Depending on the amount of leaky expression of the HIS3 reporter and concentration of 3-AT used in the CM plates, nonpositive yeast cells can still grow at a slow rate and form very small colonies. True positives should be clearly distinguished by their larger colony size; otherwise the 3-AT concentration should be raised.

8. Carefully pick up His+ positive colonies and restreak them on fresh plates with the same medium as used in step 5 and grow for 3 to 10 days in a 30°C incubator.

Usually, restreaked positives give clearly visible colonies within a few days, but the growth of yeast can be much reduced if the expression of the particular cDNA clone is somewhat toxic. Some colonies on the library plates may appear like positives because the local plating density was too high. Restreaking on fresh plates will show the potential validity.

ASSESSMENT OF HIS⁺ COLONIES: IDENTIFICATION OF TRUE POSITIVES

The number of His⁺ colonies that is obtained from a saturating screening may range from a few to hundreds, depending on the particular bait construct. The next challenge is to assess whether or not these contain a library clone encoding a transcription factor of interest. The strategy of how to discriminate most efficiently between true and false positives is somewhat dependent on the actual number of positives obtained, but basic guidelines are given in the procedure below. The nature of some of the known false positives is discussed in the commentary section of this unit. One optional step to identify a subset of common false positives is to assay the activity of the *GAL1_{UAS}-GAL1_{TATA}-lacZ* (β -galactosidase) reporter that host strain Y187 contains as a chromosomal integration. False positives encoding nonspecific DNA-binding proteins probably activate both the *lacZ* reporter and the bait-*HIS3* reporter. After this, usually the most straightforward way to continue is to amplify the library cDNA inserts by direct PCR (UNIT 15.1) on the yeast colonies, sequence the products (UNIT 15.2), and search for homology by BLAST analysis (UNIT 19.3). Promising clones should subsequently be rescued from yeast and retransformed to the bait reporter strain to validate the interaction in yeast and to rule out that a contaminant was amplified. Furthermore, the specificity for the bait sequence should be determined using other *HIS3* reporter constructs. If the binding site preferences of the transcription factor of interest are known, it is recommended that control reporters with mutant binding sites be included. Finally, gel shifts (UNIT 12.2), or other in vitro assays such as methylation or uracil interference (UNIT 12.3), or DNase footprinting (UNIT 12.4) have to be performed to confirm, by an independent method, that the library protein is a DNA-binding protein that can interact specifically with the bait sequence.

Materials

- His⁺ positive yeast colonies (see Basic Protocol 2)
- Liquid complete minimal medium (CM; UNIT 13.1) minus leucine (CM –Leu)
- 0.9 M sorbitol/50 mM EDTA, pH 8.0; sterilize by autoclaving
- 750 U/mg lyticase from *Arthrobacter luteus* (750 U/mg from Sigma, L-4025)
- 1 \times TE buffer, pH 7.5 (see recipe)
- pINT1-HIS3 reporter yeast strain(s) (see Basic Protocol 1)
- Empty cDNA library vector
- CM –Leu plates (UNIT 13.1) prepared with Difco Bacto-Agar or Duchefa Micro-Agar
- CM –Leu –His, plates with optimal concentration of 3-AT (see Basic Protocol 1, step 17; see recipe for 3-AT)
- 50-ml centrifuge tubes
- 30°C incubator, with and without shaking
- Low-speed tabletop centrifuge for 50-ml tubes (preferably swing-out)
- 1.5-ml microcentrifuge (e.g., Eppendorf tubes or equivalent)
- Additional reagents and equipment for β -galactosidase filter lift assay (UNIT 13.6), miniprep DNA isolation procedures (UNIT 1.6), transformation of *E. coli* (UNIT 1.8), restriction analyses (UNIT 3.1), gel electrophoresis (UNIT 2.5A), PCR amplification (UNIT 15.1), Southern blotting (UNIT 2.9A), hybridizations (UNIT 2.10), sequence analysis (UNIT 15.2), and in vitro binding assays (UNITS 12.2, 12.3 & 12.4)

Select initial putative positives for further analysis

1. When using Y187 as host strain, perform a colony filter lift assay for β -galactosidase activity (UNIT 13.6) and discard colonies that turn blue as false positives.

Not all false positives will turn blue, only those representing nonspecific DNA-binding proteins. Take care that a sequence similar or identical to the bait sequence is not, by

accident, also present in the GAL1 promoter of the lacZ construct, in which case the β -galactosidase assay would not be useful to determine specificity.

2. Perform PCR reactions directly on the His⁺ colonies (UNIT 15.1). Use a pipet tip to pick yeast cells from a colony and resuspend these in the PCR reaction mixture.

In the case where a large number of positives is obtained, try to reduce the number of clones to be analyzed. Organize the PCR products in smaller subgroups using Southern blots (UNITS 2.5A & 2.9A) in combination with restriction analyses (UNIT 3.1) and cross-hybridizations (UNIT 2.10). Select a representative of each group for further analysis.

Do not use wooden toothpicks to inoculate yeast cells for PCR amplification, since this interferes with the reaction.

3. Sequence the PCR products (UNIT 15.2) and run BLAST searches in GenBank or other databases in order to identify the clones (UNIT 19.3). Continue only with promising cDNAs.

See Anticipated Results for identities of commonly found false positives.

Isolate plasmid from yeast for further analysis of putative positives

To continue the analysis of the putative positives, it is necessary to isolate the plasmids from yeast. Since the amount of isolated DNA is too low to conduct further experiments, the plasmids are first introduced into calcium- or electrocompetent *E. coli* cells for further amplification. The quality of the DNA isolate from yeast is of major concern. It is not uncommon that only a few *E. coli* colonies result. Apart from the relatively low amount of DNA isolate, the difficulty is that the isolates may contain a toxic contaminant that negatively interferes with *E. coli* transformations. One useful plasmid isolation procedure is described in UNIT 13.11. An efficient commercially available alternative is the yeast plasmid isolation Y-DER Kit (Pierce). In the steps below, the authors present another simple alternative, in which spheroplasts are produced first and subsequently used in a standard *E. coli* miniprep procedure.

4. Grow 10-ml overnight cultures of the His⁺ colonies in CM –Leu medium in 50-ml tubes in a 30°C incubator with shaking.

Do not grow His⁺ colonies in YAPD medium. Usually, the cDNA libraries are based on 2- μ vectors that easily segregate without selection pressure. Only transformants carrying stable ARS-CEN-based plasmids can be grown in rich medium.

5. Harvest the cells by centrifuging for 2 min at 2400 \times g in a low-speed swing-out tabletop centrifuge.
6. Resuspend the cells in 200 μ l of 0.9 M sorbitol/50 mM EDTA, pH 8.0 containing 4 mg/ml lyticase (freshly added from 750 U/mg stock) and transfer to a 1.5-ml microcentrifuge tube.
7. Incubate 1 hr at 30°C in order to produce spheroplasts.

A quick test for proper spheroplast formation is described in UNIT 13.7.

8. Carefully microcentrifuge the spheroplasts for 5 min at 3000 rpm.
9. Discard the supernatant and use the pellet to perform a standard alkaline lysis miniprep procedure as for *E. coli* (UNIT 1.6).
10. Dissolve the DNA in 20 μ l 1 \times TE buffer, pH 7.5, and transform 1 to 2 μ l DNA to *E. coli* cells using the methods described in UNIT 1.8.
11. Isolate plasmid DNA from the resulting *E. coli* colonies (UNIT 1.6) and analyze the plasmids using restriction digestions (UNIT 3.1) and gel electrophoresis (UNIT 2.5A).

Deletions in plasmids from yeast can occur; therefore it can be worthwhile to analyze at least two E. coli colonies from each transformation with a yeast DNA isolate.

Verify positive interactions and analyze specificity

12. Reintroduce the library plasmids into the pINT1-HIS3 reporter strain and verify that they activate reporter gene expression. Perform a transformation with empty library vector as a control.

To determine the specificity for the bait sequence, also transform the library plasmids to other reporter strains to check for activation of constructs lacking the upstream bait sequence, containing a mutant bait sequence, or containing an unrelated sequence.

13. For transformation, use CM, –Leu plates and restreak the colonies on CM –Leu –His medium with the same amount of 3-AT as used in the screening or on a 3-AT titration series.
14. Compare library plasmids versus the empty library vector control for their ability to confer growth on 3-AT.
15. Proceed with other methods to validate the interaction between the identified (putative) transcription factor and the bait sequence, such as in vitro DNA binding (e.g., *UNITS 12.2, 12.3 & 12.4*) and in vivo functional assays.

AUTOMATIC SUBCLONING OF λ PHAGES INTO PLASMID LIBRARIES

The most effective way to produce and handle cDNA expression libraries is via lambda (λ) phage vectors. Cloning of cDNA in λ phages is more efficient than in plasmid vectors and the subsequent transformation and amplification rounds of the phage in *E. coli* are facilitated. Several modern λ phage vectors allow the automatic subcloning of plasmids in specific *E. coli* strains. This process can be scaled up to create a plasmid library from the original phage library via in vivo mass excision in *E. coli*. The authors standardly use the λ ACTII/pACTII' vector system (Memelink, 1997) to produce cDNA libraries for one- and two-hybrid screenings. Automatic subcloning of λ ACTII libraries is via the Cre-lox system. Vector sequences flanked by lox sites are recombined by Cre protein expressed in *E. coli*, thereby releasing a plasmid circle. Since this step is critical, a procedure for the conversion to a plasmid library is given below. Other Cre-lox-based λ phages for production of one- or two-hybrid cDNA libraries are listed in Table 12.12.3. Alternatively, the HybriZAP/pAD-GAL4 vector system can be used with automatic subcloning via the ZAP system according to the manufacturer's instructions (Stratagene). However, an advantage of the λ ACTII/pACTII' system is that it confers a higher expression level of the one-hybrid protein in yeast.

Materials

- cDNA synthesis kit (e.g., ZAP-cDNA Synthesis Kit, Stratagene)
- λ ACTII-cDNA or equivalent expression library
- Cre protein-expressing *E. coli* (e.g., BNN132)
- Liquid LB medium (*UNIT 1.1*), supplemented with 0.2% maltose, 10 mM MgSO₄, and 50 mg/liter kanamycin (add from 1000-fold kanamycin stock)
- LB-Cb plates (see recipe)
- Liquid LB medium (*UNIT 1.1*) containing 200 mg/liter carbenicillin
- Commercial maxiprep kits (optional; e.g., Qiagen or Promega)
- 30°C and 37°C incubators, with and without shaker
- 1.5-ml microcentrifuge tubes (e.g., Eppendorf or equivalent)
- Sterile cell scrapers

SUPPORT PROTOCOL

DNA-Protein Interactions

12.12.13

Centrifuge with large buckets (e.g., Sorvall GSA or GS-3 or Beckman JA-10 rotor, or equivalent)

Additional reagents and equipment for handling λ phages (UNIT 1.11), miniprep (UNIT 1.6) and maxiprep (UNIT 1.7), DNA isolation procedures, gel electrophoresis (UNIT 2.5A), restriction analyses (UNIT 3.1), and quantitation of DNA via UV spectrophotometry (APPENDIX 3D)

Prepare unidirectional cDNA expression library

1. Prepare a unidirectional cDNA expression library using λ ACTII or an equivalent vector (e.g., *EcoRI-XhoI*-digested) using a cDNA synthesis kit according to the manufacturer's instructions.
2. Determine the phage titer of the cDNA library. Carefully follow the instructions described in UNIT 1.11.

It is recommended that glassware which has been sterilized for 4 hr at 140°C be used. This procedure completely removes detergent residues, to which phages are very susceptible.

Grow Cre protein-expressing cells and determine excision frequency

3. Grow a 10-ml culture of Cre protein-expressing *E. coli* BNN132 overnight at 37°C in LB medium supplemented with 0.2% maltose, 10 mM MgSO₄, and 50 mg/liter kanamycin.

*E. coli strain BNN132 (Elledge et al., 1991) originates from JM107 and was made lysogenic with λ KC from which the Cre protein and the kanamycin resistance marker are expressed. Other λ KC-containing *E. coli* strains can also be used if compatible with the phage vector for infection.*

4. Mix 10⁹ phages with 2 ml *E. coli* BNN132 culture and incubate for 30 min at 30°C without shaking.
5. Add 4 ml LB medium and further incubate for 1 hr at 30°C with shaking.
6. Determine the excision frequency by making serial dilutions (10²-, 10⁴-, 10⁶-fold) in LB medium and plating on LB-Cb plates. For this, only take a small aliquot and store the rest at 4°C. Incubate the plates overnight at 37°C.

The excision frequency usually reaches up to 50%, but lower frequencies (>10%, resulting in 10⁸ clones) are still acceptable. Usually, the original phage library will consist of in the order of 10⁶ independent recombinants. A 100-fold excess of clones in the excised plasmid pool will ensure that the complexity of the original library is maintained.

7. Analyze the plasmid content of a number (20 to 40) of random colonies using a miniprep procedure (UNIT 1.6), digestions with restriction enzymes (UNIT 3.1), and gel electrophoresis (UNIT 2.5A). Determine the percentage of clones with insertions and the cDNA size distribution.

Process phage-infected *E. coli* and plate library

8. If the excision frequency was sufficient, divide the previously stored phage-infected *E. coli* BNN132 culture (step 6) over eight 1.5-ml microcentrifuge tubes and microcentrifuge for 1 min to pellet the bacteria.
9. Decant the supernatant, resuspend each bacterial pellet in 1 ml liquid LB medium, and spread the content of each tube on a 24 × 24-cm LB-Cb plate. Grow overnight at 37°C.

A dense field of small colonies will result. The initial growth of the plasmid library on plates avoids underrepresentation of toxic cDNA clones. If the culture is directly grown in liquid medium, bacteria containing such clones could be competed out.

10. Scrape the colonies from the plates using sterile cell scrapers. Resuspend in 1 liter prewarmed LB medium (with 200 mg/liter carbenicillin) and grow for another 4 hr, shaking at 37°C.
11. Harvest the bacteria by centrifuging in a centrifuge with large buckets (e.g., 250- or 500-ml buckets) and isolate the DNA using maxiprep procedures (*UNIT 1.7*) or commercially available maxiprep kits. Determine the DNA concentration by UV spectrometry (*APPENDIX 3D*).
12. Proceed with the library transformations, following the instructions for library screening (see Basic Protocol 2).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see *APPENDIX 2*; for suppliers, see *APPENDIX 4*.

3-Amino-1,2,4-triazole (3-AT), 1 M

Prepare a 1 M stock solution of 3-AT (e.g., Sigma). Do not autoclave, but filter sterilize the solution. Store at 4°C. Add the 3-AT to the CM medium after the latter has cooled down to ~60°C. Store up to 1 year at 4°C.

LB-Cb plates

Solidify LB medium (*UNIT 1.1*) with 1.5% agar and supplement with 200 mg/liter carbenicillin (add from 1000-fold stock). Sterilize LB medium with 1.5% agar by autoclaving 20 min. Add carbenicillin after LB medium has cooled to 60°C. Pour into 24 × 24-cm square dishes (Nunc) and standard (9-cm) petri dishes. Store up to 3 months at 4°C.

Lithium acetate stock, 10×

Prepare 1 M lithium acetate, pH 7.5, adjust with acetic acid; sterilize by autoclaving 20 min. Store indefinitely at room temperature.

PEG stock, 50% (w/v)

Prepare 50% (w/v) polyethylene glycol (PEG 3,350; e.g., Sigma); sterilize by autoclaving 20 min

Store indefinitely at room temperature, in small portions in well-closed bottles, because transformation efficiencies are critically dependent on the correct PEG concentration.

TE buffer stock, 10×

100 mM Tris·Cl, pH 7.5 (*APPENDIX 2*)

10 mM EDTA

Sterilize by autoclaving 20 min

Store indefinitely at room temperature

COMMENTARY

Background Information

To gain insight into the regulation of a gene, it is necessary to identify the transcription factors binding to regulatory sequence elements. Such *cis*-acting elements mostly have been identified in the 5' promoter regions of genes, but can also be located in introns, exons, or 3' untranslated regions. Binding of factors can result in activation or silencing of gene repression, depending on the developmental stage of

the cell or on internal or external signals. Using techniques like gel-shift assays, DNA methylation interference, or DNase footprinting, binding sites for transcription factors can be mapped. Often, these are short sequences of only 5 to 10 bp. Almost all promoters contain a TATA box close to the transcription start site. The TATA box is recognized by a complex of factors, the basal transcription machinery. In turn, this complex interacts with the transcrip-

tion factors that specifically bind to the *cis*-acting elements.

Traditionally, the cloning of transcription factors relied on biochemical strategies such as affinity chromatography. Furthermore, molecular biological methods have been developed that involve the screening of cDNA expression libraries using labeled oligonucleotides. In the past decade, newly developed yeast genetic selection methods have provided particularly useful alternatives for cloning of transcription factors. One of the possibilities is to complement yeast transcription factor mutants. An illustrative example is the cDNA cloning of a human CCAAT-binding protein via complementation of the yeast *hap2* mutant (Becker et al., 1991). With the availability of the complete yeast genome sequence, it has become relatively easy to construct yeast transcription factor mutants and to assess the feasibility of a complementation strategy to clone a heterologous factor. Obviously, the possibilities are limited to cloning of functionally conserved transcription factor genes. More generally applicable is the use of a yeast genetic selection strategy that has become known as the one-hybrid system. In fact, the one-hybrid system is a simplification of the two-hybrid approach for detection of protein-protein interactions (Fields and Song, 1989; *UNIT 20.1*). The one-hybrid concept (Fig. 12.12.1), relies on the detection of the interaction between a protein expressed from a cDNA library (prey) with a DNA sequence of interest (bait) fused to a reporter gene. Activation of this reporter gene is dependent on the interaction and can be selected for. The required cDNA libraries are designed such that the expressed proteins carry a strong transcriptional activation domain from a known factor (hence the term "one-hybrid"). Therefore, an interaction with the bait sequence will usually guarantee reporter gene activation. This makes the selection method suitable to clone all types of DNA-binding proteins, independent of their normal functional properties. It is also possible to apply a "non-hybrid" selection strategy (Grueneberg et al., 1992; Chan et al., 1993), but this limits cloning possibilities to transcription factors with an intrinsic activation domain that functions properly in yeast.

One-hybrid libraries are normally constructed with shuttle vectors containing the replication sequences and marker genes necessary for maintenance in both yeast and *E. coli*. The activation domain (AD) in the expressed hybrid proteins is usually from the

yeast Gal4p transcription factor, but there are also vectors where the *Herpes simplex* VP16 AD or the acidic B42 domain (*UNIT 20.1*; Clontech) is used. To facilitate nuclear import of the hybrid proteins, the ADs used in all vectors are equipped with an SV40 nuclear localization signal. As a frequent additional feature, an epitope domain, such as HA (hemagglutinin), is included to facilitate detection on western blots or other applications. Constitutive promoters, such as the *ADHI* promoter, are often used to drive cDNA expression, but alternatives are conditional expression systems, e.g., based on the galactose-inducible *GALI* promoter. All AD vectors designed for two-hybrid screenings are exchangeable with one-hybrid systems. Some AD vectors are available as lambda vector systems (Clontech, Stratagene), with which cDNA cloning is more efficient and it is easier to achieve and maintain high complexity. Described lambda phage vectors for AD-library construction can easily be converted into *E. coli*-yeast shuttle vectors by automatic subcloning. A selection of useful vectors is shown in Table 12.12.3. The authors and others have had good experiences with use of the λ ACTII vector (Memelink, 1997) for cloning of a wide variety of transcription factors from plants (Menke et al., 1999; Meijer et al., 2000; van der Fits et al., 2000) and human cell lines (P.B.F. Ouwkerk, unpub. observ.).

The most frequently used reporter for genetic selection procedures is the *HIS3* gene, operative in the biosynthesis of histidine and encoding the enzyme imidazoleglycerol-phosphate dehydratase. Detection of its activation is through complementation of the auxotrophic *his3* mutation. Usually, *HIS3* reporters contain the minimal *HIS3* promoter, including the TATA box and transcription start site (Grueneberg et al., 1992). There are several examples of successful application of the *HIS3* reporter in one-hybrid screenings (e.g., Wilson et al., 1991; Grueneberg et al., 1992; Wang and Reed, 1993). Alternative strategies make use of the *lacZ* (Li and Herskowitz, 1993) or green fluorescence (GFP) reporter genes (Display Systems Biotech; *UNIT 9.7C*). Furthermore, the use of *MEL1* as an alternative color marker was recently described (Melcher et al., 2000). Although detection of these reporters is easy, the use of *HIS3* as a reporter has important advantages in a genetic selection procedure. Because *HIS3* is a growth selection marker, detection of positives is very simple since these appear as clear colonies in a field of nongrowing or slowly growing cells. Screening of *lacZ*, *MEL1*,

or *GFP* activity requires that all the transformed cells grow into colonies. Therefore, the plating density must be far lower than when *HIS3* is used as reporter, which complicates the setup of saturating library screens. Another advantage is that the choice of *HIS3* offers a solution to possible problems of leaky reporter expression, also termed background activity. Leaky expression can occur when bait sequences are recognized by endogenous yeast transcription factors. Since the activity of the His3p enzyme can be competitively inhibited by 3-amino-1,2,4-triazole (3-AT), leaky *HIS3* expression can often be eliminated by a 3-AT titration, so that it remains possible to detect increased *HIS3* expression resulting from the specific binding of a library protein during the screening. With *lacZ*, *MEL1*, or *GFP* reporters, the distinction between specific and background expression is difficult, and other auxotrophic markers that could be used as reporters (*LEU2*, *ADE2*) are not titratable. A good alternative for the *HIS3* reporter is a dominant antibiotic marker such as G418, hygromycin, or chloramphenicol. Here, leaky expression can be eliminated by increasing the concentration of the selective compound. An example is the cloning of the transcription factor Nrf1 using a neomycin-resistance gene in combination with G418 selection (Chan et al., 1993). With some bait sequences, the occurrence of excessively high leaky expression, which needs to be eliminated, may be observed, which is the most important constraint on the application of the one-hybrid screening system.

Initially, one-hybrid screenings involved the use of two replicating vector systems, one for the AD library and the other for the reporter (e.g., Wilson et al., 1991; Li and Herskowitz, 1993; Wang and Reed, 1993). Afterwards, a switch was made to chromosomally integrated reporters, which has the advantage that the reporter gene copy number is constant and that DNA-protein interactions are studied within the context of the nucleosome (e.g., Clontech). The pHIS3/pINT1 vectors described by the authors (Meijer et al., 1998) provide a system for the integration of reporter genes in the yeast genome. In this system, a bait sequence is first cloned upstream of the *HIS3* gene in one of the reporter vectors pHIS3NB or pHIS3NX (Table 12.12.1 and Fig. 12.12.3). In the second step, the reporter construct is cloned in the integrative vector pINT1. Finally, the pINT1-*HIS3* reporter construct is integrated via double cross-over in the nonessential *PDC6* gene (YGR087c, Chr. VII) using selection for the

dominant *APT1* antibiotic marker. Advantages of the pHIS3/pINT1 system are discussed in the introduction to this unit, and examples of its application have been published (Menke et al., 1999; Meijer et al., 2000; van der Fits et al., 2000).

A further refinement of one-hybrid screenings lies in the use of dual or triple reporter strains to facilitate discrimination between true and false positives. The Y187 strain that the authors recommend be used in conjunction with the pHIS3/pINT1 reporter system provides the opportunity to use a dual reporter system. It contains an additional *GALI_{UAS}-GALI_{TATA}-lacZ* construct, thus, a reporter gene with an upstream sequence that is unrelated to the bait sequence. Based on the unwanted activation of this second reporter, it is possible to discard a subset of false positives, probably representing nonspecific DNA-binding proteins. The *lacZ* reporter in Y187 was integrated with the *URA3* marker and can be counterselected with 0.1% (v/v) 5-fluoro-orotic acid. If desired, it can therefore be replaced to make alternative dual-reporter strains, or another construct can be added to make a triple reporter. One possibility is addition of a construct containing the bait sequence upstream of another reporter gene that also has a different minimal promoter than that of the *HIS3* reporter (see Table 12.12.4). Such a reporter should be activated by true positives, and a negative interaction would select against false positives that activated the bait-*HIS3* reporter through sequences outside the bait itself. Another elegant alternative is to add a reporter with a mutant bait sequence, but this is only applicable if it is already known which nucleotides in the bait sequence are critical for its *cis*-acting function. A good control is also to retransform isolated library clones to a strain containing a mutant bait-*HIS3* reporter integrated via the pHIS3/pINT1 system, so that it is present in an exactly identical chromosomal context as the bait reporter. Furthermore, control transformations can be performed to strains containing pHIS3/pINT1-based reporters lacking the upstream bait sequence or containing an unrelated upstream sequence. The nature of false positives is diverse (see Anticipated Results) and it should be taken into account that even with various different control reporters, not necessarily all the false positives can be eliminated. Some may follow specificity criteria in yeast exactly as expected for true positives (Schouten et al., 2000). Therefore, it remains essential that

a yeast result be followed up by an independent confirmation of the specific interaction.

Finally, several interesting variations of the one-hybrid concept have been developed. One system, which the authors call “bridge one-hybrid,” can, for example, be applied for cloning coactivators of transcription factors (Sieweke et al., 1996; Yu et al., 1997). Here, a transcription factor, specifically interacting with a target sequence upstream of the reporter gene, is used to attract library proteins that increase the reporter gene expression. This type of “interactor hunt” differs from the conventional two-hybrid approach in that there is a specific selection for proteins that interact when the transcription factor is bound to its own target sequence. Therefore, this would more likely reflect authentic interactions. Another system is a reverse one-hybrid approach that can detect library proteins capable of dissociating the interaction between a known factor and its target sequence (Vidal et al., 1996). Both the one-hybrid and reverse one-hybrid systems can also be modified to mutation screens for identifica-

tion of critical amino acid residues in functional domains of the transcription factor (Bush et al., 1996; Vidal et al., 1996). A last and particularly challenging variation is to express an AD hybrid of a known transcription factor and screen for its target sites. This requires a reporter gene library with genomic DNA fragments or random oligonucleotides upstream of the reporter gene, and a procedure to discriminate between true positive target sequences and false-positive sequences that are activated by endogenous yeast factors (Wilson et al., 1991; Liu et al., 1993; Meijer et al., 1998).

Critical Parameters and Troubleshooting

A critical step in setting up yeast one-hybrid screenings is how to deal with the leaky *HIS3* expression that can occur due to recognition of the bait sequence by endogenous yeast transcription factors. Whether or not a particular reporter construct will be activated by a yeast transcription factor is difficult to predict in advance, but it is known that several *cis*-acting

sequences of plant or animal genes can also be recognized by yeast factors. Nevertheless, it may still be possible to screen in yeast for the corresponding plant or animal factors. One-hybrid screenings have even been used to clone factors from yeast itself (Li and Herskowitz, 1993; Kunoh et al., 2000). In recent years, a wide variety of transcription factors from plants (e.g., Kim et al., 1997; Menke et al., 1999; Meijer et al., 2000; van der Fits et al., 2000) or animals (e.g., Wang and Reed, 1993; Wei et al., 1999) have been cloned with a range of promoters and binding sites. Therefore, it does not seem that the one-hybrid approach is limited to cloning of particular transcription factor classes.

With the lack of knowledge to predict in advance whether a certain promoter will be activated in yeast, the best and fastest strategy is still trial and error. The authors have used promoters over 1 kb in length that needed to be titrated with only 5 mM 3-AT. On the other hand the authors have experienced the situation whereby occasionally even a short sequence could confer so much *HIS3* expression that this could not be inhibited with 3-AT up to 50 mM or higher, making its use in a screening impossible. Obviously, with longer promoters, the risk that such a strong enhancer is present becomes increased. Therefore, it is advised that several lengths or subfragments be tested. Screening conditions will be optimal if concentrations of 3-AT up to 25 mM suffice to reduce the *HIS3* expression to an acceptable minimum. Higher concentrations of 50 up to 100 mM can still be tried, but the growth of the positives will also be slowed considerably, and it will be more difficult to distinguish these from the background. If the background is unworkably high, it may be useful to test the reporter in other yeast strains (Table 12.12.2), because the level of leaky expression can depend considerably on the genotype. Furthermore, the use of a yeast TF mutant as host strain could be considered, if clues exist about the identity of the endogenous yeast factor that might cause the background problem. If there are no leaky expression problems, it can be useful to make multimers of the bait sequence. This can increase the sensitivity of the detection of positive interactions in the library screening. The authors have designed a stepwise unidirectional multimerization procedure (Ouwerkerk and Memelink, 1997) to tetramerize sequences ranging from 9 to 250 bp, and have used these successfully in one-hybrid screenings (e.g., Meijer et al., 2000).

It is important to keep track of the number of clones that have been screened to be able to decide at what stage the library screening has been saturating. This is dependent on the complexity of the primary cDNA library. Furthermore, discrimination between true and false positives is an important factor. Isolated library clones should be retransformed to the bait-*HIS3* strain, and preferably also to different strains with negative control reporters (see Background Information). The nature of common false-positive cDNA clones is discussed under Anticipated Results.

Finally, it is important to be aware of possible bacterial contamination in a yeast screening. Occasionally, bacterial contaminants can be very misleading because they can appear in close association with the yeast cells. Therefore, seemingly normal yeast colonies can occur on selective medium, while their capacity to grow actually results from bacterial cross-feeding rather than from expression of the auxotrophic marker gene. The presence of bacteria in suspected yeast colonies can easily be spotted with phase-contrast microscopy. Elimination is possible by streaking the colonies on CM –Leu –His plates supplemented with carbenicillin (50 to 200 mg/liter) and kanamycin (100 mg/liter)—antibiotics which do not affect the growth of yeast.

Anticipated Results

It is difficult to predict how many positive clones are to be expected from a saturating library screening. This is very much dependent on the bait sequence as well as on the cDNA library source. First of all, the frequency of false positives is extremely variable. With some bait sequences, these can represent the majority of the clones obtained, whereas nearly all positives in other screenings may be specific transcription factors. Furthermore, the frequency of isolation of a certain clone is no indication for its validity. This frequency is determined by factors such as the abundance in the mRNA population from which the library was derived and the stability in *E. coli* and yeast. If no positives are obtained at all, it is useful to change the cDNA library. However, it is also possible that a library protein that could potentially interact with the bait sequence was present, but is degraded in yeast or sequestered due to interaction with a certain yeast protein. Another cause for an unsuccessful result may be that the bait sequence is masked or repressed due to binding of a yeast transcription factor. For this reason, it may be worthwhile to try

different lengths or subfragments of the bait sequence. In the case where a very large number of positives are isolated, it is useful to attempt to sort them into classes, e.g., based on restriction or cross-hybridization patterns.

Several groups of possible false positives can be discriminated. The first group includes, among others, nucleoside transporters, ribosomal proteins, RNA binding proteins, thymine glycosylases, amino-acyltransferases, and histones (P.B.F. Ouwwerkerk, unpub. observ.; van der Fits, 2000). These factors all have in common the fact that their normal function is related to interactions with nucleic acids. As AD hybrids, such proteins are likely to turn into artifactual transcriptional activators.

A second group of artifacts are components of signal transduction pathways such as phosphatases, kinases (Schouten, 1999), and GTPases (van der Fits, 2000), or of proteolysis pathways. Strikingly, their possible occurrence is very much dependent on the bait sequence used. Therefore, it is most likely that such proteins interfere with signal transduction pathways in yeast in such a way that specific activation occurs of endogenous yeast transcription factors that recognize the bait sequence. An exemplifying case is the search for plant factors regulating the *T-cyt* gene of the tumor-inducing soil bacterium *Agrobacterium tumefaciens* (Schouten et al., 2000). Screenings in yeast resulted in several library clones that were able to activate *HIS3* expression via a wild-type bait sequence but not via a mutant sequence, suggesting that the interaction was specific. However, instead of DNA-binding proteins, the discovered clones turned out to represent plant proteins homologous with the yeast Skp1 protein that is involved in ubiquitin-mediated protein degradation. The following mechanism was proposed for the interference of the Skp1 homologs with reporter gene activation. The Skp1-like proteins would interact with the yeast F-box protein, Grr1p. This contact would result in the destabilization of Grr1p, which in turn would inactivate the yeast repressor protein Mig1p. The Mig1p repressor interacted with the bait sequence and consequently its inactivation could make this sequence accessible to another yeast factor, resulting in activation of the reporter gene. Because both the Mig1p repressor and the yet unidentified yeast activator appeared to have the same binding specificity as the searched plant *T-cyt* binding factor, the identification of this plant factor via yeast screening was impossible.

The third group of false positives are His3p homologs, which can complement the mutant *his3* locus in the yeast genome. These exist in plants and fungi, but not in animals. In the authors' experience, their frequency of isolation in one-hybrid screenings is low.

The fourth and last identified category of artifacts is miscellaneous and includes proteins involved in metabolic pathways, such as L-ascorbate peroxidase, pectinesterase, and others (van der Fits, 2000). Their occurrence is enigmatic and it is not very likely that these proteins directly activate reporter gene expression. The fact is that somehow they are beneficial for the yeast cells to survive under the selection conditions. It might be that they are involved in sequestering or degrading the His3p inhibitor 3-AT, due to which titration of leaky *HIS3* reporter expression would fail and a false positive colony would grow.

The protein-coding sequences of isolated cDNAs can be either partial or full-length. Preceding leader sequences can be translated to form a spacer between the AD and the library protein. Unexpectedly, sometimes positive cDNA clones are found for which the encoded protein sequence is not in frame with the AD sequence. Such clones can still represent true positives, as demonstrated by the following example. In a one-hybrid screening in yeast strains that contained reporters with upstream recognition sites for homeodomain proteins, the authors identified cDNAs from rice encoding homeodomain-leucine zipper (HD-Zip) proteins of two different families, I and II (Meijer et al., 2000). Strikingly all the family II members were in frame with the AD, but all the family I members were not. The authors concluded that the reporters must have been activated due to the fact that truncated HD-Zip I proteins were expressed, which possessed an intrinsic activation function. Subsequently, in plant experiments, it was indeed confirmed that HD-Zip I proteins could act as activators, whereas the HD-Zip II proteins turned out to be repressors. Since none of the isolated HD-ZIP I clones were in-frame fusions, in this case AD-hybrids might have been toxic, or the combination of Gal4p AD and intrinsic AD might have been incompatible.

Time Considerations

When the required pHIS3NB/NX and pINT1 reporter constructs have been cloned, it will take ~1 week to transform yeast and to select for G418-resistant pINT1-HIS3 reporter strains. The next week, the strains should be

tested on a range of 3-AT concentrations in order to determine the selective conditions for the actual library screening. Subsequently, it is useful to invest 1 to 2 weeks to fine tune the 3-AT concentration during pilot library transformations. Unless the transformation efficiency is suboptimal, all the transformations necessary to perform a saturating library screening, including the media preparation, can be finished within 1 week. The screening plates are incubated for 1 to 2 weeks during which positives can already be restreaked. As described in the protocol, from this point onward several strategies can be followed to discriminate between true and false positives, and to confirm the specificity of putative positives. Dependent on the numbers of positives and their nature, these analyses can take several weeks to many months.

CHAPTER 13

Yeast

INTRODUCTION

Saccharomyces cerevisiae (baker's yeast) and *Schizosaccharomyces pombe* (fission yeast) are often considered to be model eukaryotic organisms, in a manner analogous to *Escherichia coli* as a model prokaryotic organism. Both yeasts have been extensively characterized and their genomes completely sequenced. They are as easy to grow as other microorganisms, and they have a haploid nuclear DNA content only 3.5 times that of *E. coli*. However, despite the small genome sizes, these yeasts display most of the features of higher eukaryotes. The fact that many cellular processes are conserved among different eukaryotic species—combined with the powerful genetic and molecular tools that are available—has made these yeasts important experimental organisms for a variety of basic problems in eukaryotic molecular biology.

