-linked polypeptides, while the 65°C incubation results in a reversal of the formaldehyde cross-links. Note that, because fractions (especially nonprecipitated inputs) contain significant amounts of DNase I, complete inactivation of the enzyme in this step (by digestion) is essential for successful RT-PCR.

24. Add 100 μ l nuclease-free water to the 150 μ l of RNA, then add an equal volume (250 μ l) of acid-equilibrated 5:1 phenol/chloroform, pH 4.8. Use Phase Lock Gel, Heavy, as recommended by the manufacturer for quick separation of the layers.

See UNIT 2.1A for additional discussion of DNA precipitation.

25. Transfer the resulting aqueous layer to a new tube and add 25 μ l 3 M sodium acetate, pH 5.5, 20 μ g glycogen, and 625 μ l ice-cold absolute ethanol. Leave at -80°C for 1 to 2 hr to allow the RNA to precipitate.
26. Microcentrifuge 30 min at maximum speed, 4°C, and remove the supernatant. Wash precipitate by adding 500 μ l ice-cold 70% ethanol and microcentrifuging 5 min at maximum speed, 4°C. Discard supernatant and allow pellet to air dry.

27. For storage, and to help avoid degradation of the resulting RNA, redissolve the pellet in 200 μ l TE buffer, pH 7.5, then add 2.5 vol of absolute ethanol, but no salt.

This mix can be stored for weeks at -80°C .

28. Remove an appropriate aliquot of the RNA solution (typically 10 to 50 μ l). Add 1 to 5 μ l of 3 M sodium acetate, pH 5.5, for a final concentration of ~ 0.3 M, then leave the mixture on dry ice for about 20 min to precipitate RNA. Microcentrifuge and wash pellet with 70% ice-cold ethanol and dry (see step 26). Redissolve pellet in 5 μ l of TE buffer, pH 7.5.

Perform quantitative RT-PCR and analyze products

29. Design primer pairs for the desired RNA regions to be examined (See *UNIT 21.3*) and synthesize the primer oligonucleotides (*UNIT 2.11*).
30. Perform RT-PCR (also see *UNITS 15.1 & 15.7*) using the Titan kit, scaling reactions down to a final volume of 25 μ l but otherwise following the manufacturers instructions. Use the following RT-PCR program:

Initial step:	30 min	50 $^{\circ}\text{C}$	(reverse transcription)
	2 min	93 $^{\circ}\text{C}$	(denaturation)
36 cycles:	20 sec	93 $^{\circ}\text{C}$	(denaturation)
	30 sec	53 $^{\circ}\text{C}$	(annealing)
	1 min	68 $^{\circ}\text{C}$	(extension)
Final step:	7 min	68 $^{\circ}\text{C}$	(final extension).

The Titan one-step kit incorporates reverse transcription and PCR into a single reaction.

For a typical measurement, input RNA is tested along with immunoprecipitated samples. Different dilutions of both input and immunoprecipitated material are tested to ensure that the RT-PCR reactions are in the linear range. See Critical Parameters and Troubleshooting for additional discussion.

It is crucial to include a control reaction in which the RT-PCR step is performed without adding reverse transcriptase, to ensure that the final product is due to RNA rather than contaminating DNA.

31. Separate PCR samples on a 6% acrylamide/bisacrylamide gel (*UNIT 2.7*) and visualize by staining with SYBR Green at a 1/10,000 dilution.

*SYBR Green staining is typically used, although similar results can be obtained by using ^{32}P -labeled nucleotides for the RT-PCR reaction. Gels containing radiolabeled PCR products are analyzed by autoradiography or phosphor imaging (*APPENDIX 3A*).*

ALTERNATE PROTOCOL

ANALYSIS BY REAL-TIME PCR

For real-time PCR analysis, RIP is performed exactly as described in the Basic Protocol, through step 28, whereupon one-step quantitative real-time RT-PCR reactions are carried out using the ABI Prism 7000 Sequence Detection System as described below. For basic considerations, see *UNIT 21.3*.

Additional Materials (also see *Basic Protocol*)

2 \times SYBR Green QPCR mix (Abgene AB-1162; contains DNA polymerase)
Multiscribe reverse transcriptase (Applied Biosystems)
ABI Prism 7000 Sequence Detection System, or equivalent
SYBR Green QPCR mix (Abgene AB-1162)
Software for analyzing PCR primers and products

1. Perform RNA immunoprecipitation and purify RNA (see Basic Protocol, steps 1 to 28)

2. Design primer pairs for the desired RNA regions to be examined (See *UNIT 21.3*) and synthesize the oligonucleotides (*UNIT 2.11*).

3. Set up the following reactions for PCR in a volume of 30 μ l:

15 μ l 2 \times SYBR Green QPCR mix
0.1 μ l 40 U/ μ l RNasin
0.15 μ l Multiscribe reverse transcriptase
10 pmol each primers
Template RNA (see Basic Protocol, step 28)
H₂O to 30 μ l.

4. Carry out RT-PCR using the following cycling program:

First step:	30 min	50°C	(reverse transcription)
	15 min	95°C	(activation)
40 cycles:	15 sec	95°	(denaturation)
	60 sec	60°	(annealing/extension).

5. Quantitate the relative amount of PCR products using appropriate software for the accompanying instrument (also see *UNIT 21.3*).

6. Calculate the apparent immunoprecipitation efficiency for a specific fragment by dividing the amount of RT-PCR product obtained in the immunoprecipitated sample by the amount obtained from the input RNA (see *UNIT 21.3*).

REAGENTS AND SOLUTIONS

Use nuclease-free, double-distilled water in all recipes and protocol steps. For common stock solutions, see *APPENDIX 2*; for suppliers, see *APPENDIX 4*.

ChIP elution buffer

100 mM Tris-Cl, pH 8 (*APPENDIX 2*)
10 mM EDTA
1% (w/v) SDS
Autoclave
Store up to 1 year at room temperature with the above ingredients
Just before use, add 40 U RNasin (Promega) per ml buffer

FA500

50 mM HEPES, pH 7.5
500 mM NaCl
1 mM EDTA
1% (v/v) Triton X-100
0.1% (w/v) sodium deoxycholate
Autoclave
Store up to 2 months at 4°C
Just before use, add 40 U RNasin (Promega) per ml buffer

FA lysis buffer

50 mM HEPES (adjust pH to 7.5 with KOH)
140 mM NaCl
1 mM EDTA
1% (v/v) Triton X-100
0.1% (w/v) sodium deoxycholate

continued

Autoclave
Store up to 1 year at room temperature with the above components
Just before use, add 100× protease inhibitors (see recipe) to 1× final and 40 U RNasin (Promega) per ml buffer

LiCl wash

10 mM Tris·Cl, pH 8 (*APPENDIX 2*)
250 mM LiCl
0.5% (v/v) NP-40
0.1% (w/v) sodium deoxycholate
1 mM EDTA
Autoclave
Store up to 2 months at 4°C
Just before use, add 40 U RNasin (Promega) per ml buffer

Protease inhibitor stock solutions, 100×

Dissolve the following in 50 ml of 100% ethanol and store up to 6 months at −20°C:
1.42 mg leupeptin
6.85 mg pepstatin A
0.85 mg phenylmethylsulfonyl fluoride (PMSF)
1.65 mg benzamidine

TE/100 mM NaCl

10 mM Tris·Cl, pH 8 (*APPENDIX 2*)
1 mM EDTA
100 mM NaCl
Store up to 2 months at 4°C

COMMENTARY

Background Information

RNA immunoprecipitation (RIP) is, in many ways, a natural and direct extension of chromatin immunoprecipitation (ChIP). Much valuable background information can be found in *UNIT 21.3*, which should be consulted before attempting the procedures described in this unit. RIP has been used for studying the interaction of proteins with RNA by Gilbert et al. (2004) and Hurt et al. (2004), based on the idea of modifying the ChIP technique and using fairly similar protocols. The paper by Gilbert et al. (2004) forms the basis for the protocols described here. In these papers, the RNA interactions of transcription-related proteins were studied, but other papers have used RIP or similar RNA immunoprecipitation techniques to study the interaction, e.g., of the basic RNAi machinery with noncoding centromeric RNA (Motamedi et al., 2004) or the interaction of proteins with tRNA (Huang et al., 2005).

The procedure described here was developed for immunoprecipitation of myc

epitope-tagged protein in yeast (Gilbert et al., 2004). However, as in ChIP, any specific antibody directed against a protein of interest can be used. The key difference between RIP and ChIP is the use of extensive DNase I digestion of the crude extracts prior to immunoprecipitation. Importantly, the inclusion or omission of this step makes it possible to perform both ChIP and RIP on the same starting cell population, which can often be desirable. Moreover, in RIP, the final detection step for the coprecipitated nucleic acid is RT-PCR, rather than PCR. Hence, although as with ChIP both the basic idea and experimental process of RIP are simple and straightforward, RIP has several unique features that are important to keep in mind in order to obtain meaningful results.

Several basic observations about RIP are worth recapitulating. First, in contrast to ChIP, the amount of input RNA required to give a suitable RT-PCR signal (in the logarithmic range) differs from transcript to transcript in the same RIP, because transcript levels can differ dramatically from gene to gene. This often

precludes the use of multiplex RT-PCR for detecting several different RNAs at the same time. Second, when ChIP is used for studying the interaction of proteins with a gene, association with the gene region before activation of the gene (where the protein is absent) and after activation of the gene (where it is present), is often examined. Such an experiment is not meaningful for RIP, because there is no RNA expressed from the gene under noninducing conditions.

Third, it has been repeatedly observed that, at least for non-sequence-specific RNA-binding (transcription-related) proteins, cross-linking is not always restricted to the portion of the transcript predicted by protein function. For example, transcription factors typically cross-link much more readily to the beginning than to the end of the transcript (Gilbert et al., 2004). This could, of course, indicate that transcription complexes are more abundant at the 5'-end of the gene, perhaps reflecting that a proportion of polymerases abort transcription during progression through the coding region (Kristjuhan and Svejstrup, 2004). However, an alternative explanation that nicely illustrates a fundamental and important difference between RIP and ChIP should be pointed out. Whereas DNA is likely to behave spatially more or less like a "linear" molecule, there is good reason to believe that RNA is spooled into a defined ribonucleoprotein (mRNP) structure during transcription (Huertas and Aguilera, 2003; Svejstrup, 2003). Such cotranscriptional RNA packing could potentially result in transcription factors apparently being cross-linked better to regions in the beginning of the transcript, because these regions (in contrast to the corresponding DNA regions) remain in close proximity to the transcribing polymerase and associated factors even as the transcription complex reaches the end of the gene. The 5'-end of the RNA molecule is thus in contact with the protein along the entire length of the gene, whereas sequences at the 3'-end of the RNA are obviously only in contact after they have been produced. Conversely, this packing of RNA also means that proteins known to specifically associate with the 5'-end of the transcript (such as CBP, which binds the cap of the finished transcript and exports the mRNA from the nucleus (Izaurralde et al., 1995; Gorlich et al., 1996) might also be expected to cross-link to regions in the 3'-end. Indeed, preliminary evidence for this has been obtained.

Finally, as in ChIP, it is important to use primers for a predicted "non-binding site" in control reactions. If mRNA-binding proteins are studied, these control primers might, for example, be designed to detect specific tRNAs or rRNAs. Likewise, if cotranscriptional association of proteins with pre-mRNA is studied, primers across an intron-exon junction can be used. Since splicing occurs cotranscriptionally (and introns are exclusively nuclear), it is then possible to study nucleus-specific RNA interactions (Gilbert et al., 2004). Obviously, considerations about the basic differences between genomic DNA and its different RNA products impact significantly on the potential uses of RIP for research.

Critical Parameters and Troubleshooting

Because RIP is designed to specifically detect RNA, it is obviously of pivotal importance to take special precautions to avoid RNA degradation throughout the procedure. Routine use of nuclease-free water, addition of RNasin to all buffers, and use of filtered pipet tips is recommended.

Cross-linking in vivo and choice of epitope

To obtain trustworthy results with RIP, it is extremely important to carry out good control reactions. The most simple and powerful control is to use the same antibody-coupled beads (and not just "specific antibody" versus "preimmune serum" or "beads alone") in two extracts that differ only in whether or not the target protein carries an epitope tag. This is because most RNA species are much more abundant than DNA and are present in both the nucleus and cytoplasm, so the risk of nonspecific cross-linking or nonspecific coimmunoprecipitation is much higher. Varying the formaldehyde cross-linking times has an impact on the efficiency and specificity of the reaction, and it is strongly advised that an initial time-course experiment be performed for each new factor studied.

Sonication and DNase I treatment

The formaldehyde cross-linked yeast cells are lysed by the use of a bead-beating procedure, which also has the effect of shearing nucleic acids. It is not required or desirable to perform extensive sonication of the extract for RIP, presumably because RNA is already substantially sheared by bead beating. Although, in the authors' laboratory, four rounds of sonication are typically optimal for ChIP, only one

or two rounds of sonication are used for a typical RIP experiment; however, this should be empirically determined.

The sonicated extracts are then treated with DNase I to remove DNA. It is important, at least initially, to perform control experiments during the RNA-detection phase in which reverse transcriptase is left out of the PCR reactions, to ensure that only RNA is detected in the experiment. It is also a good idea to perform a control reaction in which the extract is treated with RNase, again to ensure that it is indeed RNA that is being detected.

Immunoprecipitation

The authors of this unit have observed that immunoprecipitations are more specific when performed by overnight incubation, using unconjugated antibodies directly in DNase I-treated extracts. Protein-A Sepharose beads are then added the next day, but only after a high-speed centrifugation of the antibody-incubated extract to remove material that may have precipitated during the incubation. The authors typically use only 1 to 2 μ l antibody per immunoprecipitation reaction. Less material is precipitated in this way, but the signal-to-noise ratio is improved, which may be of particular importance for RIP.

Reversal of cross-links and RNA storage and detection

ChIP procedures typically include a very long incubation at 65°C to reverse formaldehyde cross-linking (UNIT 21.3). The authors of this unit have found that incubations as short as 0.5 to 1 hr are sufficient for reversal of RNA-protein interactions. After reversal of cross-links, RNA is precipitated. Problems of reproducibility with “stored” versus “fresh” RNA are sometimes encountered, but storing the RNA according to the procedure described in the Basic Protocol does help somewhat.

RT-PCR

There are several key parameters for achieving optimal amplification. For example, it is very important to have a quality repeat pipettor that can reproducibly dispense 2- μ l samples. Pipetting inaccuracies at this stage will lead to greater well-to-well variability and poorer reproducibility among identical samples.

The PCR conditions tabulated in the Basic Protocol are generally appropriate for most situations. The annealing temperature may have to be adjusted if the melting temperature of the primers is substantially above or below 55°C. The number of cycles might also have to be

adjusted in some cases if reactions are not in the linear range.

For a typical measurement, input RNA is tested along with immunoprecipitated samples. Different dilutions of both input and immunoprecipitated material are tested to ensure that the RT-PCR reactions are in the linear range. Because different RNAs are present in different copy numbers (in contrast to DNA), the dilutions needed to achieve reproducible and reliable results will differ between different RNA molecules. Typically, the input material needs to be diluted ~500-fold relative to immunoprecipitated material. Due to the variability in RNA copy numbers, simultaneous analysis of multiple RNAs in a single reaction is often not possible.

It is crucial to include a control reaction in which the RT-PCR step is performed without adding reverse transcriptase, to ensure that the final product is due to RNA rather than contaminating DNA.

Genome-wide analysis

ChIP-on-chip experiments have become a common feature of research reports over the last couple of years (see, e.g., Robert et al., 2004). Whereas RIP-on-chip has not yet been reported, there is no reason why such experiments cannot be performed (see UNIT 21.3 for details on ChIP-on-chip)

Anticipated Results

The described technique should be capable of identifying the interaction of a protein of interest with RNA, starting with $\sim 10^7$ yeast cells. Although the protocol was developed for the detection of RNA interactions of a pre-mRNA-interacting protein in the nucleus (Gilbert et al., 2004), the authors of this unit anticipate that it can be used for detecting RNA interactions (mRNA, tRNA, rRNA) of proteins in the cytoplasm, mitochondria, or nucleolus, among other locations. An example result is shown in Figure 27.4.1.

Since it is well-known that formaldehyde makes protein-protein cross-links, one cannot assume that a positive RIP result means that a given protein is actually bound to the RNA. A positive result means that the protein is “in the vicinity” of the RNA—for example, associated via other proteins in a multi-subunit complex. This is true for chromatin immunoprecipitation as well as for RNA immunoprecipitation.

Time Considerations

The basic protocol may be completed in 2 or 3 days. On the first day, cells are fixed with

Figure 27.4.1 Results of RNA immunoprecipitation of Elp3, a subunit of the Elongator complex and relevant controls. In the left panel, immunoprecipitation of Elp3-Myc was shown to specifically co-precipitate the introns-exon junction of the *ARP2* gene. Enrichment was ~10-fold and depended on the epitope-tagged Elp3 protein (compare lanes 2 and 4). In the right panel, control experiments show that the *ARP2* product is only obtained by the use of reverse transcriptase PCR (RT-PCR), not by PCR alone (lanes 5 and 6, respectively). Reproduced from Gilbert et al. (2004) with permission from Elsevier.

formaldehyde and harvested (1 hr). Preparation of chromatin extracts (2 hr) and immunoprecipitations (primary antibody incubation, usually overnight); may be carried out on day 1, while incubation with protein A-coupled beads, ~2 hr; washing and elution, 1.5 hr, and reversal of cross-links (1-2 hours to overnight) can be done on day 2. On the final day, the DNA is purified (<4 hr), and reverse transcriptase PCR amplified (<3 hr, including 2 hr for the PCR program), and analyzed by gel electrophoresis (<2 hr, including 1 hr of gel running time). Alternatively, the samples are analyzed by reverse transcriptase real-time PCR (<3 hr, including 2 hr for the PCR program).

CHAPTER 28

Mammalian Cell Culture

INTRODUCTION

Cell culture technologies are a basic tool for most, if not all molecular biologists, and the use of established, immortal cell lines for production of proteins from cDNAs or other forms of genetic material has been an important and productive method for characterizing molecules identified by molecular biological techniques such as cloning, differential display, or microarray analyses (see Chapter 9, Introduction of DNA into Mammalian Cells, and Chapter 16, Protein Expression). Apart from using cell culture approaches for protein production, analysis of protein function also has made extensive use of immortal cell lines—for instance, in examining the effect of exogenous protein expression on cell signaling or transcriptional events. These approaches have been highly successful in delineating the role of proteins of interest, to the extent possible, in relatively uniform cell cultures. Moreover, a large number of different types of immortalized cell lines are available, representing material originally obtained from a large number of different tissues and species. These can be obtained through other investigators or purchased from organizations such as the American Type Culture Collection (ATCC) or commercial organizations.

However, there are limitations to the usefulness of established cells lines for studies of protein function. For instance, the ability of many of these cultures to grow without limitation is related to their origin from tumor tissues, and, consequently, these cells may have abnormal chromosomal content, more subtle genetic mutations, and abnormal protein expression. Consequently, the use of primary cell cultures obtained from normal tissues can be very desirable for studying protein function in a relatively normal cellular background. In addition, many molecular biological studies have incorporated the development of transgenic and knockout mice, and analyses of these mouse models frequently lead to questions and hypotheses that can be best explored in comparatively simpler cell culture systems. Genetically altered mice therefore serve as an invaluable source of tissue from which to isolate cells that either lack or overexpress the protein of interest in a relatively normal cellular background. Likewise, the establishment of cultures of cells obtained from human patients carrying genetic mutations provides an opportunity to study the function of mutated proteins, and, potentially, the basis for human disease. Finally, establishment of primary cell cultures is of importance for cell types in which the ability of immortalized cells to model the function of a given cell or tissue type is poor.

It is the goal of this chapter to provide protocols for the preparation of primary cell cultures from cells or tissues obtained from humans and other mammalian species; information on basic cell culture techniques, including the propagation of established, immortal cell lines can be found in *APPENDIX 3F*. To begin, this chapter presents a protocol for preparation of primary mouse embryonic fibroblasts and information on how to immortalize these fibroblasts for long-term studies (*UNIT 28.1*). This is followed by protocols for isolating lymphocytes from human blood and immortalizing these cells with Epstein-Barr virus (*UNIT 28.2*). In future supplements, we will incorporate additional units on the preparation of primary cultures from a variety of tissues from other sources, beginning with methods for preparing foreskin fibroblast cultures and continuing with protocols for establishing cultures of other specialized cell types.

28.0.1

Supplement 70

Preparation, Culture, and Immortalization of Mouse Embryonic Fibroblasts

UNIT 28.1

Genetically manipulated transgenic and knockout mouse lines are powerful animal models for defining the physiological function of genes during development and in organ function. Similarly, the mutant cells isolated from these mutant mouse lines are valuable tools for studying the molecular and cellular mechanisms of the mutated genes under well-defined culture conditions. The purpose of this unit is to provide convenient stepwise protocols for preparation, culture, and immortalization of mouse embryonic fibroblasts (MEFs). The complete experimental process can be divided into three major steps including: isolation of MEFs from mouse embryos (see Basic Protocol 1), culture and use of primary MEFs (see Basic Protocol 2), and immortalization of MEFs for permanent growth (see Basic Protocol 3). In addition, useful annotations and commentary relevant to the development of MEFs from mouse embryos with lethal phenotype, as well as for optimal use of MEFs in experiments are provided, based on the author's experience. Additional information for isolating MEFs for the production of mouse mutants using homologous recombination and blastocyst-mediated transgenesis can be found in *UNIT 23.2*.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

ISOLATION OF MOUSE EMBRYO FIBROBLASTS FROM MOUSE EMBRYOS

**BASIC
PROTOCOL 1**

Theoretically, MEFs can be isolated from mouse embryos with genetic backgrounds of any strain. However, it is recommended that wild-type control and mutant MEFs be prepared from mice with identical strain backgrounds, to reduce the risk of possible genetic background-dependent variations. If the transgenic or homozygous mutant mice are viable and fertile, wild-type and mutant embryos can be generated from wild-type and mutant mating pairs, respectively. If the homozygous mutant mice are infertile or lethal, heterozygous mating pairs should be used to produce wild-type, heterozygous, and homozygous embryos. The optimal ages of mouse embryos for MEF isolation are from embryonic day 13.5 (E13.5) to E15.5. However, if the mutant embryos are lethal at earlier stages, MEFs can be successfully isolated from mouse embryos at developmental stages as early as E8.5.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and aseptic technique should be used accordingly.

Materials

- 2 to 3 male and 4 to 6 female mice (8 to 18 weeks of age)
- 2.5% Avertin (see recipe)
- 70% ethanol
- Phosphate-buffered saline, pH 7.2 (PBS; *APPENDIX 2*), sterilized by autoclaving
- 0.25% trypsin-EDTA solution (Invitrogen, cat. no. 25300-056)
- MEF culture medium (see recipe)
- Mouse ear tags (National Band and Tag)
- Cages (11 in. wide × 7 in. long × 7 in. tall) with food and water dishes
- Appropriate mouse food

28.1.1

Supplement 70

Dissecting instruments, autoclaved:
Regular and fine dissection scissors
Two pairs autoclaved watchmaker's no. 5 forceps
Blunt fine forceps
Powder-free latex gloves
15- and 50-ml sterile screw-cap plastic conical tubes
10-cm tissue culture dishes or 75-cm² tissue culture flasks

Set up mice for mating

1. Number all mice with ear tags. Set up mouse mating cages by putting one adult male and one to two adult female mice in each cage.

Usually four to six females are required for each experiment, because not every female that has copulated can be identified or will become pregnant. Mice should be fed with appropriate food and water and housed in a temperature- and lighting-controlled animal facility.

2. Every morning after setting up mating, check all females for the presence of a copulation plug (vaginal plug) in the vagina.

The vaginal plug contains coagulated proteins from the male seminal fluid and can be easily seen in most strains. The vaginal plug usually dissolves 12 to 14 hr after mating (Hogan et al., 1994); therefore, the females should be checked before 8:00 am.

3. Transfer females with vaginal plugs into new cages. Record the age of its embryos as E0.5 on the day when the vaginal plug is seen.

Harvest fetuses

4. On day E14.5, anesthetize the plugged mouse by intraperitoneally injecting 0.5 ml of 2.5% avertin, then euthanize by cervical dislocation.

If null mutant embryos are lethal before E14.5, the plugged mice should be sacrificed earlier.

5. Place mouse on a paper towel and spray enough 70% ethanol to soak the entire mouse body. Using a pair of regular dissection scissors, cut a small incision through the skin at the centric position on the middle back and, wearing powder-free latex gloves, pull with both hands to peel the skin in both directions toward the head and tail. Lay the mouse carcass on its back on a sterile paper towel.

6. Dissect out the uterus as follows.

- a. Use a pair of sterile blunt forceps to lift the abdominal wall, then remove the abdominal wall using a pair of sterile dissection scissors.

Caution should be taken not to damage internal organs such as intestine, to avoid bacterial contamination.

The left and right uterine horns with the embryos in them should be seen.

- b. Use a pair of sterile blunt forceps to hold up the bottom part of the uterus and use a pair of sterile scissors to dissect out the entire uterus containing all embryos.
 - c. Transfer the uterus into a 50-ml tube with 30 ml sterile PBS and invert the tube several times to wash the uterus.
7. In a laminar flow cabinet, open the 50-ml tube and using blunt forceps, transfer the washed uterus with embryos into a 10-cm tissue culture dish containing 10 ml sterile PBS. Use a pair of fine watchmakers forceps to hold the uterine wall and use a pair of fine dissection scissors to cut through one side of the uterine wall to expose individual embryos.

If embryos are younger than E13.5, perform dissection procedure under a stereomicroscope.

8. Open the yolk sac with a pair of fine forceps and dissect out all fetuses intact.
9. Transfer all fetuses into a new dish containing 10 ml sterile PBS. Take each fetus and, using two pairs of fine watchmakers forceps, remove and discard the liver and heart, and also remove and discard the brain by first removing the upper part of the head. Wash the remaining part of each of the fetus in sterile PBS to remove as much blood as possible and then transfer the fetuses into a new dish.

Heterozygous parental mice produce embryos with all possible genotypes. If the genotype of individual embryos of genetically manipulated mice needs to be analyzed, handle embryos individually and match the identification number of each embryo with its biopsy for genotyping. Collect one of the hind limbs (for E13.5 and older embryos) or the yolk sac (for E12.5 and younger embryos) and extract DNA. Identify the genotype by PCR (UNIT 15.1) using allele-specific primer pairs as described in the literature (Hogan et al., 1994; Kuang et al., 2002).

Prepare MEF suspension

10. Add 2 to 3 ml of ice-cold 0.25% trypsin-EDTA to the dish. Use two pairs of fine forceps to tease all fetuses into fine pieces. Using a pipet, transfer all materials into a 15- (for up to four embryos) or a 50-ml tube (for more than four embryos), then add ice-cold 0.25% trypsin-EDTA to bring the total volume to 3 ml per embryo. Let the tube stand at 4°C overnight.

This allows trypsin, which has almost no activity at 4°C, to diffuse into the tissues.

11. On the next morning, without disturbing the tissue at the bottom of the tube, aspirate off most of the trypsin solution, leaving an amount equivalent to approximately two volumes of the tissue. Cap the tube and incubate 30 min in a 37°C water bath.
12. Add MEF culture medium to 25 ml (for a 50-ml tube) or 8 ml (for a 15-ml tube), and pipet vigorously and repeatedly up and down to break up the digested tissues into a cell suspension.
13. Allow sedimentation of the cell suspension by gravity for 1 min to let remaining clumps fall to the bottom of the tube. Transfer the supernatant cell suspension to a new tube. Add more MEF culture medium to the tube containing the remaining tissue clumps and vigorously pipet up and down for 1 min. Repeat the sedimentation and combine the supernatant cell suspension with the cell suspension already collected.
14. Mix the cell suspension and plate the cells in 10-cm tissue culture dishes or 75-cm² tissue culture flasks with 10 ml MEF culture medium. Continue with culture as in Basic Protocol 2.

The number of tissue culture plates to be used is dependent on the total number of MEFs isolated, which basically is proportional to the number and sizes of the embryos. MEFs isolated from each of the E14.5 embryos can be plated in five 10-cm dishes or 75-cm² flasks.

CULTURE AND USE OF PRIMARY MOUSE EMBRYO FIBROBLASTS

MEFs isolated from mouse embryos can be expanded in culture or cryopreserved in liquid nitrogen. They can be used as primary cultured cells or further immortalized to generate cell lines that can be maintained permanently in culture.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations are performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

BASIC PROTOCOL 2

Mammalian Cell Culture Techniques

28.1.3

Materials

MEFs prepared from mouse embryos (see Basic Protocol 1)
Phosphate-buffered saline, pH 7.2 (PBS; APPENDIX 2), sterilized by autoclaving
MEF culture medium (see recipe)
0.05% trypsin-EDTA solution (Invitrogen, cat. no. 25300-054)
MEF freezing medium (see recipe)
Inverted phase-contrast microscope (suitable for examining the cell culture)
0.75- or 1-ml cryovials
Centrifuge and rotor with adaptors for 15- and 50-ml plastic centrifuge tubes
Liquid nitrogen tank with canes for holding cryovials
10-cm tissue culture dishes or 75-cm² tissue culture flasks
Additional reagents and equipment for mammalian cell culture and trypsinization of cells (APPENDIX 3F)

1. Incubate MEFs prepared from mouse embryos (Basic Protocol 1) overnight.
2. Aspirate medium and wash cell monolayers twice, each time with 10 ml sterile PBS, to remove all nonadherent cells. Add 10 ml fresh MEF culture medium to each plate and continue to culture cells to near confluency (as determined by examination with phase-contrast microscope).

The cells at this stage are designated as passage 1 MEFs.

APPENDIX 3F contains additional detail on mammalian cell culture.

To freeze cells for later use

- 3a. Aspirate medium and wash cell monolayers twice, each time with 5 ml sterile PBS. Add 3.5 ml 0.05% trypsin-EDTA solution to each culture plate and incubate 3 to 5 min. Add 5 ml MEF culture medium to each plate, then resuspend cells and transfer them into 15- or 50-ml sterile centrifuge tubes.

APPENDIX 3F contains additional detail on trypsinization of cells.

- 4a. Centrifuge cells 5 min at 400 × g, room temperature. Aspirate all of the supernatant.
- 5a. Add MEF freezing medium at a volume of 0.5 ml per culture plate that went into producing the pellet. Use a 5-ml pipet to resuspend cells, then place 0.5-ml aliquots of cells into cryovials.
- 6a. Freeze all vials in a –80°C freezer or in the vapor phase of the liquid nitrogen tank overnight, then transfer all vials into the liquid nitrogen tank for long-term storage.

To revive the frozen cells, transfer the cryovials containing them from the liquid nitrogen tank to the 37°C culture incubator. Incubate 10 min, then transfer all cells into a 50-ml tube containing 40 ml MEF culture medium. Mix, then divide cell suspension into four 10-cm culture plates and grow cells as described in this protocol.

To expand MEFs in culture

- 3b. After cells from step 2 have reached near confluency, aspirate medium and wash cell monolayers twice, each time with 5 ml sterile PBS.
- 4b. Add 2.5 ml of 0.05% trypsin-EDTA solution to the cells and incubate 3 to 5 min.
- 5b. Add 5 ml MEF culture medium to each plate, resuspend cells, and split into new 10-cm culture plates or 75-cm² culture flasks at a ratio of 1:5. Add sufficient MEF culture medium to bring volume to 10 ml in each plate or flask.

6b. Continue incubation.

Cells will grow to confluence in about 3 days.

Proliferation of MEFs in primary culture dramatically decreases by passage 5. If functional analysis needs to be performed with primary MEFs, experiments should be done with MEFs at passage 3, or at least no later than passage 4.

IMMORTALIZATION OF MOUSE EMBRYO FIBROBLASTS BY SERIAL PASSAGES

BASIC PROTOCOL 3

Because the life span of primary cultured MEFs is limited and isolation of primary MEFs from mouse embryos is time-consuming and labor-intensive, most laboratories wish to develop MEFs with permanent growth features. Two major approaches have been developed to immortalize primary MEFs, including serial passages of primary MEFs until they pass their growth-crisis stage and transformation of primary MEFs by overexpression of one or more oncogenes. Here, the method of serial passage is described, which is similar to the protocol used to establish the BALB/3T3 cell line (Aronson and Todaro, 1968).

NOTE: All solutions and equipment coming into contact with cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations are performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

Materials

MEFs growing in culture (see Basic Protocol 2)

MEF culture medium (see recipe)

Phosphate-buffered saline, pH 7.2 (PBS; *APPENDIX 2*), sterilized by autoclaving
25-cm² culture flasks

Additional reagents and equipment for mammalian cell culture, trypsinization of cells, and counting cells (*APPENDIX 3F*), and expansion and cryopreservation of cultured MEFs (see Basic Protocol 2)

1. Harvest MEFs from primary culture and determine of cell number by counting with a hemacytometer or an automated cell counter (*APPENDIX 3F*).
2. Mix 3.8×10^5 cells with 5 ml MEF culture medium and plate these cells in a 25-cm² culture flask. Incubate 3 days.

IMPORTANT NOTE: MEFs grow rapidly before passage 3, but their growth significantly decreases after passage 4. Therefore, it is sufficient to set up one 25-cm² flask for cells up to passage 3, but one should set up five 25-cm² flasks of MEFs after passage 3 to ensure there will be enough cells for subsequent passages.

3. After incubation, wash cell monolayer twice, each time with 5 ml PBS. Add 2.5 ml of 0.05% trypsin-EDTA solution to the cells and incubate 3 to 5 min. Add 5 ml MEF culture medium, then resuspend cells and transfer them to a 15-ml sterile centrifuge tube. Count cells (*APPENDIX 3F*) and plate again and incubate as in step 2 for the next passage.
4. Repeat the above steps for 20 to 25 passages.

Following an initial period of rapid growth, proliferation of the primary MEFs should decline from passage 5 to 14. By the 20 to 25th passage, the growth rate of MEFs should increase and the cell number also should increase 2- to 3-fold with respect to the inoculated number of cells during each 3-day transfer schedule (Fig. 28.1.1).

Mammalian Cell Culture Techniques

28.1.5

Figure 28.1.1 A representative growth curve of MEFs during serial passages. Primary MEFs were isolated from E14.5 mouse embryos with a mixed C57BL/6 and 129SvEv strain background. MEFs were cultured and transferred every 3 days as described in the protocol. The fold of cell growth was calculated by dividing the number of harvested MEFs with the number of inoculated MEFs in each passage. Data represent the average of two samples.

- After the MEFs become immortalized, expand and prepare frozen stock (see Basic Protocol 2).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Avertin, 2.5%

Mix 5 g of 2,2,2-tribromoethanol with 5 ml *tert*-amyl alcohol to make a 100% stock solution. Dilute the 100% stock solution with sterile PBS (APPENDIX 2) to a 2.5% working solution, stirring vigorously until it is completely dissolved. Wrap bottles for both the 100% stock and 2.5% working solutions in foil to avoid exposure to light and store up to 6 months at 4°C.

MEF culture medium

Dulbecco's modified Eagle medium (DMEM) containing:
 10% (v/v) fetal bovine serum (FBS)
 0.1 mM β -mercaptoethanol (tissue culture grade)
 50 U penicillin
 50 μ g/ml streptomycin
 Filter-sterilize and store up to ~3 months at 4°C.

MEF freezing medium

Dulbecco's modified Eagle medium (DMEM) containing:
 30% (v/v) fetal bovine serum (FBS)
 10% (v/v) dimethylsulfoxide (DMSO)
 Stored up to 4 to 5 months at 4°C

COMMENTARY

Background Information

MEFs growing in culture have a very high probability of developing into permanent (“immortalized”) cell lines, probably because they are susceptible to environmental stress-induced changes of chromatin stability. It was shown many years ago that MEFs could develop into permanent cell lines under appropriate culture conditions (Todaro and Green, 1963; Aaronson and Todaro, 1968). However, most of these established MEF lines were hypotetraploid (Aaronson and Todaro, 1968). It was also demonstrated that the MEF cell lines could be established from either low inoculation densities as described in Basic Protocol 3, or from a 4-fold higher inoculation density (Aaronson and Todaro, 1968). MEF cell lines developed from a low inoculation density that avoids cell-to-cell contact before transfer are able to grow at much lower inoculation densities and are extremely sensitive to contact inhibition of cell division. In addition, primary MEFs also can be transformed using viral oncoproteins such as SV40 T antigen (Todaro and Green, 1966). The transformation protocol is rapid, but the established MEF lines acquire many features similar to tumor cells.

Primary MEFs isolated by similar protocols are widely used as the feeder layer for culturing embryonic stem cells (Abbondanzo et al., 1993; Hogan et al., 1994). It is believed that MEFs can provide factors that enhance the proliferation and maintain the undifferentiated states of embryonic stem cells. In recent years, MEF cell lines established from genetically manipulated mouse embryos have become powerful tools to study the cellular function and molecular mechanisms of genes of interest through comparing mutant MEFs with wild-type MEFs (Puigserver et al., 1999; Wu et al., 2004).

Critical Parameters and Troubleshooting

To isolate MEFs (Basic Protocol 1), if embryos are at the stage of E12.5 or younger at the dissection step, there is no need to incubate the disaggregated fetal tissues with cold trypsin-EDTA solution overnight. Instead, tease the fetuses into fine pieces as described in step 10 of Basic Protocol 1 and incubate with 0.25% trypsin-EDTA (1 ml/fetus) at 37°C for 20 min, then add MEF culture medium and disaggregate the tissues by pipetting vigorously.

During the dissection of embryos and in the following processing steps, there is a high risk

for contamination by bacteria and fungi. Careful sterilization of all materials and tools and good operating skill are very helpful in reducing the risk of contamination. The MEFs at passage 1 should be examined carefully under a phase-contrast microscope. If contamination is identified, all MEFs and their containers should be treated with bleach and discarded, and the experiment should be repeated from the beginning.

Confluent MEFs in culture stop proliferating and begin to differentiate. In addition, it is known that long-term culture of MEFs at high density causes cellular transformation (Aaronson and Todaro, 1968). These autonomously transformed MEFs are able to form tumors if injected into nude mice. Therefore, both primary and immortalized MEFs in culture should never be maintained at a cell density that is over confluency.

As shown in Figure 28.1.1, the number of MEFs harvested from passages 10 to 14 after a period of 3-day culture may be even less than the number inoculated, due to extensive cell death. In this case, it is necessary to combine cells from more than one culture flask to achieve the necessary inoculation density for next passage.

Anticipated Results

MEF immortalization (Basic Protocol 3) is a process that selects for cells that acquire growth advantages. Cell-growth advantages are caused by the accumulation of genetic mutations that enhance cell survival and proliferation and inhibit apoptosis. Since multiple signaling pathways and gene networks are involved in regulation of cell survival, death, and proliferation, the immortalized MEFs must contain heterogeneous genetic mutations, and therefore their gene-expression profiles will differ from cell to cell in the population of immortalized MEFs. These internal variations may cause difficulties in comparing experimental results observed in wild-type MEFs versus mutant MEFs, even if they are developed simultaneously under same conditions. One useful approach is to express the gene of interest in the immortalized mutant MEFs and to compare these gene-expression-rescued MEFs with their parent mutant MEFs.

Time Considerations

Once the embryos have been harvested, it takes 2 to 3 hr to dissect and prepare the tissue

for overnight incubation in trypsin. The next day, it takes 1 to 2 hr to prepare the MEF primary culture. The initial primary culture takes 1 to 3 days to reach confluence. About 1 hr is required for trypsin digestion and aliquotting of passage-1 cell samples. Expansion of these confluent cells requires a 3-day incubation cycle. Each subsequent passaging requires a 3-day incubation, followed by a wash, trypsinization, and transfer to fresh plates.

Isolation and Immortalization of Lymphocytes

A convenient renewable source for cells and genomic material from patients or patient populations is not readily available. An easy way to circumvent this problem is to utilize the intrinsic properties of Epstein-Barr virus (EBV), which are its potent ability to immortalize human B lymphocytes to produce lymphoblastoid cell lines (LCLs). Isolation of lymphocytes is relatively simple and they can be easily obtained from small volumes of blood with minimum discomfort to donors. LCLs are of great practical value as an unlimited source of stable genomic DNA and viable cells, which can be used to perform a variety of biochemical and molecular studies. The basic protocol describes simple procedures for production of EBV, isolation of lymphocytes, EBV infection of lymphocytes, and isolation of the resulting LCLs.

CAUTION: Biosafety level 2 (BSL2) practices, containment facilities, and equipment are recommended for activities utilizing known or potentially infectious clinical materials or cultures of indigenous viral agents that are associated or identified as a primary pathogen of human disease (e.g., EBV).

EPSTEIN-BARR VIRUS–MEDIATED IMMORTALIZATION OF HUMAN B LYMPHOCYTES

BASIC PROTOCOL

EBV, first discovered in cell lines derived from endemic Burkitt's lymphomas (Epstein et al., 1964), has a potent ability to transform B lymphocytes in vitro (Henle et al., 1967). In these cells EBV establishes mostly a latent infection characterized by expression of a limited number of viral proteins. The availability of cell lines that readily produce EBV and efficient methods for purification of lymphocytes along with the efficient ability of the virus to immortalize lymphocytes has resulted in EBV-induced B cell immortalization as a method of choice for generating continuously growing cells from patients or patient populations. Isolation of lymphocytes is relatively simple and they can be obtained easily from small volumes of blood. The procedure is particularly useful when cell lines from specific donors are desired.

B95-8 cells are typically used for virus production since they spontaneously produce the B95-8 strain of virus, which has been molecularly and phenotypically characterized in considerable detail. However, transforming virus can be obtained from a number of other EBV-infected cell lines but the efficiency of virus production may vary considerably between cell lines and will need to be tested empirically by the investigator.

IMPORTANT NOTE: B95-8 cells were derived from Marmoset lymphocytes infected and immortalized with Epstein-Barr virus (Miller et al., 1972). Since Marmosets are an endangered species, this cell line is no longer commercially available. However, these cells are widely distributed throughout the scientific community and should be readily available from a number of investigators. If only small quantities of virus are needed, B95-8 virus can be purchased commercially (ATCC, VR-1492).

Materials

B95-8 cells

Growth medium: RPMI-1640 medium (*APPENDIX 3F*), containing 200 mM L-glutamine, with or without fetal bovine serum (FBS; *APPENDIX 3F*)

Ficoll-Paque (Amersham Biosciences 17-1440-02) or Accuspin system-histopaque-1077 tubes (SIGMA diagnostics A 6929)

Mammalian Cell Culture

28.2.1

Anti-coagulated human blood, freshly obtained
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Cyclosporine A (Sigma-Aldrich)
Storage medium: RPMI medium containing 20% to 40% (v/v) FBS and 10% (v/v) DMSO

15- and 50-ml sterile plastic, screw-cap, conical centrifuge tubes
0.45- μ m filters
96-well flat-welled tissue culture plates, sterile
24-well sterile tissue culture plates or T-25 tissue culture flasks, sterile
Additional reagents and equipment for mammalian cell culture (*APPENDIX 3F*)

NOTE: All solutions and equipment coming into contact with cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations are performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

Prepare the virus

1. Split B95-8 cells to a density of approximately 1×10^6 /ml in growth medium containing 5% FBS. Incubate the cells for 9 to 12 days.

B95-8 cells are generally maintained and passed as standard suspension cells. However, a proportion of cells may also adhere to the bottom of the flask. The adherent cells can be removed by trypsinization or by gently tapping the side of the flask to knock them off the bottom.

The total number of cells will depend on the needs of the individual investigator and the amount of virus recovered. However, 0.5 ml to 1.0 ml of supernatant (see step 2) is generally sufficient to infect lymphocytes and recover LCLs.

Alternatively, more concentrated virus preparations can be obtained by growing the cells in flasks with an attached nutrient supply chamber (Integra Biosciences, Celline CL 350 or 1000). The flasks consist of a cell compartment base capable of holding from 5 to 15 ml of suspension cells separated from a larger compartment capable of holding 350 to 1000 ml of growth medium by a cellulose acetate membrane barrier. High concentrations of cells can be maintained in this environment, allowing virus particles to accumulate in the small lower chamber. 2.5×10^7 viable cells in growth medium containing 10% FBS are introduced into the cell compartment, and 975 ml of warm growth medium containing 5% FBS is introduced into the larger compartment. At day 7, the cells are removed from the lower chamber using a sterile pipet and placed into a sterile 15-ml centrifuge tube. The cells are then centrifuged for 5 to 10 min at $250 \times g$, room temperature. Growth medium is removed by aspiration and the cell pellet is resuspended with fresh growth medium containing 10% FBS. The growth medium from the upper chamber is then aspirated and replaced, this time without FBS to encourage virus production. The entire cell suspension is harvested at Day 17.

2. Remove the cells and growth medium and place in sterile 50-ml centrifuge tubes. Centrifuge 10 to 15 min at low speed ($250 \times g$), 25°C, to pellet the cells. Remove the supernatant and filter through sterile 0.45- μ m filters to remove any contaminating marmoset cells.

If the nutrient supply chamber system was used (see Step 1 annotation), the supernatant is harvested by centrifugation and sterile filtered. Final supernatant is then aliquoted and stored at -80°C .

3. Aliquot the virus-containing supernatant into cryovials or any sterile tube that can be conveniently sealed and store at -80°C .

Virus can also be stored at 4°C for several months but will lose titer. Aliquots of frozen virus will usually maintain titers for much longer periods but will lose significant titer if freeze-thawed more than once.

4. To obtain consistent and successful results, determine a rough estimate of virus titer based on its transformation efficiency (see Support Protocol).

Isolate and infect lymphocytes

5. To a 10-ml sterile tube add 2 ml of defibrinated or anticoagulant-treated human blood and an equal volume of PBS. Mix gently using a sterile pipet.

Fresh blood should be used to ensure high viability of isolated lymphocytes.

EBV can infect and immortalize marmoset B cells (this was how B98-5 cells were obtained). However, EBV is unable to infect and immortalize B cells from the Rhesus Macaque, which is a species more closely related to humans.

6. Add 3 ml Ficoll-Paque to a sterile 15-ml centrifuge tube and carefully layer the diluted blood sample (4 ml) on top of the Ficoll-Paque layer ensuring that the two solutions do not mix.

Alternatively, blood samples can be added to Accuspin system-histopaque-1077 tube (Sigma). The main advantage of using these tubes is that they have a polyethylene barrier between the Histopaque-1077 separation medium (which is located in a lower chamber) and the diluted blood. Therefore, blood added to the top chamber can be added more quickly without risk of mixing with the separation medium and there is a clear separation of blood components after spinning. Follow the manufacturer's recommendations for spin time, force, and temperature.

7. Centrifuge 15 to 30 min at $400 \times g$, 25°C .
8. Observe partitioning of the sample into 4 phases. On the bottom, there are granulocytes and erythrocytes (red), followed by a layer of Ficoll-Paque (clear). A small cloudy-white interface containing the lymphocytes rests on top of the Ficoll-Paque. A layer of plasma (red or yellow-brown) sits on top.
9. Carefully remove and discard the plasma layer. Remove the lymphocyte layer in as small a volume as possible (~ 2 ml) and transfer to a clean, sterile 15-ml centrifuge tube.
10. Add 3 volumes of PBS (6 ml) and centrifuge 10 min at $250 \times g$, 25°C . Remove and discard the supernatant, and add 6 to 8 ml fresh PBS. Resuspend the lymphocyte pellets by gently pipeting up and down.
11. Repeat two to three times. Before the final wash, count the cells using a hemacytometer.
12. After the final centrifugation, resuspend the lymphocytes with virus-containing supernatant from B95-8 cells (an amount equivalent to 10^5 transforming units; see Support Protocol 1) and add growth medium containing 10% FBS plus $1 \mu\text{g/ml}$ cyclosporine A (final concentration) to give 6×10^6 cells/ml in a total volume of 10 to 12 ml. Aliquot $100 \mu\text{l}$ cells per well into a 96-well plate (6×10^5 cells/well). Maintain cells at 37°C in a CO_2 incubator.

To inhibit or diminish regression of B-cell proliferation, cyclosporin A is added to inhibit suppressor or cytotoxic T-cell action.

Isolate and maintain lymphoblastoid cell lines

13. After 1 week in culture, feed cells with $100 \mu\text{l}$ growth medium containing 10% FBS and $1 \mu\text{g/ml}$ cyclosporine A (final concentration). Subsequently, remove one half the medium weekly and replace with fresh medium containing cyclosporine A.
14. After 2 to 3 weeks in culture, small to large clumps of cells begin to emerge and are visible microscopically and in some cases macroscopically. Expand cells by transferring them into 24-well plates or T-25 tissue culture flasks.

In general, LCLs can be passed as standard suspension cells in RPMI containing 10% FBS. Because LCLs produce a number of autocrine factors that facilitate proliferation and viability, it is recommended that cell densities be maintained at levels no lower than $1-2 \times 10^5$ cell/ml. Conversely, cells should be diluted in growth medium containing 10% FBS when cell densities reach saturation between $2-5 \times 10^6$ cells/ml.

- Freeze and store resulting lymphoblastoid cell lines (LCLs) for future use. Centrifuge exponentially growing cells 5 to 10 min at $250 \times g$, 25°C and resuspend in storage medium containing 20% to 40% FBS and 10% DMSO at a cell concentration of $5-10 \times 10^6$ cells/ml. Freeze cells at a rate of 1°C per minute to -40°C and store in liquid nitrogen.

SUPPORT PROTOCOL

TITRATION OF VIRUS ON LYMPHOCYTES

To minimize potential negative results and experimental variability it is useful to approximate the transforming activity of B95-8 virus stocks.

Materials

Lymphocytes, Ficoll-Paque purified (Basic Protocol, steps 5 to 11)

Culture medium: RPMI (APPENDIX 3F) containing 10% (v/v) FBS and 1 $\mu\text{g/ml}$ cyclosporine A

B95-8 virus stocks to be titered

96-well flat-bottomed plates

- Prepare lymphocytes as described above and resuspend at $5-6 \times 10^6$ cells/ml in culture medium containing 10% FBS plus 1 $\mu\text{g/ml}$ of cyclosporine A.
- Aliquot water into all wells in rows A and H and in columns 1 and 12 of a flat-bottomed 96-well plate to help prevent evaporation of medium in wells nearest to the edges of the plate.
- For each virus, aliquot 100 μl of cells per well in rows B to G in triplicate (i.e., three columns and six rows per virus, up to three viruses per plate).
- Aliquot 100 μl of cells in one column for a negative control. Add an additional 100 μl of culture medium to bring final volume to 200 μl .
- Dilute 200 μl virus stock 1:5 in culture medium (10^{-1}) and make five 10-fold dilutions of virus (10^{-2} to 10^{-6}) in culture medium in sterile 1.5-ml tubes (make sure to change tips between each dilution).
- Aliquot 100 μl of 10^{-6} dilution of virus into three wells in row G.
- Aliquot 100 μl of 10^{-5} dilution of virus into three wells in row F and continue until the 10^{-1} dilution is aliquoted into wells in row B. Transfer cells to a 37°C incubator and feed weekly by replacing half the medium with fresh culture medium.

Transformed cells clumps should be evident within a few days in the 10^{-1} and 10^{-2} dilutions but will take longer in the higher dilutions. The highest dilution giving rise to transformed cells after 4 to 5 weeks approximates the transforming titer of the virus stock.

COMMENTARY

Background Information

Epstein-Barr virus (EBV), a versatile lymphotropic γ -type human herpesvirus or Lymphocryptovirus (LCV), is endemic in all human populations (Rickinson and Kieff, 2001). Most people are infected during early child-

hood with no apparent clinical features. However, delayed infection occurring in adolescence or in young adults can result in mononucleosis, which is usually a benign lymphoproliferative disease. In combination with genetic, environmental, or iatrogenically

induced conditions, EBV is an important cofactor with a causal link to a wide variety of human malignancies including Burkitt's lymphoma, gastric carcinomas, nasopharyngeal carcinoma, T-cell lymphomas, Hodgkin's disease, post-transplant lymphoma-like disease (PTLD), and leiomyosarcomas.

EBV possesses an intrinsic ability to transform human B cells in culture. Cellular growth control is mediated through the concerted action of several latent cycle gene products including EBV nuclear antigen-leader protein (EBNA-LP), -2 (EBNA2), -3A and -C (EBNA3A and EBNA3C), and latent membrane protein one (LMP-1; Bornkamm and Hammerschmidt, 2001). Viral genomes are usually maintained as circular episomes but occasionally can integrate into host DNA.

The high efficiency of EBV-induced B cell immortalization (Sugden and Mark, 1977) makes it an ideal tool for generating cell lines derived from any individual (Neitzel, 1986). The applications for EBV-immortalized cell lines are many and include investigation of signaling pathways involved in B cell growth and proliferation, generation of cytotoxic T cells (CTLs) for cellular immunotherapy, and a variety of molecular and genetic studies.

Critical Parameters and Troubleshooting

Failure to obtain immortalized cell lines can be due to several problems. First, the viability of lymphocytes/mononuclear cells used for infection is important. Usually, freshly isolated cells work best. However, blood samples stored up to 4 days can be immortalized. Lymphocytes that have been frozen can also be thawed and immortalized, although this is often at lower efficiency. A second problem encountered may be the loss of infectious virus in the virus preparations or variability in the titer between different virus preparations. It is recommended that a large batch of virus be prepared, aliquoted, and stored. The virus can be titered for transformation efficiency and should retain good viability during long-term storage at -80°C . Addition of cyclosporine A increases the efficiency of LCL outgrowth by inhibiting the emergence of EBV-specific T cells (Bird et al., 1981).

Anticipated Results

Using the methods described here, multiple cell lines should emerge from an individual infection.

Time Considerations

After blood samples are obtained, preparation of lymphocytes, infection with EBV, and plating will take 1-3 hr for a few samples. The time required to obtain EBV-immortalized cell-lines is usually 2-4 weeks. Amplification of the cell lines to obtain cell numbers required for experimental manipulation may take additional time, depending on the amount of cells needed for a specific application.

Establishment and Culture of Human Skin Fibroblasts

UNIT 28.3

In some instances, patient-derived skin fibroblast lines afford advantages over continuous transformed cell lines, in that biochemical abnormalities underlying a disease state may be reproduced in the patient samples. Historically, human dermal fibroblast lines established from patient biopsies have been instrumental in studies designed to elucidate the pathogenesis of several diseases, such as the characterization of the low density lipoprotein (LDL) receptor in familial hypercholesterolemia (FH; Basu et al., 1978), the function of the androgen receptor (AR) in androgen insensitivity syndrome (AIS; reviewed in Quigley et al., 1995), and the deficiency of hypoxanthine-guanine phosphoribosyl transferase (HGPT) of Lesch-Nyhan Syndrome (Migeon et al., 1968).

GENITAL SKIN BIOPSY FOR GENERATION OF FIBROBLAST CULTURES

**BASIC
PROTOCOL 1**

Biopsies to obtain material for the establishment of fibroblast cultures are invasive procedures. As such, the benefits to patients should be weighed against the risks of the procedure (albeit minor), which include the risks of bleeding from and infection at the biopsy site. In all instances, protocols describing the proposed studies must be reviewed and approved by the local institutional review committees, and informed patient consent is required. While somewhat less onerous, regulations governing the use of animal subjects also require that adaptation of these methods to animal subjects be approved by the local Institutional Animal Care and Use Committee (IACUC). As with the acquisition of any sample from patient or animal, health risks to the investigator, such as the possibility of contracting various diseases from the patient, should be taken into consideration. Sterile technique is essential at all steps. While not required, the use of gloves facilitates the implementation of sterile technique and minimizes any risks from infectious diseases.

Materials

Betadine solution

Sterile saline solution: 0.9% (w/v) NaCl in deionized, distilled water

1% sterile lidocaine solution

Biopsy culture medium (see recipe)

Scalpel and forceps, sterile (autoclaved)

50-ml conical tubes

Silver nitrate sticks (silver nitrate applicators, 75% w/w, Arzol Chemical)

4-0 Vicryl suture

1. Clean skin with Betadine solution and rinse the area with sterile saline solution.
2. Achieve local anesthesia by local subcutaneous injection of a 1% sterile lidocaine solution.
3. With sterile scalpel and forceps, take two full-thickness skin biopsies ($\sim 5 \text{ mm}^3$).

Depending on the studies to be conducted, specific sites may be preferred. For example, for studies of the AR, genital skin biopsies are employed. In males, take one from the base of the phallus and the other from the base of the scrotum; for females take one from the base of the clitoris and one adjacent to the vaginal opening (labia majora).

4. Place biopsies into 50-ml conical tubes and fill with biopsy culture medium, excluding as much air as possible from the tube.

Subsequent handling should be at room temperature (25°C).

**Mammalian Cell
Culture**

28.3.1

5. To control bleeding at the biopsy site, apply a silver nitrate stick by moistening the tip of the silver nitrate stick with sterile water or saline. Apply the stick to the site of wound (there is a slight burning sensation, usually accompanied with a skin color change which indicates sealing of the wound). Apply wet gauze to wound site. If necessary, suture skin with 4-0 Vicryl suture (one to two stitches).

Optimally, specimens should be processed quickly to establish the primary cell lines. However, biopsies may be stored in culture medium for 3 to 4 days at 4°C. If samples are to be shipped, this time limit should be taken into consideration as well as the time needed to establish the primary cell line in the receiving laboratory. Samples should be shipped in containers filled completely with culture medium at room temperature. If extremes of temperature are anticipated, shipment in an insulated container will help to preserve biopsy viability.

ESTABLISHMENT OF PRIMARY CULTURES OF SKIN FIBROBLASTS

Utilization of the primary explant method (see Basic Protocol 1) for the establishment of primary cultures from biopsies provides an easy method of generating fibroblast strains. Sterility and aseptic technique play important roles in the establishment of cell lines that are viable and free of contaminating pathogens.

Materials

Biopsy (see Basic Protocol 1)
Dulbecco's modified phosphate-buffered saline (DPBS) without calcium or magnesium (Cellgro or see recipe)
Primary culture medium (see recipe)
25-cm² tissue culture–treated flasks with 0.22- μ m filter caps
Forceps, scissors, and scalpels, sterile (autoclaved)
6-cm tissue culture dish
1-ml tuberculin syringe (disposable) with 23-G needle
37°C, 5% CO₂ humidified circulating incubator
Inverted microscope

1. Label two 25-cm² tissue culture–treated flasks for each specimen with the biopsy identifier information, distinguishing them from one another by specific designations (e.g., A and B).

Each biopsy will be split into duplicate flasks and, if possible, housed in different incubators. This provides a backup in case one of the flasks becomes contaminated or lost in the primary culture setup.

2. While working under a laminar flow hood, remove the excess biopsy culture medium present in the conical tube that contains the biopsy. Add 10 ml of DPBS (without calcium and magnesium) to completely saturate and wash the biopsy. Aspirate the DPBS and repeat two additional times for a total of three washes.

The DPBS wash volume should be adequate to remove loose fibers and contaminants (such as hair) and excess biopsy culture medium; generally 10 ml should suffice.

3. Utilizing sterile forceps, remove the biopsy to a sterile 6-cm tissue culture dish containing ~7 ml primary culture medium. With a fresh pair of sterile forceps and sterile scissors, cut the biopsy into small pieces.
4. Using either a sterile scalpel or scissors, refine the size of the biopsy pieces to a size that is approximately that of a pinhead.

- Using a 1-ml tuberculin syringe with a 23-G needle attached, take one pinhead-sized explant and place it into one of the 25-cm² flasks (the explant should be moist from the primary culture medium). Repeat this procedure, adding at least seven explants to each duplicate flask.

In adding more explants, the probability of establishing the primary cell line and having better growth in the flasks is increased.

- Allow the explants sufficient time to adhere to the primary culture flask (~15 to 20 min). Then add 12 ml primary culture medium to the flask, being careful not to detach the explants.

In steps 5 and 6, speed and efficiency are important. Once the explants have been placed into the flasks, it is important to allow enough time for the explants to firmly attach to the surface of the flask, but not so long that they will dry out. If the explants are not allowed sufficient time to adhere, they will float off when medium is added and, under these conditions, outgrowth of the fibroblasts from the explants will be unlikely. A helpful frame of reference to determine whether sufficient adherence has occurred is to assess when the residual medium has dried and formed a "halo" around the explants. Once this halo has formed, it is safe to gently add primary culture medium to the explants.

- Carefully place the flasks into a 37°C, 5% CO₂ humidified circulating incubator for human skin fibroblast cultures.

- After 5 to 7 days, remove the medium and add fresh primary culture medium to the flask.

Adding medium prior to this time may perturb the explants; optimally, every advantage for the explants to firmly attach and grow should be given.

- After the initial replacement of medium, check fibroblast cultures daily for growth, surface coverage (confluence), and contamination using an inverted microscope with a 10× objective. Replace medium approximately every 3 days until cell lines are established.

Contaminants such as bacteria, mold, and fungus—if present—will be observed within a few days.

ESTABLISHMENT AND MAINTENANCE OF SKIN FIBROBLAST CELL LINES

BASIC PROTOCOL 3

The time for outgrowth of the biopsy explants to reach confluence is generally ~2 to 3 weeks. Note that the number and size of explants per flask, the health of the explants from biopsy to implantation into a culturing vessel, and the general health of the outgrowth from the explants all contribute to the growth and time of confluence of the eventual primary fibroblast cell line. In addition, cultures established from young subjects will generally grow with greater vigor than those established from older subjects. Once the biopsy explants have covered between 75% and 90% of the culture area, a fibroblast cell line may be commenced as described.

Materials

- Explants grown in 25-cm² tissue culture–treated flasks (see Basic Protocol 2)
- Dulbecco's modified phosphate-buffered saline (DPBS) without calcium or magnesium (Cellgro or see recipe)
- 0.25% trypsin/EDTA solution: 2.5 g/liter porcine trypsin and 0.38 g/liter EDTA·4Na⁺ in Hanks' balanced salt solution (HBSS; commercially available as a 1× solution)
- Fibroblast culture medium (see recipe)
- 75-cm² tissue culture–treated flasks with 0.22-μm filter cap
- 10-ml pipets

Mammalian Cell Culture

28.3.3

1. When explant growth has covered ~75% to 90% of the culture area, commence trypsinization by removing the medium.
2. Wash culture surface of the 25-cm² flask by adding 4 ml DPBS without calcium or magnesium. Rinse and remove by aspiration.
3. Add 1 ml of 0.25% trypsin/EDTA solution to the culture surface and allow cells to detach.

It is best to observe cell detachment via 10× magnification under an inverted microscope. Fibroblasts generally retract and detach after 1 to 2 min. It is preferable to minimize the length of time that the cultures are treated, as excessive trypsinization will kill cells. Tapping the flask gently will help dislodge cells that are loosely attached.

4. Add 3 ml fibroblast culture medium to the flasks. Gently pipet the trypsin and fibroblast culture medium mixture up and down to make a homogenous suspension.
5. To a 75-cm² tissue culture–treated flask that contains 10 ml of fibroblast culture medium, add all 4 ml of the cell solution. Place the 75-cm² flask into the 37°C, 5% CO₂ incubator. Allow fibroblasts to grow to confluence.

Generally, confluence of the fibroblast is seen within 5 days, depending on the health and condition of the cells.

6. Once the cells have become confluent, trypsinize and passage cells as above, with the exception of adding 2 ml trypsin/EDTA solution followed by 4 ml fibroblast culture medium into the 75-cm² culturing vessel.

Generally, the cells may be split at a ratio of one flask of confluent cells into three new flasks (i.e., 1:3). Take 2 ml of the total 6 ml of trypsinized cell solution, as previously described, and add to a 75-cm² flask containing 10 ml fibroblast culture medium. Thus, each confluent flask is sufficient to start three new flasks. A confluent 75-cm² flask contains ~1.5 × 10⁶ cells.

Each subsequent passage from the first trypsinization to the point where the cells are frozen cryogenically should be noted. Every laboratory has a specific stringency and strictness on how many passages are allowed before frozen preservation. In general, the fewer passages before cryogenic preservation and use in subsequent functional assays, the healthier the cell lines will be. After several passages (e.g., 3 months), the fibroblast growth rate will decrease and cell lines will, therefore, take longer to reach confluence. Morphological differentiation of fibroblasts may be minimal and can be hard to distinguish even under microscopic magnification. This decrease in cell growth is the best indicator of cell line differentiation and eventual cell senescence. Hence, it is best to freeze cells from initiation to no more than nine passages.

CRYOGENIC PRESERVATION OF SKIN FIBROBLAST CELL LINES

Cryogenic preservation of fibroblasts is generally the same as cryopreservation of most continuous epithelial cell lines. The addition of DMSO to a final concentration of 10% permits the long-term preservation of cells at –80°C or in a liquid nitrogen freezer (Sherman, 1965).

Materials

- Fibroblast culture medium (see recipe)
- Dimethyl sulfoxide (DMSO), sterile
- Established fibroblast cell lines in 75-cm² tissue culture flasks (see Basic Protocol 3)
- Dulbecco's modified phosphate-buffered saline (DPBS) without calcium or magnesium (Cellgro or see recipe)
- 0.25% trypsin/EDTA solution: 2.5 g/liter porcine trypsin and 0.38 g/liter EDTA·4Na⁺ in Hanks' balanced salt solution (HBSS; commercially available as a 1× solution)

15-ml conical tube
Sterile freezing vials (1.5- to 2-ml ampules)
Cryogenic freezing container (e.g., Cryo 1°C Freezing Containers, “Mr. Frosty,”
Nalgene Labware) or liquid nitrogen freezer

1. To fibroblast culture medium, add DMSO to a concentration of 10% (v/v) to make the freezing medium.
2. Wash culture surface of the 75-cm² tissue culture flask by adding 4 ml DPBS without calcium or magnesium. Rinse and remove by aspiration.
3. Add 2 ml of 0.25% trypsin/EDTA solution to the culture surface and allow for cell dissociation.

It is best to observe cell detachment via 10× magnification under an inverted microscope. Fibroblasts generally retract and detach after 1 to 2 min of trypsinization. It is preferable to minimize the time of exposure, as excessive trypsinization will kill cells. Tapping the flask gently will help dislodge cells that are loosely attached.

4. Add 4 ml fibroblast culture medium to the flask. Gently pipet the trypsin and fibroblast culture medium mixture up and down to make a homogenous suspension.
5. Add cell suspension to a 15-ml conical tube and centrifuge 5 min at 650 to 1000 × g, 4°C.
6. Aspirate off fibroblast culture medium and resuspend cell pellet in 2 ml freezing medium. Pipet up and down to make a homogenous suspension and add 1 ml to each of two 1.5- or 2-ml freezing vials (ampules).

Freezing volume can be modified to accommodate the various sizes of freezing vials/ampules that are available. Even if the freezing volume changes, the amount of DMSO for cryogenic preservation must be maintained at 10% (v/v) of the freezing volume, with the amount of cells frozen per vial roughly equal to half of those obtained from the confluent culturing vessel from which they were derived. Freezing back approximately half of a culture in each vial assures advantageous growth and survival after future thawing since a small portion of cells do not survive the freezing and/or thawing associated with cryogenic preservation. Each vial should be appropriately labeled with identifier information and cell passage number.

7. Place vials into cryogenic carrier (e.g., Mr. Frosty) and allow to freeze at a rate of 1°C/min at –80°C overnight. Cryogenically preserve in a liquid nitrogen freezer.

If cells are preserved in liquid nitrogen, in theory they can be stored indefinitely. Cells can be stored at –80°C, however not indefinitely. Fibroblasts stored at –80°C will lose viability more rapidly than those stored in liquid nitrogen.

8. Before use in functional assays, thaw cells quickly in a 37°C water bath or by quickly thawing while rubbing the vial between the hands. Wipe vial with 70% ethanol to remove any possible contaminants derived from either the water bath or hands. Allow cells to revive growth by either of the following.
 - a. Pipet thawed volume of cells directly into 10 ml of fibroblast growth medium in a 75-cm² culturing flask and allow for cells to attach to the vessel. Replace the medium on the following day.
 - b. Place thawed cell suspension into a sterile 15-ml conical tube containing fibroblast growth medium. Centrifuge cells at 650 to 1000 × g, 4°C, to pellet the cells. Remove all of the supernatant and resuspend cell pellet in fresh 10 ml fibroblast growth medium. Transfer the cell suspension into the culture vessel. Replace medium on the third day, as for normal routine feeding.

In the first option (a), the DMSO present in the freezing medium is being diluted but not removed, and in high percentages can be toxic to growing fibroblasts. As such, cells should not be left for more than 1 day in the DMSO-containing medium, which should be changed the following day (preferably in the morning). In the second option (b), the cells are quickly removed from contact with the DMSO-containing medium (when the medium is removed by centrifugation). However, the mechanical manipulation may decrease the proportion of cells that survive the thawing process.

After cells that survived the thaw have grown to confluence, they may be passaged for several months (generally 3 months). As noted above, after several passages, cells will exhibit slowing growth rates and eventual cell senescence (see Basic Protocol 3, step 6 annotation).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Biopsy culture medium

Aseptically combine:

400 ml minimum essential medium (MEM; APPENDIX 3F)

100 ml fetal bovine serum (FBS; APPENDIX 3F)

5 ml penicillin/streptomycin solution (10,000 U/ml penicillin G and 10,000 µg/ml streptomycin; commercially available from multiple sources, e.g., Sigma)

Store up to 2 months at 4°C

This mixture gives rise to 20% FBS and 1% antibiotic in MEM.

DPBS without Ca²⁺ and Mg²⁺

0.20 g/liter KCl

0.20 g/liter KH₂PO₄

8 g/liter NaCl

1.15 g/liter NaH₂PO₄

Final pH 7.4

Autoclave

Fibroblast culture medium

Aseptically combine:

400 ml minimum essential medium (MEM; APPENDIX 3F)

100 ml fetal bovine serum (FBS; APPENDIX 3F)

5 ml penicillin/streptomycin/Fungizone solution (commercially available in 10,000 U/ml penicillin G, 10,000 µg/ml streptomycin, 25 µg/ml amphotericin B; e.g., Mediatech)

Store up to 2 months at 4°C

This mixture gives rise to 20% FBS and 1% antibiotic in MEM.

Medium should be stored at 4°C, but should be warmed in a 37°C water bath prior to addition to cells. After use, close tightly to avoid oxidation of medium by air and return for long-term storage at 4°C.

Primary culture medium

Aseptically combine:

400 ml minimum essential medium (MEM; APPENDIX 3F)

100 ml fetal bovine serum (FBS; APPENDIX 3F)

5 ml penicillin/streptomycin/Fungizone solution (commercially available in 10,000 U/ml penicillin G, 10,000 µg/ml streptomycin, 25 µg/ml amphotericin B; e.g., Mediatech)

Anti-mycoplasma reagent (amount varies per manufacturer's instructions; 1 × final concentration; e.g., Mycoplasma Removal Agent, MP Biomedicals)

Store up to 2 months at 4°C

Medium should be stored at 4°C, but should be warmed in a 37°C water bath prior to addition to cells. After use, close tightly to avoid oxidation of medium by air and return for long-term storage at 4°C.

COMMENTARY

Background Information

Although there are several ways to establish fibroblast cultures from human biopsies, the methods described have been utilized to establish a large number of cell strains that have been used successfully in a variety of in vitro studies (Avila et al., 2002). With little modification, these methods can be applied to establish fibroblast strains from other species as well (Catalano et al., 2002). Generally, the characteristic appearance of spindle-shaped cells aligned in monolayers as “whirls” (see Fig. 28.3.1) is a good indication of the health of the cultures.

There are many methods for the initiation of fibroblast cultures from human biopsies. As reviewed in Freshney (2000), many techniques are based on modification of the primary explant methods initiated by the works of Harrison (1907) and Carrel (1912), and incorporate changes permitted by improvements of

tissue culture reagents. The methods described in this unit follow a generalized modified version of these techniques as applied in the studies of fibroblast cultures in the analysis of subjects with defects of the androgen receptors (AR; Avila et al., 2002, and references therein). The nature of the fibroblast cell line and any contaminant cell types will be affected by the anatomical site from which the biopsy was obtained. Adipose cells, hair cells and follicles, and necrotic cells may be present. Adipose and hair cells will be fairly evident to inspection and are respectively removed in the wash steps and fine dissection of the biopsy into pinhead-sized explants. Thus, selection is favored towards cells that should give outgrowth, which are the fibroblasts.

General growth conditions such as 37°C, carbon dioxide exchange, humidified incubation are favorable for many cell lines and contaminants (e.g., bacteria, yeast, and mold), and

Figure 28.3.1 Healthy human fibroblasts in late exponential, early log phase growth. Fibroblast monolayers established from a genital skin biopsy and grown in MEM containing 20% FBS. Cells were stained with Giemsa stain and visualized under a phase-contrast microscope (magnification ~40×). Photo is printed in grayscale.

therefore, one should check for contaminants on a weekly—if not daily—basis. The fibroblast culture medium (MEM and 20% FBS) is favorable towards fibroblasts derived from patient biopsies and thus richer media (such as DMEM or F12) are not necessary. Fibroblasts, as is true for many cell lines, may display serum sensitivity and react favorably or negatively toward certain lots of serum, due to the varying nature of serum. However, most companies are willing for laboratories to compare their stock lots of FBS and will provide 50 ml of different lots for serum testing. There are other supplemented FBS specifically directed towards fibroblast growth, however, many fibroblast cell lines have been initiated and maintained in bovine calf serum and supplemented calf serum (e.g., Cosmic Calf Serum commercially available from Pierce/Hyclone).

Critical Parameters

Biopsies. To enhance the likelihood that healthy fibroblast cell lines are successfully established, minimize the time from biopsy to the establishment of tissue culture. Biopsies are viable for a finite period of time (typically up to 3 to 4 days). The shorter the time to culture, the greater is the likelihood that a biopsy can be successfully manipulated to establish a cell line.

Primary cultures. One of the most important and most challenging aspects in establishing the primary culture from the explant arises in permitting the adherence of the explant to the culturing vessel before adding the growth medium. As mentioned in Basic Protocol 2 (also see Time Considerations), looking for the appearance of a halo around the explant and giving a 10- to 20-min settling time should allow the explant to attach before the growth medium is added. The time it takes for the halo to dry and for the explant to attach is dependent on how much medium is on each individual explant and on the size of the explant. In general, a small explant with minimal medium will take less time to attach to the culture vessel than a larger explant that is saturated in growth medium. If a portion of the explant adheres to the vessel while another portion hangs suspended in the growth medium, the explant can still produce outgrowth from the adhered portion. Although experience will aid in the timing of this critical juncture, it is not impossible for a novice to achieve successful explant adherence with minimal loss of adherence when the growth medium is added, and to have good outgrowth from the explants.

Finally, as with any tissue culture procedures, sterile technique to keep the explants free from contaminants such as fungi, mold, and bacteria will always enhance the generation of a new cell line.

Cell lines. Although fibroblast cell lines usually do not require precise methods for maintenance, establishing a regular regimen of trypsinization and feeding will optimize the health of the established cultures. Sterile technique will protect the cell lines from contamination from microorganisms (yeast and bacteria, in particular) at all stages. Although self-evident, the use of sterile pipets and plasticware specifically designated for each cell strain will minimize possible contamination by other cell lines.

Cryogenic preservation. The cryopreservation of healthy cell lines will usually yield a high rate of viability after the cells are thawed. It should be noted, however, that the rate at which the cells are frozen at -80°C and the number of passages before cryopreservation will also affect cell viability at thawing.

Troubleshooting

There should be few complications in obtaining and manipulating the skin biopsy. Bleeding by the patient, as mentioned, should be controlled with a silver nitrate stick and closure of the site with appropriate suturing. One problem that is often encountered is from attempts to permit the attachment of the biopsy explants to the culturing vessel without sufficient drying. If there is no attachment of the explant to the culture vessel, it is unlikely that cell outgrowth will occur.

Anticipated Results

By using these protocols, healthy fibroblast cell lines can be obtained from human skin biopsies. With minor modifications, these same protocols can be applied to establish fibroblast lines from most mammalian species. In addition to providing genetic material for use in studies to investigate the genetic basis of disease, these lines may provide a physiological model system in which to explore normal or altered cellular pathways present in cells derived from the patient biopsy.

Time Considerations

Biopsies. It is best to coordinate the time of biopsy with the timing of the manipulations needed to initiate the primary culture, especially if the biopsy is to be shipped. If kept in medium at 4°C , the biopsy can be stored for 4 days.

Primary cultures. As coordinated with the time of the biopsy, biopsies should be processed as quickly as possible. In utilizing the primary explant method, the main challenge is allowing sufficient time for the explants to adhere and quickly reestablishing them in growth medium without having the explants float off.

Cell lines. Daily observance of explant growth will facilitate the transition of explants to cell lines. Timing from explant to the point of the subculture of outgrowth depends on the number of healthy explants successfully attached. With five explants, this takes ~2 to 3 weeks, depending also on the natural growth of the explants.

Cryogenic preservation. Once established, samples should be preserved as early as possible and the number of passages minimized.

CHAPTER 29

Mouse Phenotyping

INTRODUCTION

When *Current Protocols in Molecular Biology* first appeared in 1987, cloning and sequencing mammalian genes was a major goal of many laboratories. That era of gene discovery ended with the completion of the genome sequences for humans and increasing numbers of mammalian and other species. From a broad perspective, these genome sequences represent a remarkable accomplishment for humankind, of which molecular biologists can be proud. However, they are certainly not just trophies to be put on the shelf or files to be stored on hard drives, but one of the most powerful tools available in the current era of gene function.

Exploiting these tools is dependent on appropriate biological systems. “Simple” model organisms have provided numerous major insights into developmental processes, for example. Some problems, however, such as metabolic diseases and complex behaviors, are best addressed in mammalian species. Decades of physiologic, endocrinologic, and behavioral studies have focused on rodents, and this deep pool of information is now complemented by extensive genetic tools. Modern genetic studies in mice, like *Drosophila*, date to pioneering work of Haldane (Haldane, J.B.S., Sprunt, A.D., and Haldan, N.M. 1915. Reduplication in mice. *J. Genet.* 5:133-135.5). As described in Chapter 23, however, classic genetic approaches have been supplemented by powerful techniques for manipulation of the mouse genome. These extensive tools make the laboratory mouse, *Mus musculus*, the mammalian system of choice for genetic analysis.

These diverse genetic technologies produce large numbers of mice with potential phenotypes of all types. In some cases, loss of gene function results in prenatal lethality. This is perhaps the most obvious phenotype and highlights the potential importance of the gene product. It can also be problematic because it substantially complicates detailed analysis of molecular mechanisms. In many other cases, the phenotypes of gene knockouts are less severe than anticipated, often due to functional redundancy. In such circumstances, more detailed analysis often reveals strong phenotypic effects that are not immediately evident. This chapter will present a variety of approaches to analyze phenotypes of mutant mice, with an initial focus on metabolic parameters.

UNIT 29A.1 reviews approaches to genetic manipulation in the mouse, including both knockout and transgenic technologies detailed in Chapter 23 and modern approaches to analysis of quantitative traits using inbred strains. General issues faced in mouse phenotyping, such as housing and other environmental factors, are considered in *UNIT 29A.2*. *UNIT 29B.1* begins the section on metabolic regulation with analysis of energy balance. Because body weight is so tightly regulated at a variety of levels, it is surprising that many mutant mice exhibit either increased or decreased weight gain, particularly in response to high fat diets or other dietary challenges. *UNIT 29B.1* presents a detailed plan for analysis of such phenotypes. Future units in metabolic regulation will focus on glucose metabolism and lipid metabolism. Techniques for analysis of behavioral phenotypes will be the basis for a forthcoming section.

Mouse
Phenotyping

29.0.1

Supplement 74

GENERAL CONSIDERATIONS IN MOUSE PHENOTYPING

Mice and humans share powerful genetic and biological similarities. In addition, mice are small in size, cheap to house, and have a short lifespan and large litter size, making them an excellent model for scientific investigation. Furthermore, problems of genetic and environmental heterogeneity can be minimized in the mouse, as genetic background and environmental factors can be rigorously controlled. The ability to insert or selectively delete predetermined genes in whole animals, as well as the use of genetic reference populations to study complex traits and quantitative trait loci, provide enormous power for analyzing gene function. With these successes in mouse genetics, the critical factor in the use of phenogenomic strategies is the need for an efficient and vigilant process for mouse phenotyping. It is now recognized that the phenotype of a mouse (behavioral, metabolic, and so on) is highly dependent on genetic, developmental, and environmental factors. All phenotyping experiments must begin with careful consideration of these factors, which can influence all variables and bias the resulting phenotype.

Uses of Forward and Reverse Genetics in Mice to Study Gene Function

The purpose of this chapter is to bridge the gap between molecular biology and physiology so that the novice mouse user has the required vocabulary and background information to understand the molecular origin of the mouse to be phenotyped (also see Argmann et al., 2005). This unit summarizes the diverse genetic strategies used in the mouse, and serves as a prelude to the detailed phenotyping protocols that follow. Protocols for carrying out the genetic manipulations themselves are described elsewhere in this manual, and appropriate units are cross-referenced here.

It is becoming common practice for genetically engineered mouse models (GEMMs) to be generated in collaboration with core facilities having technical expertise in this field. Furthermore, many GEMMs or genetic reference populations (GRPs) can be readily purchased from commercial suppliers. There are a number of ongoing attempts to facilitate the accessibility of available mouse strains, including an international resource that is presently being consolidated in the form of a searchable online database (<http://www.informatics.jax.org/imsr/index.jsp>). This database will regroup all mouse strains and stocks available worldwide, including inbred, mutant, and genetically engineered

strains. For additional mouse-related Web sites, see Internet Resources.

REVERSE GENETICS

Reverse genetics is a gene-driven approach that deduces, from directed mutations, the full range of phenotypes controlled by each gene. This strategy relies on engineering the mouse genome through adding, subtracting, and replacing genes to control gene activity temporally, spatially, and reversibly. Three reverse genetics approaches are described below.

Transgenics

The production of transgenic mice (UNIT 23.1) is a gain-of-function approach to manipulation of the mouse genome (Clarke, 2002; Nagy et al., 2003; Hedrich, 2004). Transgenic mice can be designed for numerous purposes including: (1) identification and characterization of specific regulatory sequences; (2) ubiquitous or tissue-specific overexpression of a transgene; and (3) cell lineage ablation achieved by coupling a tissue-specific promoter to a sequence encoding a toxin which kills cells that express it. Transgenic mice are typically generated by microinjection of the transgene construct into the male pronucleus of fertilized oocytes, which are then

reimplanted into the oviducts of foster females (UNIT 23.9). Expression of the transgene is dependent on its site of integration, with individual insertion sites typically containing multiple copies of the transgene. It is important to keep in mind that transgene copy number and expression levels of the transgene do not necessarily correlate. When chromosomal integration occurs in the fertilized oocyte, the developing animal will be fully transgenic, since all nucleated cells in the animal will contain the transgene; however, if integration occurs later, at a postzygotic stage, the animal will be a mosaic, with some cells containing the transgene and others lacking it. Founders are identified through analysis of tail biopsies, and copy number and transgene integrity are then evaluated. To establish a transgenic line, a founder is bred to mice of a defined genetic background and offspring are characterized for expression of the transgene. Generally at least two founders should be maintained for experiments. Due to the nature of random integration, no two transgenic lines will be identical. Details on the identification and analysis of founders and the establishment of transgenic lines can be found in UNIT 23.9.

Transgenics carrying large segments flanking a gene of interest isolated as bacterial artificial chromosomes (BACs) have been used to minimize the abovementioned variation due to the effects of different integration sites (UNIT 23.1). The versatility of this strategy has been significantly increased by the development of homologous recombination-based strategies to mutagenize and manipulate the BAC constructs (UNITS 1.16 & 23.11) and the use of regulated transgenics (e.g., with tetracycline; UNIT 23.12). In the GENSAT project (<http://www.ncbi.nlm.nih.gov/projects/gensat>; Gong et al., 2003), for example, an atlas of gene expression in the mouse central nervous system is based on large numbers of BAC transgenics in which the protein-coding sequences of genes expressed in the brain are replaced by an EGFP reporter.

Knockouts

Gene knockout or ablation (UNIT 23.1) is a powerful strategy to define the range of phenotypes associated with the loss of function of a gene of interest. The reverse genetic strategy of one gene—one protein—one phenotype can often aid in elaborating complex “wiring” diagrams and placing genes into biochemical pathways such as those defined by environmental stimuli, cell surface receptors, downstream targets, and changes in gene expres-

sion. There are a number of potential problems with full-knockout GEMMs, however, particularly when the phenotypes of homozygous null mutants are extreme (e.g., when they result in embryonic or perinatal lethality).

This drawback has been overcome through the increasing use of conditional GEMMs, whose genomes are subject to temporal and spatial controls (UNIT 23.1). To generate conditional knockout mice, a conventional gene-targeting strategy is used to generate homologous recombinants, whereby parts of the gene of interest are flanked by site-specific recombination sequences such that the gene retains normal function in the embryonic stem (ES) cells and offspring mice. The most commonly used site-specific recombination system is the Cre-*loxP* system from P1 bacteriophage (Branda and Dymecki, 2004). Gene-targeting constructs are generated so that *loxP* elements flank the region of the genome to be deleted. Following germline transmission, mice that carry alleles flanked by *loxP* (“floxed” alleles) are subsequently bred with a tissue-specific Cre transgenic mouse. The resulting bigenic mice carry both floxed alleles and a Cre transgene (which can be tissue specific). The Cre recombinase mediates recombination between two *loxP* sequences, thereby excising the sequence between the two *loxP* sites and hence creating a gene deletion. An added sophistication to such spatially controlled mutagenesis is the inclusion of temporal control, which can be achieved by using ligand-activated chimeric recombinases (Metzger and Chambon, 2001). These are usually chimeric proteins in which the recombinase is fused with the ligand-binding domain of a nuclear receptor, such as the estrogen or progesterone receptor, enabling gene ablation at any time by administration of the corresponding nuclear receptor ligand, e.g., tamoxifen or RU-486 (Metzger and Chambon, 2001). The expression of a transgene can also be controlled in a temporal fashion through the use of either hormonally (e.g., ecdysone) or pharmacologically (e.g., tetracycline) inducible gene-expression systems.

Gene Trapping

Gene trapping is a mutagenesis strategy that involves the transfection of ES cells with a gene-trap vector, which is based on the use of a reporter and/or selection marker to identify a trapping event. One strategy involves a promoter trap, which carries a promoterless reporter gene and a selection marker gene under the control of its own promoter. In this instance, the reporter gene is transcribed only

when the construct is correctly inserted in the promoter region of an endogenous gene. Alternatively, there are polyadenylation trap strategies, in which a constitutive promoter drives the transcription of the selection markers. Because the polyadenylation-trap vector lacks a poly(A) signal, the transcript is only stabilized as long as the gene-trap vector is integrated in the correct orientation and captures the poly(A) signal of the trapped gene. Once a library of “trapped” ES cells has been selected, insertion points are precisely determined for each line by sequencing the region neighboring the gene-trap vector (Koutnikova et al., 2003; Hedrich, 2004).

Since gene-trapping mutagenesis techniques are relatively high-throughput strategies, it is expected that they will greatly facilitate functional gene annotation. For this reason, several consortia plan to carry out functional annotation of the entire mouse genome via systematic mouse genome mutagenesis using gene-trapping as their primary strategy (Austin et al., 2004; Auwerx et al., 2004). One disadvantage associated with gene-trapping is that the impact of the mutation on protein function must be carefully determined.

FORWARD GENETICS

In contrast to the reverse genetic approach, forward genetics is centered on phenotype-driven gene discovery. The approach consists of identifying a phenotype of interest in mutant mice derived by chemical mutagenesis, radiation mutagenesis, or even spontaneous mutation, and then determining the mutation responsible for the phenotype. Prior to the introduction of technologies for manipulating the mouse genome, this was the only genetic strategy available. Continued enthusiasm for forward genetics over specifically targeted strategies is due to the random nature of the mutations, which cover the full gamut from point mutations to insertions, deletions, and rearrangements, and thus produce a full spectrum of changes to protein structure and function.

Many of the mutant mouse models used to date in forward genetic strategies have arisen from spontaneous single-gene mutagenesis events that produced striking phenotypes. The most notable examples in the metabolic field are mutations in leptin (*Lep^{ob}*; Zhang et al., 1994), leptin receptor (*Lepr^{db}*; Chen et al., 1996), and tubby (*Tubby*; Noben-Trauth et al., 1996) genes. Human homologs of many murine obesity genes have a confirmed associ-

ation with monogenic obesity in man and have helped advance understanding of the molecular pathogenesis of obesity and its complications.

Mutations can be generated by chemical means using chlorambucil or ethylnitrosourea (ENU), and also by radiation (X-ray) mutagenesis of sperm or ES cells. ENU is generally the mutagen of choice (O'Brien and Frankel, 2003; Hedrich, 2004) and is an alkylating agent that can transfer its ethyl group to oxygen or nitrogen atoms at a number of reactive sites in DNA bases. This can cause mispairing of the two strands of DNA and consequently base-pair substitutions. ENU generates point mutations in DNA at a rate of $\sim 10^{-5}$, such that $\sim 1/1000$ of the offspring carry a mutation in a given gene. Although the generation of mutants is fast with ENU, the success of this technique depends on the implementation of efficient, robust, and validated high-throughput phenotyping resources for screening the progeny of treated mice for obvious phenotypic abnormalities. One major obstacle is that the mutations occur essentially at random, and the identification of the structural change(s) in the DNA generally requires a laborious breeding strategy combined with a positional cloning approach. This task remains timely and costly, as every mutant must be back-crossed to other inbred strains to identify markers that cosegregate with the mutation.

POLYGENIC DISEASES AND GENETIC REFERENCE PANELS

Currently, there is increased focus on understanding the pathogenesis of complex diseases such as cancer, neurodegenerative disorders, and the metabolic syndrome. Monogenic GEMMs or randomly mutagenized mice that focus on an isolated genetic locus in a fixed background cannot model polygenic diseases inherited in a non-Mendelian fashion. Moreover, environmental factors can affect the manifestations of the genotype, resulting in incomplete penetrance, or mimic the contribution, resulting in phenocopies. Thus, it is desirable to have mouse models that mimic the genetic structure of human populations. Oligogenic mouse models, which are engineered with mutations in two or more genes, can be valuable in such a context and have illustrated many of the genetic principles underpinning complex diseases. Some key principles to keep in mind include: (1) that a major predisposing allele can have a modest effect alone, but play a major role in the context of a predisposing background, (2) that mutations in

different unrelated genes can yield the same phenotype (Nandi et al., 2004), and (3) that the interaction among some genetic loci can create strong positive or negative (protective) effects in the predisposition to a disease. Other genetic principles such as those underlying intertissue communication and cross-talk have been elucidated through the use of spatially and temporally controlled GEMMs.

An increasingly popular tool for the study of mouse physiology that complements the forward and reverse genetic strategies with a polygenic approach is the mapping of quantitative trait loci (QTLs) in inbred mice. Genetically homogeneous inbred strains have an inherent wealth of variation due to past spontaneous mutation events, and they can reveal subtle variation affecting many traits of biomedical interest (Paigen, 2003). The Complex Trait Consortium was formed to systematically exploit large-scale resources with the aim of partitioning strain differences in hundreds of quantitative traits to sets of biologically related genes or loci, and thereby identify genomic regions and genes associated with these traits (Threadgill et al., 2002). However, mapping QTLs based solely on the parental strain phenotypes is not an effective strategy, since many genetic contributors to complex diseases will be missed (Li et al., 2005). This is because the power and accuracy in detecting a QTL depends on multiple factors, including the genetic diversity of the parents, the density of the markers, the trait heritability, and the size of the cross. In any single or double cross, recombination events and mapping resolution are thus limited, as only loci that show allelic variation between two strains can be detected.

Two recent advances improve collection of data from resource-intensive breeding crosses. The first is the use of multiple crosses (two or more single crosses), which improves the power and resolution (Li et al., 2005). With single intercrosses, it is difficult to distinguish multiple tightly linked QTL from a single QTL with a large effect, and the QTL intervals defined are generally quite large, typically 20 to 40 cM. With multiple crosses, a computational meta-cross analysis can be performed. When the same QTL is found in more than one cross, the data can be combined from the crosses for the chromosome on which the QTL is found. If the QTL from multiple crosses are caused by the same gene, the impact of combining the cross data is equivalent to that of adding more recombination events in the QTL region (e.g. by additional mice in a cross). This will

narrow the QTL region and increase the power for resolving the QTL. For example, a QTL for HDL cholesterol was found on chromosome 4 in four different crosses, and, by combining the data from these crosses, the QTL was narrowed from 30 cM to 10 cM. (Li et al., 2005). The second is the generation of several large genetic reference panels (GRPs) of recombinant inbred (RI) mouse lines that have a higher rate of polymorphism between strains. GRPs are a set of genetically well-defined strains derived by crossing two different highly inbred progenitor strains and then inbreeding random pairs of the F2 generation (>20 generations) to produce a series of RI strains that represent an ~50:50 genetic mixture of the progenitor strains (Churchill et al., 2004; Peirce et al., 2004; Fig. 29A.1.1). Thus, the strains that make up a GRP are not mutants or engineered mice, but are normal mouse lines with a level of variation that more closely resembles that seen among humans. GRPs are also efficient because they are a renewable resource; genotyping only needs to be performed once, and genetically identical animals can then be distributed to many researchers (Churchill et al., 2004).

With recent advances in functional genomic technologies, such as the widespread use of high-density microarrays, the power to decipher complex molecular networks underlying the multifactorial nature of common disorders has been markedly increased. This is best illustrated when applied to the analysis of GRPs. The approach initially applied in yeast involves carrying out genome-wide genetic analyses of gene expression data, which are then considered to be a quantitative trait and are correlated with microsatellite markers of DNA variation (Damerval et al., 1994; Jansen and Nap, 2001; Brem et al., 2002; Schadt et al., 2003; Bystrykh et al., 2005; Chesler et al., 2005). Those genetic regions (loci) that account for variation in the levels of gene expression, termed expression quantitative trait loci (eQTL), reveal previously unknown gene-gene interactions and biochemical pathways. Compared to classical clinical quantitative trait loci (cQTL), which often include gross clinical measurements that are far removed from their causative biological processes, such eQTL approaches offer an additional level of sophistication, especially when combined with the analysis of disease traits such as cQTL. Many “omic” disciplines such as proteomics, metabolomics, and pharmacogenomics have followed in the

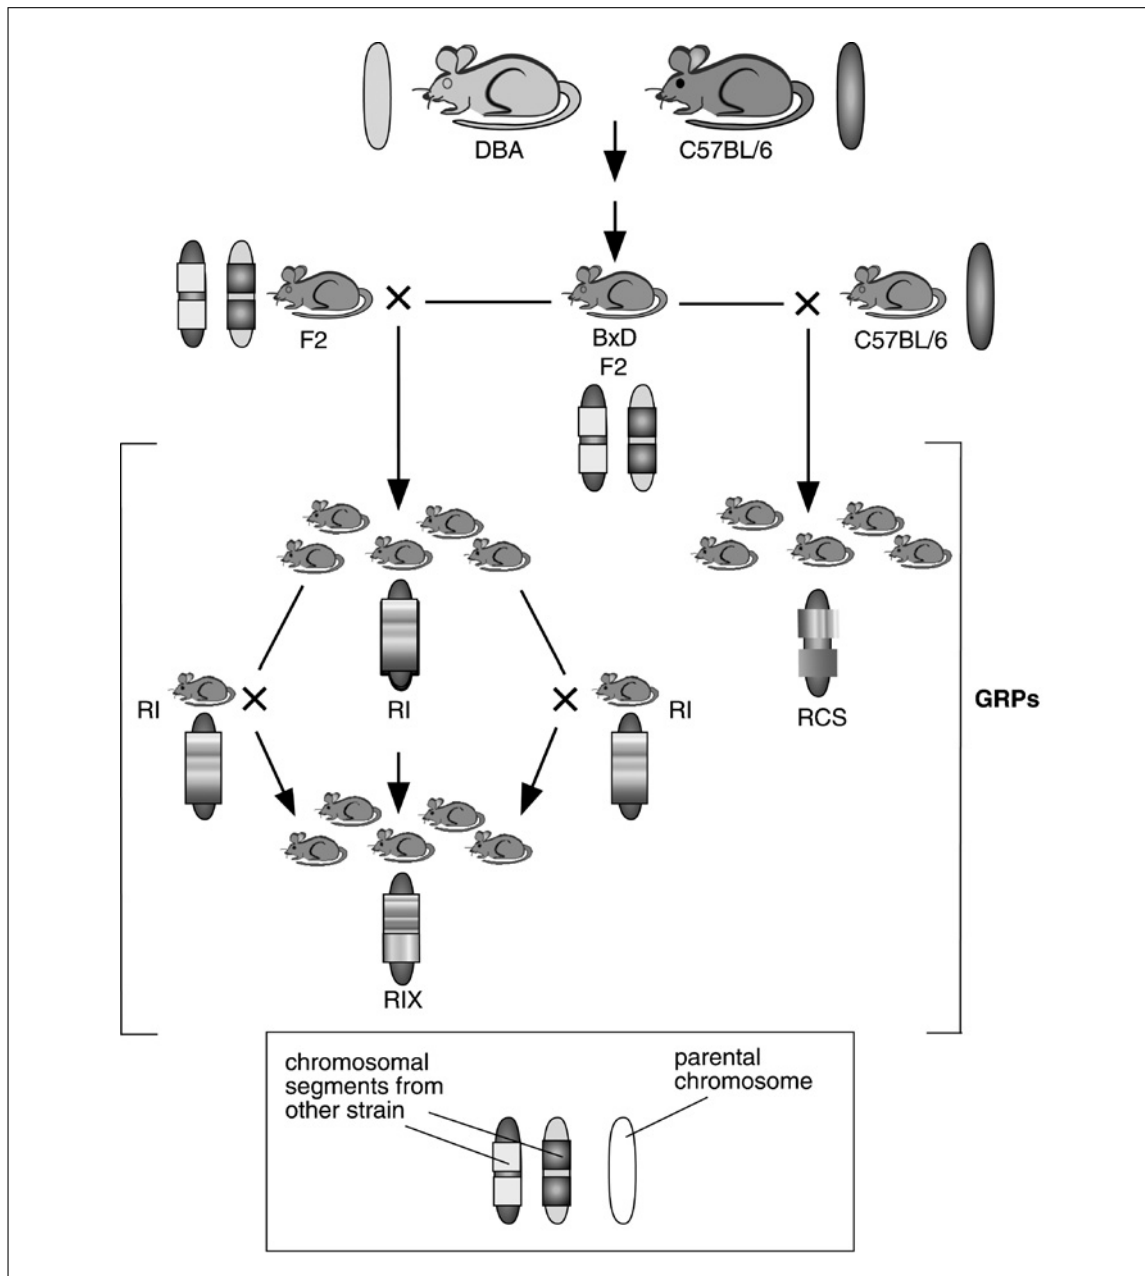

Figure 29A.1.1 GRPs can be defined as a set of genetically well-defined strains derived by systematical inbreeding, for at least 20 generations, from a single cross of two distinct inbred strains. GRPs represent an ~50:50 genetic mixture of the progenitor strains (Churchill et al., 2004; Peirce et al., 2004). Thus, the strains that make up a GRP are not mutants or engineered mice; they are normal mouse lines that have a level of variation more similar to that among humans. Approaches based on recombinant inbred (RI) strains are continually evolving to offer the variability, power, or resolution necessary for a general-purpose mapping tool, since at present there are too few GRPs with limited QTL power. Some of the sophistications include the use of recombinant congenic strains (RCS), which are variations of RI strains, whereby two parental inbred strains are initially crossed, but the resulting F1 hybrid progeny are then back-crossed with one of the parental strains prior to sib-pair matings. Instead of the mix of progenitor strain genomes approaching 50:50, the genome of RCS is representative mainly of one parent. The limitations of the current RI lines have also spurred an effort to create as many as 1000 new RI lines of mice within 7 years with the hope of covering much of the genetic variation present in natural populations. It will then be possible to generate an almost unlimited combinatorial diversity using the F1 progeny of these RI strains (RIX; Churchill et al., 2004).

footsteps of these genomic approaches. Application of these strategies to the analysis of either GEMMs or GRPs holds great promise and has clearly diversified the menu of mouse models to study human metabolic diseases.

It is becoming apparent that the best strategy for modeling complex diseases is to effectively combine data generated using relatively simple forward and reverse genetic strategies (whereby scientists drive gene elimination to precipitate disease) with global analyses of complex polygenic GRPs (where nature drives genetic variation to recreate disease). This combined strategy allows the benefits of the clear-cut results of single gene perturbations (e.g., knockout mice) to be merged with those conferred by the subtle alterations from innumerable allelic variants (GRPs).

Minimizing Variation Due to Genotype and Environment

The observation of different phenotypes in mouse strains that have undergone identical genetic manipulations, pharmacological interventions, and/or environmental stresses is not uncommon. This is because linking genotype directly to phenotype is often complicated by the fact that the genetic background of the mouse greatly impacts its phenotype. Thus, it is important that genetic factors such as strain background be considered in the context of any phenotypic studies, as they have an influence on almost all variables. Results obtained in one genetic background do not necessarily translate into another background. While this is perhaps the most obvious caveat that may affect the outcome of a phenotype, it is by certainly not the only one. In reality, there is a plethora of confounding factors (Table 29A.2.1), including genetic, developmental, environmental, and technical.

GENETIC BACKGROUND

Discrepancies in the outcomes of phenotyping tests reported by different laboratories evaluating the same genotype have provided a major driving force in addressing the need for standardization. For example, parallel testing of mouse behavior carried out by three independent laboratories on mice produced from the same litters and breeding stocks, in similar setups with identical protocols, led to significantly different results (Crabbe et al., 1999). In this experiment, the genotype accounted for

a significant proportion of the total variability in behavior, and historically documented strain differences were reproduced across all laboratories. For example, C57BL/6J mice are known to prefer ethanol, while DBA/2J mice avoid it. Similarly, C57BL/6J are good learners whereas DBA/2J are poor learners in hippocampus-dependent tasks (Upchurch and Wehner, 1988; Stiedl et al., 1999). These types of strain differences may significantly affect the outcome of certain phenotypic analyses.

Strain type must also be carefully chosen for metabolic/endocrine studies (addressed in Section 29B), as different strains are known to respond differently to metabolic challenges. For example, C57BL/6J mice are more susceptible to diet-induced diabetes and atherosclerosis compared to other strains (Paigen et al., 1985; Schreyer et al., 1998). C57BL/6J mice have low plasma cholesterol and low plasma triglycerides (TG), but high glucose levels in contrast to C3H mice, which generally have low blood pressure and high plasma cholesterol, TG, and glucose. Inbred 129 strains have a very low glucose production rate but high plasma cholesterol and low TG levels (Burgess et al., 2005). In addition, 129 strains are generally less active (Seburn, 2001) and are poor breeders. For additional information on mouse strain characteristics, readers should refer to the Mouse Phenome Database at <http://aretha.jax.org/pub-cgi/phenome/mpdcgi?rtn=docs/home> and to

Table 29A.2.1 Genetic, Environmental, and Experimental Factors that Influence Phenotypic Analysis

	Possible confounding factors
Animal	Age, gender, ovarian cycle, health status, treatment with drugs
Development	Intrauterine position effect, intrauterine feeding, maternal behavior
Genetics	Genetic background, gender, compensation, pleiotropy
Environment	Housing conditions, handling, stress, social hierarchy
Experimenter	Level of experience, same or different experimenters
Experimental design	Construction, standardization, illumination, time of testing (e.g., circadian rhythm)
Data acquisition and analysis	Calibration/thresholds, automated versus observed, experimenter bias, normalization, statistics

Michael Festing's index of inbred strains at <http://www.informatics.jax.org/external/festing/rat/STRAINS.shtml>.

Since C57BL/6J mice have a good breeding reputation, they are frequently the preferred genetic background for a large number of congenic strains, covering both polymorphic and mutant loci. However, due to the preferred use of 129 embryonic stem (ES) cells for gene targeting and gene trapping, a large number of studies have been performed in gene-targeted mice on a non-homogeneous genetic background. Yet the genetic background of the ES cells used to generate mutant mice has been proven to influence their phenotype. If the background strain of the phenotyped mouse is different from the one used to generate the knockout, the mice must be back-crossed for at least nine generations to avoid confounding factors contributed by flanking donor chromosomal DNA (Banbury Conference on Genetic Background in Mice, 1997). Alternatively, flanking donor chromosomal DNA can be monitored by using a marker-assisted selection protocol, enabling a quicker production of congenic strains compared to traditional backcrosses (Collins et al., 2003). Overall, these strain-specific differences show why it is very important to select the most appropriate strain for a particular study.

ENVIRONMENT

The environment is also critical in the outcome of phenotypic testing and must be carefully controlled to compare results from different laboratories. In one study, mice tested in a laboratory in Edmonton were on average more active than mice of the same genetic background tested in Albany and Portland (Crabbe et al., 1999). Whereas some of environmental factors have become experimental tools with which to challenge animals (e.g., diet), many others have become standard "housekeeping" parameters, whose order and consistency must be maintained. It is vital that the potential variables in phenotypic testing be minimized or carefully noted, so that only gene-elicited, environmentally defined mutant phenotypes are measured with similar outcomes wherever and whenever testing takes place.

Typical housekeeping items include animal housing and handling conditions such as the number of animals per cage (housing density), diurnal rhythm, length of fasting, blood collection procedure (retro-orbital or tail puncture, with or without anesthesia), diet, and age and gender of the mice (Champy et al., 2004). Cage housing density is an important

contributor to stress and significantly impacts many metabolic variables. Group-housed male mice behave differently than singly housed males with respect to territorial behavior and the formation of social hierarchies (Würbel, 2001). Similarly, housing conditions can influence many metabolic parameters. Glucose levels are significantly elevated when animals are caged in pairs as compared to when they are housed in groups of four, in part due to the increased stress and reduced competition for food intake between mice housed in pairs (Champy et al., 2004). Finer housekeeping details, such as the timing of blood collection, should also be critically controlled since metabolic variables are affected by activity and food intake, which is higher at night, and hormonal variations, which show marked nycthemeral (24-hr) rhythms (Champy et al., 2004).

Behaviors can also be affected by sex and age. The estrus status affects both emotionality and cognition in mice, and DBA/2J mice are known to become deaf by adulthood (Willot et al., 1995; Wotjak, 2004, and references therein). In a recent study involving a biochemical screen for thirteen analytes pertaining to lipoprotein metabolism, electrolyte balance, and organ function in C57BL/6J mice, twelve of the analytes were affected by the age and gender of the mice tested (Zhou and Hansson, 2004).

Developmental factors also contribute to the "individuality" and/or phenotype of the mouse, or to differences that occur despite seemingly identical genetics or environmental conditions (Lathe, 2004). Activation of the immune system during gestation, intrauterine factors (position of the embryo, nutrient and endocrine exchanges, and so on), and maternal behavior (grooming and licking) have all been shown to be determinants of behavior of adult offspring. For example, mice whose mothers displayed greater nursing activity showed a higher resistance to the deteriorating effects of stress in adulthood (Lathe, 2004, and references therein). These factors, despite being beyond standardization, are nonetheless important. In the study by Crabbe et al. (1999), for example, where genetic factors as well as laboratory environments were essentially similar, these effects may offer further explanations.

CONCLUSION

It is surprising that the impact of these important confounding factors on phenotyping has only recently been appreciated. In response to these observations, major

systematic phenotyping efforts, such as the European Union's Eumorphia program (<http://www.eumorphia.org/EMPreSS>), have been designed to standardize and validate phenotyping tests, linking them to standardized operating procedures (SOPs; Green et al., 2005). Quality standards and management, not only in industry but also in academic research, should ensure that SOPs and validated test paradigms guarantee highly reproducible results within one laboratory and between different research institutions. Obviously, standardization is limited by the confounding influences of the experimenter and the different resources provided by research institutions. Nonetheless, most of the confounding variables described above can be controlled in any given laboratory by following these guidelines.

1. Reduce genetic variation by using congenic mouse lines.
2. Reduce environmental variation through careful housekeeping.
3. Use mice of the same age and gender.
4. Use standardized operating procedures (SOPs).
5. Be conscientious and minimize sources of experimenter variation.
6. Repeat the experiment several times to ensure confidence in the data.

Collection of Blood and Plasma from the Mouse

**BASIC
PROTOCOL**

When working with mice, venous blood is commonly collected from the retro-orbital plexuses or the tail vein, or by cardiac puncture (Hedrich, 2004). The choice of method will depend on the quantity of blood required, the frequency of the blood draw, the skill of the blood drawer, and local animal handling guidelines. In the authors' experience, blood collection via the tail vein is the easiest method and provides sufficient material for most analyses, including lipid analysis. Furthermore, this method is used for blood sampling during numerous types of dynamic hormone tests, such as glucose tolerance tests.

In the tail of the mouse, there are three veins and one artery (Fig. 29A.3.1). As the lateral caudal veins are thicker than the dorsal caudal vein, the former are generally better for collecting large amounts of blood. The artery can also be used; however, bleeding time is longer. In general, blood is collected from awake and unrestrained mice; in this case, the procedure is easier with two persons. Alternatively, a restraining device can be employed and the blood draw can be performed by one person.

Although sometimes used interchangeably, serum and plasma are qualitatively different. In plasma, only the cells have been removed by centrifugation. In serum, the bulk of the fibrinogen has been removed by conversion into a fibrin clot together with the platelets, which have been physically bound in the fibrin matrix or activated to form aggregates or both. Since varying amounts of other proteins can be removed in the fibrin clot through interactions, and since the clotting process can induce cellular elements to secrete certain components, the quantities of various analytes (e.g., potassium) can be different in serum versus plasma. Since plasma is prepared in the presence of an anticoagulant such as EDTA, coagulation does not occur and fibrinogen is not consumed. In general, serum or plasma samples can be used for most analytes, including basic biochemistry and lipid analysis. For lipoprotein profiles, however, plasma is generally used. The researcher

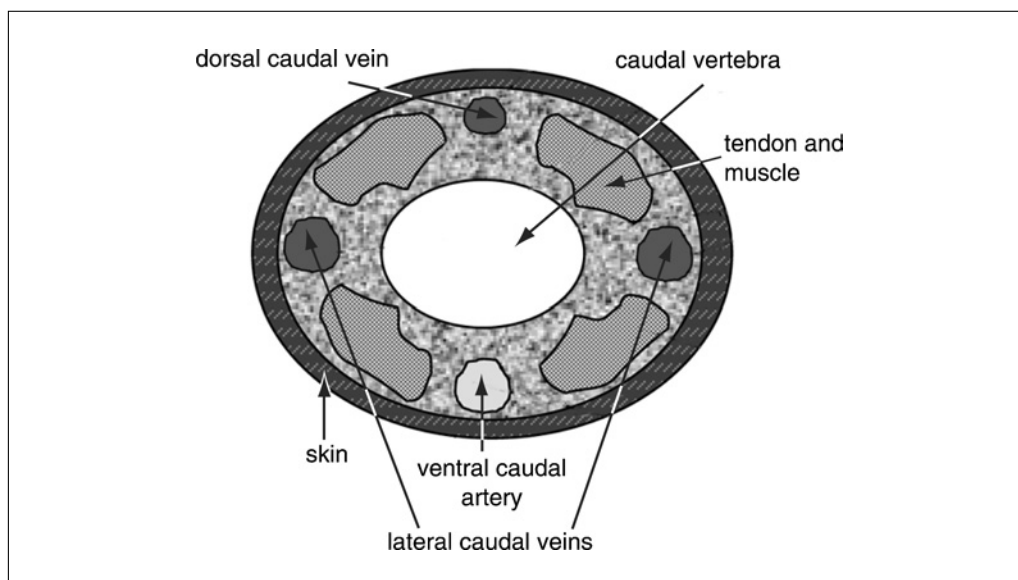

Figure 29A.3.1 A schematic drawing of a transverse section of a mouse tail showing the location of the veins and artery. The lateral caudal veins are used for venous blood collection.

should always verify for each analyte the limitations of the experimental protocols, and should use the same processing procedure when making comparisons.

NOTE: For a more complete coverage of mouse handling (e.g., the use of restraining devices) and blood collection, refer to Hoff (2000) and Coligan et al. (2006).

Materials

Mouse

Hematocrit sealing compound (e.g., <http://www.vitrex.dk>)

Alcohol-soaked cotton pads

Sterile gauze

Surgical blade, no. 10 or 11

Microhematocrit capillary tubes (with or without Na-heparin or EDTA, depending on analyte and plasma versus serum)

5-ml polypropylene centrifuge tubes

Refrigerated centrifuge

100- μ l Hamilton syringe

1. Place the mouse on the grid of a clean cage. Clean the tail with an alcohol-soaked cotton pad and then wipe it dry with sterile gauze.
2. Grip the end of the mouse's tail in one hand in such a way that the section of the tail to be cut (\sim 1 to 2 cm from tip of tail) is held steady while the mouse is moving about.
3. Using the other hand, locate the veins running on one side of the tail.

In general, if this procedure is performed on white or light-colored mice, the vein can be located visually. In black or dark-colored mice, this is more difficult and requires knowing the location of the vein.

4. Using a surgical blade held at a 90° angle with respect to the long axis of the tail, make a small cut on the side of the tail near the end.

Blood should immediately flow if the cut has been made in the right location. Care should be taken not to cut too deeply, as the tail cartilage can be affected. To improve the blood flow, the tail vein can be prewarmed by placing it in water at 40°C. A more practical and common alternative is to massage the length of the mouse's tail, as this will promote blood flow. However, for hematological analyses, massaging the tail is not recommended as this will result in leukocytosis, which increases the white blood cell count.

5. While holding and/or massaging the tail, touch a glass capillary tube to the blood droplets accumulating on the mouse's tail and allow the blood to enter the capillary tube by capillary action. To promote entry of blood into the tube via gravity, lower the opposite end of the tube so that it is below the blood droplet.

In the absence of a restraining device and with two persons performing blood collection, steps 1 to 4 should be performed by one person and the capillary tube should be manipulated by the other.

Using this procedure, at least two microhematocrit capillary tubes can be filled with blood, which corresponds to \sim 200 μ l of blood from an average-sized mouse.

For plasma, use sodium-heparinized or EDTA-containing tubes to prevent coagulation. For serum, use an untreated tube, as serum is collected in the absence of an anticoagulant.

6. Plug the capillary tubes using hematocrit sealing compound and place them in a 5-ml plastic tube on ice.
7. After blood collection, compress the cut with sterile gauze until the bleeding stops.

8. Return the mouse to its cage and monitor the animal for signs of anemia, including rapid breathing, muscle weakness, and paling of mucous membranes. Observe the site of blood collection daily for infection or irritation. When large quantities of blood are drawn, allow at least 2 weeks for recovery prior to performing another blood draw.
9. To collect plasma, centrifuge the 5-ml tube (containing the hematocrit tubes) 15 min at 3000 rpm ($1500 \times g$), 4°C .

The blood generally separates into three phases, with the bottom phase consisting of red blood cells, the top phase consisting of serum, and an interphase (referred to as the buffy coat) generally resembling a thin white layer containing mainly immune-type cells.

For serum collection, keep blood at room temperature for 1 hr in the untreated collection tubes, then centrifuge as described above.

10. Collect the plasma (or serum) from the top with a Hamilton syringe, leaving behind the buffy coat and red blood cells.

The plasma (or serum) is ready for analysis. If necessary, store at -20°C or -80°C .

COMMENTARY

Background Information

Cardiac puncture and orbital eye bleed generally yield large quantities of blood ($\sim 300 \mu\text{l}$ per draw) as compared to tail vein sampling ($\sim 150 \mu\text{l}$ per draw), assuming that an average-sized mouse is used and it is not overbled. However, these former techniques may require the sacrifice of the animal (where blood draw quantity can be even higher, $\sim 900 \mu\text{l}$), may blind the animal, and require a great deal of skill. Thus, the tail vein method provides a less invasive procedure that allows repeated blood draws from the same animal, without the confounding affects of anesthesia.

Critical Parameters

If analyses are not performed on the day of blood collection, samples should be stored at -20°C (short-term, e.g., < 2 months) or -80°C (long-term). Stability and storage depend on the different parameters to be determined. For example, free fatty acids are only stable for 2 to 3 days at -20°C .

Plasma samples can be used undiluted or diluted with deionized water if the volume is insufficient or the parameter to be measured exceeds accurate detection limits. If the blood is hemolyzed, a correction factor and/or re-sampling is suggested, as hemoglobin can interfere with certain measurements.

For plasma, a number of analyte measures favor the use of heparin over EDTA and vice versa, and this should be verified with each individual protocol before blood is drawn. For example, heparin can interfere with the assessment of plasma lipoprotein lipase activity, as heparin is a known inhibitor of this enzyme.

Because any invasive mouse technique should be considered potentially stressful, the same experimenter should perform the technique each time to minimize experimental variation due to animal handling skills. Since many factors such as centrifuge speed, clotting time, storage temperature, and time for blood processing may influence both serum and plasma preparations, carefully documented conditions of blood processing procedures should be followed to assure reproducibility of samples.

Anticipated Results

As tail vein sampling is less invasive than orbital eye bleed, multiple samplings should be well-tolerated by the mouse over the period of its lifetime. It is difficult to quantify how many samplings are possible or how much blood can be drawn at any one point in time. In general, however, the maximal volume of a single blood draw should not exceed 10% to 15% of total blood volume or 1% of the body weight of the animal. Restoration of normal blood volume takes 24 hr, but it may take up to 2 weeks for normal levels of erythrocytes and reticulocytes to be restored. Therefore, 2 weeks is the recommended minimum interval between consecutive maximal blood draws. Daily blood draws up to 1% of the total blood volume are acceptable, although the effects of stress, as well as the choice of collection site, need to be carefully considered. Blood loss exceeding 20% to 25% of total volume results in hypovolemia and cardiac failure due to decreased blood pressure, cardiac output, and oxygen delivery to vital organs.

The ratio of blood cells to plasma is typically 1:1, but a researcher should safely estimate that only ~50 μ l of plasma will be obtained from 150 μ l blood. Note that quality should not be sacrificed for quantity by removing too much plasma near the buffy coat and red blood cell layers and risking contamination. For automated analyzers such as for lipid analysis, this amount of plasma/serum is sufficient to perform a basic biochemical and lipid profile. Although the low yield of plasma from tail vein sampling is perceived as a drawback when multiple analytes are to be measured, the technique is ideal when multiple samples are required over a short period of time and the potential confounding effects of anesthesia are undesired. For example, the tail vein technique is ideal for a glucose tolerance test, which requires as many as eight blood samplings over 180 minutes but requires only 5 μ l of blood per time point.

Time Considerations

For blood draw volumes and frequencies, see Anticipated Results. Because the same experimenter should perform all blood draws, the maximum number of animals that can undergo blood draw at any time will depend on

the skills of the experimenter. An experienced blood drawer might be able to obtain samples from as many as 20 to 30 animals in 1 hr. The whole experiment should be performed within a reasonable time frame to avoid any confounding effects of changes in the animals due to diurnal rhythm and length of fasting.

METABOLIC EXPLORATION OF THE MOUSE

Endocrine and metabolic dysfunctions are among the most common diseases in developed societies. Examples of such diseases include obesity, insulin resistance, type 2 diabetes, hyperlipidemia, and atherosclerosis. Mouse models are increasingly popular tools for studying and characterizing the molecular and physiological aspects of these diseases. The characterization of endocrine and metabolic dysfunction in mice has become of utmost importance for both basic and clinical scientists. This section will describe phenotyping protocols for the evaluation of numerous metabolic parameters including energy homeostasis, serum and tissue lipids, glucose homeostasis, and select pathophysiology. Many of these protocols are based on clinical tests used to evaluate human patients with metabolic diseases.

Despite the ease of mouse manipulation, the investigator should take heed that endocrine and metabolic disturbances are often subtle in their presentation, and are thus a challenge to detect even for the best mouse physiologists. In humans, clinical history and physical examination constitute critical elements in the general diagnostic process. Although a clinical history in mice is impossible, physical examination, as with humans, can provide important hints about endocrine or metabolic dysfunction. Numerous examples illustrate this principle nicely. For example, diseases of hormone deficiency or excess are physiologic determinants of physical traits including stature, weight, complexion, hairiness, and behavior. Body aspects such as thinness or obesity can result from or be associated with abnormalities in lipid or glucose metabolism. Critical observation of mouse behavior also reveals important information. Therefore, initial metabolic exploration should begin by an in-depth clinical analysis of the mouse in its home cage using tests such as SHIRPA or the dysmorphological screen (Hrabe de Angeles et al., 2000; Nolan et al., 2000). Screening of standard blood components like glucose, lipids, calcium, and electrolytes also gives clues for the diagnosis of endocrine or metabolic dysfunction, which can be further investigated with a wide array of more specialized and detailed tests covering the whole endocrine system and metabolism in general.

The acquisition of skills in endocrine and metabolic diagnosis is facilitated by familiarity with certain simple principles and rules. In particular, endocrine and metabolic disorders are most often seen as either an excess or deficiency of a certain biologically active hormone or metabolite. Alternatively, these disorders can be the consequence of inadequate cellular responses to a particular hormone or metabolite. These principles help guide the phenotyping paradigms summarized in the following units.

Hormones and metabolites can be characterized by the pathway and location of their production, their storage and release into the serum, and their degradation and metabolism. Although hormone and metabolite levels can be regulated in all of these aspects, production rate is often the primordial factor determining their levels. It is interesting that production of most metabolites and hormones is regulated directly or indirectly by the metabolite or hormone in question through interconnected positive and negative feedback loops. This control has important implications, since plasma levels of a metabolite or hormone only make sense if the appropriate regulatory factor is taken into account (e.g., glucose and insulin). Elevation of both metabolites/hormones and their regulatory factors is often reflective of a resistant state (e.g., glucose and insulin elevation in insulin

resistance). A final interesting correlate of regulated hormone secretion is that it is the basis for various dynamic endocrine or metabolic tests for the evaluation of discrete disturbances in metabolic and endocrine function (e.g., intraperitoneal insulin tolerance test).

UNIT 29B.1

Evaluation of Energy Homeostasis

The critical factors contributing to body-weight maintenance include caloric intake and energy expenditure (Spiegelman and Flier, 2001). Alteration of either of these factors can upset the balance of the equation and result in body weight changes. Thus, the evaluation of body weight gain/loss over a period of time can be the most obvious indication of an alteration in energy homeostasis, and is typically coupled with other direct measurements such as food intake, body mass index, and fecal lipid content (see Basic Protocol 1). More sophisticated, noninvasive measurements of body composition that break down the weight in terms of body fat, lean mass, and bone mass can be obtained using dual-energy X-ray absorptiometry (DEXA; see Basic Protocol 3) or quantitative nuclear magnetic resonance (QNMR; see Alternate Protocol). To investigate the causes of energy dysregulation, several tests can be employed. Food-intake measurements such as those described in Basic Protocol 1 can indicate whether changes in caloric intake are contributing to the altered energy balance, whereas indirect calorimetry (see Basic Protocol 4) and the cold test (see Basic Protocol 2) assess the animal's expenditure of energy under basal and challenged conditions, respectively.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

STRATEGIC PLANNING

In vivo mouse experiments require a significant amount of strategic planning. To begin with, all in vivo experiments must be done in accordance with the appropriate animal care and use guidelines as defined by the country and institution where the work is carried out, and the time to acquire these approvals must be taken into consideration. Moreover, several parameters must be considered when designing a mouse experiment, which depend on the nature of the experiment. A minimum list of parameters to consider when planning the generation of a cohort of experimental animals for metabolic exploration includes mouse strain, gender, age, control mice, diet, housing conditions, time of experiment, and number of mice. For more information, refer to Champy et al. (2004).

For any experimental cohort, several variables need to be carefully controlled, such as the number of mice and their age, sex, and diet (Champy et al., 2004). In general, for metabolic exploration, male or female animals are tested after sexual maturity (~6 to 8 weeks), under chow, high-fat, and/or high-sucrose diet conditions. Preferably, all genotypes of animals should be derived from age-matched littermates with appropriate cohort sizes, since it is clear that there is substantial inter-animal variability. According to the authors' own experience and previously published work with C57BL/6J mice and power calculations, a group size of approximately ten to twelve animals is generally sufficient to observe statistically significant differences of the distinct interventions on metabolic and molecular parameters (Koutnikova et al., 2003; Cock et al., 2004). To be cautious and account for animals that might die in the course of these often long-term experiments, twelve animals per group are suggested; however, each individual user must determine the optimal number. In order to generate such a colony, depending on the size of litters and fertility of the animals, at least six to eight females will need to be bred at any one time. In cases where the number of animals is limiting, a consecutive

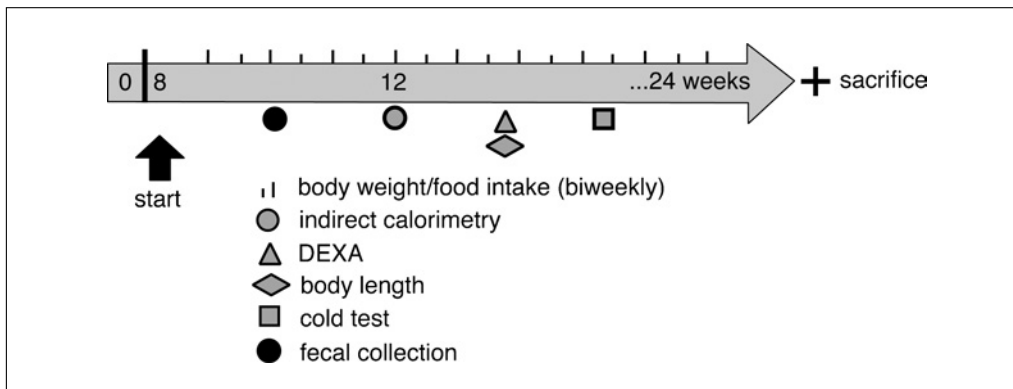

Figure 29B.1.1 A hypothetical timeline for a phenotypic analysis on a cohort of animals.

experimental strategy can be employed whereby animals are first tested under chow-fed conditions before putting them on the dietary challenge. Finally, a timeline outlining the experimental manipulations must be designed that minimizes the stress level of the animal. An example of such a timeline is provided for the procedures described in this unit (Fig. 29B.1.1); additional tests not discussed in this section can also be incorporated.

MEASUREMENT OF BODY WEIGHT, FOOD INTAKE, BODY MASS INDEX, AND FECAL LIPID CONTENT

Monitoring of body weight and food intake involves relatively simple tests that provide the first indications about metabolic homeostasis. The authors recommend initially evaluating body weight and food intake during a 6-week period, between 6 and 12 weeks of age. Body weight should be recorded twice a week at the same time of day. Care should be taken to avoid stressing the animals, since this can impact body weight gain. Twice-weekly weighing of the food given and the food remaining in the grid of the cages is a reliable method for evaluating food consumption. In general, food intake is measured when mice are housed at a density of four per cage. In the case of longer studies (e.g., aging), the frequency of weighing can be reduced to bimonthly recordings, and food intake can be measured less often, depending on results of initial testing.

Fecal lipid content is measured gravimetrically following a Folch extraction (Folch et al., 1951; Ishibashi et al., 1996). The authors recommend that feces be collected in parallel on a day when food intake is recorded, in order to measure lipid absorption. As an alternative to measuring total lipid gravimetrically, the fat extract can be partitioned according to the type of lipid (i.e., triglyceride and cholesterol) by subjecting it to enzymatic assays, thin-layer chromatography, or gas chromatography. These methods are beyond the discussion of this unit, although enzymatic assays will be included in a later unit on glucose and lipid homeostasis. A very sensitive measure of cholesterol absorption involves oral gavages of a mixture of dual-labeled [^3H]sitostanol and [^{14}C]cholesterol followed by determination of the stool sterol ratio of ^{14}C to ^3H (Schwarz et al., 2001). Whole-animal sterol synthesis rates can also be measured *in vivo* by determining the rate of incorporation of $^3\text{H}_2\text{O}$ into sterols over time (see Schwarz et al., 2001, and references therein). Finally, alternatives to the Folch lipid extraction protocol can be employed. For example, increased extraction of total fat and phospholipid can be achieved by sequential extraction with solvents chosen to optimize extraction of medium- and long-chain triglycerides and fatty acids and solvents designed to recover phospholipids (Chen and Innis, 2004).

CAUTION: Appropriate procedures for the use of radioactivity must be followed (see *APPENDIX 1F*).

BASIC PROTOCOL 1

Mouse Phenotyping

29B.1.3

Materials

Mice
Mouse food
0.1 mCi/ml [carboxyl-¹⁴C]triolein (112 mCi/mmol)
2:1 (v/v) chloroform/methanol
Container to accommodate mouse during weighing
Scale accurate to 0.01 g
Mouse cages (e.g., 24 × 38 × 20–cm) with metal floor grids (grids or screens can be custom cut to fit bottom of cage; optimal grid size is one that allows feces to pass through but is still comfortable for mouse to rest on)
Inhalation anesthesia unit (composed of a mixing and flow-controlled system for O₂/isoflurane anesthesia; e.g., TEM, <http://www.TEM.fr>)
Digital caliper (range, 0 to 20 cm; accuracy, <0.02 mm; resolution, <0.01 mm; Ted Pella, Inc.)
Analytical balance accurate to 0.0001 g
70°C vacuum oven
10-ml Erlenmeyer flasks
60°C shaking water bath
Whatman no. 1 filter paper
10-ml glass test tubes with ground glass stoppers
Clinical tabletop centrifuge
Long-stem glass Pasteur pipets
Nitrogen evaporator (e.g., N-EVAP; Organomation Associates) with dry bath at 50°C
Preweighed glass scintillation vials
β-counter and scintillation cocktail

Measure body weight

1. Place a mouse container on a scale with an accuracy of 0.01 g and calibrate to zero.
2. Place the mouse in the container and record the weight (to the same accuracy) after the measurement stabilizes.

Measure food intake

3. Place the mice in a clean standard cage (e.g., 24 × 38 × 20–cm) with a metal floor grid, optimally at four mice per cage, with free access to water.
4. Weigh a portion of food appropriate for the feeding interval (e.g., 24, 48, or 72 hr) to an accuracy of 0.001 g, and place it in the grid of the cage. Assume an average mouse consumes 3 to 5 g/day. Place a lid over the grid to prevent the food from spilling over.

For long-term food intake studies, the food quantity should be checked daily and supplementations weighed.

5. At the end of the feeding interval, remove the grid and weigh the remaining food to an accuracy of 0.001 g.
6. Calculate the amount of food consumed per mouse per day by dividing food consumed (weight of food given – weight of food remaining) by the number of animals per cage and by the number of days in the feeding interval.
7. Calculate kilocalories (kcal) of food consumed by multiplying the amount of food consumed by the caloric density of the food as provided by the manufacturer.

For example, for a chow diet of 3.37 kcal/g with 5 g food consumed, the number of kcal consumed is 16.85 kcal.

As an alternative, systems designed to specifically record and analyze liquid and food consumption can be used—e.g., Columbus Instruments Lick Counter and Feed Monitor (<http://www.colinst.com/>) and TSE Systems Drinking and Feeding Monitoring System (<http://www.tse-systems.com/>). These systems generally allow for an unlimited number of measurements to be monitored by a computer.

Measure body mass index (BMI)

8. Determine the weight of each mouse as described in steps 1 and 2.
9. Place the mouse in an inhalation anesthesia unit and anesthetize using 3.5% to 4.5% (v/v) isoflurane in O₂ for induction and 1.5% to 3.0% (v/v) isoflurane in O₂ for maintenance (Flecknell, 1993).
10. Remove the mouse from the anesthesia unit and place it in a ventral position. Gently push the back of the mouse flat and straighten the spine. Using a digital caliper, determine the nasal-to-anal length of the mouse in cm.
11. Calculate the body mass index (in g/cm²) by dividing the body weight by the square of the nasal-to-anal length.

Measure fecal lipid content

12. Place the mice in clean cages containing a metal floor grid instead of bedding.
13. Collect feces over a 24-hr period in parallel with a food intake measurement (see above) in order to determine fat balance (lipid intake and output). Dry the collected feces for 1 hr in a vacuum oven at 70°C, then clean the feces to remove remains of cage bedding and/or food pieces. Weigh total fecal output to an accuracy of 0.0001 g using an analytical balance.

Preferably, fat balance should be determined on several consecutive days to account for the variability in intestinal motility.

14. Carefully weigh a 100-mg aliquot of droppings into a 10-ml Erlenmeyer flask, and mix with 5 µl of 0.1 mCi/ml [carboxyl-¹⁴C]triolein (radioactive tracer).

To ensure that fecal aliquots are representative of the whole group, duplicate or triplicate samples should be tested.

15. Cool the sample and extract by adding 2 ml of 2:1 chloroform/methanol. Incubate 30 min at 60°C with constant agitation in a shaking water bath.
16. Pass the sample by gravity through a Whatman no. 1 filter paper into a 10-ml glass test tube. Add 2:1 chloroform/methanol up to a final volume of 4 ml.
17. Back-extract the sample by adding 1 ml water and mix well by vortexing. Induce phase separation by centrifuging 10 min at 2000 rpm in a clinical tabletop centrifuge, room temperature.

When equilibrium has been reached, there will be an upper transparent water/methanol phase, a lower chloroform phase, and an accumulation of material (“fluff”) at the interface.

18. Carefully draw off the bottom organic phase using a long-stem glass Pasteur pipet with its tip placed at the bottom of the tube, and transfer to a new tube. Evaporate the sample to dryness using a nitrogen evaporator (e.g., N-EVAP) with dry bath at 50°C. Resuspend the residue in 2 ml of 2:1 chloroform/methanol.
19. Transfer the solution into a preweighed glass scintillation vial and evaporate the solvent using a nitrogen evaporator (e.g., N-EVAP) with dry bath at 50°C. Dry the vial in a vacuum oven at 70°C for 1 hr, then carefully reweigh the vial.

20. Determine the difference in weight between the empty vial and the vial containing the dried lipid to give the amount of fecal lipid in mg.
21. To correct for loss of lipids during extraction, determine the percent recovery of radiolabeled triolein. Add scintillation cocktail to the vial and count the radioactivity in a β -counter. Adjust the weight of the fecal lipid in each sample according to the percent of triolein recovery.
22. Using the corrected amount of fecal lipid, express fecal lipid content as a percent of the weight of the starting fecal aliquot (100 mg).
23. Determine the total amount of fat excreted in the 24-hr period by multiplying the percent fecal lipid by the total fecal output (step 2).
24. Subtract the total fat excreted from the total amount of fat consumed in 24 hr (based on the fat content of the food as provided by the manufacturer) to give the amount of retained fat. Express as a percent of fat consumed.

**BASIC
PROTOCOL 2**

ASSESSMENT OF THERMOREGULATION BY THE COLD TEST

The cold test allows the evaluation of adaptive thermoregulation (Picard et al., 2002). In practice, mice are placed in individual cages without food but with free access to water. Initial body temperature is recorded by inserting a small thermoprobe into the rectum of the animal. Mice are then placed in a cold room at 4°C and rectal body temperature is recorded every hour during a 6-hr period. Results are presented as the curve of body temperature decrease over time. The authors do not normalize the cold test to body weight, but interpretation of the data should take into account whether there are differences in body weight.

Materials

Mice
 70% (v/v) isopropanol
 Mouse food
 Container to accommodate mouse during weighing
 Scale accurate to 0.1 g
 Standard mouse cages (metal grid not required)
 Thermometer with thermoprobe (accuracy <0.1°C) and rectal adapter (e.g., Bioseb; <http://www.bioseb.com>)

1. Determine the weight of the mouse as described in Basic Protocol 1, steps 1 and 2.
2. Place each test mouse individually in a clean cage, without food but with free access to water.
3. Disinfect the thermoprobe by washing it with a 70% isopropanol solution.
4. Measure the initial body temperature (T_0) of each mouse by inserting the thermoprobe into the rectum and recording the temperature on the probe once the value has stabilized (3 to 4 sec).
5. Place the individually caged mice in a cold room at 4° ± 1°C.
6. Measure and record the rectal temperature hourly, while in the cold room, over 6 hr.

The six measurements thus obtained are designated T_1 , T_2 , T_3 , T_4 , T_5 , and T_6 .

7. At the end of the experiment, place the mice into new cages in a room with normal ambient temperature (they can be regrouped if required), provide with food and water, and ensure that the animals exhibit normal behavior.

If the body temperature becomes too low (<25°C), place the cages close to a 37°C heating source for 15 to 30 min to warm the animals.

DETERMINATION OF BODY COMPOSITION BY DUAL-ENERGY X-RAY ABSORPTIOMETRY

**BASIC
PROTOCOL 3**

Bone densitometry and body composition (lean and fat content) are often measured using dual-energy X-ray absorptiometry (DEXA) analysis (Grier et al., 1996; Nagy and Clair, 2000). DEXA analysis can be performed using ultra-high-resolution densitometers such as those made by GE Medical Systems (e.g., PIXImus; <http://www.gehealthcare.com/inen/rad/bonedens/peripheral/piximus.html>) or Norland Medical Systems (pDEXA Sabre X-ray, <http://www.norland.com>) that allow for precise measurements of bone mineral and body composition from body imaging in less than 5 min in anesthetized mice.

CAUTION: Specific X-ray safety procedures should be followed.

Materials

- Anesthetic solution (see recipe)
- Mice
- PIXImus densitometer (0.18 × 0.18 mm; GE Medical Systems)
- Computer with Windows PIXImus software (e.g., version 1.4x; GE Medical Systems)
- Container to accommodate mouse during weighing
- Scale accurate to 0.1 g
- 1-ml syringe with 25-G, 0.5-mm needle
- Specimen tray for PIXImus (GE Medical Systems)

Prepare the PIXImus analyzer

1. Turn on the PIXImus analyzer at least 2 hr prior to testing.
2. Initiate the software by double-clicking the PIXImus icon.
3. Calibrate the PIXImus analyzer and perform quality control according to the operator's manual.

The field calibration procedure takes ~60 min. Each PIXImus has a "phantom," i.e., a structure with predetermined bone mineral density and fat content, which is analyzed and used for quality-control purposes.

Anesthetize the mouse

4. Determine the weight of the mouse as described in Basic Protocol 1, steps 1 and 2. Calculate and record the volume of anesthetic solution required for injection at 8 ml of anesthetic solution per kg.

When prepared as described and administered at 8 ml/kg, animals receive a dose of 200 mg/kg ketamine and 10 mg/kg xylazine.

5. Administer the appropriate volume of anesthetic solution by intraperitoneal injection using a 1-ml syringe and 25-G, 0.5-mm needle.

Perform the measurements

6. Remove the adhesive backing from the specimen tray, place the anesthetized mouse in a ventral position on the tray, and ensure that the vertebral column is straight. Wrap the mouse's tail around itself and extend the legs away from its body.

**Mouse
Phenotyping**

29B.1.7

7. Position the tray in the scanner so that the head is oriented towards the left, from the investigator's point of view.
8. Start the measurement according to the PIXImus operator's manual.

The image acquisition takes less than 5 min.

Perform the calculations and allow animals to recover

9. Following image acquisition, determine the bone mineral density (BMD, in g/cm²), bone mineral content (BMC, in mg), bone area (in cm²), and body composition (% fat and lean, and fat tissue in g) with the PIXImus software.

The specific body imaging area or the region of interest (ROI) can be manually selected within the total body image. For example, to image the spine and femur, the software positions an oval-shaped exclusion area to exclude the head and its soft tissue.

10. At the end of the experiment, remove the mouse from the plastic tray and return it to its home cage. Ensure that the test mice recover from the anesthetic and exhibit normal behavior.

Generally mice are allowed to recover on a 37°C heated surface.

**ALTERNATE
PROTOCOL**

**DETERMINATION OF BODY COMPOSITION BY QUANTITATIVE
NUCLEAR MAGNETIC RESONANCE**

As an alternative to DEXA (Basic Protocol 3), new EchoMRI quantitative magnetic resonance (QNMR) methods (e.g., Bruker Minispec NMR analyzer) can also be employed for the in vivo analysis of whole-body composition (lean and fat content) of conscious live mice. Both the DEXA and the EchoMRI methods eliminate the need for destructive chemical analysis and allow for multiple consecutive measurements throughout the lifetime of the animal.

Materials

Mice

Control/calibration sample (Bruker)

Bruker Minispec NMR analyzer (<http://www.minispec.com/mq/mice.html>), interfaced with personal computer running MS Windows 2000 or higher with Minispec software package installed

1. Turn on the NMR and then the computer.

Initially, three lights appear on the NMR indicating the preheating stage (red), the transition to normal heating (yellow), or the correct temperature (green). The NMR is ready to use ~3 hr after powering up.

2. Click the Minispec icon on the computer to load the Minispec software, then click the Daily Check icon to calibrate the machine.
3. Confirm that the control tube has been inserted into the NMR and click OK when prompted by the "Confirm minispec Daily Check sample has been inserted" message.
4. When calibration is finished, click Yes to print the results when prompted by the "minispec Daily Check OK: print out results" message.

When the calibration is not successful, an error message appears and action should be taken accordingly. Refer to troubleshooting section in the Minispec mcSeries User's Manual.

5. Weigh the mouse as described in Basic Protocol 1, steps 1 and 2. Remove the Control sample tube and insert the weighed animal into the Sample tube. Slowly insert the plunger, being careful not to drop the plunger onto the animal.

6. Insert the Sample tube, then click OK when prompted by the message “Waiting for inserting sample.”
7. Enter the animal’s identification number and the operator’s initials when the messages “Input sample ID” and “Input operator sample” appear. Click on Measure to initiate testing.

Testing takes ~3 min per animal.

8. When all testing is finished, remove the Sample tube, return the mouse to its home cage, and verify that it behaves normally. Repeat steps 5 to 8 until all animals have been tested.
9. Select the Save As option under the File menu, give the data a file name, check the “data format” radio button, and click Save. Shut down the Minispec program by selecting Exit from the File menu.

INDIRECT CALORIMETRY BY OXYMAX

Energy expenditure is evaluated through indirect calorimetry by measuring oxygen consumption with a specific apparatus such as the Oxymax (Columbus Instruments; <http://www.respirometer.com/microoxy.html>) or CaloSys (TSE Systems; <http://www.tse-systems.com/calorimetry/calorimetry.htm>; Porter, 2001). These systems monitor oxygen (O₂) and carbon dioxide (CO₂) gas volume concentrations at the inlet and outlet ports of a partially sealed chamber through which a known flow of ambient air is forcibly ventilated, either by positive pressure or by drawing the flow from the chamber. The concentration differences measured between the ports, along with the flow information, are used to compute oxygen consumption (VO₂) and carbon dioxide production (VCO₂), and the respiratory quotient (RQ) is calculated as VO₂/VCO₂. Chambers are equipped with a third port for temperature measurement.

In practice, mice are placed individually in the metabolic chambers while they have ad libitum access to food and water. Ideally, indirect calorimetry should be performed at thermoneutrality (~30°). Thermoneutrality is defined as the range of ambient temperature at which energy expenditure is lowest, no metabolic heat is required to maintain body temperature, and there is minimal oxygen consumption. At this temperature, the animal can maintain homeostasis without excessive use of energy for thermoregulation, and, hence, energy is available for maintaining optimum conditions of health and performance. When the heat load changes, the animal must expend energy to either eliminate excess heat or make heat in order to maintain internal thermal balance. Therefore, body temperature changes can affect various body functions (Gordon, 1993). If the temperature drops below 30°C, mice show an increase in metabolic rate, which can confound the outcome of the tests. The actual temperature for thermoneutrality can vary in rodents anywhere from 28° to 32°C. In general, higher temperatures should not be used. If indirect calorimetry cannot be performed at thermoneutrality, ambient temperature of (23° to 24°C) should be used. Indirect calorimetry is preferably performed for a 24-hr period while the mice have free access to food. O₂ and CO₂ measurements are taken at regular intervals during the whole experiment, and VO₂ and VCO₂ values are expressed as ml/kg/hr. As energy expenditure varies with body weight, it is important to normalize the values obtained for body mass.

The measurement of metabolic performance by calorimetry can be performed simultaneously with measurement of home cage activity and drinking and feeding behavior using modified systems—e.g., LabMaster (TSE Systems; <http://www.tse-systems.com/labmaster/labmaster.htm>) and Comprehensive Lab Animal Monitoring System (CLAMS; Columbus Instruments; <http://www.colinst.com/brief.php?id=61>). In

BASIC PROTOCOL 4

Mouse Phenotyping

29B.1.9

these types of systems, measurements of O₂ and CO₂ concentration, air flow, and temperature are recorded along with total activity (ambulatory and fine movements and rearing), food and liquid consumption, and urine and feces excretion. These systems, when available, can provide a large amount of data in a short period of time.

Materials

Mice

Container to accommodate mouse during weighing

Scale (capable of weighing 1 to 50 g to an accuracy of 0.1 g)

Respirometer: Oxymax system (Columbus Instruments;

<http://www.respirometer.com/microoxy.html>)

Computer with the Windows Oxymax software

Calibration gases: one tank with 20.5% O₂/0.8% CO₂ and a second tank with 100% N₂

1. Determine the weight of each mouse as described in Basic Protocol 1, steps 1 and 2.

As energy expenditure varies with body weight, values are normalized to body mass (see step 7).

2. In an experimentation room set to 30°C, place each mouse individually in an airtight cage (supplied with the Oxymax respirometer) with free access to food and water. Seal the cages tightly, taking care to ensure minimum leakage of gases.

3. Warm up the Oxymax respirometer for ≥2 hr, then calibrate the CO₂ and O₂ sensors according to the Oxymax operating manual prior to the start of the experiment.

The calibration of the gas sensors and flow meters is required to ensure precise measurements and involves using a gas mixture of 20.5% O₂ and 0.8% CO₂ (balance N₂) to adjust the O₂ and CO₂ sensors to reflect the contents of the calibration gas.

4. Following calibration, click the Experiment Configuration tab. Select the Chamber Configuration tab, and click on Chamber One. Enter the mouse information, including ID, weight, and sex, and then click Apply. Continue this procedure until each chamber is entered, then save the data file.

5. Ensure that the chambers are connected according to the Oxymax operating manual, and start the system by clicking Run.

Measurements of O₂ and CO₂, in units of ml/kg/hr, are acquired at regular intervals. The time interval is selected by the user, but is generally 3 min. The total duration of the recording is ~24 hr, which covers both active and resting phases.

6. At the end of the experiment, click Stop, shut off the air, and remove the mice from the chambers. Return to home cages and ensure that they exhibit normal behavior.

Chambers should be carefully washed and disinfected between experiments.

7. Normalize the values of oxygen consumption (VO₂) and carbon dioxide production (VCO₂) to body mass (ml/kg^{0.75}/hr or ml/kg^{0.67}/hr; see Critical Parameters).

Normalization is done automatically by the instrument software. In some cases (obese animals) values can be normalized to lean body mass as measured by DEXA analysis.

The respiratory exchange ratio (RER), also known as the respiratory quotient (RQ), is calculated as VO₂/VCO₂. Heat is calculated from the VO₂ and RER information using the standard formula: Heat (H) = calorific value (CV) × VO₂ × 0.001, where CV = 3.815 + 1.232 × RER. RER and heat are calculated automatically by the instrument software for each time interval. In this way, the differences in resting and active periods can be seen.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Anesthetic solution

- 1.4 ml ketamine
 - 0.35 ml 2% (w/v) xylazine
 - 3.85 ml 0.9% (w/v) NaCl (sterile)
- Prepare fresh

COMMENTARY

Background Information

The evolution of body weight gain is a critical first-line phenotyping test. Body mass and composition reflect the combined effects of three processes: energy intake, energy partitioning (storage), and energy expenditure. Body-weight evolution, to a large extent reflective of fat stores, represents the net balance between energy intake and energy expenditure. When a loss or gain of weight is evident, or when body composition is altered, a mismatch between energy intake and expenditure should be excluded. The phenotyping protocols outlined here provide a starting point for evaluating all sides of the equation and can provide a direction for subsequent molecular analysis.

Energy intake. The energy required for maintaining body function both at rest and during stress and exercise is provided in the form of carbohydrates, fat, and protein nutrients that are consumed daily (Spiegelman and Flier, 2001). In general, energy intake and energy expenditure are closely matched, such that body weight is remarkably stable even in the face of large fluctuations in caloric intake. The tight matching of energy intake and energy expenditure is governed by the central nervous system, primarily in the hypothalamus (Coppari et al., 2005). Leptin and insulin are primary effectors that activate receptors located on secondary effector neurons in the hypothalamus; these neurons express neuropeptides with long-term effects on food intake and body weight. Orexogenic neuropeptides that increase food intake, such as neuropeptide Y (NPY), are inhibited by leptin and insulin, while anorexogenic neuropeptides, such as proopiomelanocortin (POMC), are up-regulated. These neuropeptides subsequently act on local receptor populations to exert their physiological effects. As circulating insulin and leptin levels are proportional to the amount of body fat, they are critical sensors of long-term energy stores (adipose tissue).

In parallel with these more long-term regulatory signals emanating from the body's energy stores, a number of short-lived satiety factors originate within the gastrointestinal tract. For example, cholecystokinin, glucagon-like peptide, and ghrelin modulate short-term food intake by signaling to the CNS through vagal or sympathetic afferents, as well as through the circulation. Determining changes in food intake and food (lipid) absorption by measuring lipids excreted in the feces is the starting point for the evaluation of energy homeostasis.

Energy storage. The main organ used to store energy ingested in excess of immediate need is adipose tissue (Havel, 2002). In general, the energy density of adipose tissue (containing mainly fat) is >10-fold higher than that of muscle (which is principally composed of protein) or the liver (containing glycogen). The hypothalamic centers also monitor energy stores. For example, serum leptin increases with adipose tissue mass, thus informing the brain of the amount of energy stored. The role of leptin in signaling the brain about chronic changes in energy status is complemented by that of insulin, which conveys additional information about long-term changes in peripheral metabolism to the brain. The subsequent manipulation of energy stores is governed by a wide variety of enzymes, transcription factors, cytokines, and receptors. For example, changes in PPAR γ activity can alter adipocyte differentiation and, ultimately, fat stores. Techniques such as DEXA and QNMR are phenotyping tests that distinguish body composition according to lean and fat, and which can thus identify defects in the distribution or partitioning of stored/chemical energy when energy balance is challenged.

Energy expenditure. The third part of the energy balance equation is energy expenditure (Lowell and Spiegelman, 2000). Energy expenditure consists of several components, roughly separated according to obligatory basal activity (for performance of cellular

and organ functions), physical activity, and adaptive thermogenesis. Whereas energy enters the organism as food, it exits as heat and/or work on the environment. Fuel is converted step-by-step into ATP, which is then used for biological work within the cell; one side product of this reaction is heat. Energy expenditure at rest changes markedly in response to environmental temperature. Part of the response is due to shivering, but another part results from increased adaptive thermogenesis. Adaptive thermogenesis is defined as heat production in response to environmental temperature or diet. It serves to protect the organism from cold exposure or to regulate energy balance after changes in diet. In rodents, brown adipose tissue is a major site of adaptive thermogenesis. A real-life example of an extended cold test such as that described in Basic Protocol 2 is provided by animals that hibernate, such as the bear. Hibernating animals maintain a steady body temperature even though the temperature of the environment around them changes constantly. This production of heat is called non-shivering thermogenesis. The brain detects alterations in environmental temperature and diet, and, through neural circuits, activates efferent pathways to control energy expenditure. The primary efferent pathway is believed to be the sympathetic nervous system, in addition to the hypothalamic-pituitary-thyroid axis. Regulation of energy expenditure is in part achieved by tightly coupling the reactions in energy metabolism. For example, for any given molecule of fuel, a fixed amount of NADH and FADH is generated, which translates into a fixed number of protons that are pumped across the mitochondrial matrix by the electron transport chain. These protons re-enter via ATP synthase and produce a fixed number of ATP molecules that can be used to deliver a fixed amount of biological work. Because the complete combustion of food is achieved at the expense of molecular oxygen, the heat generated in these exergonic reactions can be estimated by measuring oxygen consumption using indirect calorimetry (see Basic Protocol 4). When this test is performed at rest and at thermoneutrality, it reflects mainly obligatory basal energy expenditure and modest physical activity. The cold test (see Basic Protocol 2) is one measure of adaptive thermogenesis and can provide stress that may reveal a change in energy homeostasis not seen under the experimental conditions of calorimetry. When energy expenditure is altered, as indicated by

calorimetry or cold tests, there is either an “uncoupling” of one of the reactions of cellular metabolism or a change in the amount of biological work. For example, uncoupling protein 1 (UCP1) has been shown to increase energy expenditure by uncoupling the relationship between protons entering the mitochondrial matrix and the synthesis of ATP (Lowell and Spiegelman, 2000).

Critical Parameters

Housing conditions and food intake. To determine the amount of food consumed per mouse, the total amount of food consumed per cage is divided by the number of animals per cage. Group housing can be criticized in view of issues of animal dominance as they affect food consumption. However, the authors have recently demonstrated that mice housed individually are severely stressed, which in turn significantly affects numerous parameters including blood insulin and glucose levels (Champy et al., 2004). In this instance, there is a “no win” situation regarding minimizing animal stress and maximizing the accuracy of the food intake measurement. The authors suggest that standard conditions always be used. For example, five mice cannot always be housed in one cage, especially when male littermates are being used, as males from different litters should not be housed together. Furthermore, unless the intention is to breed mice, females and males are never housed together. Thus, the number of cages and the number of mice per cage will likely change depending on the experimental cohort, and each investigator must make the best arrangement given the conditions (e.g., animal housing space, money, cohort size and distribution) available. Multiple tests can affect weight gain, so it is important to have weight values determined at times when minimal manipulations are being performed on the mouse cohorts. Comprehensive cage monitoring systems employing “metabolic cages” are an excellent alternative for automation of the measurement of food intake and various other metabolic parameters (including indirect calorimetry), thus minimizing overall animal stress and duration of the experiments. These metabolic cages can also be designed to study mouse movement and activity levels, as well as sleep patterns.

Body weight gain under calorie-dense diets. In order to accentuate differences in energy homeostasis, it is common practice to challenge mice with diets rich in caloric content. Such challenging conditions will

sometimes cause differences in body weight gain to become apparent. Unlike humans, mice in general do not like diets rich in fat and/or sucrose. This is because these diets often have a different consistency and taste from what they generally prefer. Mice usually like their food to be hard, as is the case with chow-like compositions; however, high-fat diets are generally soft. In the authors' experience, the total volume/mass of food consumed decreases when mice are switched from chow to a high-fat diet. However, despite the reduced mass of food consumed, total caloric intake increases due to the caloric density. In some instances, mice refuse to eat the new diet; to avoid this, the authors often fast mice overnight before switching to a different diet.

Body mass index. It is difficult to calculate the BMI because determining the length of a mouse is not simple. In many cases the differences will be very subtle, on the order of millimeters. In addition to measuring length by using a caliper, measurement can be obtained in parallel with DEXA and/or X-ray analysis, which require the mouse to be anaesthetized and imaged.

Fecal lipid content. The protocol described here is a rapid method for the determination of fat in feces. As the sensitivity of this assay depends on the ability to detect rather small differences in weight, care must be taken. In general, the percent recovery of radiolabeled triolein is 85% to 90%. If the recovery rate is not sufficient, an additional chloroform/methanol solvent extraction can be included and the organic phases combined.

Cold test. In general, this is a relatively simple test. Occasionally, when inserting the thermoprobe into the mouse, resistance is met due to the feces in the colon. In this instance, the lower belly of the mouse can be depressed somewhat to help with the fecal movement and excretion. As this is a fairly stressful test for mice, their health should be monitored throughout; if the body temperature of the mouse goes below 25°C, it should be removed from the cold and marked as "<25°C" for the remainder of the test. The number of mice used for the test depends on how quickly the measurements can be taken with the rectal probe and how long the investigator can stand the cold.

DEXA/QNMR. These tests can easily accommodate a large number of animals. In the case of DEXA, mice should be anesthetized in a staggered fashion, and care should be taken to ensure appropriate recovery. The actual data-acquisition steps for DEXA require

<5 min. For QNMR, mice do not need to be anesthetized, and data acquisition is faster (<2 min). In view of this advantage and the slightly better accuracy, it is expected that QNMR will rapidly become the test of choice for determining body composition (Taicher et al., 2003).

Oxymax analysis. Based on allometric scaling methods, metabolic body mass was estimated as the body weight to the power of 0.75 or 0.67 (ml/kg^{0.75}/hr or ml/kg^{0.67}/hr; Porter, 2001). Ideally, however, VO₂ should be normalized to lean body mass and not total body mass. For groups of animals with roughly the same body composition and fat mass, normalization is not required. However, in obese animals, adipose tissue consists mainly of "metabolically inactive" storage tissue, and even normalization to body weight using the power of 0.75 or 0.67 gives an incorrect estimate of metabolic body mass. In such cases, lean body mass (which reflects "metabolically active tissue") is best obtained from the analysis of body composition as determined by densitometry or an equivalent method. Taking all this into account, the authors prefer to perform indirect calorimetry in young animals, at an age when body weight differences are usually less pronounced.

In order to account for the time the animal requires to habituate to the setting of the Oxymax and overcome stress, the first hour of measurement is generally excluded from the final analysis. In some instances, indirect calorimetry measures are performed over 72 hr; however, the stress associated with continued housing of the mouse alone and on metal floor grids must also be considered. Another consideration is the number of chambers in the indirect calorimetry system, which can vary from 8 to 60 chambers, thus greatly affecting the number of mice measured at one time.

Anticipated Results

A summary of all calculations pertaining to the specific phenotyping tests is presented in Table 29B.1.1.

Body weight and food and water intake. As mice age, they will gain weight (Fig. 29B.1.2). The question is whether the mutant or treated mice gain more or less as compared to the wild-type control mice. Data are generally presented as a growth curve showing the average weight of the mouse over time. In some cases, data are expressed as percent loss or gain in weight as compared to weight at the beginning of the experiment. The length of time for the experiment is generally 6 to 12 weeks. Since

Table 29B.1.1 A Summary of the Measures Used in the Evaluation of Energy Homeostasis

	Measure	Formula (units)
Body	Body weight	(in g)
	Length	(in cm)
	Body mass index (BMI)	body weight/length (in g/cm ²)
Food intake	Food consumed	[food given – food left over (in g)]/no. mice per cage
	Energy consumed	kcal/g of diet × g food consumed (in kcal)
Fat absorption	Fecal lipid content	Retained fat = total fat consumed – excreted fat (in g)
Body composition	Fat	(in g)
	Lean	(in g)
	% Fat	[Fat (in g)/total tissue mass (in g)] × 100
	Bone mineral density (BMD)	(in g/cm ²)
	Bone mineral content (BMC)	(in g)
	Area	(in cm ²)
Cold test	Body temperature	(in °C at T ₁ , T ₂ , T ₃ , T ₄ , T ₅ , T ₆ expressed in hr)
Indirect calorimetry	VO ₂	(in ml/kg ^{0.75} /hr or ml/kg ^{0.67} /hr)
	VCO ₂	(in ml/kg ^{0.75} /hr or ml/kg ^{0.67} /hr)
	Respiratory exchange rate (RER)	VO ₂ /VCO ₂

**Figure 29B.1.2** An example of body-weight evolution in mice. A consecutive experimental strategy was employed whereby adult male wild-type and mutant mice were tested first under chow-fed conditions and then with a high-fat diet. Compared to wild-type mice, mutant mice are resistant to diet-induced obesity.

Figure 29B.1.3 An example of data obtained using DEXA analysis. Adult male wild-type and mutant mice were tested under high-fat diet conditions.

Figure 29B.1.4 An example of data obtained by Oxymax. Adult male wild-type and mutant mice were tested under high-fat diet conditions.

metabolic tests can be stressful and affect the weight, it is preferable to use weight data when the animals are undergoing a minimal number of manipulations. As stated above, calorie-rich diets can increase weight gain.

Fecal lipid content. Values of fecal lipid content in a mouse can vary greatly—anywhere from 20% to 50% of dry weight—and depend on numerous factors such as the type of diet, the genetic abnormality, and the age of the animal. When fecal lipid data are

combined with food-intake experiments, altered patterns of food consumption versus absorption can be distinguished.

DEXA and QNMR analysis. When changes in body weight are detected, parallel changes in body composition should also be found (Fig. 29B.1.3).

Indirect calorimetry. The balance of energy must be accounted for. Therefore, when there are changes in body weight, changes should either be detected in caloric intake or

loss in feces, and/or in energy expenditure (Fig. 29B.1.4).

Time Considerations

Performing *in vivo* mouse experiments is not a trivial process. Considerable planning is required to acquire ethics approvals, not to mention the time needed to generate the experimental mouse cohorts. Compared with this, the time needed to perform the actual phenotyping experiments is usually limited, especially when the protocols have already been standardized and validated. However, it is important to design and adhere to a relevant timeline of experiments, such as that proposed in Figure 29B.1.1, in order to minimize animal stress. The use of a pilot feeding study whereby mouse weight is simply monitored over several weeks is useful in order to indicate whether subsequent full metabolic phenotyping is a priority in the experimental cohort under investigation.

Lipid and Bile Acid Analysis

Clinical chemistry screening to identify changes in concentrations of serum lipids, including cholesterol, free fatty acids (FFA), and triglycerides (TG), is an important part of first-line metabolic phenotyping. Whereas cholesterol is an important body constituent necessary for membrane function and synthesis of hormones and bile acids, TG and FFA are important energy reservoirs. As a consequence of the pleiotropic functions of these lipids, many diseases have been associated with altered lipid levels. For example, elevated low-density lipoprotein (LDL) cholesterol levels increase the risk of atherosclerosis, a pathology characterized by lipid accumulation in the arterial wall (Grundy, 2004). When changes in serum lipids are observed, more detailed phenotyping screens, including lipoprotein profiling and tissue lipid content, can facilitate the identification of the underlying mechanism associated with the dyslipidemia, especially when combined with other phenotypic observations. Since bile acids are the most important pathway for eliminating cholesterol from the body, analysis of serum bile acid levels as well as bile acid pool size and composition is also valuable in a comprehensive lipid phenotyping screen. In addition, serum bile acid levels are an early and sensitive indicator for liver dysfunction. In this unit, methods associated with serum and tissue lipid analysis are outlined, as are protocols for assessing bile acids.

Basic Protocol 1 describes kit-based colorimetric procedures for determining TG, total cholesterol, LDL cholesterol, HDL cholesterol, and FFA. Alternate Protocol 1 describes similar lipid analyses using an automated laboratory workstation. Basic Protocol 2 describes separation of the different lipoprotein fractions by differential ultracentrifugation, while Alternate Protocol 2 describes a comparable fractionation procedure employing fast protein liquid chromatography (FPLC). Both of these procedures yield preparations that can be quantitated via Basic Protocol 1. Basic Protocol 3 describes extraction of lipids from tissue for analysis via Basic Protocol 1. Basic Protocol 4 and Alternate Protocol 3 describe two different methods for measurement of serum bile acids, while Alternate Protocol 4 provides a method for analyzing bile acid pool size and composition. Finally, a Support Protocol is provided for lipoprotein quantitation.

STRATEGIC PLANNING

Critical considerations with respect to the general planning of *in vivo* experiments and minimizing variation due to genotype and phenotype are discussed in *UNIT 29A.2*. Additional considerations in the context of this unit include those associated with blood drawing, such as the method and timing of blood collection and the length of fasting. As mice are small animals, their blood supply is correspondingly small. In general, the blood-draw technique chosen should give the required quantity of blood while minimizing invasiveness (see tail vein method in *UNIT 29A.3*). Although there is no hard and fast rule as to the maximum amount of blood that can be collected at any single point without endangering the mouse, anything over 10% to 15% of total blood volume or 1% of the body weight of the animal can induce hypovolemic shock and/or death. As blood lipid profiles reflect both diet-derived sources and *de novo* synthesis, a critical parameter to consider is the length of fasting prior to blood draw. For general analysis, a 4-hr fast at the end of the dark cycle is sufficient, as this allows for diet-derived lipids to be processed. A 4-hr fast will also limit responses to starvation, such as FFA release. Longer (overnight) and shorter fasts are also often used; however, data must be considered in the context of the concomitant metabolic consequences. Feeding, for instance, is associated with gallbladder contraction; therefore, fasting levels of plasma bile acids tend to be lower than those in the fed state. These considerations are critical anytime comparisons are to be made.

Supplement 75

MANUAL MEASUREMENT OF SERUM LIPIDS

Measurements of triglyceride (TG), total cholesterol, free fatty acids (FFA), and low- and high-density lipoprotein (LDL and HDL) cholesterol can be performed manually or with an automated laboratory workstation, such as the Olympus AU400 or the Cobas Integra (Roche Diagnostics), using specific colorimetric or enzymatic methods. In general, 80 to 150 μ l of plasma is sufficient for all measurements, with the lowest sample quantities being required for the automated protocols. Many of the methods are provided as kits, such that all reagents, standards, controls, and protocols are provided by the manufacturer in a standardized and user-friendly format. Several different suppliers for these kits exist, e.g., Olympus, Cobas (Roche Diagnostics), Wako, and Sigma.

The approaches are generally based on similar principles, with differences mainly in the choice of chromophore and color of the spectra. For example, cholesterol can be measured using an enzymatic color test whereby cholesterol esters (CE) are hydrolyzed by cholesterol esterase to free cholesterol, which is then oxidized by cholesterol oxidase (CHO) to cholestene-3-one. This reaction simultaneously produces hydrogen peroxide, which then is coupled with 4-aminoantipyrine and phenol in the presence of peroxidase (POD) to yield a chromophore that is measured spectrophotometrically. TGs can be measured by a series of coupled enzymatic reactions beginning with hydrolysis by lipases to give glycerol and FFA. The glycerol is then phosphorylated by glycerol kinase to produce glycerol-3 phosphate, which is oxidized by molecular oxygen in the presence of glycerol phosphate oxidase (GPO) to produce hydrogen peroxide and dihydroxyacetone phosphate. The hydrogen peroxide is then used to oxidatively couple *p*-chlorophenol and 4-aminoantipyrin catalysis by POD to give a red dye that is measured spectrophotometrically. FFA are measured using an enzymatic color test whereby acyl CoA synthase is used to convert fatty acids into acyl CoA. In a second reaction, acyl CoA oxidase catalyzes the formation of 2,3-trans-enoyl CoA and hydrogen peroxide, the later product being subsequently reacted with 4-aminophenzone and MEHA and catalyzed by POD to give a red pigment whose intensity is proportional to the concentration of FFA in the sample. HDL cholesterol can be measured using an enzyme chromogen system whereby an anti-human β -lipoprotein antibody is used to bind all non-HDL lipoproteins or apoB-containing lipoproteins (chylomicrons, VLDL, IDL, and LDL). In the first reaction, the antigen-antibody complexes formed with the apoB-containing lipoproteins block all subsequent enzyme reactions, allowing HDL cholesterol to be specifically measured in a second reaction by the CHO/POD system. LDL cholesterol can be measured following a two-step reaction in which the first step uses cholesterol esterase and cholesterol oxidase to break down all non-LDL lipoproteins in the presence of an LDL-cholesterol protecting reagent. In the second step, the protecting reagent is released from LDL, and LDL cholesterol is quantified by the CHO/POD system.

Materials

- Blood serum, plasma, or isolated lipid fraction obtained via other protocols in this unit
- Lipid analysis kits (Wako):
 - Total cholesterol kit
 - LDL cholesterol kit
 - HDL cholesterol kit
 - FFA kit
 - Free cholesterol kit
 - TG kit
- 5-ml plastic or glass tubes
- Spectrophotometer

Table 29B.2.1 Specifications for Lipid Measurements Using Wako Enzymatic Reaction Kits

Test	Sample/standard/calibrator ^a	Reagent 1	Reagent 2	Incubation time/temperature	Absorbance (nm)
Total cholesterol	20 μ l	2 ml	0	5 min, 37°C	600
Free cholesterol	50 μ l	3 ml	0	5 min, 37°C	600
Triglyceride	3 μ l	260 μ l	150 μ l	5 min, 37°C per reaction	600/700
Free fatty acids	50 μ l	1 ml	2 ml	10 min, 37°C per reaction	550
LDL cholesterol	3 μ l	270 μ l	90 μ l	5 min, 37°C per reaction	600/700
HDL cholesterol	3 μ l	270 μ l	90 μ l	5 min, 37°C per reaction	600/700

^aReaction volumes can be scaled to meet the sensitivity and/or volume capacity of spectrophotometer (e.g., 96-well microtiter plate reader).

1. Reconstitute the lipid analysis kit reagents according to the manufacturer's instructions.

Color reagents are generally stable for ~1 month following reconstitution, when stored at 2° to 10°C.

2. Prepare standards by serially diluting the stock standard solution provided at 1:1, 1:2, 1:4, and 1:8.

This should give final concentrations that cover both the lower and upper range of the linear curve. According to many manufacturers, the use of a single standard per reaction is generally sufficient after a calibration/standard curve has been established once to ensure linearity.

3. Pipet sample and standards into the appropriate tubes using the volumes indicated in Table 29B.2.1. Include a tube for a blank (deionized water).

4. Add the required amount of reagent #1 per tube and vortex. Incubate tubes for the indicated amount of time (Table 29B.2.1).

Skip step 5 and proceed to step 6 if the kit involves only a single reagent.

5. Add the required amount of reagent #2 per tube and vortex. Incubate tubes for the indicated amount of time (Table 29B.2.1).

6. Measure the absorbance of each sample (A_s) and standard (A_{std}) against the blank at the suggested wavelength(s) A_1 and A_2 (Table 29B.2.1).

7. Prepare a standard curve by plotting absorbance versus concentration for the standard. Generate an equation of the line using linear regression.

8. Calculate amount of lipid for the sample (in mg/dl) as follows:

a. *From a standard curve:* Read the concentration corresponding to the absorbance of the sample (A_s) from the calibration curve or calculate using the equation of the line $y = mx + b$, where m = slope of the curve and b = the x intercept.

b. *From a single standard:* concentration of sample (in mg/dl) = $(A_s/A_{std}) \times$ concentration of standard (in mg/dl).

c. *For dual-wavelength reactions:* Substitute A_s for $\Delta A_s [(A_{2s} - A_{2blank}) - (A_{1s} - A_{1blank})]$ and A_{std} for $\Delta A_{std} [(A_{2std} - A_{2blank}) - (A_{1std} - A_{1blank})]$.

9. Check results against the manufacturer's specifications of the linear range for the reaction.

For each parameter, a linear range is defined by the kit manufacturer. When the concentration of the parameter is outside this linear range, the results cannot be calculated accurately. If samples exceed the upper limit, they should be diluted with saline or water and the assay should be repeated. The result is then multiplied by the dilution factor. The lowest detectable level has also been estimated for each parameter; it represents the lowest measurable level of the parameter that can be distinguished from zero. It is calculated as the absolute mean plus three standard deviations of twenty replicates of an analyte-free sample.

**ALTERNATE
PROTOCOL 1**

**BLOOD LIPID ANALYSIS USING AUTOMATED LABORATORY
WORKSTATION**

Automated workstations are used increasingly for routine clinical chemistry evaluations in the mouse. Such workstations increase throughput and often reduce the sample volume required for analysis, because many measurements can be combined. Lipid analyses have been adapted for such an automated, high-throughput approach. For a comparison of automated lipid tests, see Table 29B.2.2.

Automated, high-throughput workstations are often found in laboratories that perform many assays, such as large clinical chemistry laboratories in veterinary and mouse clinics. Such high-throughput laboratories can often accommodate samples from outside laboratories. It is worthwhile to identify several laboratories with automated workstations and compare the price and quality of the services provided. One important consideration when opting to outsource tests is to verify that the tests were validated for mouse samples. Although routine cholesterol, triglyceride, and fatty acid measurements are interchangeable between species, differences exist for HDL and LDL cholesterol measurements, which often use species-specific antibodies.

This protocol uses an Olympus AU400 automated workstation, which is at present among the workstations that require the lowest sample volumes—an important advantage when analyzing mouse samples. This system is capable of analyzing serum, plasma, and urine samples, and measures the components of the samples optically. It automates the main processes, including dispensing of sample and reagent, mixing, and photometry. First, the sample probe dispenses serum or plasma in a sample cup that is set on a rack into the specified cuvette of the cuvette wheel unit (88 cuvettes are mounted on the cuvette wheel). Then the specific reagent, which has been added to the reagent refrigeration unit, is added to the sample by the reagent probe. The sample probe and reagent probe units

Table 29B.2.2 Comparison of Automated Lipid Tests

Test	Test principle	Units	Sample volume	Manufacturer/model
Cholesterol	Enzymatic color test, CHOD-PAP method	mmol/liter	3 μ l	Olympus OSR 6116
HDL cholesterol	Immuno-inhibition, enzymatic color test	mmol/liter	2 μ l	Olympus OSR 6187
LDL cholesterol	Enzymatic color test, CHOP-PAP method	mmol/liter	3 μ l	Olympus OSR 6183
Triglyceride	Enzymatic color test, GPO-PAP method	mmol/liter	3 μ l	Olympus OSR 6133
Nonesterified fatty acids (NEFA)	Enzymatic color test, AcylCoA-synthetase + ATP	mmol/liter	8 μ l	Wako

**Lipid and Bile
Acid Analysis**

29B.2.4

are equipped with a wash well for washing the probe after each sample is dispensed. The sample and reagent are mixed in the cuvette by a mixing device, and the system measures the absorbance of the sample. The system is equipped with a photometer lamp to optically measure the mixture in a cuvette. Finally, the optical density of the sample is calculated according to the absorbance measured. The data processor unit employs a personal computer to process data.

Calibration frequency using the Olympus calibrators depends on the parameters to be measured and the workflow. For most parameters described here, calibration is performed once every 5 days or when the analyzer requests a new calibration, or when the control value is outside the acceptable range. Calibrators are typically used undiluted to generate a single reference value, although manufacturer's instructions need to be followed in each case.

Materials

Calibrators for biochemistry on AU400:

Olympus OE 66300 for cholesterol and triglyceride (lyophilized human serum with chemical additives and appropriate enzymes of human, animal, and plant origin)

Olympus ODC0011 for HDL cholesterol and ODC0012 for LDL cholesterol (lyophilized human serum containing human HDL or LDL cholesterol)

Wako 994-75409 for FFA

Intralaboratory controls for biochemistry on AU400:

ODC0003 (Level 1) and ODC0004 (Level 2) Olympus System Reagent Control Serum (lyophilized preparation of stabilized human serum with adjusted levels of defined analytes)

ODC0005 LDL/HDL Cholesterol Control Serum, Levels 1/2 (lyophilized preparation of stabilized human serum with adjusted levels of defined analytes)

Interlaboratory controls: Lyphochek unassayed chemistry control, human, levels 1 and 2 (Bio-Rad C-320-10 and C-325-10)

Serum or plasma samples (80 μ l minimum)

Olympus AU400 automated laboratory workstation and operating manual (<http://www.olympus-global.com>) with appropriate sample tubes and software

Unity Plus quality control software (Bio-Rad)

4-ml, 50 \times 14-mm hemolysis tubes (Sarstedt) with bar-coded labels added in-house

NOTE: For general operation of the analyzer, refer to the operator manual of the AU400.

1. Use the yellow rack for calibration and load the blue rack at position 1 with deionized water to determine the blank value.
2. Test all parameters daily with intralaboratory control sera (Olympus ODC0003, ODC0004, and ODC0005), which consist of lyophilized human plasma with normal and pathological lipid concentrations.
 - a. Thaw and vortex the control sera before use.
 - b. Load controls according to the analyzer's display.
 - c. Manage all control data using software provided with Olympus automated workstation.

Control values must lie within three standard deviations, otherwise the measurement will have to be repeated following recalibration.

3. Test all parameters daily with interlaboratory control sera (Bio-Rad level 1 and 2). Send data monthly to Bio-Rad using Bio-Rad Unity Plus software to provide

for an interlaboratory quality control assessment by the Bio-Rad External Quality Assurance Services.

This program provides a monthly report analysis.

4. Thaw the frozen unknown plasma samples, if needed. If samples are not available in sufficient quantity and/or are very lipemic, dilute 1:2 with deionized water.
5. Aliquot samples into tubes (provided by Olympus; alternatively, use microcentrifuge tubes with lids removed), then place into matching bar-coded hemolysis tubes (bar coding added in-house). Vortex all samples.
6. Load the racks according to the working lists, starting with rack #1. Perform the analyses.
7. Calculate values from the appropriate calibrations.

Each parameter has a limit value specified by the manufacturer. The reaction is valid only within the limits of linearity. Results are generally reported as mmol/liter.

BASIC PROTOCOL 2

LIPOPROTEIN FRACTIONATION BY DIFFERENTIAL ULTRACENTRIFUGATION

When abnormalities are detected in total, HDL, or LDL cholesterol levels, it is useful to isolate and analyze the different fractions of lipoproteins. Two major techniques are used for the separation of lipoprotein fractions, differential ultracentrifugation and chromatography (see Alternate Protocol 2). Differential ultracentrifugation is a preparative method for separating lipoproteins on the basis of their hydrated density. At solvent densities higher than the lipoprotein density, lipoproteins float at a rate dependent on their density, size, and shape. The lipoprotein classes are sequentially isolated by stepwise increases in the solvent density through the addition of salts such as KBr, NaBr, or NaCl (see Fig. 29B.2.1), over a broad range of densities unequally distributed along a gradient from 0.92 to 1.25 g/ml (De Lalla and Gofman, 1954). The classification of lipoprotein particles according to buoyant density (d) includes: chylomicrons ($d < 0.94$ g/ml); very-low-density lipoproteins (VLDL; $d = 0.94$ to 1.006 g/ml); intermediate-density lipoproteins (IDL; $d = 1.006$ to 1.019 g/ml); low-density lipoproteins (LDL; $d = 1.019$ to 1.063 g/ml); and high-density lipoproteins (HDL; $d = 1.063$ to 1.21 g/ml). Their equivalent flotation rates (Sf) by analytical ultracentrifugation, at a background density of 1.063 g/ml, are >400 for chylomicrons, 20 to 400 for VLDL, 12 to 20 for IDL, and 1 to 12 for LDL. At a background density of 1.2 g/ml, HDL₂ and HDL₃ display flotation rates of 3.5 to 9 and 0 to 3.5, respectively. Once lipoprotein fractions are isolated, the particle content of cholesterol, TG, and different apolipoproteins can then be measured.

Materials

Serum or plasma: preferably 400 μ l of freshly collected sample (samples collected under the same conditions can be pooled)

Density gradient solutions (see recipe)

Potassium bromide, solid

Dialysis buffer (see recipe)

1.0-ml polycarbonate ultracentrifuge tubes (Beckman)

Optima TL-100 ultracentrifuge with TLA-100.2 rotor (Beckman) or equivalent ultracentrifuge and rotor

Digital Density Meter DMA3.5 (Anton Paar; <http://www.anton-paar.com>)

Dialysis tubing (Spectra/Por membrane 3.5, Spectrum)

Beaker for dialysis

Additional reagents and equipment for dialysis (APPENDIX 3C), lipid assays (Basic Protocol 1), and protein quantitation (Support Protocol)

Figure 29B.2.1 Isolation of lipoprotein fractions by sequential ultracentrifugation.

Isolate VLDL ($d = 1.006$)

1. Aliquot 400 μl of serum into a 1-ml polycarbonate ultracentrifuge tube and overlay with 600 μl of the $d = 1.006$ density gradient solution.
2. Ultracentrifuge 2 hr at $435,680 \times g$, 15°C , without braking.

All centrifugations in this protocol should be done with a slow deceleration rate, as braking could disrupt the phase separation.

3. Allow the centrifuged sample to return to room temperature and transfer the top layer ($\sim 400 \mu\text{l}$), corresponding to VLDL, to a clean tube using a pipet. Set the bottom fraction aside on ice for continued fractionation.

In general the top layer is an off-white color and can be distinguished from the bottom fraction, which contains the rest of the lipoproteins.

IMPORTANT NOTE: *If the donor animals are not fasted, this top layer will contain chylomicrons as well. Chylomicrons are difficult to separate completely from VLDL; however, if the sample is centrifuged initially for 20 min, the supernatant should contain the larger and lighter particles resembling chylomicrons. The bottom layer is then processed again, as in steps 1 to 3, to isolate the VLDL.*

4. Prepare dialysis tubing by presoaking it in dialysis buffer (APPENDIX 3C). Tie a double knot at one end of the dialysis tubing, then add the VLDL fraction. Double-knot the other end close to the top of the solution to minimize the dilution of the sample. Place the dialysis tubing into a beaker and dialyze against 50 ml dialysis buffer for 24 hr at 4°C with constant mixing, changing the dialysis solution at least three times over this time interval.
5. Collect the dialyzed VLDL sample into a microcentrifuge tube. Set aside for lipid analysis.

Isolate IDL ($d = 1.019$)

6. Resuspend the 600 μl of bottom fraction in a polycarbonate tube and adjust the density from 1.006 to 1.019 by adding 24.3 μl of $d = 1.34$ density gradient solution.

This volume is determined according to the formula $(A \times Y) + (B \times X) = (A + B) \times Z$, where $A =$ volume of sample (600 μl), $B =$ volume of salt solution to add (in this case 24.3 μl), $Y =$ the initial density ($d = 1.006$), $Z =$ density of added salt solution ($d = 1.34$), and $X =$ the final density ($d = 1.019$).

7. Adjust the sample to a final volume of 1 ml by adding $d = 1.019$ density gradient solution, and mix thoroughly.

8. Ultracentrifuge the sample 2 hr at $435,680 \times g$, 15°C , without braking.
9. Warm the centrifuged sample to room temperature and transfer the top layer ($\sim 400 \mu\text{l}$), corresponding to IDL, to a clean tube using a pipet. Set the bottom fraction aside on ice for continued fractionation.
10. Dialyze as in steps 4 and 5.

Isolate LDL ($d = 1.063$)

11. Resuspend the bottom fraction ($\sim 400 \mu\text{l}$) in a polycarbonate tube, add $95.3 \mu\text{l}$ of $d = 1.34$ density gradient solution, and bring the volume to 1 ml with $d = 1.063$ density gradient solution. Mix, then ultracentrifuge 2.5 hr at $435,680 \times g$, 15°C .
12. Allow the sample to return to room temperature and transfer the top layer ($\sim 400 \mu\text{l}$), corresponding to LDL, to a clean tube using a pipet. Set the bottom fraction aside on ice for continued fractionation.
13. Dialyze as in steps 4 and 5.

Isolate HDL ($d = 1.21$)

14. Resuspend the bottom fraction ($600 \mu\text{l}$) in a microcentrifuge tube. Adjust the density to 1.21 by adding $678.5 \mu\text{l}$ of $d = 1.34$ solution, and add $21.5 \mu\text{l}$ of $d = 1.21$ density gradient solution to bring the sample to a final volume of 1.3 ml.
15. Mix the sample, then transfer 1 ml to a polycarbonate tube and ultracentrifuge 3 hr at $435,680 \times g$, 15°C .
16. Allow the sample to return to room temperature and transfer the top layer ($\sim 400 \mu\text{l}$), corresponding to HDL, to a clean tube using a pipet.

The bottom fraction corresponds to the lipoprotein-depleted plasma and can also be analyzed as a control if desired.

17. Dialyze as in steps 4 and 5.

Analyze fractions

18. Analyze dialyzed fractions for total cholesterol and TG content (see Basic Protocol 1) and/or protein content (see Support Protocol).

In general, TG are the predominant lipids in the VLDL fraction, but are very low in the LDL fraction.

To determine the concentration of the various analytes in the HDL fraction, a correction factor of 1.3 is necessary. Lipid content can be normalized to the volume of initial serum to give mg/dl, or to the protein content to give mg lipid/ μg protein.

**ALTERNATE
PROTOCOL 2**

LIPOPROTEIN ANALYSIS BY GEL-EXCLUSION CHROMATOGRAPHY

Separation of lipoprotein fractions can also be performed by gel filtration, which separates proteins on the basis of particle size (Brousseau et al., 1993). Briefly, the plasma samples are applied to a column and eluted at a constant flow rate using elution buffer. The eluted sample is then passed through an online UV detector prior to collection with a fraction collector. The fractionated samples are then subjected to manual or automated lipid measurements (e.g., cholesterol and TG) using enzymatic reagents as in Basic Protocol 1. A profile is then obtained that partitions the amount of lipid or protein according to the different lipoprotein fractions, which can be identified by their known retention times (VLDL = 33 min, LDL = 38 min, and HDL = 47 min).

Figure 29B.2.2 FPLC schematic diagram.

Materials

Serum or plasma

Elution buffer (see recipe)

20% (v/v) ethanol

FPLC system (Fig. 29B.2.2) consisting of:

HPLC pump (P580 A, Dionex)

Multi-sample automatic injector (GINA 50, Dionex)

Column (Superose 6 PC 3.2/30, Amersham Biosciences)

UV/VIS detector (UV170S, Dionex)

Fraction collector (FRAC-100, Amersham Biosciences)

Integrator software (Chromeleon 6.4, Dionex)

0.22- or 0.45-µm HPLC analytical filter for Biocompatible UPCA

Additional reagents and equipment for lipid assays (Basic Protocol 1)

1. Set up an FPLC-type unit as shown in Figure 29B.2.2.
2. On day 1 of the experiment, install the Superose column according to the manufacturer's instructions. To equilibrate the column for first-time use or after long-term storage, flush out the storage solution (generally 20% ethanol) with 2.4 ml water at a flow rate of 20 µl/min, then equilibrate the column with elution buffer at a flow rate of 40 µl/min. Continue until the system is completely free of air bubbles and the UV signal is stable at the selected sensitivity (minimum of 6 hr, preferably overnight).
3. On day 2 of the experiment, prepare the samples by mixing 30 µl of plasma or serum (preferably plasma) with 30 µl of elution buffer. Filter the samples with either a 0.45- or 0.22-µm filter to remove aggregates.

The maximum protein capacity for the column is ~0.5 to 3 mg in a maximum concentration of 50 mg/ml. This range maximizes the resolution and detection of the protein.

4. Place the samples in the autoinjector and set the machine to inject 20 µl of sample onto the column.

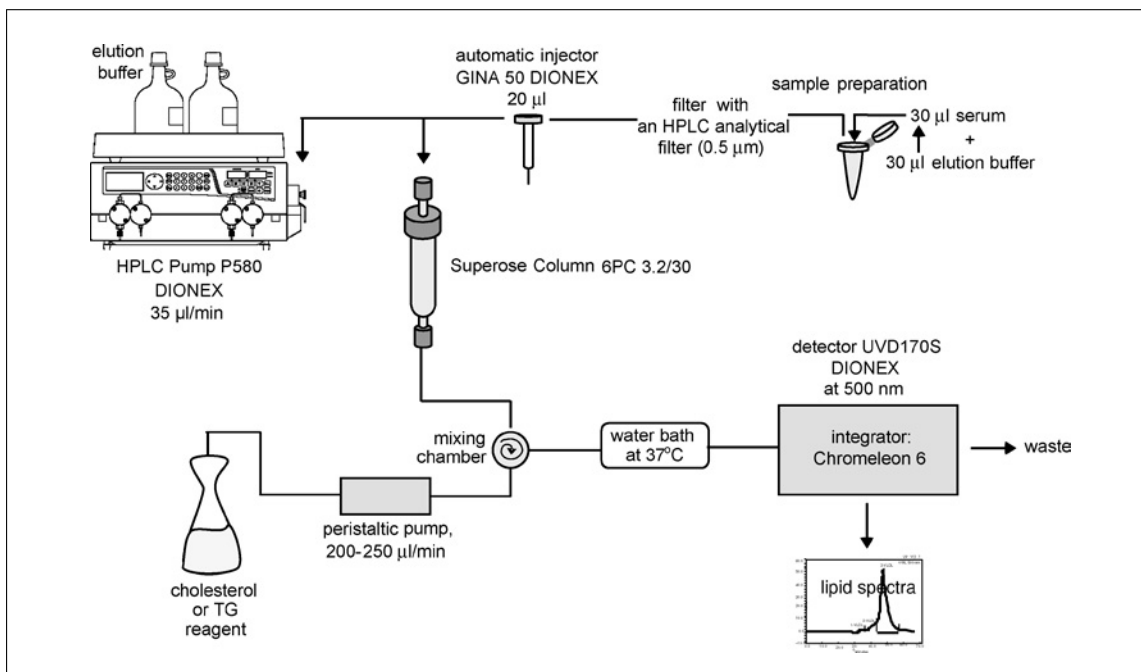

Figure 29B.2.3 Schema showing the adaptation of FPLC to include online lipid measurements.

- Inject the first sample and pass elution buffer through the column at a flow rate of 35 $\mu\text{l}/\text{min}$. Use an online fraction collector to collect ~ 30 to 40 fractions of 75 to 150 μl in microcentrifuge tubes. Measure A_{280} with the online UV detector and record the values using the Chromeleon Integrator system.

In general, the first few fractions can be discarded. Total separation time per sample is 70 min. The known retention times are 33 min for VLDL, 38 min for LDL, and 47 min for HDL.

- Prior to separating the next sample, wash column with elution buffer at a flow rate of 35 $\mu\text{l}/\text{min}$ for 10 min.
- Measure the amount of cholesterol and TG in each fraction as described in Basic Protocol 1.
- Integrate data into a lipoprotein profile using the Chromeleon software according to the manufacturer's instructions, and/or by plotting the lipid content according to fraction number or A_{280} measurement.

One possible adaptation of the FPLC technique described above is to include the capacity for online lipid measurements. A schema showing this adaptation is shown in Figure 29B.2.3; however, specific details are beyond the scope of this unit.

- At the end of the experiment, wash the column sequentially with 4.8 ml water and 4.8 ml 20% ethanol at a flow rate of 35 $\mu\text{l}/\text{min}$. Check that the UV signal is stable after each wash. To prevent drainage during storage, always fill the empty space above the filters and the rubber tubing with 20% ethanol before replacing the protective caps. Store the columns at 4°C.

Columns can be reused up to 100 times. See manufacturer's instructions for special column procedures and troubleshooting if there is a color change in the gel bed, a loss of resolution, or decreased sample recoveries.

TISSUE LIPID ANALYSIS

Lipids can be extracted from tissue (frozen or fresh) and partitioned according to type by using the method of Folch et al. (1951), which is based on a chloroform/methanol extraction. The quantity of cholesterol and TG in the tissue extracts can then be determined by the same enzymatic assays used to detect these lipids in serum. In some instances, it is of interest to distinguish between cholesterol that is esterified and free. Cholesterol ester (CE) represents the metabolically inert pool of cholesterol and is mainly found in the storage lipid droplets, as opposed to free cholesterol, which is associated with the membrane as well as with metabolic regulation. In order to obtain a measurement of CE, enzymatic assays that detect total cholesterol (esterified plus nonesterified) are used in combination with enzymatic assays that detect just free cholesterol. CE is then determined by the subtraction of the free cholesterol measurement from the total cholesterol value.

In general, the lipids that are extracted by chloroform/methanol can be dissolved in 95% ethanol or isopropanol and then quantified via the enzymatic assays. Alternatively, the chloroform/methanol extracts can be dissolved in a 1% Triton X-100 solution in chloroform; the chloroform is then evaporated away, with water being added as the final solvent prior to the measurement of the lipid content by enzymatic assay (Carr et al., 1993). This latter method can be advantageous, as some enzymatic reagents are not compatible with ethanol, and ethanol is a very volatile solvent, making it difficult to manipulate accurately.

CAUTION: Plastic tubes should be avoided due to the possibility of solvents leaching out contaminating lipids. Avoid evaporation of solvents by applying caps or corks to tubes.

Materials

Tissue (~0.5 g)
2:1 (v/v) chloroform/methanol
Methanol
1 α ,2 α -(n)-[³H]cholesteryl oleate (Amersham Biosciences)
Glycerol tri[1-¹⁴C]oleate (Amersham Biosciences)
Chloroform
0.73% (w/v) NaCl
Chloroform/methanol/NaCl (see recipe)
95% ethanol *or* 1% (v/v) Triton X-100 in chloroform
200 μ g/ml cholesterol/triglyceride standard solution: dilute cholesterol and triolein to a final concentration of 200 μ g/ml in isopropanol
14 \times 100-mm Pyrex or borosilicate glass round-bottom tubes with screw caps
Homogenizer (Polytron or equivalent)
12 \times 75-mm glass hemolysis tubes with corks
Whatman filter paper (lipid free)
Nitrogen evaporator with dry bath at ~50°C (e.g., N-EVAP from Organomation)
Scintillation vials, scintillation fluid, and β -counter with dual-channel program for ³H and ¹⁴C

Extract tissue

1. Obtain a piece of tissue with a wet weight of ~0.5 g and place in a Pyrex round-bottom tube. Add 900 μ l of 2:1 chloroform/methanol and homogenize for ~30 sec at high speed in a Polytron-type homogenizer.
2. Add 300 μ l of methanol and vortex. Add 2 μ l each of 1 α ,2 α -(n)-[³H]cholesteryl oleate and glycerol tri[1-¹⁴C]oleate to the sample. Also add the same amounts of these compounds to a scintillation vial to determine counts added.
3. Cap tubes and centrifuge 15 min at 750 \times g, room temperature.

4. Using a glass Pasteur pipet, remove the supernatant to a 12 × 75-mm glass hemolysis tube. If pieces of tissue still contaminate the sample, filter the sample into a new tube using lipid-free Whatman filter paper.
5. Add 400 µl chloroform and vortex.
6. Add 275 µl of 0.73% NaCl and vortex vigorously for ~30 sec.
7. Centrifuge samples 3 min at 750 × g, room temperature.
A phase separation should be visible.
8. Using a Pasteur pipet, remove the top phase and discard. Wash the phase interface by carefully adding 800 µl chloroform/methanol/NaCl with a Pasteur pipet, taking care not to mix the phases. Remove and discard the top phase again and wash the interface another two times in the same manner.
9. While vortexing, add a sufficient amount of methanol to the bottom phase until a single phase is obtained.
10. Evaporate the sample to dryness under a steady stream of nitrogen in a nitrogen evaporator with ~50°C dry bath.
11. Add 500 µl of 95% ethanol or 1 ml of 1% Triton X-100 in chloroform. Vortex, then evaporate to dryness as in the previous step. Resuspend sample in 500 µl deionized water.

Perform lipid assay

12. Generate a standard curve to be used in the enzymatic lipid assays, by preparing duplicate aliquots of 0 (blank), 5, 10, 20, 40, 60, 80, and 160 µl of 200 µg/ml cholesterol/triglyceride standard solution.
13. Evaporate the standards to dryness under nitrogen as in step 10. Resuspend in 500 µl of 95% ethanol or in 1 ml of 1% Triton X-100 in chloroform. For the standards in 1% Triton X-100/chloroform, dry down again and resuspend in 500 µl of deionized water.
14. Determine total cholesterol, free cholesterol, and/or TG content as in Basic Protocol 1. Retain a 25-µl aliquot of each sample and determine radioactivity by β counting.
15. Calculate the percent recovery for cholesterol and TG by dividing the number of counts extracted in the sample by the total number of counts added (step 2), and multiplying the result by 100.

$$\% \text{ recovery for cholesterol} = (\text{}^3\text{H dpm of sample} / \text{total } ^3\text{H dpm added}) \times 100\%$$

$$\% \text{ recovery for TG} = (\text{}^{14}\text{C dpm of sample} / \text{total } ^{14}\text{C dpm added}) \times 100\%$$
16. Adjust the total cholesterol, free cholesterol, and TG (step 14) by multiplying the observed values (in µg lipid/mg tissue) by the percent recovery.
17. Determine the amount of cholesterol ester (CE in µg/mg tissue) by subtracting the amount of free cholesterol from total cholesterol.