Primarily for historical reasons, most studies on yeast have involved *Saccharomyces cerevisiae* (hereafter termed yeast). Culturing yeast is simple, economical, and rapid, characterized by a doubling time of ~90 min on rich medium. In addition, yeast has been well adapted to both aerobic and anaerobic large-scale culture. Cells divide mitotically by forming a bud, which pinches off to form a daughter cell. The progression through the cell cycle can be monitored by the size of the bud; this has been used to isolate a large collection of mutants (called *cdc* mutants) that are blocked at various stages of the cell cycle. Since yeast can be grown on a completely defined medium (see UNIT 13.1), many nutritional auxotrophs have been isolated. This has not only permitted the analysis of complex metabolic pathways but has also provided a large number of mutations useful for genetic analysis.

Yeast can exist stably in either haploid or diploid states. A haploid cell can be either of two mating types, called **a** and α . Diploid **a**/ α cells—formed by fusion of an α cell and an **a** cell (UNIT 13.2)—can grow mitotically indefinitely, but under conditions of carbon and nitrogen starvation will undergo meiosis. The meiotic products, called *spores*, are contained in a structure called an *ascus*. After gentle enzymatic digestion of the thick cell wall of the ascus, the haploid spore products can be individually isolated and analyzed (UNIT 13.2). This ability to recover all four products of meiosis has allowed detailed genetic studies of recombination and gene conversion that are not possible in most other eukaryotic organisms. The existence of stable haploid and diploid states also facilitates classical mutational analysis, such as complementation tests and identification of both dominant and recessive mutations.

The haploid yeast cell has a genome size of about 15 megabases and contains 16 linear chromosomes, ranging in size from 200 to 2200 kb. Thus, the largest yeast chromosome is still 100 times smaller than the average mammalian chromosome. This small chromosome size, combined with the advent of techniques for cloning yeast genes as well as manipulating yeast chromosomes, has allowed detailed studies of chromosome structure. Three types of structural elements required for yeast chromosome function have been identified and cloned: origins of replication (*ARS elements*), centromeres (*CEN elements*), and *telomeres*. The cloning of these elements has led to the construction of artificial chromosomes that can be used to study various aspects of chromosome behavior, such as how chromosomes pair and segregate from each other during mitosis and meiosis. In addition, systems using artificial chromosomes have been designed that allow cloning of

larger contiguous segments of DNA (up to 400 kb) than are obtainable in other cloning systems. These structural elements, as well as cloned selectable yeast genes, have permitted the construction of yeast/*E. coli* shuttle vectors that can be maintained in yeast as well as in *E. coli* (UNITS 13.4 & 13.6).

Procedures for high-efficiency transformation of yeast (UNIT 13.7) have been available for nearly two decades, allowing cloning of genes by genetic complementation (UNITS 13.8 & 13.9). Because yeast has a highly efficient recombination system, DNAs with alterations in cloned genes can be reintroduced into the chromosome at the corresponding homologous sites (UNIT 13.10). This has permitted the rapid identification of the phenotypic consequences of a mutation in any cloned gene, a technique generally unavailable in higher eukaryotes. In addition, homologous recombination permits a wide variety of genetic techniques that have greatly facilitated the analysis of biological processes.

Despite its small genome size, yeast is a characteristic eukaryote, containing all the major membrane-bound subcellular organelles found in higher eukaryotes, as well as a cytoskeleton. Yeast DNA is found within a nucleus and nucleosome organization of chromosomal DNA is similar to that of higher eukaryotes, although no histone H1 is present. Three different RNA polymerases transcribe yeast DNA, and yeast mRNAs (transcribed by polymerase II) show characteristic modifications of eukaryotic mRNAs [such as a 5' methyl-G cap and a 3' poly(A) tail], although only a few *S. cerevisiae* genes contain introns. Transcriptional regulation has been extensively studied and at least one yeast transcriptional activator has been shown to function in higher eukaryotes as well. High-molecular-weight yeast DNA and RNA can be prepared fairly quickly (UNITS 13.11 & 13.12). Another characteristic of eukaryotes is the proteolytic processing of precursor proteins to yield functional products, which is often coupled to secretion. Yeast has several well-studied examples of secreted proteins and pheromones, and the large number of genes that have been identified as involved in protease processing and secretion suggests a highly complex pathway. Yeast protein extracts can be prepared using three different protocols (UNIT 13.13); the best choice will depend on the particular application. The ease and power of genetic manipulation in yeast facilitate the use of this organism to detect novel interacting proteins using the two-hybrid system or interaction trap (UNIT 20.1).

Although *Saccharomyces cerevisiae* is the most commonly studied yeast, *S. pombe* is also an important experimental organism (UNIT 13.14). Although both yeasts are unicellular microorganisms that grow in similar medium, they are evolutionarily quite distant. It has become increasingly clear that, in terms of molecular mechanisms, *S. pombe* is more similar to higher eukaryotic organisms than *S. cerevisiae*. Experimental manipulations in *S. pombe* are broadly similar to those in *S. cerevisiae*, although the technical details often differ. The chapter includes units on *S. pombe* relating to strain maintenance and media (UNIT 13.15), growth and genetic manipulation (UNIT 13.16), and introduction of DNA into cells (UNIT 13.17).

This chapter is written for the molecular biologist who has not previously worked with yeast. The glossary below introduces the terms of yeast molecular biology.

aerobic growth growth in the presence of oxygen, utilizing the Krebs cycle.

α and a factor mating type-specific polypeptides secreted by either α or a haploid cells, respectively, which interact with haploid cells of the opposite mating type to stimulate mating.

anaerobic growth growth in the absence of oxygen, utilizing fermentation (via glycolysis).

ARS elements DNA sequences present throughout the yeast genome that confer autonomous replication on plasmids in yeast; most of these sequences also function as chromosomal origins of replication as well.

ascus thick-walled sac containing the four haploid products, called spores, resulting from meiosis.

cdc mutants strains of yeast that exhibit stage-specific blocks of the cell cycle; these mutations define genes important in DNA replication, meiosis, and sporulation.

CEN element DNA sequences present at the centromere that ensure proper segregation of chromosomes during mitosis and meiosis, presumably by promoting interaction with the mitotic spindle.

cir⁺ strains of yeast that contain the naturally occurring 2 μ m plasmid.

cir^o yeast strains that have lost this endogenous 2 μ m plasmid.

δ element ~330-bp sequence, present as direct repeats at the ends of the transposable element Ty1, and also found dispersed throughout the genome.

gene disruption a mutation constructed in vitro in a cloned gene which, upon reintroduction into the genome at the homologous chromosomal site, results in inactivation of the gene function.

glusulase a digestive enzyme isolated from snails that breaks down thick cell walls of either an ascus to allow isolation of spore products, or a yeast cell to produce spheroplasts.

heterothallic common laboratory strains of yeast which—due to a mutation in the *HO* gene—stably maintain a given allele at the *MAT* locus.

homothallic strains of yeast (typically found in the wild) that, in a haploid state, rapidly interconvert the *MAT* locus, resulting in rapid switching between the α and **a** mating types; cultures of such strains rapidly diploidize.

killer strains strains of yeast that harbor a double-stranded RNA virus; such strains kill sensitive yeast strains via secretion of a protein toxin, to which killer strains are immune.

MAT the mating-type locus which is expressed and therefore determines the mating type of a haploid cell; this locus has two alleles—the *MAT_a* allele confers the **a** mating type, while *MAT α* specifies the α mating type.

meiosis the process by which the number of chromosomes present in a diploid cell is halved to yield haploid products.

mitosis vegetative cell division (of either haploid or diploid cells) in which the chromosome

number stays the same.

petites mutants of yeast (either nuclear or mitochondrial) with impaired mitochondria function; they grow as small colonies on fermentable carbon sources and are unable to grow on nonfermentable carbon sources.

schmoo a distinctive shape of a haploid cell (pear-shaped), induced by exposure to mating pheromone.

sporulation the end product of meiosis, induced by carbon and nitrogen starvation of a diploid cell, which results in four haploid progeny contained as spores within an ascus; this complicated developmental process requires over 200 genes.

telomeres DNA sequences found at the end of linear chromosomes that are essential for chromosome stability and complete replication; in *S. cerevisiae*, telomeres consist of tandem repeats of the sequence 5'dG₁₋₃dT3'.

Ty1 elements the primary transposable element found in yeast, which functions as a retrotransposon (via reverse transcription of its RNA and subsequent reinsertion into the genome).

UAS element upstream activating sequences in yeast promoters, to which regulatory proteins bind in order to enhance the rate of transcription.

zygote a morphologically distinct cellular structure formed by the fusion of two haploid cells of opposite mating type, which results in formation of a diploid.

Zymolyase β -glucanase, isolated from *Arthro-bacter luteus*, that hydrolyzes the yeast cell wall and is used to prepare spheroplasts for a variety of purposes.

BASIC TECHNIQUES OF YEAST GENETICS

SECTION I

Like *Escherichia coli*, yeast can be grown in either liquid media or on the surface of (or embedded in) solid agar plates. Yeast cells grow well on a minimal medium containing dextrose (glucose) as a carbon source and salts which supply nitrogen, phosphorus, and trace metals. Yeast cells grow much more rapidly, however, in the presence of protein and yeast cell extract hydrolysates, which provide amino acids, nucleotide precursors, vitamins, and other metabolites which the cells would normally synthesize *de novo*. During exponential or log-phase growth, yeast cells divide every 90 min when grown in such media. Log phase can be divided into three stages based on the rate of cell division (or the proportion of budded cells within a culture), which is in turn a function of the cell density of the culture. As cell density increases, nutrient supplies drop and the rate of cell division slows (the measurement of cell density, as well as techniques for the propagation and genetic manipulation of yeast, are described in *UNIT 13.2*). Early-log phase is the period when cell densities are $<10^7$ cells/ml. Mid-log phase cultures have densities between 1 and 5×10^7 cells/ml. Late-log phase occurs when cell densities are between 5×10^7 and 2×10^8 cells/ml. At a density of 2×10^8 cells/ml yeast cultures are said to be saturated and the cells enter stationary, or G_0 phase.

Recipes for media that are commonly encountered when working with yeast are provided in *UNIT 13.1*. The rich medium, YPD (yeast extract, peptone, dextrose; also called YEPD media), is most commonly used for growing *S. cerevisiae*. Additional recipes are provided for minimal and complete minimal dropout media, which are routinely used for testing mating type, selecting diploids, determining auxotrophic requirements (*UNIT 13.2*), and selecting for transformants (*UNIT 13.7*). Finally, recipes for media required in the more advanced techniques described in *UNITS 13.6* and *13.10* are presented.

Preparation of Yeast Media

UNIT 13.1

Preparation of sterile media of consistently high quality is essential for the genetic manipulation of yeast. Recipes for media needed in the protocols in this chapter are provided below. It is recommended that ingredients always be purchased from the same manufacturer. The following sources are recommended for specific ingredients (complete addresses and phone numbers are provided in *APPENDIX 4*):

J.T. Baker

dextrose
ammonium sulfate
potassium acetate
glycerol

Difco

agar (Bacto-agar)
peptone (Bacto-peptone)
yeast extract (Bacto-yeast extract)
yeast nitrogen base (YNB, *without*
amino acids or ammonium
sulfate)

Sigma

amino acids
nucleotide bases
canavanine
cycloheximide
L- α -amino adipic acid
galactose (with 0.01%
contaminating glucose)
potato starch

PCR, Inc

5-fluoroorotic acid

Autoclaving is usually carried out for 15 min at 15 lb/in², but times should be increased when large amounts of media are being prepared (20 min for 4 to 6 liters and 25 min for 6 to 12 liters).

*Saccharomyces
cerevisiae*

13.1.1

LIQUID MEDIA

Ingredients for liquid media are dissolved in water to 1 liter, mixed until completely dissolved, and autoclaved in 100- or 500-ml media bottles. Alternatively, liquid media can be filter sterilized, resulting in faster preparation, less caramelization (of dextrose), and faster growth of cells. Recipes for “premixes” are provided to minimize the number of materials that must be weighed each time media is prepared. When preparing premixes, break up any large chunks of dextrose before mixing with other components, then shake the container vigorously until contents are homogenized. It is convenient to make the premix in the empty plastic containers in which 2.5 kg of dextrose is packaged. Throughout this chapter, YNB –AA/AS refers to yeast nitrogen base without amino acids or ammonium sulfate. (See listing of recommended suppliers of ingredients in unit introduction above.)

Rich Medium

YPD medium

<i>Per liter:</i>	<i>Premix:</i>	<i>Final concentration:</i>
10 g yeast extract	250 g yeast extract	1% yeast extract
20 g peptone	500 g peptone	2% peptone
20 g dextrose	500 g dextrose	2% dextrose
	Use 50 g/liter	

This rich, complex medium—also known as YEPD medium—is widely used for the growth of yeast when special conditions are not required.

It is preferable to use a 20% (10×) solution of dextrose that has been filter sterilized or autoclaved separately (and added to the other ingredients after autoclaving) to prevent darkening of the media and to promote optimal growth.

Minimal Media

Minimal medium

<i>Per liter:</i>	<i>Premix:</i>	<i>Final concentration:</i>
1.7 g YNB –AA/AS	68 g YNB –AA/AS	0.17% YNB –AA/AS
5 g (NH ₄) ₂ SO ₄	200 g (NH ₄) ₂ SO ₄	0.5% (NH ₄) ₂ SO ₄
20 g dextrose	800 g dextrose	2% dextrose
	Use 27 g/liter	

This minimal medium—also known as synthetic dextrose (SD) medium—can support the growth of yeast which have no nutritional requirements. However, it is used most often as a basal medium to which other supplements are added (see CM dropout medium below).

Complete minimal (CM) dropout medium, per liter:

- 1.3 g dropout powder (Table 13.1.1)
 - 1.7 g YNB –AA/AS
 - 5 g (NH₄)₂SO₄
 - 20 g dextrose
- (Alternatively, replace last three ingredients with 27 g minimal medium premix)

CM dropout powder, also known as minus or omission powder, lacks a single nutrient but contains the other nutrients listed in Table 13.1.1. Complete minimal (CM) dropout medium is used to test for genes involved in biosynthetic pathways and to select for gene function in transformation experiments. To test for a gene involved in histidine biosynthesis one would determine if the yeast strain in question can grow on CM minus histidine (–His) or “histidine dropout” plates. It is convenient to make several dropout powders, each lacking a single nutrient, to avoid weighing each component separately for all the different dropout plates required in the laboratory.

Table 13.1.1 Nutrient Concentrations for Dropout Powders^a

Nutrient ^b	Amount in dropout powder(g) ^c	Final conc. in prepared media (µg/ml)	Liquid stock conc. (mg/100 ml) ^d
Adenine (hemisulfate salt)	2.5	40	500
L-arginine (HCl)	1.2	20	240
L-aspartic acid ^e	6.0	100	1200
L-glutamic acid (monosodium salt)	6.0	100	1200
L-histidine	1.2	20	240
L-leucine ^f	3.6	60	720
L-lysine (mono-HCl)	1.8	30	360
L-methionine	1.2	20	240
L-phenylalanine	3.0	50	600
L-serine	22.5	375	4500
L-threonine ^e	12.0	200	2400
L-tryptophan	2.4	40	480
L-tyrosine	1.8	30	180 ^f
L-valine	9.0	150	1800
Uracil	1.2	20	240

^aCM dropout powder lacks a single nutrient but contains the other nutrients listed in this table. Nomenclature in this manual refers to, e.g., a preparation that omits histidine as histidine dropout powder. Conditions from Sherman et al., 1979.

^bAmino acids not listed here can be added to a final concentration of 40 µg/ml (40 mg/liter).

^cGrind powders into a homogeneous mixture with a clean, dry mortar and pestle. Store in a clean, dry bottle or a covered flask.

^dUse 8.3 ml/liter of each stock for special nutritional requirements. Store adenine, aspartic acid, glutamic acid, leucine, phenylalanine, tyrosine, and uracil solutions at room temperature. All others should be stored at 4°C.

^eWhile these amino acids can be used reliably when included in autoclaved media, they supplement growth better when added after autoclaving.

^fUse 16.6 ml/liter for L-tyrosine nutritional requirement.

It may be preferable to use a 10× solution of dropout powder (i.e., 13 g of dropout powder in 100 ml water) that has been “sterilized” separately (and added to the other ingredients after autoclaving) to improve the growth rate in this medium.

Sporulation medium, per liter

10 g potassium acetate (1% final)

1 g yeast extract (0.1% final)

0.5 g dextrose (0.05% final)

This nitrogen-deficient “starvation” medium contains acetate as a carbon source to promote high levels of respiration, which induces diploid yeast strains to sporulate. Sporulation can be carried out in liquid media or on plates (see below and UNIT 13.2). If nutrients are required, add them at the concentrations listed in Table 13.1.1.

Alternative Carbon Sources

Wild-type yeast can use a variety of carbon sources other than glucose to support growth. These include galactose, maltose, fructose, and raffinose. In particular, galactose is often used to induce transcription of sequences fused to the *GAL10* promoter (UNIT 13.6). All are used at a concentration of 2% w/v (20 g/liter) and should be made by replacing dextrose in the recipe for minimal or complete minimal (CM) dropout media. For a nonfermentable carbon source—which will not support the growth of *petites* (cells lacking functional mitochondria; see glossary)—2% potassium acetate (w/v), 3% glycerol, 3% ethanol, or 2% glycerol and 2% ethanol (v/v each) can be used. YPA medium (2% potassium acetate,

Saccharomyces cerevisiae

13.1.3

2% peptone, and 1% yeast extract) is excellent for inducing high levels of respiration in cells prior to sporulation (UNIT 13.2).

SOLID MEDIA

Making solid media for yeast is—for the most part—no different from preparing plates for bacteriological work (see UNIT 1.1). For all plates, agar is added at a concentration of 2% (20 g/liter). A pellet of sodium hydroxide (~0.1 g) should be added per liter to raise the pH enough to prevent agar breakdown during autoclaving. In addition, add a stir bar to facilitate mixing after autoclaving.

After autoclaving, flasks are left for 45 to 60 min at room temperature until cooled to 50° to 60°C. (Drugs and other nutrients are added after 30 min at room temperature.) Just prior to pouring, put the flask on a stir plate at medium to high speed and mix until contents are homogeneous (~5 min). After pouring, a few bubbles can be removed from the agar surface by passing the flame of a Bunsen burner lightly over the surface of the molten agar (“flaming” the plates). One liter of media will yield 30 to 35 plates.

While a specific brand of petri plate is not required, we recommend Fisher plates (100 × 15 mm, #8-757-12), which have ridges around the tops of the covers to allow easy stacking, making plate pouring less cumbersome.

When preparing the plate recipes below, follow the general guidelines for mixing and autoclaving in the introduction to liquid media (p. 13.1.2). Most plates can be stored at room temperature for ≤4 months. Plates containing drugs (cycloheximide, 5-fluoroorotic, canavanine, and L- α -amino adipic acid) or Xgal are stable for 2 to 3 months when stored at 4°C.

Minimal Plates and Rich Plates

YPD, minimal, and CM dropout plates

Per liter: Follow recipes for liquid media above, adding 20 g agar and a pellet of NaOH.

Premixes: Follow recipes for liquid media premixes above, adding 500 g agar for YPD premix and 800 g agar for minimal premix. To prepare plates, add one NaOH pellet and the following amounts of premix (per liter):

YPD plates—70 g YPD plate premix

Minimal plates—47 g minimal plate premix

CM dropout plates—47 g minimal plate premix + 1.3 g dropout powder

Specialty Plates

The recipes for α -amino adipate, canavanine, and cycloheximide plates are included even though no specific use for them is described in this chapter. They are commonly used in negative selection experiments in the same way that 5-FOA plates are used (see below). One can select against the wild-type *LYS2*, *CAN1*, and *CYH2* genes by growth on plates that select for cycloheximide, α -amino adipate, or canavanine resistance, respectively (for review, see Brown and Szostak, 1983).

5-fluoroorotic acid (5-FOA) plates

To a 2-liter flask (containing a stir bar), add:

1 g 5-FOA powder

500 ml H₂O

5 ml 2.4 mg/ml uracil solution

Stir with low heat ~1 hr until completely dissolved; filter sterilize

To a separate 2-liter flask, add:

1.7 g YNB –AA/AS

5 g (NH₄)₂SO₄

20 g dextrose

20 g agar

1.3 g uracil dropout premix (Table 13.1.1)

H₂O to 500 ml and autoclave

(Alternatively, replace first four ingredients with 47 g minimal plate premix)

When the molten agar cools to ~65°C, gently add the sterile 5-FOA/uracil solution to the uracil dropout medium by pouring it down the inside wall of the flask containing the latter. Swirl gently to mix and pour the plates.

URA3⁺ strains are unable to grow on media containing the pyrimidine analog 5-fluoroorotic acid (Boeke et al., 1984). This observation has led to methods that use 5-FOA to select against the functional URA3 gene (see UNIT 13.10). This type of selection—termed “negative selection” (Brown and Szostak, 1983)—can also be used to select against the wild-type LYS2, CAN1, and CYH2 genes.

5-FOA is quite expensive, and plates should be used sparingly. The material is prepared in bulk and is substantially discounted for members of the Genetics Society of America (Bethesda, Md.).

Xgal plates, per liter

1.7 g YNB –AA/AS

5 g (NH₄)₂SO₄

20 g dextrose

20 g agar

0.8 g dropout powder (omitting appropriate amino acids; see Table 13.1.1)

NaOH pellet

(Alternatively, replace first four ingredients with 47 g minimal plate premix)

Add H₂O to 900 ml and autoclave. Add 100 ml of 0.7 M potassium phosphate, pH 7.0, and 2 ml of 20 mg/ml Xgal prepared in 100% *N,N*-dimethylformamide (stored as frozen stock; see Table 1.4.2).

Dissection plates

Follow the recipe for YPD plates, keeping in mind that dissection plates used for tetrad analysis should be of uniform thickness and free of imperfections. After the plates have been poured they should be flamed. Stack the plates on a level surface in piles of six and move gently in a circular motion to “even out” the agar. Certain batches of agar produce plates that have microscopic precipitates embedded in the agar, often looking much like yeast spores. If this occurs, an agar of higher purity can be used, such as Noble agar (Difco) or agarose.

α-aminoadipate plates

1.7 g YNB –AA/AS

20 g dextrose

20 g agar

H₂O to 1 liter

Add ingredients to a 2-liter flask and autoclave. When the molten agar cools to ~65°C, add 34 ml of a solution of 6% L-α-aminoadipic acid (prepared by dissolving α-aminoadipate in 100 ml water and adjusting the pH to ~6.0 with 1 M KOH). The final concentration of α-aminoadipic acid in the plates should be 0.2%. Swirl gently to mix and pour the plates.

Lys2⁻ yeast use α-aminoadipic acid as an alternate nitrogen source. Since yeast can use certain amino acids as nitrogen sources, only those amino acids which are required by the particular strain being used should be added to these plates. These can be added from liquid

Saccharomyces cerevisiae

13.1.5

stocks prior to autoclaving. When using this media for isolating *lys2⁻* yeast, lysine must be added at 30 µg/ml.

Canavanine plates

Follow recipe for complete minimal (CM) dropout plates, omitting the nutrient arginine. When the 1-liter autoclaved solution has cooled to ~65°C, add 10 ml of 6 mg/ml filter-sterilized canavanine sulfate solution. The final concentration of canavanine should be 60 µg/ml.

The sterile canavanine sulfate solution can be stored frozen.

Cycloheximide plates

Follow the recipe for YPD plates. When the agar cools to ~65°C, add 1 ml of 10 mg/ml filter-sterilized cycloheximide solution. The final concentration of cycloheximide in the plates should be 10 µg/ml.

The sterile cycloheximide stock solution can be stored frozen.

STRAIN STORAGE AND REVIVAL

Yeast strains can be stored at -70°C in 15% glycerol (viable for >5 years), or at 4°C on slants consisting of rich medium supplemented with potato starch (viable for 1 to 2 years). Both methods are described below.

Preparation and Inoculation of Frozen Stocks

Make a solution of 30% (w/v) glycerol. Pipet 1 ml into 15 × 45-mm, 4-ml screwcap vials. Loosely cap the vials and autoclave 15 min.

To inoculate vials for storage, add 1 ml of a late-log or early-stationary phase culture, mix, and set on dry ice. Store at -70°C. Revive by scraping some of the cells off the frozen surface and streak onto plates. Do not thaw the entire vial. Cells can also be stored in the same way by adding 80 µl dimethyl sulfoxide (DMSO) to 1 ml cells (8% v/v) and storing at -70°C.

Preparation and Inoculation of Slants

1. For 250 slants, add the following ingredients to a 1-liter flask:

70 g YPD plate premix
20 mg adenine (hemisulfate salt)
20 g potato starch
H₂O to 500 ml

*Excess adenine prevents *ade⁻* mutations from being lost.*

2. Set the flask in a 4-liter beaker filled with 1 liter of water. Place the beaker on a heat-controlled, magnetic stirring apparatus and stir with the heat setting on high.

With smooth and continuous stirring, the contents should not burn and should be molten after ~1 hr.

3. With the entire setup in place, begin pipetting 2-ml aliquots into 15 × 45-mm, 4-ml screwcap vials. When all vials have been filled, put the caps on loosely, pack in the original boxes, and autoclave 15 min.
4. Lean the boxes against a support at an angle of ~70°. Allow the slants to dry 2 days and screw the caps on tightly.

Slants can be stored at room temperature for at least 6 months.

**BASIC
PROTOCOL**

**ALTERNATE
PROTOCOL**

**Preparation of
Yeast Media**

13.1.6

5. To inoculate a slant, smear cells from the flat end of a sterile toothpick onto the agar surface of the slant. Cap loosely and incubate 1 or 2 days at 30°C. After growth, screw the cap on as tightly as possible and store at 4°C.

Slants are a convenient way to store and mail strains. They can be mailed immediately after inoculating since sufficient growth will occur in transit. See another method for mailing strains below.

Mailing and Reviving Strains

Yeast strains can be conveniently mailed as slants. Alternatively, transfer cells to a piece of sterile Whatman 3MM paper by pressing the paper onto the desired yeast colony using forceps that have been dipped in ethanol and flamed. Wrap the paper in sterile aluminum foil and mail to recipient.

Revive the strain by placing the paper (yeast side down) on the surface of an agar plate. Incubate the plate at 30°C. A thick patch of yeast should be visible after lifting the paper.

13.1.7

Growth and Manipulation of Yeast

Aside from different media requirements, yeast cells are physically manipulated essentially as described for bacterial cells—i.e., they are grown in liquid culture (in tubes or flasks) or on the surface of agar plates and are manipulated using the basic equipment described in *UNITS 1.1-1.3*. In addition, a well-equipped yeast laboratory requires static and shaking incubators dedicated to 30°C and a microscope with magnification up to 400×. A second microscope adapted for dissecting yeast tetrads is extremely valuable for the genetic analyses and strain constructions described in this unit. A small electric clothes dryer is indispensable when replica plating is done frequently and large numbers of velvets are regularly used.

This unit first presents the necessary details for growing yeast cells. This is followed by a description of replica plating methods for assessing the nutritional requirements and mating types of strains. Yeast genetic experiments often require the construction of strains with specific genotypes, as well as an analysis of the meiotic segregation patterns of newly introduced mutations (see *UNIT 13.8*). These genetic manipulations are carried out using the protocols presented in the final sections of this unit, which describe the construction and selection of diploids, sporulation, and tetrad analysis.

BASIC PROTOCOL

GROWTH IN LIQUID MEDIA

Wild-type *S. cerevisiae* grows well at 30°C with good aeration and with glucose as a carbon source. When using culture tubes, vortex the contents briefly after inoculation to disperse the cells. Erlenmeyer flasks work well for growing larger liquid cultures, and baffled-bottom flasks to increase aeration are especially good. It is important that all glassware be detergent-free.

For good aeration, the medium should constitute no more than one-fifth of the total flask volume, and growth should be carried out in a shaking incubator at 300 rpm. For small-scale preparations of DNA and RNA, yeast can be grown in glass or plastic culture tubes filled one-third full with medium and shaken at 350 rpm in a rack firmly attached to a shaking incubator platform.

BASIC PROTOCOL

GROWTH ON SOLID MEDIA

Yeast cells can be streaked or spread on plates as shown for bacteria in the sketches in *UNIT 1.3*. When a dilute suspension of wild-type haploid yeast cells is spread over the surface of a YPD plate and incubated at 30°C, single colonies may be seen after ~24 hr but require ≥48 hr before they can be picked or replica plated (see below). Growth on dropout media (*UNIT 13.1*) is about 50% slower.

BASIC PROTOCOL

DETERMINATION OF CELL DENSITY

The density of cells in a culture can be determined spectrophotometrically by measuring its optical density (OD) at 600 nm. For reliable measurements, cultures should be diluted such that the OD₆₀₀ is <1. In this range, each 0.1 OD₆₀₀ unit corresponds to ~3 × 10⁶ cells/ml. Thus, an OD₆₀₀ of 1 is equal to ~3 × 10⁷ cells/ml. It is advisable to calibrate the spectrophotometer by graphing the OD₆₀₀ as a function of the cell density that has been determined by some other means, such as direct counting in a hemacytometer chamber (*UNIT 1.2*) or titering for viable colonies (*UNIT 1.3*).

DETERMINATION OF PHENOTYPE BY REPLICA PLATING

Cells from yeast colonies grown on any medium can be tested for their nutritional requirements by replica plating (UNIT 1.3). An inexpensive replica plating block can be constructed by gluing a circular plexiglass disk (8-cm diameter, 1 cm thick) onto the end of a hollow plexiglass tube (8 cm long with an 8-cm outer diameter). Sterile velveteen squares (velvets) are held in place by a large adjustable tube clamp (available in any automotive supply outlet) set to fit snugly around the outside of the tube.

A master plate containing the strain or strains of interest is first printed onto a velvet. A copy of this impression is transferred to plates made with all the relevant selective media, which may include various dropout and drug media, as well as alternative carbon sources (UNIT 13.1). For analysis of temperature-sensitive mutations (UNIT 13.8), a copy of the master plate is made on a plate that will provide all the nutritional requirements of the strain. This plate is then incubated at 37°C.

DETERMINATION OF MATING TYPE

Genetic analysis of yeast often requires a knowledge of the mating type. This protocol is based on the ability of a strain with a single auxotrophic requirement (the tester strain) to complement any and all nutritional requirements of strains of the opposite mating type, *as long as the genetic deficiency in the tester strain is not present in any of the uncharacterized strains*. The genetic deficiency found in the tester strain prevents it from growing on minimal plates. This deficiency is complemented by the wild-type gene in the uncharacterized strains, which themselves usually cannot grow on minimal plates due to one or more auxotrophic mutations (see commentary following this protocol for determining the mating type of strains *without* auxotrophic requirements). When strains of opposite mating type mate, the resulting diploid can grow on minimal plates. The following protocol is useful for determining the mating types of the numerous spore colonies produced during strain construction.

Materials

YPD medium and plates (UNIT 13.1)

S. cerevisiae: *MAT α thr4⁻* (tester), *MAT α thr4⁻* (tester), and uncharacterized strains

Minimal plates (UNIT 13.1)

Replica plating block (UNIT 1.3)

Sterile velvets (UNIT 1.3)

1. Grow 1-ml overnight cultures of each tester strain.
2. Spread 200 μ l of each tester strain on a YPD plate. To get a completely even distribution of cells, replica plate this freshly spread YPD plate onto a sterile velvet, lift and rotate 90°, and print again. Lift, rotate, and print once more. Discard velvet and incubate plate at 30°C.
3. On the next day replica plate the strain to be tested onto two fresh YPD plates. Discard velvet. Onto one of these two YPD plates, replica plate one of the two tester strains prepared in step 2. Using a new velvet, repeat with the other YPD plate and the other tester strain.

If many uncharacterized strains are picked into a grid pattern on a single plate (UNIT 1.3), their mating types can be determined simultaneously.

4. Incubate plates \geq 4 hr at 30°C.
5. Replica plate each plate onto a minimal medium plate. Incubate plates overnight at 30°C.

**BASIC
PROTOCOL**

**BASIC
PROTOCOL**

***Saccharomyces
cerevisiae***

13.2.2

6. Score for mating type. Growth on the minimal plate printed with the *MAT α thr 4^-* tester strain indicates that the uncharacterized strain is *MAT α* . Growth on the minimal plate printed with the *MAT α thr 4^-* tester strain indicates that the uncharacterized strain is *MAT α* .

The thr 4^- mutation makes tester strains auxotrophic for threonine (i.e., they can't grow on threonine dropout medium). However, a mutation in any gene that leads to nutritional auxotrophy can be used for the tester strains, and strains with defects in other genes required for threonine biosynthesis can be tested using MAT α or MAT α thr 4^- testers. One or a few strains can be tested simply by patch-mating the uncharacterized cells to each tester strain (see protocol for diploid construction in this unit) for 4 hr and streaking each pair onto minimal plates.

Strains without auxotrophic requirements cannot be tested using the above basic protocol for mating-type determination. Instead, mating type can be determined by observing zygote formation microscopically. Patch-mate the strains of unknown mating type separately to MAT α and MAT α strains. After 4 hr at 30°C, examine the cells microscopically for zygote formation (zygotes will appear as relatively large 2- and 3-lobed structures in which the lobes are connected by wide, smooth "necks"). If the strain with unknown mating type is haploid, zygote formation will only be obvious in one of the two mixtures. The unknown mating type is opposite that of the strain with which it forms zygotes.

Mating type can be determined in ~24 hr if fresh tester plates are available. A stock of tester plates can be prepared as described in step 1 and stored at 4°C for 1 to 2 months. Allow mating (step 4) to proceed overnight when using tester plates that have been stored for more than a few days.

STRAIN CONSTRUCTION AND TETRAD ANALYSIS

Because meiosis and sporulation are parts of the life cycle of *S. cerevisiae*, it is relatively straightforward to create strains with different genotypes. Genes on different chromosomes assort independently, and linked genes can be separated by recombination. Diploids are constructed from parents that will each contribute some of the markers desired in the haploid products. The protocol for constructing of a new yeast strain is presented in several distinct stages: (1) diploid construction, where two haploid strains are mated; (2) sporulation, where diploid cells are induced to form spores; (3) tetrad preparation, where the ascus wall is removed from the tetrad; and (4) tetrad dissection, where each of the four haploid spores from a single tetrad is specifically positioned on a plate and grown for subsequent studies. Not all of these steps are necessary in an individual experiment. Diploids can be constructed and stored indefinitely. Spores can be stored at 4°C for 1 to 2 weeks without a significant decrease in spore viability. Finally, plates that have been streaked with glucylase-treated spores can be stored at 4°C for several days prior to dissection.

Diploid Construction

Diploids are constructed by mating strains of opposite mating types on the surface of agar plates (patch mating). Mix cells from freshly grown colonies of each haploid parent with a toothpick in a circle ~0.5 cm in diameter on an agar plate (the plate should allow growth of both haploid strains). Allow mating to proceed ≥ 4 hr at 30°C, then streak the mating mixture onto a plate that will select for the diploid genotype.