ENZYMATIC SERUM BILE ACID MEASUREMENT

Bile acids constitute a group of structurally different molecules synthesized in the liver as a breakdown product of cholesterol (Houten and Auwerx, 2004). In humans, these include the primary bile acids cholic acid (CA) and chenodeoxycholic acid (CDCA), their glycine and taurine conjugates, and the secondary bile acids deoxycholic acid (DCA) and lithocholic acid (LCA). In mice, CDCA and glycine conjugates are practically absent. Instead, muricholic acid (MCA), which is derived from CDCA, is prominent. Since

bile acid synthesis, secretion, extraction from portal blood, and re-excretion all depend on adequate liver function, quantification of serum bile acids represents a sensitive and specific test for liver function. Even more important in the context of metabolic phenotyping is the quantification of bile acid pool size, as most of the regulation of hepatic cholesterol metabolism by bile acids is attributed to the size of the bile acid pool. This is exemplified by the negative feedback mechanism by which bile acids returning to the liver control their own synthesis. However, since recent evidence suggests that the regulatory nature of the bile acid pool depends not just on its size but also on composition, the measurement of both bile acid pool size and composition (see Alternate Protocol 4) are the ultimate goal for evaluating the effect of bile acids (Houten and Auwerx, 2004). For example, a higher abundance of hydrophilic bile acids within the pool seems to induce a greater biliary lipid secretion, whereas hydrophobic bile acids seem to be less effective (Einarsson and Grundy, 1980).

In general, serum bile acids are evaluated under fasting and post-prandial conditions and can be measured using simple enzymatic colorimetric assays (manual or with an automated workstation), or more elaborate methods such as radioimmunoassays or tandem mass spectrometry (see Alternate Protocol 3; Setchell and Matsui, 1983). All bile acids contain a 3 α -hydroxyl group, which can be converted to a 3-keto group by 3 α -hydroxysteroid dehydrogenase. This enzyme simultaneously converts NAD⁺ to NADH, which can be measured spectrophotometrically using different approaches. For example, NADH can be measured by the conversion of nitroblue tetrazolium (NBT) to the formazan dye catalyzed by diaphorase (Mashige et al., 1978).

Materials

Colorimetric Total Bile Acids Assay Kit (containing reagents R1, R2, and R3; Bio-Quant, <http://www.bio-quant.com>)

10 mM taurocholic acid

Bile acid control/calibrator (high and low level; Diagnostics Chemical Limited, <http://www.dclchem.com>)

200- μ l cuvettes

Spectrophotometer

1. Reconstitute the contents of one bottle of R3 with 10 ml of reconstitution buffer (R1). Note the date of reconstitution and the expiration date as indicated by the manufacturer.
2. Prewarm R2 and the reconstituted R3 to room temperature.
3. Serially dilute 10 mM taurocholic acid with water so that the dilutions cover the upper and lower limits of the linear range (1 to 200 μ M).

The method is linear up to 200 μ M. Samples above this range should be adjusted by dilution with saline or water. This self-made taurocholic acid standard can be compared with the single standard of 35 μ M from Bio-Quant.

4. To a 200- μ l cuvette, add 150 μ l of reconstituted R3 and 20 μ l of sample, standard, quality control/calibrator (high and low level of bile acid), or blank (water). Mix well and incubate for 4 min at 37°C.
5. Add 30 μ l of R2, vortex, and immediately read the absorbance at 540 nm as A_1 .
6. Incubate 5 min and read the absorbance at 540 nm as A_2 .
7. Calculate ΔA for each sample and standard using the formula:

$$\Delta A = (A_2 - A_1).$$

8. Generate a standard curve by plotting absorbance versus concentration. Use linear regression to determine the total bile acid concentration of the sample.

Alternatively, the total bile acid concentration can be determined using a single standard (e.g., 35 μM) and the formula:

$$\text{total bile acids (in } \mu\text{M)} = \Delta A_{\text{sample}} / \Delta A_{\text{standard}} \times \text{standard (in } \mu\text{M)}.$$

However, a standard curve should be used instead of a single standard to ensure linearity of the reaction.

ALTERNATE PROTOCOL 3

SERUM BILE ACID MEASUREMENT BY HPLC TANDEM MASS SPECTROMETRY

In order to discriminate between the different bile acid molecules, a reversed-phase HPLC separation of serum can be coupled to the enzymatic detection of bile acids. For this, however, relative large volumes of plasma are needed because of the relatively low sensitivity of the enzymatic assay, which makes this somewhat impractical for measurements in the mouse. Analysis with tandem mass spectrometry (MS/MS) has many advantages. Most importantly, MS/MS gives specific structural information, which in combination with HPLC separation can unambiguously confirm the identity of a molecule. In addition, MS/MS analysis has higher sensitivity when compared with enzymatic detection methods. The sensitivity depends on the type of MS/MS used; in our method the detection limit is 0.05 $\mu\text{mol/liter}$ for conjugated bile acids. MS/MS analysis is thus considered the “gold standard” for analysis of bile acids. A disadvantage is that it requires specific equipment and the availability of stable isotope-labeled standards.

Materials

Plasma

Internal deuterium-labeled standards:

Chenodeoxycholic-2,2,4,4- d_4 acid (C/D/N Isotopes cat. no. D-2772)

Cholic-2,2,4,4- d_4 acid (C/D/N Isotopes cat. no. D-2452)

Glychenodeoxycholic-2,2,4,4- d_4 acid (C/D/N Isotopes cat. no. D-5673)

Glycocholic-2,2,4,4- d_4 acid (C/D/N Isotopes cat. no. D-3878)

Taurine conjugates (custom synthesized)

Acetonitrile (HPLC grade)

1:3 (v/v) methanol/water

1.5-ml microcentrifuge tubes

4-ml glass vials

Nitrogen evaporator with dry bath at $\sim 40^\circ\text{C}$ (e.g., N-EVAP from Organomation)

HPLC-MS/MS (e.g., Hewlett-Packard HP1100 binary pump and a Waters

Micromass Quatro II tandem mass spectrometer equipped with electrospray ionization)

Additional reagents and equipment for liquid chromatography–mass spectrometry (UNIT 10.21)

1. Premix the internal standards in water to prepare a cocktail containing 10 μM of each internal standard. Add 20 μl of this cocktail (200 pmol of each standard) to 20 μl of plasma in a 1.5-ml microcentrifuge tube.
2. Add 250 μl of acetonitrile and mix immediately to precipitate the proteins.
3. Microcentrifuge 12 min at $12,000 \times g$, 4°C .
4. Decant supernatant into a 4-ml glass vial.
5. Evaporate the solvent under a stream of N_2 with heating at 40°C .
6. Dissolve the residue in 70 μl of 1:3 methanol/water.

- Analyze the samples by HPLC-MS/MS (UNIT 10.21).
- Calculate the concentration of bile acids (in μM) by comparing the labeled stable isotopes with the specific bile acids analyzed.

BILE ACID POOL SIZE AND COMPOSITION

The bile acid pool is composed of all bile acids that are present in the liver, gallbladder, and small intestine. As only a small amount of bile acids circulate at a given time in the serum, serum bile acid levels and composition do not always accurately reflect bile acid homeostasis. For this reason, information on the bile acid pool, including of its size and relative composition, yields important additional information about whole-body cholesterol and bile acid homeostasis. Although bile acid pool size can be determined using enzymatic assays and/or radioimmunoassays, the authors recommend using HPLC-MS/MS, since this also reveals the exact composition of the bile acids present in the bile acid pool.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

Materials

- Test animal of interest
- 100% ethanol (HPLC grade)
- Recovery standard (see recipe)
- Internal deuterium-labeled standards:
 - Chenodeoxycholic-2,2,4,4- d_4 acid (C/D/N Isotopes cat. no. D-2772)
 - Cholic-2,2,4,4- d_4 acid (C/D/N Isotopes cat. no. D-2452)
 - Glycochenodeoxycholic-2,2,4,4- d_4 acid (C/D/N Isotopes cat. no. D-5673)
 - Glycocholic-2,2,4,4- d_4 acid (C/D/N Isotopes cat. no. D-3878)
 - Taurine conjugates (custom synthesized)
- Dissecting instruments
- 50-ml conical polypropylene centrifuge tubes (e.g., Falcon)
- 50-ml glass beaker
- Watch glass suitable as cover for 50-ml beaker
- Filter paper (Schleicher-Schuell, type 597)
- Glass funnels
- 50-ml volumetric flask
- HPLC-MS/MS (e.g., Hewlett-Packard HP1100 binary pump and a Waters Micro-mass Quatro II tandem mass spectrometer equipped with electrospray ionization)
- Additional reagents and equipment for liquid chromatography–mass spectrometry (UNIT 10.21)

Extract bile acids

- Remove gallbladder, liver, and the entire small intestine, with contents, from the animal. Store in a 50-ml conical polypropylene centrifuge tube at -80°C until use.

Take extra care not to tear the small intestine, as any leakage of the contents will affect the quantitative measurement. This also applies to the gallbladder and its contents.

It is not necessary to process the entire liver, since this organ normally contains only a small portion of the enterohepatic bile acids. Small pieces of liver can be removed and used for other methods, such as lipid or RNA extraction.

- Transfer the organs to a 50-ml glass beaker, rinsing the storage tube twice with 100% ethanol. Cut tissues into small pieces (1-cm long) with scissors. Add a stir bar.

The total volume of ethanol in the glass beaker should be ~ 40 ml.

ALTERNATE PROTOCOL 4

Mouse Phenotyping

29B.2.15

3. Add exactly 1 ml of recovery standard to each sample.
4. Place the beaker on a hot plate/stirrer for extraction. Cover the beaker with a watch glass. Set the heat so that the ethanol comes to a gentle boil.
5. After 5 min of boiling, remove the beaker from the hot plate and allow to cool to room temperature.
6. Filter the sample using a glass funnel and filter paper into a 50-ml volumetric flask. Rinse beaker with 100% ethanol twice. Bring sample to a volume of 50 ml with 100% ethanol.

Perform assay

7. Transfer 1 ml of ethanolic extract to a 1.5-ml microcentrifuge tube and microcentrifuge 10 min at $15,000 \times g$, room temperature.
8. Dilute supernatant 1:10 with water.
9. Premix the internal standards in water to prepare a cocktail containing 10 μM of each internal standard. Mix equal volumes of the diluted extract and internal standard cocktail (resulting mix contains 5 μM of each internal standard). Analyze the samples by HPLC-MS/MS (*UNIT 10.21*).
10. Calculate the concentration of bile acids (in μM) by comparing the labeled stable isotopes with the specific bile acids analyzed.
11. Calculate the amount of bile acids present in the enterohepatic tissues by correcting for dilution and the amount of norcholic acid added.
12. Divide the result by the body weight of the animal to calculate the amount of bile acids in $\mu\text{mol/kg}$.

SUPPORT PROTOCOL

MODIFIED LOWRY ASSAY FOR LIPOPROTEIN DETERMINATION

For the measurement of protein, several absorbance-based colorimetric methods exist. The most utilized methods rely on the reduction of copper in the presence of a chromogenic reagent. Alternatively, direct absorbance measurements of protein solutions at 280 nm can be performed (*UNIT 10.1A*). The latter technique is readily applied to online detection with FPLC-fractionated samples, whereas a modification of the Lowry procedure can be used for manual measurements. A method for the modified Lowry is provided here and readers are directed elsewhere for alternate methods (Markwell et al., 1978).

The two key modifications in this method include the addition of sodium dodecyl sulfate (SDS) and an increase in the concentration of copper tartrate reagent. The use of SDS in the alkali reagent enables the method to be used with membrane and lipoprotein samples without prior solubilization or lipid extraction. The overnight incubation in alkali is avoided, thus reducing the risk of autooxidation of the lipoprotein samples. The increase in copper tartrate reagent allows the assay of samples containing substantial amounts of sucrose or EDTA without pretreatment. Because precipitating protein quantitatively (i.e., with trichloroacetic acid) may be difficult and increases the time required, this method allows one to process large numbers of samples in a shorter period of time.

Materials

Lowry reagents A and B (see recipe)
 Folin & Ciocalteu's 2N phenol reagent (e.g., Sigma)
 1 mg/ml bovine serum albumin (BSA) standard solution (store at 4°C)
 2 N NaOH
 Spectrophotometer

1. On the day of the assay, prepare reagent 1 by mixing 1 part Lowry reagent B with 100 parts Lowry reagent A.
2. Also on the day of the assay, prepare reagent 2 by mixing Folin & Ciocalteu 2N phenol 1:1 with deionized water.
3. Generate standards by preparing duplicate aliquots of 0 (blank), 5, 10, 20, 40, 60, and 80 μl of 1 mg/ml BSA standard solution. Dilute each aliquot to 200 μl with water.
The standard dilutions should cover the linear part of the standard curve.
4. Prepare duplicate aliquots of sample (for lipoproteins, generally 5 to 10 μl is sufficient). Dilute each aliquot to 200 μl with water.
5. Add 60 μl of 2 N NaOH to each tube and vortex.
6. Add 1 ml of reagent 1 to each tube, vortex, and let incubate for 10 min at room temperature.
7. Add 100 μl of reagent 2 to each tube, vortex, and let incubate for 1 hr at room temperature.
8. Measure the absorbance at 740 nm.
9. Generate a standard curve by plotting a graph of absorbance versus standard concentration. Generate an equation of the line using linear regression. Determine protein concentrations of the unknown samples by comparison with the standard curve.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Chloroform/methanol/NaCl

3 ml chloroform
48 ml methanol
47 ml 0.58% (w/v) NaCl
Store up to 3 months at 4°C

Density gradient solutions

Prepare the following stock salt solutions:

Solution A ($d = 1.005$): dissolve 8.766 g NaCl in 1 liter of aqueous 1% (w/v) disodium EDTA for final concentration of 0.15 M NaCl.

Solution B ($d = 1.346$): dissolve 153 g NaCl and 354 g KBr in 1 liter of aqueous 1% (w/v) disodium EDTA.

Generate all density solutions needed by diluting solution B ($d = 1.346$) with solution A ($d = 1.005$) according to the following equation:

$$(A \times 1.005) + (B \times 1.346) = (A + B) \times X$$

where A = volume of solution A ($d = 1.005$); B = volume of solution B ($d = 1.346$); and X is the desired density of the mixture.

For example, to make 12.05 ml of $d = 1.063$, add 10 ml of solution A and 2.05 ml of solution B. Densities of solutions should be verified by measurement on a Digital Density Meter DMA35.

Store solutions up to several months at room temperature.

Dialysis buffer

10.8 g Na₂HPO₄·12H₂O
1.6 g NaH₂PO₄·2H₂O
35.06 g NaCl
0.4 g NaN₃
0.4 g disodium EDTA
Deionized H₂O to 4 liters
Adjust pH to 7.4 with NaOH
Store up to several months at 4°C

Elution buffer

10 mM Tris·Cl, pH 7.4 (APPENDIX 2A)
30 mM NaCl
Degas and filter through 0.22-μm filter
Store up to several months at 4°C

Lowry reagents A and B

Lowry reagent A:

2% (w/v) Na₂CO₃
0.16% (w/v) sodium tartrate
1% (w/v) SDS
Store up to several months at room temperature

Lowry reagent B:

4% (w/v) CuSO₄·5H₂O
Store up to several months at room temperature

Recovery standard

Dissolve 1 mg norcholic acid (23-nor-5β-cholanic acid-3α,7α,12α-triol) in 50 ml of 100% ethanol and adjust volume to 100 ml with Milli-Q water. Store up to 1 year at room temperature.

COMMENTARY

Background Information

Lipoproteins are supramolecular complexes consisting of lipids and proteins that function in the transport of nonpolar lipids from their sites of synthesis to their sites of utilization (Fig. 29B.2.4; Schaefer et al., 1978, Shepherd and Packard, 1989; Lee et al., 2003). These lipoproteins generally assume a spherical structure whereby the polar phospholipids, proteins, and unesterified or free cholesterol form a monolayer shell that facilitates the transport of core hydrophobic lipids, including cholesterol ester (CE) and triglycerides (TG), in the aqueous blood system. The nonpolar lipids serve numerous biological functions, acting as a transportable metabolic energy pool, as structural components for cell membranes, and as building blocks for hormones. The lipoprotein-associated proteins, or apolipoproteins (apo), have several functions including stabilizing lipid emulsions (apoA, B, C), acting as cofactors and modulators

of enzymatic reactions (apoC, and apoA-I), managing the export of lipids out of cells (apoE and apoB), assisting in the clearance of lipids by target organs and cells through specific receptor interactions (apoB, apoE and apoA), and interfering with platelet aggregation (apoH; Alaupovic, 1991). In humans, abnormalities of lipoprotein transport, synthesis, and degradation, usually of genetic etiology, often lead to disease. Most notably, the metabolic syndrome has an important lipid component including increased plasma levels of TG, apoB, and small dense LDL particles, as well as reduced apoA-I and HDL cholesterol levels. Long-term dyslipoproteinemia associated with the metabolic syndrome increases the risk of atherosclerotic vascular disease and coronary artery disease (Grundy, 2004).

Three pathways can summarize the transport of lipoproteins: exogenous cholesterol transport, forward (endogenous) cholesterol transport, and reverse cholesterol transport (Shepherd and Packard, 1989; Lee et al.,

Figure 29B.2.4 A figure depicting the exogenous, forward, and reverse cholesterol pathways.

2003; Assmann and Gotto, 2004). The exogenous pathway describes the absorption and packaging of dietary-derived lipids into large TG-rich particles called chylomicrons. Chylomicrons are synthesized within the intestinal enterocytes and contain predominantly dietary-derived TGs. Lipoprotein lipase (LPL) hydrolyzes the core TG of the chylomicron, producing CE-rich chylomicron remnants, which are cleared by receptor-mediated endocytosis by the LDL receptor and/or remnant receptors. The forward cholesterol transport pathway involves the assembly and secretion of VLDL by the liver, replacing chylomicrons as the main vehicle of TG transport in the circulation in the post-absorptive state. VLDL are synthesized within hepatocytes and contain mainly endogenously derived TG. VLDL particles are acted upon by circulating lipases, including LPL, resulting in the release of free fatty acids (FFA). The CE-enriched particles—IDL or remnants and LDL—are subsequently cleared by LDL-R-mediated endocytosis in the liver or peripheral tissues including macrophages. Alternatively, these lipoproteins can be oxidized and cleared by macrophages via scavenger

receptor-mediated endocytosis. Lipoprotein uptake by arterial macrophages promotes the formation of lipid-laden cells and consequently atherosclerosis.

The reverse cholesterol transport pathway functions to balance cholesterol deposition in the periphery through the receptor-mediated uptake and retention of apoB-containing lipoproteins. This pathway involves the hepatic secretion of nascent or lipid-poor HDL that serves to remove and carry free cholesterol from the extrahepatic tissues back to the liver, where HDL is degraded and cholesterol is excreted. The ATP-binding-cassette protein ABCA1 is one membrane protein implicated in the lipidation of these nascent HDL particles, with phospholipids thus generating HDL particles that can acquire cholesterol from membrane raft domains in the peripheral tissues. The subsequent exposure of these HDL particles to enzymatic and transfer activities in the plasma transforms them into mature spherical HDL particles designed for clearance by the liver. The interested reader is referred to an extensive review on cholesterol transport pathways (Shepherd and Packard, 1989; Lee et al., 2003; Assmann and Gotto, 2004).

Once transferred back to the liver through the reverse cholesterol transport pathway, excess cholesterol can be converted into bile acids or directly secreted into bile and eliminated from the body. As such, bile formation and bile acid biosynthesis have an important function in whole-body cholesterol homeostasis (Houten and Auwerx, 2004). Bile acids are essential for the absorption of dietary lipids, including fat-soluble vitamins. In recent years, an important role for bile acids as signaling molecules has emerged (Houten et al., 2006). Different bile acids may have different signaling capacities, underpinning the importance of determining bile acid composition and pool size. Most of the bile acids are present within the enterohepatic organs. Usually, bile acids are stored in the gallbladder; however, when a meal is ingested, they flow into the duodenum and intestine. The bile acids are efficiently (95%) absorbed again by passive diffusion and active transport from the terminal ileum, then transported back to the liver via the portal vein. The liver extracts bile acids efficiently from the portal vein and transports them back into the bile duct. From here they can go to the gallbladder for storage or flow into the intestine again. This completes their enterohepatic circulation.

In general, plasma lipoproteins exist in a dynamic equilibrium; thus, what is observed by analyzing lipoprotein fractions is really a static snapshot of this equation. It is best to evaluate lipid and lipoprotein homeostasis in the context of plasma lipid measurements combined with isolated lipoprotein determinations. For example, when there is an elevation in plasma TG in the chylomicron fraction, this may be interpreted as a disorder in chylomicron clearance subsequent to a problem with LPL-mediated hydrolysis of TGs in these chylomicrons. When TG levels are elevated together with elevations in plasma cholesterol and low HDL values, this may rather indicate the presence of the metabolic syndrome with insulin resistance. More detailed measurements, such as individual apolipoprotein content, are possible through such techniques as immunoassays and isoelectric focusing gel electrophoresis. However, these types of data are not clinically useful by themselves and should always be interpreted in the context of the plasma lipid profiles and lipoprotein fraction analysis. For example, the apoB level may provide information on the number of potentially atherogenic lipoproteins, as there is one apoB molecule per particle of chylomicron, VLDL, LDL, or IDL. In humans,

the presence of small, dense LDL particles has been shown to be associated with the metabolic syndrome, and an elevated LDL apoB level may represent the presence of small dense LDL.

Finally, when analyzing lipids in mice, it is important to remember that mice are different from humans. Mouse HDL cholesterol represents between 65% and 75% of the total cholesterol, whereas the LDL cholesterol fraction is only between 10% and 20%. In contrast, human HDL represents less than 20% of the total cholesterol and HDL over 50% to 60%. This is in part due to differences in the metabolism of HDL. Mice have a significantly higher level of circulating lipases, lack the cholesterol ester transfer protein CETP, and have high levels of the phospholipid transfer protein PLTP (Tall, 1995). This is one of the reasons why it is often difficult to mimic human lipid disorders in a mouse. In order to circumvent such problems it is necessary to use transgenic mice, such as the apoE knockout, and/or challenges with environmental conditions, such as administration of a high-fat diet, which can result in more human-like lipoprotein-associated pathophysiology.

Critical Parameters

Blood lipid parameters

To make an initial assessment of lipid and lipoprotein homeostasis in mouse models, the measurement of TG, FFA, and total, LDL, and HDL cholesterol comprise the minimal set of tests required. Blood lipid levels are sensitive to numerous parameters: length of fasting, method of blood draw, time of day for sampling, and method of quantification. Therefore, animals and samples should be manipulated and measured in a consistent way so that the results are readily comparable. In general, only small differences will be observed except under spectacular conditions. When abnormalities of lipid and glucose homeostasis are suspected, a second serum analysis after a shorter (4-hr) fast, or even in absence of fasting, is advisable. Furthermore, retesting in older mice yields quick information on the evolution of biochemical and metabolic parameters.

Manual determination of lipid parameters has a number of disadvantages, since reconstituted reagents are generally good for only 3 weeks. Therefore, samples are usually collected and then batch processed for efficiency. In addition, it is more difficult to take advantage of interlaboratory control systems, which are meant for high-throughput automated

machines. Use of automated systems allows for many more blood parameters to be analyzed simultaneously and requires a smaller volume of serum per test. This can leave sufficient sample for other measurements needed for a good first metabolic screen, including measurement of liver enzymes such as AST and ALT, urea, creatinine, total protein, albumin, glucose, insulin, and total bilirubin.

In general, plasma samples, which are collected in the presence of an anticoagulant, are preferred over serum samples, especially for the automated procedure, as the fibrin in serum can cause clogging of the tiny injection needles. In most cases, either EDTA or heparin can be used as the anticoagulant. In the case of FFA measurements, however, heparin should be avoided because it may activate lipoprotein lipase, which can result in false increases in FFA levels. The range of sensitivity for each enzymatic reaction as specified by the manufacturer should be respected; when samples are too lipemic, they need to be diluted in saline and a correction factor must be applied. Additional considerations for each kit are also given by the manufacturer and should be observed. For example, because the concentration of unesterified fatty acids rises quickly in due to the lipolysis of acylated lipids, FFA determination should be performed soon after the blood draw or on freshly frozen samples. Furthermore, exceeding the recommended incubation time for FFA reactions can lead to aberrantly increased values. This is in contrast to the cholesterol reaction, which is complete in about 2 min but shows no change in absorbance when incubation is continued for another 30 min. In general, these parameters should be carefully standardized so that intra-assay variation is minimal, a task that is more challenging with the manual method.

Lipoprotein analysis

Gel-exclusion chromatography is a quicker method than sequential ultracentrifugation for the separation of lipoproteins, but there is sometimes a disparity between the fractions isolated by centrifugation and by chromatography. This disparity is at least partially due to the difficulty in deciding where the boundaries between the conventional fractions lie on the chromatographic elution curve.

Measuring the protein content of each of the isolated fractions either by UV absorption or by a modified Lowry assay (Markwell et al., 1978) allows for the estimation of particle size. This is particularly relevant in the analysis of

LDL because the protein measurement in the LDL fraction represents the quantity of apoB, as only one apoB exists per LDL particle. Thus, a higher amount of protein can reflect a greater number of particles. When cholesterol content is normalized to protein content, LDL particle density can be compared. As small dense LDL are associated with increased risk of CAD, this is a particularly important parameter (Lada and Rudel, 2004).

Tissue lipid content

Some optimization of this protocol may be required, depending on the mouse model and tissue type used. More lipids will accumulate in a high-fat-diet mouse model than in a chow-fed mouse model. Sample volumes and/or quantity of tissue used for extraction should be titrated such that the final reaction product is within the linear range of the system as stated by the manufacturer.

Bile acid measurements

Most of the bile acids of the enterohepatic circulation can be found in the gallbladder and the small intestine. The quantitative contribution of bile acids in the liver is relatively small. Therefore, it is not critical to extract the whole liver to determine bile acid pool size; however, it is critical to prevent any loss of bile from the gallbladder and contents from the small intestine, since this will affect the quantitative recovery of bile acids.

Several types of colorimetric assays are available for use in the measurement of total bile acids (see Sigma-Aldrich, Randox, BioQuant, DCL, bioMerieux). The general enzymatic principle is that the bile acids are enzymatically oxidized by the enzyme 3 α -hydroxysteroid dehydrogenase, with the concurrent reduction of NAD⁺ to NADH. However, in the fasting state and early stages of disease, levels of bile acids are low, and relatively few molecules of bile acid are available for the enzyme to act upon. Consequently, only a small amount of NAD⁺ is reduced to NADH, making it analytically difficult to directly measure the change in NADH by absorbance at 340 nm. Assay sensitivity is increased by coupling NBT to NADH, since this produces a far greater change in absorbance (now measured at 540 nm) per molecule. Post-prandial lipemia and/or hemolysis interfere with this method (Mashige et al., 1978). In some instances, ultracentrifugation and overnight refrigeration of lipemic specimens can reduce the interference.

In addition to colorimetric assays, a radioimmunoassay (RIA) can also be used to

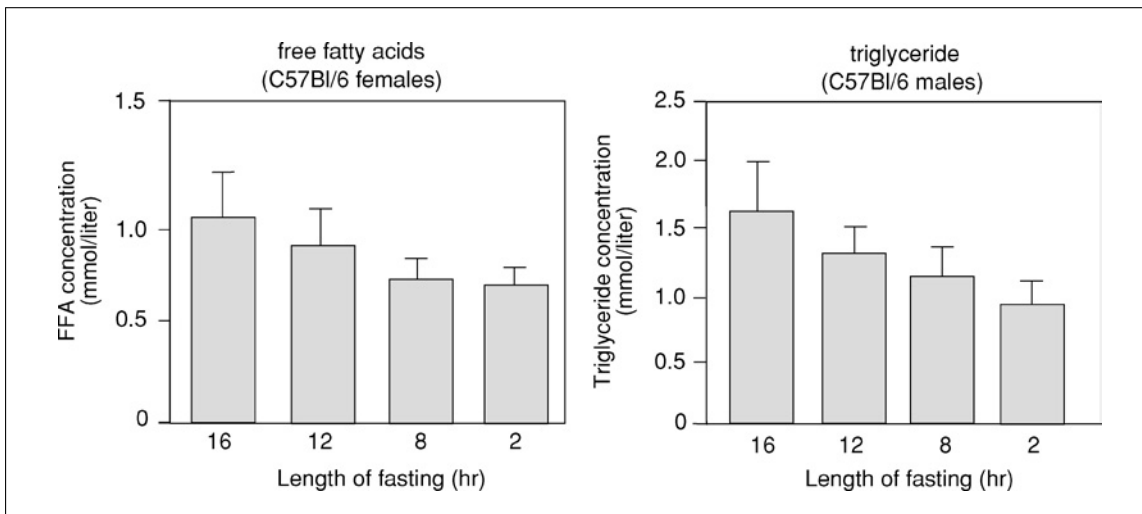

Figure 29B.2.5 Effect of length of fasting on FFA and TG plasma level in C57Bl/6 mice.

Figure 29B.2.6 Typical lipoprotein profile in plasma of C57Bl/6 mice.

Figure 29B.2.7 A typical example of the composition and size of the bile acid pool. Abbreviations: ca, cholic acid; cdca, chenodeoxycholic acid; dca, deoxycholic acid; muri-ca, muricholic acid; udca, ursodeoxycholic acid; and t-, taurine conjugates.

measure total serum bile acid concentrations. An RIA (e.g., *UNIT 10.24*) uses a labeled iodine tracker and an antiserum against the amino acids (taurine or glycine) to which the bile acid is conjugated. Several differences have been noted between the results produced by these techniques, including different absolute values of bile acids, differential interference with hemolysis and lipemia, and differences in the volume of serum required. The authors suggest that careful consideration be given by the user to the appropriateness of the method, depending on individual needs.

Blood draw and handling

If analyses are not performed on the day of blood collection, samples should be stored at -20°C or -80°C . Tests should preferably be performed within 10 days of collection. Stability and storage depend on the different parameters to be determined. Plasma samples can be used undiluted, or diluted with deionized water if the volume is insufficient. In cases where the blood is hemolyzed, hemoglobin can sometimes interfere with certain measurements, and either a correction factor and/or resampling is suggested.

Anticipated Results

Blood lipid content

Blood lipid levels are generally reported in units of mM or mg/dl. The conversion factors for changing cholesterol, TG, and

FFA concentration from mg/dl to mM are 2.586, 1.126, and 0.035, respectively. Blood lipid values are highly influenced by genetic background and environmental factors. Classically, C57BL/6 mice have low plasma cholesterol and low plasma triglyceride (TG) but high plasma glucose levels, whereas C3H mice have high plasma cholesterol, TG, and glucose levels, and 129 inbred strains have high plasma cholesterol and low TG levels. Environmental factors such as diet and length of fasting will also impact some lipid variables (see Fig. 29B.2.5).

Lipoprotein analysis

A typical lipoprotein profile as determined by FPLC is shown in Figure 29B.2.6. Lipoprotein analysis according to differential ultracentrifugation is represented as the amount of lipoprotein (cholesterol or TG) per μg of protein or is normalized to the initial volume of serum.

Tissue lipid content

TG, CE, and free cholesterol content of tissue lipid is generally expressed as mg lipid/mg tissue.

Bile acid measurements

An illustration of bile acid composition analysis is shown in Figure 29B.2.7. In mice, most of the bile acids are conjugated to taurine. Glycine conjugates are practically absent. In the liver and gallbladder, $\sim 95\%$ of the bile

acids are conjugated, whereas in the intestine 30% of the bile acids are deconjugated by microbial enzymes. Typically 42% to 46% of the bile acids are present in the liver and gallbladder; the rest can be found in the small intestine. The hydrophobic-hydrophilic balance of the pool that results from the characteristics and proportions of the individual bile acids present within the pool is critical, as it may dictate most of the effects of bile acids on hepatic cholesterol metabolism (Mashige et al., 1978). For example, hydrophobic bile acids (e.g., CDCA) seem to increase biliary lipid secretion and inhibit cholesterol and bile acid synthesis, whereas hydrophilic bile acids (e.g., CA) are less effective.

In general, the protocol for testing bile acids entails blood sampling after a period of fasting followed by refeeding. Fasting levels of serum bile acids can be used for the diagnosis and prognosis of liver disease. Post-prandial bile acid measurements are also sensitive indicators of liver, intestinal, and gallbladder function. In this sense, bile acid measurements are considered to be a superior indicator of liver disease, compared to serum liver enzyme measures.

The development of glucose intolerance and insulin resistance (IR), characteristics of type 2 diabetes mellitus (T2DM), is a multistep process that is influenced by both genetic and environmental factors. As T2DM is currently the most common endocrine disorder in humans, the detailed understanding of these processes has been critically sought, with the mouse as the leading model. The ability to measure IR and glucose tolerance in the mouse is important both for understanding the pathogenesis of T2DM and for testing potential therapeutic interventions. When an initial blood screen in the mouse indicates altered levels of insulin and/or glucose, a number of well-established tests used to estimate glucose homeostasis and insulin sensitivity should be considered. These tests include model assessments, glucose/insulin infusion sensitivity tests, and clamps.

Because no single test is appropriate under all circumstances and there is considerable variation in the complexity and labor intensity of these various methods, care should be taken in prioritizing them. In general, the choice of method depends on the size and type of study to be undertaken, the goal of the experiment, and the technical expertise at hand. In this unit, tests for exploring glucose homeostasis and insulin sensitivity are described in order of technical invasiveness and ease, with the least invasive described first. In general, this is also the order in which the researcher should evaluate glucose homeostasis and insulin sensitivity in a mouse model, with the importance of each additional test being dependent on the result of the previous test. Thus, although the euglycemic clamp has been referred to as the gold standard for measuring IR, the relevance of performing this test must be considered if prior screening gives no indications that glucose homeostasis or IR is affected.

STRATEGIC PLANNING

The circumstances under which insulin sensitivity and/or glucose tolerance are measured highly influences their interpretation. In fact, insulin sensitivity changes not only in pathological situations but also during normal physiological stresses. To make any consistent assessment of overall insulin sensitivity, it is important to report any specific terminology or descriptors associated with the circumstances of measurement. More importantly, strategic planning is required to optimally control for the tissue-specific, metabolite-specific, and process-specific effects that can influence the conclusions drawn from an experiment. For example, when measuring the effect of IR by following the metabolic clearance of glucose, glucose-mediated glucose uptake must be taken into account, since it is greatly dependent on physical activity. Glucose is liberated from glycogen stores upon exercise, and the capacity to clear glucose from the circulation also increases. Stress and the time of day are also important determinants of IR. In general, mice have increased cortisol levels in the evening, leading to higher hepatic glucose output that can inflate IR. Similarly, increased adrenaline and cortisol levels due to stress can increase hepatic glucose output and consequently affect the assessment of IR. Furthermore, most methods used in the assessment of insulin sensitivity examine the insulin response of a single metabolite, glucose, primarily in the muscle and liver, and under fasting conditions. Because these results reflect only the conditions under which they were obtained, care should be taken not to over-interpret the data.

All these types of confounders and their potential influence on the ability to compare IR among various mouse models prompted the EU-funded Eumorphia program

(<http://www.eumorphia.org>) to standardize several of the parameters associated with measures of glucose homeostasis and IR. The standardized conditions that are presented here as individual protocols are mostly based on the Eumorphia guidelines. However, individual investigators may need to modify these protocols according to their specific needs. A summary of the methods described here is presented in Table 29B.3.1.

NOTE: The protocols described here involve mouse techniques ranging from very basic (e.g., picking up a mouse) to very specialized (e.g., catheter surgery). All personnel taking part in these techniques must be trained beforehand to obtain results while minimizing stress-induced effects on the mouse. Protocols for these techniques can be found in detail elsewhere (Hedrich, 2004). All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

Table 29B.3.1 Summary of Methods Used to Assess Glucose Tolerance and Insulin Sensitivity^a

Test	Labor intensity	Method	Interpretation
FPG and FPI	One blood sample (50–100 μ l; tail bleed or retro-orbital)	Overnight or 4 hr fasting glucose and insulin measurements	Estimate of basal IR
HOMA	Simple calculations	Two formulas using FPG and FPI	Estimate of basal IR and β -cell function (not validated in mouse)
MTT	Two samples (50–100 μ l; tail bleed or retro-orbital)	Overnight fast, and glucose and insulin measurements \pm a standardized meal	Estimate of basal and postprandial IR; intestinal nutrient absorption taken into account
OGTT	Eight small samples (\sim 3 μ l) over 180 min (tail bleed)	Overnight fast, and glucose measurements after oral glucose load	Estimate of IR based on the evolution of glucose levels; intestinal glucose absorption taken into account
IPIST	Six small samples (\sim 3 μ l) over 90 min (tail bleed)	Overnight fast, and glucose measurements after IP insulin load	Estimate of basal insulin sensitivity based on the evolution of glucose levels
IPGTT	Eight small samples (\sim 3 μ l) over 180 min (tail bleed)	Overnight fast, and glucose measurements after IP glucose load	Estimate of IR based on the evolution of glucose levels
Euglycemic clamp	Catheter surgery, small blood samples every 5 to 10 min over 180 min (tail bleed)	Constant rate insulin infusion, variable rate glucose infusion; frequent glucose measurements	Estimate of IR based on average glucose infusion rate over the last 60 min; often regarded as the gold standard

^aFPG, fasting plasma glucose; FPI, fasting plasma insulin; IR, insulin resistance; HOMA, homeostatic model assessment; MTT, meal tolerance test; OGTT, oral glucose tolerance test; IPIST, intraperitoneal insulin sensitivity test; IPGTT, intraperitoneal glucose tolerance test.

GLUCOSE MEASUREMENT BY BLOOD GLUCOSE MONITOR

Circulating glucose is the first and foremost biochemical measure to be taken when evaluating the metabolic phenotype of mice, as changes in this vital and typically strictly regulated metabolite invariably indicate alterations in some aspect of metabolism.

The limited blood volume of the mouse imposes special requirements for the sensitivity of the technique by which any circulating metabolite or substance, including glucose, is measured. In the case of glucose, the problem is exaggerated by the fact that several of the metabolic test protocols provided in this unit require repeated glucose measurements from the same mouse over relatively short intervals. In addition, some tests (e.g., euglycemic clamp) require virtually on-line information about blood glucose levels, setting strict limits for the rapidity of the glucose measurement. Within these parameters, the best method for measuring blood glucose during mouse metabolic phenotyping experiments is usually the blood glucose monitor designed for diabetic humans. These monitors are readily available, easy to use, and relatively inexpensive. Most importantly, they provide reliable results within seconds from a small sample of blood.

This protocol outlines the use of the Accu-Chek Active blood glucose monitor from Roche Diagnostics. For specifics and troubleshooting, refer to the manufacturer's user manual. Examples of similar products include OneTouch Ultra (LifeScan), BD Logic Blood Glucose Monitor (BD), Precision Xtra (Abbott), and HemoCue Glucose (HemoCue). Other techniques for measuring blood glucose, more suited for the analysis of frozen plasma or serum samples at some later point in time, include enzymatic methods, mostly utilizing either hexokinase with glucose-6-phosphate dehydrogenase or glucose oxidase. These methods can be performed manually (e.g., Glucose (HK) assay kit; Sigma) or automatically (e.g., AU-400 automated laboratory work station with OSR6121 glucose reagent; Olympus).

Materials

Mice

Low- and high-level glucose control solutions (e.g., Accu-Chek active glucose control solutions, Roche Diagnostics; low concentration: 50 mg/dl, reference range 42 to 72 mg/dl, and high concentration: 300 mg/dl, reference range 290 to 328 mg/dl)

Blood glucose monitor and associated glucose test strips for glucose measurement (e.g., Accu-Chek Active, Roche Diagnostics)

Scalpel blade

1. Calibrate the blood glucose monitor by first inserting the code key into the slot on the left side with the monitor powered off. Then insert a test strip and verify that the code appearing on the monitor matches that on the test strip vial.

Perform this step every time a new box of test strips is opened.

2. Perform a performance check on the monitor. Insert a fresh test strip, and after the monitor is activated, press the button marked S. Carefully dispense one drop from the low-level control solution bottle and touch it to the center of the orange pad on the strip. Verify that the result, appearing in a few seconds, is within the low range indicated on the test strip vial. In cases where high glucose values are expected, repeat this procedure using a high-level control solution.

A performance check should be done every time a new box of test strips is opened, or if the performance of the monitor is in doubt. It is best to use the same lot number of strips for one experiment, as lot-to-lot variations can occur.

3. Insert a fresh test strip.

The blood sample must be applied within the next 2 min before the monitor powers off.

**BASIC
PROTOCOL 2**

4. Draw a small ($\sim 3 \mu\text{l}$) blood sample from a mouse by nicking the lateral tail vein 1 to 2 cm from the tip with a scalpel blade (see *UNIT 29A.3*).
5. Transfer the drop of blood to the orange pad on the test strip, preferably by touching the strip directly to the bleeding tail wound, or by pipeting. Record the result, which appears in 5 sec.
6. Apply direct pressure to the incision until the blood has clotted and return the mouse to its cage.

INSULIN MEASUREMENT BY ELISA

In addition to glucose, levels of circulating insulin are often of interest due to the importance of this β -cell hormone on the regulation of circulating glucose levels. In general, changes in insulin appear earlier than changes in glucose during the progression of experimental metabolic interventions.

This protocol outlines the use of the Ultrasensitive Mouse Insulin ELISA from Merckodia. This solid-phase direct sandwich ELISA uses two monoclonal antibodies raised against separate antigenic sites on the insulin molecule (for additional description of sandwich ELISAs, see *UNIT 11.2*). Insulin in the sample is immobilized by one anti-insulin antibody bound to the assay well, and is labeled by a second anti-insulin antibody conjugated with peroxidase. Unbound enzyme-conjugated antibody is removed during washing, and the bound conjugate is detected colorimetrically. For additional information, refer to the manufacturer's instructions. Other sources for sensitive ELISA kits for measuring insulin in small volumes of mouse blood or other samples include Alpco Diagnostics, Crystal Chem, and Linco Research.

CAUTION: The stop solution in this kit contains 0.5 M H_2SO_4 . Follow routine precautions for handling hazardous chemicals.

Materials

- Ultrasensitive Mouse Insulin ELISA kit (e.g., Merckodia) containing:
 - 96-well microtiter plates coated with mouse monoclonal anti-insulin antibody
 - Calibrators (i.e., standards)
 - Antibody-enzyme conjugate (concentrate) and buffer
 - Wash buffer (concentrate)
 - TMB substrate reagent (3',3',5',5'-tetramethylbenzidine; light sensitive)
 - Stop solution: 0.5 M H_2SO_4
- Mouse serum or plasma
- 0.9% (w/v) NaCl

- Microtiter plate shaker
- Microtiter plate washer (optional)
- Plate reader capable of measuring at 450 nm

1. Pipet 25 μl of calibrator 0 into each well of a 96-well microtiter plate coated with mouse monoclonal anti-insulin antibody.
2. Pipet calibrators (5 μl) and mouse serum or plasma (5 μl) into duplicate wells of the antibody-coated microtiter plate.
3. Add 50 μl of antibody-enzyme conjugate reagent to each well.

Prepare by diluting the enzyme conjugate concentrate eleven-fold with enzyme conjugate buffer, e.g., add 600 μl to 6 ml of buffer per one 96-well assay. Store up to 2 months at 2° to 8°C.

4. Incubate on a shaker for 2 hr at room temperature (18° to 25°C).

5. Aspirate the reaction volume, add 350 μ l of wash buffer to each well, and aspirate completely. Repeat five times for a total of six washes.

Prepare the wash buffer by diluting the wash buffer concentrate 21-fold with redistilled water, e.g., add 35 ml to 700 ml of redistilled water per one 96-well assay. Store up to 4 weeks at 2° to 8°C.

Washing can also be performed using an automated microtiter plate washer.

6. After the final wash, invert the plate and tap firmly against absorbent paper.
7. Add 200 μ l TMB substrate reagent to each well.
8. Incubate 30 min at room temperature.
9. Add 50 μ l stop solution.
10. Place the plate on the shaker for \sim 5 sec to ensure mixing of substrate and stop reagents.
11. Measure the absorbance at 450 nm and calculate the results according to the manufacturer's manual.

In short, for computerized analysis, plot the absorbance values (y-axis) for the calibrators against the corresponding insulin concentrations (x-axis) as a log-log graph, and fit a cubic spline regression curve (also called third-order polynomial trend line) to obtain the insulin concentrations for the samples. Sometimes a fourth-order polynomial trend line can provide more accurate results. Alternatively, plot the absorbance values on the x-axis against the insulin concentrations on the y-axis, and fit a power trend line to obtain an equation that is easier to solve than above. For manual calculation, plot the calibrators on a log-log or log-lin paper as above, and read the insulin concentrations for each sample from the curve.

12. If the insulin concentration exceeds the value of the highest calibrator, dilute the sample ten-fold with 0.9% NaCl and repeat the analysis.

HOMEOSTATIC MODEL ASSESSMENT

The homeostatic model assessment (HOMA) is a mathematical model that takes into account several parameters known to effect glucose homeostasis. It relies on experimental human data, and allows for values of insulin sensitivity and β -cell function to be obtained when simultaneous fasting plasma glucose and fasting insulin concentrations are known (Matthews et al., 1985; Levy et al., 1998; Wallace et al., 2004). The solutions for the full model have highly significant correlation to euglycemic clamp results in humans (Wallace et al., 2004). Due to their nonlinear nature, they are best calculated using a computerized program available at <http://www.dtu.ox.ac.uk/>. Two simple formulas can be used to approximate the HOMA indices, one for insulin resistance (HOMA-IR) and one for β -cell function (HOMA-%B). This protocol describes these two simple formulas. It should be noted that the validation of HOMA on mice is lacking, so these indices should be used with caution until such validation becomes available.

Materials

Mice

Heparinized tubes for blood sampling (e.g., Microvette, Sarstedt)

Mouse cages

Scalpel blade

Refrigerated microcentrifuge

Additional reagents and equipment for measuring blood glucose (see Basic Protocol 1) and insulin (see Basic Protocol 2)

BASIC PROTOCOL 3

Mouse
Phenotyping

29B.3.5

1. Fast mice 14 to 16 hr (overnight). Ensure that they have ad libitum access to drinking water.
2. Obtain ~100- μ l blood samples in heparinized tubes by nicking the lateral tail vein 1 to 2 cm from the tip with a scalpel blade (see UNIT 29A.3). Apply direct pressure to the incision until the blood clots and then return the mouse to its cage.

A blood glucose measurement can also be taken from whole blood before plasma separation, using a blood glucose monitor (see Basic Protocol 1).

3. Microcentrifuge the blood samples 15 min at $2300 \times g$ (5000 rpm), 4°C. Collect the plasma (~40 μ l) into clean tubes, and store at -20° or -80°C until glucose and insulin measurement (up to 1 month for glucose and 6 months for insulin).
4. Measure blood glucose (see Basic Protocol 1) and insulin (see Basic Protocol 2) levels.
5. Calculate the HOMA-IR and HOMA-%B results according to the following two equations:

$$\text{HOMA-IR} = \frac{\text{FPI} \times \text{FPG}}{22.5 \times 18}$$

$$\text{HOMA-\%B} = \frac{(20 \times \text{FPI})}{\frac{\text{FPG}}{18} - 3.5}$$

where FPI is the fasting plasma insulin concentration ($\mu\text{U/ml}$) and FPG is the fasting plasma glucose concentration (mg/dl).

Glucose values with mmol/liter as a unit can also be used by removing the factor 18 from the formulas (for glucose, 1 mM = 18 mg/dl). Insulin values with pmol/liter as a unit can be converted to $\mu\text{IU/ml}$ by dividing values by 6.945, or from $\mu\text{g/ml}$ to IU/ml by dividing values by 45.5 (for insulin, 1 $\mu\text{U/ml}$ = 6.945 pmol/liter and 1 IU = 45.5 μg of standard preparation).

BASIC PROTOCOL 4

MEAL TOLERANCE TEST

The meal tolerance test (MTT) is a simple method to explore glucose metabolism and insulin secretion following a meal by measuring fasting and fed glucose and insulin levels. First, animals fast for 14 to 16 hr, after which a fasting blood sample is collected by retroorbital venipuncture (Hedrich, 2004). The same animals are then fasted again 1 week later, and a calibrated meal (normally chow diet) is provided for 1 hr in the form of a specific weighed amount of food pellets. Alternatively, a standardized complex nutrient solution (e.g., Ensure Plus, Abbott Nutrition) can be administered in the beginning of the feeding period by oral gavage. A post-prandial blood sample is collected immediately after the 1-hr feeding period.

An alternative to collecting blood on separate days for the fasting and fed states is to use, instead of retroorbital venipuncture under anesthesia, blood sampling from the tail vein (UNIT 29A.3) before (fasting state) and after (fed state) the feeding period (see Basic Protocol 3). However, since stress may alter the feeding behavior of mice, this alternative is mostly useful with the administration of nutrient solution rather than with free pellet feeding.

Materials

Mice

Isoflurane inhalation anesthesia unit (composed of a mixing and flow-control system for O₂/isoflurane anesthesia; e.g., TEM, <http://www.TEM.fr>)

Non-heparinized glass capillaries, 50- to 100- μ l (e.g., Vitrex by Modulohm)

Mouse chow

Mouse cages

Refrigerated microcentrifuge

Additional reagents and equipment for measuring blood glucose (see Basic Protocol 1) and insulin (see Basic Protocol 2) levels

1. Fast mice for 14 to 16 hr (overnight). Ensure that they have access to drinking water at all times.
2. On the following day, before 8 a.m., prepare experiment record sheet, tubes for blood collection, and strips for glucose measurement. Calibrate the blood glucose monitor.
3. At 8 a.m., anesthetize a mouse lightly by isoflurane (see *UNIT 29B.1*, Basic Protocol 1) and take a 50- to 100- μ l blood sample by retroorbital venipuncture (see Hedrich, 2004) into a non-heparinized capillary. Drop a small amount (~ 3 μ l) of blood onto a test strip placed in the blood glucose monitor (see Basic Protocol 1), and collect the rest of the 50- to 100- μ l sample in a non-heparinized capillary on ice. Record the glucose measurement from the monitor.
4. Microcentrifuge the blood samples 15 min at $2300 \times g$ (5000 rpm), 4°C. Collect the plasma (~ 20 to 40 μ l) into clean tubes, and store at -20° or -80°C until glucose and insulin measurement (up to 1 month for glucose and 6 months for insulin).
5. Repeat the fasting 1 week later. On the following day, at 8 a.m., place mice individually in fresh cages with water and a preweighed meal (approximately three pellets of chow diet) for 60 min.
6. Prepare for blood sampling and glucose measurement as in step 2.
7. After the 60-min meal, weigh the remaining food.
8. Take blood samples as described in steps 3 and 4.
9. Perform glucose and insulin measurements according to Basic Protocols 1 and 2.
10. For data analysis, divide the increase in glucose and insulin values over fasting levels for each mouse by the weight of consumed food in grams.

Thus, results are reported as mg/dl \cdot g⁻¹ for glucose and ng/ml \cdot g⁻¹ for insulin. Sometimes, it is also useful to express the results as per calories consumed.

ORAL GLUCOSE TOLERANCE TEST

The oral glucose tolerance test (OGTT) measures the clearance of a standardized glucose load from the body. Since the glucose bolus enters the body via the natural route—it is absorbed from the intestinal tract—this test also takes into account intestinal aspects of glucose absorption. Animals undergo fasting for ~ 14 to 16 hr, a glucose solution is administered by oral gavage (Hedrich, 2004), and blood glucose is measured at different time points in a period of 3 hr.

**BASIC
PROTOCOL 5**

**Mouse
Phenotyping**

29B.3.7

An important consideration for this procedure is the size of the cohort to be assessed at any one time. For two trained persons, a maximum of sixteen animals is recommended. To minimize variation due to technical aspects, each person should be designated a role in the experiment, i.e., only one person/experiment gavages all mice. Therefore, careful planning is needed when dividing an experimental cohort of more than sixteen of animals.

Materials

Mice

20% (w/v) aqueous glucose solution (see recipe), sterile

Mouse cages

Animal scale

Blood glucose monitor and associated glucose test strips for glucose measurement (e.g., Accu-Chek Active, Roche Diagnostics)

1-ml syringes (e.g., Terumo) and 22-G ball-tip needle (e.g., Popper and Sons)

Scalpel blade

Timer

1. Fast mice for 14 to 16 hr (overnight). Ensure that they have access to drinking water at all times.
2. On the following day, at 8 a.m., place mice individually in fresh cages with only water (no food). Identify cages with the mouse number.
3. Record the weight of each mouse to within 0.1 g.
4. Calculate and record the volume of 20% glucose solution required for oral gavage of 2 g glucose/kg at an oral injection volume of 10 μ l/g body weight.

For a mouse with a body weight of 30 g, inject 300 μ l of glucose solution.

5. Prepare experiment record sheet, strips for glucose measurement, and a 1-ml syringe for each animal containing the calculated volume of glucose to be gavaged.

Unlike for intraperitoneal tests (see Basic Protocols 6 and 7), it is practical and more economic to use just one ball-tip needle, which is switched from syringe to syringe as needed, with brief external rinsing in 70% ethanol and distilled water between uses.

6. Calibrate the blood glucose monitor with the standard strip.
7. Measure the basal glucose concentration ($T = 0$) in each mouse by removing one mouse at a time from its cage, placing it on the top of its cage, and making a small incision over the lateral tail vein (1 to 2 cm from the tail tip) using a scalpel blade (see UNIT 29A.3). Touch a small (~ 3 μ l) blood sample directly onto the test strip placed in the blood glucose monitor (see Basic Protocol 1). Apply direct pressure to the incision until the blood clots and return the mouse to its cage.
8. After all mice have been measured for basal glucose concentrations, administer the glucose solution by oral gavage (Hedrich, 2004) to each animal at a 30- or 60-sec interval between animals, depending on the size of the experimental cohort. Start the timer with the first mouse gavaged.

In general, it takes a minimum of 30 sec for an experienced person to perform the gavage and/or take a blood measurement. All injections must be finished within 15 min in order to perform the next blood glucose measurement at $T = 15$ min.

9. At $T = 15$ min, measure the blood glucose again, starting with the first mouse gavaged and using the same time interval used for gavage, until all the mice in the

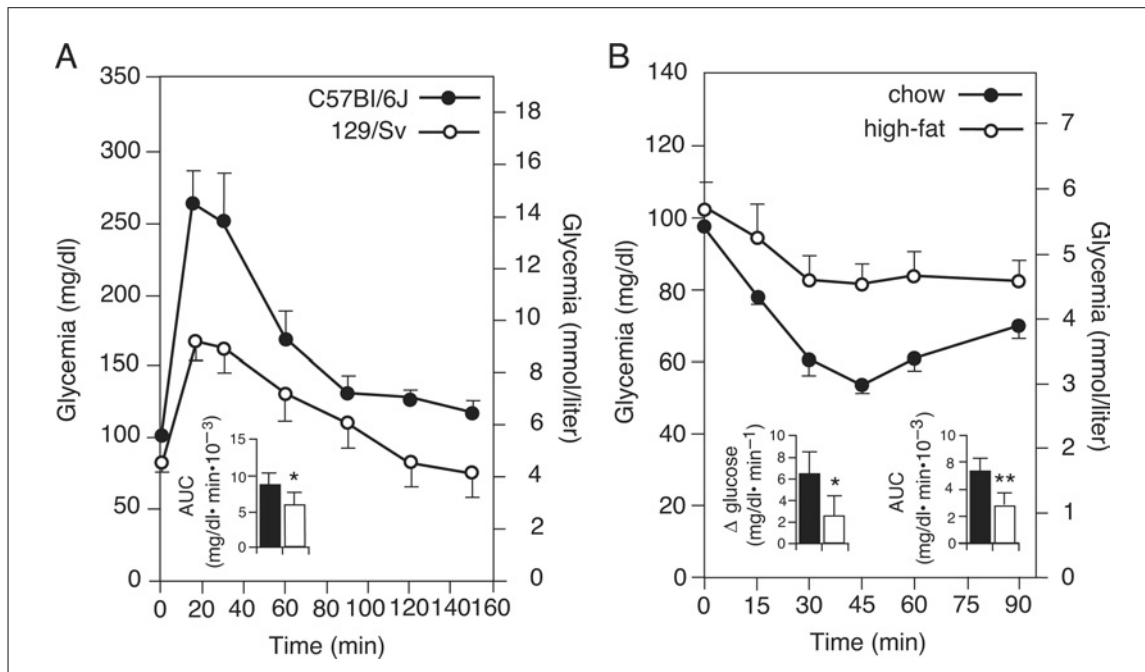

Figure 29B.3.1 Examples of the intraperitoneal insulin sensitivity test (IPIST) and intraperitoneal glucose tolerance test (IPGTT). Note that the figures represent different sets of mice. **(A)** An IPGTT showing a difference in glucose tolerance between wild-type C57Bl/6J and 129/Sv mice, the former being more insulin resistant. **(B)** An IPIST on chow-fed and high-fat-fed mice, showing decreased insulin sensitivity in the high-fat-fed group.

cohort have been measured. It is important that timing be followed as closely as possible. To restart the bleeding, remove the clot from the first incision and massage the tail if blood flow is inadequate.

10. Repeat at $T = 30, 60, 90, 120, 150,$ and 180 min after gavage.
11. At the end of the experiment, return the mice to their original cages and provide plenty of food and water. Ensure that no animal is bleeding excessively.
12. For visual representation, plot glucose values versus time (see Fig. 29B.3.1A for an example of a graph from on IPGTT).
13. For statistical analysis, calculate the area under the curve (AUC) for each mouse using the equation:

$$\text{AUC} = \sum_{n=1}^{x-1} \left((T_{n+1} - T_n) \times \left(\frac{|\text{Glc}_{T_n} - \text{Glc}_{T_{n+1}}|}{2} + \min(\text{Glc}_{T_n}, \text{Glc}_{T_{n+1}}) - \text{Glc}_{T_0} \right) \right)$$

where Glc is glucose concentration, T is time, n is the time point number, x is the total number of time points, and $\min(\text{Glc}_{T_n}, \text{Glc}_{T_{n+1}})$ is the lower of two consecutive glucose concentrations.

The rationale for this calculation is depicted in Figure 29B.3.2.

To exclude the effect of differences in fasting glucose levels between animals, AUC is usually calculated as incremental area ('above baseline'), where only the area above the fasting level for each mouse is taken into account.

Figure 29B.3.2 Rationale for calculating the area under the curve (AUC). Areas of the triangles (gray), delimited by two consecutive time points and glucose values therein, and quadrangles (white), below each triangle but above baseline value, are summed.

**BASIC
PROTOCOL 6**

INTRAPERITONEAL INSULIN SENSITIVITY TEST

The intraperitoneal insulin sensitivity test (IPIST) measures glucose levels subsequent to a standardized insulin load. It gives an estimate of the insulin sensitivity of the animals. Animals are fasted for 14 to 16 hr, a bolus of insulin is administered intraperitoneally (i.p.), and blood glucose is measured at different time points during 90 min.

An important consideration for this procedure is the size of cohort to be assessed at any one time. For two trained persons, a maximum of sixteen animals is recommended. To minimize variation due to technical aspects, each person should be designated a role in the experiment, i.e., only one person/experiment administers insulin to all mice. Therefore, careful planning is needed when dividing an experimental cohort of more than sixteen animals.

Materials

- Mice
- Insulin solution for IPIST (see recipe)
- Mouse cages
- Animal scale
- 1-ml syringes (e.g., Terumo) and 25-G × 5/8-in. needles (e.g., Terumo)
- Blood glucose monitor and associated glucose test strips for glucose measurement (e.g., Accu-Chek Active, Roche Diagnostics)
- Scalpel blade
- Timer

1. Fast mice for 14 to 16 hr (overnight). Ensure that the animals have access to drinking water at all times.

2. On the following day, at 8 a.m., place mice individually in fresh cages with only water (no food). Identify cages with the mouse number.
3. Record the weight of each mouse to within 0.1 g.
4. Calculate and record the volume of insulin working solution required for an i.p. injection of 0.5 IU/kg in an injection volume of 3.6 $\mu\text{l/g}$ body weight.

For a mouse with a body weight of 30 g, inject 108 μl of insulin working solution.

5. Prepare the 1-ml insulin syringes and 25-G \times 5/8-in. needles with the calculated volumes for each animal in the experiment. Prepare experiment record sheet and test strips for glucose measurement.
6. Calibrate the blood glucose monitor with the standard strip.
7. Measure the basal glucose concentration ($T = 0$) in each mouse by removing one mouse at a time from its cage, placing it on the top of its cage, and making a small incision over the lateral tail vein (1 to 2 cm from the tail tip) using a scalpel blade (see UNIT 29A.3). Touch a small ($\sim 3 \mu\text{l}$) blood sample directly onto the test strip placed in the blood glucose monitor (see Basic Protocol 1). Apply direct pressure to the incision until the blood clots and return the mouse to its cage.
8. After all mice have been measured for basal glucose concentrations, administer the insulin solution by i.p. injection to each animal at a 30- or 60-sec interval between animals, depending on the size of the experimental cohort. Start the timer with the first mouse injected.

In general, it takes a minimum of 30 sec for an experienced person to perform the injection and/or take a blood measurement. All injections must be finished within 15 min in order to perform the next blood glucose measurement at $T = 15$ min.

9. At $T = 15$ min, measure the blood glucose again, starting with the first mouse injected and using the same time interval used for injections, until all the mice in the cohort have been measured. It is important that timing be followed as closely as possible. To restart the bleeding, remove the clot from the first incision and massage the tail if blood flow is inadequate.
10. Repeat at $T = 30, 60,$ and 90 min after insulin injection.

CAUTION: If at any time the blood glucose falls below ~ 36 mg/dl, the value should be confirmed. If the value is accurate, the mouse should be rescued by an injection of 0.5 to 1.0 g glucose/kg from a 20% aqueous glucose solution (see Basic Protocol 5), as very low values can be lethal to the animal.

11. At the end of the experiment, return the mice to their original cages and provide plenty of food and water. Ensure that no animal is bleeding excessively.
12. For visual representation, plot absolute glucose values versus time (Fig. 29B.3.1B).

In cases where groups differ strongly in FPG values, plotting the percent of fasting value versus time can be a viable alternative.

13. For statistical analysis, calculate the rate of decline in glucose between T_0 and T_{15} using log-transformed absolute glucose values. Also, calculate the inverse area above the curve (AUC_i) below baseline, again using absolute values, for each mouse as follows:

$$\text{AUC}_i = \sum_{n=1}^{x-1} \left((T_{n+1} - T_n) \times \left(\frac{|\text{Glc}_{T_n} - \text{Glc}_{T_{n+1}}|}{2} + \text{Glc}_{T_0} - \max(\text{Glc}_{T_n}, \text{Glc}_{T_{n+1}}) \right) \right)$$

where Glc is glucose concentration, T is time, n is the time point number, x is the total number of time points, and $\max(\text{Glc}_{T_n}, \text{Glc}_{T_{n+1}})$ is the higher of two consecutive glucose concentrations.

In some cases, it may be useful to calculate AUC_i separately for the last 85 or 60 min of the test since, after the initial direct insulin effect, counter-regulatory hormones and gluconeogenesis will start playing a role. Thus, excluding the initial phase may provide additional phenotypic information.

**BASIC
PROTOCOL 7**

INTRAPERITONEAL GLUCOSE TOLERANCE TEST

The intraperitoneal glucose tolerance test (IPGTT) measures the clearance of an intraperitoneally injected glucose load into peripheral tissues. Compared to the oral glucose tolerance test (OGTT; see Basic Protocol 5), the IPGTT does not address mechanisms participating in glucose absorption from the intestine and hence can be considered a more “artificial” test than the OGTT. This procedure is performed exactly as the OGTT, except that the 20% aqueous glucose solution is administered by i.p. injection using a 25-G \times 5/8-in. needle (e.g., Terumo) and the syringes, containing the calculated volume of glucose, should be prepared for each animal with the needles already attached and voided of dead volume. Similarly to oral administration, a 2 g glucose/kg dose is used, with an i.p. injection volume of 10 μ l/g body weight. Considerations for careful timing and cohort size apply here as well.

**BASIC
PROTOCOL 8**

HYPERINSULINEMIC-EUGLYCEMIC CLAMP

The current gold standard method for measuring IR is the euglycemic clamp, described in this protocol. In this method, glucose is “clamped” at a predetermined value (100 mg/dl or 5.5 mmol/liter for euglycemia) by titrating a variable rate of glucose infusion (glucose infusion rate or GIR) against a fixed rate of insulin infusion (resulting in hyperinsulinemia). Mice are permanently catheterized using a bifurcated catheter assembly to allow for simultaneous constant and variable infusion of insulin and glucose, respectively. The clamps are performed in awake, unrestrained, unstressed, and light-cycle-inverted mice following a 5-hr fast. Mice are acclimatized for at least 30 min to the tops of cages while their catheters are attached to a syringe-infusion pump. Baseline glucose values are measured by tail vein sampling prior to the injection of insulin. Catheter placement is assessed with a short priming dose (6 μ l/min, 1 min) of insulin prior to the constant infusion of insulin at a flow rate of 2 μ l/min equivalent to 18 mU of insulin/kg/min. Blood glucose values are monitored every 5 to 10 min throughout the test. Within the first 15 min, a decrease in blood glucose should be observed, at which point a 20% glucose (in saline) infusion is started. The GIR is varied as necessary until euglycemia ($\pm 15\%$) has been reached and maintained. The animal is “clamped” at this level, and the degree of IR is inversely related to the amount of glucose necessary to maintain the required blood glucose concentrations. The GIR at clamp (mg glucose/kg/min) is calculated as an average during the last 60 min of the experiment. When the average GIR of one animal is greater than another, it indicates better insulin sensitivity or that the clearance of glucose from the plasma is much faster.

Modifications to several parameters of this test—including the duration of fasting, the amount of insulin given at the initial infusion phase, and the inclusion of tracers—may be necessary, depending on the specific aspect of glucose homeostasis that is being studied. A validation of some of these parameters was recently summarized (Ayala et al., 2006).

The details of this procedure are based on assaying six animals at a time by two experienced experimenters. The number of mice will vary depending on the number of people

involved and the size of the experimental cohort required to obtain statistically relevant results. In general, a minimum of six animals per experimental group is required.

NOTE: Catheter surgery should be performed by an experienced veterinarian or other mouse care personnel competent in performing this procedure.

Materials

Mice

Anesthesia: ketamine and xylazine

Insulin solution for euglycemic clamp (see recipe)

20% (w/v) glucose in saline solution (see recipe), sterile

Saline: 0.9% (w/v) NaCl

70% (v/v) ethanol

Mouse femoral catheter (e.g., M-FAC, Braintree Scientific)

Mouse cages with flat-grated lid

Animal scale

1- and 2-ml syringes

Single syringe infusion pumps capable of holding a 2-ml syringe with a range of infusion rates of 5 to 20 $\mu\text{l}/\text{min}$ (e.g., Harvard Apparatus or TSE Systems)

Multi-syringe infusion pump capable of holding a minimum of six individual 1-ml syringes with a range of infusion rates of 3 to 10 $\mu\text{l}/\text{min}$ (e.g., Harvard Apparatus or TSE Systems)

Tubing (e.g., Tygon tubing, \O 0.51 mm, Biorad)

Tubing connectors (e.g., 23-G needles, Terumo)

Y-shaped canula connector (e.g., C312ICP/O, Protech International)

Retort stand with a movable arm to hold the Y-shaped canula connector and tubing in place

Timer

Blood glucose monitors and associated glucose test strips for glucose measurement (e.g., Accu-Chek Active, Roche Diagnostics)

Scalpel blade

Prepare clamp set-up

Prior to the catheter surgery and clamp, mice should be acclimatized to a light-inverted cycle for at least 1 week.

1. At least 2 to 3 days before the experiment, place a catheter in the femoral vein of all mice (under anesthesia using ketamine and xylazine), with the catheter fed underneath the skin and affixed behind the head.

The catheter should not require flushing prior to the experiment if it has been filled with saline and closed the day of the surgery.

2. After surgery, house mice individually and allow to recover for at least 48 hr, preferably long enough for them to regain their pre-operative body weight.
3. On the day of the clamp, remove the food from the mice 5 hr prior to the assay. Maintain access to water.
4. A minimum of 30 min prior to beginning the clamp, weigh the mice to within 0.1 g and place them on top of their cages to acclimatize.
5. Prepare the insulin working solution and fill six 1-ml syringes. Fill six 2-ml syringes with 20% glucose solution.
6. Place all infusion pumps on a shelf above the mice on their cages and insert the six glucose syringes vertically in the six single-infusion pumps. Attach syringes with appropriate tubing and connectors and make the connections from the pump to the

Y-shaped canula connector on the retort stand. Do not make the connection to the animal at this point. Start glucose infusion pumps at a high rate of infusion to fill the line with glucose and look for bubbles or plugs. Ensure that glucose is coming out of the end of the line at a rate comparable to the setting on the infusion pump. Ensure that the mice are not exposed to drips of glucose during the priming of the system.

7. While maintaining the glucose connections, place the six insulin syringes vertically in the multi-syringe infusion pump and connect the insulin syringes with tubing to the Y-shaped canula connector. Again, purge the lines with insulin by turning the infusion pumps on at a high rate. Ensure that insulin fills the lines and there are no bubbles or plugs.

For the general setup, see Figure 29B.3.3.

8. Stop all infusion pumps. Reset the glucose pumps to 5 $\mu\text{l}/\text{min}$ and the insulin pump to 2 $\mu\text{l}/\text{min}$.

A flow rate of 2 $\mu\text{l}/\text{min}$ is equivalent to 18 mU of insulin/kg/min based on an average mouse mass of 20 g. This amount of insulin is enough to obtain hyperinsulinemic conditions in a mouse. In general, this infusion rate of insulin is used even if the mass of each mouse is different so that only one pump is required (the validity of this approach is open for discussion).

9. Connect the infusion tubes to the mice. Ensure that the tubing is not twisted during the experiment and the mice are free to roam the top of the cage.

Figure 29B.3.3 An example of a set-up for a euglycemic clamp showing a single catheterized mouse.

Perform infusions and blood sampling

10. After 30 min of acclimatization, cut the tip of the mouse tail with a scalpel blade. Measure a small sample of blood with the blood glucose monitor to obtain the basal ($T = 0$) glucose value.

This value should be near euglycemia or 100 mg/dl (5.5 mmol/liter).

11. Begin the timer and the insulin infusion pump, starting at an infusion rate of 2 $\mu\text{l}/\text{min}$. After 3 min, increase the insulin infusion rate to 6 $\mu\text{l}/\text{min}$ and maintain for 1 min, and then return to 2 $\mu\text{l}/\text{min}$ for the remaining clamp (180 min). Measure the plasma glucose value at 5-min intervals.

The glucose should be lower at ~ 15 min than at time 0.

12. When the glucose is around euglycemia, begin the glucose infusion pumps, starting at an infusion rate of 5 $\mu\text{l}/\text{min}$.

It is not necessary for all animals to start glucose infusion at the same time.

13. Continue to monitor plasma glucose every 5 min and increase or decrease the individual glucose infusion rates until euglycemia has been reached and maintained. Adjust glucose infusion rates in increments of 1 to 5 $\mu\text{l}/\text{min}$ in the beginning, and then decrease the increments as levels approach euglycemia to ensure that ‘overshooting’ does not occur.

An acceptable range of plasma glucose is within $\pm 15\%$ of 100 mg/dl (5.5 mmol/liter), i.e., from 85 to 115 mg/dl (4.68 to 6.33 mmol/liter). In general, the mice should reach stable euglycemia within 60 min. From this point on, the glucose infusion rate should not change much, and the animal is thus clamped.

14. Once euglycemia is reached, continue infusing glucose and insulin until $T = 180$ min, performing glucose measurements every 10 min instead of every 5 min.

15. At the end of the experiment, disconnect the mice and inject ~ 100 μl of saline into the catheters. Disconnect the glucose and insulin lines, purge them with water, and allow them to dry.

16. Place the mice in clean cages, provide food and water, and ensure that the mice recover from this stressful experiment.

When the mice are finally euthanized, canulae can be recovered and purged with 70% ethanol for reuse.

Analyze data

17. For qualitative purposes, draw a curve that shows the progression of the clamp, i.e., plasma glucose versus time.

This is especially useful for visualizing the stabilization at euglycemia during the last 60 min of the clamp.

18. Calculate GIR (mg glucose/kg/min) for each time point where glucose was sampled using the following equation:

$$\text{GIR} = \frac{\text{Glc}}{m} \times \text{gir}$$

where Glc is glucose concentration (i.e., 20 mg/100 μl or 20%), m is animal weight (kg), and gir is the glucose infusion rate ($\mu\text{l}/\text{min}$).

If the gir was 5 $\mu\text{l}/\text{min}$ and the mouse was 20 g (0.02 kg), then $\text{GIR} = (20 \text{ mg}/100 \mu\text{l}) \div (0.02 \text{ kg}) \times (5 \mu\text{l}/\text{min}) = 50 \text{ mg}/\text{kg}/\text{min}$.

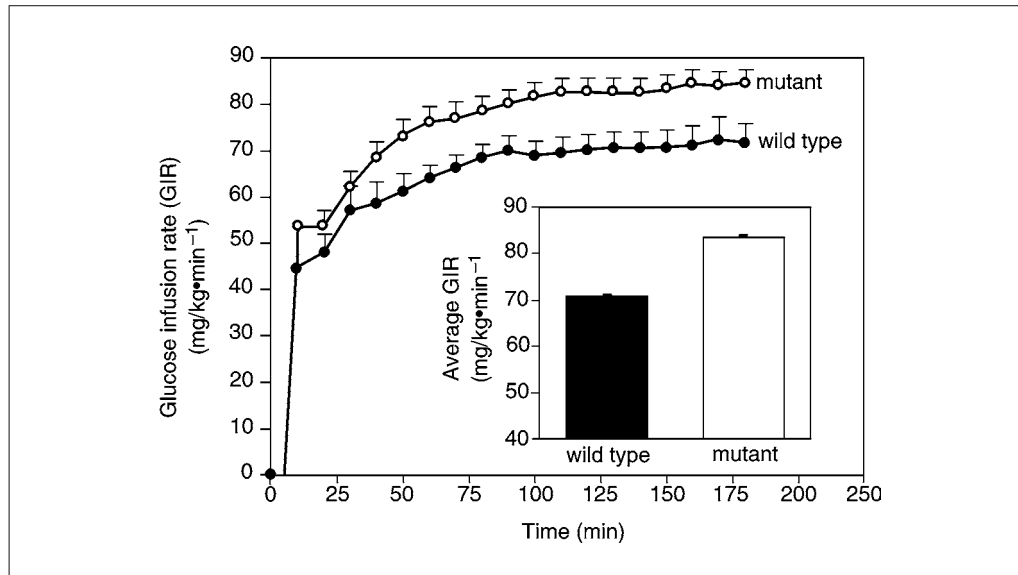

Figure 29B.3.4 Hyperinsulinemic-euglycemic clamp in wild-type and mutant mice. The evolution of glucose infusion rates (GIR), and the average thereof, show that the mutant mice are more insulin sensitive, being able to clear the infused glucose into peripheral tissues more rapidly.

19. Plot GIR versus time (see Fig. 29B.3.4).

The final result represents the GIR averaged over the last 60 min of the clamp, i.e., from 120 to 180 min, and is often depicted as a bar graph (inset in Fig. 29B.3.4).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Glucose solution, 20% (w/v)

Dissolve 20 g D-glucose in 100 ml distilled water or saline. Filter sterilize using a 0.45- μ m filter. Store up to 1 week at 4°C or 6 months at -20°C.

Insulin solution for euglycemic clamp

Diluent stock solution: Dissolve 50 mg fatty acid-free bovine serum albumin (0.5% BSA final) in 9.9 ml sterile water, and add 100 μ l of 1 M HCl (10 mM HCl final). Filter sterilize using a 0.45- μ m filter. Prepare fresh, or store in 1.5-ml aliquots up to 6 months at -20°C.

Working solution: Add 1.15 ml stock solution into 6.048 ml saline. Add 20.1 μ l of 100 IU/ml Humulin insulin (Eli Lilly; 0.278 IU/ml final). Prepare immediately before use.

Insulin solution for IPIST

Diluent stock solution: Dissolve 50 mg fatty acid-free bovine serum albumin (0.5% BSA final) in 10 ml sterile water, and add 10 μ l of 1 M HCl (1 mM HCl final). Filter sterilize using a 0.45- μ m filter. Prepare fresh, or store in 1.5-ml aliquots up to 6 months at -20°C.

Working solution: Add 1.15 ml stock solution into 6.049 ml saline. Add 10 μ l of 100 IU/ml Humulin insulin (Eli Lilly; 0.139 IU/ml final). Prepare immediately before use.

COMMENTARY

Background Information

A principle hormone in metabolic regulation is insulin, which acts to lower blood glucose by stimulating glucose uptake by skeletal muscle and fat and other tissues, and by inhibiting glucose production by the liver. Post-prandial surges and inter-prandial declines of insulin levels tightly control glucose levels such that both hypoglycemia and hyperglycemia, which are intolerable for most tissues, are prevented. One key to glucose control is the ability of pancreatic β -cells to react quickly to changes in blood glucose by altering insulin secretion.

The motivation for investigating insulin and glucose signaling in the mouse is related to the epidemic status of T2DM. The pathophysiological events leading to T2DM in the context of the metabolic syndrome in humans include β -cell failure and resistance of target tissues to insulin. When tissues become insulin resistant, organs cannot respond properly and hyperglycemia prevails. One molecular mechanism thought to contribute to insulin resistance in obese individuals is the increased availability of free fatty acids (FFA) due both to reduced capacity to store the FFA in adipose tissue and to increased lipolysis. In the muscle, increased FFA oxidation leads to reduced glucose oxidative utilization in part through the inhibition of enzymes like pyruvate dehydrogenase, required for the oxidation of glucose, and phosphofructokinase (PFK), a key glycolytic enzyme. Glycogen synthesis is also inhibited by elevated FFA levels, thereby reducing non-oxidative glucose utilization. In the liver, FFA affects the balance between glycolysis and gluconeogenesis. This is attributed to

the tendency of FFA to increase glucose production by enhancing the expression of the key gluconeogenic enzyme phosphoenolpyruvate carboxykinase. The pancreatic β -cells initially try to compensate for the reduced insulin sensitivity by inducing insulin secretion further. Although the resulting hyperinsulinemia is a short-term solution, in the long run, the vicious cycle leads to β -cell dysfunction and severe peripheral insulin resistance (Fig. 29B.3.5).

Thus, there are several indicators of insulin resistance, including elevated fasting glucose and insulin levels and impaired glucose tolerance. These pathophysiological phenomena can be detected in the mouse using similar methods used in humans, including measurements of fasting glucose and insulin levels, glucose/insulin sensitivity tests, and more invasive clamps. After measuring circulating insulin and glucose levels at steady state, the most common test is to administer a glucose load and follow the homeostatic response, which is the culmination of an increase in insulin followed by insulin-dependent processes that lower glucose. Glucose tolerance then becomes an expression of the efficiency with which homeostatic mechanisms restore glycemia to basal levels after perturbation. Finally, the most technically challenging test is the glucose clamp, which is considered the gold standard because its interpretation is based on the least number of assumptions since glycemia is fixed under hyperinsulinemic conditions. The literature shows that correlations between these diverse measures of insulin sensitivity and glucose tolerance are often quite good.

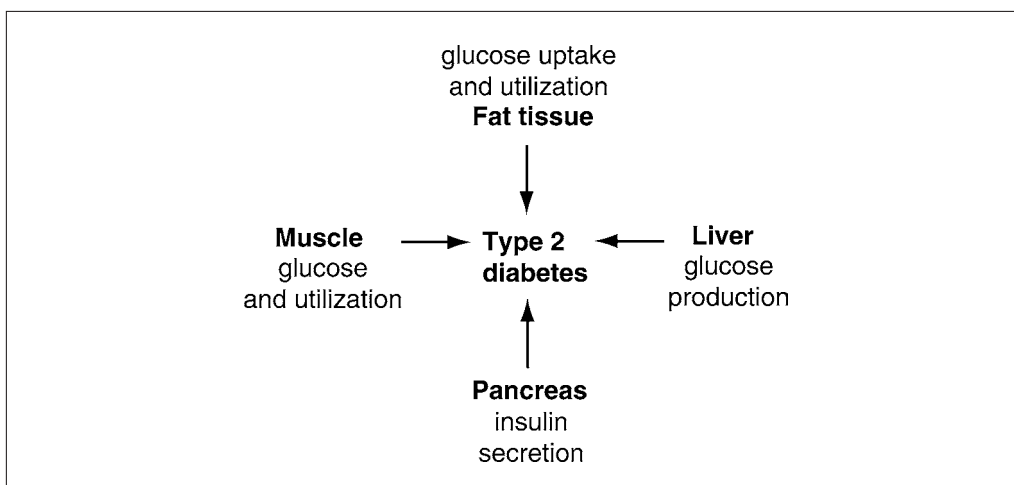

Figure 29B.3.5 Major effects of insulin resistance in different tissues, contributing to the development of type 2 diabetes mellitus (T2DM).

Critical Parameters

The validity of the results obtained from metabolic exploration phenotyping is largely dependent on methods of animal husbandry. To reduce the anxiety levels of the mice prior to and during testing, it is of vital importance that individuals performing these procedures are experienced, aware of the welfare of the mice, and familiar with the mice being tested. General laboratory procedures, and those specifically applicable to animal experimentation, should be followed throughout the protocols.

The majority of mouse metabolic studies are age, sex, and/or strain dependent (Champy et al., 2004). Therefore, it is important to keep these parameters consistent throughout a single experiment. It is also very important that all phenotyping experimentation be conducted at approximately the same time of day because physiological and biochemical parameters change throughout the day. Fasting should be done under conditions where the mice truly cannot eat, e.g., there are no fallen pieces of food pellets within the bedding material.

In tests where glucose is first administered and then measured in the blood, care should be taken not to contaminate any surfaces or materials with the glucose solution itself, as even a minute carryover into the blood samples will result in falsely high glucose measurements. Glucose syringes should be prepared cleanly and in advance, and any spillover or leakage from the injection site during the test should be carefully removed. Changing gloves after any suspected glucose contamination is recommended.

Since the changes in blood glucose (and insulin) concentrations during the tolerance tests are dynamic in nature, the number of mice that will be analyzed in any one experiment must be small enough that the sampling timetable can be precisely kept, especially during the critical initial phases where the most rapid changes are usually observed (typically T_0 to T_{30}). Although increasing the number of experimenters would facilitate the use of more mice in one experiment, for consistent results it would be best if one person obtains all blood samples. Using individual cages will aid in keeping the timepoints accurate by facilitating ease of mouse identification. Another practical method is to identify group-housed mice by marking their tails at the beginning of the test with a felt-tip pen.

Although using the composite measure AUC (or AUC_i) circumvents some of the statistical problems inherent with non-independent repeated measurements, it is still

an approximation based on a fairly limited sampling of the dynamic state. Additional timepoints at the initial phase of the tests would make AUC more accurate, but this may lead to overbleeding the mice, or compromise timely sampling. Alternate methods for calculating the AUC are available, potentially giving more precise approximation from the same number of data points, but these require sophisticated mathematical methods and specialized software beyond the scope of this unit.

Glucose measurement by blood glucose monitor. Although blood glucose monitors provide accurate readings in most situations, it is advisable to use alternate methods to confirm very low readings (<36 mg/dl or 2 mM), which are possible during IPIST or initial phases of the euglycemic clamp, and especially very high values (reported upper limit for Accu-Check glucose monitor is 600 mg/dl or 33.3 mM), which are most likely to occur during peak phase of IPGTT. In addition, some mouse models for IR or T2DM such as KK-Ay mice have high enough glucose levels to very likely require alternate methods for blood glucose analysis.

Insulin measurement by ELISA. Since the overnight fasting insulin levels of the average mouse (see Anticipated Results) are relatively close to the sensitivity limit of even the ultrasensitive insulin ELISA kits (~ 0.2 $\mu\text{g/liter}$ for the Mercodia kit), it is important to pay attention to proper sample storage conditions, minimization of freeze-thaw cycles of the samples, and good washing after the antibody incubation to obtain as many of the samples above the detection limit as possible. On the other hand, especially in some high-fat-fed diabetic mouse models, glucose-stimulated insulin levels may exceed detection limits (~ 7.0 $\mu\text{g/liter}$ for the Mercodia kit), requiring dilution and re-analysis of such samples.

Oral glucose tolerance test. Successful oral gavaging is of vital importance to this test, and should be performed by experienced personnel to minimize animal loss due to gavaging the lungs rather than the esophagus.

Meal tolerance test. The mice should not be stressed before the feeding when free pellet feeding is used to avoid modifications in feeding behavior. For example, removing the bedding material or replacing it with paper towels is not advisable, even though accurate measurement of the food remaining at the end of the feeding period may be more difficult, since small pieces of food pellets may be missed within the bedding material.

Intraperitoneal insulin sensitivity and glucose tolerance tests. It is important to perform intraperitoneal injections in a manner that avoids leakage from the injection site. Another concern, especially with obese mice, is that the injected solution may end up as an inclusion within the large amount of adipose tissue, seriously slowing down the absorption of the substance and the metabolic effects thereof. Since ways to verify this are limited, especially if further experimentation on the same mice is desired, care should be taken at the data analysis phase to exclude unreactive mice. This will be particularly difficult if the groups of mice being compared have a significantly different amount of adipose tissue in the abdominal area, or if there are experimental groups that seem to be less reactive due to physiological rather than technical reasons. Thus, solid mouse handling and injection techniques are essential for success in these tests.

For some mouse models with increased insulin sensitivity, the insulin dose suggested in the protocol may be too high, resulting in severe hypoglycemia. Such mice must either be treated with an immediate injection of ~ 0.5 mg/g body weight glucose or be euthanized. A preliminary test with a small number of mice should be performed to verify the dose-responsiveness of the mice under study. On the other hand, in some experimental setups like after high-fat feeding, increasing the insulin dose may become a necessity. From a technical standpoint, it is also important that only freshly made insulin working solutions be used. This will prevent the insulin in the dilute solution from degrading or binding excessively to the walls of the tubes and syringes. Prior to each IPIST, it is recommended that the insulin first be tested on one additional mouse to verify that a fall in glucose is achieved at the 15-min timepoint.

Euglycemic clamp. Successful catheter placement is vital in this test, and the initial bolus injection of insulin serves to test this. Decreased glucose levels within 15 to 20 min indicate successful catheterization. In addition, care should be taken throughout the entire procedure to ensure that the external catheters are not blocked by tiny air bubbles or improper connections. If bubbles do arise, eliminating them by reconnections may be attempted, but experimentation on the affected mice should be stopped if the blockage is not cleared quickly.

The timing for blood sampling (one every 5 min) is to be used only as a guide. For example, when blood glucose concentration initially starts to fall, more frequent measurements can be taken to ensure that the animal does not become too hypoglycemic before glucose infusion can rescue it; this may lead to the loss of the animal. Similarly, once the animal is clamped and the plasma glucose is obviously stable, the measurements can become less frequent, e.g., one every 10 min. Care should be taken to minimize sample blood loss from the tail bleed to prevent an excessive fall in hematocrit.

It is also important to achieve and maintain euglycemia during the last hour of the test. In non-euglycemic conditions, changes in hepatic glucose output may interfere with the interpretation of the clamp data. In some cases, insulin infusion can be administered per unit of body surface area to avoid overinsulinization of obese mice.

Because of the stressful nature of the clamp experiment, further experimentation in the animals is not recommended, and the mice should preferably be euthanized. If other procedures such as tissue collection are vital, animals should be allowed to recover for at least 1 week.

Anticipated Results

Glucose and insulin measurements. Reference values for fasting plasma glucose and insulin values for a large cohort of C57B6/J mice are presented in Table 29B.3.2. However, depending on prior treatment (e.g., fasting, diet challenges, exercise), in combination with possible genetic modifications, blood glucose and especially insulin values can vary dramatically, particularly upwards. For example, mice lacking insulin receptor specifically in the liver have over 170 times more circulating insulin in the fed state than wild-type mice in the fasting state (Michael et al., 2000). Stimulation during glucose or insulin tolerance tests leads to an even wider range of variation. In models where IR is being induced, increased insulin is usually the first observed effect, and hyperglycemia may or may not follow. As such, elevated fasting glucose level indicates basal IR, which is most often attributed to impaired suppression of hepatic glucose output (gluconeogenesis and glycogen breakdown) by insulin, especially in cases where an increase in glucose is accompanied by an increase in

Table 29B.3.2 Fasting Plasma Glucose and Insulin Values in a Large Cohort of Female and Male C57Bl/6J Mice

	Mean \pm SEM	N
<i>Glucose (mg/dl)</i>		
Female	115.5 \pm 2.7	116
Male	123.6 \pm 2.5	114
<i>Insulin (μg/liter)</i>		
Female	0.798 \pm 0.120	70
Male	0.358 \pm 0.072	78

insulin. On the other hand, low or normal insulin and high glucose levels in a fasting state is often indicative of advanced IR, including inadequate insulin secretion or even β -cell failure. Low insulin with normal glucose often indicates enhanced insulin sensitivity. In addition to conclusions drawn from these separate observations, HOMA indices for IR and β -cell function are useful for initial estimates of the phenotype and the validity of performing further, more invasive tests.

Tolerance tests in general. In all tolerance tests, excluding the IPIST, a considerable increase in glucose (and insulin, if measured) is observed in normal mice, followed by a decrease back toward basal level. Upon insulin challenge (IPIST), the reverse occurs for glucose. The amount and rate of increase and decrease in glucose (and insulin) vary widely depending on the mice and possible dietary or other challenges used. Some indication to possible ranges of outcomes is given below for each test, with a brief description of what the outcomes may indicate. In all tests, baseline (i.e., fasting) values for glucose (and insulin) should correspond to those obtained from prior blood samples from the mice in question.

Meal tolerance test. Changes in plasma glucose and insulin values upon consumption of a standardized meal not only gives information about the glucose homeostatic interplay of muscle, adipose tissue, liver, β -cells, and the brain, but also takes into account the signals that originate from the intestine upon nutrient absorption. Thus, the results of this test are best utilized when correlated with the results of other tests (e.g., IPIST and IPGTT) where intestinal absorption does not play a role. Typically, after a meal in normal mice, glucose and insulin values are expected to increase approximately two- and three-fold, respectively,

compared to the fasting values. Food intake is normally in the range of 0.1 to 0.4 g of pellet chow.

Oral glucose tolerance test. Like the meal tolerance test, an oral dose of glucose will induce some intestinal effects; however, since only glucose is given rather than a full meal containing proteins, fats, and complex carbohydrates, this test scores only for intestinal glucose absorption. Typically, blood glucose is expected to increase 1.5 to 2-fold (T_{15}), followed by a slow decline towards baseline values. The evolution of blood glucose during the test often resembles that seen in the IPGTT (Fig. 29B.3.1A), although the peak is usually somewhat delayed and blunted and the decline back to baseline slower. In insulin resistant states, peak glucose is usually higher and, at a minimum, the following decline is delayed. An increase in the composite AUC measurement is typically a strong indication of stimulated IR, especially when calculated above baseline, as this eliminates the effect of any basal IR.

Intraperitoneal insulin sensitivity test. Excluding the euglycemic clamp, the intraperitoneal insulin sensitivity test is the most direct test of basal insulin sensitivity. Upon insulin injection, glucose typically falls from the fasting level until around T_{30} , after which it stabilizes and starts to climb back towards baseline upon degradation of the injected insulin (Fig. 29B.3.1B). In cases where FPG is greatly different between groups, plotting the glucose curve as percent of baseline values may be advantageous for visual representation, although this will be inherently accounted for in the calculations for the rate of initial decline and AUC_i using absolute values. The slower rate of decline in the initial phase of the test typically indicates impaired insulin sensitivity, mostly in skeletal muscle. During the later stages

of the test, especially at the final timepoints, slower recovery from the hypoglycemic state may indicate delayed activation of counter-regulatory signals or impaired hepatic glucose output. Optimally, all mice should react to insulin by lowered blood glucose levels that stay below baseline for the duration of the test. If this is not the case, calculating AUC_i becomes complicated due to difficulties in accommodating for those values that are higher than baseline. Care should be taken when analyzing the raw data to note such 'aberrant' values and possibly remove those mice from the analysis.

Intraperitoneal glucose tolerance test. Initial peak glucose values should be at least two-fold higher than the baseline value, but can be ten-fold higher or more, greatly depending on the particulars of the experimental set-up, including the genetic background of the mice as seen in Figure 29B.3.1A. When insulin is measured in conjunction with glucose, the evolution of that curve should resemble glucose, albeit with greater potential for variation. Increased AUC in an IPGTT indicates whole-body IR, in which skeletal muscle plays a major role. A significant increase in peak glucose ($T_{15}-T_{30}$) may be indicative of β -cell dysfunction; simultaneous insulin measurement is useful to support this.

Hyperinsulinemic-euglycemic clamp. During the clamp, insulin is administered as a constant infusion and therefore the inherent variations in endogenous insulin secretion are overwhelmed. Simultaneously, the plasma glucose concentration is clamped at the normal fasting level by means of an exogenous infusion of glucose. Thus, in vivo insulin action is measured under comparable conditions of stimulus and substrate. When the steady state is achieved, the exogenous glucose infusion rate equals the amount of glucose disposed of by all tissues, thus providing a quantification of overall insulin sensitivity. An increase in the glucose infusion rate implies increased insulin sensitivity, since the animal cleared more glucose for the same insulin concentration. For an example, see Figure 29B.3.4.

Time Considerations

General time considerations for metabolic phenotyping of mice have been described in UNIT 29B.1. Thus, only those considerations concerning specific protocols in this unit are given here.

Monitoring mouse blood glucose levels using glucometers designed for diabetic persons is very rapid, giving results within seconds. This is a prerequisite for performing more elaborate tests. Performing an insulin ELISA takes the better part of 1 day, but due to the microtiterplate format, hands-on time per sample is fairly short. The tolerance tests, excluding possible prior manipulations such as feeding the mice with altered diets, have a fixed time table. The only variability comes from the number of mice in each experiment. Excluding the overnight fasting, most of the tolerance tests take only a few hours to perform. The clamp is the most time-consuming procedure due to the requirement of catheter surgery and the small number of mice that can be experimented on at one time. Each blood sampling during the tests should not take > 1 min. Analysis of the data from tolerance tests and the clamp is straightforward and fast due to the fairly small number of data points and the lack of complicated calculations. However, interpretation of the data may be a lengthy process.

NPP	nitrophenyl phosphate	PLAP	placental alkaline phosphatase
nr	nonredundant	PMF	peptide mass fingerprint
nt	nucleotide	PMS	pregnant mare's serum
NTA	nitrilotriacetic acid	PMSF	phenylmethylsulfonyl fluoride
NTA-SAM	nitrilotriacetic acid self-assembled monolayer	PMT	photomultiplier tube
NTP	nucleoside triphosphate	PNA	peanut agglutinin
OCT	optimal cutting temperature (medium)	PNGase-F	Peptide:N-Glycosidase F
o.d.	outer diameter	PNP	purine nucleoside kinase
OD₂₆₀	optical density at 260 nm	pNP	<i>p</i> -nitrophenol
OGT	O-GlcNAc transferase	PNPP	<i>p</i> -nitrophenyl phosphate
oligo	oligonucleotide, a short, single-stranded DNA or RNA.	poly(A)	polyadenylic acid or polyadenylate
oligo(dT)	oligodeoxythymidylic acid	poly(A)⁺	polyadenylated (mRNA)
OMIM	Online Mendelian Inheritance in Man	poly(A)⁻	nonpolyadenylated (mRNA)
ONPG	<i>o</i> -nitrophenyl- β -D-galactosidase	poly(dA-dT)	poly(deoxyadenylic acid-deoxythymidylic acid)
ORC	origin recognition complex	poly(U)	polyuridylic acid or polyuridylylate
ORF	open reading frame	PP1	protein phosphatase 1
ori	origin of replication	PP2A	protein phosphatase 2A
PAC	P1-derived artificial chromosome; phenoxyacetyl	PP2B	protein phosphatase 2B
PAD	pulsed amperometric detection	PPase	thermostable pyrophosphatase
PAGE	polyacrylamide gel electrophoresis	ppm	parts per million
PAH	polyaromatic hydrocarbons	PPO	2,5-diphenyloxazole
PAP	peroxidase-anti-peroxidase (reaction)	PR	prosthetic-group removing
par	partition loci on plasmid DNA	PRF	Protein Research Foundation
PB	phosphate buffer	PRINS	primed in situ (labeling)
PBMC	peripheral blood mononuclear cells	Pristane	2,6,10,14-tetramethylpentadecane
PBS	phosphate-buffered saline	ProTherm	Thermodynamic Database for Proteins and Mutants
PCD	programmed cell death	PS	copoly(styrene-1%-divinylbenzene)
PCMB	parachloromercuric benzoate	PSF	point-spread function
PCR	polymerase chain reaction	PSI-BLAST	Position-Specific Iterated BLAST
PDB	Protein Data Bank	Pth	3-phenyl-2-thiohydrantoin
PDD	Protein Disease Database	PTP	protein tyrosine phosphatase
PDMP	1-phenyl-2-decanoylamino-3-morpholino-1-propanol	Pu	purine
PE	phycoerythrin	PVA	polyvinyl alcohol
PEEK	polyethylether ketone	PVC	polyvinyl chloride
PEG	polyethylene glycol	PVDF	polyvinylidene difluoride
PEGA	polyethylene glycol polyacrylamide	PVP	polyvinylpyrrolidone
PEI	polyethylenimine	Py	pyrimidine
PEO	polyethylene oxide	PyAOP	7-azabenzotriazol-1-yl-oxytris(pyrrolidino)phosphonium hexafluorophosphate
PFA	paraformaldehyde	PyBOP	benzotriazolyl- <i>N</i> -oxytris(pyrrolidino)phosphonium hexafluorophosphate
PFGE	pulsed-field gel electrophoresis	rA	riboadenylate
pfu	plaque-forming units	RACE	rapid amplification of cDNA ends
PG	proteoglycan	RAS	Ribi adjuvant system
PGK	phosphoglycerate kinase	RBC	red blood cell
pI	isoelectric point	RBE	relative biological effectiveness
PI	phosphatidylinositol; propidium iodide	RBS	ribosome-binding site
PI-PLC	phosphatidylinositol-specific phospholipase C	RCA I	<i>Ricinus communis</i> agglutinin
PIR	Protein Information Resource		
PITC	phenylisothiocyanate		

Common Abbreviations

Tris tris(hydroxymethyl)aminomethane	VRC vanadyl-ribonucleoside complex
TRITC tetramethylrhodamine isothiocyanate	V₀ void volume
tRNA transfer ribonucleic acid	vol/vol; v/v volume/volume
TS thymidylate synthetase	VSG variant surface glycoprotein
TSA Tris/saline/azide (buffer)	VSV vesicular stomatitis virus
TTP thymidine 5'-triphosphate	WAIS Wide Area Information Service
TUNEL TdT-mediated dUTP biotin nick-end labeling	WAX weak anion exchange
U unit; uracil or uridine	WCX weak cation exchange
UAS upstream activating sequence	WGA wheat germ agglutinin
UDG uracil DNA glycosylase	WR Western Reserve strain (vaccinia)
UDP uridine 5'-diphosphate	WT wild-type
UDP-Gal uridine diphospho-D-galactose	wt/vol; w/v weight/volume
UF ultrafiltration	WWW World Wide Web
UMP uridine 5'-monophosphate	XBE Rex-binding element
UPHS U.S. Public Health Service	Xgal 5-bromo-4-chloro-3-indolyl- β -D-galactoside
URL uniform resource locator	XGPRT xanthine-guanine phosphoribosyl transferase
USDA United States Department of Agriculture	Xyl xylose
UTP uridine 5'-triphosphate	Xyl-A 9- β -D-xylofuranosyl adenine
UTR untranslated leader region	YAC yeast artificial chromosome
UV ultraviolet	YCp yeast centromeric plasmid
UWGCG University of Wisconsin Genetics Computer Group	YEp yeast episomal plasmid
VAF viral-antibody free	YIp yeast integrating plasmid
VAST Vector Alignment Search Tool	YNB-AA/AS yeast nitrogen base without amino acids or ammonium sulfate
Vent <i>Thermococcus litoralis</i> DNA (polymerase)	YPD yeast/peptone/dextrose (medium)
	YRp yeast replicating plasmid

Figure A.1B.1 A physical chemist's view of the cell. The data in this figure were assembled from *The Molecular Biology of the Cell* by Alberts, 1994, and represent the approximate concentrations of a variety of intracellular components.