When there is no selection specific for the diploid genotype (the case when one of the haploid parents has the same nutritional requirements as the diploid), isolate diploids by physically "pulling zygotes" out of the mating mixture using a dissecting microscope. After mating for 4 hr, streak the mix in several parallel lines on an agar plate that will

support the growth of the diploid. Using the dissecting microscope, identify zygotes by their characteristic shape (described above), pick them up with the dissecting needle, move them away from the streak of cells, and set them down. To ensure that the selected cells are actually diploids, patch them onto sporulation plates (UNIT 13.1) and examine microscopically for tetrad formation after appropriate incubation (see following protocols). Alternatively, attempt to mate selected cells with a pair of mating type tester strains and examine microscopically for zygote formation with each tester. Zygotes should not form if a diploid was correctly selected.

Sporulation of Diploid Cells

Starvation of diploid yeast cells for nitrogen and carbon sources induces meiosis and spore formation, during which chromosomes replicate and proceed through two divisions to produce haploid nuclei. These nuclei (along with surrounding cytoplasm) are individually packaged into spores, and the four spore products (tetrad) of a single meiosis are held together in a thick-walled sac (ascus).

The sporulation process can be induced in cells growing either on solid or in liquid medium. Because some strains do not sporulate well on plates, and other strains do not sporulate well in liquid, both methods are presented; one of the two methods should result in reasonably good spore formation for any given diploid.

Materials

Yeast cells

Sporulation plates *or* sporulation medium, with appropriate nutrients (UNIT 13.1)

YPD medium (UNIT 13.1)

Sporulation on plates

1. Patch cells that have been grown on YPD or selective plates onto a sporulation plate.

If no selective conditions are required, grow cells several days on YPD plates prior to transfer to sporulation medium. Allow single colonies to grow for 3 to 4 days on YPD; for patches of cells, allow 2 days growth on YPD. While this pregrowth is not essential, it results in much more efficient sporulation. A small dab of cells should be smeared over a relatively large area (~1 cm²) of the sporulation plate, such that no thick patches of the inoculum are visible.

2. Incubate 4 days at 25°C.

Sporulation is generally less efficient at higher temperatures. While sporulation can occur in the absence of amino acids or other nutrients that are required by the strain for mitotic growth, sporulation is much more complete when those (and only those) nutrients that the particular strain requires are added (see Table 13.1.1).

Several rounds of mitotic growth will cause the cell number to visibly increase over the sporulation incubation period.

3. Visualize tetrads by suspending a small dab of cells in a drop of water on a microscope slide and examining at a magnification of 250× to 400×.

Tetrads will appear as clusters of four small spheres (the spores), all held within a tight-fitting sac. The four spores can be in either a diamond or tetrahedral configuration.

Not all asci will contain four spores. Some cells do not package all four spore products. The proportion of cells that undergo sporulation as well as the fraction of four-spored asci that result varies from strain to strain.

Sporulation in liquid media

For unknown reasons, some strains do not sporulate well on plates. Even for strains that do, the efficiency can often be increased by sporulation in liquid. In fact, sporulation in liquid is so efficient that higher incubation temperatures (30°C) do not appear to inhibit this process. Under these conditions, sporulation is effectively complete within 48 hr. In addition, the yield of asci with four spores is usually higher using this protocol.

1. In any suitable culture vessel, grow the diploid to be sporulated to an OD₆₀₀ of 2.5 to 3.0 ($\sim 8 \times 10^7$ cells/ml) in YPD medium.
2. Transfer 1 ml culture to a sterile, disposable 15-ml polypropylene tube and centrifuge 5 min at $1200 \times g$ (3000 rpm).
3. Pour off supernatant and resuspend cells in 5 ml sterile water. Vortex to resuspend cells and spin as in step 2.
4. Pour off supernatant and resuspend cells in 1 ml liquid sporulation medium supplemented with nutritional requirements of the particular diploid.
5. Shake for 2 to 3 days at ≥ 350 rpm, 30°C, and examine the culture microscopically for spore formation.

If a strain appears refractory to induction of sporulation, try pregrowing cells in YPA medium (UNIT 13.1). The use of acetate as a carbon source requires respiration, which is a requirement for sporulation. This requirement for respiratory competence is reflected by the fact that cells which have lost mitochondrial function (petites; see glossary in introduction to this chapter) are unable to sporulate.

BASIC PROTOCOL

Preparation and Dissection of Tetrads

The analysis of yeast tetrads requires a standard light microscope with a stage that is movable along both the *x* and *y* axes in precisely measurable intervals, but that does not move up and down (focusing is accomplished by moving the objectives). The microscope must be modified with an assembly for mounting an inverted petri dish on its stage and a micromanipulator for holding and moving a fine glass needle (see support protocol that follows for preparation of dissecting needles). Plans for the construction of micromanipulators for tetrad analysis have been published (Sherman, 1973). An assembled instrument is available from Rainin Instruments.

Two methods of preparing yeast tetrads for dissection are shown below. The first employs glusulase (steps 1a-4a) and the second relies on Zymolyase-100T (steps 1b to 4b) to break down the ascus cell wall. Glusulase is relatively inexpensive and easy to work with, although the more expensive Zymolyase-100T generally gives more uniform and reproducible digestion.

Dissection of yeast tetrads requires a steady hand and a great deal of patience. Don't be discouraged. It is not uncommon for a skilled yeast geneticist to dissect up to 60 tetrads per hour. However, dissection of 20 to 30 tetrads per hour is a commendable achievement.

Materials

Glusulase (Du Pont NEN), diluted 1:10 in H₂O *or* Zymolyase-100T solution:
0.5 mg/ml Zymolyase-100T (ICN Immunobiologicals) in 1 M sorbitol

Dissecting microscope (Rainin Instruments)
Dissecting needle (support protocol)

Prepare the tetrads

For glusulase treatment:

- 1a. If spores to be examined are from a plate, wash by suspending a toothpick-full in 300 μ l sterile water in a 1.5-ml microcentrifuge tube. Vortex vigorously. If spores to be examined are from liquid cultures, centrifuge in a tabletop centrifuge 5 min at 1200 \times g (3000 rpm). Aspirate supernatant and resuspend pellet in 5 ml water. Repeat twice and resuspend final pellet in 5 ml water. Dilute 30 μ l into 270 μ l water in a 1.5-ml microcentrifuge tube. Vortex vigorously.

Subsequent glusulase treatment (for ascus removal) will not be effective unless the asci are washed extensively.

- 2a. Examine cells under a light microscope to detect intact asci.
- 3a. Add 3 μ l diluted glusulase to spore preparation. Mix by gently vortexing.

Commercial preparations of glusulase are highly concentrated and should be diluted 10-fold in water for controlled treatment of asci.

- 4a. Incubate 2 min at room temperature, then examine the cells microscopically. Continue incubation at room temperature until glusulase treatment is complete. Proceed to step 5.

The glusulase treatment is complete when approximately half of the tetrads show disruption of their ascus walls. The four spores should remain associated, but more loosely than when initially examined. The wall of the ascus should be expanded and loosely associated with the spores. Two to six minutes incubation is sufficient for most strains.

For Zymolyase-100T treatment:

- 1b. If spores to be examined are from a plate, add a small toothpick-full of tetrads to 50 μ l Zymolyase-100T solution and gently resuspend. If spores to be examined are from liquid cultures, microcentrifuge 1 ml cells for 10 sec. Pour off supernatant and resuspend pellet in 50 μ l Zymolyase-100T solution.

- 2b. Examine cells under a light microscope to detect intact asci.
- 3b. Incubate 10 min at 30°C.
- 4b. Gently add 0.8 ml sterile water by slowly running it down side of tube. Proceed with step 5.

The Zymolyase treatment is complete when approximately half of the tetrads show disruption of their ascus walls. The four spores should remain associated, but more loosely than when initially examined. The wall of the ascus should be expanded and loosely associated with the spores.

5. Set tubes on ice and leave them there. Streak treated spores (using an inoculating loop) in two parallel lines across the surface of a YPD dissection plate (*UNIT 13.1*), as shown in Figure 13.2.1.
6. Examine plate, inverted with the lid off, on the dissecting microscope. Individual tetrads, grouped into tetrahedral- or diamond-shaped clusters of spores, should be visible.

Dissect the tetrads

The following procedure is specifically adapted for the Rainin Instruments dissecting microscope (Fig. 13.2.1).

7. Position the plate so that streaks are parallel to the *x* axis of the stage. Focus on spores and position a good tetrad in center of field.

Saccharomyces cerevisiae

13.2.6

At 100× magnification, attempt to dissect a tetrad that is not near any other tetrads, so that multiple spores from unrelated tetrads are not picked up by the needle.

Be careful not to graze the tip of the dissecting needle with the petri dish as it is being placed on or removed from the stage. Lower the needle and rotate the microscope objectives away from the stage before changing plates.

8. Move dissecting needle upward using coarse adjustment to a position such that its tip is touching the plate surface when the joystick is depressed halfway.

Moving the joystick down results in the needle moving upward. When the joystick is fully up, the needle will be visible as a large black sphere looming below the plate surface. It will appear to be much larger than the tetrad itself.

9. Using a downward motion on joystick, gently touch needle to surface of plate, immediately adjacent to the tetrad.

The tetrad should disappear under the needle. When attempting to pick up individual spores or tetrads, touch the needle to the plate very close to, but not directly on top of, the spore or tetrad.

10. Gently lift joystick straight up. The tetrad should be gone.

At this point the tetrad should be on the tip of the needle. If it is still on the plate, repeat steps 9 and 10 until the spores stick to the needle. Pick up tetrads or individual spores as gently as possible, with the needle barely touching the agar surface. If glucylase or Zymolyase treatment was effective, all four spores should move together. Tetrads will fall apart at this stage if the treatment was excessive.

11. Using stage movement controls, move the plate so that the needle is at rightmost position on the plate (using x-axis control) and at a position (position *a*) ~1 cm away from streak of treated spores (using y-axis control).

*The four spores will be set in a line perpendicular to the original streak at positions *a*, *b*, *c*, and *d*. These positions should be 0.5 cm apart and are easily found by aligning an arbitrary marking on the movable stage with a fixed y-axis scale that is even with the right side of the stage (Fig. 13.2.1).*

12. Use the joystick to gently touch the needle to the agar surface. Then use the joystick to move the needle down and forward, so that the point where the needle touched the agar is visible. The tetrad should be on the agar surface. The following variations are possible:

- a. No spores were deposited. In this case repeat step 12, using more force when touching the needle to the agar.
- b. Only a single spore is on the plate (the best result). Move the y-axis adjustment to position *b* and repeat step 12.
- c. If two or three spores are on the plate, move the y-axis adjustment to position *b* and attempt to set down the remaining one or two spores on the needle. If two spores were on the needle and only one spore is deposited, move the needle to position and set down the remaining spore. If two spores were deposited at position *b*, the needle must be used to break them apart. This is best accomplished by moving the joystick in circular motion, so that the tip of the needle hits the plate and drags over the spores. When the pair of spores is broken apart, pick one up and move it to position *c*. Don't forget that there are multiple spores at position *a* that still need to be separated.
- d. If all four spores are present, use the needle to break them apart. Once this is done, pick up one or more of the spores (leaving one at position *a*) and attempt to lay down a single spore at each of the three remaining positions.

Be careful not to move the x-axis controls during the dissection of an individual tetrad. If the four spores cannot be separated after repeatedly dragging with the needle, the glusulase treatment was probably not sufficient. Let the treated culture (which should have been on ice) set at room temperature for a few minutes and then streak onto a new YPD dissection plate.

13. Use x- and y-axis controls to move the plate back to a position where the needle is directly below the streak of glusulase-treated spores. Repeat steps 7 through 12, with spores of each successive tetrad set down in a line 0.5 cm to right of and parallel to that of the preceding tetrad. Placement of these lines is determined by aligning an arbitrary marking on the movable stage (upper right-hand corner of the plate in Fig. 13.2.1) with a fixed x-axis scale that is even with back edge of stage. Alternatively, a strip of paper marked in 0.5-cm intervals can be taped along front edge of stage. In this case the lower right-hand corner of the plate holder is used as the arbitrary alignment point.
14. Continue steps 7 through 13 until all positions along the x axis are occupied by dissected tetrads. The plate is then rotated 180° for dissection of additional tetrads using the streak on the opposite side of plate as a source. Thirteen tetrads can be dissected on each side of the plate.

Figure 13.2.1 Essential features of the dissection microscope. Not all parts are shown, including the light source and condenser (below) and the objective and eyepiece (above). The micromanipulator is attached to the base of the microscope. The mark with the large dot on the y-axis guide is aligned with demarcations on the right side of the stage to identify positions a, b, c, and d (corresponding to positions 10, 15, 20, and 25 respectively, in this figure). The upper right-hand corner of the plate holder is aligned with demarcation along the rear of the stage to identify positions 1, 2...13 (corresponding to positions 60, 65...120, respectively in this figure).

Saccharomyces cerevisiae

13.2.8

Preparation of Dissecting Needles

One of the most difficult steps involved in tetrad analysis is the preparation of the dissecting needle. Like tetrad dissection, making needles requires patience and practice. The general strategy is to first produce a long fine thread of glass, which is broken into multiple short segments. Individual segments are then glued to the ends of capillary tubes. The finished product is L-shaped, with a short arm of ~1.3 cm, culminating in a needle “tip” that is 40 to 150 μm in diameter (see sketch 13.2A).

1. A thin glass thread is created by heating a piece of glass tubing until it is flexible and, in one motion, removing it from the heat source and pulling the ends apart very quickly. The goal here is to draw out the molten glass into a very fine thread before it (nearly instantly) hardens. Timing is everything here so a few attempts may be necessary before a thread that is suitably thin can be generated. Either capillary tubes or pyrex glass pipets can be used as sources of glass tubing. Suitable threads should be between 40 and 150 μm in diameter, depending upon application and personal taste. Human hairs, which range from ~40 to 100 μm in diameter can be used as a reference.
2. Once a thread of appropriate diameter is obtained, it is broken into segments ~1.3 cm long. To do this, simply begin at one end, pulling the segments straight away from the rest of the thread using your fingers. Wear latex gloves for a better grip. Alternatively, 1.3-cm segments can be cut using a fresh razor blade.
3. Examine these segments microscopically. Look for chips and protrusions in the glass as shown in the sketch. The best needles (those that easily pick up and release cells and do not cut the surface of the agar) have an absolutely flat surface that is perpendicular to the shaft (see sketch 13.2A). Save any with an acceptable end, noting which end is which, and discard those with chipped or uneven ends.
4. A dissecting needle is created by attaching a segment with an acceptable tip to the end of a capillary tube. The finished needle is L-shaped with a short arm ~1.3 cm long culminating in the flat working surface. Introduce a right-angle bend in the capillary tube 0.5 to 1.0 cm from the end by briefly heating the tube in a Bunsen burner flame and bending the tip using forceps. Glass threads can be glued in place inside, or against the outside edge, of the short arm of the L-shaped capillary tube, using any fast-acting glue (see sketch 13.2A).

Sketch 13.2A

5. Examine the finished product after mounting the needle on a dissection microscope. Place a plate on the microscope and press the needle firmly against the surface of the agar to make sure the needle leaves an even, circular impression.

Even with all these precautions, needles will perform differently when it is time to dissect, so several candidates should be made at the same time and tested to determine which function best.

Random Spore Analysis

As an alternative to separating spores by tetrad dissection, meiotic products can be released from their asci, dispersed by sonication, and plated directly onto agar plates. The spore colonies can then be screened for the desired genotypes by replica plating.

Materials

Zymolyase-20T solution: 1 mg/ml Zymolyase-20T (ICN Immunobiologicals)
in H₂O and filter sterilized

2-mercaptoethanol (2-ME)

1.5% (v/v) Nonidet P-40 (NP-40)

Ethanol

Sonicator and probe

Additional reagents and equipment for cell counting (*UNIT 1.2*) and
replica plating (*UNIT 1.3*)

1. Prepare cells for tetrad dissection as described earlier in this unit. If sporulation was done on plates, resuspend several toothpicks-full in 5 ml water in a 50-ml flask. If sporulation was done in liquid, resuspend all the cells from a 1-ml sporulation culture in 5 ml water.
2. Add 0.5 ml Zymolyase-20T solution and 10 μ l of 2-ME.
3. Incubate overnight at 30°C with gentle shaking.

Treatment of the sporulated culture with Zymolyase-20T in a hypotonic solution results in lysis of unsporulated diploid cells. The preparation should be examined microscopically after the Zymolyase treatment to evaluate its effectiveness. A higher concentration of the enzyme or the more concentrated preparation of Zymolyase (Zymolyase-100T) can be used.

4. Add 5 ml of 1.5% Nonidet P-40 (NP-40). Transfer the suspension to a 15-ml disposable tube and set 15 min on ice.
5. Hold the tube in one hand and insert the sonicator probe as far into the liquid as possible, but without touching the bottom or the sides of the tube. Before sonicating, clean the sonicator probe with water followed by a wipe-down with ethanol.
6. Sonicate 30 sec at 50% to 75% full power, then set on ice 2 min. Repeat twice.

Sonication produces heat that will warm up the spore suspension significantly. The tube should be cooled between the sonication steps.

7. Centrifuge spores 10 min at 1200 \times g (3000 rpm). Aspirate or pour off supernatant and resuspend in 5 ml of 1.5% NP-40. Vortex vigorously. Repeat twice.
8. Sonicate as in step 6 (with repeats).

The spores should be examined after the last sonication step to ensure that no spores remain stuck together. More sonication steps at higher power settings will release the more tenacious spores. If spores remain stuck to each other, add 2 ml glass beads (Type I, Sigma) and shake 30 min at 300 rpm in an Erlenmeyer flask at 30°C. Let the beads settle and remove the supernatant containing the spores.

**ALTERNATE
PROTOCOL**

***Saccharomyces
cerevisiae***

13.2.10

9. Centrifuge spores 10 min at $1200 \times g$ (3000 rpm). Aspirate or pour off supernatant and resuspend in 5 ml water. Vortex vigorously. Repeat.
10. Count a 10-fold dilution of the treated spores using a hemacytometer.
11. Dilute the spores with water to get 10^3 spores/ml. Plate 100 μ l on several YPD plates and incubate 3 days at 30°C.
12. Screen spore colonies for markers of interest by replica plating (see fourth basic protocol and *UNIT 1.3*).

COMMENTARY

Background Information

Diploids are constructed from parents that each contribute some desired markers in the haploid products. In meiosis, homologous chromosomes assort independently, resulting in haploid cells with new combinations of wild-type and mutant genes. By definition, independent assortment holds for genes located on different chromosomes (different linkage groups). However, the high frequency of crossing-over that occurs during meiosis allows even closely linked genes to be separable. If a large number of spores are scored (generated through either tetrad analysis or a random spore protocol), a strain with almost any combination of markers can be isolated. Large numbers of spores can be analyzed by random spore analysis (alternate protocol).

The frequency with which linked markers are separated by recombination is the basis for genetic mapping in all organisms and is mainly a function of the physical distance separating them. This frequency is equal to twice the genetic distance in centimorgans (cM). Thus, two genes separated by a genetic distance of 5 cM will be recombined in 10% of all tetrads. In yeast, a genetic distance of 1 cM corresponds to a physical distance of ~ 2.5 kb.

Critical Parameters

Diploids are usually selected by streaking mating mixtures on minimal plates that are supplemented (by spreading liquid stocks of the nutrients on the surface of agar plates at the concentrations listed in Table 13.1.1; see also *UNIT 1.3*) with the known nutritional requirements predicted for the diploid. If diploids cannot be obtained by this method, make sure that the haploid parents were of opposite mating type. If they were, and the selective plates are correct, the haploids probably carry at least one additional nutrient requirement that is common to both. In this case, select on CM dropout plates that select for two or more auxotrophic

requirements of the diploid (at least one auxotrophy for each haploid parent). It is important that the haploid parents be from cultures that have been freshly grown, but cells from cultures stored 1 or 2 days at 4°C will also mate well. If cells from plates that have been stored longer are used, allow mating to proceed overnight.

In most laboratory strains of *S. cerevisiae*, many diploid cells in a culture do not undergo meiosis, resulting in a population of spores contaminated to varying degrees with the original diploid. In addition, spores produced by a single meiotic event are often notoriously difficult to separate. The random spore protocol employs an extended incubation with Zymolyase to destroy contaminating diploids, followed by sonication and detergent treatment to disperse spores. The procedure should yield a spore population with <1 diploid cell per 10^4 spores. Spore colonies should be tested for mating type (described earlier in this unit) to determine the frequency of diploid contamination (identified by their nonmating phenotype). Contamination by diploids is usually not a problem when tetrads are dissected, although sometimes three spores and an unsporulated diploid are accidentally dissected as a single tetrad.

While most strains do not sporulate synchronously, pregrowth in YPA medium (*UNIT 13.1*) can result in a degree of synchrony that is useful for monitoring gene expression as meiosis progresses. For more precise synchrony, *S. cerevisiae* strain SKI can be used (Esposito and Klapholz, 1981). This strain undergoes a highly synchronous meiosis which it completes in 8 hr. For this reason, SKI and its derivatives have been extremely useful for studying the molecular and cellular events that occur in meiosis (Wang et al., 1987).

The most critical step in dissecting tetrads is the glucylase or Zymolyase treatment. Too little digestion results in spores that cannot be separated, while too much digestion makes it impossible to pick up intact tetrads with the

needle. The optimum time for glucosylase treatment varies among genetic backgrounds, but once the conditions for proper treatment are established they will give reproducible results for strains from the same genetic background.

When spores are allowed to grow up, it is not uncommon to find tetrads where only 1, 2, or 3 of the spores have grown into colonies. This should be relatively rare (<5% of the tetrads) when closely related haploids are used, but may occur at very high frequencies when the haploid parents are less closely related (as is often the case when strains from different laboratories are mated). If one is simply trying to construct a useful genotype, this is not a major problem. However, it is a problem when viability of spore products is being analyzed to determine if a mutation is lethal. If a marker is needed from a foreign strain where spore viability is poor in crosses with commonly used laboratory strains, spore products carrying that marker must be repeatedly crossed back to a laboratory standard strain—the goal being to introduce only the desired mutation into the genetic background of the laboratory strains. This procedure, called backcrossing, is carried out until spore viability reaches acceptable levels (usually between 4 and 7 backcrosses). At each meiosis, spores are identified that carry the foreign marker in conjunction with several markers found in the laboratory standard strain that is used as the backcross parent. If the foreign marker has been cloned, it is often more efficient to introduce a defined mutation into laboratory strains by transformation, since each backcross requires ~10 days.

Time Considerations

Diploid selection will require ~3 days. Sporulation will take 2 to 4 days. Tetrad preparation will require ~1 hr, and one should

allot several hours to learning how to dissect tetrads. The dissected spores need ~3 days of growth before they form colonies that can be replica plated for genotyping, which requires an additional overnight incubation on the appropriate selective plates. Thus, between 9 and 11 days is required to construct a new haploid strain when starting from haploid parents. This time does not include pregrowing diploids on YPD medium prior to sporulation, which increases sporulation efficiency.

Genome-Wide Transposon Mutagenesis in Yeast

Transposon-based insertion screens provide a convenient means to identify gene function. Transposon mutagenesis allows one to rapidly generate a large set of mutations that can be screened for mutant phenotypes and specific patterns of gene expression. Moreover, transposon-insertion alleles are much easier to detect than those generated by agents that predominantly produce single-base changes. Insertional mutagenesis is most effectively performed in yeast by means of shuttle mutagenesis. In this procedure, a library of yeast genomic DNA is mutagenized with a bacterial transposon *in vivo* in *E. coli*; mutant alleles are subsequently transferred into yeast for functional analysis. In yeast, shuttle mutagenesis is preferred over transposon mutagenesis *in vivo*, as prokaryotic transposons insert more randomly than do endogenous yeast transposable elements.

This unit provides comprehensive protocols for the use of insertional libraries generated by shuttle mutagenesis. From the Basic Protocol presented here, a small aliquot of insertional library DNA may be used to mutagenize yeast, producing strains containing a single transposon insertion within a transcribed and translated region of the genome. This transposon-mutagenized bank of yeast strains may be screened for any desired mutant phenotype. Alternatively, since the transposon contains a reporter gene lacking its start codon and promoter, transposon-tagged strains may also be screened for specific patterns of gene expression. Strains of interest may be characterized by vectorette PCR (see Support Protocol 1) in order to locate the precise genomic site of transposon insertion within each mutant. A method by which *Cre/lox* recombination may be used to reduce the transposon in yeast to a small insertion element encoding an epitope tag is described below (see Support Protocol 2). This tag serves as a tool by which transposon-mutagenized gene products may be analyzed further (e.g., localized to a discrete subcellular site). For additional considerations regarding these transposon-mutagenized libraries (see Strategic Planning).

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

STRATEGIC PLANNING

At present, the authors have generated three different transposon-mutagenized libraries of yeast genomic DNA. Each library presents its own unique advantage as an insertional mutagen; therefore, care should be taken in choosing an appropriate library when planning a genome-wide screen for gene function.

Specifically, two mutagenized libraries contain transposon insertions bearing the reporter gene, *lacZ*, lacking both its promoter and initiator ATG codon. Our first *lacZ*-insertional library (Burns et al., 1994) was derived by transposon mutagenesis of a genomic library constructed in the Tn3-free vector pHSS6 (Seifert et al., 1986); each library plasmid contains a 3 to 4 kb fragment from a *Sau3A* partial digest of yeast genomic DNA. This library (containing 18 genome equivalents of DNA) was mutagenized *in vivo* in *E. coli* with mTn-*lacZ/LEU2*, a Tn3-derived minitransposon (mTn) carrying the yeast selectable marker *LEU2* and a bacterial marker encoding resistance to ampicillin (Fig. 13.3.1). The resulting insertional library exhibits a random distribution of transposon-tagged genes, but does contain 2 μ m plasmid DNA.

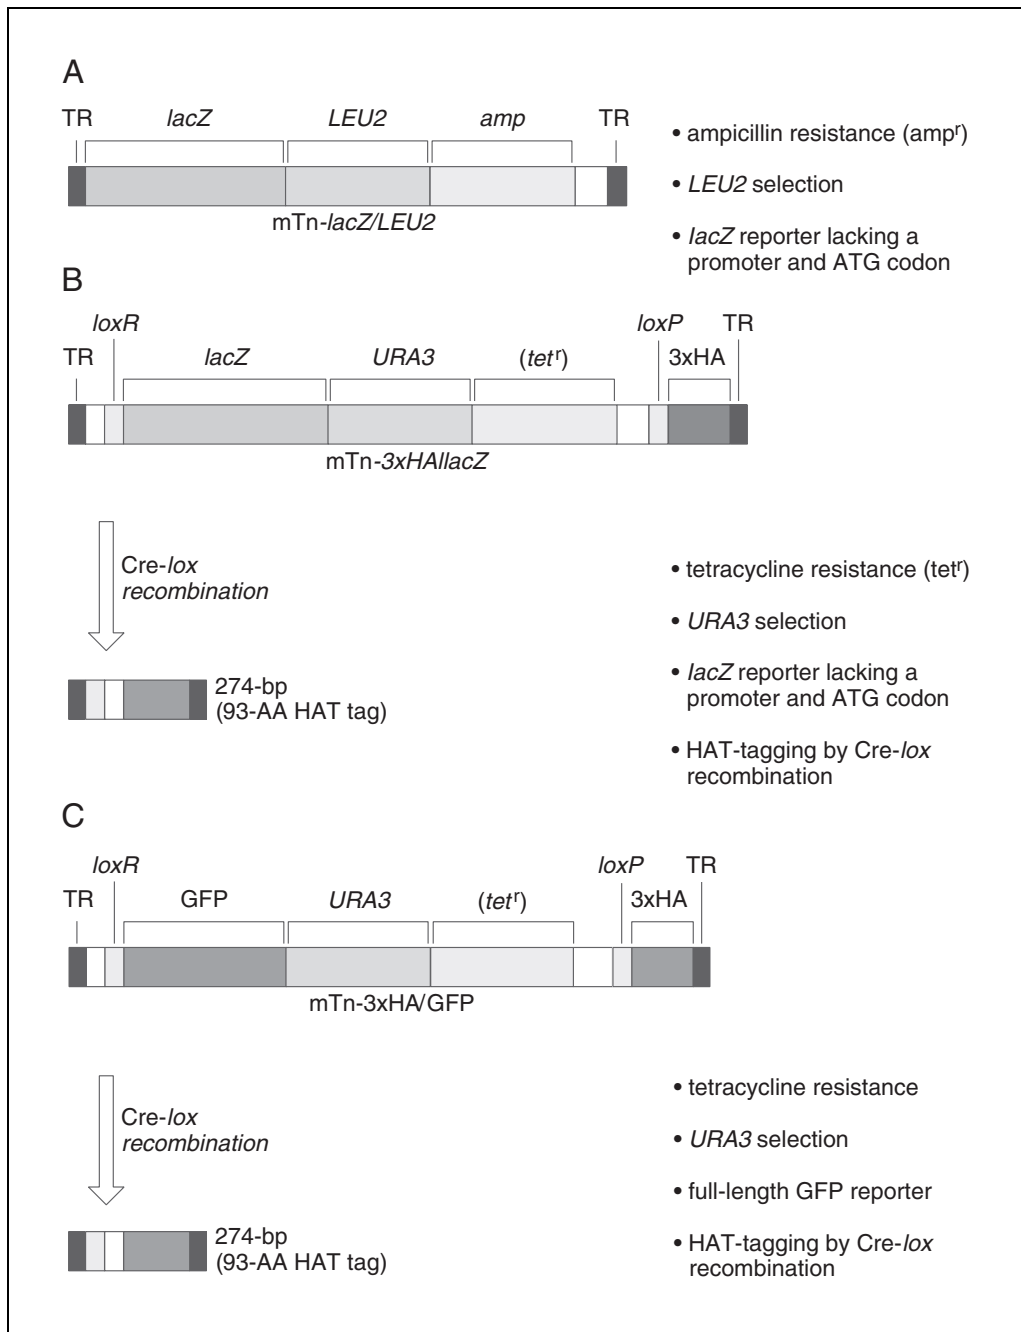

Figure 13.3.1 Transposons for genome-wide random mutagenesis in yeast. Each indicated transposon has been used to mutagenize a plasmid-based library of yeast genomic DNA in *E. coli*. Relevant features of each transposon are indicated below the corresponding schematic. **(A)** mTn-*lacZ/LEU2* Tn3-derived minitransposon capable of generating disruption alleles and reporter gene fusions. Proteins tagged by mTn-*lacZ/LEU2* insertion may be immunolocalized using antibodies directed against β -gal. **(B)** mTn-3xHA/*lacZ*. Cre/*lox* recombination may be used to reduce mTn-3xHA/*lacZ* in yeast to a 274-bp epitope-insertion element. Due to a 5-bp duplication in target-site sequence associated with Tn3 transposition, this insertion element encodes a 93-amino acid tag containing three copies of the HA epitope. mTn-3xHA/*lacZ* may be used to generate *lacZ*-fusions, disruption alleles, conditional alleles, and HA-tagged alleles. **(C)** mTn-3xHA/GFP, a minitransposon carrying full-length GFP reporter gene, in other respects, identical to mTn-3xHA/*lacZ*. Note both mTn-3xHA/GFP and mTn-3xHA/*lacZ* encode identical HA tags upon Cre/*lox* recombination. Corresponding insertion libraries may be requested at the authors' Web site (see Internet Resources).

A second *lacZ*-insertional library was generated by mutagenesis with a *URA3*-marked mTn3 transposon (mTn-3xHA/*lacZ*; Ross-Macdonald et al., 1997) modified to incorporate *lox* elements and sequence encoding three copies of an epitope from the influenza virus hemagglutinin protein (the HA epitope; Fig. 13.3.1). Cre-mediated recombination between *lox* sites (see Support Protocol 2) may be used to reduce the 6 kb mTn-3xHA/*lacZ* insertion to a smaller element encoding an in-frame epitope tag; this allele may be used to determine the subcellular localization of transposon-tagged gene products. This small 93-amino acid epitope tag is also an effective means of generating conditional alleles and hypomorphic mutants for further study. Using mTn-3xHA/*lacZ*, we have mutagenized a plasmid library (containing 50 genome equivalents) generated by *Sau3A* partial digestion of genomic DNA isolated from a *cir^ρrho⁰* yeast strain. The resulting mTn-3xHA/*lacZ* insertion library, therefore, lacks 2μ plasmid sequences and mitochondrial-encoded DNA. This mTn-3xHA/*lacZ* insertional library has been used in the bulk of our genomic studies with excellent results (Ross-Macdonald et al., 1999); however, it does possess a less random distribution of transposon insertions as compared to that found in the mTn-*lacZ*/*LEU2* library.

A third insertion library was generated by mutagenesis with a mini-Tn3 transposon (mTn-3xHA/GFP; Ross-Macdonald et al., 1997) encoding full-length green fluorescent protein (GFP) in place of β-galactosidase (Fig. 13.3.1); in all other respects, this transposon is identical to mTn-3xHA/*lacZ*. GFP is a versatile reporter facilitating a variety of biological studies in living cells (e.g., fluorescence microscopy, fluorescence-flow cytometry, and fluorescent tagging as a means of determining protein localization). We, however, have found *lacZ* to be a more sensitive reporter of gene expression and, therefore, more effective in analyzing genes expressed at a low level.

Diagrams of each transposon, with accompanying summaries, are presented in Figure 13.3.1.

Several considerations should be addressed in choosing a yeast host strain. If using an insertional library derived from mutagenesis with mTn-*lacZ*/*LEU2*, choose a *Leu2⁻* yeast strain. Use of a diploid strain will allow recovery of transposon insertions within essential genes. Also, the use of a *cir^ρ* strain will prevent recovery of insertions within the yeast 2μ plasmid (applicable to the mTn-*lacZ*/*LEU2*- and mTn-3xHA/GFP-mutagenized libraries, which were not generated from a *cir^ρ* strain). For the eventual analysis of HAT-tagged proteins (Support Protocol 2), choose a *Ura3⁻*, *Leu2⁻* strain of yeast; preferably transform this strain with pGAL-cre (pB227; see Support Protocol 2) prior to use in this protocol. Irrespective of the host strain chosen, yeast cultures should be grown to mid-log phase in order to ensure maximal transformation efficiency.

**GENERATING YEAST MUTANTS FROM mTn-MUTAGENIZED
LIBRARY DNA**

This protocol describes methods by which a transposon-mutagenized library of yeast genomic DNA may be used to produce a bank of yeast strains, each strain carrying a transposon insertion within protein-coding sequence. Specifically, the following protocol assumes use of the mTn-3xHA/*lacZ*-mutagenized library (see Strategic Planning), although an identical approach could be applied to the manipulation of any *lacZ*-based insertional library.

The mTn-3xHA/*lacZ*/*URA3*-derived insertional library (as well as any other library described above) may be requested using order forms linked to the authors' Web page (<http://ygac.med.yale.edu>; see Internet Resources). Upon receipt of this library, mutagenized DNA may be excised from pHSS6 for transformation into an appropriate Ura3⁻ yeast strain according to protocols modified from Chen et al. (1992). By homologous recombination, the mTn-mutagenized genomic DNA fragment will replace its chromosomal locus, generating a yeast strain carrying a chromosomal mTn insertion. Transformants carrying an in-frame fusion of mTn-encoded *lacZ* to yeast protein coding sequence may be identified using a color assay for β-galactosidase (β-gal) activity. The resulting bank of yeast strains containing productive *lacZ* fusions may then be screened for any desired mutant phenotype.

Materials

Transposon-mutagenized genomic library plasmid DNA (available upon request; see Internet Resources)

10× TE buffer, pH 8.0 (APPENDIX 2), sterile

E. coli tet^s, kan^s (e.g., DH5α)

14-cm LB plates and medium supplemented with 3 μg/ml tetracycline and 40 μg/ml kanamycin (UNIT 1.1)

LB medium (UNIT 1.1)

Glycerol, sterile

NotI restriction endonuclease and buffer (UNIT 3.1)

Ura3⁻ yeast culture (Chapter 13)

One-step buffer (see recipe)

10 mg/ml denatured salmon sperm DNA (UNIT 14.7)

CM dropout plates and medium without uracil (-Ura; UNIT 13.1)

YPAD plates: YPD plates (UNIT 13.1) supplemented with 80 mg/liter adenine

Chloroform

Xgal plates (UNIT 13.1)

Clinical tabletop centrifuge

45°C water bath or incubator

Sterile toothpicks

3MM filter paper (Whatman)

30°C incubator

9-cm and 15-cm glass petri dishes

Additional reagents and equipment for culturing *E. coli* (UNITS 1.1, 1.2 & 1.3), preparing and transforming competent *E. coli* (UNIT 1.8), isolating plasmid DNA by miniprep (UNIT 1.6) or large-scale preparation (UNIT 1.7), restriction endonuclease digestion (UNIT 3.1), yeast culture (UNIT 13.2), agarose gel electrophoresis (UNIT 2.5), culturing yeast (UNITS 13.1 & 13.2), transforming yeast (UNIT 13.7), and assaying for β-galactosidase activity (UNIT 13.6)

Prepare library DNA

1. Distribute plasmid DNA from individual pools of the transposon-mutagenized genomic library (~1 µg DNA per pool) as dried-down solutions. Briefly centrifuge each dry sample, and resuspend DNA from each pool in an appropriate volume of TE buffer, pH 8.0 (e.g., 10 µl per pool). Each pool of library DNA is mutagenized independently; therefore, it is advisable to process DNA from each pool separately to ensure independent insertion alleles are obtained.
2. Introduce a suitable amount of DNA from each pool into any tetracycline⁻ (tet^s) and kanamycin⁻ sensitive (kan^s) *E. coli* strain by standard transformation procedures (UNIT 1.8).

Standard E. coli strains (e.g., DH5α) are suitable hosts for this transformation. Electroporation (UNIT 9.3) is not required, although resulting transformant yields may be increased 10- to 100-fold. If electroporation is used, decrease DNA quantity appropriately.

3. Select transformants on LB plates (14 cm in diameter) supplemented with 3 µg/ml tetracycline and 40 µg/ml kanamycin.

Approximately 10,000 transformants should be obtained per pool following overnight growth at 37°C.

4. Elute transformant colonies by placing 6 ml of LB medium onto the surface of each plate and scraping cells into a homogenous suspension.

An aliquot of this suspension should be stored at -70°C in 15% glycerol.

5. Dilute a 1-ml aliquot of this eluate into 100 ml LB medium supplemented with 3 µg/ml tetracycline and 40 µg/ml kanamycin to yield a culture of nearly saturated cell density. Incubate at 37°C with aeration for 2 to 3 hr.

The remaining eluate may be stored at 4°C until completion of subsequent steps.

6. Isolate plasmid DNA by standard miniprep (UNIT 1.6) or large-scale preparation (UNIT 1.7).

Transform yeast with mTn-mutagenized library DNA

7. Digest a small aliquot (typically, at least 1 µg) of plasmid DNA from each library pool (obtained in step 6) with *NotI* restriction endonuclease (UNIT 3.1). Subsequently, analyze a portion of the reaction mixture by agarose gel electrophoresis (UNIT 2.5) to ensure release of mTn-mutagenized yeast DNA from the pHSS6 vector. Store the remaining reaction mixture at 4°C for later use (step 10).

Upon electrophoresis, a distinct 2.1-kb band (pHSS6) and broad 8-kb band (mTn-mutagenized yeast genomic DNA) should be visible.

*The broad 8-kb band generated by *NotI* digestion consists of 2- to 4-kb inserts of yeast genomic DNA carrying the 6-kb transposon construct. As this library was constructed from size-fractionated yeast genomic DNA fragments, insert sizes are relatively homogeneous.*

8. Grow a 10-ml culture of any desired Ura3⁻ yeast strain to mid-log phase (a density of 10⁷ cells/ml or OD₆₀₀ of ~1) maintaining appropriate selection, as applicable.

Several considerations should be addressed in choosing a yeast host strain (see Strategic Planning).

9. Centrifuge cells in a clinical tabletop centrifuge for 5 min at 1100 × g at room temperature. Wash pellet once with 5 vol of one-step buffer.

This initial wash in one-step buffer is particularly important if culture volumes are increased.

Saccharomyces cerevisiae

13.3.5

10. Resuspend cells in 1 ml of one-step buffer supplemented with 1 mg of denatured salmon sperm DNA. Add 100- μ l aliquots from this suspension to microcentrifuge tubes containing 0.1 to 1 μ g of *NotI*-digested plasmid DNA from step 7. Vortex tubes to mix contents thoroughly.

To minimize generation of transformants containing more than one insertion, use just enough transforming DNA to yield a reasonable number of transformants (see Anticipated Results). For best results, perform this pilot experiment after determining optimal conditions; scale up as appropriate.

11. Incubate this mixture at 45°C for 30 min.
12. Microcentrifuge cells for 5 sec at maximum speed, room temperature, and subsequently resuspend pellet in 400 μ l of CM (-Ura) dropout medium. Spread 200- μ l aliquots onto CM dropout plates (-Ura). Incubate at 30°C for 3 to 4 days.

*Up to 1×10^3 transformants may be recovered per 1 μ g of transforming DNA. If the *mTn-lacZ/LEU2*-mutagenized library and *leu2* host strain are used, recover transformants on appropriate CM without leucine (-Leu) dropout medium.*

Screen transformants for β -galactosidase activity

13. To maximize detection of *lacZ*-fusions expressed at a low level, transfer transformant colonies onto YPAD plates with sterile toothpicks (*UNIT 13.2*) at a density of up to 100 colonies per plate.

*If an *Ade2*⁻ host strain is used, the addition of adenine to growth medium will prevent any accumulation of red pigment; otherwise, accumulated red pigment may obscure the blue color produced in subsequent assays for β -galactosidase (β -gal) activity.*

14. Place a sterile disc of 3MM filter paper onto a CM dropout plate -Ura; repeat for as many plates as desired. Replicate transformant cells onto filter-covered plates, to allow easy identification of corresponding colonies on YDAP plates (step 13), and incubate overnight at 30°C.

*As some transposon insertions may impair growth even in the heterozygous state, selection for uracil prototrophy should be maintained during this period of vegetative growth. Similarly, selection for leucine prototrophy should be maintained if using a *Leu2*⁻ host. Other growth conditions (e.g., growth on sporulation medium) may be substituted above as desired.*

15. Following overnight growth, lift filters from plates and place in the lid of a 9-cm glass petri dish. Place this lid inside a closed 15-cm glass petri dish containing chloroform. Incubate for 10 to 30 min.

The minimum exposure time required to lyse a particular yeast strain must be determined empirically.

16. Place filters colony-side-up onto Xgal plates. Incubate inverted at 30°C for up to 2 days.

To minimize cost, very thin plates containing Xgal may be used with no loss in signal quality. The signal intensity observed using an Xgal plate is superior to that obtained by soaking the filters in a buffered Xgal solution.

17. Recover transformants producing β -gal (indicated by blue staining on Xgal plates) from the regrown YPAD plates generated in step 13. Maintain appropriate selection during subsequent growth and manipulation of strains.

If desired, strains of interest may be stored long-term in 15% glycerol at -70°C following overnight growth at 30°C in appropriate CM dropout medium.

VECTORETTE POLYMERASE CHAIN REACTION

Banks of transposon-mutagenized yeast strains (see Basic Protocol) represent powerful tools by which genetic screens can be performed rapidly on a genome-wide scale. Large numbers of yeast mutants exhibiting a given disruption phenotype may be easily identified in these genome-wide screens; however, in order for this analysis to be informative, the precise genomic site of mTn insertion must be located within each of these transformants. Accordingly, the following support protocol provides an adaptation of the vectorette polymerase chain reaction (PCR) method of Riley et al. (1990) by which genomic DNA from any site of mTn insertion may be easily recovered for subsequent DNA sequence analysis.

In vectorette PCR, genomic DNA is initially digested with any suitable blunt-end restriction endonuclease possessing a 4- to 6-base-pair recognition sequence. Following digestion, DNA fragments are ligated to a pair of annealed primers containing a non-homologous central region; these primer pairs form “anchor bubbles” flanking each genomic fragment. PCR is then performed using a primer complementary to mTn sequence and a primer identical to sequence within the anchor bubble. During the initial round of amplification, only the mTn primer can bind its template; however, during subsequent cycles, the anchor bubble primer can anneal to the elongated mTn primer, resulting in selective amplification of DNA sequence adjacent to the point of mTn insertion. Vectorette PCR is summarized in Figure 13.3.2.

Materials

Anchor bubble primers 1 and 2 (see Fig. 13.3.2 for sequences; see *UNITS 2.11 & 2.12* for synthesis techniques)

1 M MgCl₂ (*APPENDIX 2*)

Universal vectorette (UV) and mTn primers (see Fig. 13.3.2 for sequences; see *UNITS 2.11 & 2.12* for synthesis techniques)

Transposon-mutagenized yeast strain (see Basic Protocol)

Appropriate restriction endonucleases (e.g., *AluI* or *DraI*) and buffers (*UNIT 3.1*)

10× T4 DNA ligase buffer (*UNIT 3.4*)

5 mM ATP (*UNIT 3.4*)

400 U/μl T4 DNA ligase (measured in cohesive end ligation units)

5 U/μl *Taq* DNA polymerase and 10× buffer (*UNITS 3.5 & 15.1*)

2.5 mM 4dNTP mix (*UNIT 15.1*)

Heat block

Automated thermal cycler

Additional reagents and equipment for preparing yeast DNA (*UNIT 13.11*), restriction endonuclease digestion (*UNIT 3.1*), ligation of DNA fragments (*UNIT 3.16*), PCR amplification (*UNIT 15.1*), purification of DNA from agarose gels (*UNIT 2.6*), and DNA sequence analysis (*UNIT 7.4*)

1. In preparation for vectorette PCR, synthesize anchor bubble primers (suggested DNA sequence indicated in Fig. 13.3.2). Form anchor bubble as follows.
 - a. Prepare an aqueous solution that contains 2 to 4 mM each of anchor bubble primers 1 and 2.
 - b. Denature by incubating 5 min at 95°C in a heat block.
 - c. Add 1 M MgCl₂ to a final concentration of 2 mM.
 - d. Anneal by removing the block from the base unit and placing it on the bench top until it slowly cools to room temperature.

The annealed anchor bubble may be stored at –20°C until step 5.

Saccharomyces cerevisiae

13.3.7

2. Synthesize universal vectorette (UV) primer (suggested DNA sequence indicated in Fig. 13.3.2). Synthesize primer complementary to the mTn used to generate the insertion library (mTn primer).

If using a lacZ-insertional library, the following sequence is recommended for the mTn primer: 5'-CGC CAG GGT TTT CCC AGT CAC GAC-3'.

The UV primer is identical in sequence (not complementary) to a portion of anchor bubble primer 2 (Fig. 13.3.2). The mTn primer indicated above corresponds to sequence from the 5'-end of lacZ on the antisense strand of mTn-3xHA/lacZ. If analyzing a mTn-3xHA/GFP-mutagenized strain, the following GFP primer sequence is recommended: 5'-CAT CAC CTT CAC CCT CTC CAC TGA C-3'.

Figure 13.3.2 Vectorette PCR. **(A)** In preparation for vectorette PCR, small, blunt-ended fragments of mTn-mutagenized genomic DNA are generated by restriction enzyme digestion; DNA fragments are subsequently ligated to preannealed anchor bubble primers. Amplification is carried out using mTn and Universal vectorette (UV) primers (sequence indicated). During the first cycle of PCR, only the mTn primer can bind to template, as the UV primer is identical (not complementary) to anchor bubble sequence. During subsequent PCR cycles, the UV primer can bind to elongated product from the mTn primer, resulting in the selective amplification of genomic DNA adjacent to the mTn insertion site. Primers and major PCR products are shown in bold. **(B)** Suggested anchor bubble and PCR primers are listed below: sequence is indicated 5' to 3'. The Universal vectorette (UV) primer is identical to the boxed sequence within Anchor Bubble primer-2.

3. Prepare genomic DNA from a transposon-mutagenized yeast strain of interest (UNIT 13.11).

Care should be taken to obtain high-quality DNA; this is critical for successful PCR amplification.

4. Digest 1 to 3 μg of genomic DNA overnight at 37°C with 10 U of either *AluI* or *DraI* in a total reaction volume of 20 μl (UNIT 3.1). Following digestion, incubate at 65°C for 20 min to inactivate the enzyme.

Ideally, genomic DNA fragments should be small and blunt-ended in preparation for subsequent anchor bubble ligation; accordingly, any restriction enzyme used in step 4 should cut frequently and leave blunt-ends after cleavage.

IMPORTANT NOTE: *The enzyme must not cut between the transposon end and the mTn primer binding site.*

5. To the reaction mix from step 4, add the following:

5 μl 10 \times T4 DNA ligase buffer
22.5 μl sterile water
1 μl annealed anchor bubble (generated in step 1)
0.5 μl 5 mM ATP
1 μl (400 U) T4 DNA ligase.

Incubate 9 to 24 hr at 16°C.

To accommodate blunt-end ligation, incubation times have been extended up to 24 hr as indicated. The addition of polyethylene glycol to a final concentration of 15% may enhance blunt-end ligation.

6. Prepare PCR mix (100 μl total) as follows.

- a. Withdraw 5 μl from the ligation reaction from step 4.

- b. To this 5- μl aliquot, add:

10 μl 10 \times *Taq* PCR buffer
71 μl sterile water
8 μl 2.5 mM dNTP mix
2.5 μl 20 μM mTn primer (step 2)
2.5 μl 20 μM UV primer (step 2)
1 μl (5 U) *Taq* DNA polymerase.

If desired, the mixture above may be modified for “hot start” PCR (UNIT 15.1) using wax beads commercially available from a variety of sources; please follow manufacturer-suggested guidelines.

7. Transfer to an automated thermal cycler and denature at 92°C for 2 min. Carry out PCR (UNIT 15.1) under the following conditions:

35 cycles:	20 sec	92°C	(denaturation)
	30 sec	67°C	(annealing)
	45 sec	72°C	(extension)
1 cycle:	90 sec	72°C	(extension)

In our experience, short cycling times tend to improve product yield; however, optimum conditions for PCR amplification must be determined empirically.

- Analyze 80 μ l of the reaction mix from step 7 by nondenaturing agarose gel electrophoresis (UNIT 2.7); a single band containing 200 to 400 ng of DNA should be visible. Excise the PCR product and recover DNA in TE buffer (~12 μ l) as described in UNIT 2.6.

If multiple bands are present, excise all bands and recover DNA individually from each. DNA may be recovered with Qiaex resin (available from Qiagen) if desired.

- Analyze ~4 to 6 μ l of recovered product by DNA sequencing (UNIT 7.4) to identify the exact site of mTn insertion.

SUPPORT PROTOCOL 2

EPITOPE TAGGING OF mTn-MUTAGENIZED GENE PRODUCTS

Transposon-mutagenized yeast strains may be analyzed further by utilizing the epitope-tagging feature incorporated into mTn-3xHA/*lacZ* and mTn-3xHA/GFP. As shown in Figure 13.3.1, these minitransposons each contain a pair of *lox* elements located internal to the sequence, encoding three copies of the HA epitope. These *lox* sequences are target sites for the Cre recombinase, which catalyzes site-specific recombination between the *lox* sites. Therefore, expression of Cre results in excision of the central body of the transposon, leaving behind a 274-bp sequence containing the HA-epitope coding region. Due to a 5-bp target site duplication associated with Tn3 transposition, this reduced construct corresponds to a small element encoding 93 amino acids (the HA-epitope tag or HAT tag) inserted within the protein. This HAT tag insertion element is an effective means of generating conditional alleles, hypomorphic mutants, and epitope-tagged strains for immunodetection.

The following support protocol describes a method by which yeast strains bearing an in-frame mTn insertion may be used to derive corresponding HAT-tagged strains by Cre/*loxP* recombination in vivo. The phage P1 Cre recombinase is expressed exogenously from plasmid pGAL-*cre* (available from authors' Web site; see Internet Resources). On this plasmid, *cre* is under transcriptional control of the *GAL* promoter; therefore, induction by galactose can be used to drive *cre* expression. Following galactose induction, cells that have undergone Cre-mediated recombination (and loss of the *URA3* marker) are selected on medium containing 5-fluoroorotic acid (5-FOA). In the authors' experience, galactose induction has resulted in Cre-mediated excision of the mTn-encoded *URA3* marker in >90% of cells analyzed.

Materials

- mTn-mutagenized yeast strain (see Basic Protocol)
 - pGAL-*cre* (pB227; available upon request from authors, see Internet Resources)
 - Raff/CM dropout plates and medium –Leu, –Ura with 2% (w/v) raffinose (UNIT 13.1)
 - Gal/CM dropout medium –Leu with 2% (w/v) galactose (UNIT 13.1)
 - Glc/CM dropout medium –Leu with 2% (w/v) glucose (UNIT 13.1)
 - 5-fluoroorotic acid plates (5-FOA; UNIT 13.1)
 - Glycerol, sterile
 - 30°C shaker and incubator
- Additional reagents and equipment for culture of yeast (UNIT 13.2) and transformation of yeast cells (UNIT 13.7)

1. Transform mTn-mutagenized yeast strain with pGAL-cre (pB227) using standard procedure (see Basic Protocol or UNIT 13.7). Select transformants on CM –Leu, –Ura dropout plates.

Alternatively, pGAL-cre may be transformed into a desired yeast strain prior to transformation with mTn-mutagenized genomic DNA (see Basic Protocol, steps 8 to 11).

This plasmid contains the following elements: amp, ori, CEN, and LEU2.

2. Inoculate transformants into 2 ml Raff/CM dropout medium –Leu, –Ura with 2% raffinose as the carbon source. Incubate at 30°C with aeration until the culture has grown to saturation.

Growth in raffinose derepresses the GAL promoter.

3. Dilute cultures 100-fold into 2 ml Gal/CM –Leu dropout medium with 2% galactose as the carbon source. As a control, dilute an aliquot of this same culture 100-fold into 2 ml Glc/CM –Leu, with 2% glucose as the carbon source. Grow cultures for 2 days at 30°C with aeration.

Some strains grow very poorly in galactose; however, galactose induction is sometimes effective even without visible signs of growth.

4. Test strains for loss of *URA3* marker as follows.
 - a. If visible growth is apparent in cultures grown on 2% galactose, dilute cultures 100-fold in sterile water and withdraw a 10- μ l aliquot.
 - b. If no growth is apparent in cultures grown on 2% galactose, withdraw a 10- μ l aliquot from the undiluted culture.
 - c. Dilute cultures grown in 2% glucose 100-fold in sterile water and withdraw a 10- μ l aliquot.

Spot the aliquot onto a 5-FOA plate; isolate single colonies by streaking the droplet. Incubate 5-FOA plates at 30°C until growth is visible on those plates inoculated with strains grown in galactose.

*Loss of the transposon-encoded *URA3* gene by galactose induction of the Cre recombinase should be reflected in colony growth on 5-FOA plates containing strains grown in galactose. 5-FOA plates carrying strains grown in the presence of glucose should display little or no growth, as expression of the Cre recombinase is repressed by glucose.*

Alternatively, plate diluted cultures obtained in this step onto CM medium and replicate on CM dropout medium –Ura. Incubate at 30°C ~2 days. Cultures grown in galactose should yield roughly 100-fold more Ura⁻ cells than identical cultures grown in glucose.

5. Save single colonies from strains that have lost the *URA3* (marker exclusively following galactose induction) as a stock in 15% (w/v) glycerol at –70°C.

If desired, PCR analysis may be used to confirm the position of the HAT tag; the complete 274-bp DNA sequence encoding this tag may be viewed on the authors' Web site (see Internet Resources).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

One-step buffer

0.2 M lithium acetate
40% (w/v) PEG 4000
100 mM 2-mercaptoethanol
Store up to 1 week at 4°C in a dark bottle

COMMENTARY

Background Information

Transposable elements are powerful insertional mutagens capable of efficiently generating large numbers of informative mutant alleles for subsequent functional analysis. In particular, transposon-based mutagenesis systems offer several advantages over conventional mutagenesis techniques discussed in UNIT 13.3 (i.e., treatment with ethylmethane sulfonate and UV irradiation). In contrast to these approaches, transposon mutagenesis may be used to generate a diverse variety of insertion alleles within target DNA; transposons may be modified to incorporate reporter genes, regulatory elements, and epitope-tagging elements generating null alleles, reporter fusions, mis-expression alleles, conditional alleles, and epitope-tagged alleles. Transposon insertions are additionally advantageous in that they tag mutant loci with an easily detectable DNA element, thereby facilitating subsequent identification and analysis of mutated genes.

Several transposon systems are applicable to genome-wide mutagenesis in yeast. Endogenous yeast Ty-based transposable elements may be used for *in vivo* as well as *in vitro* transposon mutagenesis (Garfinkel and Strathern, 1991; Devine and Boeke, 1994); however, the utility of these systems may be limited by strong target bias associated with Ty transposition *in vivo* (Ji et al., 1993) and poor transposition efficiency *in vitro*. Prokaryotic transposons, such as Tn3 and Tn7, generally exhibit less bias in target-site selection and offer high mutation frequencies. Additionally, negative target regulation of bacterial transposition renders DNA molecules already containing a single transposon immune to further transposon insertion. Collectively, these properties of bacterial transposons enable them to generate large numbers of single-hit mutants—a suitable population for further functional analysis.

Using shuttle mutagenesis, yeast DNA may be mutagenized in *E. coli* with bacterial transposons; transposon-mutagenized DNA may then be returned to yeast by transformation and homologous recombination (Hoekstra et al., 1991). This unit describes the application of Tn3-based shuttle mutagenesis as a means of generating a bank of transposon-mutagenized yeast strains for functional analysis in yeast. The Basic Protocol provides methods by which a Tn3-mutagenized genomic DNA library may be used to transform yeast, generating a bank of marked genomic mutations. This mutant bank may be subsequently screened for desired disruption phenotypes and specific patterns of gene expression. Transposon insertion sites may be identified in strains of interest either by vectorette PCR (Support Protocol 1) or by plasmid rescue (Burns et al., 1994). Plasmid rescue protocols may be found at the authors' web site (<http://ygac.med.yale.edu>; see Internet Resources). Cre/lox recombination may be induced within yeast strains mutagenized by mTn-3xHA/lacZ or mTn-3xHA/GFP (Support Protocol 2); resulting epitope-tagged gene products may be immunolocalized with antibodies directed against the transposon-encoded epitope. Epitope-tagging is also an effective means of generating hypomorphic mutants exhibiting partial gene function.

These transposon insertion libraries constitute a valuable laboratory reagent facilitating genetic screening in yeast. Traditionally, genetic studies have followed a paradigm in which labor-intensive procedures such as complementation analysis or genetic mapping have been necessary as a means of identifying the affected gene within a mutant of interest. Transposon-mutagenized strain collections, as described in this unit, provide a means of altering this paradigm. Researchers may now identify affected genes within clones of interest

either by directly screening a bank of defined mutants or by simply identifying the mutated genomic loci; in either case, the mutated gene can be identified rapidly with a minimal investment in time and effort. Such labor-saving methodologies are essential in order to expedite studies of gene function.

Critical Parameters and Troubleshooting

Transposon-insertion libraries may be used as insertional mutagens in yeast through a series of simple and straightforward steps. Insertion library DNA may be amplified in *E. coli* using any standard method of DNA transformation (e.g., “heat-shock” treatment, electroporation). Transformants should be recovered on growth medium supplemented with antibiotics as indicated; note that tetracycline should be used at a final concentration of 3 µg/ml. Mutagenized DNA from the library is excised from its vector and subsequently transformed into an appropriate yeast strain; electroporation is not normally required, although its use can increase transformant yields 10- to 100-fold. Transform yeast with a small quantity of DNA in order to minimize recovery of double integrants. Diploid strains containing multiple transposon insertions may be identified by examining segregation of the transposon-encoded selectable marker (i.e., *URA3* or *LEU2*) upon tetrad dissection. Alternatively, Southern analysis (*UNIT2.9*) may be used to identify strains containing two different transposon insertions. For purposes of this analysis, *lacZ*-bearing transposons may be probed with a 817-bp *BamHI*-*ClaI* fragment from the 5′ end of *lacZ*. Care should be taken to ensure that mutant phenotypes of interest are linked to the transposon insertion, as multiple insertion events or unrelated spontaneous mutations may have occurred during yeast transformation. Within strains of interest, genetic analysis should be used to confirm segregation of the desired phenotype with the transposon-encoded marker.

The vectorette PCR (see Support Protocol 1) described in this unit allows efficient amplification of genomic DNA at the site of mTn insertion. Typical of any PCR reaction, product yield is dependent upon the quality of DNA used as template. High-quality genomic DNA may be obtained by any standard protocol; CsCl purification of prepared DNA is not required. To function as template for vectorette PCR, genomic DNA fragments must be modi-

fied by anchor bubble ligation. To facilitate blunt-ended ligation, polyethylene glycol may be added to the ligation mixture at a final concentration of 15% (w/v). Longer ligation times (in excess of 16 hr) may be beneficial. Insufficient product yield may also be addressed by trial-and-error modification of indicated cycling conditions. Per cycle, primer extension at 72°C may be increased from 45 sec to 3 min, if no PCR product is apparent; however, the authors typically have obtained better results using shorter extension times. Alternatively, annealing conditions (suggested temperature of 67°C per cycle) may be made more or less stringent as needed. If multiple PCR products are present after amplification, each product may be individually analyzed by DNA sequencing.

Anticipated Results

Amplification of library DNA in *E. coli* should generate roughly 10,000 colonies per pool. Subsequent transformation of library DNA into yeast should yield at least 2×10^5 transformants. Roughly 180,000 yeast transformants should be screened for reporter activity in order to ensure 95% coverage of the genome; the authors typically observe β-gal activity in 12% to 16% of transformants. For purposes of insertional mutagenesis without regard to in-frame reporter activity, 30,000 to 50,000 colonies should be screened.

Within yeast transformants of interest, transposon insertion sites may be identified by vectorette PCR (Support Protocol 1). Vectorette PCR can be expected to yield 200 to 400 ng of product. This quantity of DNA should constitute sufficient template for 1 or 2 sequencing reactions.

Transposon-mutagenized gene products may be HAT-tagged through galactose-induced *Cre/lox* recombination. The authors have generally observed poor growth of yeast strains on medium containing galactose as its carbon source; however, after growth for a few generations in galactose-containing medium, greater than 90% of yeast cells exhibit loss of the mTn *URA3* marker. In contrast, less than 1% of cells grown in the presence of glucose undergo recombination between mTn-encoded *lox* sites. From a pilot study of epitope-tagged proteins, the authors estimate that 40% to 75% of HAT-tagged proteins should be fully functional, while ~90% should localize properly within the cell (Ross-Macdonald et al., 1997).

Saccharomyces cerevisiae

13.3.13

Time Considerations

The protocols presented herein are neither time-consuming nor labor-intensive. Large quantities of library DNA may be prepared as described within a period of 2 days. Library DNA may be subsequently digested and transformed into yeast in one day; allow 3 to 4 days for growth of transformants. Yeast mutants may be incubated under desired growth conditions for a length of time appropriate to the given study (e.g., overnight). Subsequently, strains may be assayed for β -gal activity in <1 hr; blue staining may develop over a period of up to 2 days.

Transposon-mutagenized gene products may be epitope-tagged through Cre/lox recombination over a period of ~5 days; this protocol, however, requires very little “hands-on” time. Typically, strains should be grown 1 to 2 days in raffinose, followed by growth for 2 days in galactose or glucose. An additional 1 to 2 days may be necessary to allow growth of “pop-out” strains on 5-FOA plates.

Vectorette PCR and subsequent DNA sequence analysis may be performed within a similar time frame. In preparation for PCR, a total of 2 to 3 days may be required to synthesize appropriate primers and isolate genomic DNA. Anchor bubbles may be ligated to genomic DNA in 1 day. PCR itself requires only a few hours. PCR products may be analyzed and recovered in ~6 hr. DNA sequencing reactions can be completed in 1 day, and results may be viewed the next morning. In total, an initial attempt at vectorette PCR may require ~5 days; however, subsequent vectorette PCR may be accomplished in only 3 days. Potential stopping points for both procedures have been indicated at appropriate steps in the respective protocols.

Yeast Cloning Vectors and Genes

This unit describes some of the most commonly used yeast vectors, as well as the cloned yeast genes that form the basis for these plasmids. Yeast vectors can be grouped into five general classes, based on their mode of replication in yeast: YIp, YRp, YCp, YEp, and YLp plasmids. With the exception of the YLp plasmids (yeast linear plasmids), all of these plasmids can be maintained in *E. coli* as well as in *S. cerevisiae* and thus are referred to as shuttle vectors.

Table 13.4.1 summarizes the general features of a number of these vectors, including the phenotypes that allow selection in either *E. coli* or yeast (or both). These plasmids contain two types of selectable genes, both of which can confer a dominant phenotype: plasmid-encoded drug-resistance genes (UNIT 1.5) and cloned yeast genes. The drug resistance marker is dominant because the recipient (bacterial) cell does not encode a gene for drug

resistance. In contrast, the cloned yeast gene present on the plasmid is a copy of a gene that is present in the yeast genome as well. Thus, this gene functions as a dominant selectable marker only when the recipient yeast cell has a recessive mutation in the corresponding chromosomal copy of the cloned gene. Many of these cloned yeast genes encode functions involved in biosynthetic pathways of yeast and are capable of complementing certain mutations in similar biosynthetic pathways of *E. coli* (e.g., the cloned *URA3* gene of yeast can complement *ura3⁻* mutations of yeast as well as mutations in the *pyrF* gene of *E. coli*). The availability of bacterial mutations that can be complemented by these yeast genes can greatly simplify plasmid constructions, allowing genetic screening for the expected recombinant plasmid.

Table 13.4.2 presents characteristics of a number of cloned yeast genes, along with

n.s. = not sequenced; n.a. = not applicable.

^aThe genotypes and references for these strains can be found in the legends to Figures 13.4.1, 13.4.2, and 13.4.6, except for JA209 (*argH1 metE xyl trpA36 recA56 str^r*; Clarke and Carbon, 1978).

^bSelection for α-aminoadipate resistance produces both *lys2*⁻ and *lys5*⁻ mutants. Selection for 5-FOA resistance generates both *ura3*⁻ and *ura5*⁻ mutants.

^cThis 1453-bp fragment contains both the *TRP1* and the *ARS1* genes.

^dThe wild-type *CAN1* gene encodes dominant sensitivity to the arginine analog canavanine sulfate.

^eThe sensitive (wild-type) and resistant alleles of the *CYH2* gene are codominant.

^fThe *CYH2* and *TCM1* genes encode ribosomal proteins, which are required for viability, but which can be mutated to confer resistance to cycloheximide or tricodestermin, respectively.

^gThe resistant allele of *TCM1* is dominant to the wild-type sensitive allele.

mutants of bacteria and yeast in which the wild-type cloned gene can be selected. For two yeast genes, a positive selection for mutant alleles also exists: *ura3*⁻ cells can be selected on plates containing the drug 5-fluoroorotic acid (5-FOA), whereas *lys2*⁻ cells can be selected on α-aminoadipate plates (see UNIT 13.2 for recipes for these two types of plates).

The nomenclature of different classes of yeast vectors, as well as details about their mode of replication in yeast are described below.

PLASMID NOMENCLATURE

YIp plasmids (yeast integrating plasmids) contain selectable yeast genes but lack sequences that allow autonomous replication of the plasmid in yeast. Instead, transformation of yeast occurs by integration of the YIp plasmid

into the yeast genome by recombination between yeast sequences carried on the plasmid and homologous sequences in the yeast genome. This recombination event results in a tandem duplication of the yeast sequences that bracket the rest of the plasmid DNA. If the YIp plasmid contains an incomplete portion of a cloned gene, this technique can be used to create a gene disruption (see UNIT 13.10). The reversal of the integration process occurs at a low frequency (about 0.1% to 1% per generation), with excision of the integrated plasmid occurring by recombination between duplicated yeast sequences. The frequency of transformation of YIp plasmids is only 1 to 10 transformants/μg DNA, but transformation frequency can be increased 10- to 1000-fold by linearizing the plasmid within yeast sequences

Saccharomyces cerevisiae

13.4.2

that are homologous to the intended site of integration on the yeast chromosome. Linearization also directs the integration event to the site of the cleavage, which is useful when several different homologous yeast sequences are present on the plasmid.

Three classes of yeast vectors are circular plasmids capable of extrachromosomal replication in yeast. YRp plasmids (yeast replicating plasmids) contain sequences from the yeast genome which confer the ability to replicate autonomously. These autonomous replication sequences (*ARS*) have been shown to be chromosomal origins of replication. YRp plasmids have high frequencies of transformation (10^3 to 10^4 transformants/ μg DNA), but transformants are very unstable both mitotically and meiotically. Despite the fact that *ARS*-containing plasmids replicate only once during the cell cycle, YRp plasmids can be present in high copy number (up to 100 copies per plasmid-bearing cell, although the average copy number per cell is 1 to 10). During mitosis, both instability and high copy number are due to a strong bias to segregate to the mother cell, to the extent that as few as 5% to 10% of cells grown selectively still retain the plasmid.

Incorporation of DNA segments from yeast centromeres (*CEN* elements) into YRp plasmids, to generate vectors called YCp plasmids (yeast centromeric plasmids), greatly increases plasmid stability during mitosis and meiosis. Such plasmids—present in 1 to 2 copies per cell—have a loss rate of approximately 1% per generation and show virtually no segregation bias. During meiosis, *CEN* plasmids behave like natural chromosomes, generally segregating in a $2^+ : 2^-$ ratio.

The last class of circular replicating plasmids, YE_p vectors (yeast episomal plasmids), contain sequences from a naturally occurring yeast plasmid called the $2\mu\text{m}$ circle. These $2\mu\text{m}$ sequences allow extrachromosomal replication and confer high transformation frequencies ($\sim 10^4$ to 10^5 transformants/ μg DNA). These plasmids are commonly used for high-level gene expression in yeast, due to their ability to be propagated relatively stably through mitosis and meiosis in high copy number. YE_p vectors vary in the portion of $2\mu\text{m}$ DNA that they carry, although most carry only the sequences essential for autonomous replication. If the $2\mu\text{m}$ -encoded *REP1* and *REP2* functions are present (either on the YE_p plasmid or due to the presence of endogenous $2\mu\text{m}$ circles), transformants are relatively stable and present in high

copy number (20 to 50 copies). In the absence of *REP* functions, transformants are much more unstable, with a segregation bias and copy number similar to those observed with YRp plasmids. In the $2\mu\text{m}$ circle, a highly efficient site-specific recombination event occurs between two perfect 599-bp inverted repeats, mediated by the $2\mu\text{m}$ -encoded *FLP* gene. Most YE_p plasmids carry at least one copy of this repeat; thus, FLP-mediated recombination between YE_p vectors and other plasmids carrying one or more of these repeats (either the endogenous $2\mu\text{m}$ plasmid or other shuttle vectors) can result in a variety of recombinant plasmid multimers.