Table A.1B.1 Conversion Factors

Molecular weight (ave.) of DNA base pair: 649 Da	1 kb DNA: 333 amino acids of coding capacity
Molecular weight (ave.) of amino acid: 110 Da	$\approx 36,000$ Da
1 $\mu\text{g/ml}$ DNA: 3.08 μM phosphate	6.5×10^5 Da of double-stranded DNA (sodium salt)
1 $\mu\text{g/ml}$ of 1 kb DNA: 3.08 nM 5' ends	3.3×10^5 Da of single-stranded DNA (sodium salt)
1 μmol pBR322 (4363 bp): 2.83 g	3.4×10^5 Da of single-stranded RNA (sodium salt)
1 pmol linear pBR322 5' ends: 1.4 μg	
1 A_{260} double-stranded DNA: 50 $\mu\text{g/ml}$	10 kDa protein ≈ 91 amino acids
1 A_{260} single-stranded DNA: 37 $\mu\text{g/ml}$	≈ 273 nucleotides

Table A.1B.2 Genome Size of Various Organisms^a

Organism	Base pairs/ haploid genome	Organism	Base pairs/ haploid genome
SV40	5,243	<i>Drosophila melanogaster</i>	1.4×10^8
ΦX174	5,386	<i>Gallus domesticus</i> (chicken)	1.2×10^9
Adenovirus 2	35,937	<i>Mus musculus</i> (mouse)	2.7×10^9
Lambda	48,502	<i>Rattus norvegicus</i> (rat)	3.0×10^9
<i>Escherichia coli</i>	4.7×10^6	<i>Xenopus laevis</i>	3.1×10^9
<i>Saccharomyces cerevisiae</i>	1.5×10^7	<i>Homo sapiens</i>	3.3×10^9
<i>Dictyostelium discoideum</i>	5.4×10^7	<i>Zea mays</i>	3.9×10^9
<i>Arabidopsis thaliana</i>	7.0×10^7	<i>Nicotiana tabacum</i>	4.8×10^9
<i>Caenorhabditis elegans</i>	8.0×10^7		

^aGenome size determined either by direct sequence analysis (viruses), electrophoretic analysis (*E. coli*, *S. cerevisiae*), or a combination of DNA content per cell and hybridization kinetics. Some data are from *Gene Expression 2* by Lewin, 1980.

Characteristics of Amino Acids

PHYSICAL PROPERTIES

The physical properties of the amino acids determine the structure and function of the proteins in which they are found. Some useful details and relevant physical characteristics of the amino acids can be found in Table A.1C.1. A detailed view of the chemical structures of the amino acids, and an explanation of the role these structures play in enzymes, can be found in Figure A.1C.2. The three-dimensional structure of proteins is largely determined by the packing of their hydrophobic cores; the properties of amino acids that govern this packing are their relative hydrophobicities, which are presented in Figure A.1C.3, and their shapes and volumes, which can be assessed by referring to the space-filling models shown in Figure A.1C.4. While these figures can be useful in rationalizing amino acid functionality, it is also important to consider how natural selection views the interchangeability of amino acids, as diagrammed in Figure A.1C.5 (and Table A.1C.1).

Post-translational modifications will change the mass of a protein or peptide; values for some common mass changes are listed in Table A.1C.3. Mass changes due to some post-translational modifications are found in Table A.1C.4.

CODON USAGE (see Table A.1C.2)

While the amino acid sequence of a protein is selected for in part because of the physical properties of the amino acids themselves, a second, more subtle selection may also operate at the level of the genetic code to determine the sequence of both protein and gene. The genetic code is degenerate. Any of several codons can represent a single amino acid (up to six, in the cases of Arg, Leu, and Ser). However, the frequency with which such synonymous codons are used is not equivalent. Considerations of the bias in codon usage may be relevant to design of synthetic genes (*UNIT 8.2B*), strategies for overexpression of foreign proteins, particularly in *E. coli* (see *UNIT 16.1*), and minimizing degeneracy of oligonucleotide probes and primers (*UNIT 6.4* and *UNIT 15.1*).

The reasons for deviation from random usage seem to differ from organism to organism. For *E. coli* and other microorganisms, it is thought that the codons used more frequently correspond to abundant tRNAs, while the underrepresented codons are those associated with less abundant tRNAs. Since this bias seems particularly strong for genes encoding highly expressed proteins, it is thought to be related to maximizing translation efficiency. In higher organisms, the bias in codon usage may be more closely associated with selection pressures acting at the level of DNA. Mammalian genomes, in particular, show quite significant reductions in the frequency of the dinucleotide CpG, which is a site for methylation. In mammalian genes, codons containing this sequence can be quite strongly underrepresented.

It is worth emphasizing that the bias against particular codons is not absolute. While there may be strong trends within a particular organism, individual genes (particularly those expressed at low levels) may deviate substantially (see Sharp et al., 1988). Interestingly, codon usage is quite similar within the broad groups presented (see Wada et al., 1990, for a comparison of mammals).

Table A.1C.1 Physical Characteristics of the Amino Acids

Amino acid	3-letter code	1-letter code	Mol. wt. (g/mol)	Accessible surface area ^a	Hydrophobicity ^b	Relative mutability ^c	Surface probability ^d
Alanine	Ala	A	89.1	115	-0.40	100	62
Arginine	Arg	R	174.2	225	-0.59	65	99
Asparagine	Asn	N	132.1	160	-0.92	134	88
Aspartate	Asp	D	133.1	150	-1.31	106	85
Cysteine	Cys	C	121.2	135	0.17	20	55
Glutamate	Glu	E	147.1	190	-1.22	102	82
Glutamine	Gln	Q	146.2	180	-0.91	93	93
Glycine	Gly	G	75.1	75	-0.67	49	64
Histidine	His	H	155.2	195	-0.64	66	83
Isoleucine	Ile	I	131.2	175	1.25	96	40
Leucine	Leu	L	131.2	170	1.22	40	55
Lysine	Lys	K	146.2	200	-0.67	56	97
Methionine	Met	M	149.2	185	1.02	94	60
Phenylalanine	Phe	F	165.2	210	1.92	41	50
Proline	Pro	P	115.1	145	-0.49	56	82
Serine	Ser	S	105.1	115	-0.55	120	78
Threonine	Thr	T	119.1	140	-0.28	97	77
Tryptophan	Trp	W	204.2	255	0.50	18	73
Tyrosine	Tyr	Y	181.2	230	1.67	41	85
Valine	Val	V	117.1	155	0.91	74	46

^aAccessible surface area is in Å² and is for the amino acid as part of a polypeptide backbone (Chothia, 1976).

^bHydrophobicity is in arbitrary units and is based on the OMH scale of Sweet and Eisenberg (1983), which emphasizes the ability of amino acids to replace one another during the course of evolution.

^cRelative mutability is also in arbitrary units (with alanine set to 100) and represents the probability that an amino acid will mutate within a given time. Thus, as two closely related proteins diverge, a given tryptophan residue is only 18% as likely as a given alanine residue to mutate (Dayhoff et al., 1978).

^dSurface probability is the likelihood that 5% or more of the surface area of an amino acid will be exposed to the solution surrounding a protein (Chothia, 1976). Thus, while some portion of almost all the arginines will help make up the surface of a protein, less than half of the valines will be exposed to solution. To understand in more detail how amino acids are buried, see Rose et al. (1985); for example, although tyrosine is often found exposed to the surface of a protein, a substantial proportion of its surface area is typically buried.

Figure A.1C.1 The genetic code. Names of amino acids and chain termination codons are on the periphery of the circle. The first base of the codon is identified in the center ring; the second base of the codon is in the middle ring; and the third base(s) of the codon is in the outer ring of the circle.

A discussion of codon randomness and the relevance of this phenomenon in molecular biology experimentation can be found on p. A.1.6. (% **Column**) Percentage of synonymous codon usage. The relative percentage of each member of the set of codons that specify a particular amino acid. Four sets that are not contiguous in this table are Arg, Ser, Leu, and chain terminator. (**Freq. Column**) Frequencies are expressed as occurrences per thousand codons for the specified organisms. The GenBank nucleic acid database as of April 23, 1990, was used as the source of gene-coding regions. This corresponds to GenBank Release 63 with the addition of three weekly updates. The feature tables were utilized to automatically extract peptide-coding regions from the database. This automated process discarded sequences that were less than ten codons in length and contained more than one chain-termination codon. The extracted coding sequences were then examined to remove all pseudogenes, nonnuclear (except for the chloroplast and mitochondrial categories), viral, rearranged, and mutant sequences. The remaining collection of extracted sequences was edited to remove duplicate entries; most significantly, only one example of each class of immunoglobulin gene was allowed per species. The codon frequencies were tabulated with the aid of the CodonFrequency program from the UWGCG package (Genetics Computer Group, Madison, WI 53711).

The total number of codons used for each organism category and the source of the codons are listed below expressed as a percentage of the total: **Mammal:** Total of 1,237,027 codons from cow (*Bos taurus*; 6.43%), hamster (*Cricetus sp.*; 1.48%), human (*Homo sapiens*; 48.36%), macaque (*Macaca sp.*; 0.38%), mouse (*Mus sp.*; 19.52%), rabbit (*Oryctolagus sp.*; 4.06%), rat (*Rattus sp.*; 19.17%), and sheep (*Ovis sp.*; 0.59%). **Other**

vertebrate: Total of 159, 994 codons from chicken (*Gallus sp.*; 72.24%) and *Xenopus laevis* (27.76%). **Dicot:** Total of 71, 408 codons from *Arabidopsis thaliana* (15.21%), pea (*Pisum sativum*; 13.77%), *Petunia sp.* (6.61%), lima bean (*Phaseolus vulgaris*; 11.24%), potato (*Solanum tuberosum*; 7.89%), tobacco (*Nicotiana tabacum*; 9.54%), tomato (*Lycopersicon esculentum*; 11.63%), and soybean (*Glycine max*; 24.10%). **Monocot:** Total of 45, 622 codons from barley (*Hordeum vulgare*; 21.35%), corn (*Zea mays* 47.70%), rice (*Oryza sativa*; 11.60%) and wheat (*Triticum aestivum*; 19.35%). **Invertebrate:** Total of 151, 794 codons from *Caenorhabditis elegans* (9.11%), sea urchin (*Strongylocentrotus purpuratus*; 6.01%), and fruit fly (*Drosophila melanogaster*; 84.88%). **Yeast:** Total of 216, 375 codons from *Saccharomyces cerevisiae*. **Chloroplast:** Total of 6, 866 codons from *Zea mays* chloroplast (52.18%) and *Nicotiana tabacum* chloroplast (47.82%). **Yeast mitochondrion:** Total of 4, 986 codons from *Saccharomyces cerevisiae* mitochondria (see note below). **Gram negative bacteria:** Total of 263, 904 codons from *Escherichia coli* (70.40%), *Klebsiella pneumoniae* (3.96%), *Neisseria gonorrhoeae* (1.75%), *Pseudomonas sp.* (10.97%), *Rhizobium meliloti* (2.57%), and *Salmonella typhimurium* (10.35%). **Gram positive bacteria:** Total of 38,807 codons from *Bacillus subtilis* (73.45%) and *Staphylococcus aureus* (26.55%).

NOTE: The genetic code is universal with the exception of mitochondrial DNA. In yeast mitochondria the AUA and UGA codons that normally specify isoleucine and chain termination are used for methionine and tryptophan, respectively. These exceptions are used when calculating the yeast mitochondrion percentage of synonymous codon usage.

A

Amino acids with dissociable protons

Other amino acids with polar side chains

B

Nonpolar amino acids

glycine

proline

alanine

tryptophan

valine

methionine

leucine

isoleucine

phenylalanine

Figure A.1C.2 Line drawings of the amino acids. The amino acids are roughly divided into three groups: amino acids with dissociable protons (**A**), other amino acids with polar side chains (**A**), and nonpolar amino acids (**B**). These groupings are designed to facilitate an understanding of enzymology and the thermodynamics of protein folding.

In this representation, hydrogens are omitted except in showing ionization or stereochemistry. In the case of arginine the delocalized positive charge is indicated by dashed double bonds. At stereocenters, bold lines indicate a group is coming out of the page toward the viewer, while hashed lines indicate that the group goes into the page away from the viewer.

Amino acids with dissociable protons are generally intimately involved in the chemistry of enzymes. Acidic and basic groups can form salt bridges to substrates or to each other. They can also act as proton donors/acceptors in mechanisms that rely on acid/base catalysis. The polar side chains of some of these amino acids (notably cysteine, serine, and histidine) can act as nucleophiles. The pK_a values for the free amino acids are shown, but these values

can markedly change when these groups are buried in proteins. The pK_a s of the α -amino groups range from 8.7 to 10.7, while the pK_a s of the α -carboxylates range from 1.8 to 2.4.

Amino acids with polar side chains (**A**) can form hydrogen bonds to substrates or to each other. Cysteine, serine, and tyrosine could also be included in this group, since the ionized forms of these amino acids do not generally perform structural roles in proteins. In general, these amino acids (and the amino acids with dissociable protons) will be found on the surfaces of proteins. Cysteine is an exception, since it is slightly hydrophobic and can often be buried as a disulfide bond.

The nonpolar amino acids (**B**) are often found in the interiors of proteins or in hydrophobic substrate-binding pockets. They interact with one another like jigsaw pieces, forming tight-fitting associations that have a density similar to that of an amino acid crystal. Proline is buried less frequently than might be expected because of its predominance in turns, which are often found on the periphery of a protein.

Standard Measurements, Data, and Abbreviations

A.1C.6

Figure A.1C.3 Amino acid hydrophobicity. The hydrophobicity of an amino acid is the degree to which it prefers a nonpolar medium, such as ethanol or the interior of a protein, to a polar medium, such as water. In this graph, the more hydrophobic amino acids “sink” below zero, while the more hydrophilic amino acids “float” above the surface.

Two scales are used. The Frömmel scale (Frömmel, 1984) represents the free energy of transfer from a hydrophobic medium to water. This value is an intrinsic property of an amino acid, separate from its role in a protein. In contrast, the OMH scale (Sweet and Eisenberg, 1983) is a measure of how likely a given amino acid will be replaced by a different hydrophobic or “buried” amino acid in a protein. In effect, this scale is how evolution views the hydrophobicity of an amino acid.

The distinction between physical and evolutionary properties is important. For example, while arginine is definitely a charged, polar amino acid (Sambrook et al., 1989), it can substitute more freely for nonpolar amino acids in the interior of a protein than glutamate (also a charged, polar amino acid) because of its long aliphatic side chain.

Figure A.1C.4 Space-filling representations of the amino acids. The amino acids are arranged in order of size. The conformations shown maximize the two-dimensional area but are not necessarily the most stable geometries.

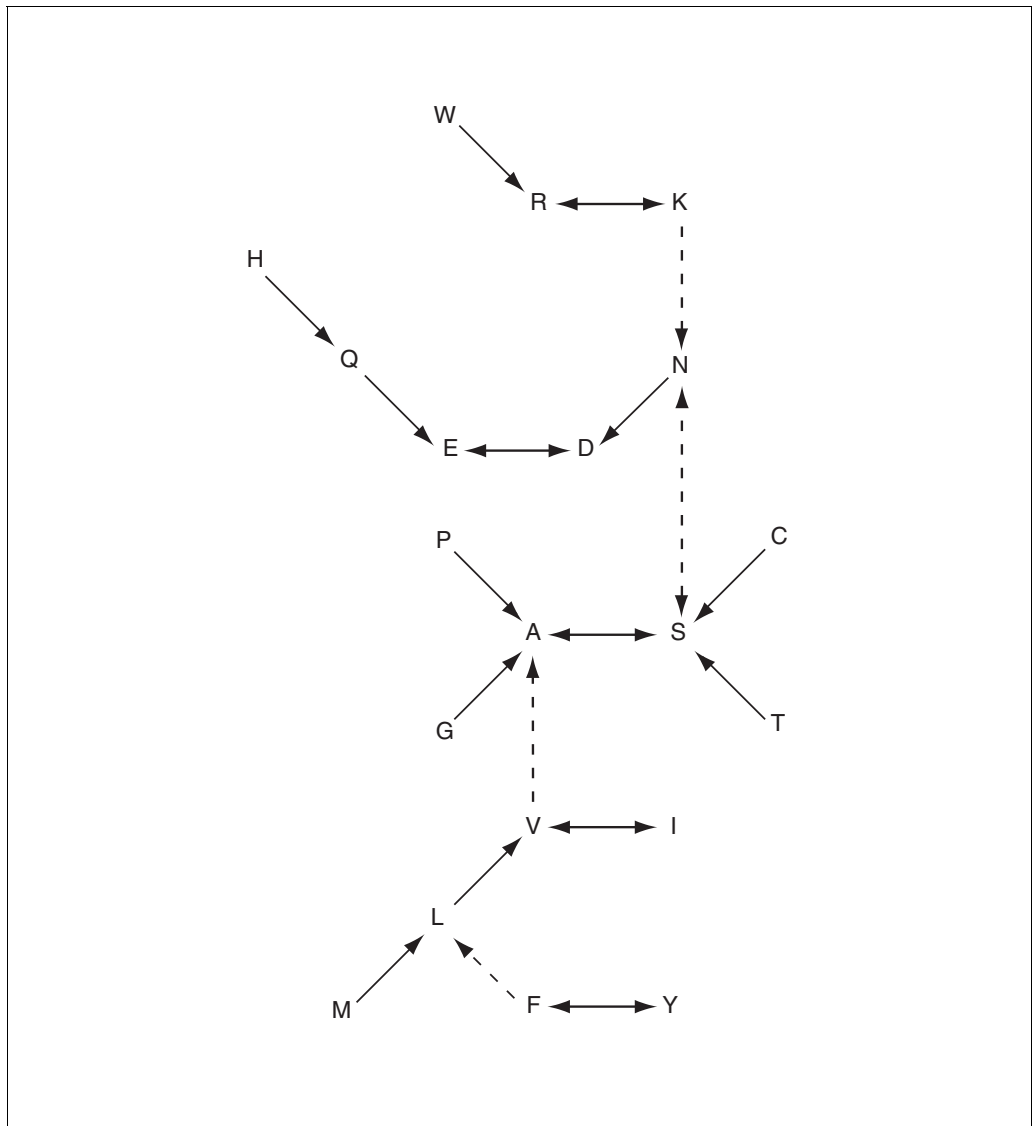

Figure A.1C.5 Mutational pathways for amino acids. In this diagram, amino acids are parsed into sets based on their ability to replace one another during the evolution of closely related proteins. Dark arrows show the *most frequent* mutational events for each of the twenty amino acids. For example, tryptophan most frequently mutates to arginine, while arginine and lysine most frequently replace one another. Dotted arrows represent the most frequent replacements *between* sets of otherwise mutationally related amino acids. Thus, while lysine mutates most frequently to arginine within the [arginine, lysine, tryptophan] set, the most likely event that will occur *outside* of this set is mutation to asparagine.

Table A.1C.3 Compositions and Masses of the Twenty Commonly Occurring Amino Acid Residues^{a,b}

Name	Composition	Monoisotopic mass	Average mass	pK _a of ionizing side chain ^c	Occurrence in proteins (%)
Alanine (Ala, A)	C ₃ H ₅ NO	71.03711	71.0788	—	8.3
Arginine (Arg, R)	C ₆ H ₁₂ N ₄ O	156.10111	156.1876	~11.5–12.5 (12)	5.7
Asparagine (Asn, N)	C ₄ H ₆ N ₂ O ₂	114.04293	114.1039	—	4.4
Aspartic acid (Asp, D)	C ₄ H ₅ NO ₃	115.02694	115.0886	3.9–4.5 (4)	5.3
Cysteine (Cys, C)	C ₃ H ₅ NOS	103.00919	103.1448	8.3–9.5 (9)	1.7
Glutamic acid (Glu, E)	C ₅ H ₇ NO ₃	129.04259	129.1155	4.3–4.5 (4.5)	6.2
Glutamine (Gln, Q)	C ₅ H ₈ N ₂ O ₂	128.05858	128.1308	—	4.0
Glycine (Gly, G)	C ₂ H ₃ NO	57.02146	57.0520	—	7.2
Histidine (His, H)	C ₆ H ₇ N ₃ O	137.05891	137.1412	6.0–7.0 (6.3)	2.2
Isoleucine (Ile, I)	C ₆ H ₁₁ NO	113.08406	113.1595	—	5.2
Leucine (Leu, L)	C ₆ H ₁₁ NO	113.08406	113.1595	—	9.0
Lysine (Lys, K)	C ₆ H ₁₂ N ₂ O	128.09496	128.1742	10.4–11.1 (10.4)	5.7
Methionine (Met, M)	C ₅ H ₉ NOS	131.04049	131.1986	—	2.4
Phenylalanine (Phe, F)	C ₉ H ₉ NO	147.06841	147.1766	—	3.9
Proline (Pro, P)	C ₅ H ₇ NO	97.05276	97.1167	—	5.1
Serine (Ser, S)	C ₃ H ₅ NO ₂	87.03203	87.0782	—	6.9
Threonine (Thr, T)	C ₄ H ₇ NO ₂	101.04768	101.1051	—	5.8
Tryptophan (Trp, W)	C ₁₁ H ₁₀ N ₂ O	186.07931	186.2133	—	1.3
Tyrosine (Tyr, Y)	C ₉ H ₉ NO ₂	163.06333	163.1760	9.7–10.1 (10.0)	3.2
Valine (Val, V)	C ₅ H ₉ NO	99.06841	99.1326	—	6.6

^aFor corresponding structures, see Figure A.1C.2 and Figure A.1C.4.

^bThe molecular mass of a normally terminated and unmodified peptide or protein may be calculated by summing the masses of the appropriate amino acid residues and adding the masses of H and OH for the N and C termini, respectively. In cases where cysteines are linked to form disulfide bridges, the mass of two hydrogen atoms should be subtracted for each disulfide bridge in the molecule. Specifically, monoisotopic masses were calculated using the atomic masses of the most abundant isotope of the elements: C = 12.0000000, H = 1.0078250, N = 14.0030740, O = 15.9949146, and S = 31.9720718. Average masses were calculated using the atomic weights of the elements: C = 12.011, H = 1.00794, N = 14.00674, O = 15.9994, and S = 32.066.

^cThese values are included for anyone wishing to make approximate isoelectric point determinations based on protein composition. Values for the terminal residues depend on the identity of the residue: α-amino, pK_a 6.8–8.2 (8.0); α-carboxyl, pK_a 3.2–4.3 (3.6). Values in parentheses are based on those given by Matthew et al. (1978) and provide a good starting point for determinations.

Table A.1C.4 Mass Changes Due to Some Post-Translational Modifications of Peptides and Proteins^a

Modification ^b	Monoisotopic mass change	Average mass change
<i>Common modifications</i>		
Pyroglutamic acid formation from Gln	-17.0265	-17.0306
Disulfide bond (cystine) formation	-2.0157	-2.0159
C-terminal amide formation from Gly	-0.9840	-0.9847
Deamidation of Asn and Gln	-0.9840	-0.9847
Methylation	14.0157	14.0269
Hydroxylation	15.9949	15.9994
Oxidation of Met	15.9949	15.9994
Proteolysis of a single peptide bond	18.0106	18.0153
Formylation	27.9949	28.0104
Acetylation	42.0106	42.0373
Carboxylation of Asp and Glu	43.9898	44.0098
Phosphorylation	79.9663	79.9799
Sulfation	79.9568	80.0642
Cysteinylation	119.0041	119.1442
Glycosylation with pentoses (Ara, Rib, Xyl)	132.0423	132.1161
Glycosylation with deoxyhexoses (Fuc, Rha)	146.0579	146.1430
Glycosylation with hexosamines (GalN, GlcN)	161.0688	161.1577
Glycosylation with hexoses (Fru, Gal, Glc, Man)	162.0528	162.1424
Modification with lipoic acid (amide bond to lysine)	188.0330	188.3147
Glycosylation with <i>N</i> -acetylhexosamines (GalNAc, GlcNAc)	203.0794	203.1950
Farnesylation	204.1878	204.3556
Myristoylation	210.1984	210.3598
Biotinylation (amide bond to lysine)	226.0776	226.2994
Modification with pyridoxal phosphate (Schiff base to lysine)	231.0297	231.1449
Palmitoylation	238.2297	238.4136
Stearoylation	266.2610	266.4674
Geranylgeranylation	272.2504	272.4741
Glycosylation with <i>N</i> -acetylneuraminic acid (sialic acid, NeuAc, NANA, SA)	291.0954	291.2579
Glutathionylation	305.0682	305.3117
Glycosylation with <i>N</i> -glycolylneuraminic acid (NeuGe)	307.0903	307.2573
5'-Adenosylation	329.0525	329.2091
Modification with 4'-phosphopantetheine	339.0780	339.3294
ADP-ribosylation (from NAD)	541.0611	541.3052
<i>Adventitious modifications</i>		
Acrylamide	71.0371	71.0788
Glutathione	304.0712	304.3038
2-Mercaptoethanol	75.9983	76.1192

^aTo obtain the molecular mass of a modified peptide or protein, the appropriate mass changes should be algebraically added to the molecular mass calculated for the unmodified molecule.

^bA more extensive list of modifications is available from the Delta mass site at <http://www.medstv.unimelb.edu.au/WWWDOCS/SVIMRDOCS/MassSpec/deltamassV2.html>.

Characteristics of Nucleic Acids

Nucleic acids have traditionally been regarded solely as informational macromolecules with limited secondary structural features, but recent discoveries have vastly expanded the repertoire of polynucleotide structure and function. While this manual has in general concentrated on how to manipulate DNA and RNA, this section details their structural features. In addition, some experimentally useful properties of the mononucleotide building blocks are listed in Table A.1D.1. The chemical structures of the mononucleotides can be seen in Figure A.1D.1, and aspects of nucleotide stereochemistry that are important to an understanding of base pairing and secondary structure can be found in Figure A.1D.2. Although Watson-Crick pairings play a critical role in defining nucleic acid secondary structures, a wide variety of alternative base pairings can be important in higher order conformations; some of these are detailed in Figure A.1D.3. Finally, even given only Watson-Crick-style pairings, secondary structures with significantly different features can be formed. Figure A.1D.4 overviews the differences between A-, B-, and Z-form helices.

^a Spectral data are assembled from Fasman (1975) at pH 7.0 except where footnoted otherwise.

^b TLC mobility is expressed as the percent distance a given spot migrates relative to the solvent front (*R_f*) in three different TLC systems using 0.5-mm polyethylenimine cellulose plates: "A" is 0.25 M LiCl, "B" is 1.0 M LiCl, and "C" is 1.6 M LiCl.

^c Spectral measurements taken at pH 6.0.

^d Spectral data assembled from Dawson et al. (1987).

A.1D.1

Figure A.1D.1 Line drawings of the nucleotides. The chemical structure that predominates at neutral pH is shown. Drawings of the nucleotide bases and their associated sugars, either ribose (R) or deoxyribose (dR), are shown separately. In the representations of ribose (as a nucleoside triphosphate) and deoxyribose (as a nucleotide), the bold lines indicate that this portion of the sugar is coming out of the page toward the reader. In this view, the base is found above the plane of the sugar, while the 3' hydroxyl group is found below the plane of the sugar.

The pK_a values for all groups are shown; pK_a s above 7 imply proton dissociation from the pictured structure, while pK_a s below 7 imply proton association to the pictured structure. The tautomeric form of a given base may change at different

pH values. The pK_a values given are for nucleotide mono-phosphates and were taken from Dawson et al. (1987); a fuller discussion of the chemical basis for these values can be found in a review by T'so (1974).

The small numbers adjacent to adenosine, uridine, and ribose indicate the nomenclature of the purines, pyrimidines, and sugars, respectively. Groups appended to a ring have the same numbering as the position to which they are linked; thus, the "O6" moiety of guanosine is the carbonyl oxygen bonded to C6 in the ring. Similarly, "O3" on ribose or deoxyribose indicates the oxygen of the hydroxyl group bonded to C3' in the ring. The α , β , and γ phosphates in a nucleoside triphosphate are also indicated.

A.1D.2

Figure A.1D.2 Nucleotide stereochemistry. Depending on the rotation about the bond between C1' of the sugar and either N1 (for pyrimidines) or N9 (for purines), a nucleotide can be described as either "anti" or "syn." Because of steric constraints, nucleotides are generally found in the "anti" configuration, with their Watson-Crick hydrogen bond donor-acceptors swung outward away from the plane of the sugar ring. However, guanosine is sometimes found in a "syn" configuration, both in polynucleotides and in solution. In this form, the bulk of the purine ring is positioned directly over the plane of the sugar. The sugar ring can also adopt

different stereochemistries. These are labeled according to which group is bent out of the plane of the ring, and in which direction. If a portion of the ring is bent "upward" toward the base, this is known as "endo," while if it is bent "downward" away from the base, this is known as "exo." In the figure, plain lines represent bonds that are within the plane of the sugar, while bold lines indicate that the bond is bent out of the plane. Hence, "C3' endo-C2' exo" describes a furanose ring in which the 2' and 3' carbons have been twisted in opposite directions and the bond connecting them crosses the plane of the ring.

Figure A.1D.3 Base pairing schemas. The chemical structures of the nucleotide bases determine the formation of secondary and tertiary structures in nucleic acids. A wide variety of hydrogen bonding schemas (indicated by dashed lines) are possible between different bases. Watson-Crick pairings are perhaps the most widely known and are the basis of the double helical structure of complementary, anti-parallel DNA strands. Other base pairs can also be accommodated within the double helix, such as “wobble pairings,” in which the bases are slightly off-center with respect to each other. By using the N7 hydrogen bond

acceptor of the purine bases adenosine and guanosine, an even wider variety of structures becomes possible, including Hoogsteen base pairs and a G-G pairing in which one of the guanosine residues assumes a “syn” conformation. Bonds involving N7 of the purine bases allow tertiary structural interactions to occur in nucleic acids, including triple base pairs (such as those found in tRNA) and the recently described “G quartet” (Sen and Gilbert, 1988). A discussion of the structural possibilities of base pairing can be found in Saenger’s superlative book, *Principles of Nucleic Acid Structure* (1993).

A.1D.5

B DNA

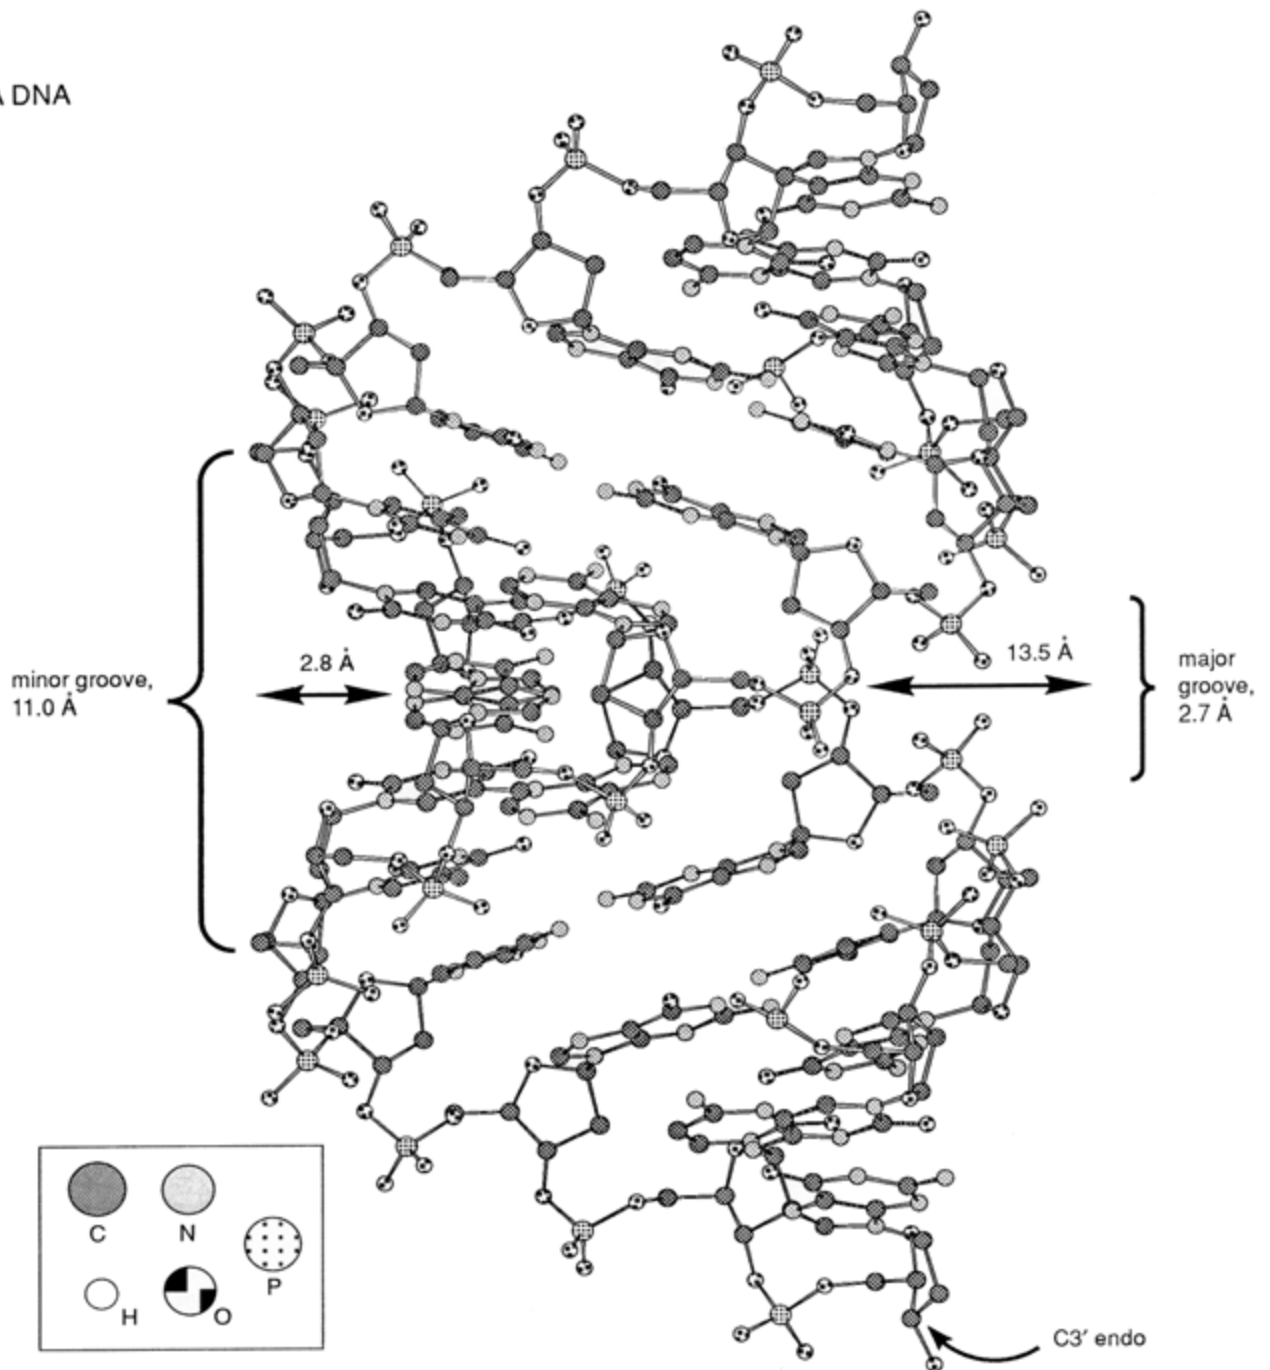

Figure A.1D.4 Nucleic acid secondary structures. The structural consequence of the ability of nucleotides to form Watson-Crick base pairs is nucleic acid double helices. In this figure, the self-complementary 12-mer CGCGAATTCGCG is shown as both A- and B-form helices. Two representations of the A helix have been shown in order to emphasize the depth of the major groove. The arrows and brackets in these figures are not drawn to scale.

While both of these helices are right-handed (in terms of anthropomorphic referents, if you were to point your thumb along a strand in a 5' to 3' manner, the twist of the helix would be the same as the curl of your right hand), their structural details are very different: B DNA has roughly 10 bases per full turn, while A DNA and A RNA have 11 to 12; the major groove of B-form helices is wide and the minor groove is narrow, while for A-form helices this is reversed; in

A.1D.6

A DNA

B-forms the base pairs are located close to the helix axis (as can be seen in end-on views), while in A-forms the base pairs are pushed out away from the long helical axis, leaving a “hole” in the middle of the polynucleotide coil (if one imagines DNA as a flat ribbon, then B DNA is twisted from its ends, while A DNA is coiled on itself).

Different helical forms are largely due to differences in sugar stereochemistry. Examples of a 2' endo deoxyribose (found in B DNA) and a 3' endo deoxyribose (found in A DNA) are indicated.

While there are a variety of other helical forms, the most

striking is that found in Z DNA. The Z DNA coil is left- rather than right-handed and contains G:C base pairs where the G is in the “syn” conformation (shown in the inset).

The uneven progression, or zigzag, of Z DNA can be more easily seen when the polynucleotide backbone is shown in isolation; the inset shows the connectivity between phosphates by 5' to 3' vector arrows. Because of its odd shape, base pairs actually protrude from what would be a cavity in A or B DNA; thus, Z DNA has a minor but no major groove. This diagram is based on the original structure of alternating C:G/G:C base pairs (Wang et al., 1979).

Radioactivity

The use of radioactive materials (Tables A.1E.1 and A.1E.2) in many protocols in this manual raises the issue of safety. Because the real hazards of low levels of radiation are not known, it is generally assumed that any unavoidable exposure is too much. It is important to know applicable regulations and approved procedures on the use of isotopes, which will certainly include using gloves when handling any radioactive materials and appropriate shielding (Table A.1E.3) when handling high levels of energetic isotopes such as ^{32}P .

In addition, investigators should check themselves and the work area frequently for radioactivity with a hand-held minimonitor. It is just as important to have a clear understanding of the properties of radioisotopes and to use common sense (Table A.1E.4; Figure A.1E.1). For example, working behind an unwieldy shield can significantly increase the likelihood of a spill. One gets less exposure by forgetting about the shield for the submicrocurie amounts of ^{32}P in a final ethanol precipitation than by dropping the pellet and having to start the labeling reaction over again. The straightforward application of common sense must sometimes be tempered by consideration of the requirements of maintaining a radiation license, however. Although it may seem highly unlikely a labeling reaction will be spilled into your coffee cup, the rule against having them on the laboratory bench altogether is not a matter to be negotiated between you and your radiation safety officer. Your authority to use radioisotopes is contingent on following the rules set up by the appropriate regulatory agency. For further information, refer to the Guide for Safe Handling of Radioisotopes (APPENDIX 1F).

Table A.1E.1 Conversion Factors for Radioactivity

Measurement of Radioactivity

The SI unit for measurement of radioactivity is the Becquerel:

$$1 \text{ Becquerel (Bq)} = 1 \text{ disintegration per second}$$

The more commonly encountered unit is the Curie (Ci):

$$\begin{aligned} 1 \text{ Ci} &= 3.7 \times 10^{10} \text{ Bq} \\ &= 2.22 \times 10^{12} \text{ disintegrations per minute (dpm)} \\ 1 \text{ millicurie (mCi)} &= 3.7 \times 10^7 \text{ Bq} = 2.22 \times 10^9 \text{ dpm} \\ 1 \text{ microcurie } (\mu\text{Ci}) &= 3.7 \times 10^4 \text{ Bq} = 2.22 \times 10^6 \text{ dpm} \end{aligned}$$

Conversion factors:

$$\begin{aligned} 1 \text{ day} &= 1.44 \times 10^3 \text{ min} = 8.64 \times 10^4 \text{ sec} \\ 1 \text{ year} &= 5.26 \times 10^5 \text{ min} = 3.16 \times 10^7 \text{ sec} \\ \text{counts per minute (cpm)} &= \text{dpm} \times (\text{counting efficiency}) \end{aligned}$$

Measurement of Dose

The SI unit for energy absorbed from radiation is the Gray (Gy):

$$1 \text{ Gy} = 1 \text{ joule/kg}$$

Older units of absorbed energy are the rad (r) and Roentgen (R):

$$\begin{aligned} 1 \text{ r} &= 100 \text{ ergs/g} = 10^{-2} \text{ Gy} \\ 1 \text{ R} &= 0.877 \text{ r in air} = 0.93 - 0.98 \text{ r in water and tissue} \end{aligned}$$

The SI unit for radiation dosage is the Sievert (Sv), which takes into account the empirically determined relative biological effectiveness (RBE) of a given form of radiation:

$$\begin{aligned} \text{dosage [Sv]} &= \text{RBE} \times \text{dosage [Gy]} \\ \text{RBE} &= \frac{(\text{biological effect of a dose of standard radiation [Gy]})}{(\text{biological effect of a dose of other radiation [Gy]})} \end{aligned}$$

RBE = 1 for commonly encountered radionuclides

The older unit for dosage is the rem (Roentgen-equivalent-man):

$$1 \text{ rem} = 0.01 \text{ Sv}$$

Figure A.1E.1 Correlation of loss of radioactivity with elapsing half-lives of an isotope.

Safe Use of Radioisotopes

The use of radioisotopes to label specific molecules in a defined way has greatly furthered the discovery and dissection of biochemical pathways. The development of methods to inexpensively synthesize such tagged biological compounds on an industrial scale has enabled them to be used routinely in laboratory protocols, including many detailed in this manual. Although most of these protocols involve the use of only microcurie (μCi) amounts of radioactivity, some (particularly those describing the metabolic labeling of proteins or nucleic acids within cells; see *UNITS 10.18 & 3.4*) require amounts on the order of tens of millicuries (mCi). In all cases where radioisotopes are used, depending on the quantity and nature of the isotope certain precautions must be taken to ensure the safety of the scientist. This appendix outlines a few such considerations relevant to the isotopes most frequently used in biological research.

In designing safe protocols for the use of radioactivity, the importance of common sense, based on an understanding of the general principles of isotopic decay and the importance of continuous monitoring with a hand-held radioactivity monitor (e.g., Geiger counter), cannot be overemphasized. In addition, it is also critical to take into account the rules, regulations, and limitations imposed by each specific institution. These are usually not optional considerations: an institution's license to use radioactivity normally depends on strict adherence to such rules.

Many of the protocols described have evolved (and are evolving still) over the years and through the millicuries in the Department of Molecular Biology and Virology at the Salk Institute. The authors are indebted to those who have trained them in the safe use of radioactivity, in particular to the members of the Salk Institute Radiation Safety Department. Most of the designs for the shields and other safety equipment shown in Figures A.1F.1A, A.1F.2, and A.1F.3 were created at the Salk Institute in collaboration with Dave Clarkin and Mario Tengco. Safety equipment of similar design is available from several commercial vendors, including CBS Scientific and Research Products International.

BACKGROUND INFORMATION

The Decay Process

As anyone who has taken a basic chemistry course will remember, each element is charac-

terized by its atomic number, defined as the number of orbital electrons or the number of protons in the nucleus of that atom. Isotopes of a given element exist because some atoms of each element, while by definition having the same number of protons, have a different number of neutrons and therefore a different nuclear weight. It should be noted that the number of electrons outside the nucleus remains the same for all isotopes of a given element, and so all isotopes of a given element are equivalent with respect to their chemical reactivity.

Radioactive decay occurs when subatomic particles are released from the nucleus of an atom of a heavy isotope. This often results in the conversion of an atom of one isotope to an isotope of a different element, because the original isotope's atomic number changes after decay. The subatomic particles released from naturally occurring radioisotopes are of three basic types: α and β particles and γ rays.

An α particle is essentially the nucleus of a helium atom, or two protons plus two neutrons. It is a relatively large, heavy particle that moves slowly and usually only across short distances before it encounters some other atom with which it interacts. These particles are released from isotopes with large nuclei (atomic number >82 ; e.g., plutonium or uranium); such isotopes are not commonly used in biological research.

In contrast to α particles, β particles are light, high-speed charged particles. Negatively charged β particles are essentially electrons of nuclear origin that are released when a neutron is converted to a proton. Release of a β particle thus changes the atomic number and elemental status of the isotope.

γ radiation has both particle and wave properties; its wavelength falls within the range of X-ray wavelengths. The distinction between γ rays and X rays was made when primitive X-ray machines produced X rays with a wavelength longer than those of the γ rays produced naturally by radioisotopes. Modern X-ray machines produce a much broader spectrum of wavelengths, including γ radiation; currently this sort of X-ray radiation is termed γ when it is of nuclear origin. Unlike β -particle release, the release of γ radiation by itself produces an isotopic change rather than an elemental one; however, the resultant nuclei are unstable and often decay further, releasing β particles.

The energy of all α particles and γ rays (measured in electron volts) is fixed, because they are of specific composition or wavelength.

**Standard
Measurements,
Data, and
Abbreviations**

A.1F.1

The energy of β particles, however, varies depending on the atom they originate from (and with concomitant release of neutrinos or anti-neutrinos that serve to balance the conservation of energy aspect of the decay equation). Thus there are (relatively) high-energy β particles released during the decay of ^{32}P and low-energy β particles released when tritium (^3H) decays.

Isotopic decay usually involves a chain or sequence of events rather than a single loss of a particle, because the resultant, equally unstable atoms try to achieve equilibrium. During this course of decay, secondary forms of radiation can be generated that may also pose a hazard to workers. For example, when high-energy β particles released during the decay of ^{32}P encounter the nuclei of atoms with a large atomic number, a strong interaction occurs. The β particle loses some energy in the form of a photon. Such photons are called Bremsstrahlung radiation; they are detectable using a monitor suitable for the detection of γ or X rays.

Following their release, α , β , and γ emissions (as well as secondary forms of radiation) travel varying average distances at varying average speeds, depending on their energy and the density of the material through which they are moving. The distance they actually travel before encountering either the electrons or nucleus of another atom is termed their degree of penetrance. This value is expressed as an average for each type of particle. The energy of the particles released (and therefore their potential penetrance) thus dictates what type of shielding, if any, is necessary for protection against the radiation generated by the decay of a given isotope. α , β , and γ emissions all have the potential, upon encountering an atom, to knock out its electrons, thereby creating ions. Thus, these three types of emissions are called ionizing radiation. The formation of such ions may result in the perturbation of biological processes: therein lies the danger associated with radioactivity!

Table A.1E.2 provides a summary of the factors discussed above for several isotopes commonly used in biochemical research.

Measuring Radioactivity and Individual Exposure to It

The radioactivity of a given substance is measured in terms of its ionizing activity. A Curie by definition is the amount of radioactive material that will produce 3.4×10^{10} disintegration (ions) per second. This, not coincidentally, happens to be the number of disintegrations that occur during the decay of one gram of radium

and its decay products. Exposure to such radiation is measured as the amount of energy absorbed by the recipient, which, of course, is directly related to the potential damage such radiation may cause. One rad is the dose of radiation that will cause 100 ergs of energy to be absorbed per gram of irradiated material. Another unit commonly used to measure radiation doses is the rem; this is related to the rad but takes into account a "quality factor" based on the type of ionizing radiation being received. For β particles and γ or X rays this factor is 1; therefore, rems β equal rads β . In contrast, the quality factor associated with α particles is 20, so an exposure of one rad due to α particles would be recorded as 20 rem.

The amount or dose of radiation received by materials (cells, scientists, etc.) near the source depends not only on the specific type and energy (penetrance) of the radiation being produced, but also on the subject's distance from the source, the existence of any intervening layers of attenuating material (shielding), and the length of time spent in the vicinity of the radiation source. To best measure such doses, every person working with or around radioactivity should wear an appropriate type of radiation detection badge (in addition to carrying a portable radiation monitor that can give an immediate, approximate reading.) This is normally a requirement (not an option) for compliance with an institution's license to use radioisotopes. Such badges are usually furnished by the safety department and collected at regular intervals for reading by a contracted company. At most institutions, the old-style film badges have been replaced with the more accurate TLDs (thermoluminescent dosimeters). These take advantage of chemicals such as calcium or lithium fluorides which, following exposure to ionizing radiation, will luminesce at temperatures below their normal thermal luminescence threshold. Different types of badges are sensitive to different types of radiation: always be sure to wear one that is appropriate for detecting exposure to the isotope being used! In most places pregnant women are asked to wear a more sensitive (and more expensive) dosimeter to better monitor their (and the developing fetus') exposure. Most often workers will be asked to wear a radiation detection badge on the labcoat lapel in order to measure whole-body radiation. When working with ^{32}P or ^{125}I it is also advisable to wear a ring badge to measure exposure to the unshielded extremities (fingers). The limit set for "acceptable" exposure to whole-body radiation is sev-

eral-fold less than the limit set for extremities. Nevertheless, we have found that the exposure recorded on ring badges is often significant with respect to the limit for extremities set by our institution.

What is known about the effects on humans of exposure to low levels of radiation (i.e., levels which would be received when briefly handling mCi or μ Ci amounts of radioactivity)? Not much, for the obvious reason that direct studies have not been undertaken. Accordingly, guidelines for exposure levels are set using extrapolations—either by extrapolating down from population statistics obtained following accidents or disasters (the Chernobyl meltdown, atomic bombings) or by extrapolating up from numbers obtained from animal experiments. Each form of extrapolation is subject to caveats, and given that predictions based on such extrapolations cannot be perfect, most health and safety personnel aim for radiation exposure levels said to be ALARA or “as low as reasonably achievable.” Further discussion of exposure limits and the statistics on which they are based may be found in B. Shleien’s health physics text (Shleien, 1987). Limiting exposure to radiation can be accomplished by adjusting several parameters of the exposure: the duration of exposure, distance from the source, and the density of the material (air, water, shielding) between the individual and the source.

Time is of the essence

When designing any experiment using radioactivity, every effort should be made to limit the time spent directly handling the vials or tubes containing the radioactive material. Speed should be encouraged in all manipulations, though not to the point of recklessness! Have everything needed for the experiment ready at hand before the radioactivity is introduced into the work area.

Distance helps to determine dose

When possible, experiments involving radioactivity should be performed in an area separate from the rest of the lab. Many institutions require that such work be performed in a designated “hot lab”; however, if many people in the laboratory routinely use radioisotopes, it is less than feasible to move them all into what is usually a smaller space. No matter where an individual is working, it is his or her responsibility to monitor the work area and ensure his or her own safety and the safety of those working nearby by using adequate shielding. Obvi-

ously, when handling the radioactive samples, it is necessary to work rapidly behind any required shielding. To protect bystanders, remember that the intensity of radiation from a source (moving through air) falls off in proportion to the square of the distance. Thus, if standing 1 foot away from a source for 5 min would result in an exposure of 45 units, standing 3 feet away for the same amount of time would result in an exposure $(1/3)^2$ of 45 units, or 5 units. This factor is also relevant when considering the storage of large amounts of radioactivity, particularly ^{125}I or ^{32}P , as no amount of shielding can completely eliminate radiation.

Shielding is the key to safety

As mentioned above, the energy of the particle(s) released during the decay of an isotope determines what, if any, type of shielding is appropriate. β particles released during the decay of ^{14}C and ^{35}S possess roughly ten times the energy of those released when ^3H decays. All three β particles are of relatively low energy, do not travel very far in air, and cannot penetrate solid surfaces. No barriers are necessary for shielding against this type of β radiation. The major health threat from these isotopes occurs through their accidental ingestion, inhalation, or injection.

β particles released during the decay of ^{32}P have 10-fold higher energy than those released from ^{14}C and pose a significant threat to workers. (One reported hazard is the potential for induction of cataracts in the unshielded eye.) The fact that these high-energy beta particles can potentially generate significant amounts of Bremsstrahlung radiation is the reason that low-density materials are used as the primary layer of shielding for ^{32}P β radiation. Water, glass, and plastic are suitable low-density materials (as opposed to lead). Obviously water is unsuitable as a shielding layer for work on the bench, although it does a reasonable job when samples are incubating in a water bath. Shields made from a thickness of glass sufficient to stop these particles would be extremely heavy and cumbersome (as well as dangerous if dropped). Fortunately, plastic or acrylic materials—variously called Plexiglas, Perspex, or Lucite—are available for shielding against ^{32}P β radiation. Shields as well as storage boxes constructed of various thicknesses of Plexiglas are necessary equipment in laboratories where ^{32}P is used. When mCi amounts of ^{32}P are used at one time it is necessary to also block the Bremsstrahlung radiation by adding a layer of high-density

material (such as 4 to 6 mm lead) to the outside of the Plexiglas shield (covering the side farthest from the radioactive source).

γ rays released during the decay of ^{125}I have much higher penetrance than the β particles from ^{32}P decay; this radiation must be stopped by very-high-density material, such as lead. Lead foil of varying thicknesses (2 to 6 mm) can be purchased in rolls and can be cut and molded to cover any container, or taped to a Plexiglas shield (used in this instance for support). Obviously this latter arrangement has the disadvantage that it is impossible to see what one is doing through the shield. For routine shielding of manipulations involving ^{125}I , it is useful to purchase a lead-impregnated Plexiglas shield that is transparent, albeit inevitably very heavy (as well as relatively expensive).

Although it seems logical that the use of more radioactivity necessitates the use of thicker layers of shielding, it is also true that no shielding material is capable of completely stopping all radiation. When deciding how thick is "thick enough," consult the half-value layer measurement for each type of shielding material. This number gives the thickness of a given material necessary to stop half the radiation from a source; Table A.1E.3 lists half-value layer measurements for the β particles released from isotopes commonly used in the biology laboratory. In general, 1 to 2 cm of Plexiglas and/or 0.02 mm of lead are sufficient to shield the amounts of radioactivity used in our experiments.

GENERAL PRECAUTIONS

Before going on to a discussion of specific precautions to be taken with individual isotopes, a short list of general precautions to be taken with all isotopes seems pertinent:

1. Know the rules. Be sure that each individual is authorized to use each particular isotope and uses it in an authorized work area.

2. Don the appropriate apparel. Whenever working at the lab bench, it is good safety practice to wear a labcoat for protection. Disposable paper/synthetic coats of various styles are commercially available: at \$4 each these may be conveniently thrown out if contaminated with radioactivity during an experiment, rather than held for decay as might be preferable with cloth coats costing about \$30 each. As an alternative, disposable sleeves can be purchased and worn over those of the usual cloth coat. Other necessary accessories include radiation safety badges, gloves, and protective eyewear. It's handy to wear two pairs of gloves

at once when using radioactivity; when the outer pair becomes contaminated, it is possible to strip it off and continue working without interruption.

3. Protect the work area as well as the workers. Lab benches and the bases of any shields used should be covered with some sort of disposable, preferably absorbent, paper sheet. Underpads or diapers (the kind normally used in hospitals) are convenient for this purpose.

4. Use appropriate designated equipment. It is very convenient, where use justifies the expense, to have a few adjustable pipettors dedicated for use with each particular isotope. Likewise, it is good practice to use only certain labeled centrifuges and microcentrifuge rotors for radioactive samples so that all the lab's rotors do not become contaminated. Although such equipment should be cleaned after each use, complete decontamination is often not possible. A few pipettors or a single microcentrifuge can easily be stored (and used) behind appropriate shielding. Actually, contamination of the insides and tip ends of pipettors can be greatly reduced by using tips supplied with internal aerosol barriers; these have recently become very popular for setting up PCR reactions and are available to fit a variety of pipettors. To prevent contamination of the outside of the pipettor's barrel, simply wrap the hand-grip in Parafilm, which can be discarded later. Several manufacturers sell disposable paper inserts for their microcentrifuges that protect the wall of the rotor chamber from contamination that might spin off the outside of sample tubes. Trying to fashion homemade liners of this sort is not recommended, as we have had disastrous experiences using laminated adhesive paper that "unstuck" during microcentrifuge spins. These liners would get caught by the rotor, shattering sample tubes and creating an even bigger mess!

5. Know where to dispose of radioactive waste, both liquid and solid. Most institutions require that radioactive waste be segregated by isotope. This is done not only so that appropriate shielding can be placed around waste containers, but so that some waste can be allowed to decay prior to disposal through normal trash channels. With a decreasing number of radioactive waste disposal facilities able or willing to accept radioactive waste for burial (and a concomitant increase in dumping charges from those that still do) this practice of on-site decay can save an institution thousands of dollars a year in disposal charges.

6. Label your label! It is only common courtesy (as well as common sense) to alert coworkers to the existence of anything and everything radioactive that is left where they may come in contact with it! A simple piece of tape affixed to the sample box—with the investigator's name, the amount and type of isotope, and the date written on it—should do the trick. Yellow hazard tape printed with the international symbol for radioactivity is commercially available in a variety of widths.

7. Monitor radioactivity early and often. Portable radiation detection monitors are essential equipment for every laboratory using radioactivity. No matter how much or how little radioactivity is being used, the investigator should keep a hand-held monitor nearby—and it should be on! Turn it on before touching any radioactivity to avoid contaminating the monitor's switch. Use a monitor with the appropriate detection capacity (β for ^{35}S and ^{32}P ; γ for ^{125}I) before, during, and after all procedures. The more frequently fingers and relevant equipment are monitored, the more quickly a spill or glove contamination will be detected. Such timely detection will keep both the potential mess and the cleanup time to a minimum. Because low-energy β emitters such as ^3H cannot be detected using such monitors, wipe tests of the bench and equipment used are necessary to ensure that contamination of the work area did not occur.

SPECIFIC PRECAUTIONS

The following sections describe precautions to be taken with individual isotopes in specific forms. Although the sections dealing with ^{35}S - or ^{32}P -labeling of proteins in intact cells are presented in terms of mammalian cells, most of the instructions are also pertinent (with minimal and obvious modifications) to the labeling of proteins in other cells (bacterial, insect, etc.).

Working with ^{35}S

Using ^{35}S to label cellular proteins and proteins translated in vitro

As discussed above, the β radiation generated during ^{35}S decay is not strong enough to make barrier forms of shielding necessary. The risk associated with ^{35}S comes primarily through its ingestion and subsequent concentration in various target organs, particularly the testes. Although willful ingestion of ^{35}S seems unlikely, accidental or unknowing ingestion may be more common. As reported several years ago (Meisenhelder and Hunter, 1988), ^{35}S -labeled methionine and cysteine, which are

routinely used to label proteins in intact cells and by in vitro translation, break down chemically to generate a volatile radioactive component. The breakdown occurs independent of cellular metabolism. Thus the radioactive component is generated to the same extent in stock vials as in cell culture dishes. The process seems to be promoted by freezing and thawing ^{35}S -labeled materials. The exact identity of this component is not known, although it is probably SO_2 or CH_3SH . What is known is that it dissolves readily in water and is absorbed by activated charcoal or copper.

The amount of this volatile radioactive component released, despite stabilizers added by the manufacturers, is about 1/8000 of the total radioactivity present. The amount of this radioactivity that a scientist is likely to inhale while using these compounds is presumably even smaller. Nevertheless, such a component can potentially contaminate a wide area because of its volatility, and also tends to concentrate in target organs. Thus, it is advisable to thaw vials of ^{35}S -labeled amino acids in a controlled area such as a hood equipped with a charcoal filter. This charcoal filter will become quite contaminated and should be changed every few months. If such an area is not available, the stock vial should be thawed using a needle attached to a charcoal-packed syringe to vent and trap the volatile compound.

Anyone who has ever added ^{35}S -labeled amino acids to dishes of cells for even short periods knows that the incubator(s) used for such labelings quickly become highly contaminated with ^{35}S . Such contamination is not limited to the dish itself, nor to the shelf on which the dish was placed. Rather, the radioactive component's solubility in water allows it to circulate throughout the moist atmosphere of the incubator and contaminate all the inside surfaces of the incubator. For this reason, in laboratories where such metabolic labelings are routine, it is highly convenient to designate one incubator to be used solely for working with ^{35}S -labeled samples. Such an incubator can be fitted with a large honeycomb-style filter, the size of an incubator shelf, made of pressed, activated charcoal. These filters are available from local air-quality-control companies. Such a filter will quickly become quite contaminated with radioactivity and should therefore be monitored and changed as necessary (usually about every three months if the incubator is used several times a week). The water used to humidify the incubator will also become quite "hot" (contaminated with radioactivity); keep-

ing the water in a shallow glass pan on the bottom of the incubator makes it easy to change it after every use, thus preventing contamination from accumulating. Even with the charcoal filter and water as absorbents, the shelves, fan, and inner glass door of the incubator will become contaminated, as will the tray on which the cells are carried and incubated. Routine wipe tests and cleaning when necessary will help to minimize potential spread of this contamination.

If such labelings are done infrequently or there is no "spare" incubator, dishes of cells can be placed in a box during incubation. This box should be made of plastic, which is generally more easily decontaminated than metal. Along with the dishes of cells, a small sachet made of activated charcoal wrapped loosely in tissue (Kimwipes work well) should be placed in the box. If the box is sealed, it will obviously need to be gassed with the correct mixture of CO₂; otherwise small holes can be incorporated into the box design to allow equilibration with the incubator's atmosphere. In either case, the incubator used for the labeling should be carefully monitored for radioactivity after each experiment.

Working with ³²P

μCi amounts of ³²P

The amount of ³²P-labeled nucleotide used to label nucleic acid probes for northern or Southern blotting is typically under 250 μCi, and the amount of [γ -³²P]ATP used for in vitro phosphorylation of proteins does not usually exceed 50 μCi for a single kinase reaction (or several hundred μCi per experiment). However, handling even these small amounts, given the time spent on such experiments, can result in an unacceptable level of exposure if proper shielding is not employed. With no intervening shielding, the dose rate 1 cm away from 1 mCi ³²P is 200,000 mrad/hr; the local dose rate to basal cells resulting from a skin contamination of 1 μCi/cm² is 9200 mrad/hr (Shleien, 1987). Such a skin contamination could be easily attained though careless pipetting and the resultant creation of an aerosol of radioactive microdroplets, because the concentration of a typical stock solution of labeled nucleotide may be 10 μCi/μl.

For proper protection during this sort of experiment, besides the usual personal attire (glasses, coat, safety badges, and gloves) it is necessary to use some form of Plexiglas screen between the body and the samples (see Fig.

A.1F.1A). Check the level of radiation coming through the outside of the shield with a portable monitor to be sure the thickness of the Plexiglas is adequate. Hands can be shielded from some exposure by placing the sample tubes in a solid Plexiglas rack, which is also useful for transporting samples from the bench to a centrifuge or water bath (see Fig. A.1F.1B).

Experiments of these types often include an incubation step performed at a specific temperature, usually in a water bath. Although the water surrounding the tubes or hybridization bags will effectively stop β radiation, shielding should be added over the top of the tubes (where there is no water)—e.g., a simple flat piece of Plexiglas. If the frequency of usage justifies the expense, an entire lid for the water bath can be constructed from Plexiglas. When hybridization reactions are performed in bags, care should be taken to monitor (and shield) the apparatus used to heat-seal the bags.

The waste generated during the experiments should also be shielded. It is convenient to have a temporary waste container right on the bench. Discard pipette tips and other solid waste into a beaker lined with a plastic bag and placed behind the shield. This bag can then be emptied into the appropriate shielded laboratory waste container when the experiment is done. Liquid waste can be pipetted into a disposable tube set in a stable rack behind the shield (see Fig. A.1F.1C).

When radiolabeled probes or proteins must be gel-purified, it may be necessary to shield the gel apparatus during electrophoresis if the samples are particularly hot. Be advised that the electrophoresis buffer is likely to become very radioactive if the unincorporated label is allowed to run off the bottom of the gel; check with a radiation safety officer for instructions on how to dispose of such buffer. It is also prudent to check the gel plates with a portable detection monitor after the electrophoresis is completed, because they sometimes become contaminated as well.

mCi amounts of ³²P

In order to study protein phosphorylation in intact mammalian cells, cells in tissue culture dishes are incubated in phosphate-free medium with ³²P-labeled orthophosphate for a period of several hours or overnight to label the proteins. The amount of ³²P used in such labelings can be substantial. Cells are normally incubated in 1 to 2 mCi of ³²P/ml labeling medium; for each 6-cm dish of cells, 2.5 to 5 mCi ³²P may be

Figure A.1F.1 Plexiglas shielding for ^{32}P . (A) Two portable shields (L and T design) made of 0.5-in. Plexiglas. Either can be used to directly shield the scientist from the radioactivity he or she is using. Turned on its side, the L-shaped shield can be used to construct two sides of a cage around a temporary work area, providing shielding for other workers directly across or to the sides of the person working with ^{32}P . (B) Tube rack for samples in microcentrifuge tubes. (C) Tube holder for liquid waste collection.

used. When this figure is multiplied by the number of dishes necessary per sample, and the number of different samples in each experiment, it is clear that the amount of ^{32}P used in one experiment can easily reach 25 mCi or more. Because so much radioactivity is used in the initial labeling phase of such experiments, it is necessary for a researcher to take extra precautions in order to adequately shield him or herself and coworkers.

When adding label to dishes of cells, it is important to work as rapidly as possible. An important contribution to the speed of these manipulations is to have everything that will be needed at hand before even introducing the label into the work area. Prepare the work area, arranging shielding and covering the bench

with diapers, in advance. Set out all necessary items, including any pipettors and tips needed, a portable detection monitor, extra gloves, and a cell house (see Fig. A.1F.2A).

Work involving this much radioactivity should be done behind a Plexiglas shield at least $\frac{3}{4}$ in. (2 cm) thick; the addition of a layer of lead to the outside lower section of this shield to stop Bremsstrahlung radiation is also needed. If one shield can be dedicated to this purpose at a specific location, a sheet of lead several centimeters thick can be permanently screwed to the Plexiglas (as shown in Fig. A.1F.2B); however, this lead makes the shield extremely heavy and therefore less than portable. If space constraints do not permit the existence of such a permanent labeling station,

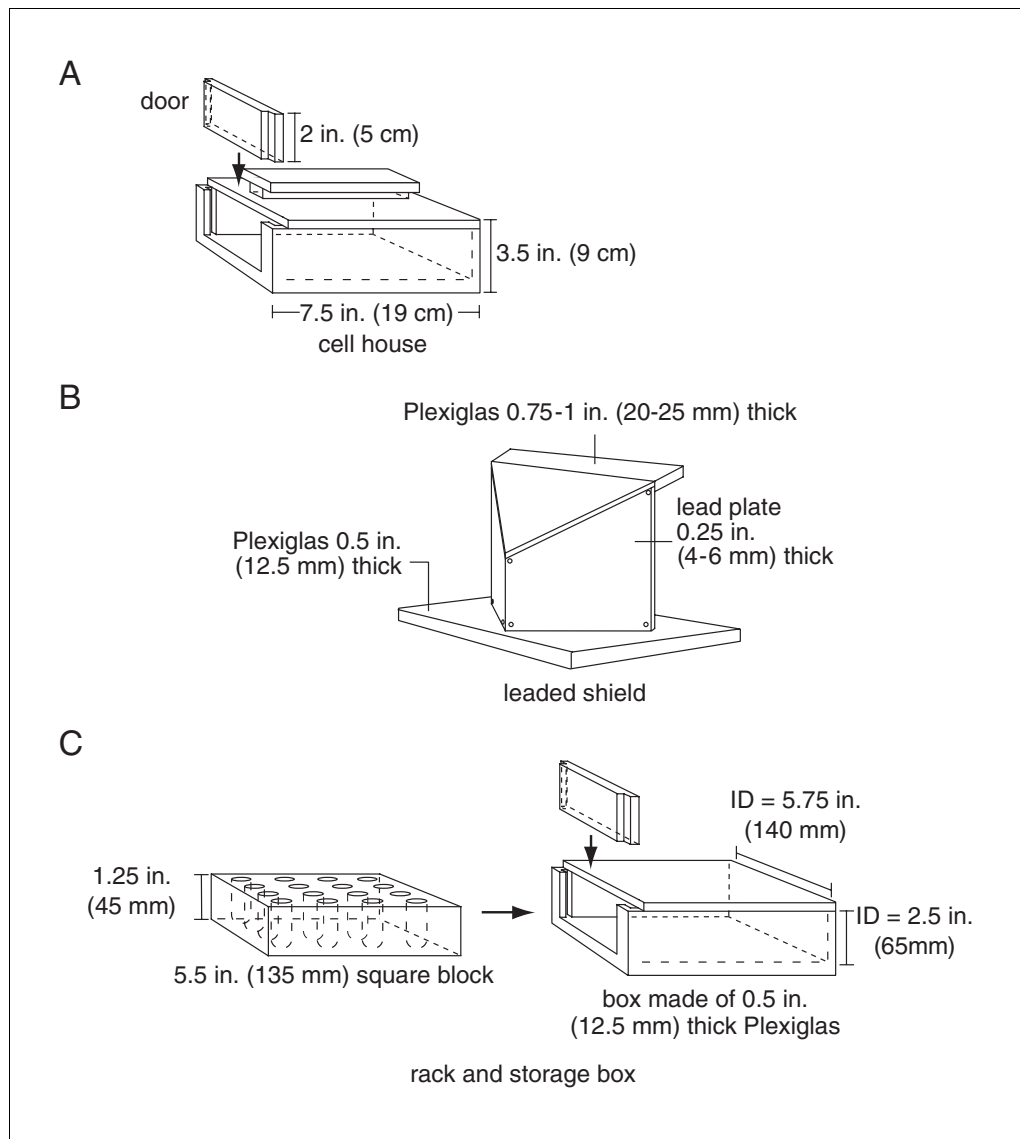

Figure A.1F.2 (A) Box for cell incubation (a “cell house”). (B) Stationary leaded shield. (C) Sample storage rack and box made of 0.5-in. Plexiglas. Abbreviations: ID, interior dimension.

a layer or two of lead foil can be taped temporarily to the outside of the Plexiglas shield.

Again, each worker should take care to shield not only him or herself, but bystanders on all sides. Handling of label should be done away from the central laboratory if possible to take maximum advantage of distance as an additional form of shielding. It is also advisable not to perform such experiments in a tissue culture room or any other room that is designed for a purpose vital to the whole laboratory. An accident involving this much ^{32}P would seriously inconvenience future work in the area, if not make it altogether uninhabitable! If care is taken to minimize the amount of time the dish of cells is open when adding the label, use of a controlled air hood to prevent fungal or bacte-

rial contamination of the cells should not be necessary.

Once the label has been added to the dishes of cells, they will also need to be shielded for transport to and from the incubator and other work areas. Plexiglas boxes that are open at one end (for insertion of the dishes) and have a handle on top (for safe carrying) make ideal “cell houses” (see Figure A.1F.2A). A Plexiglas door that slides into grooves at the open end is important to prevent dishes from sliding out if the box is tilted at all during transport. If this door is only two-thirds the height of the house wall, the open slot thus created will allow equilibration of the CO_2 level within the house with that in the incubator. Obviously, this slot will also allow a substantial stream of radiation

to pass out of the cell house, so the house should be carried and placed in the incubator with its door facing away from the worker (and others)!

Following incubation with label and any treatments or other experimental manipulations, the cells are usually lysed in some type of detergent buffer. It is probably during this lysis procedure that a worker's hands will receive their greatest exposure to radiation, because it is necessary to directly handle the dishes over a period of several minutes. It is therefore very important to streamline this procedure and use any shielding whenever possible. If the cell lysates must be made at 4°C, as required by most protocols, working on a bench in a cold room is preferable to placing the dishes on a slippery bed of ice. In either case, make the lysate using the same sort of shielding (with lead if necessary) that was used when initially adding the label. Pipet the labeling medium and any solution used to rinse unincorporated radioactivity from the cells into a small tube held in a solid Plexiglas holder (shown in Fig. A.1F.1C). The contents of this tube can later be poured into the appropriate liquid waste receptacle. If possible, it is a good practice to keep this high-specific-activity ^{32}P liquid waste separate from the lower-activity waste generated in other procedures so that it can be removed from the laboratory as soon as possible following the experiment. If it is necessary to store it in the laboratory for any time, the shielding for the waste container should also include a layer of lead.

The solid waste generated in the lysis part of these experiments (pipet tips, disposable pipettes, cell scrapers, and dishes) is very hot and should be placed immediately into some

sort of shielded container to avoid further exposure of the hands. A Plexiglas box similar in design to that in Figure A.1F.3 is convenient; placed to the side of the shield and lined with a plastic bag, it will safely hold all radioactive waste during the experiment and is light enough to be easily carried to the main laboratory waste container where the plastic bag (and its contents) can be dumped after the experiment is done. If the lid of the box protrudes an inch or so over the front wall, it can be lifted using the back of a hand, thus decreasing the possibility of contaminating it with hot gloves.

When scraping the cell lysates from the dishes, it is good practice to add them to microcentrifuge tubes that are shielded in a solid Plexiglas rack; this will help to further reduce the exposure to which the hands are subjected. At this point, the lysates are usually centrifuged at high speed ($>10,000 \times g$) to clear them of unsolubilized cell material. Use screw-cap tubes for this clarification step, as these will contain the labeled lysate more securely than flip-top tubes, which may open during centrifugation. No matter what type of tube is used, the rotor of the centrifuge often becomes contaminated, most probably due to tiny drops of lysate (aerosol) initially present on the rim of the tubes that are spun off during centrifugation. Monitor the rotor and wipe it out after each use.

The amount of ^{32}P taken up by cells during the incubation period varies considerably, depending on the growth state of the culture as well as on the cell type and its sensitivity to radiation. This makes it difficult to predict the percentage of the radioactivity initially added to the cells that is incorporated into the cell lysate; however, this figure probably does not

Figure A.1F.3 Box for solid waste collection made of 0.5-in. Plexiglas. Abbreviation: ID, interior dimension.

exceed 10%. Thus, the amount of radioactivity being handled decreases dramatically after lysis, making effective shielding much simpler. However, at least ten times more radioactivity than is usual in other sorts of experiments is still involved! It is easy to determine if the shielding is adequate—just use both β and γ portable monitors to measure the radiation coming through it. Again, be sure to check that people working nearby (including those across the bench) are also adequately shielded. It is sometimes necessary to construct a sort of cage of Plexiglas shields around the ice bucket that contains the lysates.

At the end of the day or the experiment, it may be necessary to store radioactive samples; in some experiments, it may be desirable to save the cell lysates. These very hot samples are best stored in tubes placed in solid Plexiglas racks that can then be put into Plexiglas boxes (see Fig. A.1F.2C). Such boxes may be of similar construction to the cell houses described above; however, they should have a door that completely covers the opening. Be sure to check the γ radiation coming through these layers and add lead outside if necessary.

Working with ^{33}P

Using ^{33}P -labeled nucleotides to label nucleic acid probes or proteins

Several of the major companies that manufacture radiolabeled biological molecules have recently introduced nucleotides labeled with ^{33}P (both α - and γ -labeled forms). ^{33}P offers a clear advantage over ^{32}P with respect to ease of handling, because the energy of the β particles it releases lies between that of ^{35}S and ^{32}P and thus its use does not require as many layers of Plexiglas and lead shielding as for ^{32}P . In fact, the β radiation emitted can barely penetrate through gloves and the surface layer of skin, so the hazard associated with exposure to even millicurie amounts of ^{33}P is thought to be insignificant (as reported in the DuPont NEN product brochure). Gel bands visualized on autoradiographs of ^{33}P -labeled compounds are sharper than bands labeled with ^{32}P because the lower-energy β radiation does not have the scatter associated with that from ^{32}P . The half-life of ^{33}P is also longer (25 days compared to 14 days for ^{32}P). Despite its higher cost, these features have led many researchers to choose ^{33}P -labeled nucleotides for use in experiments such as band/gel shift assays where discrimination of closely-spaced gel bands is important.

The best way to determine what degree of shielding is needed when using ^{33}P is to monitor the source using a portable β monitor and add layers of Plexiglas as necessary.

Working with ^{125}I

Using ^{125}I to detect immune complexes (Western blots)

^{125}I that is covalently attached to a molecule such as staphylococcal protein A is not volatile and therefore is much less hazardous than the unbound or free form. Most institutions do not insist that work with bound ^{125}I be performed in a hood, but shielding of the γ radiation is still necessary. Lead is a good high-density material for stopping these γ rays; its drawbacks are its weight and opacity. Commercially available shields for ^{125}I are made of lead-impregnated Plexiglas—though heavy, these are at least see-through. Alternatively, a piece of lead foil may be taped to a structural support, although this arrangement does not provide shielding for the head as a worker peers over the lead!

Incubations of the membrane or blot with the [^{125}I] protein A solution and subsequent washes are usually done on a shaker. For shielding during these steps, a piece of lead foil may simply be wrapped around the container. Solutions of ^{125}I can be conveniently stored for repeated use in a rack placed in a lead box.

Using ^{125}I to label proteins or peptides in vitro

Any experiments that call for the use of free, unbound ^{125}I should be done behind a shield in a hood that contains a charcoal filter to absorb the volatile iodine. Most institutions require that such experiments be done in a special hot lab to which access is limited. Ingested or inhaled iodine is concentrated in the thyroid; a portable γ monitor should therefore be used to scan the neck and throat before beginning and after completing each experiment. Similar scans should routinely be performed on all members of any laboratory in which unbound iodine is used.

DEALING WITH ACCIDENTS

Despite the best intentions and utmost caution, accidents happen! Accidents involving spills of radioactivity are particularly insidious because they can be virtually undetectable yet pose a significant threat to laboratory workers. For this reason it is best to foster a community spirit in any laboratory where radioisotopes are routinely used—a sense of cooperativity that

extends from shielding each other properly to helping each other clean up when such accidents occur.

The specific measures to be taken following an accident involving radioactivity naturally depend on the type and amount of the isotope involved, the chemical or biological hazards of the material it is associated with, and the physical parameters of the spill (i.e., where and onto what the isotope was “misplaced”). However, following any accident there are several immediate steps that should be taken:

1. Alert coworkers as well as Radiation Safety personnel to the fact that there has been an accident. This will give them the opportunity to shield themselves if necessary—and to help clean up as well!

2. Restrict access to and away from the site of the accident to ensure that any uncontained radioactive material is not spread around the laboratory. When leaving the site be sure to monitor the bottoms of the shoes as well as the rest of the body.

3. Take care of all contaminated personnel first, evacuating others if necessary. If anyone’s skin is contaminated, first use a portable monitor to identify specific areas of contamination. Then wipe these areas with a damp tissue to remove as much surface radioactivity as possible. Try to scrub only small areas at a time to keep the contamination localized. If the contamination is not easily removed with paper tissues, try a sponge or an abrasive pad, but be

careful not to break the skin! Sometimes soaking is required: do this only after all easily removed contamination is gone and keep the soaked area to a minimum. Contaminated strands of hair can be washed (or perhaps a new hairstyle may be in order).

4. When attempting to clean any contaminated equipment, floors, benches, etc., begin by soaking up any visible radioactive liquid with an absorbent material. Use a small amount of soap and water to clean the contaminated area, keeping the area wiped each time to a minimum to avoid smearing the contamination over an even greater surface. Many surfaces prove resistant to even Herculean cleaning efforts; in these instances the best that can be done is to remove all contamination possible and then shield whatever is left until the radioactivity decays sufficiently for safety.

Centrifuges and Rotors

Centrifugation runs described in this book usually specify a relative centrifugal force (RCF; measured in $\times g$), corresponding to a speed (in rpm) for a particular centrifuge and rotor model. As available equipment will vary from laboratory to laboratory, the investigator must be able to adapt these specifications to other centrifuges and rotors.

The relationship between RCF and speed (rpm) is determined by the following equation:

$$\text{RCF} = 1.12r (\text{rpm}/1000)^2$$

where r is the rotating radius between the particle being centrifuged and the axis of rotation. In most cases, an accurate conversion from speed to relative centrifugal force (or vice versa) can be obtained using the maximum value of r —or r_{max} —equal to the distance between the axis of rotation and the bottom of the centrifuge tube as it sits in the well or bucket of the rotor.

Table A.1G.1 provides r_{max} values for commonly used rotors manufactured by Du Pont (Sorvall), Beckman, Fisher, and IEC. There are situations (e.g., where an adapter is used to fit a smaller tube into a larger rotor well) where r_{max} will not accurately represent the effective rotating radius. In such cases, the manual for the rotor should be consulted to obtain the appropriate value of r .

As an alternative to use of the above equation, the nomograms in Figures A.1G.1 and A.1G.2 make it possible to determine the RCF where speed and r_{max} are known, or the speed where RCF and r_{max} are known. This is done by aligning a ruler across the two known values and reading the unknown value at the point where the ruler crosses the remaining column. Figure A.1G.1 should be used for centrifuge runs $<21,000$ rpm, while Figure A.1G.2 should be used for faster spins.

NOTE: In this manual, for spins involving microcentrifuges built to the Eppendorf standard, a shortened style of reference including only the speed (in rpm) is used. All of these instruments have approximately the same rotating radius; hence the same speed will yield the same RCF value from machine to machine. Microcentrifuge spins may also be described as at “top speed” or “maximum speed,” meaning 12,000 to 14,000 rpm, which is the maximum speed for all Eppendorf-type microcentrifuges.

CAUTION: Do not exceed maximum rotor speed! For Beckman ultracentrifuges, the maximum speed for each rotor is denoted by its name, e.g., the maximum speed of the Beckman VTi 80 rotor is 80,000 rpm. This speed refers only to centrifugation of solutions below a particular allowed density, which differs among rotors (see user manual). For centrifugation of high-density solutions, rotor maximum speed can be determined as: reduced rpm = rpm_{max}(A/B)^{1/2}, where A=allowed density and B=density of solution. A=1.7 g/ml for several vertical rotors (including VTi 80 and VTi 50), and 1.2 g/ml for several swinging-bucket rotors (including SW 55 Ti, 28, 28.1, 40 Ti, 50.1). For gradients using heavy salts such as CsCl, particularly at low temperatures, maximum rpm should be reduced to prevent precipitation (see user manual).

Table A.1G.2 describes centrifuge tube materials and their properties, including optical properties, appropriate methods for sterilization, and chemical resistances (tolerance to various media, organic solvents, and alcohols).

Figure A.1G.1 Nomogram for conversion of relative centrifugal force to rotor speed in low-speed centrifuge runs. To determine an unknown value in a given column, align ruler through known values in other two columns. Desired value is found at the intersection of the ruler with the column of interest. For faster centrifugations, use Figure A.1G.2. A more precise conversion can be obtained using the equation at the beginning of this appendix. See Table A.1G.1 for rotating radii of commonly used rotors.

Figure A.1G.2 Nomogram for conversion of relative centrifugal force to rotor speed in high-speed centrifuge runs. For slower centrifugations and instructions for using the nomogram, use Figure A.1G.1. A more precise conversion can be obtained using the equation at the beginning of this appendix. See Table A.1G.1 for rotating radii of commonly used rotors.

^aSorvall centrifuges and rotors are a product of Du Pont Company Medical Products, Beckman centrifuges are a product of Beckman Instruments, IEC centrifuges are a product of International Equipment Co., Clay Adams Dynac centrifuges are a product of Becton Dickinson Labware, and Fisher centrifuges are a product of Fisher Scientific. For ordering information see *APPENDIX*.

^bThese instruments are often loosely referred to as “clinical,” “tabletop,” or “low-speed” centrifuges.

^cThese instruments accept a wide range of trunnion-ring rotors with variable rotating radii, as well as fixed-angle and swinging-bucket rotors that in turn accept a variety of adapters making it possible to spin different numbers tubes of various sizes. For instance, the commonly used IEC 958 trunnion-ring rotor may be adjusted to a radii ranging from 137 to 181 mm, depending on the trunnion-ring chosen. It is therefore necessary to consult the manual for the specific system being used to obtain an accurate speed to RCF conversion.

Table A.1G.2 Centrifuge Tube Materials and Their Properties^a

Type	Optical property	Puncturable	Sliceable	Reusable	Sterilization methods	Chemical resistances ^b
Ultra-Clear thin-walled Standard tubes Quick-Seal tubes	Transparent	Yes	Yes	Yes No	Cold sterilization only, but not with alcohol	Good tolerance to all gradient media except alkaline ones (>pH 8). Satisfactory for most weak acids and a few weak bases. Unsatisfactory for DMSO and most organic solvents, including all alcohols.
Polyallomer thin-walled Standard tubes Quick-Seal tubes	Translucent	Yes	Yes	Yes No	Can be autoclaved on a test tube rack at 121°C	Good tolerance to all gradient media, including alkaline ones. Satisfactory for most acids, many bases, many alcohols, DMSO, and some organic solvents.
Polyallomer thick-walled Tubes Bottles	Translucent	No No	No No	Yes Yes	Can be autoclaved on a test tube rack at 121°C	Good tolerance to all gradient media, including alkaline ones. Satisfactory for most acids, many bases, many alcohols, DMSO, and some organic solvents.
Polycarbonate thick-walled Tubes Bottles	Transparent	No	No	Yes	Cold sterilization recommended, but not with alcohol. Can be autoclaved at 121°C, but tube life may be reduced.	Good tolerance to all gradient media except alkaline ones (>pH 8). Satisfactory for some weak acids. Unsatisfactory for all bases, alcohols, and other organic solvents.
Cellulose propionate tubes	Transparent	No	No	Yes	Cold sterilization only, but not with alcohol	Good tolerance to all gradient media, including alkaline ones. Unsatisfactory for most acids, bases, alcohols, and other organic solvents.
Polypropylene Tubes Bottles	Translucent	No	No	Yes Yes	Can be autoclaved at 121°C	Good tolerance to all gradient media, including alkaline ones. Satisfactory for many acids, bases, and alcohols. Unsatisfactory for most organic solvents.
Stainless steel tubes	Opaque	No	No	Yes	Can be autoclaved. Dry thoroughly before storage.	Good tolerance to many organic solvents. Marginal with many gradient media and salts. Unsatisfactory for most acids and many bases.
Polyethylene tubes	Translucent	No	No	Yes	Can be autoclaved at 121°C	Good tolerance to a wide range of chemicals. Suitable for use with strong acids and bases. Unsatisfactory for most organic solvents.
Corex/Pyrex Tubes Bottles	Transparent	No	No	Yes Yes	Can be autoclaved at 121°C	Good tolerance to a wide range of gradient media. Corex has greater resistance to bases and acids.

^aTable reproduced by permission of Beckman Instruments.

^bChemical resistances are described here in general terms, and are not meant by Beckman Instruments or John Wiley & Sons to express or imply any guarantee of safety based on these recommendations or resistances. If there is any doubt about a particular solution, it should be tested under actual operating conditions to evaluate the performance of a tube material. For more detailed information regarding specific media and solvents, consult Beckman Instruments. High-vapor-pressure inflammable solvents should not be handled in close vicinity to centrifuges because of possible ignition by sparking switches, relay contacts, or motor brushes.

Safe Use of Hazardous Chemicals

Carrying out the protocols in this manual may result in exposure to toxic chemicals or carcinogenic, mutagenic, or teratogenic reagents (see Table A.1H.1). Cautionary notes and some specific guidelines are included in many instances throughout the manual; however, users must proceed with the prudence and precautions associated with good laboratory practice, under the supervision of those responsible for implementing lab safety programs at their institutions.

It is not possible in the space available to list all the precautions required for handling hazardous chemicals. Many texts have been written about laboratory safety (see Literature Cited and Key References). Obviously, all national and local laws should be obeyed, as well as all institutional regulations. Controlled substances are regulated by the Drug Enforcement Administration (<http://www.doj.gov/dea>). By law, Material Safety Data Sheets (MSDSs) must be readily available. All laboratories should have a Chemical Hygiene Plan (29CFR Part 1910.1450); institutional safety officers should be consulted as to its implementation. Help is (or should be) available from your institutional Safety Office; use it.

Chemicals must be stored properly for safety. Certain chemicals cannot be easily or safely mixed with and should not be stored near certain other chemicals, because their reaction is violently exothermic or yields a toxic product. Some examples of incompatibility are listed in Table A.1H.2. When in doubt, always consult a current MSDS for information on reactivity, handling, and storage. Chemicals should be separated into general hazard classes and stored appropriately. For example, flammable chemicals such as alcohols, ketones, aliphatic and aromatic hydrocarbons, and other materials labeled flammable should be stored in approved flammable storage cabinets, with those also requiring refrigeration being kept in explosion-proof refrigerators. Strong oxidizers must be segregated. Strong acids (e.g., sulfuric, hydrochloric, nitric, perchloric, and hydrofluoric) should be stored in a separate cabinet well removed from strong bases and from flammable organics. An exception is glacial acetic acid, which is both corrosive and flammable, and which must be stored with the flammables.

Facilities should be appropriate for working with hazardous chemicals. In particular, hazardous chemicals should be handled only in chemical fume hoods, not in laminar flow cabinets. The functioning of the fume hoods should be checked periodically. Laboratories should also be equipped with safety showers and eye-wash facilities. Again, this equipment should be tested periodically to ensure that it functions correctly. Other safety equipment may be required depending on the nature of the materials being handled. In addition, researchers should be trained in the proper procedures for handling hazardous chemicals as well as other laboratory operations—e.g., handling of compressed gases, use of cryogenic liquids, operation of high-voltage power supplies, and operation of lasers of all types.

Before starting work, know the physical and chemical hazards of the reagents used. Wear appropriate protective clothing and have a plan for dealing with spills or accidents; coming up with a good plan on the spur of the moment is very difficult. For example, have the appropriate decontaminating or neutralizing agents prepared and close at hand. Small spills can probably be cleaned up by the researcher. In the case of larger spills, the area should be evacuated and help should be sought from those experienced in and equipped for dealing with spills—e.g., the institutional Safety Office.

Protective equipment should include, at a minimum, eye protection, a lab coat, and gloves. In certain circumstances other items of protective equipment may be necessary (e.g., a face shield). Different types of gloves exhibit different resistance properties (Table

Table A.1H.1 Commonly Used Hazardous Chemicals^a

Chemical	Hazards	Remarks ^b
Acetic acid, glacial	Corrosive, flammable liquid	
Acetonitrile	Flammable liquid, teratogenic, toxic	
Acridine orange	Carcinogenic, mutagenic	See Basic Protocol 2
Acrylamide	Carcinogenic, toxic	Use dust mask; polyacrylamide gels contain residual acrylamide monomer and should be handled with gloves; acrylamide may polymerize with violence on melting at 86°C
Alcian blue 8GX		See Basic Protocol 2
Alizarin red S (monohydrate)		
<i>p</i> -Amidinophenylmethanesulfonyl fluoride (APMSF)	Enzyme inhibitor	See Basic Protocol 11
7-Aminoactinomycin D (7-AAD)	Carcinogenic	
4-(2-Aminoethyl)benzenesulfonyl fluoride (AEBSF)	Mutagenic, enzyme inhibitor	See Basic Protocol 11
Ammonium hydroxide, concentrated	Corrosive, lachrymatory, toxic	
Azure A	Mutagenic	See Basic Protocol 2
Azure B	Mutagenic	See Basic Protocol 2
Benzidine (BDB)	Carcinogenic, toxic	See Basic Protocol 1
Bisacrylamide	Toxic	
Boron dipyrromethane derivatives (BODIPY dyes)	Toxic	
Brilliant blue R	Carcinogenic, mutagenic	See Basic Protocol 2
5-Bromodeoxyuridine (BrdU)	Mutagenic, teratogenic, photosensitizing	
Cetylpyridinium chloride (CPC)	Toxic	
Cetyltrimethylammonium bromide (CTAB)	Corrosive, teratogenic, toxic	
Chloroform	Carcinogenic, teratogenic, toxic	
Chlorotrimethylsilane	Carcinogenic, corrosive, flammable liquid, toxic	Reacts violently with water; see Basic Protocol 3
Chromic/sulfuric acid cleaning solution	Carcinogenic, corrosive, oxidizer, toxic	Replace with suitable commercially available cleanser
Chromomycin A3 (CA3)	Teratogenic, toxic	
Congo red	Mutagenic, teratogenic	See Basic Protocol 2
Coomassie brilliant blue G	Mutagenic	See Basic Protocol 2
Crystal violet		See Basic Protocol 2
Cresyl violet acetate	Mutagenic	See Basic Protocol 2
Cyanides (e.g., KCN, NaCN)	Toxic	Contact with acid will liberate HCN gas; see Basic Protocol 4
Cyanines (e.g., Cy3, Cy5)	Toxic	
Cyanogen bromide (CNBr)	Toxic	See Basic Protocol 4

*continued***A.1H.2**

Table A.1H.1 Commonly Used Hazardous Chemicals^a, continued

Chemical	Hazards	Remarks ^b
2'-Deoxycoformycin (dCF, pentostatin)	Teratogenic, toxic	
4',6-Diamidino-2-phenylindole (DAPI)	Mutagenic	
Diaminobenzidine (DAB)	Carcinogenic	See Basic Protocol 1
1,4-Diazabicyclo[2,2,2]-octane (DABCO)	Toxic	Forms an explosive complex with hydrogen peroxide
Dichloroacetic acid (DCA)	Carcinogenic, corrosive, toxic	
Dichloromethane (methylene chloride)	Carcinogenic, mutagenic, teratogenic, toxic	
Diethylamine (DEA)	Corrosive, flammable liquid, toxic	
Diethylpyrocarbonate (DEPC)	Carcinogenic, toxic	
Diethyl sulfate	Carcinogenic, teratogenic, toxic	See Basic Protocol 5
Diisopropyl fluorophosphate (DFP)	Highly toxic, cholinesterase inhibitor, neurotoxin	See Basic Protocol 11
Dimethyldichlorosilane	Corrosive, flammable liquid, toxic	See Basic Protocol 3
Dimethyl sulfate (DMS)	Carcinogenic, toxic	See Basic Protocol 5
Dimethyl sulfoxide (DMSO)	Flammable liquid, toxic	Enhances absorption through skin
Diphenylamine (DPA)	Teratogenic, toxic	
2,5-Diphenyloxazole (PPO)	Toxic	
Dithiothreitol (DTT)	Toxic	
Eosin B		See Basic Protocol 2
Erythrosin B	Carcinogenic, mutagenic	See Basic Protocol 2
Ether	Flammable liquid, toxic	May form explosive peroxides on standing; do not dry with NaOH or KOH
Ethidium bromide (EB)	Mutagenic, toxic	See Basic Protocol 2 or 6
Ethyl methanesulfonate (EMS)	Carcinogenic, toxic	See Basic Protocol 5
Fluorescein and derivatives	Carcinogenic, toxic	
5-Fluoro-2'-deoxyuridine (FUdR)	Teratogenic, toxic	
Fluoroorotic acid (FOA)	Toxic	
Formaldehyde	Carcinogenic, flammable liquid, teratogenic, toxic	
Formamide	Teratogenic, toxic	
Formic acid	Corrosive, toxic	May explode when heated >180°C in a sealed tube
Glutaraldehyde	Corrosive, teratogenic, toxic	
Guanidinium thiocyanate	Toxic	
Hoechst 33258 dye	Mutagenic, toxic	
Hydrochloric acid, concentrated	Corrosive, teratogenic, toxic

Table A.1H.1 Commonly Used Hazardous Chemicals^a, continued

Chemical	Hazards	Remarks ^b
Hydrogen peroxide (30%)	Carcinogenic, corrosive, mutagenic, oxidizer	Avoid bringing into contact with organic materials, which may form explosive peroxides; may decompose violently in contact with metals, salts, or oxidizable materials; see Basic Protocol 7
Hydroxylamine	Corrosive, flammable, mutagenic, toxic	Explodes in air at >70°C
3-β-Indoleacrylic acid (IAA)	Carcinogenic	
Iodine	Corrosive, toxic	See Basic Protocol 8
Iodoacetamide	Carcinogenic, mutagenic, toxic	
Janus green B	Carcinogenic, mutagenic	See Basic Protocol 2
Lead compounds	Carcinogenic, toxic	
2-Mercaptoethanol (2-ME)	Stench, toxic	
Mercury compounds	Teratogenic, toxic	See Basic Protocol 9
Methionine sulfoximine (MSX)	Teratogenic, toxic	
Methotrexate (amethopterin)	Carcinogenic, mutagenic, teratogenic, toxic	
Methylene blue	Mutagenic, toxic	See Basic Protocol 2
Methyl methanesulfonate (MMS)	Carcinogenic, toxic	See Basic Protocol 5
Mycophenolic acid (MPA)	Teratogenic, toxic	
Neutral red	Mutagenic	See Basic Protocol 2
Nigrosin, water soluble		See Basic Protocol 2
Nitric acid, concentrated	Corrosive, oxidizer, teratogenic, toxic	
Nitroblue tetrazolium (NBT)	Toxic	
Orcein, synthetic		See Basic Protocol 2
Oxonols	Toxic	
Paraformaldehyde	Toxic	
Phenol	Carcinogenic, corrosive, teratogenic, toxic	Readily absorbed through the skin
Phenylmethylsulfonyl fluoride (PMSF)	Enzyme inhibitor	See Basic Protocol 11
Phorbol 12-myristate 13-acetate (PMA)	Carcinogenic, toxic	
Phycoerythrins (PE)	Toxic	
Piperidine	Flammable liquid, teratogenic, toxic	
Potassium hydroxide, concentrated	Corrosive, toxic	Produces a highly exothermic reaction when solid is added to water
Propane sultone	Carcinogenic, toxic	See Basic Protocol 5
Propidium iodide (PI)	Mutagenic	See Basic Protocol 2 or 6
Pyridine	Flammable liquid, toxic	
Rhodamine and derivatives	Toxic	
Rose Bengal	Carcinogenic, teratogenic	See Basic Protocol 2
Safranin O	Mutagenic	See Basic Protocol 2

Table A.1H.1 Commonly Used Hazardous Chemicals^a, continued

Chemical	Hazards	Remarks ^b
Sodium azide	Carcinogenic, toxic	Adding acid liberates explosive volatile, toxic hydrazoic acid; can form explosive heavy metal azides, e.g., with plumbing fixtures— <i>do not</i> discharge down drain; see Basic Protocol 10
Sodium deoxycholate (Na-DOC)	Carcinogenic, teratogenic, toxic	
Sodium dodecyl sulfate (sodium lauryl sulfate, SDS)	Sensitizing, toxic	
Sodium hydroxide, concentrated	Corrosive, toxic	A highly exothermic reaction ensues when the solid is added to water
Sodium nitrite	Carcinogenic	
Sulfuric acid, concentrated	Corrosive, oxidizer, teratogenic, toxic	Reaction with water is very exothermic; always add concentrated sulfuric acid to water, <i>never</i> water to acid
SYTO dyes	Toxic	
Tetramethylammonium chloride (TMAC)	Toxic	
<i>N,N,N',N'</i> -Tetramethyl-ethylenediamine (TEMED)	Corrosive, flammable liquid, toxic	
Texas Red (sulforhodamine 101, acid chloride)	Toxic	
Toluene	Flammable liquid, teratogenic, toxic	
Toluidine blue O	Mutagenic, toxic	See Basic Protocol 2
<i>N</i> α- <i>p</i> -Tosyl-L-lysine chloromethyl ketone (TLCK)	Toxic, enzyme inhibitor	See Basic Protocol 11
<i>N</i> - <i>p</i> -Tosyl-L-phenylalanine chloromethyl ketone (TPCK)	Toxic, mutagenic, enzyme inhibitor	See Basic Protocol 11
Trichloroacetic acid (TCA)	Carcinogenic, corrosive, teratogenic, toxic	
Triethanolamine acetate (TEA)	Carcinogenic, toxic	
Trifluoroacetic acid (TFA)	Corrosive, toxic	
Trimethyl phosphate (TMP)	Carcinogenic, mutagenic, teratogenic	May explode on distillation
Trypan blue	Carcinogenic, mutagenic, teratogenic	See Basic Protocol 2
Xylenes	Flammable liquid, teratogenic, toxic	

^aFor extensive information on the hazards of these and other chemicals as well as cautionary details, see Bretherick (1986), O'Neil (2001), Furr (2000), Lewis (1999), Lunn and Sansone (1994a), and Bretherick et al. (1999).