YL_p plasmids (yeast linear plasmids) contain certain G-rich repeated sequences at their termini which function as telomeres and allow the plasmid to replicate as a linear molecule. In yeast, the telomeric sequence consists of tandem repeats of the sequence $5'(\text{dG}_{1-3}\text{dT})_3'$. Very short *CEN*-containing YL_p plasmids (10 to 15 kb) are unstable and present in high copy, due to random segregation during mitosis. Increasing the size to 50 to 100 kb produces YL_p vectors that disjoin from each other in a manner similar to that of natural chromosomes, resulting in a copy number of about one per cell. However, these artificial chromosomes—which are lost at a rate of 10^{-2} to 10^{-3} per cell division—are still ~ 100 -fold less stable than a natural yeast chromosome.

MAPS OF SELECTED PLASMIDS AND GENES

Restriction maps and a brief description of selected plasmid vectors from several of the five general classes are presented in Figures 13.4.1, 13.4.2, 13.4.3, 13.4.4, 13.4.5, 13.4.6, and 13.4.7. These plasmids were chosen because they are used by many investigators and are generally applicable for a wide variety of purposes. However, where different selectable markers or unique restriction sites may be required, the reader is referred to two reviews on vector systems used in yeast (Pouwels et al., 1985; Parent et al., 1985). In addition, a method for constructing new plasmids *in vivo* in yeast has been described and employed to construct an extended series of new YRp, YCp, and YE_p plasmids (Ma et al., 1987). Yeast shuttle vectors have also been constructed that are derived from either pUC18 or the Bluescript plasmids, providing a greater variety of unique cloning sites and allowing both identification of recombinant plasmids by screening for alpha-

Figure 13.4.1 Yip5. Yip5 contains the 1.1-kb *HindIII* *URA3* gene cloned into the *AvaI* site of pBR322 via the addition of poly(dG-dC) tails (Struhl et al., 1979). Since this plasmid does not contain a yeast origin of replication, transformants occur by integration into the yeast genome at the *URA3* locus; the frequency of transformation can be increased by linearization of the plasmid within the *URA3* insert. The complete nucleotide sequence is available from the Vecbase database (file name: Vecbase.Yip5) and a detailed restriction map can be found in the New England Biolabs catalog.

The *URA3* gene encodes orotidine-5'-phosphate (OMP) decarboxylase, a 267-amino-acid protein required for uracil biosynthesis. The map shown is the gene from strain +D4, which can be expressed in *E. coli* without an external bacterial promoter (Rose et al., 1984). Loss of *URA3*⁺ function can be directly selected using 5-FOA: *ura3*⁻ cells are resistant to 5-FOA, whereas 5-FOA is toxic to cells synthesizing the *URA3* gene product (Boeke et al., 1984). This negative selection has been exploited in a variety of gene replacement schemes, discussed in *UNIT 13.10*. The *URA3* gene can also complement mutations in the *pyrF* gene in *E. coli* using strain DB6656 (*pyrF*::Mu, *lacZ*_{am} *trp*_{am} *hsr*_k⁻ *hsm*_k⁺; Bach et al., 1979).

complementation of the *lacZAM15* mutation of *E. coli* (see *UNIT 1.4*) and the ability to produce single-stranded DNA (Hill et al., 1986; Elledge and Davis, 1988).

Finally, a vector system has been designed using yeast artificial chromosome (pYAC) plasmids, allowing direct cloning into yeast of contiguous stretches of DNA up to 400 kb

(Burke et al., 1987). The circular pYAC plasmids (without inserts) can replicate in *E. coli*. In vitro digestion of the pYAC vector, ligation to exogenous DNA, and direct transformation of the subsequent linear molecules (with telomeric sequences at each termini) into yeast generate a library that can then be screened by standard techniques.

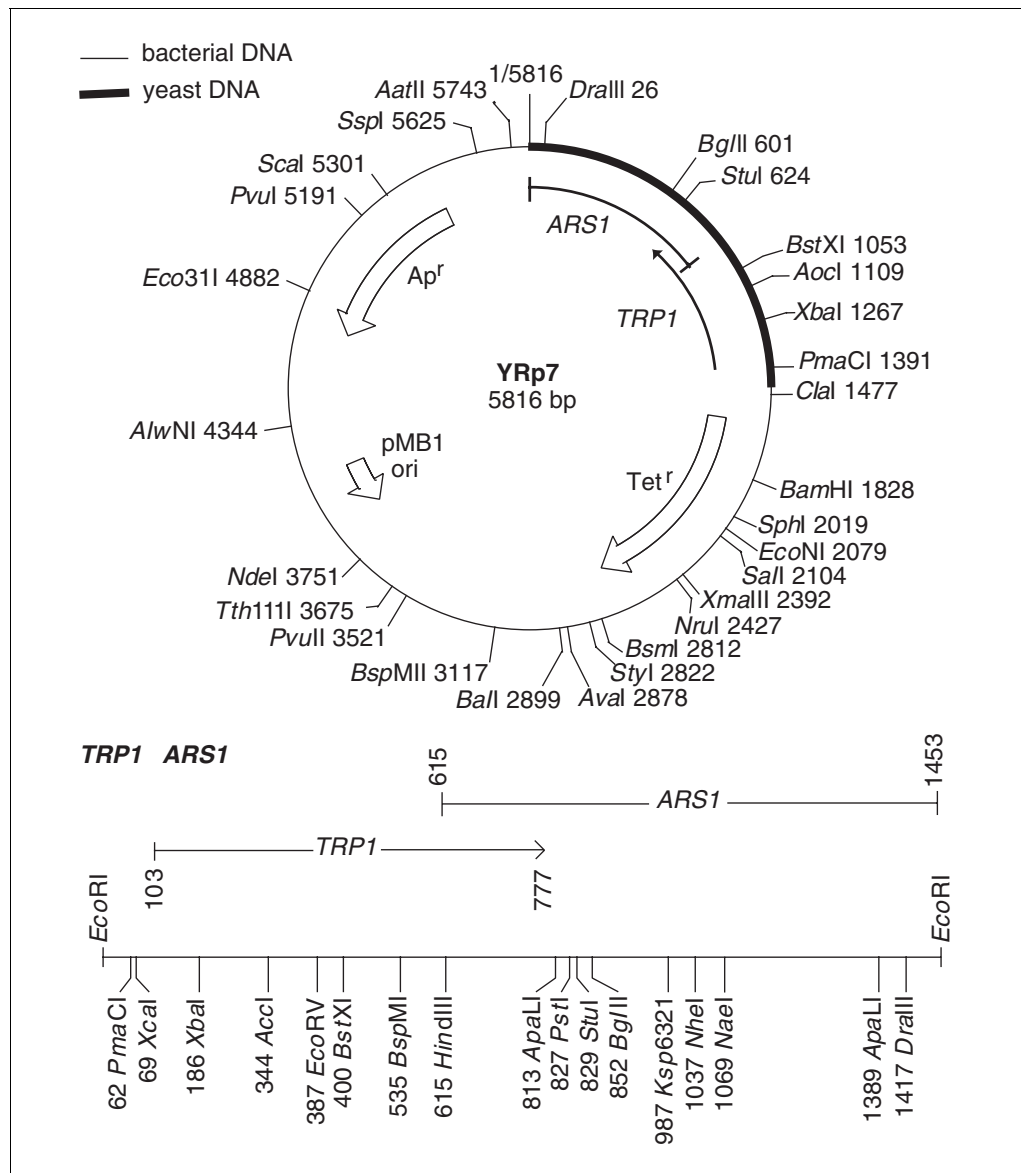

Figure 13.4.2 YRp7. This plasmid contains the 1453-bp *EcoRI* *TRP1* *ARS1* fragment from *S. cerevisiae* inserted into the *EcoRI* site of pBR322 (Struhl et al., 1979).

The *TRP1* RI circle is a derivative of YRp7 containing only the 1453-bp *TRP1* *ARS1* *EcoRI* fragment. This plasmid is mitotically and meiotically unstable, but is present in 100 to 200 copies per plasmid-bearing cell in both *cir*⁺ and *cir*⁰ strains.

A genomic plasmid bank has been constructed by inserting size-selected *Sau3A* partial fragments into the *Bam*HI site of YRp7 (Nasmyth and Reed, 1980).

The *TRP1* *ARS1* 1453-bp *EcoRI* fragment contains both the *TRP1* gene, encoding N-(5'-phosphoribosyl)-anthranilate isomerase, and the autonomous replication sequence *ARS1*. The intact *TRP1* gene can complement mutations in the *trpC* gene of *E. coli*, using *E. coli* JA300 (*thr1 leuB6 thi1 thyA trpC1117 hsr_k⁻ hsm_k⁻ str'; Tschumper and Carbon, 1982). The chromosomal replicator *ARS1* lies between positions 615 and 1453 (on a *Hind*III-*EcoRI* fragment) and is composed of three domains. Domain A contains an 11-bp core sequence (position 857 to 867) consisting of a consensus sequence found in many other *ARS* elements and which is essential for *ARS1* function. Domains B and C flank Domain A and are relatively AT-rich regions that contribute to, but are not essential, for *ARS* function.*

Figure 13.4.3 YEp24. YEp24 has the 2.2-kb *EcoRI* fragment of the B form of the 2 μ m plasmid and the 1.1-kb *HindIII* *URA3* gene inserted into the *EcoRI* and *HindIII* sites, respectively, of pBR322 (Botstein et al., 1979). The expression of the *tet^r* gene is variable among different isolates of this plasmid. YEp24 is mitotically stable in *cir⁺* strains at a copy number of about 20 but is unstable in *cir⁰* strains. The complete sequence of YEp24 is available from the Vecbase database (file name: Vecbase.Yep24) and a detailed restriction map can be found in the New England Biolabs catalog.

Figure 13.4.4 2 μ m plasmid. The 2 μ m circle is a naturally occurring DNA plasmid found in almost all strains of *S. cerevisiae*, with a copy number of ~20 to 80. The plasmid exists in two different forms, A and B (the former is shown above), due to intra-molecular recombination between two perfect 599-bp inverted repeats. Strains that carry this plasmid are called *cir⁺*; strains missing the plasmid *cir⁰* have been identified or isolated (see UNIT 13.9). It is extremely stable mitotically, with a spontaneous loss rate in haploid cells of 10^{-4} per generation; during meiosis the plasmid is transmitted to all four spore products. The plasmid has been completely sequenced (Hartley and Donelson, 1980) and the sequence is available from GenBank (Plant: yscplasm).

Figure 13.4.5 YCp50. This vector is a derivative of Ylp5 and YCp19. The *EcoRI* site of YCp19 was removed (producing an unsequenced deletion of about 190 bp) and a *PvuII-HindIII* fragment (containing *CEN4* and *ARS1*) from this derivative was cloned into the *PvuII* site of Ylp5, with loss of the *PvuII* site (Rose et al., 1987). Due to the presence of the *CEN* element, this plasmid exists in low copy in yeast (1 to 2 copies/cell) and is mitotically stable (<1% loss per cell per generation). This plasmid has not been completely sequenced; a more complete restriction map is available in Rose et al., 1987.

A set of genomic plasmid banks using YCp50 and size-selected DNA fragments has been constructed (Rose et al., 1987). These plasmid banks provide an alternative to genomic libraries constructed in high-copy-number vectors, useful when isolating genes that would be lethal in yeast when present in high copy.

Both the *CEN3* (Fig. 13.4.7) and *CEN4* (above) sequences were identified based on their ability to confer mitotic stability and proper meiotic segregation to autonomously replicating plasmids (Fitzgerald-Hayes et al., 1982; Mann and Davis, 1986). Nucleotide sequence comparison combined with functional analysis has shown that centromeres contain three conserved structural elements. Elements I and III show the highest degree of sequence conservation between different centromeres, and are separated by an extremely AT-rich region of about 90 bp, designated Element II. Full *CEN4* activity is contained within the 850-bp *PvuII-HpaI* fragment (which contains Elements I, II, and III), although the adjacent 905-bp *HpaI-EcoRI* fragment also confers some mitotic stability to unstable *ARS*-containing plasmids (Mann and Davis, 1986).

Figure 13.4.6 pYAC3. pYAC vectors are used to clone very large fragments of exogenous DNA onto artificial linear chromosomes, which can be stably maintained in yeast. This vector, which can be propagated as a circular plasmid in *E. coli*, contains a unique cloning site in the *SUP4* gene (an ochre-suppressing allele of a tyrosine tRNA), as well as *ARS1* and *CEN4* elements, required for stable single-copy propagation of the artificial chromosome. The TEL sequences are derived from *Tetrahymena* telomeres and have been shown to function as telomeres in yeast. To clone an insert, pYAC3 is digested with *Bam*HI (which cuts adjacent to the telomere sequences) and *Sna*BI; the resulting vector arms (containing either *TRP1*, *ARS1*, and *CEN4* or *URA3*) are ligated to insert fragments with *Sna*BI-compatible ends. The resulting ligation products are transformed into a *ura3*⁻ *trp1*⁻ *ade2-1* yeast strain, using the spheroplast protocol, selecting for Ura⁺ and subsequently screening for Trp⁺ (to insure that both vector arms are present). Transformants can be further screened for the presence of inserts in the middle of the *SUP4* gene by using a color assay: colonies in which the *ade2-1* ochre mutation is suppressed by *SUP4* are white, whereas inactivation of the suppressor results in red colonies.

The pYAC vector shown above is one of a collection of three plasmids, each with a different cloning site inserted into the *SUP4* gene: pYAC4 and pYAC5 contain *Eco*RI and *Not*I sites, respectively, in place of the *Sna*BI site found in pYAC3. Selected restriction sites (not necessarily unique) are shown for pYAC3, as well as sites that have been destroyed in the process of plasmid construction. The *SUP4* gene is shown as a wavy line. For more detailed discussion of the cloning protocol, as well as details of the construction of this vector, see Burke et al., 1987.

The *HIS3* gene encodes imidazoleglycerolphosphate (IGP) dehydratase, which catalyzes a step in the histidine biosynthetic pathway. This 1822-bp fragment also contains a portion of two other genes: *pet56*, required for mitochondrial function, and *ded1*, required for cell viability (Struhl, 1985). Mutations in the *hisB* gene of *E. coli* can be complemented by the cloned *HIS3* yeast gene, using *E. coli* BA1 (*thr1 leuB6 trpC1117 hisB463 Tn10::near hisB thi1 thyA hsr_k⁻ hsm_k⁻ str^r*; Murray et al., 1986).

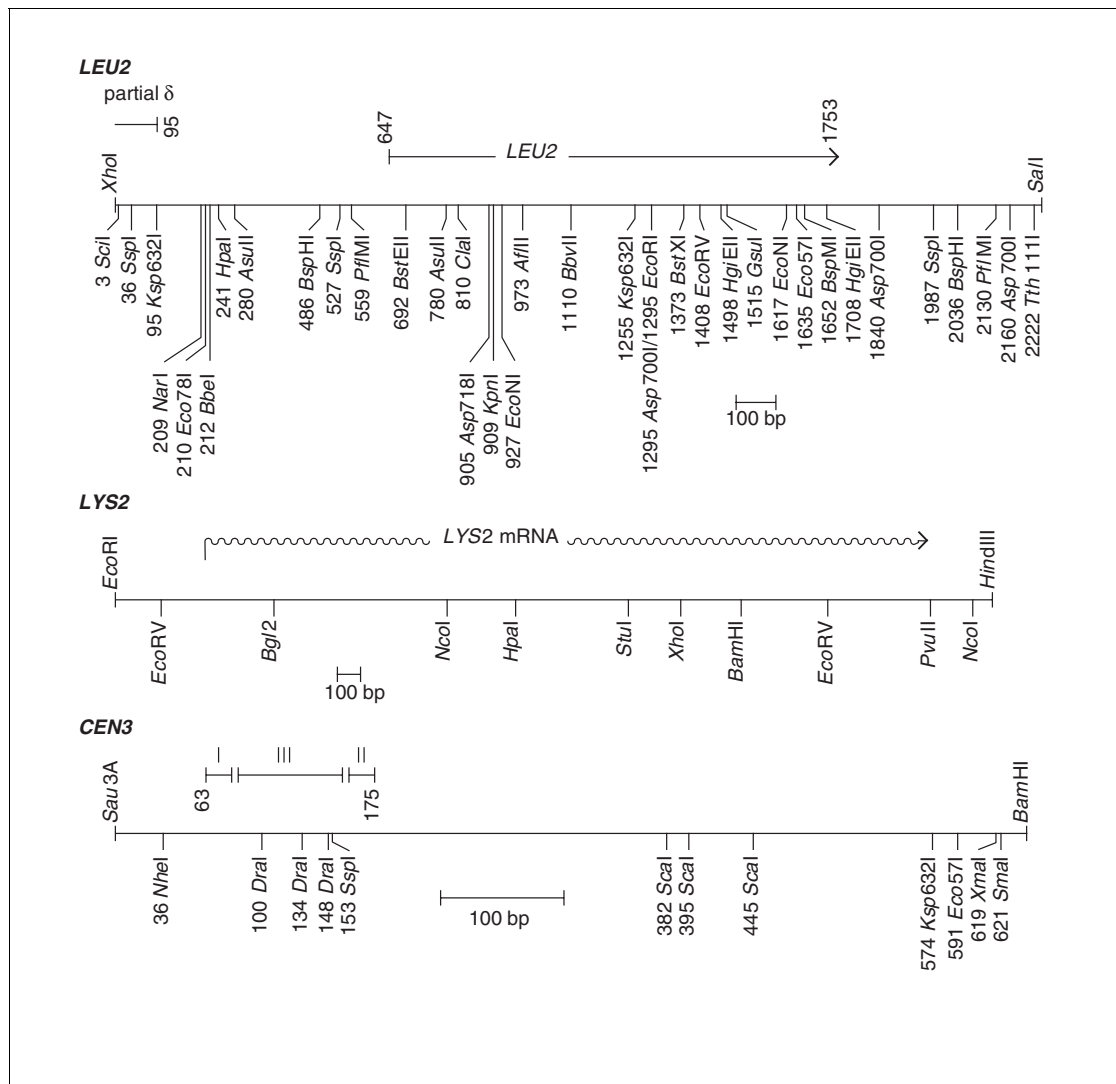

Figure 13.4.7 The *LEU2* gene encodes β -isopropylmalate (β -IPM) dehydrogenase, which catalyzes the third step in leucine biosynthesis (Andreadis et al., 1982). Unlike several other yeast genes involved in amino acid biosynthesis, *LEU2* (and *LEU1*, which is coordinately regulated with *LEU2*) is under specific amino acid control: gene expression is repressed by elevated concentrations of leucine. The *leu2-d* allele is a deletion of the 5'-flanking region of the *LEU2* message which leaves only 29 bp preceding the *LEU2* initiation codon; this derivative of the *LEU2* gene, when present on a YE_p plasmid, requires a very high plasmid copy number to give a Leu⁺ phenotype and has been used to cure cir⁺ strains of the endogenous 2 μ m plasmid (see *UNIT 13.9*). Also contained in this 2230-bp *XhoI-SalI* fragment are 95 bases of the 330-nucleotide δ element. Although this δ element diverges in sequence from other δ elements, when the entire 2230-bp fragment is used as a probe of genomic yeast DNA δ elements present elsewhere in the genome will be detected at a low level. The cloned *LEU2* gene can complement mutations in the *leuB6* gene of *E. coli* using the strain JA300 (*thr1 leuB6 thi1 thyA trpC1117 hsr_k⁻ hsm_k⁻ str^r*; Tschumper and Carbon, 1982).

The *LYS2* gene is the structural gene for α -amino adipate reductase, which catalyzes an essential step in lysine biosynthesis. The gene, which has not yet been sequenced, is present on a 4.6-kb *EcoRI-HindIII* genomic fragment, and gives rise to a 4.2-kb *LYS2* transcript, which is under general amino acid control (Eibel and Philippsen, 1983; Barnes and Thorner, 1986). Much larger genomic fragments (up to 15.7 kb) containing the *LYS2* gene have been isolated, providing a large variety of restriction sites flanking the gene for cloning purposes. As with *URA3*, a positive selection for *lys2⁻* mutants exists: such mutants can be selected on medium containing α -amino adipic acid and lysine, with a spontaneous frequency of 10⁻⁵ to 10⁻⁶. Because the pathways for lysine biosynthesis in bacteria and fungi are not the same, no *E. coli* mutations can be complemented by the cloned *LYS2* gene.

See the legend to Figure 13.4.5 for a discussion of *CEN3*.

Yeast Vectors and Assays for Expression of Cloned Genes

UNIT 13.6

CONSTRUCTION OF *LACZ* FUSION VECTORS FOR STUDYING YEAST GENE REGULATION

BASIC
PROTOCOL 1

The *lacZ* gene of *Escherichia coli* encodes the enzyme β -galactosidase, which hydrolyzes a variety of β -D-galactosides including chromogenic substrates (colorless compounds that yield a colored product when hydrolyzed). Because of the ease and sensitivity of the assays (see Basic Protocol 2 and see Alternate Protocol), yeast genes are often “tagged” with a functional portion of the *lacZ* gene in order to monitor the regulation of expression of the yeast gene in question. These fusions are constructed such that the promoter region of the yeast gene—plus several amino acids from the N terminus of the protein encoded by this gene—is fused to the carboxy-terminal region of the *lacZ* gene, which encodes a protein fragment that still retains β -galactosidase activity. The liquid β -galactosidase assay (see Basic Protocol 2) is sensitive and quantitative; it is used to accurately monitor gene expression. The filter assay (see Alternate Protocol) is less sensitive and provides only a qualitative assessment of β -galactosidase activity. However, the filter assay is particularly useful for simultaneously and rapidly analyzing a large number of yeast colonies.

When constructing *lacZ* fusions, it is crucial that the translational reading frame across the fusion junction is maintained. If the sequence of the yeast gene is known, an in-frame fusion can be engineered by choosing an appropriate fragment containing the promoter region of the yeast gene as well as the N terminus of the encoded protein. Although the same unique site preceding the *lacZ* fragment may not be present in the N terminus of the yeast gene (and if present, may not generate an in-frame fusion), ligation of flush ends (using another N-terminal restriction site) or the use of oligonucleotide linkers should result in an in-frame fusion. If the sequence of the yeast gene is not known, in-frame fusions can be identified empirically by assaying potential fusions for β -galactosidase activity in either *E. coli* or yeast. A more detailed discussion of construction of in-frame fusions can be found in Guarente (1983).

Figure 13.6.1 shows a vector, pLG670-Z, that can be used for constructing *lacZ* fusions (Guarente, 1983). This plasmid contains the 2 μ m origin of replication and *URA3* as a selectable marker in yeast, with a unique *Bam*HI site at the 5' end of the *lacZ* fragment (this fragment is actually itself a translational fusion of the *lacI* and *lacZ* genes, but for simplicity will be referred to as the *lacZ* fragment). Preceding the *Bam*HI site are unique *Xho*I, *Sa*II, and *Sma*I sites, which can aid in the insertion of various yeast fragments. The *Xho*I and *Sa*II sites are in a region of yeast DNA derived from the promoter region of the *CYC1* gene; however, a deletion of a portion of this promoter has inactivated it. The translational reading frame of the *lacZ* gene immediately following the *Bam*HI site is also shown in Figure 13.6.1.

Two other plasmids (pLG200 and pLG400)—containing different translational reading frames and/or different unique restriction sites at the 5' end of the *lacZ* fragment—have also been constructed (Guarente et al., 1980). These two plasmids do not contain yeast selectable genes or yeast replication origins but can be used to first construct an in-frame fusion, which is then transferred onto a yeast shuttle vector (UNIT 13.4).

Saccharomyces cerevisiae

13.6.1

Figure 13.6.1 pLG670-Z (derived from YEp24) contains the 2µm origin of replication, *URA3* as a selectable yeast gene, and a 3' fragment of the *lacZ* gene with a unique *Bam*HI site at the 5' end of the *lacZ* fragment. The sequence just after the *Bam*HI, as well as the translational reading frame, is shown.

**BASIC
PROTOCOL 2**

ASSAY FOR β-GALACTOSIDASE IN LIQUID CULTURES

This protocol describes a rapid, quantitative assay of β-galactosidase activity in liquid cultures of yeast. Yeast cells are either permeabilized or broken open, and the chromogenic substrate *o*-nitrophenyl-β-D-galactoside (ONPG) is added in excess. After incubation at 30°C, the reaction is stopped by raising the pH to 11, inactivating β-galactosidase. Product formation is determined spectrophotometrically.

Materials

- YPD or other appropriate medium (*UNIT 13.1*)
- Yeast strain containing *lacZ* fusion gene (see Basic Protocol 1)
- Appropriate inducing agent (optional)
- Z buffer (see recipe)
- 0.1% sodium dodecyl sulfate (SDS)
- Chloroform
- 4 mg/ml ONPG (Table 1.4.2) in 0.1 M potassium phosphate, pH 7.0 (*APPENDIX 2*;
filter sterilized and stored frozen)
- 1 M Na₂CO₃
- 30°C water bath

Grow and prepare the cells

1. Inoculate 5 ml YPD (or appropriate) medium with a single yeast colony. Grow two to three independent single-colony cultures of a yeast strain containing a *lacZ* fusion gene overnight at 30°C.

Assaying in duplicate or triplicate will help increase the accuracy. If the fusion is present on a plasmid, cells should be grown in medium that selects for the plasmid.

- Inoculate 5 ml YPD medium (or appropriate selective medium with or without inducing agent) with 20 to 50 μl of each overnight culture. Grow to mid- or late-log phase: $0.5\text{--}1 \times 10^8$ cells/ml ($\text{OD}_{600} = 2.0$) for rich medium or $2\text{--}5 \times 10^7$ cells/ml ($\text{OD}_{600} = 0.5$ to 1.0) for minimal medium.

If the goal is to investigate the activity of the yeast promoter under conditions that induce its expression, cells should be grown in parallel under inducing and noninducing conditions.

- Centrifuge cells 5 min at $1100 \times g$ (2500 rpm in a tabletop centrifuge). Resuspend in an equal volume of Z buffer and place on ice.

If the anticipated level of β -galactosidase activity is low, it may be necessary to concentrate the cells. For cells demonstrating 100 to 1000 U of activity within 30 min to 4 hr, concentration is not necessary.

- Determine OD_{600} for each sample.

If cells are in mid-log phase, no dilution is necessary to obtain an accurate OD reading; however, readings above 0.7 are inaccurate.

- Set up the following two reaction tubes for each sample (1 ml each), with mixing:
(a) 100 μl cells with 900 μl Z buffer and (b) 50 μl cells with 950 μl Z buffer.

- Add 1 drop of 0.1% SDS and 2 drops chloroform to each sample using a Pasteur pipet. Vortex 10 to 15 sec and equilibrate 15 min in a 30°C water bath.

The addition of SDS and chloroform permeabilizes the cells. Alternatively, break cells open using 0.5 g of acid-washed glass beads per sample (UNIT 13.12). Pellet the cell debris and measure β -galactosidase activity and total protein concentration of the lysate. Enzyme activity can then be normalized to protein concentration for calculating specific activity.

Assay for β -galactosidase

- Add 0.2 ml of 4 mg/ml ONPG and vortex 5 sec. Place in a 30°C water bath and begin timing.

- When a medium-yellow color has developed, stop the reaction by adding 0.5 ml of 1 M Na_2CO_3 and note the time.

For accuracy, the OD_{420} should be 0.3 to 0.7. With practice, the amount of color correlating with this OD reading can be recognized visually.

- Centrifuge cells 5 min at $1100 \times g$. Determine OD_{420} and OD_{550} of the supernatant.

If the cell debris has been well-pelleted, the OD_{550} —which measures light scattering by cell debris—is usually zero and therefore is not necessary to read.

- Calculate units with the following equation:

$$U = \frac{1000 \times [(\text{OD}_{420}) - (1.75 \times \text{OD}_{550})]}{(t) \times (v) \times (\text{OD}_{600})}$$

where t = time of reaction (min)

v = volume of culture used in assay (ml)

OD_{600} = cell density at the start of the assay

OD_{420} = combination of absorbance by *o*-nitrophenol
and light scattering by cell debris

OD_{550} = light scattering by cell debris.

Saccharomyces cerevisiae

13.6.3

SCREENING FOR β -GALACTOSIDASE-EXPRESSING YEAST COLONIES USING A FILTER LIFT ASSAY

This protocol (based on Durfee et al., 1993, and Staudinger et al., 1993) describes a relatively simple and rapid method for simultaneously analyzing a large number of yeast colonies for their ability to express β -galactosidase. This technique, based on a blue/white color assay of colonies immobilized on filters, is much less laborious than the conventional liquid assay for β -galactosidase (see Basic Protocol 2). This assay can be used to qualitatively measure the level of β -galactosidase expressed by individual yeast colonies based on the intensity of the blue color, but it is less sensitive and quantitative than the liquid β -galactosidase assay. The protocol is conveniently used as a secondary screen on potential two-hybrid positive colonies (UNIT 20.1) that have already come through a previous screening procedure or in genetic screens for mutations affecting the expression of a specific reporter construct.

Materials

Yeast strain containing *lacZ* fusion gene (see Basic Protocol 1)
Selective medium plates (UNIT 13.1)
Liquid nitrogen
Z buffer (see recipe)
20 mg/ml Xgal (Table 1.4.2) in dimethylformamide
30°C incubator
Circular nitrocellulose membrane filters
Whatman 3MM paper

1. Spot or streak yeast colonies onto a plate containing appropriate selective medium and allow to grow at 30°C until they reach optimal size (generally ~48 hr).

Assaying colonies in duplicate will increase the reliability of the results.

2. Place a circular nitrocellulose membrane filter on the plate and press it gently on the surface so that all the colonies are transferred to the membrane.

It is advisable to use reinforced nitrocellulose membranes for this procedure and treat them very gently, as they become extremely fragile when placed in liquid nitrogen.

3. Carefully peel off the membrane and place in liquid nitrogen.

To avoid shattering of the membrane, use a shallow dish containing just enough liquid nitrogen to cover the membrane.

4. Carefully remove the membrane from the liquid nitrogen container using an instrument such as a broad kitchen spatula. Place the membrane on a piece of dry Whatman paper and allow to thaw (<5 min) at room temperature.

5. Place a circular piece of Whatman 3MM paper (cut to fit) into a petri plate. Add 3 to 5 ml of Z buffer containing 1 mg/ml Xgal—enough liquid to soak the paper without flooding it. Place the thawed nitrocellulose membrane onto the Whatman paper and allow the buffer to absorb slowly into the membrane.

Flooding the Whatman 3MM paper will allow diffusion of the colonies and make the screening difficult to interpret.

6. Place the petri dish at 30°C and incubate a few minutes to overnight.

Strong positives should give a blue color after a few minutes of incubation time.

REAGENTS AND SOLUTIONS

Z buffer

- 16.1 g Na₂HPO₄·7H₂O (60 mM final)
 - 5.5 g NaH₂PO₄·H₂O (40 mM final)
 - 0.75 g KCl (10 mM final)
 - 0.246 g MgSO₄·7H₂O (1 mM final)
 - 2.7 ml 2-mercaptoethanol (50 mM final)
- Adjust to pH 7.0 and bring to 1 liter with H₂O. Do not autoclave.

COMMENTARY

Background Information

Cleavage of ONPG by β -galactosidase yields two products, galactose and *o*-nitrophenol. The *o*-nitrophenol product is yellow and can be detected by its absorption at 420 nm. Because ONPG is present in excess in this assay, the amount of *o*-nitrophenol produced is proportional to the amount of enzyme present. This assay is essentially that same as that used for *E. coli* (Miller, 1972).

Critical Parameters

Liquid assay. Always use exponentially growing cells and always normalize results by measuring *lacZ* activity from a control strain containing a previously characterized *lacZ* fusion protein that has been grown in parallel. Reproducibility between measurements taken on different days can be ensured by using the same volume of inoculum in step 2 of Basic Protocol 2 and growing cells to the same OD₆₀₀ each time. The length of the reaction should be from 30 min to 4 hr. Reaction times shorter or longer than this will affect the accuracy of the reaction. Adjust the reaction time by varying the amount of Z buffer used to resuspend the cells. If the fusion is present on a plasmid that is lost at a high frequency ($\geq 10\%$), the percentage of plasmid-bearing cells in the culture should be determined (in step 2) and a correction made in calculating units of β -galactosidase activity.

LacZ filter lift assay. Always use both positive and negative control strains in this assay. The positive control strain should give a strong blue color after a few minutes of incubation time. The negative control is especially important as this may turn a faint shade of blue depending on the strain background and the length of time of development.

Anticipated Results

Liquid assay. For a highly inducible fusion (such as a *GAL1* fusion) 5000 U can be observed, whereas other fusions (such as a *HIS3-lacZ* fusion) have only 1 to 3 U. In some cases, highly inducible fusions on high-copy-number plasmids (such as 2 μ m) may give values lower than expected, presumably due to precipitation of excess β -galactosidase present in the cell; to increase assay accuracy, it may be necessary to clone such fusions onto low-copy YCp vectors or into the yeast genome.

LacZ filter lift assay. A strong two-hybrid interaction strain should give a deep blue color after just a few minutes of development time. Weaker two-hybrid interaction strains may require up to several hours of incubation, and in this instance they should be carefully compared to the negative control to ensure that the color change is not due to strain background.

Time Considerations

For the liquid assay, once mid-log cultures are available, preparation of six samples will take ~45 min. The reaction time can vary between 30 min and 4 hr. Determining OD₄₂₀ and OD₅₅₀ and calculating units require 15 to 30 min. Once the yeast plates are grown, the filter lift assay takes 20 to 30 min followed by anywhere from 5 min to overnight for development, depending on the signal.

MANIPULATION OF YEAST GENES

Introduction of DNA into Yeast Cells

The most commonly used yeast transformation protocol is the lithium acetate procedure (basic protocol). It is reasonably fast and provides a transformation efficiency of 10^5 to 10^6 transformants/ μg . This efficiency rivals that achieved for most, but not all, strains with the more difficult and time-consuming spheroplast procedure (first alternate protocol). However, the fastest and easiest of the transformation methods is electroporation (second alternate protocol). For a number of strains, electroporation offers the highest transformation efficiency, and may prove especially useful with limiting quantities of transforming DNA. Unlike the lithium acetate procedure, however, electroporation saturates at low DNA levels, restricting its general utility.

NOTE: All solutions and glassware coming into contact with yeast cells must be sterile. Traces of soap on glassware may decrease the transformation efficiency. In addition, the water used for washes and in solution preparation must be of the highest quality; see reagents and solutions for guidelines.

TRANSFORMATION USING LITHIUM ACETATE

**BASIC
PROTOCOL**

The lithium acetate method is based on the fact that alkali cations make yeast competent to take up DNA. After yeast is briefly incubated in buffered lithium acetate, transforming DNA is introduced with carrier DNA. Addition of polyethylene glycol (PEG) and a heat shock trigger DNA uptake. The yeast are then plated on selective media.

Materials

- YPD medium (UNIT 13.1)
- Yeast strain to be transformed
- YPAD medium: YPD medium supplemented with 30 mg/liter adenine hemisulfate
- Highest-quality sterile H_2O
- 10 \times TE buffer, pH 7.5 (modify 1 \times recipe in APPENDIX 2), sterile
- 10 \times lithium acetate stock solution: 1 M lithium acetate, pH 7.5 (adjust pH with dilute acetic acid), filter sterilized
- DNA: high-molecular-weight, single-stranded carrier DNA (see support protocol) and transforming DNA
- 50% (w/v) PEG 4000 or 3350 (do not use PEG 8000), filter sterilized
- CM dropout plates (UNIT 13.1) prepared with Difco agar
- 30 $^\circ\text{C}$ incubator with shaker
- Sorvall GSA and SS-34 rotors (or equivalents)
- 42 $^\circ\text{C}$ water bath

Grow and prepare the yeast cells

1. Two days before the experiment, inoculate 5 ml YPD medium with a single yeast colony of the strain to be transformed. Grow overnight to saturation at 30 $^\circ\text{C}$.
The saturated overnight culture may, if desired, be prepared up to several weeks in advance of the transformation and stored at 4 $^\circ\text{C}$.
2. The night before transformation, inoculate a 1-liter sterile flask containing 300 ml YPAD medium with an appropriate amount of the saturated culture and grow overnight at 30 $^\circ\text{C}$ to 1×10^7 cells/ml ($\text{OD}_{600} \cong 0.3$ to 0.5, depending on strain). For 2- to 3-fold higher efficiency, dilute at this point to 2×10^6 cells/ml in fresh YPAD medium and grow for another 1 to 2 generations (2 to 4 hr).

*Saccharomyces
cerevisiae*

The presence of adenine in the medium produces a slightly higher transformation efficiency, especially with ade^- strains.

It is often difficult to know in advance how large an inoculum from the overnight culture will produce a density of 1×10^7 cells/ml at a reasonable time the next day. Because growth phase and cell density are important in achieving the highest transformation efficiency, the easiest approach is to inoculate three independent flasks with varying amounts of the saturated culture (try 1, 5, and 25 μ l for a 12-hr growth period), then check the OD_{600} of each flask the next day.

3. Harvest cells by centrifuging 5 min at $4000 \times g$ (5000 rpm in Sorvall GSA rotor), room temperature. Resuspend in 10 ml highest-quality sterile water.
4. Transfer to a smaller centrifuge tube and pellet cells by centrifuging 5 min at 5000 to $6000 \times g$ (7000 rpm in SS-34 rotor), room temperature.
5. Resuspend in 1.5 ml buffered lithium solution, freshly prepared as follows:
 - 1 vol 10 \times TE buffer, pH 7.5
 - 1 vol 10 \times lithium acetate stock solution
 - 8 vol sterile water.

Cells may be incubated ≤ 1 hr at 30°C before adding the transforming DNA (step 6), although this incubation is not required. In addition, the yeast may be stored ≤ 2 weeks at 4°C in this solution before proceeding with transformation. The transformation efficiency will be much lower, but suffices for routine introduction of plasmids.

Transform yeast cells

6. For each transformation, mix 200 μ g carrier DNA with ≤ 5 μ g transforming DNA in a sterile 1.5-ml microcentrifuge tube. Keep total volume of DNA ≤ 20 μ l.

This protocol will yield a linear increase in the number of yeast transformants with increasing input of transforming DNA over a large range (1 ng to 5 μ g).

Maximal transformation efficiency is achieved by repeating the denaturation cycle (boiling and chilling) of carrier DNA immediately prior to use.

7. Add 200 μ l yeast suspension to each microcentrifuge tube.

If the volume of DNA exceeds 20 μ l, add appropriate volumes of 10 \times lithium acetate stock solution and 10 \times TE buffer to prevent further ($>10\%$) dilution of the lithium acetate and TE concentrations.

8. Add 1.2 ml PEG solution, freshly prepared as follows:

- 8 vol 50% PEG
- 1 vol 10 \times TE buffer, pH 7.5
- 1 vol 10 \times lithium acetate stock solution.

Shake 30 min at 30°C .

9. Heat shock exactly 15 min at 42°C . Microcentrifuge 5 sec at room temperature.

Longer or shorter duration of the heat shock will decrease transformation efficiency.

10. Resuspend yeast in 200 μ l to 1 ml of 1 \times TE buffer (freshly prepared from 10 \times stock) and spread up to 200 μ l onto CM dropout plates made with Difco agar.

Difco agar gives 3-fold higher transformation efficiency than GIBCO/BRL agar.

11. Incubate at 30°C until transformants appear.

Transformants will be visible on the surface of the agar 2 to 5 days after transformation, depending on the strain, the plasmid, and the selection.

SPHEROPLAST TRANSFORMATION

This method is more time-consuming than the lithium procedure, but can result in a higher efficiency of transformation per input DNA. Thus, it is the preferred method when the DNA to be transformed is in limiting quantities or when a high efficiency of transformation is desirable—e.g., when screening a genomic plasmid bank.

Yeast cells are prepared for transformation by enzymatic digestion of the cell wall, followed by several gentle isotonic washes (to remove the digestive enzyme). DNA is mixed with the resulting spheroplasts and treated with a high-molecular-weight polymer, polyethylene glycol (PEG), to promote DNA uptake. After removal of the PEG, spheroplasts and DNA are resuspended in osmotically stable regeneration agar and are plated on appropriate selective plates.

Materials

YPD medium and plates (*UNIT 13.1*)
Yeast strain to be transformed
1 M sorbitol
2-mercaptoethanol (2-ME)
Glusulase (Du Pont NEN)
CaCl₂ solution
Sorbitol/CaCl₂ solution
DNA: transforming DNA and 5 mg/ml carrier DNA (sheared calf thymus or salmon sperm DNA; *UNIT 6.3*)
PEG/CaCl₂ solution
Selective regeneration agar
CM drop-out plates (*UNIT 13.1*)

30°C incubator with rotating platform
55°C water bath

NOTE: Before starting, melt selective regeneration agar (microwave at low setting), aliquot 10-ml samples into sterile glass test tubes, and place in a 55°C water bath.

Grow the yeast strain

1. Two days before the experiment, inoculate 5 ml YPD medium with a single yeast colony of the strain to be transformed. Grow overnight to saturation at 30°C (or lower temperature, if strain is temperature sensitive).
2. The night before transformation, inoculate a 250-ml sterile flask containing 50 ml YPD with an appropriate amount of the 5-ml culture and grow overnight to $1-2 \times 10^7$ cells/ml ($OD_{600} \cong 0.5$ to 1.0, depending on strain).

The frequency of transformation drops with cell densities higher than this. If the exact inoculum for a given strain is not known, it is best to inoculate three independent flasks with varying amounts of the saturated 5-ml overnight as described in step 2 of the basic protocol.

Prepare the spheroplasts

3. Pellet cells in a tabletop centrifuge 5 min at $1100 \times g$ (2500 rpm) and resuspend in 10 ml of 1 M sorbitol. Repeat.

These and subsequent spins/resuspensions can be performed at room temperature.

4. Pellet cells once more and resuspend in 5 ml of 1 M sorbitol. Make 10^{-5} dilution in sterile water and plate 0.1 ml onto a YPD plate. Incubate 2 days at 30°C.
5. Transfer resuspended cells to a 50-ml sterile flask and add 5 μ l 2-ME and 150 μ l glusulase. Incubate ~30 to 60 min at 30°C with very gentle shaking. Plate 0.1 ml of

ALTERNATE PROTOCOL

*Saccharomyces
cerevisiae*

13.7.3

a 10^{-3} dilution (made in sterile water) onto a YPD plate and incubate 2 days at 30°C.

The number of colonies that grow up on this plate can be compared to the number that grew on the plate from step 4 to calculate the percentage of spheroplast formation. Each new lot of glucanase and each new strain should be assayed for the percentage of spheroplast formation.

Spheroplast formation can also be monitored during the 30- to 60-min incubation with glucanase by observing the degree of lysis in water under a microscope (spheroplasts will lyse in a nonisotonic medium such as water, whereas intact yeast cells will not). At 15-min intervals, remove 10 μ l of the cells, place on a microscope slide, and cover with a cover slip. After focusing (at 240 \times to 400 \times magnification), gently touch a drop of water to the edge of the cover slip. As the water leaks under the cover slip, observe how many cells lyse. Spheroplasts should swell slightly before lysis; upon lysis, a “ghost” (membrane) should still be visible.

6. Transfer spheroplasts to a sterile 50-ml, round-bottom centrifuge tube and pellet in a tabletop centrifuge 4 min at 400 \times g (1500 rpm). Gently decant supernatant without dislodging pellet. Add 2 ml of 1 M sorbitol; resuspend pellet by gently swirling liquid across surface of pellet (which should easily come off the side of the tube).

DO NOT vortex or otherwise vigorously agitate spheroplasts. If pellet does not easily resuspend, reduce either the time or the rpm of subsequent spins.

7. Add 8 ml of 1 M sorbitol and pellet at 400 \times g. Repeat steps 6 and 7.
8. Repeat step 6, add 7 ml of 1 M sorbitol and 1 ml CaCl_2 solution, mix gently by swirling and centrifuge 4 min at 400 \times g.
9. Resuspend in 1 ml sorbitol/ CaCl_2 solution.

It has been reported that spheroplasts can be prepared and stored at -70°C in 1 M sorbitol/15% DMSO and subsequently rethawed for use, with about a 5- to 10-fold reduction in transformation efficiency (Orr-Weaver et al., 1983).

Transform the spheroplasts

10. Mix 150 to 200 μ l cells with the DNA to be transformed (up to 10 μ g) plus 10 μ l carrier DNA. Incubate 10 min at room temperature.

The total volume of added DNA should be no greater than $1/10$ the volume of the cells. For each transformation, it is advisable to mix an aliquot of cells with only carrier DNA, to monitor the frequency of reversion of the relevant mutation.

The amount of transforming DNA to be added depends on several parameters, including the frequency with which the strain can be transformed (determined experimentally) and the state of the DNA (fragments of DNA without replication origins will transform several orders of magnitude less efficiently than intact YEp, YRp or YCp plasmids—see UNIT 13.4).

11. Add a 10-fold volume of PEG/ CaCl_2 solution and thoroughly resuspend. Let sit 10 min at room temperature.
12. Pellet in tabletop centrifuge 4 min at 400 \times g and decant the PEG-containing supernatant.

Cells can also be plated in regeneration agar without removal of PEG, as long as the volume of PEG + cells is $1/10$ to $1/20$ the volume of regeneration agar added. The presence of PEG, however, will cause a decline in transformation frequency.

13. Gently resuspend pellet in 0.5 ml of sorbitol/ CaCl_2 solution and pipet into 10 ml melted regeneration agar tempered to 55°C. Vortex briefly to mix and immediately pour onto the appropriate CM dropout (selective) plate, swirling the plate to further mix cells and agar together.

The 3% agar will quickly solidify at temperatures <55°C, so it is important to plate each 10-ml aliquot as rapidly as possible.

14. Incubate at 30°C (or other appropriate temperature) until colonies appear, both on the surface of the regeneration agar overlay and embedded in the agar. Pick individual colonies and streak for single colonies on the same selective plates. If the purpose of this transformation was to disrupt genomic sequences (UNIT 13.10), make DNA from several transformants in order to analyze the relevant chromosomal region by Southern blot analysis (UNIT 13.11).

TRANSFORMATION BY ELECTROPORATION

Yeast cells are concentrated 1000-fold from a log-phase culture using multiple washes with sterile water to remove all extracellular ions. The concentrated cells are suspended in 1 M sorbitol for osmotic stabilization. DNA is introduced without carrier, and the cells are transformed using an exponential electric pulse delivered by an electroporation device. The transformed cells are spread on a selective agar plate containing 1 M sorbitol. For maximal efficiency, yeast may be incubated before concentration with DTT and lithium acetate to render the cell wall/membrane more permeable to DNA.

Additional Materials

- 1 M dithiothreitol (DTT; filter sterilize and store at –20°C)
- 1 M sorbitol
- Sorbitol selection plates
- Gene Pulser with Pulse Controller (Bio-Rad) *or* Cell-Porator (GIBCO/BRL)
- 0.2-cm-gap disposable electroporation cuvettes (Bio-Rad) *or* 0.15-cm-gap microelectroporation chambers (GIBCO/BRL); ice-cold

Grow and harvest the yeast cells

1. Two days before the experiment, inoculate 5 ml of YPD medium with a single yeast colony of the strain to be transformed. Grow overnight to saturation at 30°C.

The saturated overnight culture may be prepared up to several weeks in advance of the transformation and stored at 4°C.

2. The night before transformation, inoculate a 2-liter sterile flask containing 500 ml YPD with an appropriate amount of the saturated culture and grow overnight with vigorous shaking at 30°C to 1×10^8 cells/ml ($OD_{600} \cong 1.3$ to 1.5, depending on strain).

This cell density is achieved in mid- to late-log phase. It is often difficult to know how much inoculum from the overnight culture will produce a cell density of 1×10^8 cells/ml at a reasonable time the next day. If the exact inoculum for a given strain is not known, inoculate three independent flasks with varying amounts of the saturated culture as described in step 2 of the basic protocol.

3. Harvest culture by centrifuging at $4000 \times g$ (5000 rpm) 4°C, and resuspend vigorously in 80 ml sterile H₂O. To increase electrocompetence of the cells, proceed to step 4. If this treatment is not required, proceed to step 7.

The rotor, the exact speed, and the duration of centrifuge spins are not critical; the principal consideration is to centrifuge sufficiently hard (usually $\sim 4000 \times g$) to pellet all of the yeast, but not so hard as to make resuspension difficult. For large volumes, 5000 rpm in a Sorvall GSA rotor will suffice; for smaller volumes, 7000 rpm in a Sorvall SS-34 rotor is recommended. This and subsequent centrifugation steps should be conducted at 4°C.

ALTERNATE PROTOCOL

*Saccharomyces
cerevisiae*

13.7.5

Treat with lithium acetate and DTT to increase electrocompetence

This treatment is optional. It increases the handling time in preparing the yeast and should not be performed if the cells are to be frozen for subsequent use.

4. Add 10 ml of 10× TE buffer, pH 7.5. Swirl to mix.
5. Add 10 ml of 10× lithium acetate stock solution (see first basic protocol). Swirl to mix. Shake gently 45 min at 30°C.
6. Add 2.5 ml of 1 M DTT while swirling. Shake gently 15 min at 30°C.

This treatment increases the transformation efficiency >5-fold. Both lithium acetate and DTT, if used individually, will increase transformation efficiency. Used together, the improvement is approximately additive.

Concentrate and wash the yeast cells

7. Dilute yeast suspension to 500 ml with water.
8. Wash and concentrate the cells three times by centrifuging at 4000 to 6000 × g, resuspending the successive pellets as follows:
 - First pellet—250 ml ice-cold water
 - Second pellet—20 to 30 ml ice-cold 1 M sorbitol
 - Third pellet—0.5 ml ice-cold 1 M sorbitol.

Resuspension should be vigorous enough to completely dissociate each pellet. The final volume of resuspended yeast should be 1.0 to 1.5 ml and the final OD₆₀₀ should be ~200.

Yeast can be stored at -70°C for subsequent use by addition of glycerol to 15% (v/v) followed by freezing in a dry ice/ethanol bath. Frozen aliquots should be thawed slowly, pelleted in a sterile microcentrifuge tube, and resuspended to the same volume in 1 M sorbitol. The wash is necessary to remove ions liberated by lysis of some yeast cells. Transformation efficiency will drop ≥10-fold with freezing.

Electroporate the yeast cells

Using the Bio-Rad Gene Pulser:

- 9a. In a sterile, ice-cold 1.5-ml microcentrifuge tube, mix 40 µl concentrated yeast cells with ≤100 ng transforming DNA contained in ≤5 µl.

Transforming DNA should be in a low-ionic-strength buffer such as TE or in sterile high-quality water (see reagents and solutions). There is no required length of incubation; this time can be varied to convenience. Do not include carrier DNA in this procedure; it drastically reduces transformation efficiency. Maximal efficiency (transformants/µg) will be obtained with <10 ng of transforming DNA, while the largest number of transformants will be obtained with 100 ng. Using >100 ng will cause a precipitous drop in both transformation efficiency and the total number of transformants, with few colonies evident in transformation with 1 µg DNA.

- 10a. Transfer to an ice-cold 0.2-cm-gap disposable electroporation cuvette.
- 11a. Pulse at 1.5 kV, 25 µF, 200 Ω. It is crucial that the Bio-Rad Pulse Controller be included in the circuit; failure to do so will result in damage to the Gene Pulser.

The time constant reported by the Gene Pulser will vary from 4.2 to 4.9 msec. Times <4 msec or the presence of a current arc (evidenced by a spark and smoke) indicate that the conductance of the yeast/DNA mixture is too high.

- 12a. Add 1 ml ice-cold 1 M sorbitol to the cuvette and recover the yeast, with gentle mixing, using a sterile 9-inch Pasteur pipet.

- 13a. Spread aliquots of the yeast suspension directly on sorbitol selection plates. Incubate at 30°C until colonies appear.

Although there is a conflicting report (Lorow-Murray and Jessee, 1991), we find that the addition of sorbitol as an osmotic protectant to the agar increases survival of transformed yeast, yielding 10-fold higher transformation efficiency (Becker and Guarente, 1991).

Transformants will be visible on the agar surface 3 to 6 days after transformation, depending on the strain, the plasmid, and the selection. This is usually 1 day longer than with the lithium acetate procedure.

Using the BRL Cell-Porator:

- 9b. In a sterile, ice-cold 1.5-ml microcentrifuge tube, mix 20 μ l concentrated yeast with \leq 100 ng transforming DNA contained in \leq 5 μ l.

Incubation time can be varied for convenience (step 9a).

- 10b. Transfer to an ice-cold, 0.15-cm-gap micro-electroporation chamber.
- 11b. Pulse at 400V, 10 μ F, low resistance.
- 12b. Remove 10 μ l of electroporated mixture to a sterile 1.5-ml microcentrifuge tube containing 0.5 ml ice-cold 1 M sorbitol.
- 13b. Spread aliquots of the yeast suspension directly on sorbitol selection plates. Incubate at 30°C until colonies appear.

PREPARATION OF SINGLE-STRANDED HIGH-MOLECULAR-WEIGHT CARRIER DNA

SUPPORT PROTOCOL

Addition of denatured high-molecular-weight carrier DNA is critical to achieving high transformation efficiency using the lithium acetate protocol. Both parameters are crucial: the DNA must be single-stranded, and the larger the fragments, the better the transformation efficiency. Carrier DNA prepared according to this support protocol may also be used for spheroplast transformations, although single-stranded DNA has been reported to give a slightly lower transformation frequency than the more easily prepared double-stranded calf thymus or salmon sperm carrier DNA. (*NOTE:* Addition of this or any other carrier DNA during electroporation drastically reduces the efficiency of transformation.)

Materials

DNA (type III sodium salt from salmon testes; Sigma #D1626)

1 \times TE buffer, pH 8.0 (*APPENDIX 2*)

Buffered phenol (*UNIT 2.1*)

1:1 (v/v) phenol/chloroform

Chloroform

3 M sodium acetate, pH 5.2 (*APPENDIX 2*)

100% ethanol, ice-cold

Probe sonicator

Additional reagents and equipment for agarose gel electrophoresis (*UNIT 2.5*) and phenol extraction and ethanol precipitation of DNA (*UNIT 2.1*)

1. Dissolve DNA in 1 \times TE buffer, pH 8.0, to a final concentration of 10 mg/ml. Stir overnight at 4°C.

The solution of DNA will be extremely viscous.

Because the correct preparation of carrier DNA is crucial in achieving high transformation efficiency by the lithium acetate protocol, and because each individual transformation

*Saccharomyces
cerevisiae*

13.7.7

requires 200 μg , prepare a large amount (e.g., 1 g) and freeze aliquots at -20°C .

2. Sonicate using a large probe until viscosity appears to decrease slightly. Run 1 μg on a 0.8% agarose gel to determine size distribution of sonicated fragments. Repeat sonication as necessary to achieve the appropriate size distribution.

Each sonication should be brief— ~30 sec at 75% power (see UNIT 6.3 for guidelines on sonication of herring sperm DNA). The larger the fragments, the better the transformation efficiency will be, but the more viscous and unwieldy the solution. The optimum distribution of fragment size is that in which fragments range from 2 kb to 15 kb, with a mean size of ~7 kb.

3. Extract once with buffered phenol, once with phenol/chloroform, and once with chloroform.
4. Precipitate DNA with $\frac{1}{10}$ vol of 3 M sodium acetate, pH 5.2, and 2.5 vol ice-cold 100% ethanol.

With DNA of this size and at this concentration, the DNA will form flocculent masses immediately upon addition of the ethanol.

5. Resuspend pellet with $1\times$ TE buffer to 10 mg/ml final concentration.

Resuspension may require stirring overnight at 4°C .

6. Transfer carrier DNA to a Pyrex flask. Microwave to a rolling boil and continue to boil 2 to 3 min.
7. Chill flask rapidly in ice water. Aliquot and freeze DNA in sterile tubes at -20°C .

REAGENTS AND SOLUTIONS

CaCl₂ solution

0.1 M Tris-Cl, pH 7.4 (APPENDIX 2)

0.1 M CaCl₂

Autoclave or filter sterilize and store at room temperature

PEG/CaCl₂ solution

45% (w/v) PEG 3350

10 mM Tris-Cl, pH 7.4 (APPENDIX 2)

10 mM CaCl₂

Filter sterilize and store at room temperature

Selective regeneration agar

5 g ammonium sulfate

1.7 g yeast nitrogen base (without amino acids or ammonium sulfate)

20 g dextrose

30 g agar

1 pellet NaOH

1.3 g appropriate amino acid dropout powder (Table 13.1.1)

To above ingredients, add 500 ml of 2 M sorbitol, 20 ml YPD medium (UNIT 13.1), and 480 ml water. Mix well and autoclave 15 min in 2-liter flask. Aliquot 250-ml portions into 500-ml sterile bottles, using sterile technique. Store at room temperature or 4°C .

Sorbitol selection plates

Supplement CM dropout plates (UNIT 13.1) with sorbitol to 1 M final concentration. Sorbitol can be added as a powder prior to autoclaving. *NOTE:* Addition of sorbitol makes the agar more viscous and more prone to boiling over upon removal from the autoclave. Store at room temperature or 4°C .

Sorbitol/CaCl₂ solution

1 M sorbitol

10 mM Tris·Cl, pH 7.4 (*APPENDIX 2*)

10 mM CaCl₂

Filter sterilize or autoclave and store at room temperature

Water, high-quality and sterile

Water used in these protocols for washes and in solution preparation must be of the highest-possible quality (e.g., Millipore Milli-Q); the resistance must be at least as high as 10 MΩ/cm. Sterilize by autoclaving and store at room temperature.

COMMENTARY

Background Information

High-frequency transformation in yeast was first demonstrated using β-glucanase to remove the cell wall to generate spheroplasts (Beggs, 1978; Hinnen et al., 1978). The method has several major disadvantages. Of the procedures for transforming yeast, it is the most tedious and difficult. Yeast transformed by spheroplasting must be embedded in top agar to allow regeneration of the cell wall, which makes subsequent manipulations, such as replica plating or colony hybridization (*UNIT 13.2*), extremely difficult. In addition, the PEG treatment of spheroplasts often generates diploids and triploids by cell fusion. Nonetheless, spheroplast transformation has long remained a preferred approach for yeast transformation because it offered, until recently, the highest transformation efficiencies for most yeast strains.

More recent transformation protocols, such as that employing lithium acetate (Ito et al., 1983), do not require digestion of the cell wall and thus do not require regeneration in top agar—rather, transformants are plated on the agar surface. With lithium acetate transformation, competence for DNA uptake at the level of the cell wall is induced by treatment with lithium ions plus PEG. This procedure is easier and more rapid than spheroplasting. The finding that single-stranded, high-molecular-weight carrier DNA could increase transformation efficiency by one to two orders of magnitude (Schiestl and Gietz, 1989) has made lithium acetate transformation at least as efficient as spheroplast transformation. This modified lithium acetate procedure will likely replace spheroplast transformation for most strains.

The final and simplest approach is electroporation (Becker and Guarente, 1991). Yeast are harvested during log-phase growth, concentrated, and suspended in an osmotically stabi-

lizing medium with transforming DNA. A high-voltage electrical discharge through this suspension drives the DNA uptake. Electroporation can be extremely efficient, especially with small quantities of DNA (1 pg to 10 ng). When DNA quantities are limited, this may be the procedure of choice. Electroporation has several drawbacks, however. First, the expense of the electroporator apparatus may be prohibitive for some labs. Second, the efficiency of transformation is extremely strain-dependent. Third, the process saturates; increasing the input above 100 ng decreases the yield of transformants. Electroporation is inappropriate, therefore, for experiments that require maximizing the total number of transformants, such as screening genomic or cDNA expression libraries in yeast.

Critical Parameters

Transformation efficiency in all of these procedures depends on the yeast strain background. Lithium acetate transformation is least affected by strain variation, while electroporation is most affected. In the spheroplast method, strain-dependent variations in frequency may reflect differing sensitivities to glucanase. In electroporation, strain-dependent variations may reflect differing degrees of survival after the electric pulse. Since the response of a strain cannot be predicted a priori, strains known to transform at high efficiency should be used whenever possible. When strain selection is dictated by the particular experiment, all the protocols might have to be tested to determine which works best.

Maximal transformation efficiency in each of the procedures also depends on finding the optimal cell density. Each protocol lists the preferred starting density; strain differences may require empiric variation. The condition of the DNA has an effect as well; miniprep DNA prepared by either alkaline lysis or boil-

ing (UNIT 1.6) will transform adequately, but phenol extraction (UNIT 2.1) or purification by CsCl/ethidium bromide density gradients (UNIT 1.7) will further increase the efficiency.

In the lithium acetate protocol, the single most critical parameter is the carrier DNA. It must be of high-molecular-weight and completely denatured (Schiestl and Gietz, 1989). Denaturation can be assured by repeating the cycle of boiling and chilling immediately before use. Achieving the proper size distribution may be more difficult. If low efficiencies are obtained with several strains, another batch of carrier DNA should be prepared. In addition, using Difco agar to prepare the CM dropout plates increases the transformation efficiency.

In the spheroplast procedure, the most critical parameter is the handling of spheroplasts—vortexing, osmotic shock, or plating in regeneration agar at temperatures $>55^{\circ}\text{C}$ will reduce transformation frequency. For both the lithium and spheroplast protocols, transformation efficiency also depends on the batch of PEG used. If poor frequencies are obtained, several lots of PEG must be tested. Be certain to use PEG 3350, not PEG 8000.

In electroporation, the most important parameter after strain selection is the amount of transforming DNA used. Maximal efficiency (transformants/ μg) will be obtained with <10 ng of transforming DNA; the largest number of transformants will be obtained with 100 ng. Using more than 100 ng of plasmid or including carrier DNA will cause a precipitous drop in both transformation efficiency and total number of transformants. The electrical parameters are also important. With either of the exponential decay devices described, strain differences may require empiric variation of the initial voltage around the suggested value. For square-wave devices, see Meilhoc et al. (1990).

For all protocols, it is important that sterile technique be used throughout. Traces of soap on glassware may decrease the transformation efficiency.

Anticipated Results

Under optimal conditions, a circular plasmid (e.g., YCp or YEp; UNIT 13.4) should give 10^5 to 10^6 transformants/ μg DNA with the lithium acetate protocol, $\sim 10^4$ to 10^5 by spheroplasting, and $>10^5$ with electroporation ($>10^4$ transformants at 100 ng). With either linear molecules or circular molecules that do not

contain a yeast replication origin, stable transformation requires integration into the genome; transformation frequencies are correspondingly lower, with $\sim 10^2$ to 10^3 transformants/ μg DNA.

Time Considerations

Once the cells have reached the desired density, the lithium acetate protocol requires ~ 3 hr to complete, spheroplasting requires 3 to 4 hr, and electroporation can be completed in ~ 90 min. Because spheroplasts are metabolically active for up to 24 hr, the time spent washing the spheroplasts can be increased for convenience (e.g., each resuspension step can be left for an hour or more on a gently rocking platform).

Cloning Yeast Genes by Complementation

UNIT 13.8

**BASIC
PROTOCOL**

Yeast genes have been cloned by a variety of techniques, including use of purified RNA as hybridization probes, differential hybridization of regulated RNA transcripts, antibody screening, transposon mutagenesis, cross suppression of mutant phenotypes, cross hybridization with heterologous cDNA or oligonucleotide probes, as well as by complementation in *E. coli* (for reviews of these methods see Rothstein, 1985, or Rose, 1987). This unit presents a generalized protocol and describes the principles involved in cloning yeast genes by complementation in yeast.

The protocol is presented using a hypothetical mutation of yeast, the *cdc101-1* mutation. This mutation was isolated as a cell cycle mutant and is both recessive and temperature-sensitive for growth: it can grow relatively normally at 30°C but is unable to make a colony at 37°C. A genomic DNA clone that complements this mutation will be isolated by transforming the *cdc101-1* strain with a yeast genomic library and subsequently screening for temperature-resistant colonies. Once isolated, two steps are necessary to prove that the insert present on the plasmid contains the wild-type *CDC101* gene. First, segregation of the complementing plasmid must result in co-loss of both the plasmid-borne selectable marker and the complementing phenotype, demonstrating that the observed complementation is plasmid-specific and is not due to reversion of the *cdc101-1* mutation. Second, it must be ruled out whether the cloned gene encodes a phenotypic suppressor of the mutation, rather than the wild-type gene. This is done via a complementation test, which demonstrates whether or not a disruption of the cloned gene that is integrated into the genome can complement the original mutation.

Cloning the Gene

Transform a mutant yeast strain

1. Transform a *leu2⁻ cdc101-1* yeast strain with a yeast genomic DNA library containing *LEU2* as a selectable marker (using either protocol in UNIT 13.7) and selecting, in this case, for *Leu⁺*. Depending on the insert size, between 2,000 and 20,000 transformants must be screened (~4 to 8 genome equivalents).

If the mutation reverts at a very low frequency (<10⁻⁸), transformants that complement the mutant phenotype (in this case, temperature sensitivity) can be selected directly after transformation. However, if the mutation reverts at higher frequencies (or if the complementing phenotype cannot be directly selected), the mutation must be present in a strain that also contains a low or nonreverting mutation in the selectable gene present on the library vector.

Whenever possible, it is also preferable to have the mutation present in a strain that transforms well. If the mutation has been isolated in a strain that transforms poorly, alternate transformation protocols can be tested (see UNIT 13.7). Transformation proficiency can also be improved by backcrosses with a known strain that is more competent for transformation.

Screen for complementation of the mutant phenotype

2. Replica plate transformants onto prewarmed selective plates (leucine dropout plates; UNIT 13.1) and incubate at 37°C, to screen for complementation of the temperature-sensitive phenotype. With overnight incubation, colonies containing plasmids with inserts that complement the *cdc101-1* mutation, as well as potential *CDC101⁺* revertants that contain random noncomplementing plasmids, will grow up. Restreak each single colony that appears on this plate and save for further analysis.

*Saccharomyces
cerevisiae*

Supplement 5

Many mutant phenotypes, including *ts* phenotypes, cannot be distinguished by replica plating (presumably due to leakiness of the mutation). If this is the case, transformants must be recovered from the original transformation plate and replated directly on a second plate that screens for the mutant phenotype. If the lithium method of transformation is used, recover transformants by pipetting about 0.5 ml sterile water onto each plate and resuspending the individual colonies in the liquid by mashing about the plate with a sterile spreader (UNIT 1.3). Pipet the 0.5 ml back into a sterile tube and replate for single colonies onto the appropriate plate. If the spheroplast protocol is used, chop up the agar from each transformant plate (using a sterile spatula) and resuspend in 5 to 10 ml sterile water. Vortex extensively to further break up the agar (which releases the transformants into the liquid) and replate for single colonies.

If the mutation displays more than one phenotype, complementation of the additional phenotypes should also be tested. Complementation of some but not all of the mutant phenotypes indicates that the wild-type gene has not been cloned. However, such a complementation pattern suggests that a gene which performs a related function has been isolated.

Proof That the Correct Gene Has Been Cloned

Determine whether segregation of the complementing plasmid results in co-loss of both the plasmid-borne selectable marker and the complementing phenotype

3. Using the protocol described in UNIT 13.9, isolate Leu⁻ segregants for each candidate and test their ability to grow at 37°C. Save transformants that are only able to grow at 37°C in the presence of the plasmid.

If plasmid segregants can be isolated that still display “complementation,” this suggests that the complementation pattern is due to either reversion of the original mutation or acquisition of a suppressor mutation. Alternatively, if colonies are observed that still retain plasmid but are no longer complemented for the mutant phenotype, this indicates that the original transformant contained a mixed population of plasmids.

4. Isolate plasmid DNA from each transformant identified in step 3 by transforming total yeast DNA into *E. coli* (UNIT 13.11). Retransform each plasmid into the mutant yeast strain and confirm that the correct plasmid has been isolated (in our example, demonstrate that retransformation into a *cdc101-1* strain results in a temperature-resistant phenotype).
5. Analyze the plasmids by restriction mapping (UNIT 3.2) to determine whether genomic DNA inserts present in different plasmids have overlapping segments, which can help define the boundaries of the complementing region. Construction of various deletion and insertion mutations, and tests of their ability to complement the mutation in yeast, will provide more precise information about the location of the gene within the cloned insert.

Determine whether a disruption of the cloned gene that is integrated into the genome can complement the original mutation (complementation test)

The following steps are designed to test whether the cloned gene encodes a phenotypic suppressor of the mutation, rather than the wild-type gene.

6. Introduce a yeast selectable marker (UNIT 13.4) into a site in the middle of the complementing region (based on the information gained in step 5).
7. Transform this disrupted plasmid back into the original mutant strain and screen for the mutant phenotype to test whether complementation has been abolished as follows. Using one of several techniques discussed in UNIT 13.10, construct a diploid strain containing one wild-type copy of the gene and one disrupted copy of the gene. After sporulation and dissection (UNIT 13.2), cross a haploid spore product

containing the disruption (usually identified by the presence of the selectable marker associated with the disruption) is crossed to a strain carrying the original mutation (UNIT 13.2). If this diploid has the same mutant phenotype as the strain with the original mutation, this demonstrates lack of complementation and indicates that the wild-type gene corresponding to this mutation has been cloned. As a control, cross the strain with the gene disruption (which may itself display a non-wild-type phenotype) to a wild-type strain, in order to demonstrate that the phenotype of this diploid is wild-type (showing that the disruption is a recessive mutation).

Often, a genomic disruption of the cloned insert will have a mutant phenotype which is either similar to that of the original mutation or is a phenotype predicted for a null mutation in this gene. Although this is suggestive that the correct gene has been cloned, it does not constitute proof: a related gene may not only compensate for the original mutation when present on a plasmid, but may also give a similar phenotype when disrupted. Complementation, however, will demonstrate whether two different genes have been identified.

In the case of the hypothetical CDC101 gene, the cdc101-1 mutation is a ts lethal, indicating that this is an essential gene and that a haploid strain containing a disruption of the CDC101 gene would be inviable (techniques for determining whether this hypothesis is correct are presented in UNIT 13.10). For such an essential gene, the same complementation test described above can be performed, with one technical modification. Construct a plasmid-borne disruption of the insert region that complements cdc101-1, using URA3 as the selectable marker. Transform a ura3⁻/ura3⁻, leu2⁻/leu2⁻, diploid strain with this disruption (using techniques described in UNIT 13.10), selecting for Ura⁺. Now transform this heterozygous diploid with a LEU2 plasmid bearing an intact copy of the complementing region. After sporulation, identify a spore product that contains both the URA3 disruption and the LEU2 complementing plasmid. This strain can now be crossed to both a cdc101-1 strain and a control CDC101⁺ strain, the Leu⁺ plasmid segregated away (UNIT 13.9), and complementation (or lack of it) observed.