^b**CAUTION:** These chemicals should be handled only in a chemical fume hood by knowledgeable workers equipped with eye protection, lab coat, and gloves. The laboratory should be equipped with a safety shower and eye wash. Additional protective equipment may be required.

A.1H.3). No gloves resist all chemicals, and no gloves resist any chemicals indefinitely. Disposable gloves labeled “exam” or “examination” are primarily for protection from biological materials (e.g., viruses, bacteria, feces, blood). They are not designed for and usually have not been tested for resistance to chemicals. Disposable gloves generally offer *extremely* marginal protection from chemical hazards in most cases and should be removed immediately upon contamination before the chemical can pass through. If possible, design handling procedures to eliminate or reduce potential for contamination. Never assume that disposable gloves will offer the same protection or even have the same

A.1H.5

Table A.1H.2 Examples of Chemical Incompatibility

Chemical	Incompatible with
Acetic acid	Aldehydes, bases, carbonates, chromic acid, ethylene glycol, hydroxides, hydroxyl compounds, metals, nitric acid, oxidizers, perchloric acid, peroxides, phosphates, permanganates, xylene
Acetone	Acids, amines, concentrated nitric and sulfuric acid mixtures, oxidizers, plastics
Acetylene	Copper, halogens, mercury, oxidizers, potassium, silver
Alkali metals, alkaline earth metals	Acids, aldehydes, carbon dioxide, carbon tetrachloride or other chlorinated hydrocarbons, halogens, ketones, plastics, sulfur, water
Ammonia (anhydrous)	Acids, aldehydes, amides, calcium hypochlorite, hydrofluoric acid, halogens, heavy metals, mercury, oxidizers, plastics, sulfur
Ammonium nitrate	Acids, alkalis, chlorates, chloride salts, flammable and combustible materials, metals, organic materials, phosphorus, reducing agents, sulfur, urea
Aniline	Acids, aluminum, dibenzoyl peroxide, oxidizers, plastics
Arsenical materials	Any reducing agent
Azides	Acids, heavy metals, oxidizers
Bromine	Acetaldehyde, alcohols, alkalis, amines, ammonia, combustible materials, ethylene, fluorine, hydrogen, ketones (e.g., acetone, carbonyls), metals, petroleum gases, sodium carbide, sulfur
Calcium oxide	Acids, ethanol, fluorine, organic materials, water
Carbon (activated)	Alkali metals, calcium hypochlorite, halogens, oxidizers
Carbon tetrachloride	Sodium
Chlorates	Acids, ammonium salts, finely divided organic or combustible materials, powdered metals, sulfur
Chlorine	Acetylene or other hydrocarbons, alcohols, ammonia, benzene, butadiene, butane, combustible materials, ethylene, flammable compounds (e.g., hydrazine), hydrogen, hydrogen peroxide, iodine, metals, methane, nitrogen, oxygen, propane (or other petroleum gases), sodium carbide, sodium hydroxide
Chlorine dioxide	Ammonia, hydrogen, hydrogen sulfide, mercury, methane, organic materials, phosphine, phosphorus, potassium hydroxide, sulfur
Chromic acid, chromic oxide	Acetic acid, acetone, alcohols, alkalis, ammonia, bases, benzene, camphor, flammable liquids, glycerin (glycerol), hydrocarbons, metals, naphthalene, organic materials, phosphorus, plastics
Copper	Acetylene, calcium, hydrocarbons, hydrogen peroxide, oxidizers
Cumene hydroperoxide	Acids (organic or inorganic)
Cyanides	Acids, alkaloids, aluminum, iodine, oxidizers, strong bases
Flammable liquids	Ammonium nitrate, chromic acid, halogens, hydrogen peroxide, nitric acid, oxidizing agents in general, oxygen, sodium peroxide
Fluorine	All other chemicals

continued

Table A.1H.2 Examples of Chemical Incompatibility, continued

Chemical	Incompatible with
Hydrocarbons (liquid or gas)	See flammable liquids
Hydrocyanic acid	Alkali, nitric acid
Hydrofluoric acid	Ammonia, metals, organic materials, plastics, silica (glass, including fiberglass), sodium
Hydrogen peroxide	All organics, most metals or their salts, nitric acid, phosphorus, sodium, sulfuric acid
Hydrogen sulfide	Acetaldehyde, fuming nitric acid, metals, oxidizers, sodium, strong bases
Hydroperoxide	Reducing agents
Hypochlorites	Acids, activated carbon
Iodine	Acetaldehyde, acetylene, ammonia, hydrogen, metals, sodium
Mercury	Acetylene, aluminum, amines, ammonia, calcium, fulminic acid, lithium, oxidizers, sodium
Nitric acid	Acids, nitrites, metals, most organics, plastics, sodium, sulfur, sulfuric acid
Nitrites	Acids
Nitroparaffins	Amines, inorganic bases
Oxalic acid	Mercury, oxidizers, silver, sodium chlorite
Oxygen	All flammable and combustible materials, ammonia, carbon monoxide, grease, metals, oil, phosphorus, polymers
Perchloric acid	All organics, bismuth and alloys, dehydrating agents, grease, hydrogen halides, iodides, paper, wood
Peroxides, organic	Acids (organic or mineral), avoid friction, store cold
Phosphorus (white)	Air, alkalis, oxygen, reducing agents
Potassium chlorate	Acids, ammonia, combustible materials, fluorine, hydrocarbons, metals, organic materials, reducing agents, sugars
Potassium perchlorate	Alcohols, combustible materials, fluorine, hydrazine, metals, organic matter, reducing agents, sulfuric acid
Potassium permanganate	Benzaldehyde, ethylene glycol, glycerin, sulfuric acid
Selenides and tellurides	Reducing agents
Silver	Acetylene, ammonium compounds, fulminic acid, oxalic acid, ozonides, peroxyformic acid, tartaric acid
Sodium	Acids, carbon dioxide, carbon tetrachloride, hydrazine, metals, oxidizers, water
Sodium nitrate	Acetic anhydride, acids, metals, organic matter, peroxyformic acid, reducing agents
Sodium peroxide	Acetic anhydride, benzaldehyde, benzene, carbon disulfide, ethyl acetate, ethyl or methyl alcohol, ethylene glycol, furfural, glacial acetic acid, glycerin, hydrogen sulfide, metals, methyl acetate, oxidizers, peroxyformic acid, phosphorus, reducing agents, sugars, water
Sulfides	Acids
Sulfuric acid	Alcohols, bases, chlorates, perchlorates, permanganates of potassium, lithium, sodium, magnesium, calcium

^aPerformance varies with glove thickness and duration of contact. An asterisk indicates limited use. Abbreviations: VG, very good; G, good; F, fair; P, poor (do not use).

properties as nondisposables. Select gloves carefully and always look for some evidence that they will protect against the materials being used. Inspect all gloves before every use for possible holes, tears, or weak areas. Never reuse disposable gloves. Clean reusable gloves after each use and dry carefully inside and out. Observe all common-sense precautions—e.g., do not pipet by mouth, keep unauthorized persons away from hazardous chemicals, do not eat or drink in the lab, wear proper clothing in the lab (sandals, open-toed shoes, and shorts are not appropriate).

Order hazardous chemicals only in quantities that are likely to be used in a reasonable time. Buying large quantities at a lower unit cost is no bargain if someone (perhaps you) has to pay to dispose of surplus quantities. Substitute alcohol-filled thermometers for mercury-filled thermometers, which are a hazardous chemical spill waiting to happen.

Although any number of chemicals commonly used in laboratories are toxic if used improperly, the toxic properties of a number of reagents require special mention. Chemicals that exhibit carcinogenic, corrosive, flammable, lachrymatory, mutagenic, oxidizing, teratogenic, toxic, or other hazardous properties are listed in Table A.1H.1. Chemicals listed as carcinogenic range from those accepted by expert review groups as causing cancer in humans to those for which only minimal evidence of carcinogenicity exists. No effort has been made to differentiate the carcinogenic potential of the compounds in Table A.1H.1. Oxidizers may react violently with oxidizable material (e.g., hydrocarbons, wood, and cellulose). Before using any of these chemicals, thoroughly investigate all its characteristics. Material Safety Data Sheets are readily available; they list some hazards but vary widely in quality. A number of texts describing hazardous properties are listed at the end of this unit (see Literature Cited). In particular, Sax's *Dangerous Properties of Industrial Materials*, 10th ed. (Lewis, 1999) and the *Handbook of Reactive Chemical Hazards*, 6th ed. (Bretherick et al., 1999) give comprehensive listings of known hazardous properties; however, these texts list only the known properties. Many chemicals, especially fluorochromes, have been tested only partially or not at all. Prudence dictates that, unless there is good reason for believing otherwise, all chemicals should be regarded as volatile, highly toxic, flammable human carcinogens and should be handled with great care.

Waste should be segregated according to institutional requirements, for example, into solid, aqueous, nonchlorinated organic, and chlorinated organic material, and should always be disposed of in accordance with all applicable federal, state, and local regulations. Extensive information and cautionary details along with techniques for the disposal of chemicals in laboratories have been published (Bretherick, 1986; Lunn and Sansone, 1994a; O'Neil, 2001; Furr, 2000). Some commonly used disposal procedures are outlined in Basic Protocols 1 to 11. Incorporation of these procedures into laboratory protocols can help to minimize waste disposal problems. Alternate Protocols 1 to 7 describe decontamination methods for some of the chemicals. Support Protocols 1 to 9 describe analytical techniques that are used to verify that reagents have been decontaminated; with modification, these assays may also be used to determine the concentration of a particular chemical.

DISPOSAL METHODS

A number of procedures for the disposal of hazardous chemicals are available; protocols for the disposal and decontamination of some hazardous chemicals commonly encountered in molecular biology laboratories are listed in Table A.1H.4. These procedures are necessarily brief; for full details consult the original references or a collection of these procedures (see Lunn and Sansone, 1994a).

CAUTION: These disposal methods should be carried out only in a chemical fume hood by workers equipped with eye protection, a lab coat, and gloves. Additional protective equipment may be necessary.

DISPOSAL OF BENZIDINE AND DIAMINOBENZIDINE

Benzidine and diaminobenzidine can be degraded by oxidation with potassium permanganate (Castegnaro et al., 1985; Lunn and Sansone, 1991a). This protocol presents a method for decontamination of benzidine and diaminobenzidine in bulk. This method can also be adapted to the decontamination of benzidine and diaminobenzidine spills (see Alternate Protocol 1). These compounds can also be removed from solution using horseradish peroxidase in the presence of hydrogen peroxide (see Alternate Protocol 2). Destruction and decontamination are >99%. Support Protocol 1 is used to test for the presence of benzidine and diaminobenzidine.

BASIC PROTOCOL 1

Safe Use of Hazardous Chemicals

A.1H.10

Table A.1H.4 Protocols for Disposal of Some Hazardous Chemicals

Protocol	Disposal method for
Basic Protocol 1	Benzidine and diaminobenzidine
Alternate Protocol 1	Spills of benzidine and diaminobenzidine
Alternate Protocol 2	Aqueous solutions of benzidine and diaminobenzidine
Support Protocol 1	Analysis for benzidine and diaminobenzidine
Basic Protocol 2	Biological stains
Alternate Protocol 3	Large volumes of dilute biological stains
Support Protocol 2	Analysis for biological stains
Basic Protocol 3	Silanes
Basic Protocol 4	Cyanide and cyanogen bromide
Support Protocol 3	Analysis for cyanide
Basic Protocol 5	Dimethyl sulfate, diethyl sulfate, methyl methanesulfonate, ethyl methanesulfonate, diepoxybutane, 1,3-propane sultone
Support Protocol 4	Analysis for dimethyl sulfate, diethyl sulfate, methyl methanesulfonate, ethyl methanesulfonate, diepoxybutane, 1,3-propane sultone
Basic Protocol 6	Ethidium bromide and propidium iodide
Alternate Protocol 4	Equipment contaminated with ethidium bromide
Alternate Protocol 5	Ethidium bromide in isopropanol containing cesium chloride
Alternate Protocol 6	Ethidium bromide in alcohols
Support Protocol 5	Analysis for ethidium bromide and propidium iodide
Basic Protocol 7	Hydrogen peroxide
Basic Protocol 8	Iodine
Basic Protocol 9	Mercury compounds
Alternate Protocol 7	Waste water containing mercury
Support Protocol 6	Analysis for mercury
Basic Protocol 10	Sodium azide
Support Protocol 7	Analysis for sodium azide
Support Protocol 8	Analysis for nitrite
Basic Protocol 11	Enzyme inhibitors
Support Protocol 9	Analysis for enzyme inhibitors

Materials

Benzidine or diaminobenzidine tetrahydrochloride dihydrate
 0.1 M HCl (for benzidine)
 0.2 M potassium permanganate: prepare immediately before use
 2 M sulfuric acid
 Sodium metabisulfite
 10 M potassium hydroxide (KOH)

Additional reagents and equipment for testing for the presence of aromatic amines
 (see Support Protocol 1)

1. For each 9 mg benzidine, add 10 ml of 0.1 M HCl *or* for each 9 mg diaminobenzidine tetrahydrochloride dihydrate, add 10 ml water. Stir the solution until the aromatic amine has completely dissolved.

2. For each 10 ml of solution, add 5 ml freshly prepared 0.2 M potassium permanganate and 5 ml of 2 M sulfuric acid. Allow the mixture to stand for ≥ 10 hr.
3. Add sodium metabisulfite until the solution is decolorized.
4. Add 10 M KOH to make the solution strongly basic, $\text{pH} > 12$.
CAUTION: *This reaction is exothermic.*
5. Dilute with 5 vol water and pass through filter paper to remove manganese compounds.
6. Test the filtrate for the presence of aromatic amines (i.e., benzidine or diaminobenzidine; see Support Protocol 1).
7. Neutralize the filtrate with acid and discard.

**ALTERNATE
PROTOCOL 1**

**DECONTAMINATION OF SPILLS INVOLVING BENZIDINE AND
DIAMINO BENZIDINE**

Additional Materials (also see Basic Protocol 1)

Glacial acetic acid

1:1 (v/v) 0.2 M potassium permanganate/2 M sulfuric acid: prepare immediately before use

Absorbent material (e.g., paper towels, Kimwipes)

High-efficiency particulate air (HEPA) vacuum (Fisher)

Additional reagents and equipment for testing for the presence of aromatic amines (see Support Protocol 1)

CAUTION: This procedure may damage painted surfaces and Formica.

1. Remove as much of the spill as possible using absorbent material and high-efficiency particulate air (HEPA) vacuuming.
2. Wet the surface with glacial acetic acid until all the amines are dissolved, then add an excess of freshly prepared 1:1 (v/v) 0.2 M potassium permanganate/2 M sulfuric acid to the spill area. Allow the mixture to stand ≥ 10 hr.
3. Ventilate the area and decolorize with sodium metabisulfite.
4. Mop up the liquid with paper towels. Squeeze the solution out of the towels and collect in a suitable container. Discard towels as hazardous solid waste.
5. Add 10 M KOH to make the solution strongly basic, $\text{pH} \geq 12$.
CAUTION: *This reaction is exothermic.*
6. Dilute with 5 vol water and filter through filter paper to remove manganese compounds.
7. Test the filtrate for the presence of aromatic amines (i.e., benzidine or diaminobenzidine; see Support Protocol 1).
8. Neutralize the filtrate with acid and discard it.
9. Verify complete decontamination by wiping the surface with a paper towel moistened with water and squeezing the liquid out of the towel. Test the liquid for the presence of benzidine or diaminobenzidine (see Support Protocol 1). Repeat steps 1 to 9 as necessary.

DECONTAMINATION OF AQUEOUS SOLUTIONS OF BENZIDINE AND DIAMINOBENZIDINE

ALTERNATE
PROTOCOL 2

The enzyme horseradish peroxidase catalyzes the oxidation of the amine to a radical which diffuses into solution and polymerizes. The polymers are insoluble and fall out of solution.

Additional Materials (also see Basic Protocol 1)

Aqueous solution of benzidine or diaminobenzidine
1 N HCl or NaOH
3% (v/v) hydrogen peroxide
Horseradish peroxidase (see recipe)
1:1 (v/v) 0.2 M potassium permanganate/2 M sulfuric acid
5% (w/v) ascorbic acid
Porous glass filter *or* Sorvall GLC-1 centrifuge or equivalent

Additional reagents and equipment for testing for the presence of aromatic amines (see Support Protocol 1)

1. Adjust the pH of the aqueous benzidine or diaminobenzidine solution to 5 to 7 with 1 N HCl or NaOH as required and dilute so the concentration of aromatic amines is ≤ 100 mg/liter.
2. For each liter of solution, add 3 ml of 3% hydrogen peroxide and 300 U horseradish peroxidase. Let the mixture stand 3 hr.
3. Remove the precipitate by filtering the solution through a porous glass filter or by centrifuging 5 min at room temperature in a benchtop centrifuge to pellet the precipitate.

The precipitate is mutagenic and should be treated as hazardous waste.

4. Immerse the porous glass filter in 1:1 (v/v) 0.2 M potassium permanganate/2 M sulfuric acid. Clean the filter in a conventional fashion and discard potassium permanganate/sulfuric acid solution as described for benzidine and diaminobenzidine (see Basic Protocol 1).
5. For each liter of filtrate, add 100 ml of 5% ascorbic acid.
6. Test the filtrate for the presence of aromatic amines (see Support Protocol 1).
7. Discard the decontaminated filtrate.

ANALYTICAL PROCEDURES TO DETECT BENZIDINE AND DIAMINOBENZIDINE

SUPPORT
PROTOCOL 1

Reversed-phase HPLC (Snyder et al., 1997) is used to test for the presence of aromatic amines. The limit of detection is 1 $\mu\text{g/ml}$ for benzidine and 0.25 $\mu\text{g/ml}$ for diaminobenzidine.

Materials

Decontaminated aromatic amine solution
10:30:20 (v/v/v) acetonitrile/methanol/1.5 mM potassium phosphate buffer (1.5 mM K_2HPO_4 /1.5 mM KH_2PO_4) (benzidine) *or* 75:25 (v/v) methanol/1.5 mM potassium phosphate buffer (diaminobenzidine)
250-mm \times 4.6-mm-i.d. Microsorb C-8 reversed-phase HPLC column (Varian) or equivalent

Additional reagents and equipment for reversed-phase liquid chromatography (Snyder et al., 1997)

Standard
Measurements,
Data, and
Abbreviations

A.1H.13

Analyze the decontaminated aromatic amine solution by reversed-phase HPLC using a 250-mm × 4.6-mm-i.d. Microsorb C-8 column or equivalent. To detect benzidine, elute with 10:30:20 (v/v/v) acetonitrile/methanol/1.5 mM potassium phosphate buffer at a flow rate of 1.5 ml/min and UV detection at 285 nm. To detect diaminobenzidine, elute with 75:25 (v/v) methanol/1.5 mM potassium phosphate buffer at a flow rate of 1 ml/min and UV detection at 300 nm.

DISPOSAL OF BIOLOGICAL STAINS

Biological stains (Table A.1H.5), as well as ethidium bromide and propidium iodide, can be removed from solution using the polymeric resin Amberlite XAD-16. The decontaminated solution may be disposed of as nonhazardous aqueous waste and the resin as hazardous solid waste. The volume of contaminated resin generated is much smaller than the original volume of the solution of biological stain, so the waste disposal problem is greatly reduced. The final concentration of any remaining stain should be less than the limit of detection (see Support Protocol 2 and Table A.1H.5). In each case decontamination should be >99%. This protocol describes a method for batch decontamination in which the resin is stirred in the solution to be decontaminated and removed by filtration at the end of the reaction time. Large volumes of biological stain can be decontaminated using a column (see Alternate Protocol 3). For full details refer to the original literature (Lunn and Sansone, 1991b) or a compilation (Lunn and Sansone, 1994a).

Table A.1H.5 Decontamination of Biological Stains

Compound	Time required for complete decontamination	Volume of solution (ml) decontaminated per gram resin
Acridine orange	18 hr	20
Alcian blue 8GX	10 min	500
Alizarin red S	18 hr	5
Azure A	10 min	80
Azure B	10 min	80
Brilliant blue R	2 hr	80
Congo red	2 hr	40
Coomassie brilliant blue G	2 hr	80
Cresyl violet acetate	2 hr	40
Crystal violet	30 min	200
Eosin B	30 min	40
Erythrosin B	18 hr	10
Ethidium bromide	4 hr	20
Janus green B	30 min	80
Methylene blue	30 min	80
Neutral red	10 min	500
Nigrosin	2 hr	80
Orcein	2 hr	200
Propidium iodide	2 hr	20
Rose Bengal	3 hr	20
Safranin O	1 hr	20
Toluidine blue O	30 min	80
Trypan blue	2 hr	40

Materials

Amberlite XAD-16 resin (Supelco)
100 µg/ml biological stain in water

Additional reagents and equipment for testing for the presence of biological stain
(see Support Protocol 2)

For batch decontamination of 20 ml stain

1a. Add 1 g Amberlite XAD-16 to 20 ml of 100 µg/ml biological stain in water.

For aqueous solutions having stain concentrations other than 100 µg/ml, use proportionately greater or lesser amounts of resin to achieve complete decontamination.

For solutions of erythrosin B, use 2 g Amberlite XAD-16 for 20 ml stain.

2a. Stir the mixture for at least the time indicated in Table A.1H.5.

For batch decontamination of larger volumes of stain

1b. Add 1 g Amberlite XAD-16 to the volume of a 100 µg/ml biological stain in water indicated in Table A.1H.5.

2b. Stir the mixture for at least 18 hr.

3. Remove the resin by filtration through filter paper.

4. Test the filtrate for the presence of the biological stain (see Support Protocol 2).

5. Discard the resin as hazardous solid waste and the decontaminated filtrate as liquid waste.

CONTINUOUS-FLOW DECONTAMINATION OF AQUEOUS SOLUTIONS OF BIOLOGICAL STAINS

For treating large volumes of dilute aqueous solutions of biological stains (Table A.1H.5), it is possible to put the resin in a column and run the contaminated solution through the column in a continuous-flow system (Lunn et al., 1994). Limited grinding of the Amberlite XAD-16 resin increases its efficiency.

Additional Materials (also see Basic Protocol 2)

25 µg/ml biological stain in water
Methanol (optional)

300-mm × 11-mm-i.d. glass chromatography column fitted with threaded adapters and flow-regulating valves at top and bottom nut and insert connectors, and insertion tool (Ace Glass) *or* 300-mm × 15-mm-i.d. glass chromatography column (Spectrum 124010, Fisher)

Glass wool

1.5-mm-i.d. × 0.3-mm-wall Teflon tubing

Waring blender (optional)

Rubber stopper fitted over a pencil

QG 20 lab pump (Fluid Metering)

Additional reagents and equipment for testing for the presence of biological stain
(see Support Protocol 2)

Using a slurry of Amberlite XAD-16

1a. Prepare a 300-mm × 11-mm-i.d. glass chromatography column. To prevent clogging of the column outlet, place a small plug of glass wool at the bottom of the chromatography column. Connect 1.5-mm-i.d. × 0.3-mm wall Teflon tubing to the adapters using nut and insert connectors. Attach the tubing using an insertion tool.

ALTERNATE PROTOCOL 3

Standard Measurements, Data, and Abbreviations

A.1H.15

Table A.1H.6 Breakthrough Volumes for Continuous-Flow Decontamination of Biological Stains

Compound	Breakthrough volume (ml)		
	Limit of detection	1 ppm	5 ppm
Acridine orange	465	>990	>990
Alizarin red S	120	150	240
Azure A	615	810	>975
Azure B	630	882	>1209
Cresyl violet acetate	706	>1396	>1396
Crystal violet	1020	>1630	>1630
Ethidium bromide	260	312	416
Janus green B	170	650	>870
Methylene blue	420	645	1050
Neutral red	>2480	>2480	>2480
Safranin O	365	438	584
Toluidine blue O	353	494	606

- 2a. Mix 10 g Amberlite XAD-16 and 25 ml water in a beaker and stir 5 min to wet the resin.

Using a finely ground Amberlite XAD-16 slurry

- 1b. Prepare a 300-mm × 15-mm-i.d. glass chromatography column. To prevent clogging of the column outlet, place a small plug of glass wool at the bottom of the chromatography column.
- 2b. Grind 20 g Amberlite XAD-16 with 200 ml water for exactly 10 sec in a Waring blender.
3. Pour the resin slurry into the column through a funnel. As the resin settles, tap the column with a rubber stopper fitted over a pencil to encourage even packing. Attach a QG 20 lab pump.
4. Pump the 25- μ g/ml biological stain solution through the column at 2 ml/min.

Alternatively, gravity flow coupled with periodic adjustment of the flow-regulating valve can be used.

5. Check the effluent from the column for the presence of biological stain (see Support Protocol 2). Stop the pump when stain is detected.

Table A.1H.6 lists breakthrough volumes at different detection levels for a number of biological stains.

6. Discard the decontaminated effluent and the contaminated resin appropriately.
7. Many biological stains can be washed off the resin with methanol so the resin can be reused. Discard the methanol solution of stain as hazardous organic liquid waste.

^bSee Support Protocol 2

ANALYTICAL PROCEDURES TO DETECT BIOLOGICAL STAIN

Depending on the biological stain, the filtrate or eluate from the decontamination procedure can be analyzed using either UV absorption (A) or fluorescence detection (F).

Materials

Filtrate or eluate from biological stain decontamination (see Basic Protocol 2 or Alternate Protocol 3)

pH 5 buffer (see recipe)

1 M KOH solution

20 µg/ml calf thymus DNA in TBE electrophoresis buffer, pH 8.1 (APPENDIX 2A)

Test the filtrate or eluate from the biological stain decontamination procedure using the appropriate method as indicated in Table A.1H.7.

Traces of acid or base on the resin may induce color changes in the stain. Accordingly, with cresyl violet acetate or neutral red, mix aliquots of the filtrate with 1 vol pH 5 buffer before analyzing. With alizarin red S and orcein, mix aliquots of the filtrate with 1 vol of 1 M KOH solution before analyzing.

Increase the fluorescence of solutions of acridine orange, ethidium bromide, and propidium iodide by mixing an aliquot of the filtrate with an equal volume of 20 µg/ml calf thymus DNA in TBE electrophoresis buffer, pH 8.1. Let the solution stand 15 min before measuring the fluorescence.

SUPPORT PROTOCOL 2

Standard Measurements, Data, and Abbreviations

A.1H.17

**DISPOSAL OF CHLOROTRIMETHYLSILANE AND
DICHLORODIMETHYLSILANE**

Silane-containing compounds are hydrolyzed to hydrochloric acid and polymeric silicon-containing material (Patnode and Wilcock, 1946).

1. Hydrolyze silane-containing compounds by cautiously adding 5 ml silane to 100 ml vigorously stirred water in a flask. Allow the resulting suspension to settle.
2. Remove any insoluble material by filtration and discard it with the solid or liquid hazardous waste.
3. Neutralize the aqueous layer with base and discard it.

DISPOSAL OF CYANIDES AND CYANOGEN BROMIDE

Inorganic cyanides (e.g., NaCN) and cyanogen bromide (CNBr) are oxidized by sodium hypochlorite (NaOCl; e.g., Clorox) in basic solution to the much less toxic cyanate ion (Lunn and Sansone, 1985a). Destruction is >99.7%.

Materials

Cyanide (e.g., NaCN) or cyanogen bromide (CNBr)
1 M NaOH
5.25% (v/v) sodium hypochlorite (NaOCl; i.e., standard household bleach)

Additional reagents and equipment for testing for the presence of cyanide (see Support Protocol 3)

1. Dissolve cyanide in water to give a concentration ≤ 25 mg/ml *or* dissolve CNBr in water to give a concentration ≤ 60 mg/ml.

If necessary, dilute aqueous solutions so the concentration of NaCN or CNBr does not exceed the limit.

2. Mix 1 vol NaCN or CNBr solution with 1 vol 1 M NaOH and 2 vol fresh 5.25% NaOCl. Stir the mixture 3 hr.

IMPORTANT NOTE: *With age bleach may become ineffective; use of fresh bleach is strongly recommended.*

3. Test the reaction mixture for the presence of cyanide (see Support Protocol 3).
4. Neutralize the reaction mixture and discard it.

ANALYTICAL PROCEDURE TO DETECT CYANIDE

This protocol is used to detect cyanide or cyanogen bromide at ≥ 3 $\mu\text{g/ml}$.

Materials

Cyanide or cyanogen bromide decontamination reaction mixture (see Basic Protocol 4)

Phosphate buffer (see recipe)

10 mg/ml sodium ascorbate in water: prepare fresh daily

100 mg/liter NaCN in water: prepare fresh weekly

10 mg/ml chloramine-T in water: prepare fresh daily

Cyanide detection reagent (see recipe)

Sorvall GLC-1 centrifuge or equivalent

1. If necessary to remove suspended solids, centrifuge two 1-ml aliquots of the cyanide or cyanogen bromide decontamination reaction mixture 5 min in a benchtop centrifuge, room temperature. Add each supernatant to 4 ml phosphate buffer in separate tubes.
2. If an orange or yellow color appears, add 10 mg/ml freshly prepared sodium ascorbate dropwise until the mixture is colorless, but do not add more than 2 ml.
3. Add 200 μ l of 100 mg/liter NaCN to one reaction mixture (control solution).
4. Add 1 ml freshly prepared 10 mg/ml chloramine-T to each tube. Shake the tubes and let them stand 1 to 2 min.
5. Add 1 ml cyanide detection reagent, shake, and let stand 5 min.

A blue color indicates the presence of cyanide. If destruction has been complete and the analytical procedure has been carried out correctly, the treated reaction mixture should be colorless and the control solution, which contains NaCN, should be blue.

6. Centrifuge tubes 5 min, room temperature, if necessary to remove suspended solids. Measure the absorbance at 605 nm with appropriate standards and blanks.

DISPOSAL OF DIMETHYL SULFATE, DIETHYL SULFATE, METHYL METHANESULFONATE, ETHYL METHANESULFONATE, DIEPOXYBUTANE, AND 1,3-PROPANE SULFONE

**BASIC
PROTOCOL 5**

Dimethyl sulfate is hydrolyzed by base to methanol and methyl hydrogen sulfate (Lunn and Sansone, 1985b). Subsequent hydrolysis of methyl hydrogen sulfate to methanol and sulfuric acid is slow. Methyl hydrogen sulfate is nonmutagenic and a very poor alkylating agent. The other compounds can be hydrolyzed with base in a similar fashion (Lunn and Sansone, 1990a). Destruction is >99%. A method to verify that decontamination is complete is also provided (see Support Protocol 4).

NOTE: The reaction times given in the protocol should give good results; however, reaction time may be affected by such factors as the size and shape of the flask and the rate of stirring. The presence of two phases indicates that the reaction is not complete, and stirring should be continued until the reaction mixture is homogeneous.

Materials

Dimethyl sulfate, diethyl sulfate, methyl methanesulfonate, ethyl methanesulfonate, diepoxybutane, or 1,3-propane sulfone
5 M NaOH

Additional reagents and equipment for testing for the presence of dimethyl sulfate, diethyl sulfate, methyl methanesulfonate, ethyl methanesulfonate, diepoxybutane, or 1,3-propane sulfone (see Support Protocol 4)

For bulk quantities of dimethyl sulfate

- 1a. Add 100 ml dimethyl sulfate to 1 liter of 5 M NaOH. Stir the reaction mixture.
- 2a. Fifteen minutes after all the dimethyl sulfate has gone into solution, neutralize the reaction mixture with acid.

For bulk quantities of diethyl sulfate

- 1b. Add 100 ml diethyl sulfate to 1 liter of 5 M NaOH. Stir the reaction mixture 24 hr.
- 2b. Neutralize the reaction mixture with acid.

**Standard
Measurements,
Data, and
Abbreviations**

A.1H.19

For bulk quantities of methyl methanesulfonate, ethyl methanesulfonate, diepoxybutane, and 1,3-propane sultone

- 1c. Add 1 ml methyl methanesulfonate, ethyl methanesulfonate, or diepoxybutane, or 1 g of 1,3-propane sultone to 10 ml of 5 M NaOH. Stir the reaction mixture 1 hr for 1,3-propane sultone, 2 hr for methyl methanesulfonate, 22 hr for diepoxybutane, or 24 hr for ethyl methanesulfonate.
- 2c. Neutralize the reaction mixture with acid.
3. Test the reaction mixture for the presence of the original compound (see Support Protocol 4).
4. Discard the decontaminated reaction mix.

**SUPPORT
PROTOCOL 4**

ANALYTICAL PROCEDURE TO DETECT THE PRESENCE OF DIMETHYL SULFATE, DIETHYL SULFATE, METHYL METHANESULFONATE, ETHYL METHANESULFONATE, DIEPOXYBUTANE, AND 1,3-PROPANE SULTONE

This protocol is used to verify decontamination of solutions containing dimethyl sulfate, diethyl sulfate, methyl methanesulfonate, ethyl methanesulfonate, diepoxybutane, or 1,3-propane sultone. The detection limit for this assay is 40 µg/ml for dimethyl sulfate, 108 µg/ml for diethyl sulfate, 84 µg/ml for methyl methanesulfonate, 1.1 µg/ml for ethyl methanesulfonate, 360 µg/ml for diepoxybutane, and 264 µg/ml for 1,3-propane sultone.

Materials

Reaction mixture containing dimethyl sulfate, diethyl sulfate, methyl methanesulfonate, ethyl methanesulfonate, diepoxybutane, or 1,3-propane sultone

98:2 (v/v) 2-methoxyethanol/acetic acid

5% (w/v) 4-(4-nitrobenzyl)pyridine in 2-methoxyethanol

Piperidine

2-Methoxyethanol

1. Dilute an aliquot of the reaction mixture with 4 vol water.
2. Add 100 µl diluted reaction mixture to 1 ml of 98:2 (v/v) 2-methoxyethanol/acetic acid. Swirl to mix.
3. Add 1 ml of 5% (w/v) 4-(4-nitrobenzyl)pyridine in 2-methoxyethanol. Heat 10 min at 100°C, then cool 5 min in ice.
4. Add 0.5 ml piperidine and 2 ml of 2-methoxyethanol.
5. Measure the absorbance of the violet reaction mixture at 560 nm against an appropriate blank.

The absorbance of a decontaminated solution should be 0.000.

**BASIC
PROTOCOL 6**

DISPOSAL OF ETHIDIUM BROMIDE AND PROPIDIUM IODIDE

Ethidium bromide and propidium iodide in water and buffer solutions may be degraded by reaction with sodium nitrite and hypophosphorous acid in aqueous solution (Lunn and Sansone, 1987); destruction is >99.87%. This reaction may also be used to decontaminate equipment contaminated with ethidium bromide (see Alternate Protocol 4; Lunn and Sansone, 1989) and to degrade ethidium bromide in organic solvents (see Alternate Protocol 5 and Alternate Protocol 6; Lunn and Sansone, 1990b). Ethidium bromide and propidium iodide may also be removed from solution by adsorption onto Amberlite XAD-16 resin (see Basic Protocol 2).

**Safe Use of
Hazardous
Chemicals**

A.1H.20

Materials

Ethidium bromide– or propidium iodide–containing solution in water, buffer, or 1 g/ml cesium chloride

5% (v/v) hypophosphorous acid: prepare fresh daily by diluting commercial 50% reagent 1/10

0.5 M sodium nitrite: prepare fresh daily

Sodium bicarbonate

Additional reagents and equipment for testing for the presence of ethidium bromide or propidium iodide (see Support Protocol 5)

1. If necessary, dilute the ethidium bromide– or propidium iodide–containing solution so the concentration of ethidium bromide or propidium iodide is ≤ 0.5 mg/ml.
2. For each 100 ml solution, add 20 ml of 5% hypophosphorous acid solution and 12 ml of 0.5 M sodium nitrite. Stir briefly and let stand 20 hr.
3. Neutralize the reaction mixture by adding sodium bicarbonate until the evolution of gas ceases.
4. Test the reaction mixture for the presence of ethidium bromide or propidium iodide (see Support Protocol 5).
5. Discard the decontaminated reaction mixture.

DECONTAMINATION OF EQUIPMENT CONTAMINATED WITH ETHIDIUM BROMIDE

Glass, stainless steel, Formica, floor tile, and the filters of transilluminators have been successfully decontaminated using this protocol. No change in the optical properties of the transilluminator filter could be detected, even after a number of decontamination cycles.

Materials

Equipment contaminated with ethidium bromide

Decontamination solution (see recipe)

Sodium bicarbonate

Additional reagents and equipment for testing for the presence of ethidium bromide (see Support Protocol 5)

1. Wash the equipment contaminated with ethidium bromide once with a paper towel soaked in decontamination solution.
The pH of the decontamination solution is 1.8. If this would be too corrosive for the surface to be decontaminated, wash with a paper towel soaked in water instead.
2. Wash the surface five times with paper towels soaked in water using a fresh towel each time.
3. Soak all the towels 1 hr in decontamination solution.
4. Neutralize the decontamination solution by adding sodium bicarbonate until the evolution of gas ceases.
5. Test the decontamination solution for the presence of ethidium bromide (see Support Protocol 5).
6. Discard the decontamination solution and the paper towels as nonhazardous liquid and solid wastes.

**ALTERNATE
PROTOCOL 4**

**Standard
Measurements,
Data, and
Abbreviations**

A.1H.21

**DECONTAMINATION OF ETHIDIUM BROMIDE IN ISOPROPANOL
SATURATED WITH CESIUM CHLORIDE**

Materials

Ethidium bromide in isopropanol saturated with cesium chloride
Decontamination solution (see recipe)
Sodium bicarbonate

Additional reagents and equipment for testing for the presence of ethidium bromide (see Support Protocol 5)

1. If necessary, dilute the ethidium bromide in isopropanol saturated with cesium chloride so the concentration of ethidium bromide is ≤ 1 mg/ml.
2. For each volume of ethidium bromide solution, add 4 vol decontamination solution. Stir the reaction mixture 20 hr.
3. Neutralize the reaction mixture by adding sodium bicarbonate until the evolution of gas ceases.
4. Test the reaction mixture for the presence of ethidium bromide (see Support Protocol 5).
5. Discard the decontaminated solution.

**DECONTAMINATION OF ETHIDIUM BROMIDE IN ISOAMYL
ALCOHOL AND 1-BUTANOL**

Materials

Ethidium bromide in isoamyl alcohol or 1-butanol
Decontamination solution (see recipe)
Activated charcoal
Sodium bicarbonate
Separatory funnel

Additional reagents and equipment for testing for the presence of ethidium bromide

1. If necessary, dilute the ethidium bromide in isoamyl alcohol or 1-butanol so the concentration is ≤ 1 mg/ml final.
2. For each volume of ethidium bromide solution, add 4 vol decontamination solution. Stir the two-phase reaction mixture rapidly for 72 hr.
3. For each 100 ml of reaction mixture, add 2 g activated charcoal. Stir another 30 min.
4. Filter the reaction mixture.
5. Neutralize the filtrate by adding sodium bicarbonate until the evolution of gas ceases. Separate the layers using a separatory funnel.

More alcohol may tend to separate from the aqueous layer on standing.

6. Test the alcohol and aqueous layers for the presence of ethidium bromide.
7. Discard the alcohol and aqueous layers appropriately. Discard the activated charcoal as solid waste.

The aqueous layer contains 4.6% 1-butanol or 2.3% isoamyl alcohol.

ANALYTICAL PROCEDURE TO DETECT ETHIDIUM BROMIDE OR PROPIDIUM IODIDE

SUPPORT
PROTOCOL 5

This protocol is used to verify that solutions no longer contain ethidium bromide or propidium iodide. The limits of detection are 0.05 parts per million (ppm) for ethidium bromide and 0.1 ppm for propidium iodide.

Materials

Reaction mixture containing ethidium bromide or propidium iodide
TBE buffer, pH 8.1 (APPENDIX 2A)
20 µg/ml calf thymus DNA in TBE buffer, pH 8.1

1. Mix 100 µl reaction mixture containing ethidium bromide or propidium iodide with 900 µl TBE buffer, pH 8.1.
2. Add 1 ml of 20 µg/ml calf thymus DNA in TBE, pH 8.1. Prepare a blank solution (100 µl water + 900 µl TBE + 1 ml of 20 µg/ml calf thymus DNA) and control solutions containing known quantities of ethidium bromide or propidium iodide. Let the mixtures stand 15 min.
3. To detect ethidium bromide, measure the fluorescence with an excitation wavelength of 540 nm and an emission wavelength of 590 nm. To detect propidium iodide, measure the fluorescence with an excitation wavelength of 350 nm and an emission wavelength of 600 nm.

If a spectrophotofluorometer is not available, fluorescence of ethidium bromide can be qualitatively determined using a hand-held UV lamp on the long-wavelength setting (Lunn and Sansone, 1991c).

DISPOSAL OF HYDROGEN PEROXIDE

BASIC
PROTOCOL 7

Hydrogen peroxide can be reduced with sodium metabisulfite (Lunn and Sansone, 1994b).

Materials

30% hydrogen peroxide
10% (w/v) sodium metabisulfite
10% (w/v) potassium iodide
1 M HCl
1% (w/v) starch indicator solution

1. Add 5 ml of 30% hydrogen peroxide to 100 ml of 10% sodium metabisulfite. Stir the mixture at room temperature until the temperature starts to drop, indicating that the reaction is over.
2. Test for the presence of hydrogen peroxide by adding a few drops of the reaction mixture to an equal volume of 10% potassium iodide. Add a few drops of 1 M HCl to acidify the reaction mixture, then add a drop of 1% starch indicator solution.

A deep blue color indicates the presence of excess oxidant. If necessary, add more 10% sodium metabisulfite until the starch test is negative.

3. Discard the decontaminated mixture.

Standard
Measurements,
Data, and
Abbreviations

A.1H.23

REDUCTION OF IODINE

Iodine is reduced with sodium metabisulfite to iodide (Lunn and Sansone, 1994b).

Materials

Iodine
10% (w/v) sodium metabisulfite
1 M HCl
1% (w/v) starch indicator solution

1. Add 5 g iodine to 100 ml of 10% sodium metabisulfite. Stir the mixture until the iodine has completely dissolved.
2. Acidify a few drops of the reaction mixture by adding a few drops of 1 M HCl. Add 1 drop of 1% starch indicator solution.

A deep blue color indicates the presence of iodine. If reduction is not complete, add more sodium metabisulfite solution.

3. Dispose of the decontaminated solution.

DISPOSAL OF MERCURY COMPOUNDS

Solutions of mercuric acetate can be decontaminated using Dowex 50X8-100, a strongly acidic gel-type ion-exchange resin with a sulfonic acid functionality. Solutions of mercuric chloride can be decontaminated using Amberlite IRA-400(Cl), a strongly basic gel-type ion-exchange resin with a quaternary ammonium functionality. The final concentration of mercury is <3.8 ppm (Lunn and Sansone, 1994a). On a small scale it is most convenient to stir the resin in the solution to be decontaminated, but on a larger scale, or for routine use, it may be more convenient to pass the solution through a column packed with the resin. Although the volume of waste that must be disposed of is greatly reduced using this technique, a small amount of waste (i.e., the resin contaminated with mercury) remains and must be discarded appropriately. Resin can be regenerated by washing with acid, but the concentrated metal-containing solution generated by this must also be disposed of appropriately. Mercury may also be removed from laboratory waste water using a column of iron powder (see Alternate Protocol 7). Support Protocol 6 is used to detect the presence of mercury.

Materials

Solution containing ≤ 1600 ppm mercuric acetate *or* ≤ 1350 ppm mercuric chloride
Dowex 50X8-100 ion-exchange resin *or* Amberlite IRA-400(Cl) ion-exchange resin

Additional reagents and equipment to test for the presence of mercury (see Support Protocol 6)

- 1a. *For mercuric acetate:* For each 200 ml of solution containing ≤ 1600 ppm mercuric acetate, add 1 g Dowex 50X8-100 ion-exchange resin. Stir the mixture 1 hr, then filter through filter paper.
- 1b. *For mercuric chloride:* For each 200 ml of solution containing ≤ 1350 ppm mercuric chloride, add 1 g Amberlite IRA-400(Cl) ion-exchange resin. Stir the mixture 6 hr, then filter through filter paper.

The speed and efficiency of decontamination will depend on factors such as the size and shape of the flask and the rate of stirring.

3. Test the filtrate for the presence of mercury (see Support Protocol 6).
4. Discard the decontaminated filtrate and the mercury-containing resin appropriately.

DECONTAMINATION OF WASTE WATER CONTAINING MERCURY

Laboratory waste water that contains mercury is decontaminated by passing it through a column of iron powder. The mercury forms mercury amalgam and stays on the column. Some metallic mercury remains in solution but this can be removed by aeration. The final concentration of mercury is <5 ppb (Shirakashi et al., 1986).

Materials

Iron powder, 60 mesh
Waste water containing ≤ 2.5 ppm mercury
6-mm-i.d. column

1. Pack a 6-mm-i.d. column with 1 g of 60-mesh iron powder.

Use a fresh column for each treatment.

2. Pass ≤ 2 liters of water containing ≤ 2.5 ppm of mercury through the column at a flow rate of 250 ml/hr.

Solutions containing a higher concentration of mercury may also be treated, but this will result in a higher final concentration of mercury (e.g., treating a 100-ppm solution in this fashion yielded 33 ppb final).

Some iron ends up in solution and can be removed by adjusting the pH to 8. The resulting precipitated $\text{Fe}(\text{OH})_3$ can then be removed by filtration.

3. Aerate the resulting effluent to remove traces of metallic mercury and continue aeration 30 min after the last of the effluent has emerged from the column. Vent the metallic mercury removed from the solution by aeration into the fume hood or capture it in a mercury trap.

The effluent contains <5 ppb mercury. The presence of iodide or polypeptone may necessitate several treatments to reduce the mercury to an acceptable level.

ANALYTICAL PROCEDURE TO DETECT MERCURY

Atomic absorption spectroscopy with detection at 253.7 nm, a slit width of 0.7 nm, and a limit of detection of 3.8 ppm can be used to determine the concentration of mercury in solution for experiments involving ion-exchange resins. A Hiranuma mercury meter model HG-1 can be used for experiments involving iron powder.

DISPOSAL OF SODIUM AZIDE

Sodium azide can be oxidized by ceric ammonium nitrate (Manufacturing Chemists Association, 1973) to nitrogen (Mason, 1967) or by nitrous acid (National Research Council, 1983) to nitrous oxide (Mason, 1967); destruction is >99.996%. Sodium azide in buffer solution may also be degraded by the addition of sodium nitrite (Lunn and Sansone, 1994a). The reaction proceeds much more readily at low pH, but if sufficient sodium nitrite is added, it will proceed to completion even at high pH. At low pH, it may be possible to completely degrade the azide present in the buffer with less than the amount of sodium nitrite indicated. However, the reaction mixture must be carefully checked to ensure that no azide remains (see Support Protocol 7). At high pH it is possible for unreacted azide to remain in the presence of excess nitrite. Residual nitrite can be detected using Support Protocol 8.

CAUTION: Some toxic nitrogen dioxide may be produced as a by-product of these reactions, so they should always be carried out in a chemical fume hood.

ALTERNATE
PROTOCOL 7

SUPPORT
PROTOCOL 6

BASIC
PROTOCOL 10

Standard
Measurements,
Data, and
Abbreviations

A.1H.25

Materials

Sodium azide or solution containing sodium azide
Ceric ammonium nitrate
10% (w/v) potassium iodide
1 M HCl
1% (w/v) starch indicator solution
Sodium nitrite
4 M sulfuric acid

Additional reagents and equipment to test for the presence of sodium azide (see Support Protocol 7) *or* nitrite (see Support Protocol 8)

Decontamination using ceric ammonium nitrate

- 1a. For each gram of sodium azide, add 9 g ceric ammonium nitrate to 30 ml of water, and stir until it has dissolved.
- 2a. Dissolve each gram of sodium azide in 5 ml water. Add this solution to the ceric ammonium nitrate solution at the rate of 1 ml each min. Stir 1 hr.
If the reaction is carried out on a larger scale, an ice bath may be required for cooling.
- 3a. Check that the reaction is still oxidizing by adding a few drops of the reaction mixture to an equal volume of 10% potassium iodide. Acidify the mixture with 1 drop 1 M HCl and add 1 drop 1% starch indicator solution.

The deep blue color of the starch-iodine complex indicates that excess oxidant is present. If excess oxidant is not present, add more ceric ammonium nitrate.

- 4a. Test for the presence of sodium azide (see Support Protocol 8).
- 5a. Discard the decontaminated reaction mixture.

Decontamination using sodium nitrite

- 1b. For each 5 g sodium azide, dissolve 7.5 g sodium nitrite in 30 ml water.
- 2b. Dissolve each 5 g sodium azide in 100 ml water. Add the sodium nitrite solution with stirring. Slowly add 4 M sulfuric acid until the reaction mixture is acidic to litmus. Stir 1 hr.
CAUTION: It is important to add the sodium nitrite, then the sulfuric acid. Adding these reagents in reverse order will generate explosive, volatile, toxic hydrazoic acid.
If the reaction is carried out on a large scale, an ice bath may be required for cooling.
- 3b. Check that there is excess nitrous acid in the reaction. Add a few drops of the reaction mixture to an equal volume of 10% potassium iodide. Acidify the mixture with 1 drop 1 M HCl. Add 1 drop starch indicator solution.

The deep blue color of the starch-iodine complex indicates that excess nitrous acid is present. If excess nitrous acid is not present, add more sodium nitrite.

- 4b. If excess nitrous acid is present, test for the presence of sodium azide (see Support Protocol 7).
- 5b. Discard the decontaminated reaction mixture.

Decontamination of sodium azide in buffer

- 1c. If necessary, dilute the buffer solution with water so the concentration of sodium azide is ≤ 1 mg/ml.
- 2c. For each 50 ml buffer solution add 5 g sodium nitrite. Stir the reaction 18 hr.

3c. Test for the presence of sodium azide (see Support Protocol 7).

4c. Discard the decontaminated reaction solution.

ANALYTICAL PROCEDURES TO DETECT SODIUM AZIDE

Sodium azide is analyzed by reacting azide ion with 3,5-dinitrobenzoyl chloride to form 3,5-dinitrobenzoyl azide, which can be detected by reversed-phase HPLC. The limit of detection of this assay is 0.2 µg/ml sodium azide. This protocol works only in the absence of nitrite; verify that all of the nitrite has been destroyed by sulfamic acid by using the method detailed later in this unit (see Support Protocol 8).

Materials

Reaction mixture from sodium azide treated with ceric ammonium nitrate or sodium nitrite

1 M KOH

Acetonitrile

Sodium azide indicator solution (see recipe)

0.2 M HCl

20% (w/v) sulfamic acid

3,5-dinitrobenzoyl chloride

50:50 (v/v) acetonitrile/water

Sorvall GLC-1 centrifuge or equivalent

25-cm × 4.6-mm-i.d. Microsorb C-8 reversed-phase HPLC column (Varian) or equivalent

Additional reagents and equipment for reversed-phase liquid chromatography (Snyder et al., 1997)

To analyze for azide in the presence of ceric salts

1a. To a 10-ml aliquot of the reaction mixture from sodium azide treated with ceric ammonium nitrate add 40 ml water. Add 5 ml of this diluted solution to 3 ml of 1 M KOH and mix by shaking.

If <3 ml of 1 M KOH is used, precipitation of ceric salts will not be complete.

2a. Centrifuge the mixture 5 min, room temperature.

3a. Remove 2 ml supernatant and add to 1 ml acetonitrile. Add 1 drop sodium azide indicator solution, add 0.2 M HCl dropwise until the mixture turns yellow, then add 1 drop more.

To analyze for azide in the presence of nitrite

1b. To 5 ml of the reaction mixture from sodium azide treated with sodium nitrite add ≥1 ml sulfamic acid to remove excess nitrite. Let stand ≥3 min.

More sulfamic acid solution may be required for strongly basic reaction mixtures or those containing high concentrations of nitrite. Complete removal of nitrite can be checked by using a modified Griess reagent (see Support Protocol 8).

At high pH the reaction between azide and nitrite is quite slow, so the presence of excess nitrite does not mean that all the azide has been degraded.

2b. Add 1 drop sodium azide indicator solution, then basify the mixture by adding 1 M KOH until it turns purple (typically, 3 to 10 ml are required).

3b. Add 2 ml acetonitrile. Add 0.2 M HCl dropwise until the mixture turns yellow, then add 1 drop more.

If >1 ml sulfamic acid is used, add 4 ml acetonitrile.

4. Prepare a 10% (w/v) solution of 3,5-dinitrobenzoyl chloride in acetonitrile.
5. Add 50 μ l of 10% dinitrobenzoyl chloride/acetonitrile to the reaction mix (step 3a or 3b). Shake the mixture and let it stand \geq 3 min.

Longer standing times have no effect on the HPLC analysis. However, it is crucial to use freshly prepared 3,5-dinitrobenzoyl chloride solution within minutes of its preparation. It is generally most convenient to prepare all the analytical samples with the fresh solution at the beginning of the day and analyze them over the course of the day.

6. Analyze 20 μ l of each reaction mixture by reversed-phase HPLC (Snyder et al., 1997) using a mobile phase of 50:50 (v/v) acetonitrile/water with a flow rate of 1 ml/min and UV detection at 254 nm.

The peak for 3,5-dinitrobenzoyl azide elutes at ~9 min.

**SUPPORT
PROTOCOL 8**

ANALYTICAL PROCEDURE TO DETECT NITRITE

This protocol uses a modified Griess reagent to test for the presence of nitrite. The limit of detection of this assay is 0.06 μ g/ml nitrite. A similar procedure uses *N*-(1-naphthyl)-ethylenediamine (Cunniff, 1995).

Materials

- α -Naphthylamine
- 15% (v/v) aqueous acetic acid
- Sulfanilic acid solution (see recipe)
- Reaction mixture treated to remove excess nitrite (see Support Protocol 7, step 1b)

Table A.1H.8 Conditions for the Destruction of Enzyme Inhibitors

Compound	Concentration	Solvent	Solution: 1 M NaOH	Time
AEBSF	1 mM	Buffer(pH 5.0-8.0)	1:0.1	1 hr
AEBSF	20 mM	DMSO	1:10	24 hr
AEBSF	20 mM	Isopropanol	1:10	24 hr
APMSF	2.5 mM	Buffer(pH 5.0-8.0)	1:0.1	1 hr
APMSF	25 mM	DMSO	1:5	24 hr
APMSF	25 mM	50:50 isopropanol:pH 3 buffer	1:5	24 hr
APMSF	100 mM	Water	1:5	24 hr
DFP	10 mM	Buffer (pH 6.4-7.2)	1:0.2	18 hr
DFP	200 mM	DMF	1:2	18 hr
DFP	pure	—	1:25	1 hr
DFP	10 mM	Water	1:0.2	18 hr
PMSF	10 mM	Buffer (pH 5.0-8.0)	1:0.1	1 hr
PMSF	100 mM	DMSO	1:5	24 hr
PMSF	100 mM	Isopropanol	1:5	24 hr
TLCK	1 mM	Buffer (pH 5.0-8.0)	1:0.1	18 hr
TLCK	5 mM	DMSO	1:5	18 hr
TLCK	5 mM	Water	1:0.1	18 hr
TPCK	1 mM	Buffer (pH 5.0-8.0)	1:0.1	18 hr
TPCK	1 mM	DMSO	1:0.1	18 hr
TPCK	1 mM	Isopropanol	1:0.1	18 hr

1. Prepare the modified Griess reagent by boiling 0.1 g α -naphthylamine in 20 ml water until it dissolves. While the solution is still hot, pour it into 150 ml of 15% aqueous acetic acid. Add 150 ml sulfanilic acid solution.

This reagent should be stored at room temperature in a brown bottle.

CAUTION: α -Naphthylamine is a carcinogen.

2. Add 3 ml of the reaction mixture treated to remove excess nitrite to 1 ml modified Griess reagent. Let stand 6 min at room temperature.
3. Measure the absorbance at 520 nm against a suitable blank.

DISPOSAL OF ENZYME INHIBITORS

The enzyme inhibitors *p*-amidinophenylmethanesulfonyl fluoride (APMSF), 4-(2-aminoethyl)benzenesulfonyl fluoride (AEBSF), phenylmethylsulfonyl fluoride (PMSF; Lunn and Sansone, 1994c), diisopropyl fluorophosphate (DFP; Lunn and Sansone, 1994d), *N* α -*p*-tosyl-L-lysine chloromethyl ketone (TLCK), and *N*-*p*-tosyl-L-phenylalanine chloromethyl ketone (TPCK; Lunn and Sansone, 1994c) may be degraded by reaction with 1 M NaOH. Destruction is >99.8% (except TPCK >98.3%). The exact reaction conditions depend on the solvent (see Table A.1H.8). The solutions that were decontaminated are representative of those described in the literature.

Materials

Solutions of APMSF, AEBSF, PMSF, DFP, TLCK, or TPCK in buffer, DMSO, isopropanol, or water

1 M NaOH

Glacial acetic acid

Additional reagents and equipment for testing for the presence of the enzyme inhibitors (see Support Protocol 9)

1. If necessary, dilute the solutions with the same solvent so that the concentrations given in Table A.1H.8 are not exceeded.

Bulk quantities of AEBSF, PMSF, and TPCK may be dissolved in isopropanol and bulk quantities of APMSF and TLCK may be dissolved in water at the concentrations shown in Table A.1H.8. Bulk quantities of DFP (a liquid) may be mixed directly with 1 M NaOH, taking care to make sure that all the DFP has mixed thoroughly, in the ratio shown in Table A.1H.8 (e.g., 40 μ l DFP with 1 ml of 1 M NaOH).

2. Add 1 M NaOH so that the ratio of solution to 1 M NaOH is that listed in Table A.1H.8.
3. Shake to ensure complete mixing, check that the solution is strongly basic (pH \geq 12), and allow to stand for the time given in Table A.1H.8.
4. Neutralize the reaction mixture with acetic acid and test for the presence of residual enzyme inhibitor (see Support Protocol 9).
5. Discard the decontaminated reaction mixture.

Table A.1H.9 HPLC Conditions for Enzyme Inhibitors

Compound	Mobile phase	Detector	Retention time	Limit of detection
AEBSF	40:60 (v/v) acetonitrile:0.1% trifluoroacetic acid	UV 225 nm	9.5 min	0.1 µg/ml
APMSF	40:60 (v/v) acetonitrile:0.1% trifluoroacetic acid	UV 232 nm	7.7 min	0.5 µg/ml
PMSF	50:50 (v/v) acetonitrile:water	UV 220 nm	8 min	0.9 µg/ml
TLCK	40:60 (v/v) acetonitrile:0.1% trifluoroacetic acid	UV 228 nm	9.5 min	0.37 µg/ml
TPCK	48:52 (v/v) acetonitrile:10 mM pH 7 phosphate buffer	UV 228 nm	10.5 min	2 µg/ml

**SUPPORT
PROTOCOL 9****ANALYTICAL PROCEDURES TO DETECT ENZYME INHIBITORS**

DFP can be determined using a complex procedure involving the inhibition of chymotrypsin activity. For more information, refer to Lunn and Sansone (1994d). A gas chromatographic method has also been described by Degenhardt-Langelan and Kientz (1996). AEBSF, APMSF, PMSF, TLCK, and TPCK may be determined by reversed-phase HPLC (Snyder et al., 1997). The chromatographic conditions and limits of detection are shown in Table A.1H.9 (Lunn and Sansone, 1994c).

Materials

- Decontaminated enzyme inhibitor solutions
- Acetonitrile (HPLC grade)
- Water (HPLC grade)
- 0.1% (v/v) trifluoroacetic acid in water
- 10 mM phosphate buffer, pH 7
- 250-mm × 4.6 mm-i.d. Microsorb C-8 reversed-phase HPLC column (Varian) or equivalent
- Additional reagents and equipment for reversed-phase liquid chromatography (Snyder et al., 1997)

Analyze the decontaminated enzyme inhibitor solutions by reversed-phase HPLC using a 250-mm × 4.6-mm-i.d. Microsorb C-8 reversed-phase column, or equivalent, using the conditions shown in Table A.1H.9. In each case, the injection volume was 20 µl, the separation occurred at ambient temperature, and the flow rate was 1 ml/min. Check the analytical procedures by spiking an aliquot of the acidified reaction mixture with a small quantity of a dilute solution of the compound of interest.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Cyanide detection reagent

Stir 3.0 g barbituric acid in 10 ml water. Add 15 ml of 4-methylpyridine and 3 ml concentrated HCl while continuing to stir. Cool and dilute to 50 ml with water. Store at room temperature.

CAUTION: *This reaction is exothermic.*

Decontamination solution

Dissolve 4.2 g sodium nitrite (0.2 M final) and 20 ml hypophosphorous acid (3.3% w/v final) in 300 ml water. Prepare fresh.

Horseradish peroxidase

Dissolve hydrogen-peroxide oxidoreductase (EC 1.11.1.7 [Type II]; specific activity 150 to 200 purpurogallin U/mg, Sigma) in 1 g/liter sodium acetate to give 30 U/ml. Prepare fresh daily.

For small-scale reactions, a more dilute solution can be used to avoid working with inconveniently small volumes.

pH 5 buffer

2.04 g potassium hydrogen phthalate (0.05 M final)

38 ml 0.1 M potassium hydroxide (15 mM)

H₂O to 200 ml

Store at room temperature

Phosphate buffer

13.6 g monobasic potassium phosphate (KH₂PO₄; 0.1 M final)

0.28 g dibasic sodium phosphate (Na₂HPO₄; 2 mM final)

3.0 g potassium bromide (KBr; 25 mM final)

1 liter H₂O

Store at room temperature

Potassium bromide is necessary to make the assay for cyanide work correctly.

Sodium azide indicator solution

0.1 g bromocresol purple (0.4% final)

18.5 ml 0.01 M potassium hydroxide (KOH; 7.4 mM final)

H₂O to 25 ml

Store at room temperature

Sulfanilic acid solution

Dissolve 0.5 g sulfanilic acid in 150 ml of 15% (v/v) aqueous acetic acid. Use immediately.

Commonly Used Detergents

Detergents are polar lipids that are soluble in water. The presence of both a hydrophobic and hydrophilic portion makes these compounds very useful for lysis of lipid membranes, solubilization of antigens, and washing of immune complexes.

TYPES OF DETERGENTS

A large variety of detergents are available (Helenius et al., 1979). For biochemical studies, they are usually categorized according to the type of hydrophilic group they contain— anionic, cationic, amphoteric, or nonionic. Tables A.11.1 and A.11.2 list commonly used members of each type. In general, nonionic and amphoteric detergents are less denaturing for proteins than ionic detergents. Sodium cholate and sodium deoxycholate are the least denaturing of the commonly used ionic detergents.

Two properties of detergents are important in their consideration for biological studies: the critical micelle concentration (CMC) and the micelle molecular weight (Table A.11.1). The CMC is the concentration at which monomers of detergent molecules combine to form micelles; each detergent micelle has a characteristic micelle molecular weight. Detergents with a high micelle molecular weight, such as nonionic detergents, are difficult to remove from samples by dialysis. The CMC and the micelle molecular weight will vary depending on the buffer, salt concentration, pH, and temperature. In general, adding salt will lower the CMC and raise the micelle size.

Table A.11.1 Physical Properties of Commonly Used Detergents^{a,b}

Detergent	mp (°C)	Molecular weight (Da)		CMC	
		Monomer	Micelle	% (w/v)	M
<i>Anionic</i>

^cDenaturing refers to disruption of secondary and tertiary protein structure.

^dIonic detergents are unsuitable for ion-exchange chromatography (UNIT 10.10).

CHOICE OF DETERGENTS

Ionic detergents are very good solubilizing agents, but they tend to denature proteins by destroying native three-dimensional structures. This denaturing ability is useful for SDS-PAGE (UNIT 10.2), but is detrimental where native structure is important, as when functional activities must be retained (antibody activity is usually retained in <0.1% SDS). Nonionic and mildly ionic detergents are less denaturing and can often be used to solubilize membrane proteins while retaining protein-protein interactions. The following detergent properties are detrimental in certain procedures:

1. Phenol-containing detergents (e.g., Triton X-100 and NP-40) have a high absorbance at 280 nm and hence interfere with protein monitoring during chromatography (most ionic detergents do not absorb at 280 nm; Brij- and Lubrol-series detergents are nonionic detergents that do not have substantial absorbance at 280 nm). Phenol-containing detergents also induce precipitation in the Folin protein assay (but they can be used with the Bradford protein assay; UNIT 10.1A). Finally, they are readily iodinated and so should not be present during radioiodination.
2. Many detergents have a very high micelle molecular weight (Table A.11.1), which makes their use in gel filtration impossible since protein sizes are insignificant relative to the micelle size. In addition, such detergents cannot be readily removed by dialysis.
3. Sodium cholate and sodium deoxycholate are insoluble below pH 7.5 or above an ionic strength of 0.1%. SDS will often crystallize below 20°C.
4. Ionic detergents interfere with nondenaturing electrophoresis and isoelectric focusing.

Detergents can be removed or exchanged for other detergents by a variety of procedures (Hjelmeland, 1979; Furth et al., 1984; Harlow and Lane, 1988). Ionic and amphoteric detergents can usually be removed by dialysis (*APPENDIX 3C*). Pierce makes Extracti-Gel D for removing a variety of detergents from protein solutions (*Pierce Immunotechnology Catalog and Handbook on Protein Modification*).

Common Conversion Factors

Table A.1J.1 lists some of the more common conversion factors for units of measure used throughout Current Protocols manuals, while Table A.1J.2 gives prefixes indicating powers of ten for SI units.

Table A.1J.3 gives conversions between temperatures on the Celsius (Centigrade) and Fahrenheit scales. Celsius temperatures are converted to Fahrenheit temperatures by multiplying the Celsius figure by 9, dividing by 5, and adding 32, or by multiplying the Celsius figure by 1.8 and adding 32. Fahrenheit is converted to Celsius by subtracting 32 from the Fahrenheit figure, multiplying by 5, and dividing by 9. In Table A.1J.3, the center figure represents the temperature one has read on one of the scales; the figure to the left is the conversion of that figure into Celsius if read in Fahrenheit, while that to the right represents the conversion to Fahrenheit if read in Celsius: e.g., the temperature 88 Fahrenheit converts to 31.1°C, while the temperature 88 Celsius converts to 190.4°F.

Compendium of Drugs Commonly Used in Molecular Biology Research

The following appendix includes an alphabetical list of drugs commonly used to examine various biological processes. Table A.1K.1 lists the drugs by activity and provides recent references. Indicated under each drug listed is its mode of action, generally including several specific experimental examples; solvent(s) used to solubilize the drug; stock and working concentrations or ranges; storage conditions; and duration of incubation with cells to achieve the desired effects. Except where indicated, the majority of drugs in this list are cell-permeant. However, despite the well characterized selectivity of many of the following drugs in vitro, the corresponding effects upon their intracellular targets may not be precisely determined directly by their extracellular concentrations, since their cell-permeation properties are not known. Therefore, several different concentrations of any particular drug, as well as alternative methods of determining drug selectivity, should be examined.

Several of these drugs are members of large families, such as those targeting protein kinases and phosphatases, as well as those that affect intracellular Ca^{2+} levels. Many of these family members have different selectivities and potencies toward similar targets, and a complete listing is not included here. The reader may consult catalogs from the following companies, which have several of these family members available: Sigma, Alexis Biochemicals (including LC Laboratories), Calbiochem, Biomol, Molecular Probes, Boehringer Mannheim, Oxford Glycosystems, and Avanti Polar Lipids.

Although not specifically indicated, many of the following drugs are hazardous and should be handled with extreme care. Material Safety Data Sheets (MSDSs) are often provided for products that are hazardous or toxic. In some cases, these products are new and have not been tested for toxicity. Thus, care should be taken to ensure the safe handling of all products.

Table A.1K.1 Biological Activity of Drugs Commonly Used In Molecular Biological Research, continued

Drug	References
Drugs affecting the cytoskeleton	
Colcemid	Barlow et al., 1994. <i>J. Cell Biol.</i> 126:1017-1029; Bonfoco et al., 1995. <i>Exp. Cell Res.</i> 218:189-200; Goswami et al., 1994. <i>Exp. Cell Res.</i> 214:198-208
Colchicine	Bonfoco et al., 1995. <i>Exp. Cell Res.</i> 218:189-200; Lindenboim et al., 1995. <i>J. Neurochem.</i> 64:1054-1063
Cytochalasin B	Benya and Padilla, 1993. <i>Exp. Cell Res.</i> 204:268-277; Takeshita et al., 1998. <i>Cancer Lett.</i> 126:75-81; Tanaka et al., 1994. <i>Exp. Cell Res.</i> 213:242-252
Cytochalasin D	Cooper, 1987. <i>J. Cell Biol.</i> 105:1473-1478; Radhakrishna and Donaldson, 1997. <i>J. Cell Biol.</i> 139:49-61; Sasaki et al., 1995. <i>PNAS</i> 92:2026-2030; Wang et al., 1994. <i>Am. J. Physiol.</i> 267:F592-F598
Latrunculins	Wada et al., 1998. <i>J. Biochem.</i> 123:946-952; Lamaze et al., 1997. <i>JBC</i> 272:20332-20335; Spector et al., 1989. <i>Cell Motil. Cytoskeleton</i> 13:127-144
Nocodazole	Cole et al., 1996. <i>Mol. Biol. Cell.</i> 7:631-650; Liao et al., 1995. <i>J. Cell Sci.</i> 108:3473-3483; Vasquez et al., 1997. <i>Mol. Biol. Cell</i> 8:973-985
Taxol	Derry et al., 1995. <i>Biochemistry</i> 34:2203-2211; Ding et al., 1990. <i>Science</i> 248:370-372; Gallo, 1998. <i>J. Neurobiol.</i> 35:121-140; Jordan et al., 1993. <i>PNAS</i> 90:9552-9556; Mogensen and Tucker, 1990. <i>J. Cell Sci.</i> 97:101-107
Vinblastine	Dhamodharan et al., 1995. <i>Mol. Biol. Cell</i> 6:1215-1229; Lobert et al., 1998. <i>Cell Motil. Cytoskeleton</i> 39:107-121; Panda et al., 1996. <i>JBC</i> 271:29807-29812; Rai and Wolff, 1996. <i>JBC</i> 271:14707-14711; Taki et al., 1998. <i>J. Neurooncol.</i> 36:41-53; Tsukidate et al., 1993. <i>Am. J. Pathol.</i> 143:918-925
Drugs affecting intracellular Ca²⁺	
A23187	Elia et al., 1996. <i>JBC</i> 27:16111-16118; Kao, 1994. <i>Methods Cell Biol.</i> 40:155-181; Kao et al., 1990. <i>J. Cell Biol.</i> 111:183-196
BAPTA	Bissonnette et al., 1994. <i>Am. J. Physiol.</i> 267:G465-G475; Smith et al., 1992. <i>Biochem. J.</i> 288:925-929; Tsien, 1980. <i>Biochemistry</i> 19:2396-2404
Ionomycin	Aagaard-Tillery and Jelinek, 1995. <i>J. Immunol.</i> 155:3297-3307; Rock et al., 1997. <i>JBC</i> 272:33377-33383; Stewart et al., 1998. <i>J. Cell Biol.</i> 140:699-707
Thapsigargin	Kuznetsov et al., 1993. <i>JBC</i> 268:2001-2008; Lodish et al., 1992. <i>JBC</i> 267:12753-12760; Takemura et al., 1989. <i>JBC</i> 264:12266-12271; Won and Orth, 1995. <i>Endocrinology</i> 136:5399-5408; Wong et al., 1993. <i>Biochem. J.</i> 289:71-79
Drugs affecting oligosaccharide biosynthesis/processing	
Castanospermine	Ahmed et al., 1995. <i>Biochem. Biophys. Res. Commun.</i> 208:267-273; Bass et al., 1998. <i>J. Cell Biol.</i> 141:637-646; Gruters et al., 1987. <i>Nature</i> 330:74-77; Martina et al., 1998. <i>JBC</i> 273:3725-3731
Deoxymannojirimycin	Elbein et al., 1984. <i>Arch. Biochem. Biophys.</i> 235:579-588; McDowell et al., 1987. <i>Virology</i> 161:37-44; Slusarewicz and Warren, 1995. <i>Glycobiology</i> 5:154-155; Wojczyk et al., 1998. <i>Glycobiology</i> 8:121-130
Deoxynojirimycin	Labriola et al., 1995. <i>J. Cell Biol.</i> 130:771-779; Martina et al., 1998. <i>JBC</i> 273:3725-3731; Romero et al., 1985. <i>Biochem. J.</i> 226:733-740; Schlesinger et al., 1984. <i>JBC</i> 259:7597-7601
Tunicamycin	Bush et al., 1994. <i>Biochem. J.</i> 303:705-708; Kuznetsov et al., 1997. <i>JBC</i> 272:3057-3063; Lodish and Kong, 1984. <i>J. Cell Biol.</i> 98:1720-1729

Table A.1K.1 Biological Activity of Drugs Commonly Used In Molecular Biological Research, continued

Drug	References
Drugs affecting the pH of intracellular organelles	
Ammonium chloride	Breuer et al., 1995. <i>JBC</i> 270:24209-24215; Davis and Mecham, 1996. <i>JBC</i> 271:3787-3794; Smith et al., 1997. <i>JBC</i> 272:5640-5646
Bafilomycin A ₁	Bowman et al., 1988. <i>PNAS</i> 85:7972-7976; Calvert and Sanders, 1995. <i>JBC</i> 270:7272-7280; Furuchi et al., 1993. <i>JBC</i> 268:27345-27348
CCCP	Arai et al., 1996. <i>Biochem. Biophys. Res. Commun.</i> 227:433-439; Babcock et al., 1997. <i>J. Cell Biol.</i> 136:833-844; Kao, 1994. <i>Methods Cell Biol.</i> 40:155-181; Simpson and Russell, 1996. <i>JBC</i> 271:33493-33501
Chloroquine	Claus et al., 1998. <i>JBC</i> 273:9842-9851; Garcia-Sainz and Mendoza-Mendoza, 1998. <i>Eur. J. Pharmacol.</i> 342:333-338; Passos and Garcia, 1998. <i>Biochem. Biophys. Res. Commun.</i> 245:155-160; Wunsch et al., 1998. <i>J. Cell Biol.</i> 140:335-345
Concanamycin B	Akifusa et al., 1998. <i>Exp. Cell Res.</i> 238:82-89; Nishihara et al., 1995. <i>Biochem. Biophys. Res. Commun.</i> 212:255-262; Yilla et al., 1993. <i>JBC</i> 268:19092-19100
Monensin	Griffiths et al., 1983. <i>J. Cell Biol.</i> 96:835-850; Hardy et al., 1997. <i>JBC</i> 272:6812-6817; Kallen et al., 1993. <i>Biochim. Biophys. Acta</i> 1166:305-308; Shiao and Vance, 1993. <i>JBC</i> 268:26085-26092
Nigericin	Sandvig et al., 1989. <i>Methods Cell Biol.</i> 32:365-382; Scorrano et al., 1997. <i>JBC</i> 272:12295-12299; Vercesi et al., 1993. <i>JBC</i> 268:8564-8568
Drugs that lead to increased intracellular cAMP levels	
8-Bromo-cyclic AMP	Boyer and Thiery, 1993. <i>J. Cell Biol.</i> 120:767-776; Hei et al., 1991. <i>Mol. Pharmacol.</i> 39:233-238; Sandberg et al., 1991. <i>Biochem. J.</i> 279:521-527
Cholera toxin	Hansen and Casanova, 1994. <i>J. Cell Biol.</i> 126:677-687; Lencer et al., 1995. <i>J. Cell Biol.</i> 131:951-962; Ma and Weiss, 1995. <i>Methods Cell Biol.</i> 49:471-485; Moss and Vaughan, 1992. <i>Curr. Top. Cell. Regul.</i> 32:49-72
Dibutyryl cyclic AMP	Cong et al., 1998. <i>JBC</i> 273:660-666; O'Malley et al., 1997. <i>J. Cell Biol.</i> 138:159-165; Sandvig et al., 1994. <i>J. Cell Biol.</i> 126:53-64; Yuan et al., 1996. <i>JBC</i> 271:27090-27098
Forskolin	Galli et al., 1995. <i>J. Neurosci.</i> 15:1172-1179; Lippincott-Schwartz et al., 1991. <i>J. Cell Biol.</i> 112:567-577; Laurenza et al., 1989. <i>Trends Pharmacol. Sci.</i> 10:442-447; Nickel et al., 1996. <i>JBC</i> 271:15870-15873
Kinase inhibitors	
Bisindolylmaleimide I (GF 109203 X)	Das and White, 1997. <i>JBC</i> 272:14914-14920; Toullec et al., 1991. <i>JBC</i> 266:15771-15781; Uberall et al., 1997. <i>JBC</i> 272:4072-4078
Calphostin C	Dubyak and Kertesy, 1997. <i>Arch. Biochem. Biophys.</i> 341:129-139; Hartzell and Rinderknecht, 1996. <i>Am. J Physiol.</i> 270:C1293-C1299; Jarvis et al., 1994. <i>Cancer Res.</i> 54:1707-1714
Chelerythrine chloride	Barg et al., 1992. <i>J. Neurochem.</i> 59:1145-1152; Herbert et al., 1990. <i>Biochem. Biophys. Res. Commun.</i> 172:993-999; Jarvis et al., 1994. <i>Cancer Res.</i> 54:1707-1714; Jia et al., 1997. <i>JBC</i> 272:4978-4984; Kandasamy et al., 1995. <i>JBC</i> 270:29209-29216
Genistein	Akiyama et al., 1987. <i>JBC</i> 262:5592-5595; Chen et al., 1997. <i>JBC</i> 272:27401-27410; Kranenburg et al., 1997. <i>J. Cell Sci.</i> 110:2417-2427
H-7	Barria et al., 1997. <i>Science</i> 276:2042-2045; Kawamoto and Hidaka, 1984. <i>Biochem. Biophys. Res. Commun.</i> 125:258-264; Wang et al., 1997. <i>JBC</i> 272:1817-1821

DRUGS COMMONLY USED IN MOLECULAR BIOLOGY

A23187

Calcium ionophore; forms stable complexes with divalent cations and increases their passage across biological membranes. Useful tool for increasing intracellular calcium concentration. The effectiveness of A23187 is dependent on the presence of extracellular calcium. Can be used as a fluorescent probe for investigating protein hydrophobicity. 4-Bromo-A23187 is a nonfluorescent derivative.

Soluble in: DMSO, methanol

Stock concentration: 100 mM (store at 4°C protected from light)

Working concentration: 0.1 to 20 μM

Duration of incubation: 2 min to 24 hr

Aggregates over time in aqueous systems.

Actinomycin D

Inhibits transcription by complexing with deoxyguanosine residues on DNA and blocking the movement of RNA polymerase. A potent inducer of apoptosis in many cell lines. However, actinomycin D has also been shown to suppress programmed cell death of PC12 cells induced by the topoisomerase II inhibitor etoposide.

Soluble in: Methanol

Stock concentration: 100 mM (store at 4°C)

Working concentration: 1 to 5 μM

Duration of incubation: 5 min to 24 hr

α-Amanitin

Acts as a potent and specific inhibitor of mRNA synthesis by binding preferentially to RNA polymerase II. At high concentrations also inhibits RNA polymerase III.

Soluble in: Methanol, water

Stock concentration: 2 to 10 mg/ml (store at 4°C protected from light)

Working concentration: 1 to 10 μg/ml (pol II) to 200 μg/ml (pol III)

Duration of incubation: 15 to 60 min

Ammonium chloride (NH₄Cl)

Permeant weak base. Used to neutralize acidic endomembrane compartments.

Inhibits synthesis of sphingoid bases.

Soluble in: Water (freely soluble)

Stock concentration: 5 M (store at 4°C)

Working concentration: 1 to 50 mM

Duration of incubation: Effective within 15 sec

Anisomycin

Inhibits protein synthesis by blocking the peptidyl transferase step during translation. Activates p54 (JNK2) and MAP kinases. May be a useful tool to study cytoplasmic signals that result in nuclear signaling and *c-fos* and *c-jun* induction. Also known to induce apoptosis in U937 cells.

Soluble in: DMSO

Stock concentration: 100 μg/ml (store at 4°C)

Working concentration: 50 ng/ml to 1 μg/ml.

Duration of incubation: 30 min to 16 hr, depending on properties studied

Aphidicolin

Cell synchronization reagent. Reversible inhibitor of DNA polymerase α and δ; blocks cell cycle at early S phase. Potentiates apoptosis induced by arabinosyl nucleosides in leukemia cell lines.

Soluble in: DMSO, methanol

Stock concentration: 2 mg/ml (store at 4°C)

Working concentration: 0.5 to 100 μg/ml.

Duration of incubation: 12 to 24 hr

Ara-C (cytosine arabinoside)

Inhibits DNA synthesis. S-phase-toxic reagent whose active metabolite (ara-CTP) is a substrate for DNA polymerases and is incorporated into DNA. Anticancer, antiviral agent that is especially effective against leukemias. Induces apoptosis in human myeloid leukemia cells and in rat sympathetic neurons.

Soluble in: Water

Stock concentration: 20 mg/ml (store at 4°C)

Working concentration: 0.1 to 1 μg/ml

Duration of incubation: >3 hr

Bafilomycin A₁

A potent and specific inhibitor of vacuolar-type H⁺-ATPases. Valuable tool for distinguishing different types of ATPases. Blocks lysosomal trafficking in macrophages.

Soluble in: DMSO

Stock concentration: 50 μM (store at -20°C protected from light)

Working concentration: 10 to 100 nM

Duration of incubation: 10 min to 2 hr

BAPTA

Ca²⁺ chelator with a 10⁵-fold greater affinity for Ca²⁺ than for Mg²⁺; can be used to control the level of both intracellular (using its membrane-permeant AM ester) and extracellular Ca²⁺.

Soluble in: DMSO

Stock concentration: 1 to 10 mM (store at –20°C in aliquots, protected from light; avoid repeated freeze-thawing)

Working concentration: (BAPTA-AM): 1 to 20 μM

Duration of incubation: 15 to 60 min at 20° to 37°C

Before incubation with BAPTA, wash cells 2 to 3 times with serum-free medium (serum may contain esterase activity). The cell-loading medium should also be free of amino acids or buffers containing primary or secondary amines that may cleave the AM esters and prevent loading.

Bisindolylmaleimide I (GF 109203X)

A highly selective cell-permeant protein kinase C (PKC) inhibitor that is structurally similar to staurosporine, but has higher selectivity. May inhibit protein kinase A at high concentrations. Acts as a competitive inhibitor for the ATP-binding site of the PKC catalytic domain. Since ATP levels are generally very high in cells, the potency of bisindolylmaleimide I is reduced accordingly in whole-cell assays.

Soluble in: DMSO

Stock concentration: 2 mM (store at ≤4°C)

Working concentration: 20 nM to 1 μM

Duration of incubation: 15 min to 6 hr

Water-soluble salts are available.

Brefeldin A

Inhibits GTP nucleotide exchange onto several members of the ARF (ADP ribosylation factor) family. Inhibits binding of the cytosolic coatamer (COPI) complex to Golgi membranes; induces the rapid redistribution of the Golgi apparatus into the ER; blocks transport out of the ER in a number of cell lines. Reversible.

Soluble in: Methanol

Stock concentration: 1 to 20 mM (store at –20°C)

Working concentration: 1 to 5 μM

Duration of incubation: 5 min to 24 hr; effects are rapid (30 sec)

8-Bromo–cyclic AMP

Cell-permeant cyclic AMP analog. Activates protein kinase A. Increased resistance to degradation by cellular phosphodiesterases as compared to cyclic AMP.

Soluble in: Water

Stock concentration: 100 mM (store at –20°C)

Working concentration: 10 to 500 μM

Duration of incubation: Up to 24 hr

Calpain inhibitor I (ALLN)

Inhibitor of calpain I, calpain II, cathepsin B, and cathepsin L. A peptide aldehyde, which inhibits neutral cysteine proteases and the proteasome. Protects against neuronal damage caused by hypoxia and ischemia. Inhibits proteolysis of IκB by the ubiquitin-proteasome complex. Inhibits cell-cycle progression at G₁/S and metaphase/anaphase in CHO cells by inhibiting cyclin B degradation. Membrane-permeant due to low molecular weight and lack of charged residues.

Soluble in: DMSO, methanol, dimethylformamide

Stock concentration: 25 mM (store at 4°C)

Working concentration: 25 to 100 μM

Duration of incubation: 1 to 18 hr

Calphostin C

Potent and highly selective inhibitor of protein kinase C (PKC; $K_i = 50$ nM). Competes with phorbol esters and diacylglycerol for binding to the PKC regulatory domain. Does not compete with Ca^{2+} or phospholipids. At higher concentrations inhibits myosin light chain kinase ($K_i > 5$ μM), protein kinase A ($K_i > 50$ μM), protein kinase G ($K_i > 25$ μM), and p60^{v-src} ($K_i > 50$ μM).

Soluble in: DMSO

Stock concentration: 1 mM (store 4°C protected from light)

Working concentration: 10 nM to 3 μM

Duration of incubation: 15 to 60 min

Brief exposure to visible light in the presence of PKC is required for PKC inhibition by calphostin C. See Table 1 (Selectivity of Selected Kinase Inhibitors) in the Biomol Catalog and Handbook, 5th ed., and Technical Note #11 from Alexis Biochemicals for additional information.

Calyculin A

Potent cell-permeant inhibitor with high specificity for the Ser/Thr protein phosphatases 1 and 2A. Calyculin A is 20 to 300 times more potent than okadaic acid as a PP-1 class phosphatase inhibitor. Stimulates contraction of smooth muscle, induces intracellular protein phosphorylation in cultured human keratinocytes, and inhibits apoptosis.

Soluble in: DMSO, ethanol

Stock concentration: 10 μM (store at -20°C protected from light and moisture)

Working concentration: 0.5 to 50 nM

Duration of incubation: 15 min to 2 hr

See Technical Note #19 from Alexis Biochemicals for additional information. May cause cell rounding.

Camptothecin

A reversible DNA topoisomerase I inhibitor. Induces breaks at replication forks by binding to and stabilizing the topoisomerase-DNA covalent complex. Causes S-phase cytotoxicity. Possesses anti-leukemic and anti-tumor properties. Inhibits *tat*-mediated transactivation of HIV-1.

Soluble in: DMSO

Stock concentration: 1 to 10 mM (store at 4°C)

Working concentration: 0.1 to 10 μM

Duration of incubation: Literature shows use from 15 min to 24 hr

Castanospermine

Inhibitor of α - and β -glucosidases; inhibitor of glycoprotein processing. Prevents calnexin and calreticulin binding to N-linked glycans on newly synthesized glycoproteins. Inhibits HIV infectivity.

Soluble in: Water

Stock concentration: 1 mM (store at 4°C)

Working concentration: 1 to 5 μM

Duration of incubation: 15 min to 3 hr

CCCP (carbonyl cyanide-*m*-chlorophenyl hydrazone)

Proton ionophore. Uncoupling agent for oxidative phosphorylation that inhibits mitochondrial function. Approximately 100 times as effective as 2,4-dinitrophenol at collapsing membrane potential. Inhibits transport processes and depresses growth.

Soluble in: DMSO, ethanol

Stock concentration: 1 to 10 mM (store at 4°C)

Working concentration: 1 to 5 μM

Duration of incubation: 5 to 15 min

Chelerythrine chloride

Potent, selective, cell-permeant inhibitor of protein kinase C ($K_i = 0.66 \mu\text{M}$). Acts on the catalytic domain. Chelerythrine shows competitive kinetics with PKC substrates, but is not competitive with ATP. Thus, the high concentration of ATP within cells should not lower the potency of chelerythrine in whole cells as compared with that seen in purified enzyme preparations. Inhibits thromboxane formation and phosphoinositide metabolism in platelets. Induces apoptosis in HL-60 cells.

Soluble in: DMSO

Stock concentration: 10 mM (store at -20°C)

Working concentration: 1 μM

Duration of incubation: 15 min to 2 hr

See Technical Note #8 from Alexis Biochemicals for additional information.

Chloroquine

Tertiary amine that accumulates within and neutralizes the pH of acidic organelles; various effects on phagosome-endosome and phagosome-lysosome fusion. Antimalarial drug that works via carrier-mediated uptake in *P. falciparum*. May activate protein kinases.

Soluble in: Water

Stock concentration: 1 to 10 mg/ml (store at room temperature)

Working concentration: 10 to 200 μg/ml

Duration of incubation: 15 min to 2 hr

Cholera toxin

Contains a single A subunit (mol. wt. = 29 kDa) and a B subunit (mol. wt. = 55 kDa) containing five B polypeptide chains. The B subunit binds to GM₁ ganglioside receptors on the surface of cells and facilitates transport of the A subunit through the membrane. The A subunit catalyzes the ADP-ribosylation of an arginine residue on the α subunit of heterotrimeric G proteins (primarily G_s), reducing its intrinsic GTPase activity. Toxicity results from activation of membrane-bound adenylate cyclase. Consequently, increased intracellular cAMP levels result in increased electrolyte transport out of the cell and water loss. Cholera toxin requires ADP-ribosylation factor (ARF) for maximal activity.

Soluble in: Water

Stock concentration: 1 mg/ml (store at 4°C, do not freeze)

Working concentration: 100 ng/ml to 2 μg/ml

Duration of incubation: 2 to 24 hr

Colcemid

Cell synchronization agent. Depolymerizes microtubules and limits microtubule formation. Low concentrations inactivate spindle dynamics. Induces apoptosis by blocking mitosis in HeLa S3 cells. Colcemid is a less toxic derivative of colchicine.

Soluble in: Ethanol

Stock concentration: 1 mM (store at or below room temperature)

Working concentration: 1 to 10 μ M

Duration of incubation: 1 to 24 hr, depending on process studied

Colchicine

Inhibitor of mitosis, used in cell-division studies. Disrupts microtubules and inhibits tubulin polymerization. Induces apoptosis in PC 12 cells and in cerebellar granule cells.

Soluble in: Ethanol

Stock concentration: 1 mM (store at or below room temperature protected from light and moisture)

Working concentration: 1 to 10 μ M

Duration of incubation: 1 to 24 hr, depending on process studied

Concanamycin B

Highly specific and sensitive inhibitor of vacuolar-type H⁺-ATPases ($K_i = 20$ pM). Related to concanamycin A (folimycin). More potent and specific than bafilomycin A₁. Inhibits acidification of organelles such as lysosomes and the Golgi apparatus. Blocks cell-surface expression of viral glycoproteins without affecting their synthesis.

Soluble in: Methanol, ethanol

Stock concentration: 10 μ M (store at -20°C protected from light)

Working concentration: 50 nM

Duration of incubation: 5 min to 1 hr

Cycloheximide

Inhibits protein synthesis in eukaryotes but not prokaryotes. Blocks the translocation step during translation. Induces apoptosis in a number of cell types. However, it inhibits DNA cleavage in rat thymocytes treated with thapsigargin and ionomycin.

Soluble in: Water, ethanol, methanol

Stock concentration: 10 mg/ml (store at or below room temperature)

Working concentration: 1 to 100 μ g/ml, depending on cell type

Duration of incubation: Effective within 10 min

To achieve >90% inhibition of protein synthesis, only 1 to 10 μ g/ml is required in CHO and HeLa cells, but 100 μ g/ml is required in COS cells.

Cyclosporin A (CsA)

Cyclic oligopeptide with immunosuppressant properties. Induces apoptosis in some cell types, while inhibiting apoptosis in others. A complex of cyclosporin A and cyclophilin inhibits protein phosphatase 2B (calcineurin) with affinity at the nanomolar level. Inhibits nitric oxide synthesis induced by interleukin-1 α , lipopolysaccharides, and TNF α .

Soluble in: Ethanol, methanol

Stock concentration: 1 to 5 mM (store at 4°C)

Working concentration: 0.1 to 10 μ M

Duration of incubation: Used anywhere from 15 min to 24 hr

Cytochalasin B

Cell-permeant fungal toxin that blocks the formation of contractile microfilaments. Shortens actin filaments by blocking monomer addition at the barbed (fast-growing)

continued

end of polymers. Inhibits cytoplasmic division, cell movement, phagocytosis, platelet aggregation, and glucose transport.

Soluble in: DMSO, ethanol

Stock concentration: 10 mM (store at -20°C protected from light)

Working concentration: 1 to 20 μM

Duration of incubation: 15 min to 2 hr

Cytochalasin D

Approximately 10-fold more potent than cytochalasin B in inhibiting actin filament function. Does not inhibit sugar transport in cells. Modulates CD4 cross-linking in T lymphocytes and increases intracellular Ca^{2+} . Exhibits antitumor activity.

Soluble in: DMSO

Stock concentration: 10 mM (store at -20°C protected from light)

Working concentration: 1 to 20 μM

Duration of incubation: 15 min to 2 hr.

Desferrioxamine (DFO)

Iron-chelating agent. Commonly used in therapy as a chelator of ferric iron in iron overload disorders. Protects against dopamine-induced cell death. Also interferes with hydroxy-radical formation. Shows an antiproliferative effect on vascular smooth muscle cells.

Soluble in: DMSO; slightly soluble in water

Stock concentration: 10 to 50 mM (store at 4°C)

Working concentration: 10 μM to 2 mM

Duration of incubation: Up to 18 hr

2-Deoxyglucose

Nonmetabolizable derivative of glucose. Competes with glucose for the GLUT-2 transporter; phosphorylation of 2-deoxyglucose by hexokinase effectively inhibits glucose flux through the glycolytic pathway. Used in combination with sodium azide or oligomycin to reduce cellular ATP levels. Blocks inhibition of IL-1 release by high glucose levels in RAW 264.7 cells.