COMMENTARY

Cloning a gene by complementation in yeast requires not only a low-reverting recessive mutation in the gene of interest, but the appropriate yeast genomic DNA library. A number of yeast genomic libraries have been published and may be available (e.g., see Rose et al., 1987; Meeks-Wagner et al., 1986; Kuo and Campbell, 1983). The parameters to consider when selecting a preexisting library are the auxotrophic mutation(s) present in the strain of interest (which determines the selectable marker that must be present on the vector), whether the strain is cir⁺ or cir⁰ (libraries constructed in YEp plasmids are much less stable in cir⁰ strains; see UNIT 13.4), and the copy number of the vector (some genes, when present in high copy, are toxic to yeast). In some cases, it may be necessary to construct a yeast plasmid library *de novo*. This is the case when the only mutation available in yeast is dominant to the wild-type allele. Construction of a library from DNA isolated from the mutant strain will allow isolation of the mutant gene (by screening transformants of a wild-type strain for the mutant phenotype), from which the wild-type gene can be obtained by standard cloning techniques (UNITS 6.1 to 6.3). In addition,

some yeast genes have been demonstrated to be toxic when expressed in *E. coli*. Thus, preexisting yeast libraries which have been amplified through *E. coli* will be under-represented for plasmids containing these genes. This can be solved by constructing a library and transforming directly into yeast. A more detailed discussion of the issues involved in choosing a library, as well as a protocol for constructing a yeast genomic library, are presented in Rose, 1987 (see also Chapter 5).

Cloning yeast genes by complementation when the only available mutation is dominant presents special problems. As mentioned above, a genomic library must be constructed from the mutant strain. In addition, once a candidate gene has been isolated, if either the original mutation or a genomic disruption in this candidate gene are dominant, a complementation test cannot be used to prove that the correct gene has been cloned. In this case, another genetic test can be used to demonstrate tight genetic linkage between a selectable marker introduced at the chromosomal site of the cloned gene and the original mutation. In this test, a plasmid carrying the cloned gene as

well as a selectable marker are integrated into the genome of a wild-type haploid strain, using the technique of integrative transformation (UNIT 13.10). This haploid strain is crossed with a strain carrying the (dominant) mutation, and the subsequent diploid is sporulated and analyzed for the pattern of segregation of the mutation and the selectable marker associated with the integrated gene. If the cloned gene has integrated at the genetic locus corresponding to the original mutation, the selectable marker will always cosegregate with wild-type—i.e., spore products will never be recovered that display both the mutation and the selectable marker. If the cloned gene has integrated at another unlinked genetic locus, the selectable marker will segregate independently of the mutant/wild-type phenotypes, with approximately one-fourth of the spores containing both the mutation and the selectable marker (e.g., however, <25% of the spores will contain both markers if the cloned DNA has integrated at a site that is somewhat linked to the mutation). If tight genetic linkage can be demonstrated in this test, this provides evidence for the identity of the cloned piece of DNA. However, it is possible that a suppressor gene has been cloned that is tightly linked to the original mutant allele; such a possibility would not be ruled out by the above test.

Cloning of heterologous genes by complementation in yeast follows the same general principles presented in this section but requires a library of genomic DNA or cDNA from the relevant organism cloned into a vector that can be maintained in yeast. Although in some cases the heterologous gene can be expressed in yeast by its own promoter, in most cases the gene must be fused to a yeast promoter. Several heterologous libraries containing DNA from *S. pombe* (Beach et al., 1982) and *Drosophila* have already been constructed. Vectors for ex-

pression of genes in yeast that can be used for construction of heterologous libraries are discussed in UNIT 13.4. One principle that cannot be applied to cloned heterologous genes is the use of complementation (or linkage analysis, as described in the previous paragraph) to prove that the correct gene has been cloned. In these situations, evidence that the correct gene has been cloned may require comparison of nucleic acid and protein sequence between the two genes, as well as functional analysis (e.g., demonstrating that the two genes encode the same enzymatic function).

Manipulation of Plasmids from Yeast Cells

UNIT 13.9

This unit describes several procedures for manipulating plasmids in yeast cells. The first (see Basic Protocol 1) is a general method to segregate autonomously replicating plasmids from cells: plasmid-containing yeast cells are grown in nonselective medium, and colonies lacking the plasmid are identified by replica plating. The second, plasmid shuffling (see Basic Protocol 2), represents a specialized version of plasmid segregation that is useful for analyzing the function of essential genes and for identifying conditional lethal mutations in essential genes. This method involves introduction of a plasmid containing mutated versions of essential genes into a strain carrying the wild-type gene on a *URA3* plasmid followed by a genetic selection to remove the *URA3* plasmid. The genetic selection for plasmid loss permits the rapid analysis of many thousands of colonies. The third approach, plasmid gap repair (see Basic Protocol 3), is based on the efficient homologous recombination characteristics of yeast cells. Plasmid gap repair can be used as a method to incorporate mutagenized DNA fragments into a yeast plasmid, rescue genomic mutations onto plasmids, or map alleles of a given gene.

SEGREGATION OF PLASMIDS FROM YEAST CELLS

Most *E. coli* yeast shuttle vectors are lost at a frequency of ~1% when grown nonselectively. In this simple protocol, a plasmid-bearing yeast strain is grown nonselectively (to allow segregation of the plasmid) and plated for single colonies. Replica plating onto selective plates then permits identification of colonies that no longer contain the plasmid.

Materials

Plasmid-bearing yeast strain

YPD or other nonselective liquid medium and plates (UNIT 13.1)

CM dropout plates (UNIT 13.1)

Sterile velvets and replica block (UNITS 13.2 & 1.3)

Additional reagents and equipment for growth and manipulation of yeast (UNIT 13.2)

1. Inoculate several single colonies of a plasmid-bearing yeast strain into individual 10-ml aliquots of nonselective medium (UNIT 13.2) and grow overnight at 30°C.

If no other selection is necessary, YPD medium can be used. If, however, other unstable genetic markers or plasmids are to be retained, use defined medium supplemented with the nutrient corresponding to the selectable marker to be lost (e.g., when segregating a LEU2 plasmid, grow in medium supplemented with leucine).

2. Plate for single colonies (UNIT 13.2) on the corresponding nonselective plates and incubate 2 days at 30°C.

In most cases, ~200 to 300 single colonies should be examined (~100/plate).

3. Replica plate onto selective plates that will identify colonies which have lost the plasmid-borne selectable marker. Incubate both the selective plates and the nonselective master plate overnight at 30°C.

Those colonies that are present on the master plate but fail to grow on the selective plate have lost the plasmid.

**BASIC
PROTOCOL 1**

*Saccharomyces
cerevisiae*

PLASMID SHUFFLING

This technique (based on Boeke et al., 1987) provides a method of analyzing the function of essential genes as well as a rapid means for identifying conditional lethal mutations in an essential cloned gene carried on a plasmid (Fig. 13.9.1). In this system, the chromosomal copy of the essential gene is deleted or otherwise disrupted. Viability is maintained by the presence of a YEp plasmid carrying an intact copy of this essential gene, as well as the *URA3* gene. Introduction of a second plasmid carrying a temperature-sensitive copy of this gene can relieve selective pressure on the YEp plasmid at the permissive temperature, generating *Ura*⁻ derivatives due to loss of the YEp plasmid. However, at the nonpermissive temperature, the YEp plasmid cannot be lost and no *Ura*⁻ segregants are generated. Loss of this plasmid is assayed by replica plating single colonies onto 5-FOA plates grown at the permissive and nonpermissive temperatures. On these plates, *Ura*⁻ segregants appear as 5-FOA-resistant papillae. This replica plating technique allows a large number of mutagenized clones to be screened rapidly.

Materials

- YCp vector (UNIT 13.4) bearing a selectable marker other than *URA3*
- Dropout plates +Ura (UNIT 13.1)
- Plates with medium selective for YCp vector and containing 5-FOA (UNIT 13.1)
- YPD plates (UNIT 13.1)
- YIp5 vector (UNIT 13.4)

Additional reagents and equipment for cloning yeast genes by complementation (UNIT 13.8), subcloning (UNIT 3.16), mutagenesis (see Chapter 8), lithium acetate transformation (UNIT 13.7), replica plating (UNIT 13.2), yeast plasmid DNA preparation (UNIT 13.11), *E. coli* transformation (UNIT 1.8), and gene replacement by transplacement (UNIT 13.10)

1. Construct a haploid strain that contains a chromosomal disruption of the essential gene and a YEp or YCp plasmid carrying both the intact essential gene and *URA3* as a selectable marker (see UNIT 13.8 for a discussion of how to construct such a strain).

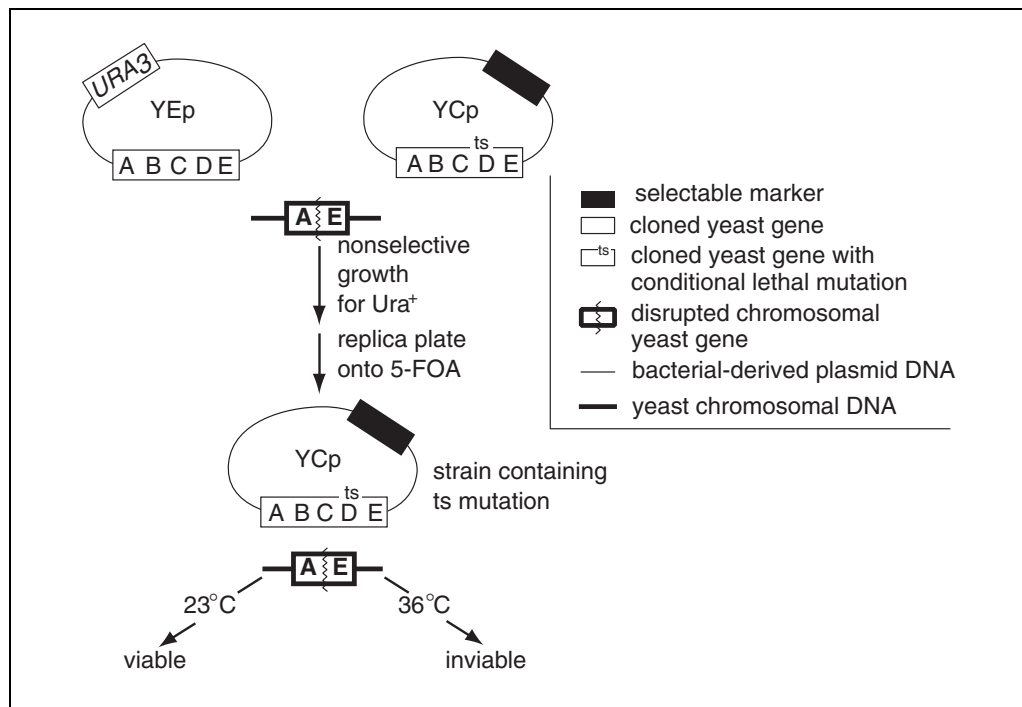

Figure 13.9.1 Plasmid shuffling is a rapid means of identifying conditional lethal mutations in an essential cloned gene carried on a plasmid (see accompanying text).

2. For mutagenesis, subclone (*UNIT 3.16*) the essential gene onto a YCp vector (bearing a selectable marker other than *URA3*) and mutagenize ~10 to 20 μg using hydroxylamine or other techniques (see Chapter 8). Alternatively, clone mutated derivatives of an essential gene into the YCp vector.
3. Transform into the strain from step 1 using lithium acetate (*UNIT 13.7*), selecting for the YCp plasmid on dropout plates that are supplemented with uracil. Incubate plates at the permissive temperature (usually 25°C).

This period of growth in the presence of uracil relieves selection for the YEp plasmid, such that in each transformant colony, a portion of the cells will have lost the plasmid (which carries the unmutagenized copy of the essential gene). However, note that any transformants carrying a null mutation in this gene on the YCp vector will be unable to lose the YEp vector.

4. Replica plate (*UNIT 13.2*) each transformation plate onto two plates that contain 5-FOA and that still maintain selection for the YCp vector. Incubate one plate at the permissive temperature and one plate at the nonpermissive temperature (usually 36°C). As a control, replica plate each transformation plate onto two YPD plates and incubate at the same two temperatures.

Replica plating distinguishes between different categories of transformants by determining whether a portion of the colony has lost the Ura^+ YEp plasmid: such Ura^- cells appear as 5-FOA⁺ papillae growing out of the background of the mostly Ura^+ replica. Transformants that carry an unmutagenized copy of the essential gene on the YCp vector will give Ura^- papillae at both temperatures, whereas transformants that contain a temperature-sensitive mutation in the YCp-borne essential gene will only produce Ura^- papillae at the permissive temperature. Those transformants containing a null mutation in this gene will not generate papillae at either temperature.

Yeast transformation is often somewhat mutagenic, introducing unlinked chromosomal mutations in the recipient. Discard all candidates that display a temperature-sensitive phenotype in the YPD control.

5. Recover from the transformation plate those colonies that gave Ura^- papillae at the permissive temperature but not at the nonpermissive temperature (and which grew normally at both temperatures on the YPD plates) and streak for single colonies.
6. Retest about six single colonies from each candidate for Ura^- papillation at the two temperatures.
7. For each candidate that retests as a temperature-sensitive mutation in step 6, recover Ura^- papillae from the permissive temperature 5-FOA plate (by streaking out papillae on a separate plate that maintains selection for the YCp vector). Recover plasmid from these strains (which now contain only the YCp vector) by isolation of the plasmid (*UNIT 13.11*) followed by transformation into *E. coli* (*UNIT 1.8*).
8. Subclone (*UNIT 3.16*) the gene (now carrying a temperature-sensitive mutation) onto a YIp5 vector, and introduce this mutagenized gene into its chromosomal site using the transplacement technique described in *UNIT 13.10*.

**PLASMID GAP REPAIR FOR LOCALIZED MUTAGENESIS AND
ALLELE REPAIR**

This gap repair technique protocol is useful for several purposes. First, it can be used as a method of localized mutagenesis in which a mutagenized DNA fragment (typically obtained by PCR; *UNIT 15.1*) can be incorporated into a desired DNA molecule in yeast cells (Muhlrad et al., 1992). Second, it can be used to introduce a mutation at a specific position using a mutagenic PCR primer (Brenner et al., 1994). Third, it can be used to rescue genomic mutations onto a plasmid-borne copy of the same gene for subsequent analysis. Fourth, it can be used to map multiple alleles of a given gene. In all of these cases, a gene conversion event initiated by the gapped molecule rescues the introduced DNA fragment or the chromosomal locus covered by the gapped region; this results in yeast strains with autonomously replicating plasmids containing the mutagenized DNA fragment or chromosomal locus of interest (Fig. 13.9.2). The resulting yeast strains can be directly analyzed for a mutant phenotype, and the plasmids can be rescued and analyzed.

Materials

- YRp or YCp plasmid (*UNIT 13.4*) with selectable marker
- Appropriate restriction enzyme(s) (*UNIT 3.1*)
- Yeast strain with mutation corresponding to selectable marker
- Plates with medium selective for the plasmid marker

Additional reagents and equipment for subcloning (*UNIT 3.16*), PCR (*UNIT 15.1*), yeast transformation (*UNIT 13.7*), growth and manipulation of yeast (*UNIT 13.2*), and plasmid segregation (*UNIT 13.9*)

1. Subclone (*UNIT 3.16*) the gene of interest into a YRp or YCp plasmid with an appropriate selectable marker.
2. Gap the plasmid by cutting at two restriction enzyme sites. Gel purify the resulting plasmid fragment.

An overlap of ~200 bp on either side of the gap is often used, although as few as 40 bp will be sufficient.

For introducing a mutation at a specific position, the plasmid may also simply be linearized rather than gapped; however, contamination with uncut plasmid must be avoided. The gap or cut must be as close as possible to the mutated site to ensure a high frequency of recovery of the mutation.

Figure 13.9.2 Plasmid gap repair rescues genomic DNA mutations onto a plasmid-borne copy of the gene (see accompanying text).

3. For mutagenesis applications, prepare the desired mutagenized fragment by PCR (UNIT 15.1). For recovering or mapping chromosomal alleles, proceed to step 4.

A mutagenic PCR reaction using Taq DNA polymerase will introduce mutations at random positions; mutations at a specific position can be made using a mutagenic primer.

4. Co-transform (UNIT 13.7) 1 µg of gapped plasmid and the PCR-generated fragment into a yeast strain with appropriate markers. If using gap repair to rescue the genomic allele, transform with gapped plasmid alone.

Although it is not essential, a 5-fold molar excess of insert is often used.

To ensure that recombination occurs only between the gapped plasmid and the PCR insert, it is preferable to use a yeast strain deleted for the genomic locus. However, the method will work even if the genomic locus is present, although a background of undesired recombination events will arise.

5. Identify successful repair events by plating transformants onto medium selective for the plasmid marker (UNIT 13.2). For recovering or mapping chromosomal alleles, identify transformants that are unstable for the selectable marker using the plasmid segregation technique (UNIT 13.9).

When a mutation is located within the gap, it will be carried on the repaired plasmid. However if it is next to the gap, the outcome will depend on where the cross-over occurs. The farther the mutation is from the gapped region, the lower will be the proportion of plasmids containing the mutation.

6. If using this as a scheme for PCR-based mutagenesis, screen these transformants for the desired mutant phenotype.

*The plasmid can be isolated from yeast (UNIT 13.11) and transformed into *E. coli* (UNIT 1.8) for subsequent analysis.*

COMMENTARY

Background Information

Techniques for segregating plasmids from yeast are useful in several experimental situations. For example, after a plasmid containing a DNA sequence that complements a yeast mutation has been isolated, it is necessary to determine whether complementation is due to sequences present on the plasmid (UNIT 13.8). This is achieved by demonstrating that the complementation phenotype is lost following segregation of the plasmid.

Plasmid shuffling is a specialized version of plasmid segregation which is particularly useful for the analysis or mutagenesis of genes that are essential for cell growth and viability. The manipulation of such essential genes is complicated by the obvious fact that cells containing mutated versions of such genes cannot be propagated. Plasmid shuffling circumvents this problem by generating a yeast strain in which the sole copy of an essential gene is present on a *URA3*-marked plasmid—i.e., the chromosomal copy of the essential gene is deleted. This strain is transformed by a second plasmid (which carries a different marker) containing a

mutated version of the essential yeast gene (carried on a plasmid with a different marker), whereupon the *URA3* plasmid carrying the wild-type genes is eliminated (shuffled out) by replica plating the cells on 5-FOA. This procedure efficiently generates yeast cells that contain only the plasmid with the mutated copy of the essential gene. If the mutated gene is sufficiently functional to support cell growth, the colonies can be examined under a variety of conditions (e.g., low or high temperature). Alternatively, if the mutated gene is nonfunctional, colonies will not arise on the plates containing 5-FOA.

Although yeast plasmids replicate autonomously from chromosomal DNA, the plasmid and chromosomal DNAs are similar in virtually all respects. For this reason, efficient homologous recombination occurs between plasmids and chromosomes, thereby permitting a number of useful genetic manipulations. In particular, the ends of linearized plasmids can recombine efficiently with introduced DNA fragments or with chromosomal DNA in a process called plasmid gap repair. This process permits

Saccharomyces cerevisiae

13.9.5

one to incorporate DNA fragments (either wild-type or mutagenized) or genomic alleles into autonomously replicating plasmids without using standard cloning methods. It is particularly useful for localized mutagenesis, rescuing genomic mutations, and genetic mapping (see Basic Protocol 2).

Manipulation of Cloned Yeast DNA

A major advantage of working with yeast is the ability to replace the wild-type chromosomal copy of a gene with a mutant derivative that is constructed *in vitro* using a cloned copy of the gene. This technique—unavailable in most other eukaryotes—allows the phenotype of the mutation to be studied under accurate *in vivo* conditions, with the mutation present in single copy at its normal chromosomal location.

Once a cloned gene has been obtained (see UNIT 13.8), there are a variety of techniques available for introducing a mutant derivative into its corresponding chromosomal site. All of these methods rely on homologous recombination between the transforming DNA and the yeast genomic sequences. If the gene has been cloned by complementation, several of these techniques can be used to demonstrate that the cloned gene corresponds to the gene defined by the mutation (UNIT 13.8). Gene replacement techniques also allow analysis of partial or complete gene deletions, which can be introduced into the genome to determine the null phenotype. In addition, once a cloned gene is available, previously identified mutant alleles can be recovered via the technique of plasmid gap repair (UNIT 13.9). Gene replacement techniques also allow the creation of modified genes that are regulated by a desirable (usually inducible) promoter. A specialized version of these methods permits a general approach for generating conditional alleles by a copper-inducible double shutoff.

INTEGRATIVE TRANSFORMATION

In the steps presented below (based on the procedure described by Hinnen et al., 1978), a YIp plasmid (UNIT 13.4) harboring both a selectable marker and a cloned gene of interest is integrated at the chromosomal location of the cloned gene via homologous recombination. The resulting integrant contains the entire plasmid, bracketed by intact copies of the gene (see Fig. 13.10.1). In the case of cloned genes for which no mutations have been identified (or where identified mutations have a phenotype that is difficult to score), the integrated plasmid can be used as a genetic marker—by virtue of the presence of the selectable gene—for mapping and other genetic studies. Integrative transformation of a cloned gene can also be used to demonstrate genetic linkage to the mutation used to clone the gene, providing evidence that the cloned DNA is the corresponding wild-type gene (discussed in the commentary in UNIT 13.8). It is important to note that this method introduces a selectable marker at the genomic site of the cloned gene but does not disrupt the copy of the duplicated gene. Often, multiple tandem integrations can occur, which can

BASIC PROTOCOL 1

Figure 13.10.1 Integrative transformation introduces a selectable marker at the chromosomal site of a cloned gene, via integration of the entire plasmid (see accompanying text).

Saccharomyces cerevisiae

be identified by isolating genomic DNA and performing Southern blot analysis (UNITS 13.11, 2.9 & 2.10). In addition, these integrants are unstable and are lost at a frequency of ~1% per generation when grown nonselectively.

Although the frequency of integrative transformation is low, it can be increased by linearizing the plasmid at a restriction site within the cloned gene that is homologous to the intended site of integration. Linearization also directs, or targets, the recombination event to the chromosomal homologue of the cloned gene: without a double-strand break in the cloned gene, the plasmid will integrate at the chromosomal site of either the selectable gene or the cloned gene, at about equal frequencies. In Figure 13.10.1, the dashed line indicates the region in which a double-strand break should be introduced.

Materials

YIp shuttle vector (UNIT 13.4)

Appropriate restriction enzyme (UNIT 3.1)

Purified DNA from gene of interest

Carrier DNA

Selective medium (UNIT 13.1)

Additional reagents and equipment for subcloning (UNIT 3.16), yeast transformation (UNIT 13.7), yeast genomic DNA isolation (UNIT 13.11), and Southern blotting (UNITS 2.9 & 2.10) or PCR (UNIT 15.1)

1. Subclone (UNIT 3.16) the gene to be studied into a YIp vector.
2. Linearize the plasmid with a restriction enzyme that cuts within the cloned gene.

As long as no other DNA is being cotransformed, it is not necessary to inactivate the restriction enzyme prior to transformation. If a unique restriction site is not available, digestion with one or more enzymes to produce a gap in this region is also acceptable, as long as sufficient homology is present on either side of the gap (>250 bp).

3. Transform an appropriately marked strain with 1 to 10 µg DNA plus carrier DNA (UNIT 13.7), selecting for the marker present on the plasmid.
4. Purify several transformants on selective medium and isolate genomic DNA (UNIT 13.11). Confirm by Southern hybridization (UNITS 2.9 & 2.10) or PCR (UNIT 15.1) that the integration has occurred at the desired genomic site and determine whether multiple integrations have occurred.

GENE REPLACEMENT TECHNIQUES

The four methods described below provide a means of constructing a mutation in vitro in a cloned gene and reintroducing this mutation at the correct chromosomal site. This allows assessment of the genetic consequences of a mutation, and is often used to determine whether or not a gene is essential (by determining if a complete gene deletion is viable). Two of these techniques—integrative disruption and one-step gene disruption—generate either insertion or deletion mutations. The third technique—transplacement—is more generally applicable: it can be used to introduce insertion or deletion mutations containing a selectable marker, but it can also be used to introduce nonselectable mutations, such as conditional lethal mutations in an essential gene.

In each of these procedures, if the goal is to examine whether or not a null mutation is viable, a diploid strain should be transformed with the appropriate DNA construct. This allows a potentially lethal mutation to be complemented by the wild-type allele on the other chromosome. After transformation, the diploid is examined by Southern blot analysis to confirm that there is one wild-type and one disrupted copy of the gene.

Figure 13.10.2 Integrative disruption introduces a selectable marker at the chromosomal site of a cloned gene and simultaneously generates either a 3' or 5' deletion in the two copies of the gene that bracket the plasmid (see accompanying text).

Subsequent sporulation and tetrad dissection (*UNIT 13.2*) will reveal whether the disruption is viable. Disruption of an essential gene should result in a ratio of $2^+ : 2^-$ (2 live spores:2 dead spores) in the tetrad analysis; in addition, if a selectable marker (e.g., *URA3*) is associated with the disruption, all viable spores should be auxotrophic for this marker (e.g., *Ura*⁻).

Integrative Disruption

This technique (first described by Shortle et al., 1982) generates a deletion in the chromosomal copy of a cloned gene. An internal fragment of a cloned gene is introduced into the chromosome on an integrating plasmid. As shown in Figure 13.10.2, this generates a gene duplication (which brackets the integrated plasmid), but neither copy of the gene consists of an intact copy: one copy is missing the 3' end of the gene and one copy is missing the 5' end. The procedure is the same as for integrative transformation, with two exceptions: (1) the starting YIp plasmid, instead of containing an intact gene, contains a completely internal fragment of the cloned gene, and (2) the strain to be transformed should be diploid, as explained above.

Two limitations of this technique are that a knowledge of the 5' and 3' boundaries of the coding region of the gene is required and the size of the subcloned fragment must be at least 250 bp, to promote efficient recombination. However, the disruption can be constructed in one step, without requiring an insertion or insertion/deletion mutation in the cloned gene, and a selectable phenotype (from the selectable marker on the integrated YIp plasmid) is associated with the disruption. Like integrative transformation, the integrants are unstable when grown nonselectively, and multiple integration events can occur. In addition, linearization of the plasmid increases the frequency of transformation, as well as targets the integration to the desired site.

Materials

- YIp shuttle vector (*UNIT 13.4*)
- Purified DNA from gene of interest
- Appropriate restriction enzyme (*UNIT 3.1*)
- Additional reagents and equipment for subcloning (*UNIT 3.16*) and integrative transformation (see Basic Protocol 1)

1. Subclone (*UNIT 3.16*) an internal fragment of the gene into a YIp vector.
2. Linearize the plasmid within this internal fragment by restriction enzyme digestion.

BASIC PROTOCOL 2

Saccharomyces cerevisiae

13.10.3

Figure 13.10.3 One-step gene disruption recombines a fragment of DNA containing a cloned gene—disrupted by the insertion of a selectable marker—into the chromosomal site of the same gene (see accompanying text). **(A)** No portion of the cloned gene fragment is deleted. **(B)** Sequences BCD are removed from the cloned gene fragment.

3. Continue with transformation and analysis of transformants as for integrative transformation (see Basic Protocol 1, steps 3 and 4).

BASIC PROTOCOL 3

One-Step Gene Disruption

Like integrative disruption, this method (from Rothstein, 1983) generates a gene disruption in one step via transformation, using a fragment of DNA containing a cloned gene that is disrupted by a selectable genetic marker. Homologous recombination between the free DNA ends, which are highly recombinogenic, and homologous sequences in the yeast genome results in replacement of the wild-type gene by the disrupted copy (see Fig. 13.10.3). The disrupted gene can contain either a simple insertion (of the selectable marker) or a deletion/insertion mutation. Introduction of these disruptions into the genome can be achieved in a single step, resulting in stable, nonreverting mutations.

Materials

- Purified DNA from gene of interest
- Purified DNA from a selectable gene
- Appropriate restriction enzyme (*UNIT 3.1*)
- Appropriate yeast strain (e.g., Table 13.10.2)

Additional reagents and equipment for subcloning (*UNIT 3.16*), gel purification of DNA (*UNIT 2.6*), yeast transformation (*UNIT 13.7*), yeast plasmid DNA isolation (*UNIT 13.11*), Southern blotting (*UNITS 2.9 & 2.10*) or PCR (*UNIT 15.1*), and tetrad analysis (*UNIT 13.2*; optional)

1. Subclone (*UNIT 3.16*) a suitable selectable gene into the gene of interest, creating in the process of subcloning a deletion as well, if desired.

Insertion mutations into the cloned gene can also be generated in vivo in E. coli by transposon mutagenesis. Several transposons have been designed with selectable markers in E. coli and yeast (Seifert et al., 1986; Huisman et al., 1987).

2. Using appropriate restriction sites, excise a linear fragment that contains the disrupted gene from the plasmid constructed in step 1 and gel-purify (*UNIT 2.6*).

Small amounts of vector sequences (≤ 200 bp) can be retained on this fragment without deleterious effects. Ideally, at least 250 bp of the cloned gene should bracket either side of the inserted selectable gene, to promote recombination at the chromosomal locus of the cloned gene, rather than at the site of the selectable marker.

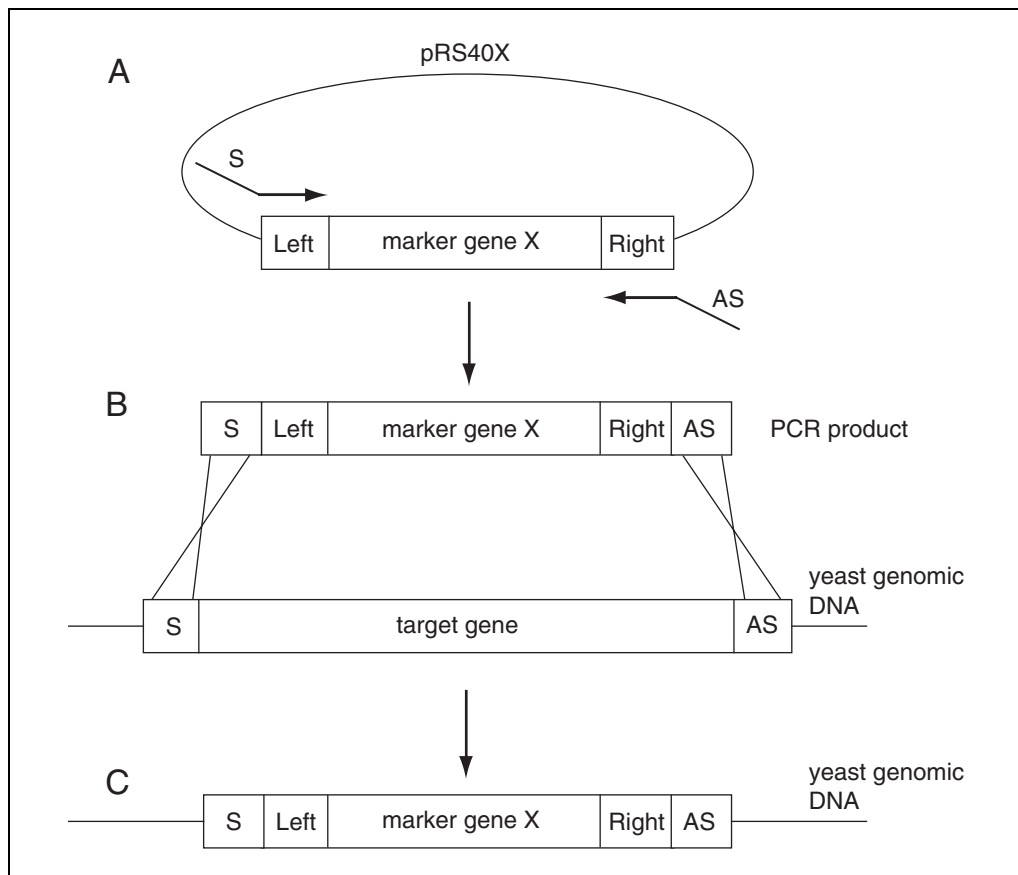

Figure 13.10.4 PCR mediated one-step gene disruption. **(A)** The one-step gene-disruption cassette is generated by PCR amplification of marker gene X using primers whose 3' ends are derived from the sequences Left and Right found in all pRS40X series vectors. The 5' 40 nucleotides of these primers are derived from sequences S (sense strand) and AS (anti-sense strand), which flank the open reading frame of the target gene. **(B)** When transformed into yeast, the gene-disruption cassette can replace the target gene by recombination between the homologous sequences S and AS. **(C)** Recombinants can be identified by selection for expression of gene X and confirmed by subsequent PCR or Southern blot analysis of the target gene locus in the transformants.

3. Transform yeast with 1 to 10 μg of the gel-purified fragment (*UNIT 13.7*), selecting for the inserted marker.
4. Confirm the structure of the disruption isolation of genomic DNA (*UNIT 13.11*) followed by Southern hybridization (*UNITS 2.9 & 2.10*) or PCR (*UNIT 15.1*). If a diploid was transformed, sporulate and dissect (*UNIT 13.2*) to obtain haploid spore products with the disruption (or to observe inviability).

PCR-Mediated One-Step Gene Disruption

One-step gene disruption (first described by Baudin, 1993) is a simple and powerful technique for removal of specific DNA sequences from the yeast genome. A gene disruption cassette is constructed that consists of a selectable marker flanked by sequences derived from the 5' and 3' ends of the target gene to be detected. When this linear DNA fragment is transformed into yeast, homologous recombination between the identical sequences flanking the marker and target genes results in replacement of the target gene by the marker gene. In the past, this method suffered from the drawback that a plasmid carrying the gene disruption cassette had to be constructed before it could be carried out. Often, suitable restriction sites near the 5' and 3' ends of the ORF of the target gene were not available, making complete deletion of the ORF difficult or impractical. This draw-

^aMany other suitable strains are available from the ATCC (strains 200866 to 200902). A recipient diploid can be made by mating BY4736 and BY4727 and selecting for Ade⁺ Leu⁺ Lys⁺ colonies.

back can be overcome by using PCR to create the gene disruption cassette (see Fig. 13.10.4). Because only very small regions of homology between DNA sequences are required to direct homologous recombination in yeast, PCR primers that will amplify the desired auxotrophic marker flanked by 30 to 40 nucleotides of homology to the target gene can be used to create the gene disruption cassette. The efficiency of this technique depends upon two factors. First, the homology of the PCR product to the target gene should be as long as possible, typically 40 nucleotides. Second, this technique works best if the sequences encoding the auxotrophic marker gene have been completely deleted from the yeast genome, thus minimizing the chances for homologous recombination elsewhere in the genome. A set of convenient auxotrophic markers and plasmids for this technique are shown in Table 13.10.1. Yeast strains carrying different combinations of these markers (see Brachman et al., 1997) are available from the ATCC (strains 200866 to 200902); some suggested strains are described in Table 13.10.2. Using the pRS40X series of vectors as the template for PCR, one set of PCR primers is sufficient to make a gene knockout marked by any one of the six different auxotrophic markers listed in Table 13.10.1.

Materials

- 10× PCR buffer (e.g., as supplied with *Taq* DNA polymerase from Boehringer Mannheim)
- 100 mM Tris·Cl/15 mM MgCl₂/500 mM KCl, pH 8.3 (20°C)
- 4dNTP mixture (UNIT 3.4)
- pRS40X-series vector (e.g., Table 13.10.1)
- pRS Left and Right primers (see step 1)
- Taq* DNA polymerase
- Appropriate yeast strain (e.g., Table 13.10.2)
- Selective medium (UNIT 13.1)

Additional reagents and equipment for PCR (UNIT 15.1), yeast transformation (UNIT 13.7), yeast genomic DNA isolation (UNIT 13.11) and Southern blotting (UNITS 2.9 & 2.10; optional)

1. Design PCR primers for the disruption cassette as follows (see Fig. 13.10.4). Pick 40 nucleotides of sequence from the sense strand at the 5' end of the target gene ORF and add to the 5' end of one of the two sequences given below. Similarly, pick 40 nucleotides of sequence from the anti-sense strand at the 3' end of the target-gene ORF to be deleted and add to the 5' end of the other sequence listed below (found in all pRS-series vectors). Obtain primer from oligonucleotide supplier.