Soluble in: Water

Stock concentration: 1 M (store at 4°C)

Working concentration: 5 to 50 mM

Duration of incubation: 15 min to 3 hr

Deoxymannojirimycin

Competitive α -mannosidase I inhibitor that blocks conversion of high mannose forms to complex oligosaccharides. Inhibits mammalian Golgi α -mannosidase I (an α -1,2-mannosidase). Other rat liver mannosidases are not significantly affected (α -1,2-specific ER mannosidase is only inhibited 2% to 5% by 100 mM deoxymannojirimycin, and Golgi α -mannosidase II is inhibited \sim 14%).

Soluble in: Water

Stock concentration: 100 mM (store at -20°C)

Working concentration: 1 to 5 mM

Duration of incubation: Anywhere from 30 min to 24 hr

Deoxynojirimycin

Specific glucosidase inhibitor. Inhibits endoplasmic reticulum trimming glucosidases I and II, which sequentially remove three glucose residues from $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$ in N-linked glycan biosynthesis. Prevents calnexin and calreticulin binding to N-linked glycoproteins within the ER.

continued

**Standard
Measurements,
Data, and
Abbreviations**

A.1K.13

Soluble in: Water

Stock concentration: 100 mM (store at 4°C)

Working conditions: 1 to 5 mM.

Duration of incubation: 15 min to 24 hr

At concentrations >1 mM, deoxynojirimycin may inhibit lipid-linked oligosaccharide biosynthesis as well as trimming. In such cases, N-methyldeoxynojirimycin may be a more effective inhibitor, possibly owing to an increased ability to cross cell membranes, afforded by the N-methyl group.

Dibutyl cyclic AMP

Highly membrane-permeant cAMP analog resistant to phosphodiesterase cleavage. Constitutive activator of protein kinase A. This product releases butyrate due to intracellular and extracellular esterase action. Butyrate may have its own distinct biological effects (see sodium butyrate).

Soluble in: DMSO, ethanol

Stock concentration: 1 M (store at -20°C)

Working concentration: 100 µM to 1 mM

Duration of incubation: Anywhere from 1 to 48 hr

Dithiothreitol (DTT; Cleland's reagent)

Cell-permeant protective agent for SH groups; maintains monothiols completely in the reduced state and reduces disulfides quantitatively. DTT interferes with the folding and export of proteins located in the endoplasmic reticulum, but it does not prevent the transfer from the intermediate compartment to the Golgi complex. Reversible.

Soluble in: Water, ethanol

Stock concentration: 1 M (store at 4°C)

Working concentration: 1 to 10 mM

Duration of incubation: 1 min to several hours

E-64

Irreversible inhibitor of cysteine proteases (papain and cathepsins B and L). Has no action on cysteine residues in other proteins.

Soluble in: Water

Stock concentration: 1 mg/ml (store at -20°C)

Working concentration: 0.5 to 10 µg/ml

Duration of incubation: Up to 24 hr

Emetine

Irreversibly blocks protein synthesis by inhibiting movement of ribosomes along mRNA. Stimulates rapid and differential phosphorylation of the stress-activated protein kinase/c-Jun kinase (SAPK/JNK) pathway. Prevents apoptosis in several cell lines. In primary rat hepatocytes, the relative potency of inhibition of several protein synthesis inhibitors is in the order: emetine > anisomycin > cycloheximide > puromycin, with puromycin exhibiting only marginal inhibition at a concentration of 1 µM. In fact, 90% to 95% inhibition of protein synthesis was achieved only with emetine and anisomycin, at 10 µM concentrations. Cycloheximide and puromycin exerted only 80% and 60% inhibition, respectively, at a similar concentration.

Soluble in: Ethanol

Stock concentration: 10 to 100 mM (store at 4°C protected from light)

Working concentration: 10 to 20 µM

Duration of incubation: 15 to 30 min; can incubate 24 hr

Etoposide (VP-16)

Topoisomerase II inhibitor. Stabilizes the covalent complexes of topoisomerase II with DNA. Has major activity against a number of tumors, including germ cell neoplasms, small cell lung cancer, and malignant lymphoma. Induces apoptosis in mouse thymocytes and HL-60 cells. Activates PKC α .

Soluble in: DMSO

Stock concentration: 100 to 500 mM (store at room temperature)

Working concentration: 50 to 200 μ M

Duration of incubation: 1 to 24 hr

Filipin

A cholesterol-binding fluorochrome. Specific for unesterified cholesterol. Binds and removes cholesterol from cell surface membranes. Reversibly disassembles caveolae.

Soluble in: Methanol

Stock concentration: 500 μ g/ml (store 4°C protected from light)

Working concentration: 5 to 50 μ g/ml

Duration of incubation: 1 hr

Forskolin

Activates adenylate cyclase by interacting directly with the catalytic subunit. Leads to an increase in the intracellular concentration of cAMP. Several forskolin derivatives are available having different and improved properties. Enhances detoxification of brefeldin A.

Soluble in: DMSO, ethanol

Stock concentration: 10 to 100 mM (store at 4°C)

Working concentration: 10 μ M (to increase cAMP levels); 100 μ M (to inhibit brefeldin A)

Duration of incubation: Depending on assay, incubate cells 15 min to 12 hr

Fumonisin B₁

Inhibits sphingolipid biosynthesis via inhibition of sphingosine *N*-acyltransferase (ceramide synthase). Sphingomyelin biosynthesis is preferentially inhibited versus glycosphingolipids in neuronal cells. Inhibits the butyric acid-induced increase in transport of cell-associated Shiga toxin to the Golgi apparatus and the ER. Induces apoptosis in monkey kidney cells.

Soluble in: methanol

Stock concentration: 10 to 100 mM (store at 4°C)

Working concentration: Anywhere from 1 to 100 μ M

Duration of incubation: 15 min to 18 hr, depending on process studied

Geneticin (G418)

Aminoglycoside toxic to bacteria, yeast, higher plants, protozoa, and mammalian cells. Used for the selection and maintenance of eukaryotic cells stably transfected with the neomycin (*neo*) resistance genes from transposons Tn5 and Tn601.

Soluble in: Water or culture medium

Stock concentration: 2 mg/ml (active G418) in cell culture medium, adjust pH to ~7.4 (store at 4°C)

Working concentration: Usually 50 to 1000 μ g/ml (optimal concentration must be determined experimentally and varies with the cell type used)

Duration of incubation: >1 week

In cell types with relatively stable genomes (e.g., CHO), continuous incubation in geneticin is not generally necessary once stable cells have been selected. Expression in stable cells with down-regulated viral promoters can be enhanced with sodium butyrate.

Genistein

Inhibits protein tyrosine kinases by acting as a competitive inhibitor of ATP. Prevents EGF-stimulated tyrosine phosphorylation in A431 cells, as well as inhibiting kinases in other cultured cells.

Soluble in: DMSO

Stock concentration: 100 to 500 mM (store at -20°C)

Working concentration: 50 to 300 μM

Duration of incubation: 15 min to 1 hr

See Table II (Selectivity of Tyrosine Protein Kinase Inhibitors) in the Biomol Catalog and Handbook, 5th ed.

H-7

A broad-based, cell-permeant serine/threonine kinase inhibitor. Inhibits protein kinase C ($K_i = 6.0 \mu\text{M}$), protein kinase A ($K_i = 3.0 \mu\text{M}$), protein kinase G ($K_i = 5.8 \mu\text{M}$), and myosin light chain kinase ($K_i = 97 \mu\text{M}$). Induces apoptotic DNA fragmentation and cell death in HL-60 cells. Numerous analogs with different selectivities are available.

Soluble in: Water

Stock concentration: 100 mM (store at 4°C)

Working concentration: 10 to 100 μM

Duration of incubation: 15 min to 3 hr

See Table I (Selectivity of Selected Kinase Inhibitors) in the Biomol Catalog and Handbook, 5th ed., and Technical Note #10 from Alexis Biochemicals.

Herbimycin A

An irreversible and selective cell-permeant protein tyrosine kinase inhibitor; reacts with thiol groups. It is effective on Src, Yes, Fps, Ros, Abl, and ErbB oncogene products. Inhibits PDGF-induced phospholipase D activation in a dose-dependent manner.

Soluble in: DMSO

Stock concentration: 10 mM (store at -20°C protected from light)

Working concentration: 1 to 10 μM

Duration of incubation: 15 min to 1 hr

Hydroxyurea

Antineoplastic reagent. Blocks DNA synthesis by inhibiting ribonucleotide reductase; accumulates cells at G1/S interface.

Soluble in: Water

Stock concentration: 1 M (store at 4°C)

Working concentration: 50 μM to 1 mM

Duration of incubation: Up to 24 hr

Hygromycin

Inhibitor of both prokaryotic and eukaryotic protein synthesis; inhibits at the translocation step on 70S ribosomes and causes misreading of mRNA. The *E. coli hph* hygromycin B-resistant gene is widely used for selection of recombinant clones in a variety of cell types.

Hygromycin B is sold as an aqueous solution. Actual activity and concentration are given for each lot of product. Concentrations used must be experimentally determined.

Ionomycin

Ca^{2+} ionophore. Useful for increasing intracellular Ca^{2+} concentrations and in measurement of cytoplasmic free Ca^{2+} . More effective than A23187 and is nonfluorescent.

Soluble in: DMSO and methanol

Stock concentration: 1 mM (store at 4°C protected from light)

continued

Working concentration: Usually 1 μM

Duration of incubation: 15 to 30 min.

KN-62

Potent and selective inhibitor of Ca^{2+} /calmodulin kinase II ($K_i = 0.9 \mu\text{M}$), displaying a K_i for CaM kinase II more than 2 orders of magnitude lower than those for protein kinase C, protein kinase A, and myosin light chain kinase. A second inhibitor of CaM kinase II, KN-93, is more soluble in water and equally selective for CaM kinase II ($K_i = 0.3 \mu\text{M}$). Prevents agonist-mediated activation of $\text{Ins}(1,4,5)\text{P}_3$ 3-kinase. Inhibits differentiation of 3T3-L1 embryonic fibroblasts to adipocytes. Inactive analogs are available.

Soluble in: DMSO

Stock concentration: 10 mM (store at 4°C)

Working concentration: 2 to 10 μM

Duration of incubation: 30 min (can incubate cells up to 48 hr)

Lactacystin

A cell-permeant and irreversible proteasome inhibitor. Blocks proteasome activity by targeting the catalytic β subunit. Induces neurite outgrowth in Neuro 2A mouse neuroblastoma cells and inhibits progression of synchronized Neuro 2A cells and MG-63 human osteosarcoma cells beyond the G_1 phase of the cell cycle. Inhibits $\text{NF}\kappa\text{B}$ activation. Has revealed the role of the proteasome in the degradation of many ER proteins.

Soluble in: DMSO

Stock concentration: 10 mM (store at -20°C)

Working concentration: 10 to 20 μM

Duration of incubation: 1 to 12 hr

Latrunculin A

Inhibits actin polymerization and disrupts microfilament organization as well as microfilament-mediated processes; 10 to 100-fold more potent than cytochalasins. Whereas cytochalasins induce dissolution of F-actin and stress-fiber contraction in fibroblasts in culture, the latrunculins (A and the less potent B) cause a shortening and thickening of stress fibers. In addition, the latrunculins sequester actin monomers, whereas with the cytochalasins, actin remains in an oligomer form. Thus, the two classes of compounds may have different target sites. Reversible.

Soluble in: DMSO, ethanol

Stock concentration: 10 mg/ml (store at -20°C)

Working concentration: 0.2 to 10 $\mu\text{g/ml}$

Duration of incubation: 1 to 12 hr

Leptomycin B

A potent and specific inhibitor of the NES-dependent nuclear export of proteins; binds to the export receptor CRM1. Exhibits antifungal and antitumor effects, inhibits the nucleo-cytoplasmic translocation of the human immunodeficiency virus type 1 regulatory protein Rev, and exhibits significant antiproliferative activity.

Soluble in: Ethanol

Stock concentration: 100 μM to 1 mM (store at -20°C)

Working concentration: 10 to 100 nM

Duration of incubation: 30 min to 3 hr

Leupeptin

A reversible inhibitor of trypsin-like and cysteine proteases (including trypsin, plasmin, proteinase K, papain, thrombin, and cathepsin A and B). Inhibits activation-induced programmed cell death in T lymphocytes.

Soluble in: Water

Stock concentration: 1 to 10 mM (store at -20°C)

Working concentration: 10 to 100 μM

Duration of incubation: 15 min to several hours

Lovastatin

An antihypercholesterolemic agent and inhibitor of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase; depletes endogenous pools of mevalonic acid, thereby blocking protein isoprenylation and cholesterol synthesis. Has a number of cellular effects. Blocks *N-ras* oncogene-induced neuronal differentiation, inhibits growth factor signaling and causes cells to arrest in late G_1 phase.

Soluble in: DMSO, ethanol

Stock concentration: 4 mg/ml (store at -20°C)

Working concentration: 20 μM

Duration of incubation: 6 to 24 hr

Lysophosphatidic acid (LPA)

Activates a number of signaling pathways and processes via heterotrimeric G proteins (primarily G_i and G_q) including: inhibition of adenylate cyclase, activation of Ras and the Raf/MAP kinase pathway, stimulation of phospholipases C and D, and stress-fiber formation through the activation of Rho.

Solubility: A stock solution may be prepared at 10 mg/ml in 95:5:5 chloroform/methanol/acetic acid (gives a clear solution). Solubility in dimethylsulfoxide (DMSO) or ethanol is limited. The sodium salt of oleoyl-LPA is reported to be readily soluble at 5 mg/ml (~ 11 mM) in calcium and magnesium-free buffers (Jalink et al., 1990). Solubilization has also been achieved (Seufferlein and Rozengurt, 1994) in phosphate-buffered saline (PBS), pH 7.4, or calcium- and magnesium-free Dulbecco's PBS (CMF-DPBS), pH 7.4 (see APPENDIX 2 for recipes), at up to 3 mM (0.14 mg/ml) in the presence of 0.1% (w/v) BSA (essentially fatty-acid free).

Storage. LPA should be stable in solution under neutral conditions. Freezer storage is recommended for solutions or aqueous preparations. Maintaining the product under an inert atmosphere (nitrogen or argon) may be appropriate for some applications.

Working concentration. Anywhere from 500 nM (1-hr incubation) to 100 μM (15-min incubation).

LY294002 (PI 3-kinase inhibitor)

Reversible inhibitor of phosphatidylinositol-3-kinase that acts on the ATP-binding site of the enzyme. Does not affect the activity of EGF receptor kinase, MAP kinase, PKC, PI4-kinase, S6 kinase, and *c-src*. Blocks proliferation of cultured rabbit aortic smooth muscle cells without inducing apoptosis. Wortmannin is more selective and more potent, but is irreversible.

Soluble in: DMSO and ethanol

Stock concentration: 1 to 10 mM (store in aliquots at -20°C)

Working concentration: 1 to 2 μM

Duration of incubation: 15 min to 3 hr

Mastoparan

Relatively cell-permeant synthetic peptide capable of directly activating pertussis toxin-sensitive G proteins by a mechanism analogous to that of G-protein-coupled receptors. Acts preferentially on G_i and G_o rather than G_s. Stimulates insulin secretion in permeabilized cells, and can increase intracellular Ca²⁺ levels. Inhibits calmodulin and activates phospholipase A₂.

Soluble in: Water

Stock concentration: 1 mM (store at –20°C)

Working concentration: 10 to 50 μM

Duration of incubation: 15 min to 1 hr

Microcystin-LR

Cyclic heptapeptide; potent inhibitor of protein phosphatases 1 and 2A (PP-1 and PP-2A). Unlike okadaic acid, microcystin-LR is equally effective on both PP-1 ($K_i = 1.7$ nM) and PP-2A ($K_i = 0.04$ nM). Has no effect on protein kinases, making it useful for reducing the effect of contaminating phosphatases in protein kinase assays. It is not cell-permeant, but can enter hepatocytes via the multispecific organic anion transporter.

Soluble in: DMSO, ethanol, methanol

Stock concentration: 1 mM (store at –20°C)

Working concentration: 1 to 5 μM in hepatic cells; 10 μM in vitro

Duration of incubation: 15 min to 1 hr

MG-132

A potent, reversible and cell-permeant proteasome inhibitor. Reduces the degradation of ubiquitin-conjugated proteins by the 26S complex without affecting its ATPase or isopeptidase activities. Has been used to implicate the proteasome in the breakdown of membrane proteins, including the CFTR, within the ER (see also lactacystin). Inhibits NFκB activation.

Soluble in: DMSO

Stock concentration: 10 to 100 mM (store at –20°C)

Working concentration: 20 to 200 μM

Duration of incubation: 30 min to 24 hr

ML-7 (MLCK inhibitor)

Potent, cell-permeant, and selective inhibitor of myosin light chain kinase ($K_i = 300$ nM). Inhibits protein kinase A ($K_i = 21$ μM) and protein kinase C ($K_i = 42$ μM) at much higher concentrations.

Soluble in: DMSO, ethanol, water

Stock concentration: 100 to 500 mM (store at 4°C protected from light)

Working concentration: 10 to 50 μM

Duration of incubation: 15 min to 1 hr

See Table 1 (Selectivity of Selected Kinase Inhibitors) in the Biomol Catalog and Handbook, 5th ed.

L-Mimosine

An inhibitor of DNA replication that may act by preventing the formation of replication forks. L-mimosine blocks the camptothecin-induced apoptosis of PC12 cells, whereas aphidicolin does not.

Soluble in: Water

Stock concentration: 10 mM (store at room temperature)

Working concentration: 25 to 400 μM

Duration of incubation: 2 to 24 hr

Monensin

Polyether antibiotic that functions as a Na⁺ ionophore. Forms stable complexes with monovalent cations that are able to cross cell membranes. Inhibits glycoprotein secretion by blocking transport through the Golgi. Neutralizes acidic endomembrane compartments. Reduces sphingomyelinase activity.

Soluble in: DMSO, methanol

Stock concentration: 2 to 30 mM (store at 4°C)

Working concentration: 1 to 30 μM

Duration of incubation: Effective within seconds; use up to 3 hr.

Nigericin

Dual antiporter ionophore that acts as a K⁺/H⁺ exchanger. Stimulates Ca²⁺ release from mitochondrial stores by disruption of membrane potential. Allows adjustment of cytoplasmic pH (when combined with K⁺ ionophore such as valinomycin).

Soluble in: Ethanol

Stock concentration: 1 mg/ml (store at 4°C)

Working concentration: 1 to 10 μM

Duration of incubation: Effective within 2 to 5 min

Nocodazole

Has specific antimicrotubular activity for mammalian cells in culture. Promotes microtubule depolymerization. Nanomolar concentrations alter microtubule dynamics and interfere with fibroblast locomotion without affecting polymer levels. Arrests cells in mitosis.

Soluble in: DMSO

Stock concentration: 10 to 30 mM (store at room temperature)

Working concentration: 50 nM (low concentrations) to 30 μM (for effective microtubule depolymerization)

Duration of incubation: For rapid depolymerization of microtubules, preincubate cells on ice with nocodazole for 15 min; use up to 24 hr.

Okadaic acid

Potent inhibitor of protein phosphatases, especially the PP-1 class ($K_i = 10\text{--}15$ nM) and PP-2A class ($K_i = 0.1$ nM), in numerous cell types. Does not affect the activity of acid or alkaline tyrosine phosphatases. It mimics the effects of insulin, enhances neurotransmitter release, causes vasodilation, and is a potent tumor promoter. Induces dispersal of the Golgi apparatus. Okadaic acid is a useful tool for studying cellular processes regulated by serine/threonine phosphorylation.

Soluble in: DMSO, ethanol, methanol

Stock concentration: 1 mM (store at -20°C protected from light)

Working concentration: 50 to 200 nM

Duration of incubation: 15 min to 2 hr

May cause cell rounding. See Technical Note #18 from Alexis Biochemicals for additional information.

Olomoucine

Adenine derivative that acts as a competitive inhibitor for ATP binding and inhibits p34^{cdc2}/cyclin B ($K_i = 7$ μM) as well as several other CDKs at low concentrations. Does not significantly affect the activity of other protein kinases at 1 mM. Inhibits DNA synthesis in IL-2 stimulated T lymphocytes. Also used to synchronize cells in G₁. Can affect microtubule dynamics at higher concentrations.

Soluble in: DMSO

Stock concentration: 100 mM (store in aliquots at -20°C)

Working concentration: Usually 10 μM (up to 100 μM)

continued

Duration of incubation: 15 min to 24 hr, depending on process studied.

See Technical Note #25 from Alexis Biochemicals for additional information.

Ouabain

Selective Na⁺/K⁺-ATPase inhibitor. Causes net influx of Ca²⁺; also initiates the rapid protein kinase C-dependent inductions of early-response genes.

Soluble in: Water

Stock concentration: 100 mM (store at –20°C protected from light)

Working concentration: 1 to 100 μM

Duration of incubation: 30 min to 24 hr

PDMP

Useful tool for studying the effects of cellular glycosphingolipid depletion. Blocks ceramide glucosylation by inhibiting UDP-glucose:ceramide glucosyltransferase (glucosylceramide synthetase). Has antitumor activity; arrests 3T3 cells at both G₁/S and G₂/M. Prevents sensitization of A431 cells to Shiga toxin. Slows the rate of both anterograde vesicular traffic and endocytosis in CHO and BHK-21 cells. Redistributes *cis*-Golgi proteins to the ER.

Soluble in: Ethanol

Stock concentration: 10 to 100 mM (store at 4°C)

Working concentration: 20 to 100 μM

Duration of incubation: 1 to 18 hr, depending on process studied

PD 98059 (MEK Inhibitor)

Potent and selective inhibitor of MAP kinase kinase (MEK or MAPK/ERK kinase). Blocks the activity of MEK, thereby inhibiting the phosphorylation and activation of MAP kinase. Inhibits cell growth and reverses the phenotype of *ras*-transformed 3T3 mouse fibroblasts and rat kidney cells. Inhibits Golgi reassembly in vitro. Cell-permeant.

Soluble in: DMSO

Stock concentration: 50 mM (store at –20°C protected from light)

Working concentration: 10 to 50 μM

Duration of incubation: 30 min to 2 hr

PMSF (phenylmethanesulfonyl fluoride)

Inhibits serine proteases like chymotrypsin, trypsin, and thrombin, as well as acetylcholinesterase and the cysteine protease papain (reversible by DTT treatment). PMSF inhibits serine proteases by sulfonating serine residues at the active site. Does not inhibit metalloproteases, most cysteine proteases, or aspartic proteases.

Soluble in: Anhydrous isopropanol at 35 mg/ml with heating, resulting in a clear to very slightly hazy, colorless to faint yellow solution, or in anhydrous (100%, not 95%) ethanol

Stock concentration: 17 mg/ml (store at room temperature)

Working concentration: 17 to 170 μg/ml

Duration of incubation: 15 min to 1 hr

PMSF is very unstable in the presence of water. The half-life of aqueous PMSF at 25°C at pH 7.0, 7.5, and 8.0 is 110, 55, and 35 min, respectively.

Pepstatin A

Inhibitor of aspartyl proteases, including pepsin, renin, cathepsin D, and HIV-1 protease. Inhibits degradation of ApoB in rat hepatocytes; inhibits cytokine-induced programmed cell death. Accelerates amyloid fibril formation in mice.

Soluble in: DMSO

Stock concentration: 10 to 35 mM (store at –20°C)

Working concentration: 50 to 100 μM in cells

Duration of incubation: 30 min to 2 hr

Pertussis toxin

Protein endotoxin that catalyzes ADP-ribosylation of GDP-bound α subunits of the G proteins G_i , G_o , and G_t . Uncouples G proteins from receptors, thereby keeping the G protein in the inactive state. Used in the study of adenylate cyclase regulation and the role of G_i proteins. Consists of an enzymatically active A protomer subunit (S-1) which possesses both NAD^+ glycohydrolase and ADP-ribosylation activities and a B oligomer subunit (S-2, S-3, S-4, and S-5) that is responsible for cell surface attachment.

Stock solution: Reconstitute commercial preparation in water. Generally, commercially available pertussis toxin (Alexis Biochemicals, Biomol, Calbiochem) contains 50 μg of protein in 10 mM sodium phosphate buffer, pH 7.0/50 mM sodium chloride after being resuspended in 0.5 ml water. It is an insoluble protein that should be shaken gently before use. Store stock solutions at 4°C. Do not freeze.

Working concentration: 50 to 100 ng/ml

Duration of incubation: 2 to 24 hr

Phenylarsine oxide (PAO)

A cell-permeant phosphotyrosine phosphatase inhibitor ($K_i = 18 \mu\text{M}$). Induces a dose-dependent increase in the free Ca^{2+} intracellular concentration in rat peritoneal macrophages, human foreskin fibroblasts, and cultured human endothelial cells, without affecting intracellular stores. Inhibits insulin activation of phosphatidylinositol 3'-kinase. Dithiol cross-linking agent.

Soluble in: DMSO and chloroform

Stock concentration: 50 mM (store at room temperature)

Working concentration: 10 to 50 μM

Duration of incubation: Anywhere from 15 sec to 2 hr

Phorbol esters

An example is phorbol myristate acetate (PMA). Extremely potent tumor promoters. Activate protein kinase C by mimicking diacylglycerols (DAGs), causing a wide range of effects in cells and tissues.

Soluble in: DMSO

Stock concentration: 1 mM (store at -20°C)

Working concentration: 50 nM to 3 μM

Duration of incubation: Cells can be incubated anywhere from 5 min to 48 hr; stable in cells; results in long-term activation of PKC. However, long-term treatment may cause down-regulation of certain PKC subtypes.

See Technical Notes #13 and #14 from Alexis Biochemicals for additional information.

Piceatannol

At low concentrations, inhibits the receptor-mediated activation of the protein tyrosine kinase Syk as compared to the Src family in mast cells and B cells. Inhibits Fc ϵ R1-mediated signaling in RBL-2H3 cells.

Soluble in: DMSO, ethanol

Stock concentration: 10 to 50 mg/ml (store at 4°C protected from light)

Working concentration: 10 to 30 $\mu\text{g}/\text{ml}$

Duration of incubation: 1 hr

Puromycin

Protein synthesis inhibitor. Causes premature release of nascent polypeptide chains by its addition to the growing chain end; structural analog of aminoacyl-tRNA.

Soluble in: Water

Stock concentration: 100 mM (store at -20°C)

Working concentration: 10 to 100 μM

Duration of incubation: 5 min to 1 hr

Rapamycin

Member of a family of macrolide immunosuppressants that binds to and inhibits the peptidylproline *cis-trans* isomerase (PPIase) activity of the immunophilin FKBP12; effectors include a large protein termed FRAP (FKBP12 rapamycin-associated protein). FKBP12-rapamycin binds to but does not inhibit the activity of the Ca^{2+} /calmodulin-dependent serine/threonine phosphatase calcineurin. Blocks signaling, leading to the activation of p70 S6 kinase.

Soluble in: DMSO, methanol, ethanol

Stock concentration: 2 mM (store at -20°C)

Working concentration: 1 to 20 nM

Duration of incubation: 30 min to 1 hr

Sodium azide (NaN_3)

Inhibits mitochondrial ATPases; generally used to deplete ATP levels within cells (often in combination with 50 mM 2-deoxyglucose).

Soluble in: Water

Stock concentration: 1 M (store at room temperature)

Working concentration: 10 to 20 mM

Duration of incubation: 15 to 90 min

Sodium butyrate

A physiologically produced short-chain fatty acid that is generally used to increase expression of transfected genes with viral promoters (inhibits histone deacetylation). Blocks serum-stimulated DNA synthesis via a G_1 block. Induces apoptosis in colon carcinoma cell lines by a p53-independent process. Interferes with signal-transduction processes, including the release of Ca^{2+} from intracellular stores.

Soluble in: Water

Stock concentration: 5 M (store at -20°C)

Working concentration: 2 to 5 mM

Duration of incubation: Usually >12 hr

Sodium orthovanadate

Broad-spectrum inhibitor of protein tyrosine phosphatases. Also inhibits other ATPases, by mimicking the γ phosphate of ATP, including Na^+/K^+ ATPase, acid and alkaline phosphatases, and adenylate cyclase. Vanadate is also a strong inhibitor of lysosomal proteolysis in hepatocytes, the effect being ascribed to a direct inhibition of lysosomal enzymes. Stimulates pp60 (*v-src*) kinase activity in intact cells. It also stimulates amino acid transport activity in skeletal muscle, in a rapid and concentration-dependent manner.

Simple aqueous solutions of $(\text{VO}_4)^{3-}$ ion involve a dozen or more ionic species, both monomeric and oligomeric, whose abundances depend upon pH and $[\text{VO}_4]^{3-}$ concentration. See Fohr et al. (1989) for directions on preparing monomeric orthovanadate. It is unclear how readily vanadate ions enter cells (likely through anion transporters). At the concentration required for maximum inhibition, vanadate may have side effects that limit its application in cell culture. Can be combined with

continued

hydrogen peroxide (forming peroxyvanadate) to facilitate cell entry (combine 100 μl 0.1 M orthovanadate, 900 μl water, and 3.3 μl 30% H_2O_2 ; use 1:100 dilution of this on cells). However, the effect of hydrogen peroxide itself should be tested.

Soluble in: Water

Stock concentration: 100 mM (store at room temperature). To ensure the presence of monomers, the solution is heated to boiling until translucent and the pH is readjusted to 10. Solutions can be divided into aliquots, stored in plastic, and frozen. The orange color observed before boiling is due to decavanadate. At pH 10 this will slowly depolymerize over several hours to the colorless monovanadate. Vanadyl, metavanadate, orthovanadate, and decavanadate will interconvert in aqueous solution without suitable precautions (i.e., control of pH, oxidation state, complexing compounds, and concentration).

Working concentration: 200 μM to 2 mM

Duration of incubation: 15 min to 2 hr

Staurosporine

A potent cell-permeant inhibitor of protein kinases, most potently protein kinase C ($K_i = 0.7$ nM), protein kinase A ($K_i = 7$ nM), and myosin light chain kinase ($K_i = 1.3$ nM). Interaction is with the ATP binding site. Induces apoptosis, but not DNA fragmentation in MCF-7 cells. Arrests normal cells at the G_1 checkpoint.

Soluble in: DMSO, methanol

Stock concentration: 1 mM (store at -20°C protected from light)

Working concentration: 10 to 200 nM

Duration of incubation: 30 min to 24 hr, depending on the assay used

See Table I (*Selectivity of Selected Kinase Inhibitors*) in the *Biomol Catalog and Handbook*, 5th ed.

Taxol (Paclitaxel)

Antitumor and antileukemic agent. Promotes assembly of microtubules and inhibits microtubule disassembly. Bundles microtubules after several hours. Similar to nocodazole, taxol can inhibit microtubule dynamics without affecting overall polymer levels at nanomolar concentrations. Blocks cells at the G_2/M stage. Induces apoptosis in several cell types.

Soluble in: DMSO, methanol

Stock concentration: 20 mM (store at -20°C protected from light)

Working concentration: 10 nM to 20 μM

Duration of incubation: Taxol works rapidly to stabilize microtubules (within several minutes), although bundling takes several hours (this may be facilitated by first depolymerizing the polymer pool with ice treatment and/or washout of low levels of nocodazole)

Thapsigargin

Potent inhibitor of sarcoplasmic reticulum (SR)/endoplasmic reticulum (ER) Ca^{2+} -ATPases. Induces IP_3 -independent release of Ca^{2+} from the endoplasmic reticulum, causing an increase in intracellular Ca^{2+} . Depletion of Ca^{2+} from intracellular stores induces stress response and defects in protein folding and processing. Induces apoptosis in rat thymocytes and in human hepatoma cells. Irreversible.

Soluble in: DMSO, ethanol

Stock concentration: 1 mM (store at -20°C in aliquots, protect from light)

Working concentration: 20 nM to 1 μM

Duration of incubation: 15 sec to 2 min produces rise in intracellular Ca^{2+} ; longer incubations may be used, depending on effect to be analyzed

See Technical Note #15 from Alexis Biochemicals for additional information.

Trifluoperazine

Calmodulin antagonist. At 10 μ M, potentiates rise in cytosolic calcium induced by agonists. Antagonizes calmodulin at higher concentrations. Inhibits IL-2 production in activated Jurkat T cells. Structurally distinct from W-7.

Soluble in: Water (dihydrochloride salt)

Stock concentration: 10 mM (store at 4°C)

Working concentration: 10 to 50 μ M

Duration of incubation: 10 min to 3 hr

Tunicamycin

Nucleoside antibiotic that inhibits N-linked glycosylation, specifically by blocking the transfer of *N*-acetylglucosamine-1-phosphate from UDP-*N*-acetylglucosamine to dolichol monophosphate; has no effect on other glycosylation forms, such as Ser/Thr-linked oligosaccharides. Causes misfolding and retention of numerous glycoproteins in the endoplasmic reticulum, which induces synthesis of ER chaperones.

Soluble in: DMSO, ethanol

Stock concentration: 10 mg/ml (store at -20°C)

Working concentration: 1 to 10 μ g/ml

Duration of incubation: Cells can be treated from 1 to 24 hr

Tyrphostins

Large family of protein tyrosine kinase inhibitors. Inhibits receptors such as EGF receptor and PDGF receptor.

Soluble in: DMSO, ethanol

Stock concentration: 20 to 100 mM (store at -20°C protected from light)

Working concentration: 10 to 150 μ M

Duration of incubation: Anywhere from 1 to 48 hr

See Technical Note #22 from Alexis Biochemicals for additional information. Also see Table II (Selectivity of Tyrosine Protein Kinase Inhibitors) in the Biomol Catalog and Handbook, 5th ed.

Valinomycin

Potassium ionophore. Decreases ATP synthesis by decreasing membrane potential at mitochondrial membranes. Reported to inhibit NGF-induced neuronal differentiation. Used with nigericin to adjust cytoplasmic pH.

Soluble in: DMSO

Stock concentration: 1 mM (store at room temperature)

Working concentration: 1 to 20 μ M

Duration of incubation: Normally 15 min to 2 hr

Vinblastine

Vinca alkaloid; antitumor drug. Inhibitor of cell proliferation that acts by disrupting spindle microtubule function. Binds tubulin and suppresses microtubule dynamics. Depolymerizes microtubules at higher concentrations. Induces apoptosis in cultured hepatocytes and human lymphoma cells. Similar, but not identical effects observed with another vinca alkaloid, vincristine.

Soluble in: Methanol

Stock concentration: 20 mM (store at 4°C protected from light)

Working concentration: <10 nM (suppresses microtubule dynamics); 100 nM to 1 μ M (depolymerizes microtubules); >10 μ M (forms non-microtubule polymers)

Duration of incubation: 30 min to 24 hr

W-7

Member of a family of calmodulin antagonists, inhibiting calcium/calmodulin regulated enzyme activity. W-7 inhibits the Ca^{2+} /calmodulin-induced activation of myosin light chain kinase ($K_i = 51 \mu\text{M}$) and phosphodiesterase ($K_i = 28 \mu\text{M}$). Inhibits membrane tubulation in cells treated with brefeldin A.

Soluble in: Water

Stock concentration: 10 to 100 mM (store at 4°C protected from light)

Working concentration: 10 to 100 μM

Duration of incubation: 30 min to 2 hr

Wortmannin

Selective and potent phosphatidylinositol 3-kinase (PI 3-kinase) inhibitor; forms covalent associations with the kinases and is, therefore, irreversible. Abolishes PDGF-mediated $\text{Ins}(3,4,5)\text{P}_3$ formation in fibroblasts. Blocks the metabolic effects of insulin in isolated rat adipocytes without affecting the insulin receptor tyrosine kinase activity. Inhibits the formation of constitutive transport vesicles from the TGN. In human fetal undifferentiated cells, wortmannin induces morphological and functional endocrine differentiation.

Soluble in: DMSO

Stock concentration: 1 to 20 mM (store at -20°C in aliquots, protected from light)

Working concentration: 10 to 100 nM

Duration of incubation: 30 min to 4 hr

At nanomolar concentrations, wortmannin is specific to PI 3-kinases, while at higher concentrations other kinases are affected. Once diluted into aqueous solutions, wortmannin is less stable and should be made fresh daily.

COMMONLY USED REAGENTS AND EQUIPMENT

BUFFERS AND STOCK SOLUTIONS

This collection describes the preparation of buffers and reagents used in the manipulation of nucleic acids and proteins (see Table A.2.1). When preparing solutions, use deionized, distilled water and reagents of the highest grade available. Sterilization—by filtration through a 0.22- μm filter or by autoclaving—is recommended for most applications. Recipes for the following can be found elsewhere in the manual: culture media (UNIT 1.1), antibiotics (Table 1.4.1), lactose analogs (Table 1.4.2), and enzyme buffers (UNIT 3.4).

CAUTION: *Handle strong acids and bases carefully.*

Table A.2.1 Molarities and Specific Gravities of Concentrated Acids and Bases

Acid/base	Molecular weight	% by weight	Molarity (approx.)	1 M solution (ml/liter)	Specific gravity
<i>Acids</i>					
Acetic acid (glacial)	60.05	99.6	17.4	57.5	1.05
Formic acid	46.03	90	23.6	42.4	1.205
		98	25.9	38.5	1.22
Hydrochloric acid	36.46	36	11.6	85.9	1.18
Nitric acid	63.01	70	15.7	63.7	1.42
Perchloric acid	100.46	60	9.2	108.8	1.54
		72	12.2	82.1	1.70
Phosphoric acid	98.00	85	14.7	67.8	1.70
Sulfuric acid	98.07	98	18.3	54.5	1.835
<i>Bases</i>					
Ammonium hydroxide	35.0	28	14.8	67.6	0.90
Potassium hydroxide	56.11	45	11.6	82.2	1.447
Potassium hydroxide	56.11	50	13.4	74.6	1.51
Sodium hydroxide	40.0	50	19.1	52.4	1.53

Acid precipitation solution

1 M HCl

0.1 M sodium pyrophosphate

Nucleic acids can also be precipitated with a 10% (w/v) solution of trichloroacetic acid (TCA); however, this recipe is cheaper, easier to prepare, and just as efficient.

Ammonium acetate, 10 M

Dissolve 385.4 g ammonium acetate in 150 ml H₂O

Add H₂O to 500 ml

BBS (BES-buffered solution), 2×

50 mM *N,N*-bis(2-hydroxyethyl)-2-aminoethanesulfonic acid (BES; Calbiochem)

280 mM NaCl

1.5 mM Na₂HPO₄, pH 6.95

800 ml H₂O

Adjust pH to 6.95 with room temperature 1 M NaOH

H₂O to 1 liter

continued

Contributed by David D. Moore

Current Protocols in Molecular Biology (1996) A.2.1-A..2.8

Copyright © 2000 by John Wiley & Sons, Inc.

Filter sterilize through a 0.45- μ m nitrocellulose filter (Nalgene)
Store in aliquots at -20°C (can be frozen and thawed repeatedly)

The pH of this solution is critical (pH 6.95 to 6.98). When a new batch of 2 \times BES buffer is prepared, its pH should be checked against a reference stock prepared (and tested) earlier.

CaCl₂, 1 M

147 g CaCl₂·2H₂O
H₂O to 1 liter

Denhardt solution, 100 \times

10 g Ficoll 400
10 g polyvinylpyrrolidone
10 g bovine serum albumin (Pentax Fraction V; Miles Laboratories)
H₂O to 500 ml
Filter sterilize and store at -20°C in 25-ml aliquots

Dithiothreitol (DTT), 1 M

Dissolve 15.45 g DTT in 100 ml H₂O
Store at -20°C

EDTA (ethylenediamine tetraacetic acid), 0.5 M (pH 8.0)

Dissolve 186.1 g Na₂EDTA·2H₂O in 700 ml H₂O
Adjust pH to 8.0 with 10 M NaOH (~50 ml)
Add H₂O to 1 liter

Ethidium bromide, 10 mg/ml

Dissolve 0.2 g ethidium bromide in 20 ml H₂O
Mix well and store at 4 $^{\circ}\text{C}$ in dark

CAUTION: *Ethidium bromide is a mutagen and must be handled carefully.*

HBSS (Hanks balanced salt solution)

5.4 mM KCl
0.3 mM Na₂HPO₄
0.4 mM KH₂PO₄
4.2 mM NaHCO₃
1.3 mM CaCl₂
0.5 mM MgCl₂
0.6 mM MgSO₄
137 mM NaCl
5.6 mM D-glucose
0.02% phenol red (optional)
Add H₂O to 1 liter and adjust pH to 7.4

HBSS can be purchased from Biofluids or Whittaker.

HBSS may be made or purchased without CaCl₂ and MgCl₂. These are optional components that usually have no effect on an experiment. In some cases, however, their presence may be detrimental to a procedure. Consult the individual protocol to see if the presence or absence of these components is recommended in the materials list.

HCl, 1 M

Mix in the following order:
913.8 ml H₂O
86.2 ml concentrated HCl

HeBS (HEPES-buffered saline) solution, 2×

16.4 g NaCl

11.9 g HEPES acid

0.21 g Na₂HPO₄

800 ml H₂O

Titrate to pH 7.05 with 5 M NaOH

Add H₂O to 1 liter

Filter sterilize through a 0.45- μ m nitrocellulose filter

Test for transfection efficiency and store at -20°C in 50-ml aliquots

An exact pH is extremely important for efficient transfection. The optimal pH range is 7.05 to 7.12.

KCl, 1 M

74.6 g KCl

H₂O to 1 liter

MgCl₂, 1 M

20.3 g MgCl₂·6H₂O

H₂O to 100 ml

MgSO₄, 1 M

24.6 g MgSO₄·7H₂O

H₂O to 100 ml

MOPS buffer

0.2 M MOPS [3-(*N*-morpholino)propanesulfonic acid], pH 7.0

0.5 M sodium acetate

0.01 M EDTA

Store in the dark and discard if it turns yellow.

NaCl, 5 M

292 g NaCl

H₂O to 1 liter

NaOH, 10 M

Dissolve 400 g NaOH in 450 ml H₂O

Add H₂O to 1 liter

PBS (phosphate-buffered saline)

10× stock solution, 1 liter:

80 g NaCl

2 g KCl

11.5 g Na₂HPO₄·7H₂O

2 g KH₂PO₄

Working solution, pH ~7.3:

137 mM NaCl

2.7 mM KCl

4.3 mM Na₂HPO₄·7H₂O

1.4 mM KH₂PO₄

Potassium acetate buffer, 0.1 M

Solution A: 11.55 ml glacial acetic acid/liter (0.2 M).

Solution B: 19.6 g potassium acetate (KC₂H₃O₂)/liter (0.2 M).

Referring to Table A.2.2 for desired pH, mix the indicated volumes of solutions A and B, then dilute with H₂O to 100 ml.

This may be made as a 5- or 10-fold concentrate by scaling up the amount of potassium acetate in the same volume. Acetate buffers show concentration-dependent pH changes, so check concentrate pH by diluting an aliquot to the final concentration.

To prepare buffers with pH intermediate between the points listed in Table A.2.2, prepare closest higher pH, then titrate with solution A.

Table A.2.2 Preparation of 0.1 M Sodium and Potassium Acetate Buffers^a

Desired pH	Solution A (ml)	Solution B (ml)
3.6	46.3	3.7
3.8	44.0	6.0
4.0	41.0	9.0
4.2	36.8	13.2
4.4	30.5	19.5
4.6	25.5	24.5
4.8	20.0	30.0
5.0	14.8	35.2

^aAdapted by permission from CRC (1975).

SDS electrophoresis buffer, 5×

15.1 g Tris base
72.0 g glycine
5.0 g SDS
H₂O to 1000 ml
Dilute to 1× or 2× for working solution, as appropriate
Store up to 1 month at 0° to 4°C

Do not adjust the pH of the stock solution, as the solution is pH 8.3 when diluted.

SED (standard enzyme diluent)

20 mM Tris·Cl, pH 7.5
500 µg/ml bovine serum albumin (Pentax Fraction V)
10 mM 2-mercaptoethanol
Store up to 1 month at 4°C

Sodium acetate, 3 M

Dissolve 408 g sodium acetate·3H₂O in 800 ml H₂O
Add H₂O to 1 liter
Adjust pH to 4.8 or 5.2 (as desired) with 3 M acetic acid

Sodium acetate buffer, 0.1 M

Solution A: 11.55 ml glacial acetic acid/liter (0.2 M).
Solution B: 27.2 g sodium acetate (NaC₂H₃O₂·3H₂O)/liter (0.2 M).
Referring to Table A.2.2 for desired pH, mix the indicated volumes of solutions A and B, then dilute with H₂O to 100 ml. (See Potassium acetate buffer recipe for further details.)

Sodium phosphate buffer, 0.1 M

Solution A: 27.6 g NaH₂PO₄·H₂O per liter (0.2 M).
Solution B: 53.65 g Na₂HPO₄·7H₂O per liter (0.2 M).
Referring to Table A.2.3 for desired pH, mix the indicated volumes of solutions A and B, then dilute with H₂O to 200 ml. (See Potassium phosphate buffer recipe for further details.)

SSC (sodium chloride/sodium citrate), 20×

3 M NaCl (175 g/liter)
0.3 M Na₃citrate·2H₂O (88 g/liter)
Adjust pH to 7.0 with 1 M HCl

STE buffer

10 mM Tris·Cl, pH 7.5
10 mM NaCl
1 mM EDTA, pH 8.0

TAE (Tris/acetate/EDTA) electrophoresis buffer

<i>50× stock solution:</i>	<i>Working solution, pH ~8.5:</i>
242 g Tris base	40 mM Tris·acetate
57.1 ml glacial acetic acid	2 mM Na ₂ EDTA·2H ₂ O
37.2 g Na ₂ EDTA·2H ₂ O	
H ₂ O to 1 liter	

TBE (Tris/borate/EDTA) electrophoresis buffer

10× stock solution, 1 liter:
108 g Tris base (890 mM)
55 g boric acid (890 mM)
40 ml 0.5 M EDTA, pH 8.0 (see recipe; 20 mM)

TE (Tris/EDTA) buffer

10 mM Tris·Cl, pH 7.4, 7.5, or 8.0 (or other pH; see recipe)
1 mM EDTA, pH 8.0

TEA (triethanolamine) solution

50 mM triethanolamine, pH ~11.5
0.1% Triton X-100
0.15 M NaCl

Add Triton X-100 as a 10% stock sterilized by Millipore filtration and stored in the dark to prevent photooxidation (stock is stable 5 years at room temperature).

TEN (Tris/EDTA/NaCl) solution

40 mM Tris·Cl, pH 7.5
1 mM EDTA, pH 8.0
150 mM NaCl
Store up to 6 months at room temperature

TM buffer, 10×

100 mM Tris·Cl, pH 8.0
100 mM MgCl₂

Tris-buffered saline (TBS)

100 mM Tris·Cl, pH 7.5
0.9% (150 mM) NaCl
Store up to several months at 4°C

Tris·Cl [tris(hydroxymethyl)aminomethane], 1 M

Dissolve 121 g Tris base in 800 ml H₂O
Adjust to desired pH with concentrated HCl
Mix and add H₂O to 1 liter

Approximately 70 ml of HCl is needed to achieve a pH 7.4 solution, and approximately 42 ml for a solution that is pH 8.0.

IMPORTANT NOTE: *The pH of Tris buffers changes significantly with temperature, decreasing approximately 0.028 pH units per 1°C. Tris-buffered solutions should be adjusted to the desired pH at the temperature at which they will be used. Because the pK_a of Tris is 8.08, Tris should not be used as a buffer below pH ~7.2 or above pH ~9.0.*

TTBS (Tween 20/TBS)

0.1% Tween 20 in Tris-buffered saline (TBS; see recipe)
Store up to several months at 4°C

EQUIPMENT

Special equipment is also itemized in the materials list of each protocol. We have not attempted to list all items required for each procedure, but rather have noted those items that might not be readily available in the laboratory or that require special preparation. Listed below are standard pieces of equipment in the modern molecular biology laboratory, i.e., items used extensively in this manual and thus not included in the individual materials lists.

Autoclave

Balances, analytical and preparative

Bench protectors, plastic-backed (including “blue pads”)

Centrifuges a low-speed (20,000 rpm) refrigerated centrifuge and an ultracentrifuge (20,000 to 80,000 rpm) are required for many procedures. Vertical ultracentrifuge rotors are very convenient for preparing plasmid DNA. At least one microcentrifuge that holds stan-

dard 1.5-ml microcentrifuge tubes is essential. It is also useful to have a large-capacity, low-speed centrifuge (such as the Beckman J-6M) for spinning down large bacterial cultures and a tabletop swinging-bucket centrifuge with adapters for spinning 96-well microtiter plates.

NOTE: *Centrifuge speeds are provided as $\times g$ or as rpm (with example rotor models) throughout the manual. Readers should consult the nomograms in APPENDIX 1G to convert these speeds to their own rotor models.*

Computer (PC or Macintosh) and printer

Darkroom and developing tanks or X-Omat automatic X-ray film developer.

Dry ice

Filtration apparatus for collecting acid precipitates on nitrocellulose filters or membrane.

Flasks, glass (e.g., Erlenmeyer, Florence)

Fraction collector

Freezers and refrigerators for 4°, -20°, and -70°C incubation and storage.

Fume hood

Geiger counter

Gel dryer

Gel electrophoresis equipment at least one full-size horizontal apparatus and one horizontal minigel apparatus, two sequencing gel setups for each person engaged in large-scale sequencing projects, one vertical gel apparatus for polyacrylamide protein gels, and specialized equipment for two-dimensional protein gels as required.

Heating blocks thermostat-controlled metal heating blocks that hold test tubes and/or microcentrifuge tubes are very convenient for carrying out enzymatic reactions.

Ice maker

Incubator (37°C) for growing bacteria. We recommend an incubator large enough to hold a “tissue culture” roller drum that can be used to grow 5-ml cultures in standard 18 \times 150 mm test tubes. A convenient and durable tube roller is made by New Brunswick Scientific.

Incubator/shaker(s) an enclosed shaker (such as the New Brunswick Controlled Environment Incubator Shaker) that can spin 4-liter flasks is essential for growing 1-liter *E. coli* cultures. A rotary shaking water bath (New Brunswick R76) is useful for growing smaller cultures in flasks.

Light box for viewing autoradiograms.

Liquid nitrogen

Magnetic stirrers (with heater is useful).

Microcentrifuge, Eppendorf-type, maximum speed 12,000 to 14,000 rpm

Microcentrifuge tubes, 1.5-ml

Microwave oven to melt agar and agarose.

Mortar and pestle

Paper cutter large size, for 46 cm \times 57 cm Whatman sheets.

Paper towels

Parafilm

Pasteur pipets and bulbs

PCR machine (Perkin-Elmer or MJ Research)

pH meter

pH paper

Pipettors that use disposable tips and dispense 1 to 1000 μ l. It is best to have a set for each full-time researcher.

Plastic wrap (e.g., Saran Wrap)

Polaroid camera and UV transilluminator for taking photographs of stained gels.

Policemen, rubber or plastic

Power supplies 300-volt power supplies are sufficient for agarose gels; 2000-volt power supply required for DNA sequencing.

Racks, test tube

Radiation shield (Lucite or Plexiglas)

Radioactive ink

Radioactive waste containers, for liquid and solid waste

Refrigerator, 4°C

Safety glasses

Scalpels and blades

Scintillation counter

Scissors

Seal-A-Meal bag sealer or equivalent

Shakers, orbital and platform, room temperature or 37°C

Spectrophotometer UV and visible

Speedvac evaporator (Savant)

Tissue culture equipment CO₂ incubator, phase contrast microscope, liquid nitrogen storage container, and laminar flow hood.

UV cross-linker (e.g., Stratalinker, Stratagene)

UV light sources, long- and short-wave

UV transilluminator

Vacuum desiccator/lyophilizer

Vacuum oven

Vortex mixers

Water baths at least two with 80°C capacity

Water purification equipment or glass distillation apparatus to purify all water used in molecular biology experiments.

X-ray film cassettes and intensifying screens

COMMONLY USED TECHNIQUES IN BIOCHEMISTRY AND MOLECULAR BIOLOGY

APPENDIX 3

The protocols in this appendix have been included because of their universal application in molecular biology experiments. Other commonly used protocols can be found in early chapters of this manual, for example, growing bacteria (*UNITS 1.2 & 1.3*), plasmid preps (*UNITS 1.6 & 1.7*), CsCl/ethidium bromide gradient purification (*UNITS 1.7 & 1.13*), phenol extraction and alcohol precipitation (*UNIT 2.1*), acid precipitation (*UNIT 3.4*), agarose gel electrophoresis (*UNIT 2.5*), restriction digests (*UNIT 3.1*), and radiolabeling DNA (*UNIT 3.5*). See individual chapter tables of contents for complete listings of protocols.

Detection and Quantitation of Radiolabeled Proteins and DNA in Gels and Blots

APPENDIX 3A

This unit presents procedures for visualizing and quantitating radiolabeled proteins or DNA separated by polyacrylamide gel electrophoresis (PAGE; *UNITS 2.5A & 2.7; UNIT 10.2*) or affixed to filter membranes. Autoradiography (see Basic Protocol) is the most common method by which this is accomplished, and X-ray film is the traditional recording medium. The use of autoradiography with gels requires that the gel be dried prior to being placed in contact with the film (see Support Protocol 1). The decay of radioactive materials within the dried gel or filter leaves an image on the film that reflects its distribution in the sample. Film images can be analyzed by densitometry (see Support Protocol 4) to obtain a relative quantitative measure of the amount of radioactivity in the sample.

The use of X-ray films for autoradiography, however, suffers from two drawbacks: lack of sensitivity and a limited linear range over which the image density reflects the amount of radioactivity. Lack of sensitivity can be overcome by fluorography (see Alternate Protocol 1) or by the use of intensifying screens (see Support Protocol 2), both of which enhance the radioactive signal. Ensuring that the exposure is within a linear range requires careful controls; film is often preflashed (see Support Protocol 3) to increase the linear measurement range for weakly radioactive samples, and it is important to ensure that the film not be saturated to attain strong radioactive signals. Sensitivity and linear ranges of measurement can be greatly extended by using a phosphor imaging system (see Alternate Protocol 2). Phosphor imaging also makes it much faster and easier to quantify radioactive samples.

To enhance radioactive signals, solid-state scintillation is frequently employed to convert the energy released by radioactive molecules to visible light. This is accomplished in several different ways. In fluorography (see Alternate Protocol 1), organic scintillants are incorporated into the sample to increase the proportion of emitted energy detected from low-energy β particles (e.g., from ^3H , ^{14}C , and ^{35}S). Another method uses high-density fluorescent “intensifying screens” (see Support Protocol 2), which are placed next to the sample and used to capture the excess energy of γ rays (e.g., those produced by ^{125}I) and high-energy β particles (e.g., from ^{32}P).

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated areas, following the guidelines provided by your local radiation safety officer (also see *APPENDIX 1F*).

Supplement 48

AUTORADIOGRAPHY

In autoradiography, X-ray film is used to visualize and quantitate radioactive molecules that have been electrophoresed through agarose or polyacrylamide gels (*UNITS 2.5A & 2.7; UNIT 10.2*), hybridized to filters (e.g., immunoblots; *UNIT 6.2*), or chromatographed through paper or thin-layer plates. A photon of light or a β particle or γ ray released from a radioactive molecule “activate” silver bromide crystals on the film emulsion. This renders them capable of being reduced through the developing process to form silver metal (a “grain”). The silver grains on the film form the image.

The choice of film is critical for autoradiography. Double-coated films (e.g., Kodak X-Omat AR and Fuji RX) contain two emulsion layers on either side of a polyester support and are most commonly used for autoradiography (Laskey and Mills, 1977). Double-coated films are ideal for detecting the high-energy β particles emitted by ^{32}P and ^{125}I , since they can penetrate the polyester support and expose both emulsion layers. These films are normally used with calcium tungstate (CaWO_4) intensifying screens at reduced temperature (-70°C); they are highly sensitive to the blue light emitted by these screens. The green-light-sensitive BioMax MS film (Kodak) is a double-coated film spectrally matched to the blue- and green-light-emitting BioMax MS intensifying screen. The BioMax MS film/BioMax MS intensifying screen system normally gives greatest sensitivity to ^{32}P (four times greater than that of X-Omat AR film with CaWO_4 screens).

Single-coated films, containing one emulsion layer (e.g., Kodak BioMax MR), are optimized for direct-exposure techniques with medium-energy radioisotopes (e.g., ^{14}C , ^{35}S , and ^{33}P , but not ^3H). The majority of β particles emitted by these isotopes cannot pass through the polyester support of double-coated films, and therefore the emulsion layer on the other side of the film is useless. Even though direct exposure with single-coated films gives better clarity for medium-energy isotopes, single-coated films often require longer exposure times. Fluorography, therefore, is often used to enhance sensitivity. The blue-light-sensitive double-coated X-Omat AR film is generally used for fluorography with 2,5-diphenyloxazole (PPO) which emits at 388 nm; sodium salicylate, which emits at 420 nm; and commercial fluorographic solutions and sprays (e.g., from Amersham and DuPont NEN), which emit light in the blue end of the spectrum.

Materials

Dried gel (see Support Protocol 1) or filter (e.g., from immunoblotting; *UNIT 10.8*)

Developer: Kodak developer and replenisher, prepared according to the manufacturer’s instructions, 18° to 20°C

Fixer: Kodak fixer and replenisher, prepared according to the manufacturer’s instructions, 18° to 20°C

Metal film cassette or paper film cassette with particle-board supports and metal binder clips

Plastic wrap (e.g., Saran Wrap)

X-ray film (optionally preflashed; see Support Protocol 3)

Trays to hold film processing solutions

Clips for hanging film

1. In a darkroom illuminated with a safelight, place the sample (e.g., dried gel or filter) in the film cassette. Cover the sample with plastic wrap to prevent it from sticking to the film and contaminating the cassette with radioactivity.

The safelight should be a bulb of <15 W that is equipped with a Kodak GBX-2 red filter (or equivalent). The safelight should be located 1.2 meters from the film.

Fluorescent glow-in-the-dark ink (available at craft stores) is a convenient way to mark samples exposed to film. The ink can be spread on adhesive labels, which in turn are placed

Figure A.3A.1 Autoradiography setup: intensifying screen, film, and sample in film cassette.

on the plastic wrap around the edge of the sample. If exposed to light prior to autoradiography, the ink will fluoresce and expose the film, making it possible to orient the film image on the dried gel after developing.

2. Place a sheet of X-ray film on top of the sample, then close and secure the film cassette (see Fig. A.3A.1).

If preflashed film is used for direct exposure (see Support Protocol 3), the exposed side should face the sample. Preflashed film should be used if sample is weakly radioactive or if quantitation of the radioactivity is desired. For single-coated film, the emulsion layer should face the sample.

If a paper cassette is used, particle-board supports the same size as the cassette should be placed on either side and secured with the metal binder clips. This will ensure that the sample and film are held in contact and do not shift during exposure.

3. Expose the film for the desired length of time and at the appropriate temperature.

Time of exposure will depend on the strength of the radioactivity in the sample and, in most cases, will have to be determined empirically by making multiple exposures for different lengths of time. To help estimate exposure time, a Geiger counter can often be used to detect the relative amount of radioactivity in a sample. With experience, this can help alleviate the trial and error often associated with obtaining the optimum exposure. Time of exposure and use of internal controls are particularly important if quantitative comparisons between experiments are desired.

4. After exposure, return cassette to the darkroom and remove film for developing.

If the film was exposed at -70°C , allow the cassette to come to room temperature before developing. This will avoid static discharge, which can cause black dots or stripes on the autoradiogram.

Automated film developers are also available and can be used to develop the film.

5. Immerse the film for 5 min in 18° to 20°C developer, then wash 1 min in running water at room temperature.

Shorter periods of time in developer will yield a lighter image. The amount of time in developer, therefore, can be used to roughly control intensity of the image.

6. Immerse the film for 5 min in 18° to 20°C fixer, then wash for 15 min in running water.

7. Hang the film to dry.

The orientation of the film with respect to the gel can be determined by the images of the fluorescent markers.

PREPARING GELS FOR AUTORADIOGRAPHY

Polyacrylamide gels containing radiolabeled proteins or DNA should be dried before exposure to film. Protein gels should be fixed prior to drying to prevent the gel from sticking to the film, improve the sharpness of the image, and increase sensitivity slightly. However, if the specific activity of the sample is high or the detection method is sensitive (e.g., where a phosphor imager is used; see Alternate Protocol 2), then fixing and drying the gel may not be necessary. Gel dryers are available from a number of manufacturers (e.g., Bio-Rad; most use heat and a vacuum to accelerate the drying process).

Materials

Polyacrylamide gel

Fixing solution: 10% glacial acetic acid/20% methanol (v/v) in water *or* 3% glycerol/10% glacial acetic acid/20% methanol (v/v/v) in water

Protein (for gels with $\geq 15\%$ acrylamide or thicker than 1.5 mm: 3% glycerol/10% glacial acetic acid/20% methanol (v/v/v) in water

Glass dish

Rotary shaker

Filter paper (Whatman 3MM) in sheets at least 1 to 2 cm larger than gel

UV-transparent plastic wrap (e.g., Saran Wrap)

Gel dryer with vacuum pump

1. After electrophoresis, remove the gel and the supporting glass plates from the electrophoresis apparatus and place in a glass dish. Carefully remove the upper glass plate by gently prying apart the corners with a metal spatula. Make a notch in the upper right-hand corner of the gel for orientation.

Since the gel contains radiolabeled protein or DNA, be sure to follow the necessary guidelines for handling radioactivity (see APPENDIX 1F). Everything that comes in contact with the gel is potentially radioactive.

- 2a. *For DNA gels:* Proceed to step 4.

- 2b. *For protein gels with $< 15\%$ acrylamide and < 1.5 mm thick:* Place the glass dish in a fume hood and pour enough fixing solution (without glycerol) into the dish to cover the gel. Place the dish on a rotary shaker and gently rotate until 5 min after all of the blue color from the bromphenol blue in the sample buffer (if used) has disappeared (~30 min total).

The bromphenol blue typically used in PAGE sample buffer will turn yellow as the acidic fixing solution diffuses into the gel.

During fixing, the gel will typically slide off the lower glass plate, which can be removed.

- 2c. *For protein gels with $\geq 15\%$ acrylamide or > 1.5 mm thick:* Fix gel as in step 2b, but soak 1 hr in alternative fixing solution containing 3% glycerol.

The glycerol should help prevent cracking during drying.

3. Pour off the fixing solution and rinse the gel for a few minutes with deionized water. Drain.

CAUTION: Remember that solutions which come in contact with the gel are potentially radioactive.

4. Position the gel in the center of the glass dish. Place a sheet of Whatman 3MM filter paper, at least 1 to 2 cm larger than the gel, over the gel.

The gel will stick to the filter paper, which will allow it to be lifted and turned over with the gel side facing up.

5. Cover gel with plastic wrap. Smooth the wrap with a piece of tissue paper to remove any air bubbles or wrinkles.
6. Place a piece of filter paper on the gel support of the gel dryer to prevent contamination of the dryer by radioactivity.
7. Place the filter paper/gel/plastic wrap sandwich on the filter paper in the gel dryer with the plastic sheet facing up.
8. Position the rubber sealing gasket of the gel dryer over the gel. Set the appropriate heat setting on the gel dryer (normally 80°C; 60°C if the gel contains a fluor). Apply the vacuum and allow the gel to dry (typically 2 hr for a gel of 1 mm thickness).

Removing the gel before it is completely dry can lead to cracking; it is therefore not a good idea to rush the drying process. A rough indication of whether the gel is dry can be obtained by feeling the gel under the sealing gasket. If the gel is dry, it should be warm over the entire surface.
9. Remove gel from dryer and proceed with autoradiography (see Basic Protocol).

USE OF INTENSIFYING SCREENS

Intensifying screens enhance the film image generated by radioactive molecules (Laskey and Mills, 1977; Laskey, 1980). They are used strictly in conjunction with strong β -emitting isotopes such as ^{32}P or γ -emitting isotopes such as ^{125}I . Emissions from these forms of radiation will frequently pass completely through a film, but they can be absorbed by an intensifying screen that fluoresces and exposes the film with multiple photons of light. While an intensifying screen will substantially enhance the film image as compared with direct exposure (Table A.3A.1), some loss of image resolution will occur due to light scatter. Intensifying screens are distributed by most laboratory supply companies (e.g., Fisher, Sigma, and Kodak).

As shown in Figure A.3A.1, the film should be placed between the sample and the intensifying screen. Preflashed film (see Support Protocol 3) should be used if the sample is weakly radioactive or if quantitation of the radioactivity is desired. The preflashed side of the film should be placed adjacent to the intensifying screen. For very weakly radioactive samples, a second screen can be placed on the other side of the radioactive sample (i.e., screen, then sample, then film, then screen), but this causes further light-scatter and loss of resolution. Also, the sample and sample support must be sufficiently transparent to allow light from the second screen to reach the film. The film should be exposed at -70°C to stabilize the silver bromide crystals activated by the radioactivity or the light emitted from the screen.

Table A.3A.1 Different Methods for Isotope Detection and Their Sensitivities^a

Isotope	Method ^b	Sensitivity ^c	Enhancement over direct autoradiography ^d
^{125}I	S	100	16
^{32}P	S	50	10.5
^{14}C	F	400	15
^{35}S	F	400	15
^3H	F	8000	>100

^aExposures conducted at -70°C using preexposed film.

^bS, intensifying screen; F, fluorography using PPO.

^cDefined as dpm/cm^2 required for detectable image ($A_{540} = 0.02$) in 24 hr.

^dDirect autoradiography for comparison was performed on Kodirex film (Laskey, 1980).

SUPPORT PROTOCOL 2

Commonly Used Techniques

A.3A.5

PREFLASHING (PREEXPOSING) FILM

Silver bromide crystals activated by light, β particles, or γ rays are highly unstable and quickly revert back to their stable form. The absorption of several photons increases their stability but does not ensure development; approximately five photons of light are required to obtain a 50% probability that any single silver bromide crystal will be developed during film processing. This inefficiency means that film images produced by very low levels of exposure will be disproportionately faint. Two measures can be taken to maximize efficiency and linearity of exposure at the low levels commonly encountered in ordinary use. First, the film should be preexposed to a hypersensitizing flash of light, which provides several photons per silver bromide crystal and stably activates them without providing enough exposure to cause them to become developed. This allows a linear relationship to be drawn between the film image and the amount of radioactivity in the sample. Second, film exposure should be conducted at low temperatures (-70°C) to slow the reversion of activated silver bromide crystals to their stable form (Laskey and Mills, 1975).

Film can be hypersensitized by exposure to a flash of light (<1 msec) provided by a photographic flash unit or a stroboscope before being placed onto the radioactive sample for exposure of the autoradiogram (Laskey and Mills, 1975, 1977). As the optimal light intensity required for preexposure varies with the type of film and the flash unit being used, the ideal exposure is best determined empirically as described below.

Materials

Stroboscope or flash unit (e.g., Auto 22 Electronic Flash from Vivitar or Sensitize Pre-Flash from Amersham Pharmacia Biotech)
Neutral-density filter (Kodak)
Orange filter (Wratten 22; Kodak)
X-ray film
Spectrophotometer

1. Cover the stroboscope or flash unit with the neutral-density and orange filters.

This serves to decrease the intensity of emitted light, particularly the blue wavelengths to which X-ray films are most sensitive. Filters are not required for the Amersham flash unit.

2. Place the film perpendicular to the light source at a distance of ≥ 50 cm to ensure uniform illumination.
3. Expose a series of test films for different flash lengths, then develop them (see Basic Protocol).

An uneven fog level on film can be remedied by placing a porous paper diffuser, such as a piece of Whatman no. 1 filter paper, between the film and the light source.

4. Cut the films into pieces that fit into a cuvette holder of a spectrophotometer and measure the absorbance at 540 nm.

Choose an exposure time that causes the absorbance of the preexposed film to increase by 0.15 with respect to film that was not preexposed.

FLUOROGRAPHY

Organic scintillants can be included in radioactive samples to obtain autoradiograms of weak β -emitting isotopes such as ^3H , ^{14}C , and ^{35}S . The scintillant fluoresces upon absorption of β particles from these isotopes, facilitating film exposure. Fluorographs of radioactive molecules in polyacrylamide gels have traditionally used the scintillant PPO (2,5-diphenyloxazole; Laskey and Mills, 1975). PPO, however, has largely been replaced with commercial scintillation formulations that reduce the amount of preparation time and are considerably safer to use. These scintillants (e.g., Enhance from NEN Life Science) come with complete instructions for their use. In addition, spray applicators are also available that can be used on filters or thin-layer plates. The expected levels of image enhancement obtained through fluorography are listed in Table A.3A.1. Sodium salicylate can also be used for fluorography as described below (Chamberlain, 1979). It yields levels of image enhancement comparable to those from organic scintillants, although it sometimes causes a more diffuse film image. The conditions should work for most standard sizes and thicknesses of gels.

CAUTION: Gloves should be worn at all times; sodium salicylate can elicit allergic reactions and is readily absorbed through the skin.

Materials

Polyacrylamide gel

1 M sodium salicylate, pH 5 to 7, freshly prepared

Additional reagents and equipment for fixing and drying gels (see Support Protocol 1)

1. If gel is acid-fixed, soak for 1 to 5 hr in ~ 20 vol water to prevent precipitation of salicylic acid from the sodium salicylate.
2. Soak gel 30 min in 10 vol of 1 M sodium salicylate, pH 5 to 7.

To prevent cracking of gels with $>15\%$ acrylamide or thicker than 1.5 mm, 2% (v/v) glycerol can be added to the 1 M sodium salicylate.

3. Dry the gel (see Support Protocol 1) and proceed with autoradiography (see Basic Protocol).

DENSITOMETRY

Film images obtained by autoradiographic methods can be quantified by densitometry. Densitometers work by comparing the intensity of light transmitted through a sample with the intensity of the incident light. The amount of light transmitted will be proportional to the amount of radioactivity in the gel, provided that the film has been properly preexposed (see Support Protocol 3). The linear range of correctly preexposed film is 0.1 to 1.0 absorbance units. However, if the preexposure is excessive—i.e., an increase of >0.2 absorbance units (A_{540}) treated film/untreated film—smaller amounts of radioactivity will produce disproportionately dense images. Autoradiograms that exceed an absorbance of 1.4 absorbance units (A_{540}) have saturated all available silver bromide crystals and also cannot be evaluated quantitatively.

Densitometers are available from several manufacturers (e.g., Molecular Dynamics, Bio-Rad, and UVP). Most models come with software that facilitates calculations and allows the user to define the region of the film to be measured. Procedures for the use of these machines vary and instructions are provided by the manufacturer. Densitometers are also available that measure light reflected from a sample. Reflectance densitometers are useful in instances where the sample medium is completely opaque—e.g., filters that have been probed using nonradioactive colorimetric detection assays.

PHOSPHOR IMAGING

Phosphor imaging screens can be used as an alternative to film for recording and quantifying autoradiographic images (Johnston et al., 1990). They can detect radioisotopes such as ^{32}P , ^{125}I , ^{14}C , ^{35}S , and ^3H . There are several advantages of phosphor imaging over film: (1) linear dynamic ranges are 5 orders of magnitude, compared to ~ 1.5 orders of magnitude for film (Fig. A.3A.2); (2) exposure times are 10 to 250 times faster than with film; (3) quantification is much easier and faster, and most imagers come with software to directly analyze data; (4) fluorography and gel drying are often unnecessary because of the sensitivity of phosphor imaging; and (5) phosphor screens can be reused indefinitely if handled carefully.

Phosphor imaging screens are composed of crystals of BaFBr:Eu^{+2} . When the screen is exposed to ionizing radiation such as α , β , or γ radiation, or wavelengths of light shorter than 380 nm, the electrons from Eu^{+2} are excited and then trapped in an "F-center" of the BaFBr^- complex; this results in the oxidation of Eu^{+2} to Eu^{+3} , which forms the latent image on the screen. After exposure, the latent image is released by scanning the screen with a laser (633 nm). During scanning, Eu^{3+} reverts back to Eu^{+2} , releasing a photon at 390 nm. The luminescence can then be collected and measured in relation to the position of the scanning laser beam. The result is a representation of the latent image on the storage phosphor imaging plates. The image can then be viewed on a video monitor and analyzed with the aid of appropriate software.

Some companies (e.g., Bio-Rad) offer different screens for use with different isotopes. They vary principally in the protective coating on the screen, which is optimized for low- or high-energy β particles or γ rays. No coating is typically used for weak β emitters such as tritium. More recently, screens have also been developed that measure chemiluminescence. Such screens are particularly valuable for use with many nonradioactive labeling protocols.

The protocol below is for the PhosphorImager system from Molecular Dynamics; other phosphor imaging systems are available from Bio-Rad, Imaging Research, and National Diagnostics.

Figure A.3A.2 ^{32}P dilution series quantified on Model GS-525 phosphor imager (squares), compared to film (circles). Image courtesy of Bio-Rad, Hercules, Calif.

Materials

Gel or filter (e.g., from immunoblotting; *UNIT 10.8*)
PhosphorImager system (Molecular Dynamics) including:
ImageEraser light box
Exposure cassette with phosphor screen
Scanning software

1. Erase any latent image on the phosphor screen left by a previous user, or caused by background radiation, by exposure to visible light.

The PhosphorImager system comes with an extra-bright light box (ImageEraser) for this purpose. Standard laboratory light boxes may also be used.

2. Cover gel or filter with plastic wrap to protect the exposure cassette. Place wrapped gel or filter in the PhosphorImager cassette and close to begin exposure.

The gel does not have to be dried for this procedure. The phosphor screen is affixed to the lid of the cassette. Exposure times are typically one-tenth of the time required for film exposure.

3. After exposure, slide the screen face down into the PhosphorImager system.
4. Select the scanning area using the software supplied with the PhosphorImager and start scanning.

The blue light emitted during scanning is collected to produce the latent image.

5. Analyze and quantitate the image using the software provided.
6. Erase the phosphor screen by exposing it to visible light as in step 1.

COMMENTARY

Background Information

The ability to detect radiolabeled proteins or DNA is critical to many studies in molecular biology. More often than not, detection is coupled with the resolving power of polyacrylamide gel electrophoresis (PAGE; *UNITS 2.7 & 10.2*). Radiolabeled proteins or DNA separated on gels can be used directly to obtain an autoradiographic image. Alternatively, separated by PAGE are frequently transferred to membranes (*UNIT 10.8*) and detected using radiolabeled probes such as DNA, RNA, or antibodies. The autoradiographic image, whether generated on film or a phosphor screen, reflects the distribution of the radioactive molecules on the two-dimensional surface of the gel or filter. Molecular sizes of radiolabeled proteins or DNA species, therefore, can be determined by correlating their positions with molecular markers. Also, the density of the band images can be used to determine the relative quantities of the radiolabeled molecules in the sample.

Critical Parameters

The sensitivity of the detection device and the strength of the radioactive signal are the two

most important parameters for autoradiography. Sensitivity can be enhanced by treating samples with fluors or by using intensifying screens (Table A.3A.2). Because phosphor imaging is 10 to 250 times more sensitive than film (Johnston et al., 1990), this technology makes it possible to monitor radioactive samples that would previously have gone undetected with film.

A second important parameter is the range over which the measurement device is linear. Film must be preflashed in order for the intensity of the image to be linear with respect to the amount of radioactivity, particularly for weakly radioactive samples (Laskey and Mills, 1975, 1977). Phosphor imaging offers a much wider linear range of measurement (5 orders of magnitude compared to 1.5 for film; Johnston et al., 1990). This makes it possible to quantitate very weak or very strong radioactive samples accurately.

Troubleshooting

Cracking is one of the most common problems encountered when drying gels. This often occurs if the gel is removed from the dryer

Table A.3A.2 Film Choice and Exposure Temperature for Autoradiography

Isotope	Enhancement method	Film	Exposure temperature
³ H	Fluorography	Double-coated	-70°C
³⁵ S, ¹⁴ C, ³² P	None	Single-coated	Room temperature
³⁵ S, ¹⁴ C, ³² P	Fluorography	Double-coated	-70°C
³² P, ¹²⁵ I	CaWO ₄ intensifying screens	Double-coated	-70°C

before it has adequately dried or if drying temperatures are too high. To overcome this problem, drying times should be extended and the performance of the vacuum pump and heater unit should be checked. For protein gels, with high percentages of polyacrylamide or >1.5 mm thick, cracking can be reduced by using an alternative fixing solution containing glycerol (3% glycerol/10% glacial acetic acid/20% methanol; see Support Protocol 1).

Among the biggest problems encountered in autoradiography are images that are either too weak or too intense. Such problems can be solved by varying the exposure time. Estimating initial exposure time is difficult, since the amount of radioactivity in the sample is often unknown. A Geiger counter can offer some guidance with certain isotopes. For highly exposed film, the length of time the film sits in developer can be reduced to produce a lighter image. It is particularly important to remember that if accurate quantification of the film image is desired, film must be preflashed so that there is a linear relationship between the amount of radioactivity in the sample and the image intensity.

Artifacts such as black spots and stripes can be avoided by making sure that no moisture comes in contact with the film during developing and that films exposed at -70°C are brought to room temperature before developing. Also, it must be noted that β particles from weak isotopes such as ³H cannot penetrate plastic wrap, and plastic wraps can attenuate signals from ³⁵S and ¹⁴C up to 2-fold.

Anticipated Results

The protocols described here should yield a film image of a gel that can be quantified, stored, and photographed for publication.

Time Considerations

Fixing a protein gel will require ~45 min. Drying will take an additional 2 hr for a gel 1 mm in thickness. Incorporation of a fluor will add ~45 min to the processing time.

For protein gels >1.5 mm thick or with >15% acrylamide, an additional 30 min will be required for fixing and ~30 additional minutes will be required for drying.

The length of exposure for films in autoradiography can range from a few minutes to a few weeks, depending on the strength of the radioactivity in the sample. Most exposures last from several hours to a few days. Exposure time can be reduced >10-fold with a phosphor imager.

Silanizing Glassware

Glassware is silanized (siliconized) to prevent adsorption of solute to the glass surface or to increase its hydrophobicity. This is particularly important when dealing with low concentrations of particularly “sticky” solutes such as single-stranded nucleic acids or proteins.

**BASIC
PROTOCOL**

Materials

Chlorotrimethylsilane *or* dichlorodimethylsilane
Vacuum pump
Desiccator, equipped with a valve

1. In a fume hood, place glassware or equipment to be silanized into desiccator along with a beaker containing 1 to 3 ml of chlorotrimethylsilane or dichlorodimethylsilane.

CAUTION: Chlorotrimethylsilane and dichlorodimethylsilane vapors are toxic and highly flammable.

2. Connect desiccator to vacuum pump until silane starts to boil, and close connection to pump (maintaining vacuum in desiccator). Leave the desiccator evacuated and closed until liquid silane is gone (~1 to 3 hr).

During the incubation the silane will evaporate, be deposited on the surface of the glassware, and polymerize. Do not leave the desiccator attached to the vacuum pump. This will suck away the silane, minimizing deposition and damaging the pump.

3. Open desiccator in a fume hood, and leave open for several minutes to disperse silane vapors.
4. If desired, bake or autoclave the glassware or apparatus.

Autoclaving or rinsing with water removes the reactive chlorosilane end of the dimethylsiloxane polymer generated by dichlorodimethylsilane.

COMMENTARY

Untreated glass contains silicate and silanol groups that can act as ion-exchange and nucleophilic centers. To mask these groups and decrease the hydrophilicity of the surface, various reactive silanes are frequently used to coat the glass surface. The same or related chemistries can be used to introduce functional groups, including large molecules, onto the glass surface. On contact with a silanol (SiOH) group, chlorosilanes react to give HCl and a siloxane Si-O-Si linkage. For most applications “silanizing” or “siliconizing” a piece of glassware or equipment means introducing onto the glass surface either a short polymer of dimethylsiloxane

using dichlorodimethylsilane, or a trimethylsiloxane cap

using chlorotrimethylsilane. Polydimethylsiloxane is silicone oil; the use of dichloromethylsilane essentially gives a light coating of oil to the glassware. The polymerization of dichlorodimethylsilane is mediated by residual water adsorbed to the glass surface; chlorosilanes also react with water and alcohols to give HCl and silanol or alkoxy silane, respectively. Thus, in the polymerization reaction, the residual water reacts with the chloride endgroup to give HCl and a silanol, which then reacts with more

**Commonly Used
Techniques**

A.3B.1

dichlorodimethylsilane and more water to give polymers. Chlorotrimethylsilane just gives a trimethyl cap to the silanol or silicate group.

Items too large to fit in a desiccator can be silanized by briefly rinsing with or soaking in a solution of approximately 5% dichlorodimethylsilane in various volatile organic solvents such as chloroform or heptane. The organic solvent is removed by evaporation, depositing the dichlorodimethylsilane on the surface. This approach is particularly useful for

treating glass plates for denaturing polyacrylamide sequencing gels (see *UNIT 7.4*).

CAUTION: If a flammable solvent is used, do not bake the glassware until the solvent is completely evaporated.

Dialysis and Ultrafiltration

The first section describes dialysis of large- and small-volume samples using cellulose membranes with pore sizes designed to exclude molecules above a selected molecular weight (basic and alternate protocols). A support protocol describes preparation of membranes for dialysis. The second section describes protocols for ultrafiltration, and the third section describes simple methods of concentrating solutions.

DIALYSIS

Conventional dialysis separates small molecules from large molecules by allowing diffusion of only the small molecules through selectively permeable membranes. Dialysis is usually used to change the salt (small-molecule) composition of a macromolecule-containing solution. The solution to be dialyzed is placed in a sealed dialysis membrane and immersed in a selected buffer; small solute molecules then equilibrate between the sample and the dialysate. Concomitant with the movement of small solutes across the membrane, however, is the movement of solvent in the opposite direction. This can result in some sample dilution (usually <50%).

Large-Volume Dialysis

This protocol describes the use of membranes, prepared using the support protocol, for dialysis of samples in large, easily handled volumes, typically 0.1 to 500 ml.

Materials

For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

- Dialysis membrane (see support protocol)
- Clamps (Spectrapor Closures, Spectrum, or equivalent)
- Macromolecule-containing sample to be dialyzed
- Appropriate dialysis buffer

1. Remove dialysis membrane from ethanol storage solution and rinse with distilled water. Secure clamp to one end of the membrane or knot one end.

Always use gloves to handle dialysis membrane because the membrane is susceptible to cellulolytic microorganisms.

See support protocol for a discussion of commercially available membranes and preparation and storage procedures.

Clamps are less likely to leak than knots.

2. Fill membrane with water or buffer, hold the unclamped end closed, and squeeze membrane. A fine spray of liquid indicates a pinhole in the membrane; discard and try a new membrane.

Pinholes are rare but cause traumatic sample loss. Hard squeezing will cause some liquid to seep from the bag; this is normal.

3. Replace the water or buffer in dialysis membrane with the macromolecule-containing sample and clamp the open end. Again, squeeze to check the integrity of the membrane and clamps.

If dialyzing a concentrated or high-salt sample, leave some space in the clamped membrane; there will be a net flow of water into the sample, and if sufficient pressure builds up the membrane can burst.

BASIC
PROTOCOL

Commonly Used
Techniques

A.3C.1

Supplement 41

4. Immerse dialysis membrane in a beaker or flask containing a large volume (relative to the sample) of the desired buffer. Dialyze for several hours at the desired temperature with gentle stirring of the buffer.

Dialysis rates are dependent on membrane pore size, sample viscosity, and ratio of membrane surface to sample volume. Temperature has little effect on dialysis rate, but low temperatures are usually chosen to enhance macromolecule stability. Common salts will equilibrate across a 15,000-MWCO membrane (see support protocol) in ~3 hr with stirring.

5. Change dialysis buffer as necessary.

Usually two dialysis buffer changes are sufficient. For example, when CsCl is removed from equilibrium density gradient-banded DNA, two equilibrations against a 1000-fold volume excess of buffer will decrease CsCl concentration 10^6 -fold, to ~5 μ M.

6. Remove dialysis membrane from the buffer. Hold the membrane vertically and remove excess buffer trapped in end of membrane outside upper clamp. Release upper clamp and remove the sample with a Pasteur pipet.

ALTERNATE PROTOCOL

Small-Volume Dialysis

For solution volumes less than ~100 μ l, the use of dialysis membrane as described above can result in unacceptable sample loss. The method described below can easily dialyze volumes as small as 10 μ l. The sample is held in a 0.5- or 1.5-ml microcentrifuge tube, with dialysis membrane covering the open end of the tube.

Additional Materials

Cork borer

1. Cut a hole in the cap of a 0.5- or 1.5-ml microcentrifuge tube using a cork borer. Be sure that there are no rough edges on the inside of the cap (which will be in contact with the dialysis membrane).

The success of this protocol is dependent on a tight-fitting cap, so make sure the cap is well-seated. On the other hand, an excessively tight-fitting cap can rip the membrane when it is inserted. Sarstedt tubes work well.

2. Place sample in the microcentrifuge tube, cover tube opening with dialysis membrane, and snap on the tube cap in which a hole has been cut.

This places a fair amount of stress on the dialysis membrane, so use a fairly thick membrane and make sure there are no rough edges on the cap.

3. To get the sample in contact with the dialysis membrane, *gently* centrifuge the microcentrifuge tube in an inverted position in a tabletop centrifuge.

4. Keep the tube inverted, immerse it in dialysis buffer, and anchor it so that it will remain inverted and immersed.

This is easily done by clamping the tube to the side of a beaker containing the dialysis buffer. For many samples, immerse and anchor a microcentrifuge tube rack in the buffer, then insert the inverted tube into the bottom of the rack. Air in the microcentrifuge tube will keep the tube pressed up into the rack.

5. Use a bent Pasteur pipet to blow out any air bubbles trapped under the cap to allow dialysis buffer to contact the membrane.

6. Stir the dialysis buffer and dialyze at an appropriate temperature for at least several hours (see first basic protocol, step 4).

7. To recover the sample, remove microcentrifuge tube from the buffer and centrifuge briefly right-side-up.

Commercially available alternatives to this method include use of individual hollow-fiber filters from Spectrum (with sample capacities of 1 to 140 μ l; see Ultrafiltration), and many different microdialysis machines, both single-sample and multisample (Spectrum, Cole-Parmer, Hofer, and others).

Selection and Preparation of Dialysis Membrane

Dialysis membranes are available in a number of thicknesses and pore sizes. Thicker membranes are tougher, but restrict solute flow and reach equilibrium more slowly. Pore size is defined by “molecular weight cutoff” (MWCO)—i.e., the size of the smallest particle that cannot penetrate the membrane. The MWCO designation should be used only as a very rough guide; if accurate MWCO information is required, it should be determined empirically (see Craig, 1967, for a discussion of parameters affecting MWCO). Knowledge of the precise MWCO is usually not required, however; it is necessary only to use a membrane with a pore size that is much smaller than the macromolecule of interest. For most plasmid and protein dialyses, a MWCO of 12,000 to 14,000 is appropriate.

Most dialysis membranes are made of derivatives of cellulose. They come in a wide variety of MWCO values, ranging from 500 to 500,000, and also vary in cleanliness, sterility, and cost. Spectrum has the most impressive inventory. The least expensive membranes come dry on rolls; these contain glycerol to keep them flexible as well as residual sulfides and traces of heavy metals from their manufacture. For most DNA dialysis applications, such as removing CsCl from gradient-purified samples (*UNIT 1.7*) and electroelution (*UNIT 2.6*), these dialysis membranes can be used directly from the roll after wetting and a brief rinse in water. If glycerol, sulfur compounds, or small amounts of heavy metals are problematic, clean membranes should be purchased or membranes should be prepared as described below. Protein dialysis should only be done with clean membranes.

Additional Materials

For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

10 mM sodium bicarbonate
10 mM Na₂EDTA, pH 8.0
20% to 50% (v/v) ethanol

1. Remove membrane from the roll and cut into usable lengths (usually 8 to 12 in.).

Always use gloves to handle dialysis membrane, as it is susceptible to a number of cellulolytic microorganisms. Membrane is available as sheets or preformed tubing.

2. Wet membrane and boil it several minutes in a large excess of 10 mM sodium bicarbonate.
3. Boil several minutes in 10 mM Na₂EDTA. Repeat.

Boiling speeds up the treatment process but is not necessary. A 30-min soak with some agitation can substitute for the boiling step.

4. Wash several times in distilled water.

5. Store at 4°C in 20% to 50% ethanol to prevent growth of cellulolytic microorganisms.

Alternatively, noxious buffers (e.g., sodium azide or sodium cacodylate) may be used for storage; however, ethanol is preferred for ease and convenience.

Describe the theory and practice of dialysis and diffusion.

ULTRAFILTRATION

Ultrafiltration (UF) is a type of pressure-driven membrane filtration in which a pressure differential across a semipermeable membrane is used to separate solvent and small solute molecules from a solution containing larger molecules. UF usually uses membranes with MWCOs of 1000 to 1,000,000. The pressure differential is usually achieved by vacuum, pressurized inert gas, or centrifugal force. UF is frequently used to concentrate protein solutions; because buffer concentration does not change, this is one of the most gentle methods for concentrating proteins. UF is also used to separate molecules of grossly different molecular weight (e.g., plasmids or PCR products from dNTPs or primers).

The major technical difficulty with UF is concentration polarization, in which rejected large-molecule solute builds up as a gel layer that obstructs the membrane. Various stirring and pumping regimes are used to keep the solution flowing tangentially to the membrane, and this serves to dissipate the gel layer.

UF can be broadly divided into vacuum-dialysis, centrifugal-concentration, stirred-cell dialysis, and tangential-flow systems. Choice of system will depend on the nature of the solution (i.e., volume, viscosity, presence of particulates, and shear lability), concentration rate needed, and cost. In general, vacuum dialysis is cheapest, but is also slowest and has the lowest volume capacity. Centrifuge concentrators are fairly inexpensive (on a per-use basis), moderately slow, and restricted to volumes ≤ 20 ml. Stirred cells come next on the scale of increasing volume capacity, concentration rate, and cost. Tangential-flow systems can concentrate large volumes rapidly, but at substantial cost.

Vacuum dialysis can be done with common laboratory equipment; construction of a homemade apparatus is described in the basic protocol. Centrifuge concentrators are single-use disposable units. The other types of UF generally require a commercial apparatus. There is a plethora of such apparatuses; because their design and availability can change rapidly, the following discussion is meant as a general guideline to the available methods. It should be noted that most UF apparatus can also be used for large-volume dialysis.

NOTE: For a more complete listing of suppliers of ultrafiltration equipment, see the *Biotech Buyer's Guide* (ACS, 1994), published annually.

Ultrafiltration Using Vacuum Dialysis

In vacuum dialysis, a vacuum is placed on the dialysis buffer while the sample remains at atmospheric pressure. This is a very gentle method; however, as membrane polarization can be a problem, it is usually used with dilute samples. Vacuum dialysis can typically handle ≤ 20 ml sample volume.

Materials

For common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.

Sample
Appropriate dialysis buffer
Vacuum flask
One-hole cork stopper
Pasteur pipet
Dialysis membrane of desired MWCO

1. Connect outlet of vacuum flask to vacuum line or aspirator (see Fig. A.3C.1).
2. Prepare or purchase a one-hole cork stopper into which the large end of a Pasteur pipet fits snugly, even with lubrication. Cut off the thin end of a Pasteur pipet and smooth the end using the flame from a Bunsen burner.
3. Prepare the dialysis membrane, clamp one end, and slip the other end through the hole in the stopper. Insert the Pasteur pipet into the open end of the dialysis tubing, using glycerol as a lubricant if necessary.

A 6.4-mm-diameter membrane fits snugly over a Pasteur pipet.

4. Insert the Pasteur pipet with dialysis membrane into the stopper until firmly seated. Keep the membrane wet at all times.

Figure A.3C.1 Vacuum dialysis apparatus (from Craig, 1967).

5. Put the stopper/Pasteur pipet/dialysis membrane assembly into the mouth of a buffer-filled vacuum flask and apply a mild vacuum. The dialysis membrane will inflate.

Check for trails of small bubbles, which indicate leaks.

6. If no leaks are detected, put the sample into the membrane via the Pasteur pipet and dialyze under vacuum until the desired sample volume is achieved. Add sample continuously or at intervals throughout dialysis.

Because vacuum pumps can rupture the membrane, the use of an aspirator with overnight stirring at 4°C is recommended. This reduces 10 to 15 ml of fairly dilute protein solution to <0.5 ml. Vacuum ≤ 3 lb/in² (150 mm Hg) will cause little membrane distortion, but 5 lb/in² will cause some change in pore size. Commercial apparatuses are also available (e.g., Spectrum); they are more expensive, but can more easily handle multiple samples.

ALTERNATE PROTOCOL 1

Ultrafiltration Using Centrifuge Concentrators

Centrifuge concentrators use centrifugal force imparted by a centrifuge to force solvent through a membrane. They are more expensive than home-made vacuum dialyzers, but are faster and more amenable to small samples and multiple samples. Centrifuge concentrators are currently available to handle sample volumes of 0.05 to 20 ml, with a huge variety of MWCOs ranging from 100 to 500,000. Polarization is avoided by spinning in fixed-angle rotors so the membrane is not at a right angle to the force; any gel that forms is pushed off to one side of the membrane. This design also prevents complete drying of the sample. Centriprep concentrators (Amicon) use a clever design to force the solution upward through the membrane, allowing any gel to pellet at the bottom of the apparatus, away from the membrane. Centrifuge concentrators are made by Amicon, Corning, Millipore, and Spectrum, among others.

ALTERNATE PROTOCOL 2

Ultrafiltration Using Stirred-Cell Apparatus

Stirred-cell units (Amicon or Spectrum) are a relatively inexpensive means for concentrating moderate volumes of dilute, nonparticulate samples. They use pressurized inert gas (usually N₂) to drive the solvent through membrane disks. A stir bar suspended above the disk keeps the solution stirred in an attempt to dissipate any gel layer. The disks are available in various MWCOs and compositions. It is possible to concentrate 3 to 400 ml with stirred-cell units. They are cheaper than a tangential-flow apparatus (see below), but have a lower concentration rate and are more prone to concentration polarization than tangential-flow systems. However, they are less prone to concentration polarization than vacuum dialysis.

ALTERNATE PROTOCOL 3

Ultrafiltration Using Tangential-Flow Systems

Like stirred-cell apparatuses, tangential-flow ultrafiltration systems are pressure-driven. However, instead of stirring the solution, these units pump the pressurized solution tangentially with respect to the membrane, greatly reducing the concentration-polarization problem. Tangential-flow systems are more expensive than stirred-cell units. Most tangential-flow systems can also be adapted for large-volume dialysis.

One design, known as thin-channel or flat-plate, uses a flat ultrafiltration membrane. The Thin Channel System (Amicon) and Minitan System (Millipore) are examples of this design. The solution is pumped across one face of the membrane through either a spiral channel or a series of linear channels. This design has a surface area similar to that of stirred cells, but can handle larger volumes (~200 ml to 2 liters). The technique is much

less susceptible to concentration polarization and can thus handle more concentrated solutions. The concentration rate is greater than that of stirred cells, as greater pressure can be achieved before concentration polarization becomes a problem. Tangential-flow systems are somewhat cheaper and simpler than the high-capacity systems described below.

Stacked-flat-plate, spiral-wound, and hollow-fiber systems (e.g., Amicon, Millipore, Spectrum) are designed for large-volume samples (1 to >1000 liters) and high concentration rates, requirements usually encountered in an industrial setting. The choice between them will normally depend more on sample characteristics than on cost (see below). Also, the filter cartridges are not cheap, so preventing sample cross-contamination usually involves extensive cleaning, rather than simply changing a membrane as with stirred-cell or lower-capacity tangential-flow systems.

The principle behind the stacked-flat-plate system (e.g., Pellicon System; Millipore) is self-explanatory. The surface area of such systems is limited, and the apparatus may be difficult to clean.

Spiral-wound systems consist of a large membrane wound on a core with a mesh separating the two faces of the membrane, thereby creating two noncontiguous spiral channels. Pressure is applied to the channel containing the input solution, and filtrate is collected from the other. This design achieves a very high surface-to-volume ratio, and thus a high concentration rate. These systems are susceptible to clogging, and are recommended only for particle-free solutions.

Hollow-fiber systems are collections of hollow fibers of ultrafiltration membrane; pressure is applied to the sample as it is pumped through the fibers. This design has the advantage of handling particulate samples (i.e., cellular material) and precipitates. They are also easy to clean, but cannot achieve high pressures, and so have lower concentration rates than spiral-channel systems.

CONCENTRATION USING SOLID-PHASE OR SLURRY ABSORBENTS

A cheap, low-tech alternative to dialysis and ultrafiltration is concentration with solid-phase or slurry absorbents. In this method, the sample is placed in dialysis membrane and surrounded with dry matrix or immersed in an absorbent slurry, whereupon water and small solute molecules are drawn out of the sample. This technique is slow and requires constant monitoring; otherwise, complete drying can occur, to the potential detriment of the sample. Common absorbents are polyethylene glycol (PEG) and carboxymethyl cellulose (Aquacides; Calbiochem), Sephadex beads, and polyacrylamide derivatives (Spectra/Gel, Spectrum).

Quantitation of DNA and RNA with Absorption and Fluorescence Spectroscopy

Reliable quantitation of nanogram and microgram amounts of DNA and RNA in solution is essential to researchers in molecular biology. In addition to the traditional absorbance measurements at 260 nm (see Basic Protocol), three more sensitive fluorescence techniques (see Alternate Protocols 1 to 3) are presented below. These four procedures cover a range from 5 to 10 ng/ml DNA to 25 pg/ml DNA (see Commentary and Table A.3D.3 therein).

Absorbance measurements are straightforward as long as any contribution from contaminants and the buffer components are taken into account. Fluorescence assays are less prone to interference than A_{260} measurements and are also simple to perform. As with absorbance measurement, a reading from the reagent blank is taken prior to adding the DNA. In instruments where the readout can be set to indicate concentration, a known concentration is used for calibration and subsequent readings are taken in $\mu\text{g/ml}$, ng/ml , or pg/ml DNA.

DETECTION OF NUCLEIC ACIDS USING ABSORPTION SPECTROSCOPY

BASIC PROTOCOL

Absorption of the sample is measured at several different wavelengths to assess purity and concentration of nucleic acids. A_{260} measurements are quantitative for relatively pure nucleic acid preparations in microgram quantities. Absorbance readings cannot discriminate between DNA and RNA; however, the ratio of A at 260 and 280 nm can be used as an indicator of nucleic acid purity. Proteins, for example, have a peak absorption at 280 nm that will reduce the A_{260}/A_{280} ratio. Absorbance at 325 nm indicates particulates in the solution or dirty cuvettes; contaminants containing peptide bonds or aromatic moieties such as protein and phenol absorb at 230 nm.

This protocol is designed for a single-beam ultraviolet to visible range (UV-VIS) spectrophotometer. If available, a double-beam spectrophotometer will simplify the measurements, as it will automatically compare the cuvette holding the sample solution to a reference cuvette that contains the blank. In addition, more sophisticated double-beam instruments will scan various wavelengths and report the results automatically.

Materials

- 1 \times TNE buffer (see recipe)
- DNA sample to be quantitated
- Calf thymus DNA standard solutions (see recipe)
- Matched quartz semi-micro spectrophotometer cuvettes (1-cm pathlength)
- Single- or dual-beam spectrophotometer (ultraviolet to visible)

1. Pipet 1.0 ml of 1 \times TNE buffer into a quartz cuvette. Place the cuvette in a single- or dual-beam spectrophotometer, read at 325 nm (note contribution of the blank relative to distilled water if necessary), and zero the instrument. Use this blank solution as the reference in double-beam instruments. For single-beam spectrophotometers, remove blank cuvette and insert cuvette containing DNA sample or standard suspended in the same solution as the blank. Take reading. Repeat this process at 280, 260, and 230 nm.

It is important that the DNA be suspended in the same solution as the blank.

2. To determine the concentration (C) of DNA present, use the A_{260} reading in conjunction with one of the following equations:

$$\text{Single-stranded DNA: } C \text{ (pmol/}\mu\text{l)} = \frac{A_{260}}{10 \times S}$$

$$C \text{ (}\mu\text{g/ml)} = \frac{A_{260}}{0.027}$$

$$\text{Double-stranded DNA: } C \text{ (pmol/}\mu\text{l)} = \frac{A_{260}}{13.2 \times S}$$

$$C \text{ (}\mu\text{g/ml)} = \frac{A_{260}}{0.020}$$

$$\text{Single-stranded RNA: } C \text{ (}\mu\text{g/ml)} = \frac{A_{260}}{0.025}$$

$$\text{Oligonucleotide: } C \text{ (pmol/}\mu\text{l)} = A_{260} \times \frac{100}{1.5 N_A + 0.71 N_C + 1.20 N_G + 0.84 N_T}$$

where S represents the size of the DNA in kilobases and N is the number or residues of base A, G, C, or T.

For double- or single-stranded DNA and single-stranded RNA: These equations assume a 1-cm-pathlength spectrophotometer cuvette and neutral pH. The calculations are based on the Lambert-Beer law, $A = ECl$, where A is the absorbance at a particular wavelength, C is the concentration of DNA, l is the pathlength of the spectrophotometer cuvette (typically 1 cm), and E is the extinction coefficient. For solution concentrations given in mol/liter and a cuvette of 1-cm pathlength, E is the molar extinction coefficient and has units of $M^{-1}cm^{-1}$. If concentration units of $\mu\text{g/ml}$ are used, then E is the specific absorption coefficient and has units of $(\mu\text{g/ml})^{-1}cm^{-1}$. The values of E used here are as follows: ssDNA, $0.027 (\mu\text{g/ml})^{-1}cm^{-1}$; dsDNA, $0.020 (\mu\text{g/ml})^{-1}cm^{-1}$; ssRNA, $0.025 (\mu\text{g/ml})^{-1}cm^{-1}$. Using these calculations, an A_{260} of 1.0 indicates 50 $\mu\text{g/ml}$ double-stranded DNA, $\sim 37 \mu\text{g/ml}$ single-stranded DNA, or $\sim 40 \mu\text{g/ml}$ single-stranded RNA (adapted from Applied Biosystems, 1987).

For oligonucleotides: Concentrations are calculated in the more convenient units of pmol/ μl . The base composition of the oligonucleotide has significant effects on absorbance, because the total absorbance is the sum of the individual contributions of each base (Table A.3D.1).

3. Use the A_{260}/A_{280} ratio and readings at A_{230} and A_{325} to estimate the purity of the nucleic acid sample.

Table A.3D.1 Molar Extinction Coefficients of DNA Bases^a

Base	$\epsilon_{260 \text{ nm}}^{\text{IM}}$
Adenine	15,200
Cytosine	7,050
Guanosine	12,010
Thymine	8,400

^aMeasured at 260 nm; see Wallace and Miyada, 1987. Detailed spectrophotometric properties of nucleoside triphosphates are listed in UNIT 3.4.

Table A.3D.2 Spectrophotometric Measurements of Purified DNA^a

Wavelength (nm)	Absorbance	A_{260}/A_{280}	Conc. ($\mu\text{g/ml}$)
325	0.01	—	—
280	0.28	—	—
260	0.56	2.0	28
230	0.30	—	—

^aTypical absorbancy readings of highly purified calf thymus DNA suspended in 1× TNE buffer. The concentration of DNA was nominally 25 $\mu\text{g/ml}$.

Ratios of 1.8 to 1.9 and 1.9 to 2.0 indicate highly purified preparations of DNA and RNA, respectively. Contaminants that absorb at 280 nm (e.g., protein) will lower this ratio.

Absorbance at 230 nm reflects contamination of the sample by phenol or urea, whereas absorbance at 325 nm suggests contamination by particulates and dirty cuvettes. Light scatter at 325 nm can be magnified 5-fold at 260 nm (K. Hardy, pers. comm.).

Typical values at the four wavelengths for a highly purified preparation are shown in Table A.3D.2.

DNA DETECTION USING THE DNA-BINDING FLUOROCHROME HOECHST 33258

ALTERNATE PROTOCOL 1

Use of fluorometry to measure DNA concentration has gained popularity because it is simple and much more sensitive than spectrophotometric measurements. Specific for nanogram amounts of DNA, the Hoechst 33258 fluorochrome has little affinity for RNA and works equally well with either whole-cell homogenates or purified preparations of DNA. The fluorochrome is, however, sensitive to changes in DNA composition, with preferential binding to AT-rich regions. A fluorometer capable of an excitation wavelength of 365 nm and an emission wavelength of 460 nm is required for this assay.

Additional Materials (also see Basic Protocol)

Hoechst 33258 assay solution (working solution; see recipe)

Dedicated filter fluorometer (Hoefer TKO100) *or* scanning fluorescence spectrophotometer (Shimadzu model RF-5000 or Perkin-Elmer model LS-5B or LS-3B)

Fluorometric square glass cuvettes *or* disposable acrylic cuvettes (Sarstedt)

Teflon stir rod

1. Prepare the scanning fluorescence spectrophotometer by setting the excitation wavelength to 365 nm and the emission wavelength to 460 nm.

The dedicated filter fluorometer has fixed wavelengths at 365 and 460 nm and does not need adjustment.

2. Pipet 2.0 ml Hoechst 33258 assay solution into cuvette and place in sample chamber. Take a reading without DNA and use as background.

If the fluorometer has a concentration readout mode or is capable of creating a standard curve, set instrument to read 0 with the blank solution. Otherwise note the readings in relative fluorescence units. Be sure to take a blank reading for each cuvette used, as slight variations can cause changes in the background reading.

3. With the cuvette still in the sample chamber, add 2 μl DNA standard to the blank Hoechst 33258 assay solution. Mix in the cuvette with a Teflon stir rod or by capping and inverting the cuvette. Read emission in relative fluorescence units or set the

Commonly Used Techniques

A.3D.3

concentration readout equal to the final DNA concentration. Repeat measurements with remaining DNA standards using fresh assay solution (take background zero reading and zero instrument if needed).

If necessary, the DNA standards should be quantitated by A_{260} measurement (Basic Protocol) before being used here.

Small-bore tips designed for loading sequencing gels minimize errors of pipetting small volumes. Prerinse tips with sample and make sure no liquid remains outside the tip after drawing up the sample.

Read samples in duplicate or triplicate, with a blank reading taken each time. Unusual or unstable blank readings indicate a dirty cuvette or particulate material in the solution, respectively.

4. Repeat step 3 with unknown samples.

A dye concentration of 0.1 $\mu\text{g/ml}$ is adequate for final DNA concentrations up to ~ 500 ng/ml . Increasing the working dye concentration to 1 $\mu\text{g/ml}$ Hoechst 33258 will extend the assay's range to 15 $\mu\text{g/ml}$ DNA, but will limit sensitivity at low concentrations (5 to 10 ng/ml). Sample volumes of ≤ 10 μl can be added to the 2.0-ml aliquot of Hoechst 33258 assay solution.

**ALTERNATE
PROTOCOL 2**

**DNA AND RNA DETECTION WITH ETHIDIUM BROMIDE
FLUORESCENCE**

In contrast to the fluorochrome Hoechst 33258, ethidium bromide is relatively unaffected by differences in the base composition of DNA. Ethidium bromide is not as sensitive as Hoechst 33258 and, although capable of detecting nanogram levels of DNA, will also bind to RNA. In preparations of DNA with minimal RNA contamination or with DNA samples having an unusually high guanine and cytosine (GC) content where the Hoechst 33258 signal can be quite low, ethidium bromide offers a relatively sensitive alternative to the more popular Hoechst 33258 DNA assay. A fluorometer capable of an excitation wavelength of 302 or 546 nm and an emission wavelength of 590 nm is required for this assay.

Additional Materials (also see Basic Protocol)

Ethidium bromide assay solution (see recipe)

1. Pipet 2.0 ml ethidium bromide assay solution into cuvette and place in sample chamber. Set excitation wavelength to 302 nm or 546 nm and emission wavelength to 590 nm. Take an emission reading without DNA and use as background.

If the instrument has a concentration readout mode or is capable of creating a standard curve, set instrument to read 0 with the blank solution. Otherwise note the readings in relative fluorescence units.

The excitation wavelength of this assay can be either in the UV range (~ 302 nm) using a quartz cuvette or in the visible range (546 nm) using a glass cuvette. In both cases the emission wavelength is 590 nm.

2. Read and calibrate these samples as described in step 3 of the Hoechst 33258 assay.
3. Read emissions of the unknown samples as in step 4 of the Hoechst 33258 assay.

A dye concentration of 5 $\mu\text{g/ml}$ in the ethidium bromide assay solution is appropriate for final DNA concentrations up to 1000 ng/ml . 10 $\mu\text{g/ml}$ ethidium bromide in the ethidium bromide assay solution will extend the assay's range to 10 $\mu\text{g/ml}$ DNA, but is only used for DNA concentrations > 1 $\mu\text{g/ml}$. Sample volumes of up to 10 μl can be added to the 2.0-ml aliquot of ethidium bromide assay solution.

DNA DETECTION USING PICOGREEN dsDNA QUANTITATION REAGENT

ALTERNATE PROTOCOL 3

PicoGreen dsDNA quantitation reagent enables researchers to quantitate as little as 25 pg/ml of dsDNA (50 pg dsDNA in a 2-ml assay volume) with a standard spectrofluorometer and fluorescein excitation and emission wavelengths. This sensitivity exceeds that achieved with the Hoechst 33258-based assay (Alternate Protocol 1) by 400-fold. Using a fluorescence microplate reader, it is possible to detect as little as 250 pg/ml dsDNA (50 pg in a 200- μ l assay volume). The standard PicoGreen assay protocol is also simpler than that for Hoechst 33258 because a single concentration of the PicoGreen reagent allows detection over the full dynamic range of the assay. In order to achieve more than two orders of magnitude in dynamic range with Hoechst-based assays, two different dye concentrations are recommended. In contrast, the linear detection range of the PicoGreen assay in a standard fluorometer extends over more than four orders of magnitude in DNA concentration—from 25 pg/ml to 1000 ng/ml—with a single dye concentration (Fig. A.3D.1). Linearity is maintained in the presence of several compounds that commonly contaminate nucleic acid preparations, including salts, urea, ethanol, chloroform, detergents, proteins, and agarose.

CAUTION: No data are available addressing the mutagenicity or toxicity of PicoGreen dsDNA quantitation reagent. Because this reagent binds to nucleic acids, it should be treated as a potential mutagen and handled with appropriate care. The DMSO stock solution should be handled with particular caution, as DMSO is known to facilitate the entry of organic molecules into tissues. It is strongly recommended that double gloves be used when handling the DMSO stock solution. As with all nucleic acid reagents, solutions of PicoGreen reagent should be poured through activated charcoal before disposal. The charcoal must then be incinerated to destroy the dye.

Figure A.3D.1 Dynamic range and sensitivity of the PicoGreen dsDNA quantitation assay. Calf thymus DNA was added to cuvettes containing PicoGreen dsDNA quantitation reagent diluted in 10 mM Tris-Cl/1 mM EDTA, pH 7.5 (TE). The samples were excited at 480 nm and the fluorescence emission intensity was measured at 520 nm using a spectrofluorometer. Fluorescence emission intensity was then plotted versus DNA concentration.

Commonly Used Techniques

A.3D.5

Additional Materials (also see Basic Protocol)

PicoGreen dsDNA quantitation kit containing:

PicoGreen dsDNA quantitation reagent (Component A), 1 ml solution in DMSO (store frozen up to 6 months at -20°C , protected from light)

20 \times TE (Component B), 25 ml of 200 mM Tris-Cl/20 mM EDTA, pH 7.5 (store up to 6 months at 4°C ; may be frozen for long-term storage)

Lambda DNA standard (Component C), 1 ml of 100 $\mu\text{g}/\text{ml}$ in TE (store up to 6 months at 4°C ; may be frozen for long-term storage)

Spectrofluorometer or fluorescence microplate reader

NOTE: For either the kits or the stand-alone reagent, sufficient reagent is supplied for 200 assays using an assay volume of 2 ml according to the protocol below. Note that the assay volume is dependent on the instrument used to measure fluorescence; with a microplate reader and a 96-well microplate, the assay volume is reduced to 200 μl and 2000 assays are possible. The PicoGreen reagent supplied in the kits is exactly the same as the reagent sold separately. The DMSO stock solution should be stored frozen at -20°C and protected from light. The 20 \times assay buffer and lambda DNA standard in the kits are best stored at 4°C ; however, either may be frozen for long-term storage. When properly stored, components should be stable for at least 6 months.

Prepare the reagent

1. On day of experiment, prepare an aqueous working solution of the PicoGreen reagent by making a 200-fold dilution of the concentrated DMSO solution in 1 \times TE.

Allow the PicoGreen reagent to warm to room temperature before opening the vial. Because the PicoGreen dye is an extremely sensitive detection reagent for dsDNA, it is imperative that the TE solution be free of contaminating nucleic acids. The 20 \times TE buffer included in the PicoGreen dsDNA Quantitation Kits is certified to be nucleic acid-free and DNase-free. Prepare a 1 \times TE working solution by diluting the concentrated buffer 20-fold with sterile, distilled, DNase-free water.

To prepare enough working solution to assay 20 samples in a 2-ml final volume, add 100 μl PicoGreen dsDNA quantitation reagent to 19.9 ml TE. The author recommends preparing this solution in a plastic container rather than glass, as the reagent may adsorb to glass surfaces. Protect the working solution from light by covering it with foil or placing it in the dark, as the PicoGreen reagent is susceptible to photodegradation. For best results, this solution should be used within a few hours of its preparation.

Establish the DNA standard curve

2. Prepare a 2 $\mu\text{g}/\text{ml}$ stock solution of dsDNA in 1 \times TE. Determine the DNA concentration on the basis of absorbance at 260 nm (A_{260}) in a cuvette with a 1-cm pathlength (see Basic Protocol); an A_{260} of 0.04 corresponds to 2 $\mu\text{g}/\text{ml}$ dsDNA solution.

For a standard curve, the author commonly uses bacteriophage lambda DNA (provided with kit) or calf thymus DNA, although any purified dsDNA preparation may be used. The lambda DNA standard, provided at 100 $\mu\text{g}/\text{ml}$ in the PicoGreen Kits, can simply be diluted 50-fold in 1 \times TE to make the 2 $\mu\text{g}/\text{ml}$ working solution. For example, 30 μl of the DNA standard mixed with 1.47 ml of TE will be sufficient for the standard curve described below. It is sometimes preferable to prepare the standard curve with DNA similar to the type being assayed; e.g., long or short linear DNA fragments when quantitating similar-sized restriction fragments or plasmid when quantitating plasmid DNA. However, most linear dsDNA molecules yield approximately equivalent signals, regardless of fragment length. Results have shown that the PicoGreen assay remains linear in the presence of several compounds that commonly contaminate nucleic acid preparations, although the signal intensity may be affected (Table A.3D.3). Thus, to serve as an effective control, the dsDNA solution used to prepare the standard curve should be treated the same way as the experimental samples and should contain similar levels of such compounds.

Table A.3D.3 Effects of Several Compounds that Commonly Contaminate Nucleic Acid Preparations on the Signal Intensity of the PicoGreen dsDNA Quantitation Assay

Compound	Concentration	% Signal change ^a
<i>Salts</i>		
Ammonium acetate	50 mM	3% decrease
Sodium acetate	30 mM	3% increase
Sodium chloride	200 mM	30% decrease
Zinc chloride	5 mM	8% decrease
Magnesium chloride	50 mM	33% decrease
Urea	2 M	9% increase
<i>Organic solvents</i>		
Phenol	0.1%	13% increase
Ethanol	10%	12% increase
Chloroform	2%	14% increase
<i>Detergents</i>		
Sodium dodecyl sulfate	0.01%	1% decrease
Triton X-100	0.1%	7% increase
<i>Proteins</i>		
Bovine serum albumin	2%	16% decrease
IgG	0.1%	19% increase
<i>Other compounds</i>		
Polyethylene glycol	2%	8% increase
Agarose	0.1%	4% increase

^aThe compounds were incubated at the indicated concentrations with PicoGreen reagent in the presence of 500 ng/ml calf thymus DNA. All samples were assayed in a final volume of 200 μ l in 96-well microplates using a CytoFluor microplate reader (PerSeptive Biosystems). Samples were excited at 485 nm and fluorescence intensity was measured at 520 nm.

- 3a. *For high-range standard curve:* Create a five-point standard curve from 1 ng/ml to 1 μ g/ml by combining the 2 μ g/ml stock prepared in step 2 with 1 \times TE, in disposable cuvettes (or plastic test tubes for transfer to quartz cuvettes), according to Table A.3D.4.
- 3b. *For low-range standard curve:* Prepare a 40-fold dilution of the 2 μ g/ml DNA solution to yield a 50 ng/ml DNA stock solution. Create a five-point standard curve from 25 pg/ml to 25 ng/ml by combining this 50 ng/ml stock with 1 \times TE in disposable cuvettes (or plastic test tubes for transfer to quartz cuvettes), according to Table A.3D.4.

To create the low-range standard curve, adjust the fluorometer gain to accommodate the lower fluorescence signals.
4. Add 1.0 ml of the aqueous working solution of PicoGreen reagent (prepared in step 1) to each cuvette. Mix well and incubate for 2 to 5 min at room temperature, protected from light.
5. After incubation, measure sample fluorescence using a spectrofluorometer or fluorescence microplate reader and standard fluorescein wavelengths (excitation \sim 480

Table A.3D.4 Preparing Standard Curve with the PicoGreen Reagent (Alternate Protocol 3)

Vol. (μl) DNA stock	Vol. (μl) 1× TE	Vol. (μl) PicoGreen working solution	Final DNA conc. in PicoGreen assay
<i>High-range (stock contains 2 μg/ml DNA)^a</i>			
1000	0	1000	1 μg/ml
100	900	1000	100 ng/ml
10	990	1000	10 ng/ml
1	999	1000	1 ng/ml
0	1000	1000	Blank
<i>Low range (stock contains 50 ng/ml DNA)^b</i>			
1000	0	1000	25 ng/ml
100	900	1000	2.5 ng/ml
10	990	1000	250 pg/ml
1	999	1000	25 pg/ml
0	1000	1000	Blank

^aSee Alternate Protocol 3, step 3a.^bSee Alternate Protocol 3, step 3b.

nm, emission ~520 nm). To ensure that the sample readings remain in the detection range of the fluorometer, set the instrument's gain so that the sample containing the highest DNA concentration yields a fluorescence intensity near the fluorometer's maximum. To minimize photobleaching effects, keep the time for fluorescence measurement constant for all samples.

- Subtract the fluorescence value of the reagent blank from that of each of the samples. Use corrected data to generate a standard curve of fluorescence versus DNA concentration (see Fig. A.3D.1).

Analyze samples

- Add 1.0 ml of the aqueous working solution of the PicoGreen reagent (prepared in step 1) to each sample. Incubate 2 to 5 min at room temperature, protected from light.
- Measure fluorescence of sample using instrument parameters that correspond to those used when generating standard curve (see steps 2 to 6). To minimize photobleaching effects, keep time for fluorescence measurement constant for all samples.
- Subtract fluorescence value of reagent blank from that of each sample. Determine DNA concentration of the sample from standard curve.
- If desired, repeat assay using a different dilution of the sample to confirm results.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Calf thymus DNA standard solutions

Kits containing calf thymus DNA standard for fluorometry are available (Fluorometry Reference Standard Kits, Hoefer). Premeasured, CsCl-gradient-purified DNA of defined GC content, for use in absorption and fluorometric spectroscopy, is available from Sigma (e.g., calf thymus DNA, 42% GC; *Clostridium perfringens* DNA, 26.5% GC).

Ethidium bromide assay solution

Add 10 ml of 10× TNE buffer (see recipe) to 89.5 ml H₂O. Filter through a 0.45-μm filter, then add 0.5 ml of 1 mg/ml ethidium bromide.

Add the dye after filtering, as ethidium bromide will bind to most filtration membranes.

CAUTION: *Ethidium bromide is hazardous; wear gloves and use appropriate care in handling, storage, and disposal.*

Hoechst 33258 assay solutions

Stock solution: Dissolve in H₂O at 1 mg/ml. Stable for ~6 months at 4°C.

Working solution: Add 10 ml of 10× TNE buffer (see recipe) to 90 ml H₂O. Filter through a 0.45-μm filter, then add 10 μl of 1 mg/ml Hoechst 33258.

Hoechst 33258 is a fluorochrome dye with a molecular weight of 624 and a molar extinction coefficient of $4.2 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$ at 338 nm.

The dye is added after filtering because it will bind to most filtration membranes.

CAUTION: *Hoechst 33258 is hazardous; use appropriate care in handling, storage, and disposal.*

TNE buffer, 10×

100 mM Tris base

10 mM EDTA

2.0 M NaCl

Adjust pH to 7.4 with concentrated HCl

As needed, dilute with H₂O to desired concentration

COMMENTARY

Background Information

In deciding what method of nucleic acid measurement is appropriate, three issues are critical: specificity, sensitivity, and interfering substances. Properties of the four assays described in this section are listed in Table A.3D.5. The traditional method for determining the amount of DNA in solution is by measuring absorbance at 260 nm. Because many potential contaminants of DNA and RNA preparations also absorb in the UV range, absorption spectroscopy is a reliable method to assess both the purity of a preparation and the quantity of DNA or RNA present. Absorption spectroscopy does have serious limitations. Relatively large amounts of DNA are required to get accurate readings—for example, 500 ng/ml DNA is equivalent to only 0.01 A_{260} units. Furthermore, the method cannot discriminate between RNA and DNA, and UV-absorbing contaminants such as protein will cause discrepancies.

The assay using Hoechst 33258 dye (Alternate Protocol 1) is the only procedure in common use that is specific for DNA (i.e., it does not measure RNA). This assay is the method of choice for rapid measurement of low quantities of DNA, with a detection limit of ~1 ng DNA. Concentrations of DNA in both crude cell lysates and purified preparations can be quan-

tified (Labarca and Paigen, 1980). Because the assay quantifies a broad range of DNA concentrations—from 10 ng/ml to 15 μg/ml—it is useful for the measurement of both small and large amounts of DNA (e.g., in verifying DNA concentrations prior to performing electrophoretic separations and Southern blots). The Hoechst 33258 assay is also useful for measuring products of the polymerase chain reaction (PCR) synthesis.

Upon binding to DNA, the fluorescence characteristics of Hoechst 33258 change dramatically, showing a large increase in emission at ~458 nm. Hoechst 33258 is nonintercalating and apparently binds to the minor groove of the DNA, with a marked preference for AT sequences (Portugal and Waring, 1988). The fluorochrome 4',6-diamidino-2-phenylindole (DAPI; Daxhelet et al., 1989) is also appropriate for DNA quantitation, although it is not as commonly used as Hoechst 33258. DAPI is excited with a peak at 344 nm. Emission is detected at ~466 nm, similar to Hoechst 33258.

Ethidium bromide is best known for routine staining of electrophoretically separated DNA and RNA, but it can also be used to quantify both DNA and RNA in solution (Le Pecq, 1971). Unlike Hoechst 33258, ethidium bromide fluorescence is not significantly impaired

Table A.3D.5 Properties of Absorbance and Fluorescence Spectrophotometric Assays for DNA and RNA

Property	Absorbance (A_{260})	Fluorescence		
		H33258	Ethidium bromide	PicoGreen
<i>Sensitivity</i>				
DNA	1-50 $\mu\text{g/ml}$	0.01-15 $\mu\text{g/ml}$	0.1-10 $\mu\text{g/ml}$	25-1000 ng/ml
RNA	1-40 $\mu\text{g/ml}$	NA	0.2-10 $\mu\text{g/ml}$	Minimal sensitivity
<i>Ratio of signal (DNA/RNA)</i>	0.8	400	2.2	>100

by high GC content. The ethidium bromide assay (with excitation at 546 nm) is ~20-fold less sensitive than the Hoechst 33258 assay.

In addition to the advantages mentioned in the protocol itself (see Alternate Protocol 3), the PicoGreen assay protocol also minimizes the fluorescence contribution of RNA and single-stranded DNA (ssDNA). Although the Hoechst 33258-based method is not significantly affected by the presence of RNA when the assay is carried out in the recommended high-salt buffer, Hoechst 33258 does exhibit a large fluorescence enhancement with ssDNA under these conditions. Furthermore, when the Hoechst 33258-based assay is carried out in TE alone (10 mM Tris-Cl/1 mM EDTA, pH 7.5, with no NaCl added), RNA contributes a significant fluorescence signal. Using the PicoGreen dsDNA quantitation reagent as described in Alternate Protocol 3, researchers can quantitate dsDNA in the presence of equimolar concentrations of ssDNA and RNA with minimal effect on the quantitation results.

Critical Parameters

Care should be taken when handling sample cuvettes in all spectrophotometric procedures. Fluorometers use cuvettes with four optically clear faces, because excitation and emitting light enter and leave the cuvette through directly adjacent sides. Thus, fluorometric cuvettes should be held by the upper edges only. In contrast, transmission spectrophotometers use cuvettes with two opposite optical windows, with the sides frosted for easy handling. It is important to check that the optical faces of cuvettes are free of fingerprints and scratches. In addition, for accurate absorbance readings, spectrophotometer cuvettes must be perfectly matched.

Proteins in general have A_{280} readings considerably lower than nucleic acids on an equiva-

lent weight basis. Thus, even a small increase in the A_{280} relative to A_{260} (i.e., a lowering of the A_{260}/A_{280} ratio) can indicate severe protein contamination. Other commonly used buffer components absorb strongly at 260 nm and can cause interference if present in high enough concentrations. EDTA, for example, should not be present at ≥ 10 mM.

Sensitivity of the Hoechst 33258 fluorescence assay decreases with nuclease degradation, increasing GC content, or denaturation of DNA (Labarca and Paigen, 1980; Stout and Becker, 1982). Increased temperature of the assay solution and ethidium bromide contamination also decrease the Hoechst 33258 signal. Sodium dodecyl sulfate (>0.01% final concentration) also interferes with accurate readings (Cesarone et al., 1979). The pH of the assay solution is critical to sensitivity and should be pH ~7.4 (Labarca and Paigen, 1980; Stout and Becker, 1982). At a pH <6.0 or >8.0 the background becomes much higher and there is a concomitant loss of fluorescence enhancement.

High-quality double-stranded DNA is recommended, although single-stranded genomic DNA also works well with this assay. However, with very small fragments of DNA, the Hoechst 33258 dye binds to double-stranded DNA only. Thus, the assay will not work with single-stranded oligomers. Linear and circular DNA give approximately the same levels of fluorescence (Daxhelet et al., 1989). When preparing DNA standards, an attempt should be made to equalize the GC content of the standard DNA and that of the sample DNA. In most situations, salmon sperm or calf thymus DNA is suitable. An extensive list of estimated GC content for various organisms is available (Marmur and Doty, 1962). Eukaryotic cells vary somewhat in GC content but are generally in the range of 39% to 46%. Within this range, the fluorescence per microgram of DNA does not vary

Table A.3D.6 Sensitivity of the PicoGreen dsDNA Assay for Quantitating dsDNA in the Presence of Single-Stranded Nucleic Acids

[dsDNA] ^a	[RNA]	Amount of RNA relative to dsDNA	[ssDNA]	Amount of ssDNA relative to dsDNA
1 µg/ml	10 µg/ml	10×	300 ng/ml	0.3×
500 ng/ml	500 ng/ml	1×	50 ng/ml	0.1×
10 ng/ml	100 ng/ml	10×	30 ng/ml	3×
5 ng/ml	50 ng/ml	10×	15 ng/ml	3×
100 pg/ml	1 ng/ml	10×	1 ng/ml	10×
50 pg/ml	500 pg/ml	10×	500 pg/ml	10×

^aFor several concentrations of dsDNA, the concentration of RNA or ssDNA is shown that results in no more than a 10% increase in the sample's signal intensity.

Figure A.3D.2 Fluorochrome H33258 (A) and ethidium bromide (B) DNA concentration standard curves. Assays were performed as described in alternate protocols, at indicated excitation and emission wavelengths. The concentrations of H33258 and ethidium bromide were 0.1 and 5 µg/ml, respectively. Assays contained the indicated concentrations of calf thymus DNA standards suspended in a final volume of 2.0 ml. Inset shows low DNA concentration curve for the H33258 assay. Note that, under these conditions, H33258 produces ~20 times more relative fluorescence units than ethidium bromide. A Shimadzu RF-5000 scanning fluorescence spectrometer was used for both assays.

substantially. In contrast, the GC content of prokaryotes can vary from 26% to 77%, causing considerable variation in the fluorescence signal. In these situations, the sample DNA should be first quantitated via transmission spectroscopy and compared to a readily available standard (e.g., calf thymus DNA). Future measurements would then use calf thymus as a standard, but with a correction factor for difference in fluorescence yield between the two DNA types. For further troubleshooting information, see Van Lancker and Gheysens (1986), in which the effects of interfering substances on the Hoechst 33258 assay (and several other assays) are compared.

In the ethidium bromide assay, single-stranded DNA gives approximately half the

signal as double-stranded calf thymus DNA. Ribosomal RNA also gives about half the fluorescent signal as double-stranded DNA, and RNase and DNase both severely decrease the signal. Closed circular DNA also binds less ethidium bromide than nicked or linear DNA. Further critical parameters of the ethidium bromide assay are described by Le Pecq (1971).

With PicoGreen, dsDNA can be quantitated in the presence of equimolar concentrations of single-stranded nucleic acids with minimal interference. Table A.3D.6 shows the concentrations of RNA or ssDNA that, for a given dsDNA concentration, result in less than a 10% change in the signal intensity using the PicoGreen assay protocol. Fluorescence due to PicoGreen reagent binding to RNA at high concentrations

can be eliminated by treating the sample with DNase-free RNase. The use of RNase A/RNase T1 with S1 nuclease will eliminate all single-stranded nucleic acids and ensure that the entire sample fluorescence is due to dsDNA.

Anticipated Results

The detection limit of absorption spectroscopy will depend on the sensitivity of the spectrophotometer and any UV-absorbing contaminants that might be present. The lower limit is generally ~0.5 to 1 µg nucleic acid. Typical values for a highly purified sample of DNA are shown in Table A.3D.2.

For the Hoechst 33258, ethidium bromide, and PicoGreen assays, a plot of relative fluorescence units or estimated concentration (y axis) versus actual concentration (x axis) typically produces a linear regression with a correlation coefficient (r^2) of 0.98 to 0.99 (Fig. A.3D.2). Table A.3D.3 provides a comparison of the sensitivities and specificities of the three assays.

Time Considerations

The three assays described can be performed in a short period of time. In a well-planned series of assays, 50 samples can be prepared and read comfortably in 1 hr. Although some error might be introduced, DNA samples can be sequentially added to the same cuvette containing working dye solution. The increase in fluorescence with each sample is noted and subtracted from the previous reading to give relative fluorescence or concentration of the new sample, eliminating the need to change solutions for each sample. Be certain that the final amount of DNA does not exceed the linear portion of the assay.

Introduction of Restriction Enzyme Recognition Sequences by Silent Mutation

Site-directed mutagenesis has been an invaluable tool in understanding structure-function relationships. A number of techniques have been developed for introducing site-directed mutations. These techniques exploit in vitro and in vivo features of enzyme systems that act on nucleic acids (see Chapter 8) and have been immensely aided by development of the polymerase chain reaction (PCR; UNIT 15.7). Any changes in primer sequence can be easily incorporated into the DNA product of PCR; this facilitates subsequent incorporation of the changes into the gene sequence.

Sequence analysis and other strategies have identified biologically important motifs within proteins. This knowledge together with the tools of recombinant DNA technology can be used to design, construct, and express hybrid sequences that have a particular function. For example, development of multivalent recombinant vaccines requires design of a protein with immune-neutralizing domains from several pathogens expressed as a fusion protein. Alternatively, very small regulatory sequences can be introduced as part of the coding sequence to develop novel products that exert multiple effects as products of transcription and translation. Thus it is often necessary to generate gene cassette structures that encompass these motifs to facilitate manipulation of each motif for subsequent studies. Restriction enzyme recognition sequences are rarely found flanking such biologically important domains and motifs, and it is often desirable to introduce restriction sites at flanking regions. Because the restriction enzyme recognition sequence will form part of the coding sequence, it is imperative that the introduction of restriction sites does not alter the amino acid sequence of the encoded protein. The following strategy enables identification of a large number of potential sites where restriction enzyme recognition sequences can be introduced via silent mutations.

The first step for introducing a restriction enzyme recognition sequence by silent mutagenesis involves translating the sequence in all the three reading frames (Shankarappa et al., 1992a; Tables A.3E.1 and A.3E.2). Due to degeneracy of the genetic code, translation of a six-base recognition sequence yields a large number of di- and tripeptides. Next, the sequence of the protein to be modified is analyzed for the presence of any of these peptides. The presence of a peptide indicates that it is possible to introduce the corresponding restriction enzyme recognition sequence at that site by silent mutagenesis. For example, translation of the recognition sequence for *Pst*I (CTGCAG) yields a dipeptide Leu-Gln. However, translation of the same sequence in the second and third reading frames yields an additional 20 and 30 tripeptide sequences respectively. Hence, it is now possible to introduce *Pst*I recognition sequence at any of the 51 di- or tripeptide motifs by silent mutagenesis. Similarly, an analysis of the recognition sequences for *Not*I, an eight-base restriction enzyme, identifies 75 different tri- and tetrapeptide sequences that have the potential to be changed by silent mutations to incorporate the recognition sequence.

Introduction of restriction enzyme recognition sequences by silent mutations also provides a simple strategy to generate unique cohesive sites at the ends of DNA fragments (see also UNIT 3.17). It is possible to ligate several fragments containing unique overhangs at their ends, thus generating a large fragment containing all the desired mutations (Shankarappa et al., 1992b). Introduction of silent mutation can be coupled with introduction of a second mutation downstream of the restriction site. Digestion of the DNA fragment generated by PCR using such a primer will generate unique cohesive sites at the ends to facilitate subsequent ligation.

^aSequences recognized by six-base restriction enzymes that do not contain degeneracy in the recognition sequence.

^bIdentity of amino acid at position 1, 2, or 3 in the translation sequence.

^cSingle-letter amino acid code (see Table A.1C.1); X indicates a stop codon.

Tables A.3E.1 and A.3E.2 list di-, tri-, and tetrapeptide translation sequences that can be used to introduce sequences recognized by common restriction enzymes that do not contain any degeneracy. A computer program, SILMUT, uses either amino acid or nucleic acid sequence to identify potential sites for silent mutations. The program is available from the author and at many anonymous ftp sites (Shankarappa et al., 1992c). When using this mutagenesis strategy, due consideration should be given to codon usage of the host organism.

Techniques for Mammalian Cell Tissue Culture

Tissue culture technology has found wide application in the field of molecular biology (see, in particular, Chapter 9, Introduction of DNA into Mammalian Cells, and Chapter 16, Protein Expression). Monolayer cell cultures are utilized in cytogenetic, biochemical, and molecular laboratories for research as well as diagnostic studies. The isolation and culture of specific types of cells is described in Chapter 28 (Mammalian Cell Culture). This appendix addresses general concerns and procedures needed for successful culture of mammalian cells. In most cases, cells or tissues must be grown in culture for days or weeks to obtain sufficient numbers of cells for analysis. Maintenance of cells in long-term culture requires strict adherence to aseptic technique to avoid contamination and potential loss of valuable cell lines. The first section of this unit discusses basic principles of sterile technique.

An important factor influencing the growth of cells in culture is the choice of tissue culture medium. Many different recipes for tissue culture media are available and each laboratory must determine which medium best suits its needs. Individual laboratories may elect to use commercially prepared medium or prepare their own. Commercially available medium can be obtained as a sterile and ready-to-use liquid, in a concentrated liquid form, or in a powdered form. Besides providing nutrients for growing cells, medium is generally supplemented with antibiotics, fungicides, or both to inhibit contamination. The second section of this unit discusses medium preparation (see also the introduction to Chapter 9).

As cells grown in monolayer reach confluency, they must be subcultured or passaged. Failure to subculture confluent cells results in reduced mitotic index and eventually in cell death. The first step in subculturing is to detach cells from the surface of the primary culture vessel by trypsinization or mechanical means. The resultant cell suspension is then subdivided, or reseeded, into fresh cultures. Secondary cultures are checked for growth and fed periodically, and may be subsequently subcultured to produce tertiary cultures, etc. The time between passaging of cells varies with the cell line and depends on the growth rate.

The Basic Protocol describes subculturing of a monolayer culture grown in petri plates or flasks. Support Protocols describe freezing of monolayer cells, thawing and recovery of cells, counting cells using a hemacytometer, and preparing cells for transport. Alternate Protocols 1 and 2 describe the passaging and freezing of cells in suspension culture.

CAUTION: Radioactive, biological, and chemical substances require special handling; see *APPENDIX 1E* for guidelines.

STERILE TECHNIQUE

It is essential that sterile technique be maintained when working with cell cultures. Aseptic technique involves a number of precautions to protect both the cultured cells and the laboratory worker from infection. The laboratory worker must realize that cells handled in the lab are potentially infectious and should be handled with caution. Protective apparel such as gloves, lab coats or aprons, and eyewear should be worn when appropriate (Knutsen, 1991). Care should be taken when handling sharp objects such as

needles, scissors, scalpel blades, and glass that could puncture the skin. Sterile disposable plastic supplies may be used to avoid the risk of broken or splintered glass (Rooney and Czepulkowski, 2001).

Frequently, specimens received in the laboratory are not sterile, and cultures prepared from these specimens may become contaminated with bacteria, fungus, or yeast. The presence of microorganisms can inhibit growth, kill cell cultures, or lead to inconsistencies in test results. The contaminants deplete nutrients in the medium and may produce substances that are toxic to cells. Antibiotics and antimycotics can be used to combat potential contaminants (see Table A.3F.1). The solutions can be used to wash specimens prior to culture or to rinse contaminated cultures, and can be added to medium used for tissue culture. Antibiotics (penicillin, streptomycin, kanamycin, neomycin, or gentamycin) can be used individually or in combinations (i.e., penicillin/streptomycin/neomycin and penicillin/streptomycin/gentamycin). Likewise, fungicides such as amphotericin B (Fungizone) and mycostatin (Nystatin) can be used alone or as antibiotic/antimycotic solutions (i.e., penicillin/streptomycin/Fungizone). Particular care should be taken when using Fungizone, as it is typically very toxic to cell cultures, and adequate data are not available regarding potential adverse effects on the growth of human cells. Antibiotics and antimycotics are available from a number of vendors including Invitrogen, Sigma-Aldrich, and BioWhittaker.

All materials that come into direct contact with cultures must be sterile. Sterile disposable dishes, flasks, pipets, etc., can be obtained directly from manufacturers. Reusable glassware must be washed, rinsed thoroughly, then sterilized by autoclaving or by dry heat before reusing. With dry heat, glassware should be heated 1.5 to 2 hr at 160°C to ensure sterility. Materials that may be damaged by very high temperatures can be autoclaved 20 min at 120°C and 15 psi. All media, reagents, and other solutions that come into contact with the cultures must also be sterile; media may be obtained as a sterile liquid from the manufacturer, autoclaved if not heat-sensitive, or filter sterilized. Supplements can be added to media prior to filtration, or they can be added aseptically after filtration. Filters with 0.20- to 0.22- μm pore size should be used to remove small gram-negative bacteria from culture media and solutions.

Contamination can occur at any step in handling cultured cells. Care should be taken to maintain the sterility of petri plates, pipets, and flasks that are used for tissue culture. The use of disposable, sterile culture supplies is convenient and has virtually eliminated

Table A.3F.1 Working Concentrations of Antibiotics and Fungicides for Mammalian Cell Culture

Additive	Final concentration
Penicillin	50–100 U/ml
Streptomycin sulfate	50–100 $\mu\text{g/ml}$
Kanamycin	100 $\mu\text{g/ml}$
Gentamycin	50 $\mu\text{g/ml}$
Neomycin	50 $\mu\text{g/ml}$
Mycostatin (Nystatin)	20 $\mu\text{g/ml}$
Amphotericin B (Fungizone)	0.25 $\mu\text{g/ml}$
Pen/strep/neomycin ^a	1 \times

^aUsually supplied as 100 \times concentrated stock solution, which is diluted to 1 \times concentration in the medium.

the need to flame-sterilize instruments and vessels used for tissue culture. The initial cost of purchasing these single-use supplies outweighs the expense associated with the time and effort of washing, packaging, and sterilizing nondisposables. Good sterile technique must be followed. For example, if a sterile pipet tip should come into contact with the benchtop or other nonsterile surface, the pipet tip should be discarded and a fresh one obtained. If disposables are not an option, the necks of sterile containers, such as bottles and flasks, and the tips of pipets should be passed through a flame before the pipet is introduced into the container. After pipetting, the neck of the bottle or flask should again be flamed.

Certain instruments used for tissue culture (forceps, scissors, scalpels, and in some instances, glass bottles) may require autoclave sterilization prior to initial use. The autoclave relies on pressurized steam to destroy microorganisms. Instruments to be autoclaved should be thoroughly washed and dried, then packaged if necessary to ensure that sterility will be maintained after removal from the autoclave until use. Indicator tape or autoclave bags with indicator strips should be used to document that the items have been autoclaved. The indicator tape demonstrates that the item has been autoclaved, but does not ensure sterility.

Historically, if instruments such as forceps, tweezers, scissors, or scalpels were going to be re-used to handle several sequential specimens, they were rapidly sterilized between uses by dipping in 70% alcohol and flaming. Other methods of rapid decontamination are now available. For example, the Germinator 500 (Cellpoint Scientific) is a small benchtop unit [height, 6.76 in. (~17 cm) × width, 5.25 in. (~13 cm) × depth 5.25 in. (~13 cm)] used in tissue culture labs for decontamination of metal dissecting instruments. Instruments must be clean, dry, and free of debris prior to sterilization. The instruments are inserted into a stainless steel well [inside dimensions: diameter, 2 in. (~5 cm) × depth, 4 in. (~10 cm)] filled with glass beads that are maintained at a constant temperature of 500°F (~260°C). Dry heat decontamination occurs through heat transfer from the glass beads to the instruments. The inserted parts of small instruments are dry sterilized within ~15 sec, while larger instruments may take as long as 1 min. The Germinator 500 eliminates the need for alcohol and open flames for sterilization. Due to the lack of a method for routine monitoring of sterilization by glass beads, the Germinator 500 operating manual recommends that this equipment be used for research purposes only.

Although tissue culture work can be done on an open bench if aseptic methods are strictly enforced, many labs prefer to perform tissue culture work in a room or low-traffic area reserved specifically for that purpose. At the very least, biological safety cabinets are recommended to protect the cultures as well as the laboratory worker. In a laminar flow hood, the flow of air protects the work area from dust and contamination and acts as a barrier between the work surface and the worker. Many different styles of safety hoods are available, and the laboratory should consider the types of samples being processed and the types of potential pathogenic exposure in making a selection. Manufacturer recommendations should be followed regarding routine maintenance checks on air flow and filters. For day-to-day use, the cabinet should be turned on for at least 5 min prior to beginning work. All work surfaces both inside and outside of the hood should be kept clean and disinfected daily and after each use. A 10% household bleach solution, 70% alcohol, an iodophor, a quarternary ammonium compound, or commercially available liquid disinfectants can be used (<http://www.ehs.cornell.edu/bio/cabinets.htm>, last updated December, 2000).

Some safety cabinets are equipped with ultraviolet (UV) lights for decontamination of work surfaces. However, UV lamps are not required in biological safety cabinets, and their effectiveness has been questioned (<http://www.niehs.nih.gov/odhsb/>

[biosafe/bsc/section6.htm](http://www.biosafe/bsc/section6.htm); <http://www.ehs.cornell.edu/bio/cabinets.htm>). UV lamps may produce a false sense of security as they maintain a visible blue glow long after their germicidal effectiveness is lost. Effectiveness diminishes over time as the glass tube gradually loses its ability to transmit short UV wavelengths, and may also be reduced by dust on the glass tube, distance from the work surface, temperature, and air movement. Even when the UV output is adequate, the rays must directly strike a microorganism in order to kill it; bacteria or mold spores hidden below the surface of a material or outside the direct path of the rays will not be destroyed. Another rule of thumb is that anything that can be seen cannot be killed by UV. UV lamps will only destroy microorganisms such as bacteria, viruses, and mold spores; they will not destroy insects or other large organisms. Aside from their general ineffectiveness, UV lights pose a safety hazard, as exposure can cause damage to the eyes and skin (http://www.yale.edu/oehs/cad2_0.htm). A more reliable approach to eliminate contamination is the use of well-practiced microbiological procedures, good aseptic techniques, and standard operational procedures for working in a biological safety cabinet, including thorough decontamination with an effective disinfectant before and after use of the biological safety cabinet. The current recommendation is that work surfaces be wiped down with ethanol instead of relying on UV lamps, although some labs use the lamps in addition to ethanol wipes to decontaminate work areas. If UV lamps are used as a secondary method of disinfecting the work surface, their radiation output should be tested with a UV meter during the annual certification of the biological safety cabinet to ensure that the proper intensity of light is reaching the work surface. The radiation output should be at least $40 \mu\text{W}/\text{cm}^2$ at 254 nm when measured with a UV flux meter placed in the center of the work surface. The UV lamps should be replaced when they fall below the minimum requirements for protection (<http://www.ehs.cornell.edu/bio/cabinets.htm>).

Cultures should be visually assessed on a routine basis for evidence of contamination. Indicators in the tissue culture medium change color when contamination is present: for example, medium that contains phenol red changes to yellow because of increased acidity. Cloudiness and turbidity are also observed in contaminated cultures. Once contamination is confirmed with a microscope, infected cultures are generally discarded. Keeping contaminated cultures increases the risk of contaminating other cultures. Sometimes a contaminated cell line can be salvaged by treating it with various combinations of antibiotics and antimycotics in an attempt to eradicate the infection. In this procedure, the tissue culture medium is aspirated from the affected cultures and discarded. The cultures are rinsed with fresh “wash” medium that has been prepared by supplementing the routinely used tissue culture medium with the appropriate concentration of antibiotic and/or antimycotic (Table A.3F.1). The petri dish or flask should be gently swirled so that the cell surface is bathed in the clean medium. The wash medium can be left on the cultures for 1 to 5 min. Due to the toxicity of Fungizone and amphotericin, it is recommended that cell exposure to these agents be limited to less than 2 min. Aspirate the wash medium, replace with fresh medium and return the cultures to the incubator. Even under the best conditions, such treatment may adversely affect cell growth and it is often unsuccessful in ridding cultures of contaminants.

Mycoplasma are small (0.2 to 0.3 μm) intracellular bacteria that attach to the cell membrane, inhibit cell growth, and eventually lead to cell death. Because these parasites do not have cell walls, do not grow in colonies, and do not change the pH of the medium, they are difficult to detect visually in cultures. Mycoplasma can multiply to very high concentrations (10^7 to 10^8 organisms/ml) and adversely affect cultures by altering cell growth characteristics, inhibiting cell metabolism, disrupting nucleic acid synthesis, inducing chromosome aberrations, changing cell membrane antigenicity, and altering transfection rates and viral susceptibility (<http://www.unc.edu/depts/tcf/mycoplasma.htm>).

Mycoplasma are spread by cross-contamination from infected cultures through aerosolization during pipetting, or via the transfer of contaminated cells or contaminated reagents used in cell culture (<http://www.unc.edu/depts/tcf/mycoplasma.htm>). There are several methods of detecting mycoplasma in cell cultures and in cell culture reagents. In the direct method, both cultures and reagents can be plated on agar in order to grow and thereby reveal the presence of mycoplasma. Disadvantages of this method are that some strains of mycoplasma cannot be cultivated on agar and that the results can take from 2 to 4 weeks to obtain (<http://www.lerner.ccf.org/services/cell/cellculture.php>). Several indirect methods are available and should be selected based on the capabilities of the laboratory and the needs of the laboratory in terms of sensitivity, specificity, and time requirements. The DNA staining method uses Hoechst 33258 to highlight the A-T rich DNA of mycoplasma, so that mycoplasma appear as bright extranuclear spots in the cytoplasm. Results are available in 24 hr, but this method is not as sensitive as the direct method and can be difficult to interpret due to background bacterial/yeast/fungal contamination, excess debris, reduced or absent live cells, and broken nuclei from dead cells. The addition of an indicator such as Vero (Sigma-Aldrich) increases the sensitivity of this method. PCR primers that selectively amplify part of the mycoplasma DNA are also available. Kits include the ELISA mycoplasma detection kit from Roche Applied Science, the Mycoplasma Detection kit from Minerva Biolabs, the Myco Alert Mycoplasma Detection Assay by Cambrex (with results available in <20 min using the Cambrex instrument), and the VenorGem Mycoplasma PCR Detection Kit from Sigma-Aldrich.

Good aseptic technique and routine testing are the most effective methods for preventing mycoplasma contamination. Most standard antibiotics are not effective in treating mycoplasma contamination, and many laboratories prefer to dispose of contaminated cultures. In the event that the cultures are valuable and backup cultures are not available, it is imperative to attempt to salvage the contaminated cells. Agents such as Mynox Mycoplasma Elimination Reagent and Mycoplasma Removal Agent (MRA) are commercially available from ICN Flow, and usually require a single treatment to decontaminate cultures (<http://www.unc.edu/depts/tcf/mycoplasma.htm>).

CULTURE MEDIUM PREPARATION

Choice of tissue culture medium comes from experience. An individual laboratory must select the medium that best suits the type of cells being cultured. Chemically defined media are available in liquid or powdered form from a number of suppliers. Sterile, ready-to-use medium has the advantage of being convenient, although it is more costly than other forms. Powdered medium must be reconstituted with tissue-culture-grade water according to manufacturer's directions. Distilled or deionized water is not of sufficiently high quality for medium preparation; double- or triple-distilled water or commercially available tissue culture water should be used. The medium should be filter-sterilized and transferred to sterile bottles. Prepared medium can generally be stored ≤ 1 month in a 4°C refrigerator. Laboratories using large volumes of medium may choose to prepare their own medium from standard recipes. This may be an economical approach, but it is time-consuming and the savings may not offset the time required.

Basic media such as Eagle minimal essential medium (MEM, *UNIT 16.16*), Dulbecco's modified Eagle medium (DMEM; see recipe), Glasgow modified Eagle medium (GMEM, *UNIT 16.23*), and RPMI 1640 and Ham F10 nutrient mixture (e.g., Invitrogen) are composed of amino acids, glucose, salts, vitamins, and other nutrients. A basic medium is supplemented by addition of L-glutamine, antibiotics (typically penicillin and streptomycin sulfate), and usually serum to formulate a "complete medium." Where serum is

added, the amount is indicated as a percentage of fetal bovine serum (FBS) or other serum. Some media are also supplemented with antimycotics, nonessential amino acids, various growth factors, and/or drugs that provide selective growth conditions (see *UNIT 9.5*). Supplements should be added to medium prior to sterilization or filtration, or added aseptically just before use.

The optimum pH for most mammalian cell cultures is 7.2 to 7.4. Adjust pH of the medium as necessary after all supplements are added. Buffers such as bicarbonate and HEPES are routinely used in tissue culture medium to prevent fluctuations in pH that might adversely affect cell growth. HEPES is especially useful in solutions used for procedures that do not take place in a controlled CO₂ environment.

Fetal bovine serum (FBS; sometimes known as fetal calf serum, FCS) is the most frequently used serum supplement. Calf serum, horse serum, and human serum are also used; some cell lines are maintained in serum-free medium (Freshney, 1996). Complete medium is supplemented with 5% to 30% (v/v) serum, depending on the requirements of the particular cell type being cultured. Serum is obtained frozen, then is thawed, divided into smaller portions, and refrozen until needed.

There is considerable lot-to-lot variation in FBS. Most suppliers will provide a sample of a specific lot and reserve a supply of that lot while the serum is tested for its suitability. The suitability of a serum lot depends upon the use. Frequently the ability of serum to promote cell growth equivalent to a laboratory standard is used to evaluate a serum lot. Once an acceptable lot is identified, enough of that lot should be purchased to meet the culture needs of the laboratory for an extended period of time.

Although the use of heat-inactivated serum was once preferred, it is no longer standard, or may be standard in some labs simply because it is an established and routine practice (http://www.unc.edu/depts/tcf/tech_tipsHI.htm). Historically, heat inactivation was considered necessary to destroy complement protein due to its role in cell lysis. It has since been shown that the level of complement components in commercially available FCS was only 1% to 3% of adult levels, and that no significant cell lysis was detected with the use of commercially available FCS, even when undiluted (Triglia and Linscott, 1980). In addition, many researchers prewarm FBS to 37°C, which is enough to inactivate heat-labile complement components. Improvements in the filtration of serum products have also made the use of heat-inactivated serum nonessential for most cell types. In the past serum was filtered through 0.45- μ m or 0.22- μ m filters, raising concern that adventitious agents such as mycoplasma could persist. Today media suppliers use 0.1- μ m or 0.04- μ m porosity membranes to eliminate the need for heat inactivation (http://www.unc.edu/depts/tcf/tech_tipsHI.htm; Hyclone Labs, 1996). Not only is heat inactivation unnecessary for most cell types, it may sometimes be detrimental to cell growth. Heat inactivation not only destroys complement, it also degrades amino acids, vitamins, growth factors, and other nutrients that enhance cell growth. Furthermore, heat inactivation can increase the formation of precipitates that can be mistaken for microbial contamination (Hyclone Labs, 1996). Laboratories that continue the use of heat inactivation should conduct studies to determine whether this step is really indicated. Heat activation may be warranted when conducting immunologic studies or when culturing embryonic stem cells, insect cells, and smooth muscle cells. For cells obtained from a commercial vendor such as ATCC, serum requirements are included in the cell descriptions.

Although FBS has historically been the serum of choice, many investigators are moving towards the use of alternative types of animal serum or to serum-free media. An

increasing number of companies are offering serum-free media for a wide range of cell types. Focus on Alternatives (FOA) lists over 300 types of serum-free products along with their suppliers, applications, and the cell types supported for each product (<http://www.focusonalternatives.org.uk>, compiled in July, 2005). Although the term “serum-free” implies that a medium contains no serum, the medium may not be entirely free of serum-derived products. For example, bovine serum albumin may be used as the protein component of particular types of serum-free media (Newman, 2003). While some media are designed for culturing a particular cell type, others are general-purpose media that can support a variety of cell types.

Commercially prepared media containing L-glutamine are available, but many laboratories choose to obtain medium without L-glutamine, and then add it to a final concentration of 2 mM just before use. L-Glutamine is an unstable amino acid that, upon storage, converts to a form cells cannot use. Breakdown of L-glutamine is temperature- and pH-dependent. At 4°C, 80% of the L-glutamine remains after 3 weeks, but at near incubator temperature (35°C) only half remains after 9 days (Barch et al., 1991). To prevent degradation, 100× L-glutamine should be stored frozen in aliquots until needed.

Another option to prevent degradation is the use of a stabilized dipeptide form of L-glutamine such as GlutaMAX (Invitrogen), which is available both as a stand-alone medium and as a medium supplement. GlutaMAX media contain the dipeptide L-alanyl-L-glutamine, which is split by aminopeptidases in culture to release L-glutamine and L-alanine. This mechanism provides a controlled delivery of L-glutamine to the cells in culture. The GlutaMAX dipeptide is also available as a medium supplement to be used as a direct substitute for L-glutamine in cell culture medium preparations with minimal or no adaptation. Both GlutaMAX Media and Supplement are reported by the manufacturer to maximize cell performance, improve cell viability and growth, extend cell culture life, and minimize toxic ammonium build-up during cell culture (<http://www.invitrogen.com>).

In addition to practicing good aseptic technique, most laboratories add antimicrobial agents to medium to further reduce the risk of contamination. A combination of penicillin and streptomycin is the most commonly used antibiotic additive; kanamycin and gentamycin are used alone. Mycostatin and amphotericin B are the most commonly used fungicides (Rooney and Czepulkowski, 2001). Table A.3F.1 lists the final concentrations for the most commonly used antibiotics and antimycotics. Combining antibiotics in tissue culture media can be tricky, as some antibiotics are not compatible and one may inhibit the action of another. Furthermore, combined antibiotics may be cytotoxic at lower concentrations than the individual antibiotics. In addition, prolonged use of antibiotics may cause cell lines to develop antibiotic resistance. For this reason, some laboratories add antibiotics and/or fungicides to medium when initially establishing a culture but eliminate them from medium used in later subcultures.

Commercially available tissue culture media have been tested for sterility prior to release, and further testing within the research laboratory is generally not required. In clinical laboratories, sterility checks on tissue culture media are often performed as a quality-control monitor in compliance with requirements from the College of American Pathologists (CAP). A small aliquot from each lot of medium is incubated 48 hr at 37°C and monitored for evidence of contamination such as turbidity (infected medium will be cloudy) and color change (if phenol red is the indicator, infected medium will turn yellow). Any contaminated medium should be discarded.

TRYPsinIZING AND SUBCULTURING CELLS FROM A MONOLAYER

A primary culture is grown to confluency in a 60-mm petri plate or 25-cm² tissue culture flask containing 5 ml tissue culture medium. Cells are dispersed by trypsin treatment and then reseeded into secondary cultures. The process of removing cells from the primary culture and transferring them to secondary cultures constitutes a passage, or subculture.

Materials

Primary cultures of cells

HBSS (APPENDIX 2) without Ca²⁺ and Mg²⁺, 37°C

0.25% (w/v) trypsin/0.2% EDTA solution (see recipe), 37°C

Complete medium with serum: e.g., DMEM supplemented with 10% to 15% (v/v) fetal bovine serum (complete DMEM-10; see recipe), 37°C

Sterile Pasteur pipets

37°C warming tray or incubator

Tissue culture plasticware or glassware including pipets and 25-cm² flasks or 60-mm petri plates, sterile

NOTE: All incubations are performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO₂ to maintain pH 7.4.

1. Remove all medium from primary culture with a sterile Pasteur pipet. Wash adhering cell monolayer once or twice with a small volume of 37°C HBSS without Ca²⁺ and Mg²⁺ to remove any residual FBS that may inhibit the action of trypsin.

Use a buffered salt solution that is Ca²⁺- and Mg²⁺-free to wash cells. Ca²⁺ and Mg²⁺ in the salt solution can cause cells to stick together.

If this is the first medium change, rather than discarding medium that is removed from primary culture, put it into a fresh dish or flask. The medium contains unattached cells that may attach and grow, thereby providing a backup culture.

2. Add enough 37°C trypsin/EDTA solution to culture to cover adhering cell layer.
3. Place plate on a 37°C warming tray 1 to 2 min. Tap bottom of plate on the countertop to dislodge cells. Check culture with an inverted microscope to be sure that cells are rounded up and detached from the surface.

If cells are not sufficiently detached, return plate to warming tray for an additional minute or two.

4. Add 2 ml 37°C complete medium. Draw cell suspension into a Pasteur pipet and rinse cell layer two or three times to dissociate cells and to dislodge any remaining adherent cells. As soon as cells are detached, add serum or medium containing serum to inhibit further trypsin activity that might damage cells.

If cultures are to be split 1/3 or 1/4 rather than 1/2, add sufficient medium such that 1 ml of cell suspension can be transferred into each fresh culture vessel.

5. Add an equal volume of cell suspension to fresh plates or flasks that have been appropriately labeled.

Alternatively, cells can be counted using a hemacytometer (Support Protocol 3) or Coulter counter and diluted to the desired density so a specific number of cells can be added to each culture vessel. A final concentration of $\sim 5 \times 10^4$ cells/ml is appropriate for most subcultures.

For primary cultures and early subcultures, 60-mm petri plates or 25-cm² flasks are generally used; larger petri plates or flasks (e.g., 150-mm plates or 75-cm² flasks) may be used for later subcultures.

Cultures should be labeled with at least two unique identifiers, as well as date of culture and passage number.

6. Add 4 ml fresh medium to each new culture. Incubate in a humidified 37°C, 5% CO₂ incubator.

If using 75-cm² culture flasks, add 9 ml medium per flask.

Some labs now use incubators with 5% CO₂ and 4% O₂. The low oxygen concentration is thought to simulate the in vivo environment of cells and to enhance cell growth.

7. If necessary, feed subconfluent cultures after 3 or 4 days by removing old medium and adding fresh 37°C medium.
8. Passage secondary culture when it becomes confluent by repeating steps 1 to 7, and continue to passage as necessary.

PASSAGING CELLS IN SUSPENSION CULTURE

Passaging of suspension cultures is somewhat less complicated than passaging of monolayer cultures. Because the cells are suspended in medium rather than attached to a surface, it is not necessary to disperse them enzymatically before passaging. However, before passaging, cells must be maintained in culture by feeding every 2 to 3 days until they reach confluency (i.e., until the cells clump together in the suspension and the medium appears turbid when the flask is swirled).

NOTE: All incubations are performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO₂ to maintain pH 7.4.

For materials, see Basic Protocol.

1. Feed cells as follows every 2 to 3 days until the cultures are confluent:
 - a. Remove flask of suspension cells from incubator, taking care not to disturb those that have settled to the flask bottom.
 - b. Aseptically remove and discard about one-third of the medium from the flask and replace with an equal volume of prewarmed (37°C) medium. If the cells are growing rapidly, add an additional 10% medium by volume in order to maintain an optimum concentration of 1×10^6 cells/ml. Gently swirl flask to resuspend cells.
 - c. Return flask to incubator. If there is <15 ml of medium in the flask, incubate flask in horizontal position to enhance cell/medium contact.

At higher volumes of medium, the flask can be incubated in the vertical position.

If using a 25-cm² flask, there should be 20 to 30 ml of medium in the flask at confluency.

2. On the days cultures are not being fed, check by swirling flask to resuspend cells and observing color changes from pink to yellow/orange in the medium, which indicate active cell metabolism.
3. When cultures are confluent ($\sim 2.5 \times 10^6$ cells/ml), passage culture as follows:
 - a. Remove flask from incubator and swirl flask so that cells are evenly distributed in the medium.
 - b. Aseptically remove half of the volume of cell suspension and place into a fresh flask, retaining the other half of the cell suspension in the original flask.

ALTERNATE PROTOCOL 1

Commonly Used Techniques

A.3F.9

Alternatively, the entire cell suspension can be removed from the original flask and divided equally into two fresh flasks. The original flask can be discarded, or if there is concern about the need for additional cells, the original flask can be retained and fed in an attempt to salvage any residual cells.

- c. Feed each flask with 7 to 10 ml prewarmed medium and return flasks to incubator.

Some labs prefer to split the cells 1/3 or 1/4, although increasing the split ratio will result in a longer interval before subcultures reach confluency.

SUPPORT PROTOCOL 1

FREEZING HUMAN CELLS GROWN IN MONOLAYER CULTURES

It is sometimes desirable to store cell lines for future study. To preserve cells, avoid senescence, reduce the risk of contamination, and minimize effects of genetic drift, cell lines may be frozen for long-term storage. Without the use of a cryoprotective agent, freezing would be lethal to the cells in most cases. Generally, a cryoprotective agent such as dimethylsulfoxide (DMSO) is used in conjunction with complete medium for preserving cells at -70°C or lower. DMSO acts to reduce the freezing point and allows a slower cooling rate. Gradual freezing reduces the risk of ice crystal formation and cell damage.

Materials

Log-phase monolayer culture of cells in petri plate

Complete medium

Freezing medium: complete medium (e.g., DMEM or RPMI; see recipes)
supplemented with 10% to 20% (v/v) FBS and 5% to 10% (v/v) DMSO, 4°C

Benchtop clinical centrifuge with 45° fixed-angle or swinging-bucket rotor

NOTE: All incubations are performed in a humidified 37°C , 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

1. Trypsinize cells from plate (see Basic Protocol, steps 1 to 4).

It is best to use cells in log-phase growth for cryopreservation.

2. Transfer cell suspension to a sterile centrifuge tube and add 2 ml complete medium with serum. Centrifuge 5 min at 300 to $350 \times g$ (~ 1500 rpm in Fisher Centrifuge rotor), room temperature.

The benchtop centrifuge can be accessorized depending on the anticipated volume. A variety of brands are available, including Eppendorf, Thermo Electron, and Beckman, and can be obtained from Fisher Scientific, VWR, and other laboratory equipment vendors.

Cells from three or more dishes from the same subculture can be combined in one tube.

3. Remove supernatant and add 1 ml of 4°C freezing medium. Resuspend pellet to obtain a density of 1×10^6 cells/ml.
4. Add 4 ml of 4°C freezing medium, mix cells thoroughly, and place on wet ice.
5. Count cells using a hemacytometer (see Support Protocol 3). Dilute with more freezing medium as necessary to get a final cell concentration of 10^6 or 10^7 cells/ml.

To freeze cells from a nearly confluent 25-cm^2 flask, resuspend in roughly 3 ml freezing medium.

6. Pipet 1-ml aliquots of cell suspension into labeled 2-ml cryovials. Tighten caps on vials.

7. Place vials 1 hr to overnight in a -70°C freezer, then transfer to a liquid nitrogen storage freezer.

Keep accurate records of the identity and location of cells stored in liquid nitrogen freezers. Cells may be stored for many years and proper information is imperative for locating a particular line for future use.

FREEZING CELLS GROWN IN SUSPENSION CULTURE

Freezing cells from suspension culture is similar in principle to freezing cells from monolayer. The major difference is that suspension cultures need not be trypsinized.

NOTE: All incubations are performed in a humidified 37°C , 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

1. Transfer cell suspension to a centrifuge tube and spin 10 min at 300 to $350 \times g$ (-1500 rpm in Fisher Centrifuge), room temperature.
2. Remove supernatant and resuspend pellet in 4°C freezing medium at a density of 10^6 to 10^7 cells/ml.

Some laboratories freeze lymphoblastoid lines at the higher cell density because they plan to recover them in a larger volume of medium and because there may be a greater loss of cell viability upon recovery as compared to other types of cells (e.g., fibroblasts).

3. Transfer 1-ml aliquots of cell suspension into cryovials and freeze as for monolayer cultures.

THAWING AND RECOVERING HUMAN CELLS

When cryopreserved cells are needed for study, they should be thawed rapidly and plated at high density to optimize recovery.

CAUTION: Protective clothing, particularly insulated gloves and goggles, should be worn when removing frozen vials or ampules from the liquid nitrogen freezer. The room containing the liquid nitrogen freezer should be well-ventilated. Care should be taken not to spill liquid nitrogen on the skin.

NOTE: All incubations are performed in a humidified 37°C , 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

Materials

Cryopreserved cells stored in liquid nitrogen freezer

70% (v/v) ethanol

Complete medium (e.g., DMEM or RPMI; see recipes) containing 10% to 20% FBS (see recipe), 37°C

1. Remove vial from liquid nitrogen freezer and immediately place it into a 37°C water bath. Agitate vial continuously until medium is thawed.

The medium usually thaws in <60 sec. Cells should be thawed as quickly as possible to prevent formation of ice crystals that can cause cell lysis. Try to avoid getting water around the cap of the vial.

2. Wipe top of vial with 70% ethanol before opening.

Some labs prefer to submerge the vial in 70% ethanol and air dry before opening.

**ALTERNATE
PROTOCOL 2**

**SUPPORT
PROTOCOL 2**

**Commonly Used
Techniques**

A.3F.11

3. Transfer thawed cell suspension into a sterile centrifuge tube containing 2 ml warm complete medium containing 20% FBS. Centrifuge 10 min at 150 to 200 × g (~1000 rpm in Fisher Centrifric), room temperature. Discard supernatant.

Cells are washed with fresh medium to remove residual DMSO.

4. Gently resuspend cell pellet in small amount (~1 ml) of complete medium/20% FBS and transfer to properly labeled culture plate containing the appropriate amount of medium.

Cultures are reestablished at a higher cell density than that used for original cultures because there is some cell death associated with freezing. Generally, 1 ml cell suspension is reseeded in 5 to 20 ml medium.

5. Check cultures after ~24 hr to ensure that cells have attached to the plate.
6. Change medium after 5 to 7 days or when pH indicator (e.g., phenol red) in medium changes color. Keep cultures in medium with 20% FBS until cell line is reestablished.

If recovery rate is extremely low, only a subpopulation of the original culture may be growing; be extra careful of this when working with cell lines known to be mosaic.

SUPPORT PROTOCOL 3

DETERMINING CELL NUMBER AND VIABILITY WITH A HEMACYTOMETER AND TRYPAN BLUE STAINING

Determining the number of cells in culture is important in standardization of culture conditions and in performing accurate quantitation experiments. A hemacytometer is a thick glass slide with a central area designed as a counting chamber. Cell suspension is applied to a defined area and counted so cell density can be calculated.

The exact design of the hemacytometer may vary; the one described here is the Improved Neubauer from VWR (Fig. A.3F.1). The central portion of the slide is the counting platform, which is bordered by a 1-mm groove. The central platform is divided into two counting chambers by a transverse groove. Each counting chamber consists of a silver footplate on which is etched a 3 × 3-mm grid. This grid is divided into nine secondary squares, each 1 × 1 mm. The four corner squares and the central square are used for determining the cell count. The corner squares are further divided into 16 tertiary squares and the central square into 25 tertiary squares to aid in cell counting.

Accompanying the hemacytometer slide is a thick, even-surfaced coverslip. Ordinary coverslips may have uneven surfaces, which can introduce errors in cell counting; therefore, it is imperative that the coverslip provided with the hemacytometer be used in determining cell number.

Materials

- 70% (v/v) ethanol
- Cell suspension
- 0.4% (w/v) trypan blue or 0.4% (w/v) nigrosin, prepared in HBSS (APPENDIX 2)
- Hemacytometer with coverslip (Improved Neubauer, Baxter Scientific)
- Hand-held counter

Prepare hemacytometer

1. Clean surface of hemacytometer slide and coverslip with 70% alcohol.

Coverslip and slide should be clean, dry, and free from lint, fingerprints, and watermarks.

Figure A.3F.1 Hemacytometer slide (Improved Neubauer) and coverslip. Coverslip is applied to slide and cell suspension is added to counting chamber using a Pasteur pipet. Each counting chamber has a 3×3 -mm grid (enlarged). The four corner squares (1, 2, 4, and 5) and the central square (3) are counted on each side of the hemacytometer (numbers added).

2. Wet edge of coverslip slightly with tap water and press over grooves on hemacytometer. The coverslip should rest evenly over the silver counting area.

Prepare cell suspension

3. For cells grown in monolayer cultures, detach cells from surface of dish using trypsin (see Basic Protocol).
4. Dilute cells as needed to obtain a uniform suspension. Disperse any clumps.

When using the hemacytometer, a maximum cell count of 20 to 50 cells per 1-mm square is recommended.

Load hemacytometer

5. Use a sterile Pasteur pipet to transfer cell suspension to edge of hemacytometer counting chamber. Hold tip of pipet under the coverslip and dispense one drop of suspension.

Suspension will be drawn under the coverslip by capillary action.

Hemocytometer should be considered nonsterile. If cell suspension is to be used for cultures, do not reuse the pipet and do not return any excess cell suspension in the pipet to the original suspension.

6. Fill second counting chamber.

Count cells

7. Allow cells to settle for a few minutes before beginning to count. Blot off excess liquid.
8. View slide on microscope with 100× magnification.

A 10× ocular with a 10× objective = 100× magnification.

Position slide to view the large central area of the grid (section 3 in Fig. A.3F.1); this area is bordered by a set of three parallel lines. The central area of the grid should almost fill the microscope field. Subdivisions within the large central area are also bordered by three parallel lines and each subdivision is divided into sixteen smaller squares by single lines. Cells within this area should be evenly distributed without clumping. If cells are not evenly distributed, wash and reload hemacytometer.

9. Use a hand-held counter to count cells in each of the four corner and central squares (Fig. A.3F.1, squares numbered 1 to 5). Repeat counts for other counting chamber.

Five squares (four corner and one center) are counted from each of the two counting chambers for a total of ten squares counted.

Count cells touching the middle line of the triple line on the top and left of the squares. Do not count cells touching the middle line of the triple lines on the bottom or right side of the square.

Calculate cell number

10. Determine cells per ml by the following calculations:

$\text{cells/ml} = \text{average count per square} \times \text{dilution factor} \times 10^4$

$\text{total cells} = \text{cells/ml} \times \text{total original volume of cell suspension from which sample was taken.}$

The volume correction factor for the hemacytometer is 10^4 : each square is 1×1 mm and the depth is 0.1 mm.

Stain cells with trypan blue to determine cell viability

11. Determine number of viable cells by adding 0.5 ml of 0.4% trypan blue, 0.3 ml HBSS, and 0.1 ml cell suspension to a small tube. Mix thoroughly and let stand 5 min before loading hemacytometer.

Either 0.4% trypan blue or 0.4% nigrosin can be used to determine the viable cell number. Nonviable cells will take up the dye, whereas live cells will be impermeable to it.

12. Count total number of cells and total number of viable (unstained) cells. Calculate percent viable cells as follows:

$$\% \text{ viable cells} = \frac{\text{number of unstained cells}}{\text{total number of cells}} \times 100$$

13. Decontaminate coverslip and hemacytometer by rinsing with 70% ethanol and then deionized water. Air dry and store for future use.

PREPARING CELLS FOR TRANSPORT

Both monolayer and suspension cultures can easily be shipped in 25-cm² tissue culture flasks. Cells are grown to near confluency in a monolayer or to desired density in suspension. Medium is removed from monolayer cultures and the flask is filled with fresh medium. Fresh medium is added to suspension cultures to fill the flask. *It is essential that the flasks be completely filled with medium to protect cells from drying if flasks are inverted during transport.* It is also imperative that the flasks have nonvented caps. The cap is tightened and taped securely in place. The flask is sealed in a leak-proof plastic bag or other leak-proof container designed to prevent spillage in the event that the flask should become damaged. The primary container is then placed in a secondary insulated container to protect it from extreme temperatures during transport. A biohazard label is affixed to the outside of the package. Generally, cultures are transported by same-day or overnight courier.

Cells can also be shipped frozen. The vial containing frozen cells is removed from the liquid nitrogen freezer and placed immediately on dry ice in an insulated container to prevent thawing during transport.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. Suitable suppliers for media and components include Invitrogen, Cambrex, Hyclone, and Sigma-Aldrich. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Complete DMEM

Dulbecco's modified Eagle medium, high-glucose formulation (e.g., Invitrogen), containing:

5%, 10%, or 20% (v/v) FBS (optional; see recipe)

1% (v/v) nonessential amino acids

2 mM L-glutamine (see recipe)

100 U/ml penicillin

100 µg/ml streptomycin sulfate

Filter sterilize and store ≤1 month at 4°C

Throughout this manual, the percentage of serum (usually fetal bovine serum) used in a protocol step is indicated by a numeral hyphenated to the base medium name. Thus, "complete DMEM-10" indicates that 10% FBS is used. Absence of a numeral indicates that no serum is used. See Chapter 9 introduction for a full discussion concerning media preparation and use of serum (heat-inactivation, screening, commercial sources, etc.).

DMEM containing 4500 mg/liter D-glucose can be obtained from Invitrogen. DMEM is also known as Dulbecco's minimum essential medium.

Complete RPMI

RPMI 1640 medium (e.g., Invitrogen) containing:

2%, 5%, 10%, 15%, or 20% FBS (optional; see recipe)

2 mM L-glutamine (see recipe)

100 U/ml penicillin

100 µg/ml streptomycin sulfate

Filter sterilize and store ≤1 month at 4°C

FBS (fetal bovine serum)

Thaw purchased fetal bovine serum (shipped on dry ice and kept frozen at –20°C until needed). Store 3 to 4 weeks at 4°C. If FBS is not to be used within this time, aseptically divide into smaller aliquots and refreeze until used. Store ≤1 year at –20°C.

continued

Repeated thawing and refreezing should be avoided as it may cause denaturation of the serum.

In some cases, heat inactivation may be warranted (see Culture Medium Preparation). To inactivate FBS, heat 30 to 60 min in a 56°C water bath. Alternatively, FBS may be inactivated through radiation treatment.

L-Glutamine, 0.2 M (100×)

Thaw frozen L-glutamine, aliquot aseptically into usable portions, then refreeze. For convenience, L-glutamine can be stored in 1-ml aliquots if 100-ml bottles of medium are used, and in 5-ml aliquots if 500-ml bottles are used. Store ≤ 1 year at -20°C .

Many laboratories supplement medium with 2 mM L-glutamine—1% (v/v) of 100× stock—just prior to use.

Trypsin/EDTA solution

Prepare in sterile HBSS (APPENDIX 2) or 0.9% (w/v) NaCl:

0.25% (w/v) trypsin

0.2% (w/v) EDTA

Store ≤ 1 year (until needed) at -20°C

Most laboratories prefer to purchase trypsin/EDTA as a prepared solution, which is available from vendors including Sigma-Aldrich, Invitrogen, and Cambrex. This is a convenient and cost-effective alternative to preparing the solution within the laboratory. Trypsin/EDTA solution is available in various concentrations including 10×, 1×, and 0.25% (w/v). It is received frozen from the manufacturer and can be thawed and aseptically aliquotted into smaller volumes. Specific applications may require different concentrations of trypsin; the appropriate methods should be consulted for details.

EDTA (disodium ethylenediamine tetraacetic acid) is added as a chelating agent to bind Ca^{2+} and Mg^{2+} ions that can interfere with the action of trypsin.

COMMENTARY

Background Information

At its inception in the early twentieth century, tissue culture was applied to the study of tissue fragments in culture. New growth in culture was limited to cells that migrated out from the initial tissue fragment. Tissue culture techniques evolved rapidly, and since the 1950s culture methods have allowed the growth and study of dispersed cells in culture (Freshney, 1996). Cells dispersed from the original tissue can be grown in monolayers and passaged repeatedly to give rise to a relatively stable cell line.

Four distinct growth stages have been described for primary cells maintained in culture. First, cells adapt to the *in vitro* environment. Second, cells undergo an exponential growth phase lasting through ~ 30 passages. Third, the growth rate of cells slows, leading to a progressively longer generation time. Finally, after 40 or 50 passages, cells begin to senesce and die (Lee, 1991). It may be desirable to study a particular cell line over several months or years, so monolayer cultures can be preserved to re-

tain the integrity of the cell line. Aliquots of early-passage cell suspensions are frozen, then thawed, and cultures reestablished as needed. Freezing monolayer cultures prevents changes due to genetic drift and avoids loss of cultures due to senescence or accidental contamination (Freshney, 1996).

Cell lines are commercially available from a number of sources, including the American Type Culture Collection (ATCC; <http://www.atcc.org>) and the Human Genetic Mutant Cell Repository at the Coriell Cell Repository (CCR; <http://www.coriell.org>). These cell repositories are a valuable resource for researchers who do not have access to suitable patient populations. An up-to-date listing of available cell lines will be provided upon request. The cell lines are preserved in liquid nitrogen, and information on the characteristics are supplied by the distributor. Immortalized cell lines can be maintained in culture indefinitely, while nontransformed cells have a limited life-span *in vitro*. For human fibroblasts, about 20 population doublings occur

between the initial growth in the primary culture and the first subculture (Priest, 1997). About 50 to 60 population doublings is the standard rule for maintaining fibroblast cell lines in culture before risking the loss of cell lines through senescence, cytogenetic or biochemical changes, or contamination. If it is anticipated that these cells will be needed for future study, cells should be frozen at an early culture stage and retrieved for future use (Verma and Babu, 1995).

Critical Parameters

Use of aseptic technique is essential for successful tissue culture. Cell cultures can be contaminated at any time during handling, so precautions must be taken to minimize the chance of contamination. All supplies and reagents that come into contact with cultures must be sterile, and all work surfaces should be kept clean and free from clutter.

Cultures should be 75% to 100% confluent when selected for subculture. Growth in monolayer cultures will be adversely affected if cells are allowed to become overgrown. Passing cells too early will result in a longer lag time before subcultures are established. Following dissociation of the monolayer by trypsinization, serum or medium containing serum should be added to the cell suspension to stop further action by trypsin that might be harmful to cells.

When subculturing cells, add a sufficient number of cells to give a final concentration of $\sim 5 \times 10^4$ cells/ml in each new culture of human cell lines. Optimal concentrations are cell-type specific. Package inserts provided with commercially available cell lines contain information on recommended cell density, culture media, and appropriate culture temperatures. Cells plated at too low a density may be inhibited or delayed in entry into growth stage. Cells plated at too high a density may reach confluence before the next scheduled subculturing; this could lead to cell loss and/or cessation of proliferation. The growth characteristics for different cell lines vary. A lower cell concentration (10^4 cells/ml) may be used to initiate subcultures of rapidly growing cells, and a higher cell concentration (10^5 cells/ml) may be used to initiate subcultures of more slowly growing cells. Adjusting the initial cell concentration permits establishment of a regular, convenient schedule for subculturing—e.g., once or twice a week (Freshney, 1996).

Cells in culture will undergo changes in growth, morphology, and genetic characteristics over time. Such changes can adversely af-

fect reproducibility of laboratory results. Non-transformed cells will undergo senescence and eventual death if passaged indefinitely. The time of senescence will vary with cell line, but generally at between 40 and 50 population doublings fibroblast cell lines begin to senesce. Cryopreservation of cell lines will protect against these adverse changes and will avoid potential contamination.

Cultures selected for cryopreservation should be in log-phase growth and free from contamination. Cells should be frozen at a concentration of 10^6 to 10^7 cells/ml. Cells should be frozen gradually and thawed rapidly to prevent formation of ice crystals that may cause cells to lyse. Cell lines can be thawed and recovered after long-term storage in liquid nitrogen. The top of the freezing vial should be cleaned with 70% alcohol before opening to prevent introduction of contaminants. To aid in recovery of cultures, thawed cells should be reseeded at a higher concentration than that used for initiating primary cultures. Careful records regarding identity and characteristics of frozen cells as well as their location in the freezer should be maintained to allow for easy retrieval.

For accurate cell counting, the hemacytometer slide should be clean, dry, and free from lint, scratches, fingerprints, and watermarks. The coverslip supplied with the hemacytometer should always be used because it has an even surface and is specially designed for use with the counting chamber. Use of an ordinary coverslip may introduce errors in cell counting. If the cell suspension is too dense or the cells are clumped, inaccurate counts will be obtained. If the cell suspension is not evenly distributed over the counting chamber, the hemacytometer should be washed and reloaded.

Anticipated Results

Confluent cell lines can be successfully subcultured in the vast majority of cases. The yield of cells derived from monolayer culture is directly dependent on the available surface area of the culture vessel (Freshney, 1996). Overly confluent cultures or senescent cells may be difficult to trypsinize, but increasing the time of trypsin exposure will help dissociate resistant cells. Cell lines can be propagated to get sufficient cell populations for cytogenetic, biochemical, and molecular analyses.

It is well accepted that anyone can successfully freeze cultured cells; it is thawing and recovering the cultures that presents the problem. Cultures that are healthy and free from

contamination can be frozen and stored indefinitely. Cells stored in liquid nitrogen can be successfully thawed and recovered in over 95% of cases. Several aliquots of each cell line should be stored to increase the chance of recovery. Cells should be frozen gradually, with a temperature drop of $\sim 1^{\circ}\text{C}$ per minute, but thawed rapidly. Gradual freezing and rapid thawing prevents formation of ice crystals that might cause cell lysis.

Accurate cell counts can be obtained using the hemacytometer if cells are evenly dispersed in suspension and free from clumps. Determining the proportion of viable cells in a population will aid in standardization of experimental conditions.

Time Considerations

Establishment and maintenance of mammalian cell cultures require a regular routine for preparation of media and feeding and passaging cells. Cultures should be inspected regularly for signs of contamination and to determine if the culture needs feeding or passaging.

Molecular Pathology Laboratory Network
Maryville, Tennessee

Scientific cooperation between laboratories in the United States is no longer confined to those at the same institution, nor even within the boundaries of the country. More than ever, scientists are forming collaborations with their peers outside the U.S., leading not only to the exchange of knowledge and ideas, but also to the exchange of biological reagents. Thus, investigators need be aware that an import permit may be required to obtain purified proteins, chemically synthesized materials, cell lines, tissues, and other biological materials from abroad. Before requesting any biological material from a laboratory outside the U.S., it is the responsibility of the “receiver” to ascertain whether an import permit is required, to apply for the permit if one is determined to be necessary, and to provide the “shipper” with an official copy of the permit to be included with the shipped material.

There are two government agencies in place to issue permits for the importation of most biologicals. All materials derived from animals are subject to regulations set forth by the United States Department of Agriculture (USDA) and must be cleared by USDA inspectors at the port of arrival before entry into the United States is authorized. In general, an import permit issued by the USDA is necessary for receipt of any animal-derived material or any biological material (including proteins) that has been in contact with materials of animal origin. The USDA does not have regulatory authority over the importation of human or nonhuman primate material unless it is produced via tissue culture, due to the use of bovine material (fetal bovine serum or calf serum) in tissue culture. The U.S. Public Health Service (UPHS) has jurisdiction over human and nonhuman primate materials. According to UPHS regulations, no etiologic agent, animal host, or vector of human disease may be imported into the United States or distributed after importation without being accompanied by a permit issued by the Director of the Centers for Disease Control. Failure to obtain the appropriate import permit will result in the shipment being held at the port of entry until a permit is applied for and issued (a 4- to 6-week process) or may result in shipment confiscation and destruction by the quarantine officer present.

IMPORTING RESTRICTED BIOLOGICAL MATERIALS

The following is a list of restricted biological materials requiring an import permit: proteins, monoclonal and polyclonal antibodies, antisera, immunoglobins, recombinant products, enzymes, hormones, immunoassay components or kits, animal tissues, blood, cells, cell lines, RNA/DNA extracts, plasmids, vectors, microorganisms—e.g., fungi, bacteria, viruses—and other products that are derived from animals or have been in contact with animal-derived materials. In addition, materials received from countries shown not to be free of foot-and-mouth disease (see Title 9, code of Federal Regulations, Part 94.1) require an import permit. Note that the USDA will not permit the importation of cell cultures, monoclonal antibodies, ascites fluid, or bovine serum from countries where rinderpest and foot-and-mouth disease are present unless the imported materials are determined to be virus-free. Cell cultures being imported into the U.S. must have been grown only with fetal bovine serum of U.S., Canadian, New Zealand, or Australian origin. Material exposed to bovine products originating in the United Kingdom, Switzerland, Ireland, France, or Portugal may NOT be used, either directly or indirectly, in any animals due to the presence of bovine spongiform encephalopathy (BSE) in those countries, and the material is restricted to *in vitro* uses only.

CRITERIA FOR HANDLING IMPORTED RESTRICTED MATERIALS

An import permit is valid only for transfer of the material(s) listed on the permit (a permit can cover more than one item), and for shipment between the two laboratories listed on the permit. Therefore, for each laboratory abroad from which biological materials are to be imported, a separate import permit is required. Once biological materials have been received from abroad, the import permit still imposes regulations on how the materials are handled by the receiver. Import permits do not usually authorize direct or indirect exposure of domestic animals—work is limited to *in vitro* uses only. In addition, permits are only valid for work conducted or directed by the permit holder at his or her facilities. Materials cannot

Supplement 40

be removed to another location, nor distributed to others, without USDA authorization. There is one exception: monoclonal antibodies produced by hybridoma cell lines may be commercially distributed for in vitro uses.

IMPORTING NONRESTRICTED BIOLOGICAL MATERIALS

Any of the restricted materials that do not contain animal- or cell culture-derived products or additives such as albumin, serum, or gelatin, and were not exposed to any infectious agents of agricultural concern, do not need an official import permit. However, an accompanying declaration is required with each shipment to indicate that the material does not contain any animal- or cell culture-derived products or additives. This information should be supplied with each shipment in a clear and concise manner, and be available for the USDA Port of Entry Inspector's review. A separate memo or letter, such as U.S. Customs declaration and invoice, should be included with the shipping documents. Note that whether a particular biological material requires an import permit cannot be decided by the investigator; the investigator must contact the USDA for a decision well in advance of making arrangements for importing the material.

PACKAGING BIOLOGICAL MATERIALS FOR IMPORTATION

Imported biological materials are subject to packaging and shipping requirements of various federal and international regulations. Proper packaging is the primary consideration and of utmost importance in the safe transportation of hazardous materials. If the biological material being shipped is infectious or radioactive, this information has to be noted on the outside of the package. In addition, if dry ice is used for shipment, that must be clearly stated on the package. It is of course advantageous to the investigator that the shipped material be packaged in the most efficient way possible, as well as in a form which will ensure its stability. If proteins are to be shipped, it may be better to send the samples lyophilized or blotted on a membrane, rather than in liquid form. This will omit the need for dry ice or ice packs in the packaging, which will save on shipping costs as well as ensure the samples will be stable if receipt of the package meets with unforeseen delays. If sending materials that require dry ice or ice packs, such as antibodies or antisera, there must be enough dry ice to allow the package to maintain the appropriate tempera-

ture during shipping for approximately 5 days. This requires utilizing much larger packaging boxes than are normally used to ship the same material within the United States. When shipping cell lines, sometimes it is better to send cells in culture, rather than frozen aliquots. To send cells in culture, the tissue culture flask containing the live cells must be filled to the very top with the appropriate medium, tightly capped, and the seal secured with Parafilm. If the tissue culture flask is not completely filled with medium, the resulting air pockets will cause the flasks to explode in flight. Thus, the packaging of any biological material for shipping is an import consideration to ensure success of the scientific collaboration!

OBTAINING AN IMPORT PERMIT APPLICATION

The Division of Veterinary Services of the USDA Animal and Plant Health Inspection Service (APHIS) administers regulatory programs to control the import/export of biological materials. Import permits can be obtained from either local USDA port offices or from APHIS directly: USDA, APHIS, VETERINARY SERVICES, National Center for Import-Export Products Program, 4700 River Road Unit 40, Riverdale, MD 20737-1231, Tel: (301) 734-7830, Fax: (301) 734-8226.

When submitting an import application, (1) obtain the import permit well in advance of the proposed shipping date; (2) inform the supplier of the USDA's requirements, and do not allow shipment of materials until an import permit has been issued and the supplier has received a copy of the permit; (3) list all the potential U.S. ports of entry; (4) specify whether the material is for in vitro or in vivo use and whether it is for commercial distribution or for research in one's own laboratory; (5) list any treatments the material has undergone, such as processing and purification steps involving pH, heat, chromatography, or other methods; and (6) indicate the source(s) of nutrient factors in culture media, cell line designation and history, whether enzymes were used, and what types of viruses (if any) are being studied in the laboratory of origin (all must be listed).

RESOURCES

APHIS Web Site

More information regarding APHIS programs and import/export can be obtained on their internet home page at <http://www.aphis.usda.gov>.

**Fax Service of Veterinary Services,
National Center for Import-Export**

By calling (301) 734-4952, the investigator can access an automated document retrieval system and arrange to have an import application faxed directly, and choose from a menu of documents that describe general instructions for completing the application, as well as information regarding the importation of biological materials from 18 distinct categories.

The design and use of a particular enzyme assay is dependent on the objectives of the particular investigation. If the focus is on enzyme purification or issues of clinical biochemistry, experimental protocols typically require optimizing conditions for all substrates and effectors—e.g., with respect to pH value, temperature, buffering agent, and ionic strength. However, optimal conditions may not be reasonable for all parameters and factors. For example, substrate instability may preclude studies at the enzyme's optimal pH or at the physiological temperature. Thus, Silverstein and Sulebele (1969) examined the exchange rates of malate dehydrogenase at 1°C to avoid problems arising from the decomposition of oxaloacetate. Likewise, in clinical studies and enzyme purification, saturating concentrations of substrate(s) are typically required, although this may not be possible or even desirable in many instances, as limitations in substrate solubility or substrate inhibition of the enzyme may discourage the use of elevated concentrations. The focus in clinical studies and enzyme purification is on providing good estimates of the activities of a specific enzyme in a number of physiological samples with a rapid, straightforward, and reproducible assay method. However, for the kineticist the objective is to characterize the initial rates of the enzyme-catalyzed reaction under a wide set of conditions. It is through these detailed studies, often carried out at subsaturating substrate concentrations, that the investigator is able to determine the true optimal parameters to be used in protein purification and clinical studies, as well as to probe the dynamics and mechanism of the reaction and its modulation by other factors. The purpose of this appendix is to provide a brief review of issues important in the design of initial-rate assay methods.

In most instances, the investigator already has some information about the kinetic properties of the enzyme, obtained from preliminary experiments as well as from the literature. It is necessary to have an approximation of the magnitude of the Michaelis constants of all the substrates in order that detailed initial rate studies can be effectively designed. Certainly, information on the identity of the substrates and products is required, along with an effective procedure for monitoring substrate depletion or product accumulation. The nature of the reac-

tion and the properties of the substrates help dictate the assay procedure used. Enzyme-assay methods include those based on spectrophotometry, radiometry, pH-stat, turbidometry, polarography, and fluorometry. Spectrophotometric and fluorometric assay protocols rely on the differences in spectral or fluorescent properties, respectively, of the product(s) relative to the substrate(s). With radiometric procedures, effective means for separating labeled substrate(s) from labeled product(s) must be available so that the amount of product formed at a given time can be accurately measured. Those reactions that utilize or generate protons (or hydrons) can be followed by pH-stat methods. If the reaction studied results in a change in solution turbidity (e.g., caused by aggregation of a macromolecular complex), then turbidometric protocols can effectively assay for the protein that causes the change in turbidity. All of these methods, as well as others, can be found in Bergmeyer (1983).

GENERAL ASPECTS OF ASSAY DESIGN

An enzyme's progress curve (i.e., a plot of product formation or substrate depletion as a function of time; see Fig. A.3H.1) consists of four phases that are of interest to the investigator. The duration of the **pre-steady-state** region is relatively short and is typically followed via rapid-flow or relaxation techniques. Discussion of this region of the progress curve is beyond the scope of this appendix, but a review of these techniques has recently appeared (Fierke and Hammes, 1995). The next portion of the curve is the **steady-state** phase, a longer phase characterized by relatively constant concentrations of each of the individual enzyme forms (e.g., the enzyme-substrate binary complexes). During the third phase of the progress curve—the **post-steady-state** region—the levels of these enzyme complexes change rapidly, until the last phase—**equilibrium**—has been reached. Each of these phases contains information of use to the investigator. The steady-state portion of the curve typically exists for a few to several hundred seconds. It is this region of the curve that is most accessible to the majority of investigators. In addition, the relatively straightforward mathematical treatment of steady-state kinetics provides an excellent foundation for the subsequent characterization

of the enzyme system. Because enzyme rate expressions can be quite complex, a number of assumptions are made to linearize the equations. The investigator should ensure that each of these factors are addressed when any assay protocol is being designed.

Maintaining Constant Reaction Conditions

The status of each experimental parameter—e.g., temperature, ionic strength, and pH—should remain constant over the time course of the assay.

Temperature

Prior to initiation of the reaction by addition of a small aliquot of enzyme or substrate, the reaction mixture should be thermally equilibrated with an accurately controlled constant-temperature water bath for several minutes. If the substrate is thermally stable, this incubation should be for ≥ 10 min or until the desired reaction temperature is reached. If the substrate is unstable at this temperature, it may be necessary either to assay at a different temperature, to correct for substrate decay with time, or to initiate the reaction by addition of a small aliquot of substrate solution that was freshly prepared and maintained in an ice bath. When the reaction is initiated by addition of either the enzyme or the substrate, the volume of the

aliquot should be small enough to minimize any alterations in temperature upon addition. Typically, there is at least a hundred-fold difference in volume between the reaction mixture and the initiating aliquot. If the enzyme and substrate are stable under the assay conditions, then both solutions should be preincubated at this temperature.

It should be emphasized that valid initial rate experiments are only obtained when good temperature control is maintained. The temperature-regulated water bath should have a variability of $\leq 0.1^\circ\text{C}$. When the reaction is initiated, the solution should be thoroughly mixed. If reaction progress is followed using an instrument such as a spectrophotometer, the sample compartment should be thermally isolated.

Another issue of concern is choice of the temperature at which enzyme activity will be measured. In 1964, the International Union of Biochemistry (IUB) recommended a temperature of 30°C . Clinical chemists have often suggested a change to 37°C . However, the final choice of temperature will be dependent on the system being investigated. For example, the activity of glutamate dehydrogenase isolated from the hyperthermophile *Pyrococcus furiosus* is negligible at both 30°C and 37°C ; the enzyme exhibits maximal activity at 97°C (Klump et al., 1992). Clearly, at some point in the investigation, the effect of temperature on

the catalytic activity will have to be characterized.

Buffer selection

In setting up the assay protocol, care should also be exercised in selecting an appropriate buffer agent. Unfortunately, many investigators choose a buffer solely on the basis of the desired pH of the reaction medium. Many excellent buffers, however, have a significant oxidation-reduction potential that can severely alter an enzyme's activity. For example, cacodylate ($pK_a = 6.27$) and other organoarsenicals have a potent oxidizing potential under acidic conditions. Borate ($pK_a = 9.23$) and other borate-based buffers form complexes with many diols, polyols, carbohydrates, and ribonucleotides; for example, in the presence of borate ion, both L- and D-serine form a transition complex and strongly inhibit γ -glutamyl transpeptidase (Tate and Meister, 1978). Hence, care should be exercised in selecting a buffer.

In determining which buffer is optimal for a given enzyme system, it is best to examine the enzyme's activity with as many buffers as possible. Buffers in whose presence the enzyme exhibits high activity should then be examined to determine if the buffering agent interacts with the protein. If pH and ionic strength are held constant, the enzyme activity should be independent of the buffer concentration. Another factor of importance in selecting the appropriate buffer is the capacity of the buffering agent to bind metal ions. Ideally, a good buffer will not form any significant complexes with metal-ion cofactors.

Metal-ion concentrations

The role of metal ions is crucial with many enzymes, particularly with systems that require nucleotides—e.g., phosphotransferases. Care must be exercised in designing initial-rate assays to ensure that the concentration of free metal ions does not vary significantly with substrate concentration. Thus, when varying the concentrations of substrates such as ATP, the concentration of free, uncomplexed Mg^{2+} should remain relatively constant. One of two methods is commonly utilized to achieve this end: either (1) maintaining the total nucleotide concentration and the metal concentration at a constant stoichiometric ratio (e.g., 10:1) or (2) maintaining a constant excess of metal ion over the total nucleotide concentration (e.g., 1.0 mM free Mg^{2+}). The second method, which has been demonstrated to be the preferable of the two (O'Sullivan and Smithers, 1979), requires

knowledge of the stability constant for the metal ion–nucleotide complex under the conditions of the assay.

Substrate Stability and Purity

It is crucial to establish the degree of stability of the substrate as well as that of any enzyme effector under the assay conditions (also see discussion of Maintaining Constant Reaction Conditions). Substrate and effector stabilities can be tested by preparing a solution of the compound at a concentration that will be used experimentally with the other components of the assay mixture, but without the enzyme. Then, samples are removed at different periods of time, usually over a period of several hours, and assayed either chemically or enzymatically (Bergmeyer, 1983). A plot of concentration as a function of time will reveal if the substrate is stable or if there is a decay. When present, this decomposition is usually a first-order process and can be described by the equation $[S]_t = [S]_0 e^{-kt}$, where $[S]_t$ and $[S]_0$ are the substrate concentrations at time t and time 0, respectively, and k is the first-order rate constant. If the decomposition is greater than first-order or composed of more than one first-order process, then the decay must be evaluated by the appropriate expression, which can be found in any basic kinetics text.

An issue related to substrate stability is substrate purity. Impurities in the substrate, effectors, or enzyme preparation can be potential sources of experimental error. Because alternative substrates and competitive inhibitors are often structurally similar to the substrate and frequently have similar chemical and physical properties, it is not surprising to find these compounds as impurities in commercial substrate preparations. Spectral and chromatographic analyses, as well as enzymatic analysis, are crucial in establishing the purity of a particular biochemical substance. If impurities are present in a reaction mixture, a kinetic analysis will give wrong estimates of the kinetic parameters (Allison and Purich, 1979). Heavy-metal ions are often found as impurities in commercial substrates. To remove these, it may be necessary to recrystallize the substrates, possibly in the presence of a chelating agent such as EDTA.

These issues of purity and stability are also pertinent for any modulators of enzyme activity, including the product(s). The products have to be stable over the time course of the assay. In some instances, the precise nature of the true product of the enzyme-catalyzed reaction may

not be known. In these cases, the investigator may follow the reaction via substrate depletion. It is frequently useful to do a kinetic analysis of freshly prepared substrate in the absence and presence of enzymatically prepared product. A decent understanding of the possible presence of product inhibition in initial-rate experiments is always useful to the protein chemist.

Enzyme Stability and Purity

Enzymes often undergo a slow inactivation. Usually, the rate of this inactivation is accelerated by dilution of the stock enzyme preparation. Efforts have to be made to eliminate or lessen the loss of enzyme activity with time. Often, multisubstrate enzymes are stabilized by the presence of a substrate. For example, tubulin:tyrosine ligase is stabilized by the presence of its protein substrate (Deans et al., 1992) and the presence of Mg^{2+} -ATP is known to stabilize a number of phosphotransferases. If the enzyme inactivation can be retarded by the presence of a substrate, the investigator should note the amount of that substrate that is present with the enzyme so that proper corrections can be made when the reaction is initiated with the full assay mixture.

Other agents—e.g., glycerol, certain salts, high-ionic-strength solutions, and EDTA—have also been used to stabilize proteins. Often, inactivation is a result of surface denaturation or adsorption of the enzyme on glass surfaces following dilution. The presence of stabilizing agents and/or use of plastic containers can lessen these effects significantly. The presence of serum albumin or another protein will frequently minimize the effects of enzyme dilution; the investigator should test several proteins when this technique is used. The stabilizing protein may also bind the substrates or the enzyme's cofactors; if this is the case, corrections have to be made.

If a stabilizing agent cannot be identified, the inactivation should be minimized by using the smallest dilution possible. If practical, the reaction may be initiated by the addition of one of the substrates. Corrections for loss of enzyme activity can also be made by establishing an activity-decay curve. However, it should be verified that the loss of activity is due to total inactivation and not simply to a conformational change to a form having less activity (i.e., a form with different kinetic parameters). This possibility could be tested by kinetic assays at significantly different times following dilution or by two reference assays, one using a saturat-

ing substrate level and the other using a saturating substrate level.

The presence of thiol reagents—e.g., 2-mercaptoethanol, dithiothreitol, or dithioerythritol—is routinely helpful in maintaining activity for those enzymes that require reduced thiol groups for activity. Care must be exercised that the reducing agent does not produce other effects. For example, γ -glutamylcysteine synthetase is inhibited by the presence of thiol reagents even though cysteine is a substrate (Seelig and Meister, 1985).

Enzyme purity is also an issue of concern. It is important in early initial-rate studies to eliminate contaminating activities and to demonstrate that any minor activity does not substantially affect the reaction being studied. For multisubstrate enzymes, this can be readily accomplished by observing the stability of each substrate, effector, and product separately in the presence of the enzyme preparation. Adenylate kinase is a common contaminant in preparations of a wide variety of phosphotransferases and other nucleotide-dependent enzymes. This contaminating enzyme can be inhibited by performing the assay at high ionic strength (Bowen and Kerwin, 1955). Addition of elevated levels of AMP will also inhibit adenylate kinase. However, many phosphotransferases are also inhibited by this mononucleotide or are themselves inhibited by high ionic strength. Purich and Fromm (1972) and Lienhard and Secemski (1973) have shown that the multisubstrate analogs P^1, P^4 -di(adenosine-5')-tetrphosphate and P^1, P^5 -di(adenosine-5')-pentaphosphate are potent and specific inhibitors of this activity.

In some instances it may be impossible to completely eliminate side reactions. Enzymes that have branched reaction pathways (i.e., multifunctional enzymes) will exhibit two pathways. Most multifunctional enzymes are transferases having multiple acceptor specificity. Glucose-6-phosphatase catalyzes not only the hydrolysis of glucose-6-phosphate but also its synthesis; thus, it may effect the transfer of phosphoryl groups from pyrophosphate, carbamoyl phosphate, or other glucose-6-phosphate molecules (Nordlie, 1982). This synthetic role of glucose-6-phosphatase is not a minor activity; at a concentration of 100 mM D-glucose, the synthesis and hydrolysis activities are approximately equal. The enzyme γ -glutamyl transpeptidase catalyzes the hydrolysis of a number of γ -glutamyl-containing molecules (including glutathione and glutathione disulfide) and also exhibits a transferase activ-

ity in which the glutamyl moiety is transferred to any of a number of amino acid acceptors, particularly cysteine, glutamine, and methionine (Allison, 1985). The hydrolase and transferase activities of γ -glutamyl transpeptidase are approximately equal in the presence of a pool of acceptor substrates at their physiological concentrations (Allison and Meister, 1981). Asparagine synthetase catalyzes the glutamine-dependent synthesis of L-asparagine and also exhibits a significant glutaminase activity (Boehlein et al., 1994). In all of these cases, it is possible to use inactivation studies to observe the parallel loss of both (or all) activities with time.

Enzyme Concentration

The duration of the steady-state phase of an enzyme-catalyzed reaction is dependent on a number of factors. Perhaps the most important of these is the relative concentration of the enzyme and substrate. The ratio of the initial substrate concentration to the total enzyme concentration should be $\geq 100:1$. With lower values, the steady-state phase will be of very short duration. It should be pointed out that this relationship holds for enzyme effectors as well. Thus, when investigating the influences of an activator or competitive inhibitor on enzyme activity, the total enzyme concentration should be much less than the concentration of the effector. This may prove difficult if the effector has a very tight affinity with the enzyme. In these cases, the protocols outlined by Williams and Morrison (1979) will prove useful.

Initial Rate and Steady-State Condition

In an experiment, the investigator typically measures the rate of an enzyme-catalyzed reaction by calculating the slope of the progress curve. This procedure is only valid if the plot of product concentration as a function of time has been demonstrated to be linear within the time frame of the assay. However, this is not the only criterion that determines initial rate and steady-state kinetics. Linearity has been observed in many non-steady-state systems (Allison and Purich, 1979).

The general rule of thumb is that initial rate conditions prevail when the substrate concentration is still within 10% of its starting value. This value is clearly acceptable for reactions that are thermodynamically quite favorable and that do not exhibit any significant product inhibition. However, if the equilibrium constant for the reaction is not large, an estimate of the

degree of substrate-to-product conversion should be made. With smaller equilibrium constants, the initial-rate assay protocol necessarily must be more sensitive. In addition, if the product has very tight affinity for the enzyme, product accumulation can lead to significant errors in initial-rate determinations even in those cases where the degree of conversion is low. A preliminary test to assess this possibility is to look at initial rates in the absence and presence of a known amount of product. Where product inhibition is a problem, product can be depleted if an auxiliary enzyme system for doing this is present. Nevertheless, product inhibition can be an important regulatory scheme for an enzyme. Any kinetic characterization of an enzyme should include accurate measurements of the dissociation constants for all products. Product-inhibition studies can also assist the investigator in establishing mechanistic details of the protein undergoing evaluation (Rudolph, 1979).

In addition to establishing that the progress curve is truly linear, demonstrating that the degree of substrate depletion in the initial time course of the assay is low, and assessing the degree of product inhibition that may be present, the investigator should also demonstrate in the early stages of the kinetic studies that the rates observed are linear with respect to the total enzyme concentration ($[E]_{\text{total}}$). If true steady-state conditions are present, a plot of initial rates versus $[E]_{\text{total}}$ (in which the enzyme concentration is varied above and below the final value to be used in the initial-rate assays) should be linear.

Substrate Concentration Ranges

A wide range of substrate concentrations should be tested in preliminary studies. Such trials will provide an estimate of the Michaelis constant (K_m) and an assessment of whether substrate inhibition occurs at elevated substrate levels. These tests will also detect the possible existence of cooperativity. Once an estimate of the Michaelis constant has been made, a more detailed kinetic study can be made, in which the substrate concentration is typically varied from ~ 0.2 to 5.0 times the value of the apparent constant. It should be emphasized that reasonable estimates of the K_m value can only be made when initial rates have been obtained from substrate concentrations both below and above the true K_m value. For a one-substrate enzyme-catalyzed reaction:

$$K_m = [A](V_{\text{max}} - v)/v$$

Commonly Used
Techniques

A.3H.5

where $[A]$ is the substrate concentration, V_{\max} is the maximal velocity of the reaction, and v is the velocity of the reaction at the substrate concentration. A series of substrate concentrations with their respective initial rate velocities will provide an estimate of the Michaelis constant. In a standard double-reciprocal plot, the horizontal intercept is numerically equal to $-1/K_m$. For multisubstrate enzymes (see below), estimates of the Michaelis constants will be obtained from slope and intercept replots of the initial rate data. In addition, appropriate statistical treatment of the raw data should be provided (Wilkinson, 1961; Cleland, 1979a) for both K_m and V_{\max} values (or k_{cat} values, equal to $V_{\max}/[E]_{\text{total}}$, if those are reported). Note that, regardless of whether V_{\max} or k_{cat} values are reported, the total protein concentration, as well as the specific activity of the enzyme used, should be reported whenever possible.

With enzyme systems utilizing two substrates, the concentrations of both substrates must be varied as described above. Typically, three solutions are prepared. One solution contains one of the substrates at its highest level. A second solution contains the second substrate at its highest level. The third solution contains the buffer, all cofactors, metal ions, auxiliary

enzymes, and any other effectors, but no substrates. This third solution is used to prepare serial dilutions of the other two stock solutions. Thus, a matrix of initial rate measurements on both substrates can be evaluated from a single experimental trial. Figure A.3H.2 illustrates a typical double-reciprocal plot for a two-substrate enzyme-catalyzed reaction (where the two substrates are A and B). In this example, Michaelis constants for the two substrates can be obtained by constructing slope and/or intercept replots of the data. For example, plotting the slopes of the five lines as a function of the reciprocal of the concentration of B will yield a straight line with a horizontal intercept numerically equal to $-1/K_B$, where K_B is the Michaelis constant for B.

For enzymes that utilize three or more substrates, the protocol described above can become unwieldy. Two procedures have been described to address the design of kinetic studies for these proteins. In the first method (Frieden, 1959), one of the three substrates is held constant at a concentration above its respective Michaelis constant that is still subsaturating. The other two are then varied as described above. This same procedure is then followed with each of the remaining substrates. Thus, multisubstrate enzymes are reduced to pseudo-

Figure A.3H.2 Double-reciprocal plot of a two-substrate enzyme-catalyzed reaction, where v = the velocity of the reaction and $[A]$ and $[B]$ represent the concentrations of substrates A and B respectively.

two-substrate systems. One distinct advantage of this procedure is that standard graphical presentations of the data thus produced (e.g., via double-reciprocal plots) are identical to that shown in Figure A.3H.2. However, the concentration value for the third substrate have to be provided. In the second procedure, the concentration of one substrate is varied while the other substrates are held at a constant ratio, although the absolute amounts are varied. This is then repeated for all remaining substrates until the concentration of each of the substrates has been varied (Fromm, 1967). One limitation with this approach is the difficulty in obtaining true Michaelis constants.

The presence of substrate inhibition can be an annoyance to an investigator who is attempting to determine the kinetic parameters of an enzyme as well as identify the binding pattern. However, the pattern of such inhibition can serve as a tool in understanding the kinetic and possibly the regulatory scheme for the enzyme. Substrate inhibition can occur as a result of a number of different causes—i.e., the formation of a dead-end complex with a particular enzyme form, the appearance of a different binding mechanism at elevated levels of substrate, the presence of an allosteric site for the substrate, or nonspecific inhibition that is due to an elevated ionic strength or another factor. When substrate inhibition occurs, in the case of multisubstrate enzymes, estimates of the K_i value (i.e., the dissociation constant for inhibition) for the substrate can be obtained from slope and intercept replots of the kinetic data. For enzymes having a single substrate, the data can be fit to an enzyme-rate expression containing a term for substrate inhibition ($v = V_{\max}[S]/\{K_m + [S] + [S]^2/K_i\}$). In addition, estimates of K_m , K_i , and V_{\max} can be obtained from double-reciprocal plots (Cleland, 1979b). Note that in such cases, double-reciprocal plots will be nonlinear, with the degree of curvature dependent on the magnitude of the K_i value. In these cases, it may be necessary to use a computer program to fit the data. Cleland (1979a) has provided a program to address substrate inhibition. In addition, one might consider utilizing a Marmasse plot (Marmasse, 1963). Although rarely used, this plot provides good estimates of K_m and K_i . A Marmasse plot is a plot of $1/v$ versus $(\alpha + 1/\alpha)$, where $\alpha = [A]/[A]_m$ and $[A]_m$ represents the concentration of substrate at which the velocity is highest (note that this is not V_{\max} , as substrate inhibition is present.) This plot, when combined with the observation that $[A]_m =$

$(K_m/K_i)^{1/2}$, will provide values for the kinetic parameters (Cleland, 1979b).

CONTINUOUS VERSUS STOP-TIME ASSAYS

As the best estimate for the initial rate of an enzyme-catalyzed reaction derives from the slope of the steady-state region of the progress curve, continuous assays are greatly preferable to single-point assays. If it is not possible to use a continuous assay, the investigator must demonstrate that the single-point assay is a true measure of the steady-state velocity of the reaction. In the single-point method, an aliquot of the reaction mixture is removed from the sample at a given time point after the reaction has been initiated (after a “blank” aliquot has been removed from the reaction mixture prior to the initiation step). Aliquots from at least four different time points are removed from the reaction solution; then the reaction is terminated and the amount of product formed (or substrate depleted) is determined. It should be ascertained that the termination procedure truly quenches the reaction. Once the steady-state relationship has been established, replicate kinetic analyses at each substrate concentration will provide sufficient data for a statistical analysis. The number of replicate samples that are assayed should also be reported.

COUPLED ENZYME ASSAYS

In many instances, continuous assays are made possible by the presence of auxiliary enzymes. Product formation is measured by having the product react further with another enzyme (or enzymes). Although such assay systems are convenient, precautions must be exercised to ensure that the initial rates observed reflect the enzyme that is undergoing investigation and not the auxiliary system. If the auxiliary system is influencing the initial-rate results, the reported values for the kinetic parameters will be in error and the double-reciprocals may exhibit considerable nonlinearity.

The product or products formed by the enzyme undergoing study clearly direct the choice of auxiliary enzyme(s). This coupling system should provide turnover in excess over that due to the enzyme being investigated. However, the degree of excess will vary depending upon the assay method, the nature of the coupling system, and the magnitude of the kinetic parameters for each auxiliary enzyme as measured under the same conditions being

observed with the target enzyme. Once this information is in hand, the amount of auxiliary enzyme needed can be calculated (McClure, 1969; Storer and Cornish-Bowden, 1974). Test runs should then be undertaken using both the calculated and higher levels of auxiliary enzymes to insure that identical rates are obtained, indicating that a sufficient excess has been achieved. The auxiliary enzyme system should also have minimal effect on cofactors and effectors required by the target enzyme.

Frequently, a small amount of product may be present in the reaction mixture as a contaminant. For example, commercial preparations of ATP often include a small amount of ADP. The contaminating product can be removed prior to initiation of the assay by incubating the reaction mixture with the auxiliary system. The system should also be checked to insure that no activity is observed in the absence of the auxiliary enzymes. Finally, care should be exercised when using commercial preparations for the auxiliary enzymes. Often these sources of proteins contain contaminating activities that may cause serious difficulties unless they are addressed.

BINDING STUDIES

Measurements of equilibrium ligand binding can frequently add to the characterization of an enzyme's binding mechanism, and also act as a tool in such procedures as molecular-receptor binding studies and radioimmunoassays. A wide variety of methods have been utilized in characterizing binding phenomena—e.g., gel filtration and equilibrium dialysis. The theory underlying this valuable tool can be found in any physical biochemistry text. Commonly, the binding data are analyzed with Scatchard plots (Scatchard, 1949) in which the number of moles of ligand bound per mole of total protein (v) are plotted versus the ratio of v to the free molar concentration of the ligand. These plots are frequently used to obtain values for the ligand dissociation constant, to identify interacting sites, and to estimate the binding capacity of the protein. Care should be exercised in this last use of the binding data, as it is easy to obtain a poor estimate of the stoichiometry of binding from Scatchard plots (Klotz, 1982, 1983). For example, a Scatchard plot of the binding of diazepam to benzodiazepine receptors is reported to provide an incorrect total number of receptor sites. Often, such problems are due to having only a few data points in the Scatchard plot at which the ligand concentration is above the half-maximum bind-

ing point. Just as in kinetic data, concentrations of the binding ligand both above and below this half-maximum point should be investigated (Klotz, 1982). Feldman (1983) has recently presented a statistical analysis associated with ligand binding data and Scatchard plots. As this paper points out, estimates of molar binding capacity should always be reported with the appropriate degree of statistical certainty. Without such statistical analyses, reports of the number of binding sites can be meaningless.

PRESENTATION OF INITIAL-RATE DATA

The description of the assay protocols used in connection with enzyme purifications, in clinical studies, and in all kinetic investigations should include a clear definition of the unit of enzyme activity. When possible, velocities should be expressed in terms of molarity changes with time, as molarity is an intensive variable. Other units, proportional to molarity, are in common use. In all cases, the conditions of the assay should be fully described, including the volume of the initiating aliquot, the specific activity, and the amount of enzyme used in each experiment. The international unit (U), defined as the conversion of 1 μ mol of substrate to product per minute, is in common use. Another unit of catalytic activity, the katal, corresponding to the transformation of one mole of substrate per second, is also in use. It has been suggested that the latter unit be restricted to catalytic activities measured in a clinical context (Dybkaer, 1979).

Initial-rate data is frequently best presented via graphical displays. These visual linearizations of kinetic information provide a straightforward evaluation of the binding sequence and mechanism, as well as a ready appraisal of the kinetic parameters, reversible inhibition, cooperativity (both allosteric and hysteretic), and many other steady-state parameters. Whenever possible, slope and/or intercept replots should also be provided in the graphical display, perhaps as insets of the initial rate data. There are three methods frequently employed for depicting kinetic data, with the double-reciprocal plot (i.e., $1/v$ versus $1/[A]$; see Fig. A.3H.2) being the most common. The other common plots are $[A]/v$ versus $[A]$ and v versus $v/[A]$. Wilkinson (1961) has discussed each of these plots in terms of statistics. When the data are unweighted, the three graphical presentations are not statistically equivalent. However, this problem is considerably mitigated by proper analysis using computer methods and data weighting

(Siano et al., 1975). As mentioned earlier, Cleland (1979a) has provided a number of computer programs for the analysis of data. Eisenthal and Cornish-Bowden (1974) have also introduced a novel method for graphical treatment of data that provides a useful tool for evaluating experimental error. An Eisenthal–Cornish-Bowden plot is based on the equation $(V_{\max}/v) - (K_m/[A]) = 1$. Instead of a particular set of data (i.e., a single initial rate velocity with its respective substrate concentration) being represented by a point in a Cartesian coordinate system, the velocity (v) is denoted along the vertical axis and the substrate concentration ($[A]$) is denoted along the horizontal axis. The two points thus plotted are then connected by a line. Thus, whereas in the other graphical procedures the velocity and substrate-concentration data are represented by points, in the Eisenthal–Cornish-Bowden plot the same data are represented by lines. These lines, obtained from a set of initial-rate experiments, will intersect about a point equivalent to $v = V_{\max}$ and $[A] = K_m$. Because median values of intersection points are used, outlier (i.e., aberrant) data will have minimal effects on estimates of the kinetic parameters. In addition, this plot is very useful in that calculations are not required and data do not have to be weighted. However, it does have limitations (Cornish-Bowden and Endrenyi, 1981, 1986). For example, the plot can become quite unwieldy with multisubstrate enzymes and in inhibition studies.

It has recently been suggested (Brand and Johnson, 1992; Johnson and Brand, 1994) that all of the graphical methods described above may be unnecessary now that personal computers and associated new methods of data analysis are available. For example, global analysis of biochemical data is a powerful tool that may prove to be quite useful in the analysis of enzyme kinetics (Beechem, 1992). However, these numerical methods have not yet been commonly applied to studies such as those of multisubstrate systems, equilibrium exchanges, or product inhibition. At this time, with proper statistical weighting of the data, multisubstrate systems are more readily appraised by one of the common graphical procedures. More importantly, these visual depictions of initial-rate data are a clear aid to any individual reviewing the kinetic experiments.

CONCLUDING REMARKS

Initial-rate assays are extremely useful tools in the detailed characterization of an enzyme. The behavior, mechanism, and regulatory prop-

erties of an enzyme can be readily assessed by straightforward assays. Such assays can frequently be completed within a day, once preliminary runs have identified the magnitude of the kinetic parameters and revealed those factors that affect activity. However, the details of the kinetic mechanism and regulatory properties of the enzyme can easily be obscured by poor assay design. The structural/functional role of an enzyme, as well as its regulation and control, can only be assessed by a reliable initial-rate assay. In addition, the data assembled from these rigorous studies permit the development of more reliable and sensitive assay protocols for protein purification and identification.

Statistics for the Molecular Biologist: Group Comparisons

In this appendix, we will consider some of the statistical tests most commonly used (and misused) in biological research. The tests discussed here are those used for comparisons among groups (e.g., *t* test and ANOVA). A number of other important areas (e.g., linear regression, correlation, and goodness-of-fit testing) are not covered. The purpose of the Appendix is to enable you to determine rapidly the most appropriate way to analyze your data, and to point out some of the most common errors to avoid. Toward this end, we have included a flow chart to provide a quick guide to choosing the right statistical test (Fig. A.3I.1). Instead of including the voluminous statistical tables necessary to perform these tests, we assume you will have access to a spreadsheet software program such as Microsoft Excel or to a statistical software package to do the actual calculations involved and to supply critical values. Clearly, this Appendix is a very superficial treatment of statistics! There are of course many statistics texts available; a few that the authors have found particularly useful are listed at the end of this Appendix (see Literature Cited and Key References).

BASIC STATISTICAL BACKGROUND

Samples and Independence

It is important to think about how you will collect your data and what statistical tests you will perform before you begin your experiment. Suppose you want to compare the immune response of normal mice with that of mice carrying a mutation of interest. You examine a sample of mice from each of these populations. For any statistical test to be valid, all subjects in a sample must come from the same population, and subjects must be selected independently of each other. For example, selecting the same mouse twice would violate the independence assumption; on the other hand, selecting mutant mice from different genetic backgrounds to form one sample would violate the assumption that all mice in a sample are coming from the same population. For some experiments, subjects may be *measured* twice (or more) by design, and this information is incorporated into the statistical test. For example, mouse immune response could be meas-

ured before and after a treatment (see discussion of Paired *t* Test), or several measurements may be made from each mouse (see discussion of Multiple Comparison Testing). However, each mouse in the sample is still chosen independently of other mice.

Hypothesis Testing

Statistical tests always test a null hypothesis, H_0 . The null hypothesis usually states that there is no difference between two (or more) populations. If the null hypothesis is true, any observed differences between samples from these populations arose by chance alone. The alternative hypothesis, H_a , states that differences observed in the samples reflect a real difference between the populations from which they were drawn. We usually hope to reject H_0 , in order to show something interesting. In our immune response experiment, for example, our H_0 would be that mutant mice have the same response as normal mice. We hope to be able to reject H_0 , and show that mutant mice have a different immune response from normal mice.

Although statistical tests can never tell us with absolute certainty whether our samples arose from two different populations, they can give us an idea about how probable our H_0 is. What we would like to know is the probability that any difference we find between samples arose by chance alone. Unfortunately, statistical tests cannot tell us this probability. What they do tell us is a related probability—i.e., the probability that we would see at least as large a difference between samples as we do, given that the null hypothesis is true. This probability is the famous *p* value.

For example, if $p = 0.50$, it means that there was a 50% chance of getting a difference between samples at least as large as we did, if the populations we sampled were really the same. This is a large probability, so we would accept the null hypothesis H_0 , and conclude that there is no difference between the two populations we sampled. The accepted standard is that we should reject H_0 if $p \leq 0.05$ —i.e., there was only a 5% chance (or less) of getting at least as large a difference between samples as we did, if the populations sampled were really the same. The value of *p* below which we will reject the H_0 is called the α value; α is usually chosen as 0.05. A difference between samples that results in a

p value of $\leq \alpha$ is called statistically significant. Note that statistical tests are not black and white; if $p = 0.05$, there is a 5% chance that we will reject the null hypothesis when it is actually true! This is called a Type I error. You might think we could avoid this error by only rejecting H_0 if the p value is even smaller; say, 0.01 or 0.001. However, if we do this, we are likely to accept H_0 when it is false! This is called a Type II error. Setting $\alpha = 0.05$ is a standard that is

generally accepted as a good compromise between Type I and Type II errors.

In practice, once you have chosen a statistical test, you calculate (or the computer calculates) the value of a statistic from your sample data using a formula. You then compare this value to a critical value in a table (or provided by the computer) to decide whether to accept or reject H_0 . The critical value (e.g., F_c for the F test, or t_c for the t test; see discussion of The

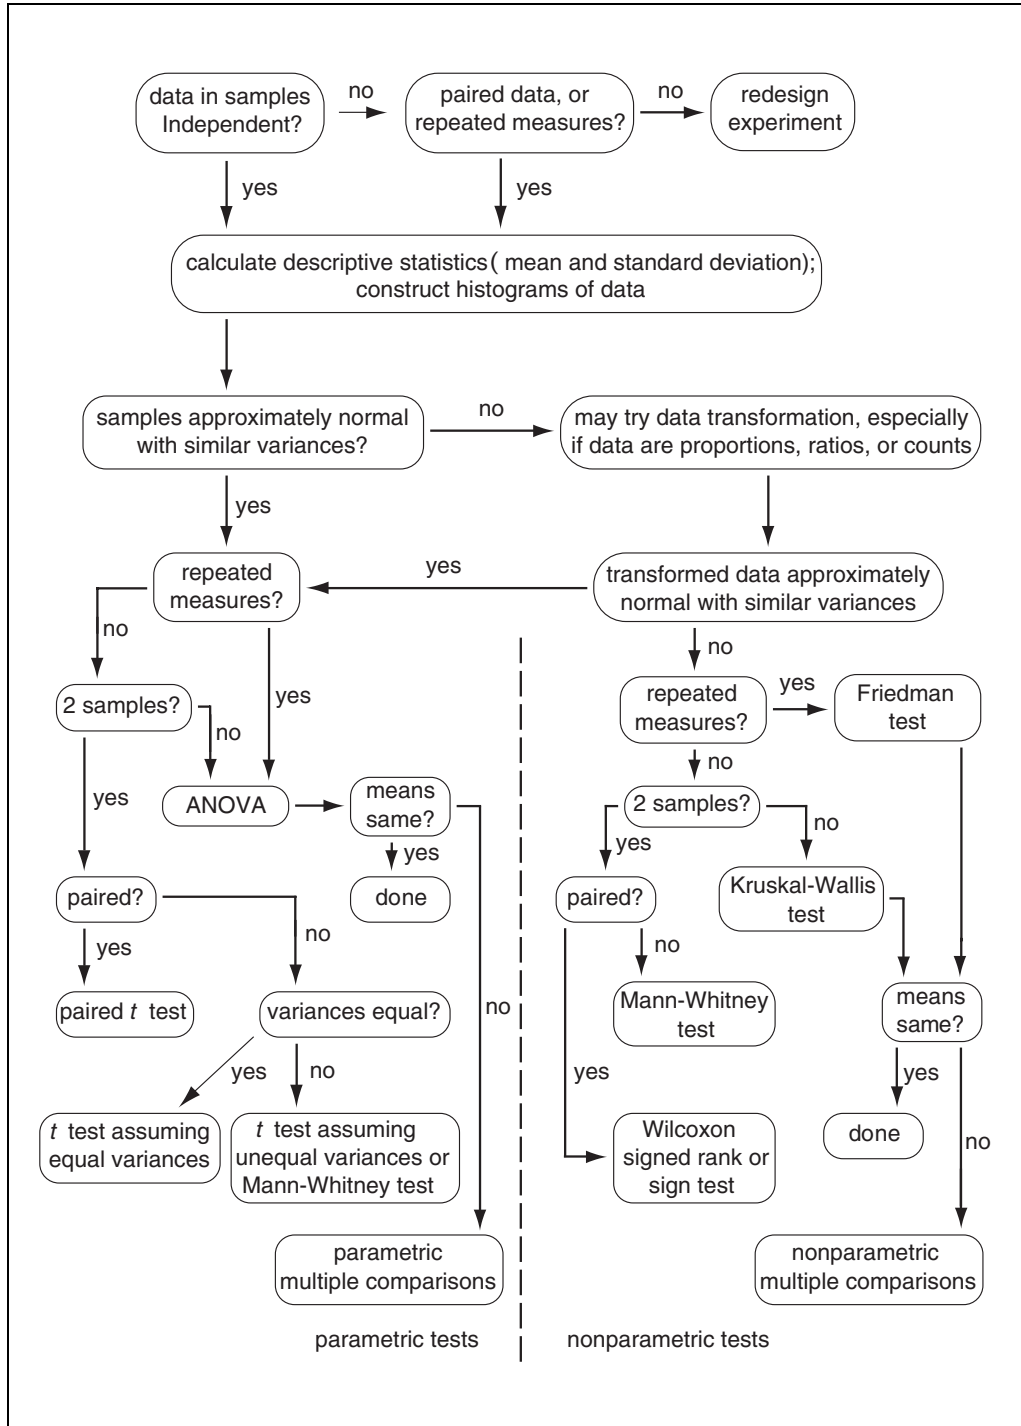

Figure A.3I.1 Flow chart for comparisons among groups.

t Test) is determined by the *p* value you have decided upon (usually, *p* = 0.05) and the degrees of freedom (df) of the data, which vary depending on the test being performed. Usually, you reject H_0 if your statistic is greater than the critical value.

Most tables (and statistical packages) give critical values with one-tailed and two-tailed levels of significance. You are doing a two-tailed test when your H_a does not specify the direction of difference between populations. You perform a one-tailed test when your H_a predicts, based, for example, on a theory that you have, that populations will differ in a particular way. For example, if you think that there may be a difference between the immune response of mutant and normal mice, but you can't predict whether the mutants will do better or worse, you should perform a two-tailed test. If you predict that the response of the mutant mice will be reduced (due to the loss of your gene of interest), you could perform a one-tailed test. There is some controversy in the literature over the use of one-tailed tests. When in doubt, perform a two-tailed test; it is always more conservative (i.e., less likely to reject the null hypothesis).

CHOOSING A TEST— EXPLORATORY DATA ANALYSIS

Parametric and Nonparametric Tests

It can be difficult to sort out what test is appropriate to apply to your data when confronted with a bewildering array of possible tests and formulas. One important distinction you need to make is between parametric and nonparametric tests. Parametric tests (such as the *t* test) assume your data follow a statistical distribution with known mathematical properties (the normal distribution, for the parametric tests we will discuss). Often, parametric tests require that the variability of all the samples you are comparing be the same. Nonparametric tests make fewer assumptions about the distribution of your data. Nonparametric tests are thus less likely than parametric tests to commit a Type I error (rejecting H_0 when it is true), but are usually less powerful (that is, more likely to commit a Type II error, and fail to detect a difference between groups). However, with data sets of reasonable size (say, 25 or more data points per group), nonparametric tests are often nearly as powerful as parametric ones. In order to determine which type of test is appropriate to your data, the first thing you need to do is examine the characteristics of that data.

What Are Parameters?

In order to perform parametric tests, we need to calculate parameters—i.e., numbers that summarize the data in some descriptive way. The statistical parameters we want to calculate are the mean (average) and amount of variability of the population (variance and standard deviation). Your data are a sample from a large population. We estimate the population parameters by sampling a subset of the population. The larger the sample size (*n*), the closer your sample statistics are to the true population parameters.

Any spreadsheet program or statistical package will allow you to determine the mean, variance, and standard deviation of your data; we show the formulas for these parameters below so that you can better interpret what such programs are telling you about the data.

The following is the equation for the sample mean \bar{x} :

$$\bar{x} = \frac{\sum_{i=1}^n x_i}{n}$$

Here, x_i is the value of the *i*th data point, and *n* is the number of data points in the sample.

The sample variance (s^2) is expressed as follows:

$$s^2 = \frac{\sum_{i=1}^n (x_i - \bar{x})^2}{n - 1}$$

The sample standard deviation (*s*), is just the square root of the variance:

$$s = \sqrt{s^2}$$

You can think of the standard deviation as the average deviation from the mean; the magnitude of *s* tells you how much variability there is in the data. If your data are normally distributed, then ~68% of the data should fall within 1 standard deviation of the mean and ~95% of your data should fall within 2 standard deviations of the mean.

The final parameter of interest is the standard error of the mean (s.e.m.; also called the standard error):

$$\text{s.e.m.} = \frac{s}{\sqrt{n}}$$

The standard error of the mean tells you how much the mean of a sample of size *n* taken from your population varies. That is, if you were to

take a number of different samples of size n from your population, the mean of each sample would be slightly different. If you were to plot the means of a number of such samples, they would be distributed across a range of values, but there would be far less variability in those values than in the data of the original samples. While the standard deviation gives you a description of the variability of your data, the s.e.m. is the parameter used to compare two sample means and to determine whether or not they are statistically different. For this reason, the s.e.m. is what is normally plotted as the “error bars” around the mean on a graph showing samples that are being compared. Note that the s.e.m. does not tell you much about the variability of your original data; you can see from the equation for s.e.m. that even highly variable data can give a small s.e.m. if the sample size is large enough.

Suppose we are interested in the ability of neurons to sprout neurites in response to growth factors. We want to compare a population of neurons exposed to nerve growth factor (NGF), a factor of known importance, with a population exposed to factor X. Our H_0 would be that neurite outgrowth in response to NGF is the same as neurite outgrowth in response to factor X. We hope to be able to reject H_0 , and show

Table A.3I.1 Neurite Outgrowth Data

Neurite outgrowth (μm)	
NGF	Factor X
22.5	43.2
35.4	56.9
38.2	60.2
40.4	62.4
41.3	65.7
46.7	75.8
55.4	85.4
62.5	91.3
81.2	95.3
99.2	105.2

Table A.3I.2 Sample Parameters from Neurite Outgrowth Data

	NGF	Factor X
Mean (\bar{x})	52.28	74.14
Variance (s^2)	535.00	388.26
Standard deviation (s)	23.13	19.70
Standard error (s.e.m.)	7.31	6.23

that neurons respond differently to factor X. Tables A.3I.1 and A.3I.2 show a (rather small) data set, with calculated sample parameters.

If these data are normally distributed, then ~68% of the data for NGF should fall within one standard deviation of the mean—i.e., between 29.15 and 75.41 (52.28 ± 23.13). In fact, $\frac{7}{10}$ or 70% of the data points fall within these limits. About 95% of the data should fall within two standard deviations of the mean—between 6.02 and 98.54 ($52.28 \pm 2 \times 23.13$). In fact, 90% of the data fall within these limits. The distribution of factor X data is similar. This is reasonable agreement with the normal distribution, given the small sample sizes.

Determining Whether Data Are Normally Distributed with Equal Variances

In order to determine whether to use a parametric or nonparametric test on your data, it is important to determine whether the data are normally distributed, with equal variances. Statistical tests for normality exist (e.g., the Kolmogorov-Smirnov test; Zar, 1984), and we will discuss tests for homogeneity of variance later. However, you can often find out most of what you need to know about your data by simply plotting it and looking at it.

For reasonably large data sets, the parametric tests that we will discuss are not much affected by small departures from normality (this property is called being “robust” to small departures from normality). As a rule of thumb, if you have ≥ 25 samples in each group that you are comparing, you can simply plot your data using a frequency histogram and examine it visually to see if it falls roughly into a bell-shaped curve. Our neurite outgrowth data is plotted in Figure A.3I.2. In this example, the data points are continuous numbers, so in order to make a histogram, we had to divide the data up into arbitrary “bins” (e.g., 0 to 20, 20 to 40, and so forth). The samples in our data set look approximately normally distributed, although the sample sizes are a bit small to be really sure. The variability in the two data sets also looks similar by eye. Looking back at our sample parameters, the calculated variance and standard deviation of the two data sets look reasonably similar.

If you have a small data set, it may be difficult to determine visually whether your data are normally distributed, and statistical tests also do not have much power to make the determination. If you use a parametric test in this situation, and the data are really not drawn

from a normal distribution, then you may reject your null hypothesis when it is actually true. If you use a nonparametric test, you may accept your null hypothesis when it is false. It is more conservative to use nonparametric tests in this situation; but you can see that the best solution (when possible) is to collect reasonably large data sets!

If visual inspection suggests your data are not normally distributed, or if the variance differs widely among groups, it is sometimes useful to perform a transformation (see discussion of Data Transformations). The transformed data points may then form a normal distribution with similar variances among samples, and parametric statistical tests can be performed on the transformed data points. If neither the original nor the transformed data produce approximately normally distributed data with similar variances, then nonparametric statistical tests generally should be used.

Data Transformations

The parametric tests that we will describe usually assume that the data are normally distributed, and that the variances are the same for all groups being compared (this latter property is known as “homoscedasticity”). There are a number of common situations—e.g., in which the data are expressed as proportions or counts

of randomly occurring objects or events—where these assumptions are violated, but you can still use a parametric test if you first perform a data transformation.

Data expressed as proportions of 0 to 1.00 (i.e., 0% to 100%) are not normally distributed. However, you can make them nearly normally distributed, with reasonably homogeneous variances among groups, by performing the following transformation for each data point, and then using the p' values for all of your calculations (e.g., mean, and standard deviation):

$$p' = \arcsin \sqrt{p}$$

When the data are counts of randomly occurring objects (such as the number of butterflies per square foot of a field) or events (such as the number of cars passing by a location), the data will follow a Poisson rather than a normal distribution. Group variances will then be proportional to their means. In this case, the square root transformation, shown in the following equation, should be performed. As with proportions, statistical tests are then performed on the transformed values.

$$x' = \sqrt{x + 0.5}$$

If variances among groups are very different and if the standard deviations are proportional

Figure A.3I.2 Neurite outgrowth histogram. Black bars correspond to results for nerve growth factor (NGF) gray bars correspond to results for “factor X.”

to the means of your groups, the logarithmic transformation can be used:

$$x' = \log(x + 1)$$

If your data are expressed as ratios, a logarithmic transformation is likely to make them more nearly normally distributed (for an example, see discussion of Ratio Paired *t* Tests).

Other types of transformations are possible (Zar, 1984). If your data still don't fit the assumptions of a parametric test after being transformed, then a nonparametric test should be used.

STATISTICAL TESTS FOR COMPARISONS BETWEEN TWO UNPAIRED GROUPS

The *t* Test

The *t* test is a parametric test that allows us to determine whether the means of two samples are statistically different. The nonparametric equivalent is the Mann-Whitney test (see discussion below; also called the Wilcoxon Rank Sum test).

Assumptions of the *t* test

1. Only two samples are being compared. If more than two samples are compared, you *must* use a test specifically designed for multiple comparisons, such as ANOVA (see discussion under Multiple Comparison Testing). Using multiple *t* tests to compare among three or more samples is invalid, and the computed *p* values will be wrong. This is one of the most common errors in the use of the *t* test.

2. Subjects in samples were chosen independently. If repeated measurements were made from individual subjects, ANOVA (or the nonparametric equivalent) should be used.

3. The two samples were not paired in any way (such as before-and-after measurements or matched cases and controls). If samples were paired, the paired *t* test (or the nonparametric Wilcoxon Signed Rank test; see discussion below) should be used.

4. The samples are approximately normally distributed. If this assumption is not met, either transform your data (see discussion of Data Transformations) or use the nonparametric Mann-Whitney test instead.

The simplest form of the *t* test assumes that both samples have the same variance. A somewhat more complicated form is necessary if the sample variances are different. Therefore, in order to determine which form of the *t* test to

use, we must first determine whether the sample variances are statistically different, by using the variance ratio test, or *F* test. Figure A.3I.3 shows a flow chart for the *t* test.

Performing the *F* test

The *F* test is summarized as follows:

$$H_0: s_1^2 = s_2^2$$

$$F = \frac{s_1^2}{s_2^2} \text{ or } F = \frac{s_2^2}{s_1^2}, \text{ whichever is larger}$$

(*F* will always be ≥ 1)

reject H_0 if $F > F_c$; accept H_0 if $F < F_c$

In the above equations, *F* is referred to as the "*F* statistic," s_1^2 and s_2^2 are the variances of sample 1 and sample 2, respectively, and F_c is the critical value.

Statistical computer packages will report the *F* statistic, along with the appropriate critical value, F_c . Note that if the variances of the two samples are very different, *F* will be large, so it makes sense to reject H_0 if $F > F_c$. If we reject H_0 , we would use the *t* test assuming unequal variances. If we accept H_0 , we would use the *t* test assuming equal variances. If the differences in variance are extreme, a data transformation may be indicated or the (nonparametric) Mann-Whitney test could be performed instead of the *t* test.

F_c is chosen based on the significance level (usually $\alpha = 0.05$), and the degrees of freedom (df) in the data. The value of df is equal to one less than the number of data points in each sample. In the case of the experiment in Table A.3I.1, which will be used as an example here, there are 10 data points in each sample, so $df = 9$ for each sample. F_c is usually written " $F_{\text{numerator df, denominator df, } \alpha}$." For our example, F_c would be written $F_{9,9,0.05(2)}$. The 2 in parentheses denotes that this is a two-tailed critical value. If the computer package reports both a one-tailed and two-tailed critical value, use the two-tailed value. You would only use a one-tailed value if you had reason to think *before* computing the variances that one variance would be larger than the other. When in doubt, use a two-tailed test.

Performing the *t* test

The *t* test with equal variances and sample sizes is summarized as follows:

$$H_0: \bar{x}_1 = \bar{x}_2$$

$$t = \frac{|\bar{x}_1 - \bar{x}_2|}{\sqrt{\frac{s_1^2 + s_2^2}{n_1}}}$$

reject H_0 if $t > t_c$; accept H_0 if $t < t_c$

In the above equations, t is referred to as the “ t statistic” and t_c is the critical value.

Statistical packages will report t and t_c . To choose t_c from a table, the number of degrees of freedom is calculated as the sum of the number of data points in samples 1 and 2, minus 2 ($df = n_1 + n_2 - 2$). The critical value, t_c , is often written $t_{df,0.05(2)}$ for a two-tailed test. As with the F test, use a two-tailed test if both one- and two-tailed critical values are given.

Examining the formula for the t statistic, you can see that t will be large if the difference between the sample means is large. However, as the variances of the samples get larger, the t statistic gets smaller. Thus, the equation makes intuitive sense; you will be able to reject the null hypothesis if the difference between means is large and the scatter in the data is small, so that there is little overlap between the two samples.

There are several different formulas for the t test with unequal variances, which give

slightly different results; they are not presented here (see Zar, 1984). The t test with unequal variances tests the same H_0 and follows the same intuitive reasoning given above for the t test with equal variance. However, the calculation of df for this test is quite different than for the test with equal variance—they are calculated using a more complicated formula—a statistical package will calculate them, and print them for you.

Example of the t test

Let us assume that our neurite outgrowth data (see Table A.3I.1 and Table A.3I.2) fit all the assumptions for the t test, and let us perform the t test on this data set.

H_0 for the F test: variances of the two samples are equal.

$$F = 535.00/388.26 = 1.378.$$

$$F_c = F_{9,9,0.05(2)} = 4.03.$$

Thus, $F < F_c$, so we accept H_0 and conclude that the variances of the two samples are not statistically different. We proceed to the t test assuming equal variances.

H_0 for the t test: means of the two samples are equal.

We use a spreadsheet to calculate the t statistic. The computer reports:

$$t = 2.275$$

$$t_c = t_{18,0.05(2)} = 2.10.$$

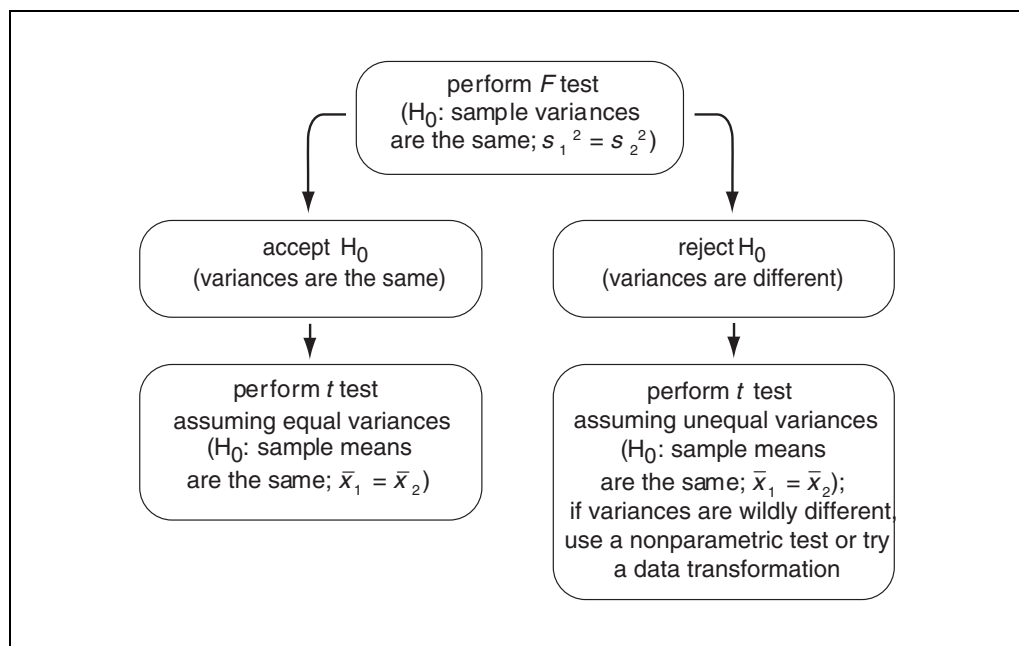

Figure A.3I.3 Flow chart for the t test. Here, we want to compare sample 1 and sample 2, with means \bar{x}_1 and \bar{x}_2 , variances s_1^2 and s_2^2 , and sample sizes n_1 and n_2 . Whichever t test you use, accepting H_0 for the t test says that the sample means are the same; rejecting H_0 for the t test says that the sample means are different.

Thus, $t > t_c$, so we reject H_0 and conclude that the means of the two samples are different, with statistical significance at the $\alpha = 0.05$ level. The calculated p value for our data is $p = 0.035$. Note that some spreadsheets print out negative values for the t statistic; in this case, simply use the absolute value.

The Mann-Whitney Test

The Mann-Whitney test (also called the Wilcoxon Rank Sum test) is the nonparametric equivalent to the t test, and is used to determine if two samples are statistically different, with no assumptions about whether the data are normally distributed.

This test is nearly as powerful as the t test. When you perform the Mann-Whitney test, you are comparing the order, or rank, of the data rather than its numerical value. To perform the Mann-Whitney test, you rank your entire data set (treating all data from both samples as a single list). For our neurite outgrowth data, the largest data point is 105.2; it has a rank of 1. The next largest is 99.2, with a rank of 2, and so on. You then sum the ranks for each individual data set.

If your two samples have similar values, the ranks would tend to go back and forth between samples. For example, the highest-ranking value might be in sample 1, the next two highest in sample 2, the next in sample 1, and so on. If you then summed the ranks from each sample, the two sums would be about equal. On the other hand, if sample 1 had mostly larger numbers than sample 2, the ranks of sample 1 would all be small numbers, and the sum of the ranks of sample 1 would be much smaller than that of sample 2. The Mann-Whitney test tells us how different the rank sums must be to indicate a significant difference between the two samples.

Assumptions of the Mann-Whitney test

Assumptions 1 to 3 of the t test (see discussion The t Test) apply also to the Mann-Whitney test. The Mann-Whitney test, however, makes no assumption about normality of data

Performing the Mann-Whitney test

The Mann-Whitney test is summarized as follows.

H_0 : There is no significant difference between the two samples (of sizes n_1 and n_2).

1. Order all the data from both samples into a single list, from greatest to smallest value, keeping track of which sample the data came from. Tied values get the average of the two

ranks they would have had if they had not tied (e.g., if two values tie for 8th largest, they would have been 8th and 9th largest, they each get a rank of 8.5).

2. Sum the ranks for each sample. Call the sums R_1 and R_2 .

3. Calculate the U and U' statistics according to the following equations:

$$U = n_1 n_2 + \frac{n_1(n_1 + 1)}{2} - R_1$$

$$U' = n_1 n_2 - U$$

4. If either U or U' is greater than the critical value, $U_c (U_{0.05(2),n_1,n_2})$, in a table of U values; see, e.g., Zar, 1984), then reject H_0 .

5. With more than 20 measurements in one or both samples, the Z statistic is used, as calculated by the following equation. Only U or U' needs to be calculated in this case, not both.

$$Z = \frac{|U - \bar{U}| - 0.5}{s}$$

where

$$\bar{U} = \frac{n_1 n_2}{2} \text{ and}$$

$$s = \sqrt{\frac{n_1 n_2 (n_1 + n_2 + 1)}{12}}$$

The Z statistic is approximately normally distributed, even though the original data may not be at all normally distributed. For $\alpha = 0.05$, if $Z > 1.96$, H_0 is rejected.

Example of the Mann-Whitney test

Let us say that we were a bit uncomfortable assuming that our neurite outgrowth data (see Table A.3I.1 and Table A.3I.2) are really normally distributed, and we decide to perform the Mann-Whitney test instead of the t test. These data are shown ranked for the Mann-Whitney test in Table A.3I.3.

From the data in Table A.3I.3 we can make the following calculations, based on the above equations for the Mann-Whitney test:

$$U = 100 + 55 - 134 = 21$$

$$U' = 100 - 21 = 79$$

$$U_c = U_{0.05, 10, 10} = 77$$

Since $U' > U_c$, H_0 is rejected and it is concluded that the two samples are significantly different.

Table A.3I.3 Neurite Outgrowth Data Ranked for the Mann-Whitney Test

Outgrowth	Rank (NGF)	Rank (factor X)
NGF		
22.5	20	—
35.4	19	—
38.2	18	—
40.4	17	—
41.3	16	—
46.7	14	—
55.4	13	—
62.5	9	—
81.2	6	—
99.2	2	—
Factor X		
43.2	—	15
56.9	—	12
60.2	—	11
62.4	—	10
65.7	—	8
75.8	—	7
85.4	—	5
91.3	—	4
95.3	—	3
105.2	—	1
Rank sum	134	76

Note that both the t and Mann-Whitney statistics were very close to the critical values for these data. The power of the Mann-Whitney test to reject H_0 is almost as great as that of the t test.

COMPARING TWO PAIRED GROUPS: PAIRED t TEST, WILCOXON SIGNED RANK TEST, AND SIGN TEST

When to Use a Paired Analysis

A paired analysis is indicated under the following circumstances.

1. You measure a variable before and after some treatment is performed upon a subject.
2. You match subjects in pairs (e.g., for age, sex, and exposure) and then treat one of the subjects and not the other (or the other receives alternative treatment).
3. You compare relatives (e.g., siblings or parent/child).

4. You perform an experiment several times, each time with experimental and control preparations treated in parallel.

Paired t Test

The paired t test is a parametric test used to compare two groups whose members are paired. When the assumptions of a paired t test are met, another approach is to perform a repeated-measures ANOVA (see discussion under Multiple Comparison Testing) with only two groups. However, most nonstatisticians find the paired t test easier to understand and perform.

Assumptions of the paired t test

1. Pairs must be representative of a larger population. Each pair must be selected independently of other pairs.
2. Pairs must be made *before* data is collected.
3. The calculated *differences* between the two members of each pair must be approximately normally distributed.

Table A.3I.4 Paired Neurite Outgrowth Data

Neurite outgrowth (μm)		
NGF	Factor X	Difference
22.5	43.2	20.7
35.4	56.9	21.5
38.2	65.7	27.5
40.4	62.4	22.0
41.3	75.8	34.5
46.7	85.4	38.7
55.4	95.3	39.9
62.5	60.2	-2.3
81.2	105.2	24
99.2	91.3	-7.9

**Figure A.3I.4** Change in neurite outgrowth after addition of factor X, in cells treated first with NGF.**Performing the paired *t* test**

The paired *t* test is summarized as follows.

Assume you have a set of n pairs: $x_{11}, x_{21}, x_{12}, x_{22}, \dots$ through x_{1n}, x_{2n} .

H_0 : There is no difference between members of pairs. (i.e., the mean difference between the pairs, \bar{d} , is equal to 0).

1. For each pair, calculate the difference between the pairs ($d_i = x_{1i} - x_{2i}$).

2. Calculate the mean, \bar{d} , and the s.e.m. of these differences.

3. Calculate the *t* statistic according to the following equation:

$$t = \frac{\bar{d}}{\text{s.e.m.}}$$

4. Determine t_c from a table using $df = n - 1$. Note that each pair counts as 1 in computing the df ; for the unpaired *t* test, each data point counted as 1.

5. If $t > t_c$, reject H_0 .

Example of the paired *t* test

For our neurite outgrowth data, suppose that instead of looking at two different sets of neurons treated separately with NGF and factor X, we were looking at neurons treated sequentially, first with NGF and then with factor X. We were able to keep track of each individual neurite, and want to know if neurites continued to grow out in the presence of factor X after NGF was removed. We will analyze the same

Table A.3I.5 Original and Transformed Densitometry Data from Northern Blotting of Mutant Versus Wild-Type Gene Expression^a

Mutant	Wild-type	Ratio: mutant/ wild-type	log(mutant)	log(wild-type)	log(mutant) – log(wild-type)
500	300	1.67	2.6990	2.4771	0.2218
6000	4200	1.43	3.7781	3.6232	0.1549
750	500	1.5	2.8751	2.6990	0.1761

^aValues expressed in arbitrary densitometry units.

data as before, but now it is paired, as shown in Table A.3I.4 and Figure A.3I.4.

H_0 : There is no change in neurite outgrowth when factor X is added to the medium

$$\bar{d} = 21.86$$

$$\text{s.e.m.} = 5.03$$

$$t = 21.86/5.03 = 4.35$$

$$t_c = t_{9,0.05(2)} = 2.26$$

$$t > t_c; \text{ therefore reject } H_0.$$

The p value for the paired t test is $p = 0.0018$ (the p value for the unpaired test on the same data was $p = 0.035$). Clearly, having data that are paired can give us much more power to reject H_0 .

If we are uncertain whether our differences are normally distributed, we can use a nonparametric alternative (either the Wilcoxon Signed Rank test, or the Sign test; see discussion below).

Ratio Paired t Tests

Sometimes it makes sense to compare values as ratios rather than as differences. For example, you might want to look at densitometric data from a northern blot of your favorite gene's expression in a mutant animal, compared to the signal from a wild-type animal. For each experiment, the densitometry units can be adjusted arbitrarily, and may vary widely depending on how good your probe is and how long the exposure was. However, the ratio of the mutant to wild-type readings is what is important. In this case, what you really want to know is whether the ratio of mutant to wild-type is significantly different from 1 (implying that gene X is expressed either more or less in the mutant than in the wild type).

Ratios are not normally distributed, but logarithms of ratios are quite likely to be normally distributed. The logarithm of a ratio can be written as a difference:

$$\log\left(\frac{\text{mutant}}{\text{wild-type}}\right) = \log(\text{mutant}) - \log(\text{wild-type})$$

Thus, to analyze data of this type, simply take the logarithm of each data point and perform a paired t test on this transformed data (Table A.3I.5). If the transformed data do not appear to be approximately normal, the Wilcoxon Signed Rank test can be used instead. The null hypothesis for the transformed data is that the mean difference is 0, as before; this means that for the original (untransformed) data, the null hypothesis is that the ratio of mutant to wild-type expression is 1. Rejecting the null hypothesis says that the amount of expression in mutant and wild-type animals is significantly different.

Let us perform the calculation as follows on the data in Table A.3I.5.

H_0 : Ratio of mutant to wild-type expression = 1 (there is no difference between mutant and wild-type animals).

Transform data, and perform paired t test of differences of logarithms of data as described for the paired t test.

$$\bar{d} = 0.1843$$

$$\text{s.e.m.} = 0.019755$$

$$t = 9.33$$

$$t_c = t_{2,0.05(2)} = 4.30$$

$$t > t_c$$

Thus, reject H_0 and conclude that there is a significant difference in expression between mutant and wild-type animals. (the calculated p value was 0.01). Note that this is a very significant result, even with only three pairs of data.

Wilcoxon Signed Rank Test

The Wilcoxon Signed Rank test is a nonparametric equivalent to the paired t test. It is used for data that may not be normally distributed.

Table A.3I.6 Differences Computed from Neurite Outgrowth Data, and Ranked for Use in the Wilcoxon Signed Rank Test

Difference	Rank (-)	Rank (+)
20.7	—	3
21.5	—	4
27.5	—	7
22.0	—	5
34.5	—	8
38.7	—	9
39.9	—	10
-2.3	1	—
24	—	6
-7.9	2	—
Rank Sum	3	52

Assumptions of the Signed Rank test

Assumptions 1 and 2 of the paired *t* test apply also to the Wilcoxon Signed Rank test. An additional assumption is made that the sampled population is symmetrical about the median. If the data do not fit this assumption very well, the Sign test (see discussion below) can be performed.

Performing the Signed Rank test

The Wilcoxon Signed Rank test is summarized as follows.

H_0 : There are no differences between members of pairs.

1. For each pair, calculate the difference between the members of the pair. Keep track of the sign.
2. Rank the absolute value of all differences from low to high.
3. Sum the ranks of the negative differences (call the sum T^-) and the ranks of the positive differences (call the sum T^+).
4. Reject H_0 if either T^- or T^+ is less than or equal to the critical value, T_c , as determined from a Wilcoxon Signed Rank table.

Example of the Signed Rank test

If we were concerned about the normality of our neurite outgrowth differences (Table A.3I.1 and Table A.3I.2), we could perform the Wilcoxon Signed Rank test on these data rather than the paired *t* test we did earlier. Consider the data in Table A.3I.6.

H_0 : There is no change in neurite outgrowth when factor X is added to the medium.

$$T^- = 3; T^+ = 52$$

$$T_c = 8$$

$T^- < T_c$; therefore reject H_0 .

The Sign Test

The Sign test is another nonparametric paired test that comes in especially handy when you are sure of the *direction* of a difference between the members of your pair (positive or negative), but you may not know exactly how much difference there is.

Assumptions of the Sign test

The assumptions of the Sign test are the same as those of the Wilcoxon Signed Rank test, but no symmetry assumption is made. This is a less powerful test.

Performing the Sign test

The Sign test is summarized as follows.

H_0 : There are no differences between members of pairs.

1. For each pair, record whether the first member is greater than the second (+) or less than the second (-). Ignore any pairs with equal members. C^+ is the total number of (+) pairs; C^- is the total number of (-) pairs.
2. Reject H_0 if either C^+ or C^- is less than or equal to the critical value of C for the Sign test (C_c).

Example of the Sign test

H_0 : There is no change in neurite outgrowth when factor X is added to the medium.

For our neurite outgrowth data (Table A.3I.6), $C^+ = 8$ and $C^- = 2$. For $n = 10$ and $p =$

0.05, the critical value, C_c is equal to 1. Therefore, H_0 cannot be rejected.

MULTIPLE COMPARISON TESTING

Why Not Lots of t Tests?

If we find that we want to compare multiple groups in an experiment, then the t test just will not do. Using pairwise comparisons ignores the experimental effects in our design in all but the two groups being compared. Even if it were appropriate to use multiple pairwise comparisons (and it is not), we would still run afoul of the problem of hypothesis rejection. If we used the typical $\alpha = 0.05$, that would mean that for every 20 pairwise tests we ran, we would expect to get the wrong answer for one of them. This is not a desirable situation. There are a number of methods, however, that avoid these problems by allowing us to consider our entire design in our model for analysis. The most common in current literature is the analysis of variance (ANOVA). There are classical and nonparametric methods to analyze variance differences, and we will first consider the classical, or parametric case.

Assumptions of ANOVA

As with any statistical test, there are several assumptions of the classical analysis of variance that need to be examined. Some of these are more critical than others, and we will try to make that clear. In this chapter, we are dealing only with one-way analysis of variance; additional assumptions hold for more complex ANOVA procedures. If in doubt about the ability of your own data to meet these criteria, use nonparametric alternatives, for which the assumptions are less stringent.

Independent observations

Observations must be independent even if you end up doing nonparametric analysis. Data points need to have been collected such that the magnitude of one observation does not affect another. Certain tests, such as the repeated-measures analysis of variance or Friedman's nonparametric analysis of variance, however, allow for multiple measurements on a single subject. Care should be taken to avoid interdependence of data during your experimental design because no amount of adjustment or transformation can rectify the problems inherent in nonindependent data. An example of nonindependent data would be taking three measurements of pH from a single cell culture

dish and entering them as $n = 3$ in your ANOVA. In this case, $n = 1$, and you are just as well off taking a single measurement as you are averaging the three readings.

Continuous variable

This assumption is not an extremely strong one as long as you bear several things in mind. The data need to be numerical and ordinal. Continuous data, that is, data that can take on any possible numerical value, are the kind of data for which ANOVA was designed to be used. Deviations from this will affect the sensitivity of the test. It is permissible for data to be discrete (having only a certain set of possible values, like counting numbers) if the numerical values have a fairly wide range. For ANOVA, this would mean something on the order of a 1 to 10 scale or greater. The numbers applied to observations must have some tie to a "greater than or less than" scale; they cannot simply be a classification system of your data. If you have discrete data, you should pay closer attention to the adherence of your data to the additional assumptions detailed below, or just choose a nonparametric test from the outset.

Homogeneity of variance

This is probably the strongest assumption of ANOVA, since, as we will see later, the whole test hinges on the variability within each of our experimental groups being similar. As in the case of the t test (see discussion of The t Test), the variances for each group need to be tested for similarity. The big difference here, however, is that for the greater-than-two-groups case, there is no way to continue with the test if the variances of the groups are significantly different. Instead, we need to transform the data mathematically to make the variances more similar, or move on to a nonparametric equivalent.

Checking for homogeneity of the variances should start with drawing a frequency histogram of each group and seeing how spread out the data are. It is also a good idea to calculate variances for each group and see if the numbers look close. In many cases, this is all the checking that needs be done. If you remain unsure, there is a simple test called the F_{\max} test, which is a simple matter of setting up the following ratio:

$$\frac{\text{largest group variance in the study}}{\text{smallest group variance in the study}} = F_{\max}$$

This is equivalent to using an F ratio of two groups in the t test (see discussion of The t Test),

Commonly Used Techniques

A.3I.13

but the tabled critical value to which it is compared is from a cumulative F distribution. Degrees of freedom are calculated as $n - 1$, where n is the number of observations in a single group. If n varies among groups, then the lowest value should be chosen, to be most conservative in the test. As in the case of the t test, if you fail to reject the null hypothesis, then the variances can be assumed to be roughly equivalent.

Normality

Although this is touted as an important assumption in most classical statistics, it is not as strong an assumption in practice for ANOVA as the assumption of homogeneous variances. Again, using a frequency histogram to give an idea of the shape of your distribution is often a good enough test of normality (see discussion of Determining Whether Data Are Normally Distributed with Equal Variances). If the data are distributed with a marked hump toward the average value and trailing off to either side, then ANOVA will probably work fine. Computer programs provide several different tests of normality that can also be used for this purpose.

Partitioning the Variance

It may seem odd that we wish to analyze variance when, in the long run, our question is to find the differences in means among groups in our experiment. Analysis of variance, however, takes advantage of the underlying assumption that the variation in a measurable quantity is similar within all groups in a population. One or more of these groups, however, may have a very different mean relative to the other groups. If this were the case, the total variance of the whole population would increase relative to the amount seen in each group. It is this observation that gives us the null hypothesis for ANOVA, which is that the means of all the groups are the same:

$$H_0: \mu_1 = \mu_2 = \mu_3 = \dots = \mu_n$$

In ANOVA, we break down the total variance into two basic components: within-group and among-group variance. Within-group or error variance is the naturally occurring variance among individuals due to inherent genetic differences and the differential effects of environment that each individual experiences. This contrasts with among-group or treatment variance, which is the variance observed among groups due to perturbations of the experiment. The treatment variance is the mathematical difference between the total variation observed in our experimental model and the natural vari-

ance measured across individuals (the error variance). Partitioning the variance into components allows us to establish the ratio of the two components of variance, defined as F_s , as shown in the following equation:

$$\frac{\text{among-group (treatment) variance}}{\text{within-group (error) variance}} = F_s$$

Testing the Null Hypothesis

After partitioning the variance into its two components (see discussion of Partitioning the Variance), we can then compare our calculated F_s to the F distribution, which is tabled in numerous statistics texts. The tables are usually organized with the critical values listed for many combinations of the numerator (treatment) versus denominator (error) degrees of freedom. Treatment degrees of freedom are the number of groups minus 1, and the error degrees of freedom are the total number of individual observations in all groups minus the number of groups. While it is unlikely that you will ever have to look up tabled F values, since computers do it for us, it is important to understand the convention used for F ratios. The F value given for a particular tested proportion is written as:

$$F_{(\text{treatment df, error df, } \alpha)} = \text{critical value from table.}$$

So, the critical value of F for an hypothetical experiment with a rejection level (α) of 0.05, four treatment groups, and a total experimental population of 48 organisms would be written as:

$$F_{(3,44,0.05)} = 2.82.$$

If α is chosen as 0.05, it is often omitted from the statistical reporting for brevity's sake. This critical value is important in our analysis because, if our calculated F ratio gives a value higher than the critical value from the table, we reject our null hypothesis. For ANOVA, the null hypothesis is that all the means for all the groups are equal. Rejecting the null hypothesis tells us only one thing: that at least one of the groups differs from the others. It does not tell us how many differ or from how many of the other groups any one might differ. For this answer we need to proceed to a method of multiple-means comparisons.

The ANOVA Table

Assuming a hypothetical experiment such as the one summarized in Table A.3I.7 and Table A.3I.8, the output from any ANOVA computer package is likely to produce an

Table A.3I.7 Hypothetical Optical Density Data for Bacterial Cultures

Total	0.328725	27	—	—	—	—

^aAbbreviations: *F*_c, critical value of *F* statistic; SS, sum of squares; MS, mean square.

ANOVA table similar to Table A.3I.9, originally generated by Microsoft Excel. The data are hypothetical optical density readings for plasmid-transformed bacteria that have been transformed by three different experimental protocols, along with a control that has not been transformed.

The first part of the data analysis is a simple descriptive summary table (Table A.3I.8) that gives the sample size, mean, and variance for each group. Based on this table, it is fairly clear that the variances within groups are similar, but that the means for some of the groups seem to be different from others. The ANOVA table (Table A.3I.9) then gives the variance components and degrees of freedom accounted for among and within groups. The “SS” column indicates the sum of squares for each component, and the “MS” indicates mean square. Sum of squares is the summation of the square of the amount by which each observation differs from

the total mean. The mean square is the same as the variance, and is calculated by dividing the SS by the appropriate degrees of freedom. The mean square within-groups value is often called the “mean square error,” and figures prominently into tests of differences among the means.

The table also reports the calculated *F* ratio for the among versus within variance comparison. The computer then provides the exact *p* value associated with this ratio and sample size, and further indicates the critical *F* value that is necessary for rejection at the 0.05 level.

Which Means Are Different?

We have finally reached the point where we are ready to answer the question we asked, which was whether the average value of one or more of our groups differs from the others. While statisticians differ on this issue, it is the authors’ opinion that if you fail to reject the null

hypothesis of your ANOVA you should not test for significant means differences unless you planned certain comparisons *before* you ran the experiment. That having been said, it is possible that you will find significant means differences even if you fail to reject the ANOVA null hypothesis. If that is the case, however, it is worth asking how robust your initial test was—did you have large-enough sample sizes, were your variances “equal enough,” and were the distributions of your data groups normal or at least all similarly shaped? If not, you would probably be better off reworking your analysis with a nonparametric equivalent.

Assuming that you have rejected H_0 , how can you tell which means differ? Again, a first approximation is to look at the average values for each group and see which appear most different from the others. Next, you will want to proceed to a test that will provide you with a p value for those differences. For the special case of testing a control versus treatments, the Dunnett test is appropriate. Other test names you might see are Bonferroni or Tukey; computer packages have many options and you should refer to the statistical documentation of your package to determine which option best suits your data.

Since means comparisons are cumbersome to do by hand and are part of most statistical packages, we will not go into the specific calculations here. Make sure, however, that you understand how the computer is reporting the significance of your data to you. The computer will usually give you a p value. As you perform more mean-versus-mean comparisons, your acceptable α level will change, and the computer rarely keeps track of this, so it is important to know how to calculate these adjustments in α . One of these techniques is discussed below.

Planned or unplanned comparisons

The use of certain techniques in your final means comparison will depend, in part, on whether you planned before the experiment among which groups you were going to look for differences (a priori tests) or whether you waited to peruse your data first (a posteriori). This turns out to be a theoretically very complex subject and one that is not worth delving into here. A detailed treatment can be found in Sokal and Rohlf (1981).

It is worth pointing out here a common mistake in choosing significance levels for multiple means comparisons. In general, planned comparisons allow the researcher a greater rejection level (bigger α or p value) than un-

planned comparisons. The reasoning is simple: if you first look at your data, then choose your comparisons, you are introducing a bias to your analysis. To account for this, the level of rejection needs to be tightened. Even if you have planned your comparisons, however, it is easy to abuse the power of multiple means tests.

For example, declaring a priori that you are going to conduct all possible pairwise comparisons in your experiment is tantamount to using multiple t tests (see discussion of Why Not Lots of t Tests?). If you have k groups in your analysis, the number of all possible pairwise comparisons would be $k(k - 1)/2$. Since each comparison is not independent of all others, there is a need to alter the significance level of the tests. In order to use the experiment-wise error (i.e., $\alpha = p = 0.05$), the degrees of freedom for all the tests you perform should not exceed $k - 1$. So, if you have four groups (a, b, c, d), you might declare to test a versus b, c, d (1 df); a versus d (1 df); and b, c versus d (1 df). That would burn up 3 degrees of freedom at $\alpha = 0.05$. Note that in the very common case of comparing each treatment to a control, we stay within this limit as well (assume a is the control and compare it pairwise with each of the three treatments b, c, d).

If we were to go beyond this level of comparison, however, we would need to adjust the rejection level for *all* the tests we perform to account for a loss of independence. A simple and conservative technique that does this is the Bonferroni method (Sokal and Rohlf, 1987). To make an adjustment to the experiment-wise error term, α , calculate a test significance, α' , by dividing the experiment-wise error by the number of degrees of freedom used in your selected tests (df_T):

$$\alpha' = \frac{\alpha}{df_T}$$

Applying this technique to the example above, if we choose to compare the control a to each of the three treatment groups (3 df), and perform two additional internal treatment tests of b versus c, d (1 df) and c versus d (1 df), we have a total of 5 degrees of freedom, which exceeds our “allowable” number by 2. The Bonferroni method would then require that we adjust α' as follows:

$$\alpha' = \frac{0.05}{5} = 0.01$$

Therefore, for all the tests we perform, including all three of the control-versus-treatment tests, we have decreased our rejection

Table A.3I.10 Turbidity Data (see Table A.3I.7) Scored on a Scale of 1 (least turbid) to 10 (most turbid)

Control	Treatment A	Treatment B	Treatment C
5	1	4	8
5	3	4	9
5	2	6	9
5	3	5	8
6	2	6	8
5	5	7	9
5	1	6	10

Table A.3I.11 Turbidity Data (see Table A.3I.10) Ranked from 1 to N

	Control	Treatment A	Treatment B	Treatment C
	11.5	1.5	7.5	23
	11.5	5.5	7.5	26
	11.5	3.5	18.5	26
	11.5	5.5	11.5	23
	18.5	3.5	18.5	23
	11.5	11.5	21	26
	11.5	1.5	18.5	28
Rank sums	87.5	32.5	103	175
Rank averages	12.50	4.64	14.71	25.00

level to $p = 0.01$, a level that could make a big difference in the significance of our results. This should point out the importance of good experimental design and of choosing only those tests that are important to the experimental goals.

The Nonparametric ANOVA Equivalent

If the data you end up with do not meet the assumptions of ANOVA, you can still perform multiple comparisons with a nonparametric test. For a one-way ANOVA, the nonparametric equivalent most popularly used is the Kruskal-Wallis one-way analysis of variance. The assumptions of the Kruskal-Wallis test are less stringent than those of the parametric ANOVA. The samples are drawn from a population with a continuous distribution and the sampling must be random. The samples must be independent. Their values must be rankable, that is, on at least an ordinal scale. Many computer programs provide the option of calculating the Kruskal-Wallis statistic. It is simple to do by hand, and is worth outlining here.

In the hypothetical example of the optical densities for transformed bacteria strains (see

Table A.3I.7, Table A.3I.8, and Table A.3I.9), assume that the researcher, instead of using a spectrophotometer, simply used an ordinal scale of 1 to 10 to approximate the turbidity of the sample (see Table A.3I.10). (Okay, so it's not very precise science, but, who knows, maybe the spec was broken that day and the samples needed to be measured!) In this case, there is an expectation that the scores would not be distributed in such a way as to meet the criteria for a parametric ANOVA.

To proceed through the analysis, it is then necessary to find the average value for the ranks of the data in each of the groups. To do this, we will give the data across all groups a rank score. The smallest number will have the lowest rank, and so on until we have ranked all the data. Equivalent values are termed "ties" and are given the average rank of the tied observations (see Table A.3I.11).

From these ranks, the test statistic (KW) is calculated according to the following formula:

$$KW = \left[\frac{12}{N(N-1)} \sum_{j=1}^k n_j \bar{R}_j^2 \right] - 3(N+1)$$

In the above equation, N = total population size, n_j = number of observations in a group (note that groups need not be equal in size), k = number of groups, and R_j = rank average for each group.

For small samples (usually $k \leq 3$ with $n_j \leq 5$) there are special tabled values for the KW statistic. For larger samples, the resulting value is compared to a χ^2 distribution with $(k - 1)$ degrees of freedom. If the KW value is larger than the tabled value at a chosen α , then H_0 is rejected. As in the case of the parametric ANOVA, a significant result implies that at least one of the groups is different from the rest. A means comparison test needs to be done to show which group it is. For the data in Table A.3I.11, the calculation is as follows:

$$\begin{aligned} \text{KW} &= \left[\frac{12}{(28)(29)} \right] \left[7(12.5)^2 + 7(4.64)^2 \right. \\ &\quad \left. + 7(14.71)^2 + 7(25)^2 \right] - [3(28 + 1)] \\ &= 18.45 \end{aligned}$$

The critical value for $\alpha = 0.05$, with $df = (k - 1) = 3$, is 7.82. Since our KW test statistic is larger than that, our test is significant and we reject H_0 . A problem that we might have encountered with our data, however, is that we ended up with many tied ranks. There are mathematical corrections for ties that will yield a slightly higher KW statistic than the calculation without the correction. This means that if you reject H_0 without the correction, you will also reject with the correction, so it is unnecessary if your results are significant. If, on the other hand, if your significance is marginal and you are concerned about the ties in your data, you may choose to perform a ties correction. Siegel and Castellan (1988) gives one such correction. For our example, the ties correction would yield $\text{KW} = 19.0$.

Nonparametric Means Comparison

Having demonstrated a significant difference somewhere among the groups with the Kruskal-Wallis test (see discussion of The Nonparametric ANOVA Equivalent), it is then appropriate to proceed to find out where those differences are. The technique that we will apply will allow us to perform only pairwise comparisons, but it is adjusted so that all possible pairwise comparisons can be made with the same level of rejection.

Treatment versus treatment

Multiple comparisons among all treatments, as in the case of ANOVA, require attention to the error inherent in the entire experiment relative to each pairwise test we choose to do. To account for this, we adjust our test statistic by the total possible pairwise comparisons in the experiment. Whether we plan to do only some of them or all of them is irrelevant to the adjustment; however, there is a special case, outlined below, if all we wish to do is compare a single control to several treatments.

The many possible differences between pairs of observations in a data set will become approximately normal as the sample size increases, regardless of the underlying distribution of the data. This allows us to use the normal distribution probabilities to test for significant differences between groups. In effect, we can use the normal distribution to establish a confidence interval for the difference between two groups. If they fall beyond this value, we can say that their rank average values differ significantly.

To be able to use the normal approximation, we first need to adjust the value we look up in a normal probability table (z) by the number of pairwise group comparisons possible in the experiment:

$$z_{\alpha'} = z_{\alpha/k(k-1)}$$

In this equation, k is the number of groups in the experiment. For the data in Table A.3I.11, if we chose an experiment-wise $\alpha = 0.05$, this would yield $z_{\alpha'} = z_{0.05/(4)(3)} = z_{0.004}$. The numerical value of $z_{\alpha'}$ can be looked up on a normal table or derived from a computer program. In our case, $z_{0.004} = 2.65$.

Now that we have determined the correct normal approximation for our test, we apply it to determine the critical value for rejection at $\alpha = 0.05$ (not $\alpha' = 0.004$) between any two groups in the population. If the mathematical difference between the two rank averages of the groups is greater than the critical value, then we reject at $p < 0.05$. The calculation of the critical value (CV) is dependent on sample sizes:

$$\text{CV} = z_{\alpha'} \sqrt{\frac{N(N+1)}{12} \left(\frac{1}{n_u} + \frac{1}{n_v} \right)}$$

In the above equation, N is the total population size and n_u and n_v are the sample sizes of the two groups that you are comparing (they may be different sizes).

Table A.3I.12 Pairwise Comparisons of Hypothetical Turbidity Ranked Data in Table A.3I.11

Comparison	Calculation	Significance ^a
Control vs. A	$ 12.5 - 4.64 = 7.86$	NS
Control vs. B	$ 12.5 - 14.71 = 2.21$	NS
Control vs. C	$ 12.5 - 25 = 12.5$	*
A vs. B	$ 4.64 - 14.71 = 10.07$	NS
A vs. C	$ 4.64 - 25 = 20.36$	*
B vs. C	$ 14.71 - 25 = 10.29$	NS

^aNS, not significant; asterisk refers to differences significant at $p < 0.05$.

For our example (see Table A.3I.11), since all group sizes are the same, the CV will be identical for any and all of the six possible pairwise comparisons. If sample sizes are different, you need to calculate a new CV for each comparison:

$$\begin{aligned} CV &= 2.65 \sqrt{\frac{28(29)}{12} \left(\frac{1}{7} + \frac{1}{7} \right)} \\ &= 11.65 \end{aligned}$$

To determine which differences are significant, we first calculate the absolute value of the difference between all pairs of rank averages (Table A.3I.12). If the difference exceeds the critical value, then the difference can be determined to be significant at $p < 0.05$.

From this analysis it is clear that while the entire model was quite significant the differences in the data set are due mostly to the large value of Treatment C.

Control versus treatment

The test above provides a powerful nonparametric tool for comparing multiple samples. A researcher often is interested, however, in a less broad model—one that looks only at the differences between a control and two or more treatments. Following the same procedure as above, it is possible to approximate these differences with a normal distribution. A different correction is needed, however, to account for fewer, more defined comparisons. In this case the following equation applies:

$$z_{\alpha'} = z_{\alpha} / \sqrt{2(k-1)}$$

For our example, this equation would yield $z_{\alpha'} = z_{0.005/(2)(3)} = z_{0.008} = 2.41$. Because fewer comparisons are being done, this smaller z

value will lead to a smaller critical value and provide greater probability of finding a difference between the control and a treatment. Furthermore, if we expected a priori that our treatments would yield a directional result (either smaller or greater, but not both) relative to the control, we could reduce this number even more by adjusting by $\alpha/(k-1)$ rather than $\alpha/2(k-1)$.

Since we did not have this expectation in our data, we will use the two-tailed option and calculate as follows:

$$CV = z_{\alpha'} \sqrt{\frac{N(N+1)}{12} \left(\frac{1}{n_c} + \frac{1}{n_u} \right)}$$

In the equation above, N is the total population size, n_c is the sample size of the control, and n_u is the sample size of the treatment being compared.

Again, because all of our treatments have the same number of observations, we need calculate only one value for CV.

$$\begin{aligned} CV &= 2.41 \sqrt{\frac{28(29)}{12} \left(\frac{1}{7} + \frac{1}{7} \right)} \\ &= 10.60 \end{aligned}$$

This value is then compared as above to the differences between the control and treatment rank averages. We would reject any difference greater than 10.60. Despite the tighter rejection interval (compared with 11.65 from the all comparisons model) the only treatment that differs significantly from control at $p < 0.05$ is Treatment C. Note that the previously significant comparison (A versus C) is not valid in this model.

Table A.3I.13 Hypothetical Immunoprecipitation Data for Repeated-Measures ANOVA

Mouse ID	IgG precipitate (mg/ml)

Repeated Measures—A Special Case

Sometimes we wish to collect more than one sample from an individual organism in our study. Given that we would expect there to be less variability in samples taken from one individual than in samples taken among several individuals, it would seem that we need to adjust our analysis of variance somewhat. And indeed we do. Instead of a simple one-way analysis of variance, we perform a repeated-measures analysis of variance. This technique allows us to statistically control for the variance attributable to the inherent differences in the test subjects relative to the variance in response to the treatments. Once you determine that a difference exists somewhere in the data set, you can test for means differences in the same way as described above for one-way ANOVA.

Parametric

The same assumptions hold true for the repeated measures ANOVA as for the one-way ANOVA. For our parametric ANOVA example, let us consider the following case (see Table A.3I.13). You are producing an antibody in a strain of mice and want to know when antibody

production reaches a peak. To collect data, you perform immunoprecipitation on serum collected for 5 days from eight study animals.

As you can see, certain animals have higher values overall than others, some respond with IgG production very quickly, others lag a bit and so on. If we were to do a one-way ANOVA on these data, the variability among the animals (rather than across days) might compromise the significance of our test. To avoid this problem, the repeated-measures ANOVA calculates variances for the rows and columns separately. The final output for such an analysis would resemble Table A.3I.14, originally produced by Microsoft Excel.

In this table there are significance values reported for the rows (mice) and columns (days). For our example, both factors are clearly significant. This implies that there is a difference in the precipitation of IgG over the 5 days of measurement and a difference in IgG expression in different mice.

Nonparametric

If you have repeated measures that violate the assumptions of the parametric ANOVA,

Table A.3I.15 Hypothetical Immunoprecipitation Data in Table A.3I.13 Ranked for Friedman's Analysis of Variance

Mouse ID	IgG precipitate (ranks)				
	Day 1	Day 2	Day 3	Day 4	Day 5
A	1.5	1.5	3	4	5
B	1	2	4	5	3
C	1	2	4	5	3
D	1.5	1.5	4	5	3
E	1	2	3	5	4
F	1	2	4	5	3
G	1	2	3	5	4
H	1	2	3	4	5
Rank sums	9	15	28	38	30

then there is a nonparametric equivalent for the repeated-measures ANOVA as well. As in the turbidity example above, a common case would be when a response was scored on an ordinal scale rather than measured on a continuous one.

The nonparametric equivalent in this case is the Friedman's analysis of variance. The data are handled in a fashion similar to the Kruskal-Wallis test (see discussion of The Nonparametric ANOVA Equivalent), except that ranks are assigned only within an individual rather than across the entire data set. In this way, an individual that overall got higher responses than the others would not contribute unduly to the overall variance of the population. To illustrate, let us simply use the immunoprecipitation data in Table A.3I.13. We begin by ranking the values within each individual from 1 to 5 (see Table A.3I.15).

We then sum the ranks for each column. Under the null hypothesis, the ranks should be distributed in random order for any individual, which would result in the column rank sums being approximately equal. Clearly the rank sums are not equal, but are the differences significant? We can determine this by using the Friedman test and comparing the resulting value to a χ^2 distribution with $k - 1$ degrees of freedom for our selected α level of rejection. The calculation of the statistic (Fr) is similar to the calculation of the Kruskal-Wallis statistic:

$$Fr = \left[\frac{12}{Nk(k+1)} \sum_{j=1}^k R_j^2 \right] - 3N(k+1)$$

In the above equation, N is the number of rows (subjects), k is the number of columns

(treatments), and R_j is equal to the rank sum of each column.

For our example, this would yield the following:

$$Fr = \left[\frac{12}{(8)(5)(6)} (81 + 225 + 784 + 1444 + 900) \right] - (3)(8)(6)$$

$$Fr = 27.7$$

The χ^2 critical value for $\alpha = 0.05$ with 4 degrees of freedom is 9.48. Since our Fr statistic is greater than that, we reject the null hypothesis and conclude that there are differences in IgG production over the course of 5 days (columns), irrespective of differences inherent in the test subjects (rows).

CONCLUSION

While the methods for dealing with comparisons of data outlined above are just a small sampling of those available, we hope they add to the arsenal of tools available to biologists. By performing simple descriptive analyses of your data and following the guidelines for test selection outlined in this Appendix, you should be able to avoid many of the statistical pitfalls frequently encountered in groups comparisons.

VECTORS

The following tables collect vectors described throughout the manual, organized by particular function. Individual entries in each table provide figure citations, some specific characteristics, and restriction site data for each vector, as well as sources when available. Restriction site information was generated using MAPSORT (part of the Wisconsin Package of analysis programs; copyright 1982-1992 Genetics Computer Group, Inc., e-mail *help@gcg.com*) from sequence information compiled in part from published sequence data; therefore, although all possible care has been taken, accuracy of the listings cannot be guaranteed. A listing of the contents of each table is provided below; listings in italics represent cross-references to other tables for vectors that belong to more than one category.

NOTE: Enzymes are listed alphabetically across rows of tables, not down columns.

Table A.5.1	<i>E. coli</i> General-Purpose Cloning Vectors	A.5.3

Table A.5.3 Vectors for Construction of DNA Libraries in *E. coli*

Name (figure)	Size (bp)	Selection/screening method	Cloning sites	Sources (GenBank accession number)
λ EMBL3 (Fig. 1.10.2)	42364 ^a	Recombinant phage are Spi ⁻	<i>EcoRI</i> , <i>BamHI</i> , <i>SalI</i>	Stratagene, Promega (U02425—left arm; U02453—right arm)
<i>COMMENTS:</i> Used for cloning large (10.4-20 kbp) fragments; see Fig. 1.10.2 for restriction enzyme information.				
λ gt10 (Fig. 1.10.4)	43340 ^a	Recombinant phage are cI ⁻ , Int ⁻ , Red ⁺	<i>EcoRI</i>	Stratagene, Promega (U02447—region flanking the cloning site)
<i>COMMENTS:</i> Used for cloning 0-5 kb DNA fragments and for nucleic acid probe screening; see Fig. 1.10.4 for restriction enzyme information.				
λ gt11 ^b (Fig. 1.10.5)	43700 ^a	Recombinant phage are cI ^{ts} , Int ⁺ , Red ⁺ ; fusion proteins are Lac ⁺ on Lac ⁻ hosts	<i>EcoRI</i>	Stratagene, Promega (X04122— <i>lac</i> operon and phage junction from <i>SacI</i> to <i>KpnI</i>)

COMMENTS: Used for cloning up to 7.8-kbp DNA fragments to create cDNA libraries; screen with antibodies against native protein or nucleic acid probes; see Fig. 1.10.5 for restriction enzyme information.

^aSize information provided by Stratagene.

^bParticularly suitable for construction of cDNA libraries.

continued

Table A.5.3 Vectors for Construction of DNA Libraries in *E. coli*, continued

Name (figure)	Size (bp)	Selection/screening method	Cloning sites	Sources (GenBank accession number)
λZAP and λZAPII^b (Fig. 1.10.8)	40820 ^a	Dephosphorylated arms select against nonrecombinants; recombinants containing fusion proteins are Lac ⁺ on appropriate host (detectable by blue/white screen using Xgal and IPTG)	<i>Xho</i> I, <i>Eco</i> RI, <i>Spe</i> I, <i>Sba</i> I, <i>Not</i> I, <i>Sac</i> I	Stratagene (X52324—pBluescript SK ⁻ only)

COMMENTS: Used for making cDNA libraries; libraries can be screened with antibody or nucleic acid probes; cloning sites are within pBluescript SK⁻ (2958 bp), which can be excised with helper phage and recircularized to generate subclones and single-stranded DNA. λZAP contains the *s100* mutation, which is not present in λZAPII. **IMPORTANT NOTE:** For λZAP restriction site information, see Fig. 1.10.8; restriction site data for pBluescript SK⁻ follow.

Table A.5.5 Vectors for Expression of Genes from Heterologous Promoters in *E. coli*, continued

Name (figure)	Size (bp)	Selection/screening method	Cloning sites	Sources (GenBank accession number)
pTrc99A (Fig. 1.5.11)	4176	Amp ^r	Polylinker (see Fig. 1.5.11)	Pharmacia Biotech (M22744)

COMMENTS: Uses hybrid *trp/lac* promoter, *lacZ* ribosome binding site, pUC18 multiple cloning site, and *rrnB* transcription terminators. Multiple cloning site is inserted behind an *NcoI* site in three reading frames to give pTrc99A, B, and C. Cloning into *NcoI* site gives expression of authentic protein; cloning into multiple cloning site gives fusion protein. *lacI^q* repressor gene is present for repression of *trp/lac* promoter.

Vectors**A.5.40**

Table A.5.9 Vectors for Specialized Functions

Name (figure)	Size (bp)	Selection/screening method	Cloning sites	Sources (GenBank accession number)
mGP1-2 (Fig. 16.2.3)	9955	<i>E. coli</i> containing F or F' factor necessary for susceptibility to infection	Not applicable	Stanley Tabor, Harvard Medical School

COMMENTS: M13-based vector that produces T7 RNA polymerase; useful for production of gene products that are toxic to *E. coli* cell, in conjunction with pT7-5, pT7-6, and pT7-7 (see Table A.5.5) or other plasmids using the T7 promoter to express recombinant genes.

ENZYMES THAT CUT ONCE:

ENZYMES THAT DO NOT CUT:

AatII, AgeI, ApaI, AscI, AvrII, BamHI, BclI, BsaI, BspEI, BssHII, Bst1107I, BstEII, EagI, Eam1105I, Eco57I, EcoNI, EcoO109I, EcoRV, FseI, MluI, NcoI, NheI, NotI, NsiI, NspV, PflMI, PmeI, PmlI, PshAI, Psp5II, RsrII, SacII, SapI, ScaI, SexAI, SfiI, SgfI, SgrAI, SpeI, SphI, SrfI, Sse8387I, StuI, StyI, SunI, Tth111I, XbaI, XcmI, XhoI

pAD1 (Fig. 6.12.2)	~4000	<i>E. coli</i> : Kan ^r	<i>EcoRI, SfiI, NotI, SacII, PstI, PvuII, BamHI</i>	David Kurnit, University of Michigan—Ann Arbor
------------------------------	-------	-----------------------------------	-----------------------------------------------------	------------------------------------------------

COMMENTS: Used to screen λ library by homologous recombination with sequences cloned into pAD1. See Fig. 6.12.2 for restriction site information.

pEG202 (Fig. 20.7.3)	~9800	<i>E. coli</i> : Amp ^r ; Yeast: HIS3 ⁺	<i>EcoRI, XmaI, BamHI, SalI, NcoI, NotI, XhoI, SalI, PstI</i>	Roger Brent, Massachusetts General Hospital and Harvard Medical School
--------------------------------	-------	--------------------------------------------------------------	---------------------------------------------------------------	------------------------------------------------------------------------

COMMENTS: Used to clone “bait” proteins as fusions to the DNA-binding protein *lexA*. See Fig. 20.7.4 for restriction site information.

pJG4-5	6200	<i>E. coli</i> : Amp ^r ; Yeast: TRP1 ⁺	<i>EcoRI, XhoI</i>	Roger Brent, Massachusetts General Hospital and Harvard Medical School
---------------	------	--------------------------------------------------------------	--------------------	------------------------------------------------------------------------

COMMENTS: Used to express cDNAs or other coding sequences to look for proteins that interact with “bait” protein cloned in pEG202. See Fig. 20.7.3 for restriction site information.

continued

Table A.5.9 Vectors for Specialized Functions, continued

Name (figure)	Size (bp)	Selection/screening method	Cloning sites	Sources (GenBank accession number)
pGP1-2 (Fig. 16.2.2)	7267	<i>E. coli</i> : Kan ^r	Not applicable	Stanley Tabor, Harvard Medical School

COMMENTS: Used to produce T7 RNA polymerase by heat induction for expression of genes cloned on pT7-5, pT7-6, and pT7-7 (see Table A.5.5) or other plasmids using the T7 promoter to express recombinant genes.

ENZYMES THAT CUT ONCE:

ENZYMES THAT DO NOT CUT:

AatII, AflIII, Alw44I, ApaI, AscI, AvrII, BaeI, BglII, BsaAI, BsaHI, BspLU11I, BssHII, DrdI, EagI, EcoO109I, EcoRV, FseI, MluI, MscI, NarI, NcoI, NgoAIV, NotI, PacI, PmeI, PmlI, Psp5II, PvuII, RsrII, SalI, SapI, ScaI, SexAI, SfiI, SnaBI, SpeI, SphI, SrfI, Sse8387I, StyI, SunI, SwaI, Tth111I, XbaI, XcmI

pNTK (Fig. 23.5.1)	6993	Mammalian cells: G418 ^r , negative selection with gancyclovir for HSV-TK ⁻ ; <i>E. coli</i> : Amp ^r	See Fig. 23.5.1	Richard Mortensen, University of Michigan Medical Center
------------------------------	------	--------------------------------------------------------------------------------------------------------------------------------------	-----------------	----------------------------------------------------------

COMMENTS: Used for disrupting targeted cloned genes in mammalian cells by homologous recombination; negative selection with gancyclovir selects against single crossover/integration events by the plasmid. **NOTE:** Partially sequenced, so additional sites may be present; some locations approximate.