Left primer: 5'-CTGTGCGGTATTTACACCG-3'

Right primer: 5'-AGATTGTACTGAGAGTGAC-3'

This results in two 60-nucleotide primers sufficient to amplify any of the auxotrophic markers in the pRS-series vectors. The overall primer length is set at 60 nucleotides because this is the longest primer length that is convenient and economical to obtain commercially, and because primers of this length typically give satisfactory results.

2. Set up several 100- μ l PCR reactions containing:

10 μ l 10 \times PCR buffer
200 μ M 4dNTP mixture
100 pmol of each Left and Right primer
10 ng pRS40X
2.5 U *Taq* DNA polymerase.

pRS40X series vectors are used as the template because they lack sequences that allow their stable maintenance in yeast, thus obviating need for purification of the PCR product away from the template DNA. Because the number of transformants obtained from a yeast transformation is proportional to the amount of input DNA, it is worthwhile to perform several 100- μ l reactions, combine and concentrate them by ethanol precipitation (UNIT 2.1), and then transform all of the DNA together.

3. Perform PCR amplification (UNIT 15.1) using the following cycling conditions:

1 cycle:	2 min	94°C	(denaturation)
30 cycles:	30 sec	94°C	(denaturation)
	1 min	55°C	(annealing)
	2 min	72°C	(extension)
1 cycle:	10 min	72°C	(extension).

4. Transform (UNIT 13.7) the PCR product into an appropriate yeast strain and select for expression of the auxotrophic marker.

Because the transformation efficiency of these PCR products is low, it is critical that a high-efficiency transformation procedure—such as lithium acetate transformation with early log-phase cell (see UNIT 13.7)—be used. Also, if the gene being deleted is essential for life, the deletion mutation must be created in a diploid strain.

5. Isolate genomic DNA (UNIT 13.11) and identify strains carrying the gene disruption by PCR (UNIT 15.1) with primers that flank the expected mutation, or by Southern blot analysis (UNITS 2.9 & 2.10).

As noted above, the efficiency of this procedure is dependent upon the complete absence of homology to the auxotrophic marker in the recipient strain. In cases where substantial homology to the auxotrophic marker remains, the frequency of transformants with the expected deletion may drop to as low as a few percent. In such cases, the deletions may still be found by screening many clones by PCR or, if possible, by first identifying potential deletion strains among the transformants by some expected mutant phenotype.

Saccharomyces cerevisiae

13.10.7

Figure 13.10.5 Transplacement allows the introduction of any mutation in a cloned gene that does not have a selectable phenotype (see accompanying text).

**BASIC
PROTOCOL 4**

Transplacement

This method (based on Scherer and Davis, 1979), also called allele replacement, provides a general means of introducing any type of mutation constructed *in vitro* that does not have a selectable phenotype into its corresponding chromosomal location. It can be used either to introduce a single defined mutation or to screen a mutagenized collection of plasmids. The mutated gene is introduced into yeast on a YIp plasmid, which usually contains the *URA3* gene as a selectable marker. After transformation, selection for Ura⁺ results in an integration event, such that mutant and wild-type alleles bracket the *URA3*-containing plasmid sequences (Fig. 13.10.5). Subsequent eviction of the plasmid (containing one copy of the gene) is monitored by screening for colonies that are URA⁻ and therefore resistant to the drug 5-fluoroorotic acid (5-FOA). The 5-FOA^r colonies are then screened for the desired mutant phenotype; the proportion of 5-FOA^r colonies containing the mutant allele will depend on the position of the mutation relative to the length of the flanking homologous DNA.

Materials

- YIp shuttle vector (UNIT 13.4)
- Purified DNA from gene of interest
- Nonselective liquid medium (YPD or uracil-containing minimal medium; UNIT 13.1)
- 5-FOA plates (UNIT 13.1)
- Additional reagents and equipment for subcloning (UNIT 3.16), integrative transformation (see Basic Protocol 1), yeast genomic DNA isolation (UNIT 13.11), and Southern blotting (UNITS 2.9 & 2.10) or PCR (UNITS 15.1.)

1. Subclone (UNIT 3.16) the gene of interest into YIp5.
2. Mutagenize the plasmid as desired, either via the techniques presented in Chapter 8, or by introducing defined deletion or insertion mutations.
3. Proceed with linearization, transformation, and analysis of transformants as for integrative transformation (see Basic Protocol 1, steps 2 to 4).
4. Grow transformants overnight in liquid medium without selection. Plate for single colonies on nonselective medium (~100 single colonies) and grow 2 days at 30°C.

Figure 13.10.6 A single integrative transformation step introduces the desired allele at the normal genome locus and truncates the wild-type allele.

Alternatively, cells can be plated or streaked directly on 5-FOA plates, in which case proceed to step 6.

If the goal is to identify conditional lethal mutants, a large number of transformants should be examined (since some proportion of transformants will have received unmutagenized plasmid and since conditional lethal mutations can be rare events). In addition, this nonselective period of growth should be at the permissive temperature (usually 23°C).

5. Replica plate onto 5-FOA plates and grow overnight to identify Ura⁻ segregants.

Colonies that have evicted the plasmid during the period of growth in liquid medium will give completely resistant replicas on the 5-FOA plates; these colonies should be recovered from the nonselective plate (rather than from the 5-FOA plate) and used in step 6, below. Other colonies that have evicted the plasmid during the period of growth of the colony will appear “patchy” on the 5-FOA replica (often referred to as papillation).

6. Screen 5-FOA^r colonies for the presence of a mutant phenotype. If the mutation is expected to alter the restriction pattern, confirm the genotype of mutant colonies in comparison to wild-type by isolation of genomic DNA (UNIT 13.11) followed by Southern hybridization (UNITS 2.9 & 2.10) or PCR (UNIT 15.1).

CREATING MODIFIED GENES BY ONE-STEP INTEGRATIVE REPLACEMENT

This method may be used to create a yeast strain in which a gene of interest is controlled by any desired (usually inducible) promoter. The same method may be used to create an N-terminal fusion to any chosen epitope tag or other cassette. A single integration event introduces the new allele of the gene at its normal locus and simultaneously truncates the normal endogenous copy of the gene, rendering it nonfunctional (Fig. 13.10.6).

Materials

- Purified DNA from gene of interest
- Yeast integrating shuttle vector with selectable marker
- Appropriate restriction enzyme (UNIT 3.1)
- Appropriate yeast strain
- Selective medium (UNIT 13.1)

BASIC PROTOCOL 5

Saccharomyces cerevisiae

13.10.9

Additional reagents and equipment for subcloning (UNIT 3.16), yeast transformation (UNIT 13.7), yeast genomic DNA isolation (UNIT 13.11), and Southern blotting (UNITS 2.9 & 2.10) or PCR (UNIT 15.1)

1. Select a short 5' fragment of the open reading frame (ORF) of the gene of interest. This fragment should:

- a. begin at the first codon of the gene;
- b. be too short to encode a functional product; in addition, its short product should not have the potential to interfere with the normal activity of the full-length gene product;
- c. be long enough (preferably ≥ 300 bp) to be efficiently targeted by homology to the corresponding chromosomal region; and
- d. contain a restriction site (to be used for targeting the final integrating plasmid to the correct locus) that will remain unique in the final construct and that leaves reasonable stretches of homology to the target gene on both sides of the double strand break.

In order to minimize the chances of undesired integration at the promoter locus, it is preferable for the restriction site to be located slightly closer to the 3' end of the ORF fragment than to its 5' end.

2. Subclone (UNIT 3.16) this 5' fragment downstream of the desired promoter in an integrating yeast shuttle plasmid. If desired, this construct may also include an epitope tag (or other fusion cassette) appended in frame to the N terminus of the ORF fragment.

This subcloning is usually most easily accomplished by PCR. Be certain to situate the initial ATG in the appropriate promoter context. Occasionally, an N-terminal epitope tag may interfere with proper function of a gene. In these situations it is advisable to try subcloning the ORF fragment downstream of the promoter with no N-terminal fusion. Alternatively, a modification of this procedure (using a short, nonfunctional 3' piece of the ORF fused upstream of the desired tag) may be used to create a C-terminal fusion to an epitope tag.

3. Linearize the construct at a unique restriction site within the ORF fragment.

If no restriction site in the ORF fragment is unique, a partial digest may be used to create a mixed population of linearized molecules for transformation. A correspondingly larger number of transformants should then be screened in step 6 for correctly targeted integration. On the other hand, if no restriction sites are present in the ORF fragment, it may be necessary to introduce one by silent PCR mutagenesis (UNIT 8.5).

4. Transform the linearized molecule into an appropriate yeast strain (UNIT 13.7).
5. Plate the transformations onto medium selecting for the plasmid marker (UNIT 13.2).

Remember that if placing an essential gene under the control of an inducible promoter, it is important to plate the cells onto inducing medium.

6. Isolate genomic DNA (UNIT 13.11) and identify clones containing the modified genes by Southern blotting (UNITS 2.9 & 2.10), genomic PCR (UNIT 15.1), or phenotypic assessment.

When working with strains created by this method, be sure to maintain selection for the plasmid marker in order to prevent looping out of the integrated plasmid.

CREATING MODIFIED GENES BY TRANSPLACEMENT

For some genes, it may be difficult or impossible to select a 5' ORF fragment that is long enough for efficient integration yet too short to retain function. In these situations, inducible alleles may be introduced by complete allele replacement (see Basic Protocol 4). Such replacements are stable, leave no short 5' ORF fragment upstream, and avoid the need to maintain selection for the plasmid marker. The allele replacement may be accomplished as follows:

1. Create a molecule as for one-step integrative replacement (see Basic Protocol 5, steps 1 and 2), being sure to use an integrating vector with *URA3*.
2. Just upstream of the promoter, subclone (*UNIT 3.16*) a fragment (usually ≥ 500 bp) of the 5' flanking region of the target gene.

When selecting this fragment, take care to preserve the uniqueness of the targeting restriction site in the ORF fragment.

3. Linearize the molecule and integrate into yeast (see Basic Protocol 5, steps 3 to 5).
4. Streak the *URA*⁺ transformants onto 5-FOA plates (see Basic Protocol 4, step 5).
5. Screen the 5-FOA^r clones obtained for the correctly replaced allele (see Basic Protocol 4, step 6).

CREATION OF CONDITIONAL ALLELES BY COPPER-INDUCIBLE DOUBLE-SHUTOFF PROCEDURE

This method (first described in Moqtaderi et al., 1996), which is useful in the functional analysis of essential genes, allows the creation of conditional expression strains in which the addition of copper causes expression of a gene of interest to be shut off at both the RNA and the protein levels. The RNA shutoff is accomplished by harnessing a transcriptional repressor, and the protein degradation is achieved by exploitation of the N-end rule, whereby a protein's rate of turnover is dictated by its N-terminal amino acid (Varshavsky, 1992). Traditional depletion systems generally rely on the removal of positive agents or on a complete change in medium (e.g., galactose to glucose shift), requiring the cells to be washed at the time of the shift to nonpermissive conditions. In contrast, this method works indirectly, by the induction of negative agents (the simple addition of copper to stimulate the production of a transcriptional repressor and a protein degradation factor), which obviates the need to wash the cells.

Specifically, the parent strain used must harbor copper-inducible alleles of *ROX1*, a transcriptional repressor, and of *UBR1*, which encodes the N-end recognition component of the ubiquitin protein degradation pathway. In this background, the gene of interest is replaced with an allele fused to an N-end recognition sequence for rapid degradation and driven by the *ANB1* promoter, a natural target of Rox1. In the absence of copper, neither Rox1 nor Ubr1 is produced, and the target gene is expressed. The addition of copper results in rapid activation of both *ROX1* and *UBR1*, leading to the simultaneous repression of the target gene's transcription and rapid degradation of its existing protein product (Figs. 13.10.7 and 13.10.8).

Materials

Plasmid ZM168, containing the *ANB1* promoter driving a ubiquitin-arginine-*lacI*-HA (URLF) cassette immediately followed by a polylinker

cerevisiae*

13.10.11

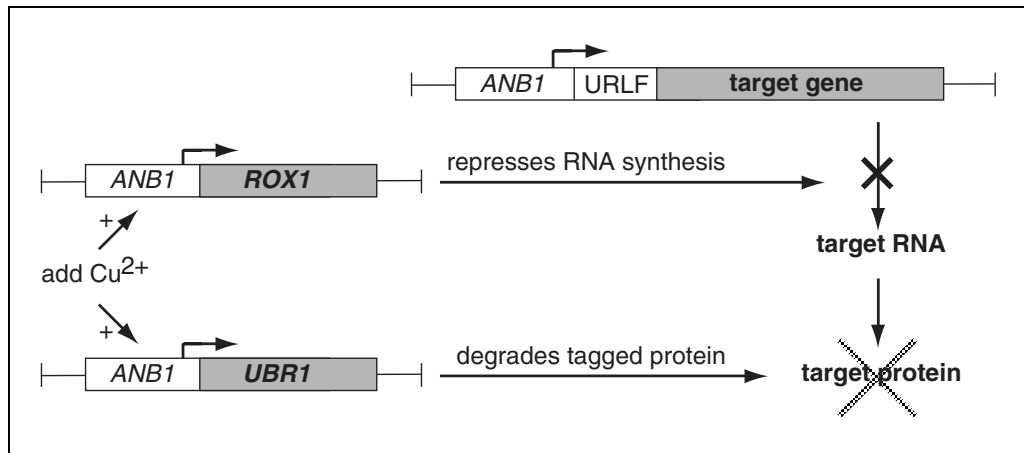

Figure 13.10.7 A two-pronged conditional knock-out strategy shuts off the target gene's expression at both the RNA and the protein levels.

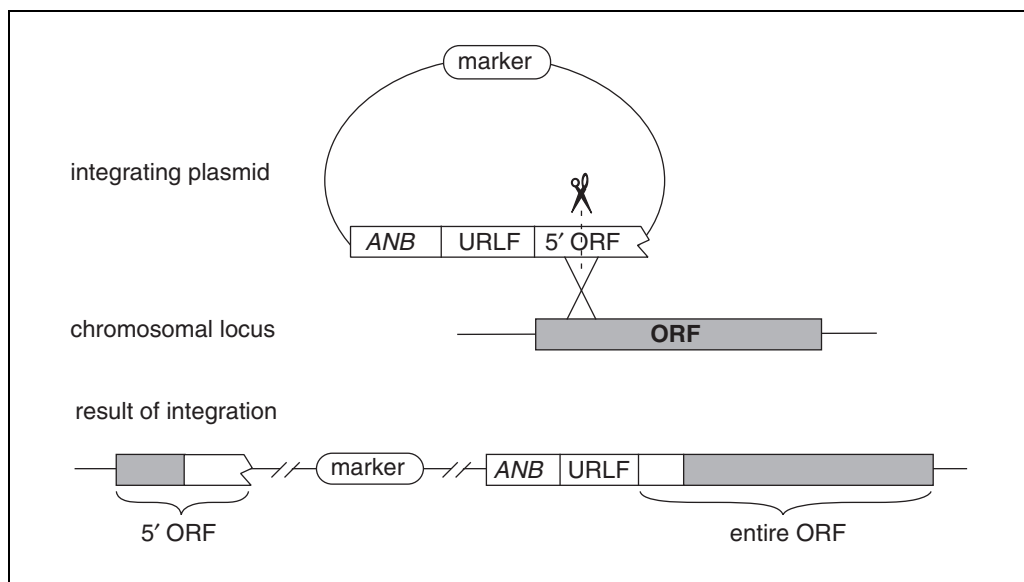

Figure 13.10.8 Introduction of URLF-tagged, *ANB1*-driven allele of the desired target gene into the genome.

Centromeric plasmid bearing the same marker as the integrating vector
 Synthetic medium plates selecting for the integrated plasmid marker (*UNIT 13.1*),
 with and without 500 μ M cupric sulfate (CuSO_4)

1. Following the guidelines provided for one-step replacement (see Basic Protocol 5, steps 1 and 2), select a short, nonfunctional 5' fragment of the intended target gene, and subclone it (*UNIT 3.16*) into the polylinker of the plasmid ZM168 in frame with the URLF cassette.
2. Subclone the entire *ANB1*-URLF-ORF fragment into a yeast integrating shuttle vector bearing the preferred selectable marker.

Take care to maintain the uniqueness of the targeting restriction site in the ORF.

3. Linearize the final construct at the unique restriction site within the ORF fragment and transform it (*UNIT 13.7*) into yeast strain ZMY60. In parallel, transform ZMY60

with a centromeric plasmid bearing the same yeast marker as the final integrating construct. Plate onto synthetic medium selecting for the plasmid marker.

A different strain background may be desired. If this is the case, it is possible to generate another strain containing stably integrated, copper-inducible alleles of ROX1 and UBR1 by using the two-step gene replacement constructs ZM195 and ZM197. (See Basic Protocol 4 for details of how to construct stable gene replacements.)

4. Streak the transformants onto (a) synthetic medium selecting for the integrated plasmid marker with no added copper and (b) synthetic medium selecting for the integrated plasmid marker and containing 500 μM CuSO_4 . Grow plates 2 days at 30°C.

When preparing solid medium for this purpose, it is generally advisable to add all necessary amino acids and the copper when pouring the plates. Attempts to spread liquid amino acid supplements or copper on top of a previously poured plate may result in an uneven copper concentration, making strain growth patterns more difficult to interpret.

5. Analyze transformant growth to assess integration. If the target gene is essential, correct integrants should fail to grow on copper-containing medium. Transformants carrying the centromeric plasmid should grow normally on both media.

If the depletion is inefficient, the copper concentration may be raised to 1 mM, but beyond this level cell growth may begin to be impaired due to copper toxicity. If the target gene is not essential, test for an expected phenotype in the presence of copper or analyze the transformants by isolating genomic DNA (UNIT 13.11) and Southern blotting (UNITS 2.9 & 2.10).

6. For time-course experiments, grow both the conditional strain and the centromeric plasmid control strain in liquid synthetic medium without copper but selective for the plasmid marker. Add 500 μM CuSO_4 to initiate depletion and harvest cells at varying time-points for analysis.

A standard procedure is to assay the cellular process under investigation at time-points over the next several hours after the addition of copper (usually up to 8 hr) to test the effects of increasing levels of depletion. The centromeric plasmid control strain is included to represent a strain expressing a wild-type level of the gene product of interest. The conditional strain, even under permissive conditions, harbors an allele of the target gene driven by a heterologous promoter, and it therefore may not yield a truly wild-type level of expression. It is important to maintain selection for the marker at all times to avoid loss of the integrated plasmid. Even after the addition of copper, it is normal for the cells to continue to grow for several hours. The need to maintain the cells in exponential growth throughout most experiments thus makes it inadvisable to add copper at too high a cell density; a typical OD_{600} at the time of shift is ~ 0.25 .

PREPARATION OF YEAST DNA, RNA, AND PROTEINS

Preparation of Yeast DNA

Molecular studies in yeast often require the isolation of both plasmid and chromosomal yeast DNA. Plasmid DNA is used in the transformation of *E. coli*, whereas chromosomal DNA is used for Southern hybridization analysis, in vitro amplification by the polymerase chain reaction (PCR), or cloning of integrated plasmids. This unit presents two variations of the “smash and grab” protocol (Hoffman and Winston, 1987) that produce suitable DNA for all these applications. These protocols work for both *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe*, although for *S. pombe* a suitable liquid medium must be used to grow the cells.

RAPID ISOLATION OF PLASMID DNA FROM YEAST

Plasmid DNA is released from a yeast transformant along with chromosomal DNA in a rapid, 10-min protocol by vortexing with glass beads in the presence of detergents, phenol, chloroform, and isoamyl alcohol. After centrifugation to pellet cell debris, no further purification of the DNA is required for transformation of competent *E. coli* cells.

Materials

- YPD or appropriate selective medium (UNIT 13.1)
- Yeast colony containing the plasmid of interest
- Breaking buffer (see recipe)
- 25:24:1 (v/v/v) phenol/chloroform/isoamyl alcohol (with buffered phenol; UNIT 2.1)
- 0.45- to 0.52-mm acid-washed glass beads (UNIT 13.12; Thomas Scientific)
- Competent *E. coli* cells HB101 or MH1 (UNIT 1.8)
- LB plates (UNIT 1.1) containing appropriate antibiotic (UNIT 1.4)
- 13 × 100-mm glass tubes, sterile
- 30°C incubator with shaker or roller drum
- Additional reagents and equipment for growth of *E. coli* on solid medium (UNIT 1.3) and transformation of *E. coli* (UNIT 1.8)

1. Inoculate 2 ml medium in a 13 × 100-mm sterile glass tube with a single yeast colony containing the plasmid of interest. Grow overnight to stationary phase at 30°C in either a roller drum or a shaking incubator.

Transformants carrying stable plasmids (UNIT 13.4) should be grown in YPD to get a dense culture. Transformants carrying unstable plasmids should be grown in selective medium to increase the percentage of plasmid-containing cells.

2. Transfer 1.5 ml of the overnight culture to a microcentrifuge tube and spin 5 sec at high speed, room temperature. Pour off supernatant and disrupt pellet by vortexing briefly.
3. Resuspend cells in 200 µl breaking buffer. Add 0.3 g glass beads (~200 µl volume) and 200 µl phenol/chloroform/isoamyl alcohol. Vortex 2 min at highest speed.

The amount of vortexing required can vary depending upon the vortex used. Determine by microscopic examination the minimum vortexing required for a particular machine to break 80% to 90% of the cells.

For simultaneous preparation of DNA from several yeast strains, a multi-tube vortexer or a multi-tube head for a standard vortexer can be used (VWR Scientific) and vortexing time should be increased to 3 min.

4. Microcentrifuge 5 min at high speed, room temperature.
5. Transform competent *E. coli* HB101 or MH1 with 1 to 2 μ l of the aqueous layer. Plate on LB plates containing the appropriate antibiotic to select for the drug-resistance marker on the plasmid.

See Critical Parameters and Troubleshooting for guidelines on transformation.

Save 50 μ l of the aqueous layer and store at -20°C in case additional transformations are required.

ALTERNATE PROTOCOL

RAPID ISOLATION OF YEAST CHROMOSOMAL DNA

The DNA preparation described in the Basic Protocol can be easily scaled up to prepare chromosomal DNA for use in Southern hybridization analysis (UNIT 2.9A), in vitro DNA amplification by PCR (UNIT 15.1), or restriction digestion and ligation (UNITS 3.1 & 3.16) to clone integrated plasmids. This procedure is significantly faster than other protocols used to isolate high-molecular-weight DNA. Although the DNA is subject to shearing in this protocol, the resulting DNA is of sufficiently high molecular weight to enable detection of 19-kb restriction digestion products by Southern hybridization analysis.

Additional Materials (also see Basic Protocol)

- TE buffer (APPENDIX 2)
- 1 mg/ml DNase-free RNase A (UNIT 5.5)
- 4 M ammonium acetate solution (APPENDIX 2)
- 100% ethanol
- 18 \times 150-mm glass culture tubes *or* 17 \times 100-mm disposable polypropylene tubes, sterile
- Tabletop centrifuge

Prepare yeast cells

1. Grow a 10-ml culture of yeast in YPD overnight to stationary phase in either 18 \times 150-mm sterile glass culture tubes or in 17 \times 100-mm sterile, polypropylene tubes (see Basic Protocol, step 1).
2. Spin culture 5 min in a tabletop centrifuge at $1200 \times g$ (3000 rpm), room temperature. Aspirate or pour off supernatant, and resuspend cells in 0.5 ml water.
3. Transfer the resuspended cells to a microcentrifuge tube and spin 5 sec at room temperature. Pour off supernatant and disrupt pellet by vortexing briefly.

This wash step in water removes any remaining medium.

Break open the cells

4. Resuspend cells in 200 μ l breaking buffer. Add 0.3 g glass beads (\sim 200 μ l volume) and 200 μ l phenol/chloroform/isoamyl alcohol and vortex at highest speed for 3 min.

The amount of vortexing required can vary depending upon the vortex used. Determine by microscopic examination the minimum vortexing required for a particular machine to break 80% to 90% of the cells.

If using a multi-tube vortex rather than a single-tube vortex, the time of vortexing may need to be increased up to 4 or 5 min to get more efficient breakage of cells. However, longer vortexing can result in shearing of DNA molecules.

5. Add 200 μ l TE buffer and vortex briefly.
6. Microcentrifuge 5 min at high speed, room temperature, and transfer aqueous layer to a clean microcentrifuge tube. Add 1 ml of 100% ethanol and mix by inversion.

7. Microcentrifuge 3 min at high speed, room temperature. Remove supernatant and resuspend pellet in 0.4 ml TE buffer.

Degrade RNA contaminants and recover DNA

8. Add 30 μ l of 1 mg/ml DNase-free RNase A, mix, and incubate 5 min at 37°C.
9. Add 10 μ l of 4 M ammonium acetate and 1 ml of 100% ethanol. Mix by inversion.
10. Microcentrifuge 3 min at high speed, room temperature. Discard supernatant and dry pellet. Resuspend DNA in 100 μ l TE buffer.

Yields of ~20 μ g of chromosomal DNA should be obtained. This DNA is ready to use for restriction digestion (UNIT 3.1), in vitro PCR amplification (UNIT 15.1), or Southern blot analysis (UNIT 2.9). For Southern blots, best results are obtained when 5 μ l DNA (~1 μ g) is digested in a total volume of 20 μ l. To amplify by PCR, 2 μ l of DNA should be used in a 50- μ l reaction.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Breaking buffer

- 2% (v/v) Triton X-100
 - 1% (v/v) sodium dodecyl sulfate (SDS)
 - 100 mM NaCl
 - 10 mM Tris-Cl, pH 8.0
 - 1 mM EDTA, pH 8.0
- Store \leq 1 year at room temperature

COMMENTARY

Background Information

These DNA isolation protocols simultaneously break yeast cells by vortexing with glass beads in a detergent solution and separate nucleic acids from protein by phenol/chloroform extraction. They differ in the amount of additional manipulation required to obtain DNA of the quality needed for a particular procedure. Other protocols also describe the isolation of high-molecular-weight DNA (Cryer et al., 1975; Winston et al., 1983; Davis et al., 1980). However, even the protocols designed to be rapid DNA preparations require >3 hr time. In general, the protocols described here produce DNA of sufficient molecular weight for any desired application, except for the production of insert DNA for the construction of genomic libraries.

Many situations require the isolation of plasmid DNA from a yeast transformant to transform *E. coli*. Examples include cloning of (1) the wild-type copy of a gene by complementation of a recessive mutant (UNIT 13.8), (2) a dominant mutant allele of a gene by transformation of a wild-type strain, or (3) a mutant allele of a gene by plasmid gap repair (UNIT 13.10). Plasmid DNA is also needed to identify a de-

sired mutant allele of a gene by the plasmid shuffle technique (UNIT 13.10). Most yeast plasmids used in molecular biology are shuttle vectors carrying a selectable marker and an origin of replication (*ori*) for transformation and maintenance in *E. coli* (UNIT 13.4). Because significantly more plasmid DNA can be isolated from an *E. coli* transformant than from a yeast transformant, *E. coli* is used to amplify the DNA for restriction mapping and other in vitro manipulations of the DNA as well as for retransformation of yeast strains.

Other situations require the isolation of chromosomal DNA. The most common use of this DNA is for Southern hybridization analyses. Such analyses are needed to confirm that integration of a YIp plasmid or of a marked gene disruption has occurred by homologous recombination. Chromosomal DNA can also be used as a template for in vitro amplification by PCR in place of Southern analyses to determine whether DNA is integrated by homologous recombination. PCR can also be used in place of gap repair to clone mutant alleles of a given gene. Finally, chromosomal DNA is needed to clone DNA adjacent to an integrated plasmid. This is done by digesting the chromosomal

Saccharomyces cerevisiae

13.11.3

DNA with a restriction enzyme that creates a restriction fragment containing the plasmid origin of replication and selectable marker, as well as the flanking DNA of interest (Southern analyses are required to determine the appropriate restriction enzyme for this construction). Ligation of this yeast DNA, followed by transformation of *E. coli*, results in the isolation of the cloned flanking DNA, as only the appropriate piece of DNA will confer drug resistance upon the *E. coli* strain.

These protocols do not produce intact chromosomal DNA. Yeast chromosomes can be isolated by methods involving gentle lysis of cells in agarose blocks (UNIT 2.5B; Carle and Olson, 1987). Intact chromosomes can be used to map a cloned gene to a given chromosome by Southern hybridization analysis or as a size standard for field-inversion or orthogonal-field-alteration gel electrophoresis (UNIT 2.5B).

Critical Parameters and Troubleshooting

There is a significant difference among *E. coli* strains regarding their transformation efficiency with plasmid DNA isolated by this protocol. One commonly used strain, HB101 (Table 1.4.5), works well with either CaCl₂ transformation or electroporation protocols (UNIT 1.8). A less commonly used strain, MH1 (Hall et al., 1984), is even better suited for these transformations when made competent by the RbCl method (Hanahan, 1983). Because MH1 is a derivative of MC1061, it is possible that this strain would also transform well using the Hanahan protocol. Many other strains do not work as well, even when they appear to be more competent as judged by transformation with a control plasmid used to standardize transformation efficiency. Therefore, problems with transformations may be due to the choice of the *E. coli* host strain.

It is important to note that only 1 or 2 μ l of the aqueous layer should be used per transformation, as larger amounts are increasingly toxic to *E. coli*. Attempts to purify the DNA with ethanol precipitations are generally unsuccessful, possibly due to co-precipitation of material that inhibits transformation. A 1:1 isopropanol precipitation can be effective in concentrating the DNA when the original attempt fails to produce transformants. In general, however, this additional manipulation is unwarranted.

When preparing DNA for use in Southern hybridization analysis, it is important to minimize the vortexing time needed to break the cells in order to reduce shearing of the DNA.

Three minutes is generally sufficient, but this time can vary from vortex to vortex. Too much vortexing can result in a weak signal for restriction fragments <10 kb. The other consideration for optimizing Southern blot analysis is the amount of DNA used per digest. This protocol generates a very consistent yield of readily digested DNA. Increasing the amount of DNA per digest can result in incomplete cutting and is not recommended.

Anticipated Results

The basic protocol for isolating plasmid DNA from yeast transformants gives sufficient DNA for transformation of *E. coli*. The number of transformants obtained is a function of copy number of plasmid and transformation efficiency of *E. coli* host strain. The protocol for isolating chromosomal DNA yields ~20 μ g DNA from a 10-ml stationary-phase culture.

Time Considerations

It should take ~10 min to prepare plasmid DNA for transformation of *E. coli*. The genomic DNA preparation takes from 45 min to 1 hr for twelve cultures. The vortexing step can become much more time-consuming if only a single-tube vortex is available, as only three microcentrifuge tubes can be vortexed simultaneously.

Preparation of Yeast RNA

UNIT 13.12

This unit provides two protocols for extraction of RNA from yeast that differ primarily in the method for lysing the yeast cells. The first (basic) protocol isolates RNA directly from intact yeast cells by extraction with hot acidic phenol. This procedure yields RNA that is relatively free of contaminating DNA, is convenient to perform with multiple samples, and gives little or no sample-to-sample variation. In contrast, the first alternate protocol relies upon disruption of cells by vigorous mixing with glass beads and denaturing agents. Although this procedure results in efficient breaking of the cells, the product is associated with residual DNA, and the procedure itself is troublesome when one is working with multiple samples. A second alternate protocol describes the scaling up of the first two procedures to isolate enough total RNA for poly (A)⁺ RNA preparation.

NOTE: Take precautions to avoid contamination by RNases. See UNIT 4.1, reagents and solutions, for instructions.

PREPARATION OF YEAST RNA BY EXTRACTION WITH HOT ACIDIC PHENOL

**BASIC
PROTOCOL**

Yeast RNA can be isolated efficiently and directly from intact cells by extraction with acidic phenol (pH 5) and SDS at 65°C. Because this procedure does not require vortexing individual samples with glass beads (alternate protocol), which is tedious and a source of variability, it is well-suited for obtaining reproducible quantities of RNA from multiple samples. In addition, RNA preparations are largely devoid of contaminating DNA which partitions into the interface during the extraction step.

Materials

Yeast cells and desired medium (UNITS 13.1 & 13.2)

TES solution

Acid phenol

Chloroform

3 M sodium acetate, pH 5.3

100% and 70% ethanol, ice-cold

50-ml centrifuge tube (Falcon)

Centrifuge: tabletop *or* Sorvall equipped with an SS-34 rotor

Additional reagents and equipment for ethanol precipitation (UNIT 2.1) and spectrophotometric quantitation of cells and RNA (APPENDIX 3)

1. Grow yeast cells in 10 ml of desired medium to mid-exponential phase ($OD_{600} = 1.0$).

It is not advisable to prepare RNA from cells that have reached a higher density because as the stationary phase is approached, the results are less consistent and RNA yields will vary.

2. Transfer culture to 50-ml centrifuge tube and centrifuge cells 3 min at $1500 \times g$ (7000 rpm in a tabletop centrifuge or SS-34 rotor), 4°C.

The time and speed of the centrifugation are not critical.

3. Discard supernatant, resuspend pellet in 1 ml ice-cold water. Transfer to a clean 1.5-ml microcentrifuge tube. Microcentrifuge 10 sec at 4°C, and remove supernatant. Proceed to step 4 or if desired immediately freeze pellet by placing tube in dry ice.

Liquid nitrogen may also be used to freeze the pellets. Although not essential, freezing is particularly useful when RNA is to be prepared from multiple cultures or multiple time points from a given culture; this permits simultaneous processing of the samples. The frozen

13.12.1

Supplement 23

cell pellets can be stored for months at -70°C . Thaw on ice just before continuing the procedure.

4. Resuspend cell pellet in 400 μl TES solution. Add 400 μl acid phenol and vortex vigorously 10 sec. Incubate 30 to 60 min at 65°C with occasional, brief vortexing.

It is crucial to incubate for ≥ 30 min (with occasional vortexing) to obtain quantitative recovery of both large and small RNA species.

5. Place on ice 5 min. Microcentrifuge 5 min at top speed, 4°C .
6. Transfer aqueous (top) phase to a clean 1.5-ml microcentrifuge tube, add 400 μl acid phenol, and vortex vigorously. Repeat step 5.
7. Transfer aqueous phase to a clean 1.5-ml microcentrifuge tube and add 400 μl chloroform. Vortex vigorously and microcentrifuge 5 min at top speed, 4°C .
8. Transfer aqueous phase to a new tube, add 40 μl of 3 M sodium acetate, pH 5.3, and 1 ml of ice-cold 100% ethanol and precipitate. Microcentrifuge 5 min at top speed, 4°C . Wash RNA pellet by vortexing briefly in ice-cold 70% ethanol. Microcentrifuge as before to pellet RNA.
9. Resuspend pellet in 50 μl H_2O . Determine the concentration spectrophotometrically by measuring the A_{260} and A_{280} (UNIT 4.1). Store at -70°C , or at -20°C if it is to be used within 1 year.

Make sure that the RNA is well dissolved; if necessary, heat the resuspended pellet at 65°C for 10 to 20 min and/or dilute further with more water. The yield from 10 ml of cells grown in YPD medium is ~ 300 μg . Cells grown in less optimal medium will yield less RNA per ml culture.

ALTERNATE PROTOCOL

PREPARATION OF RNA USING GLASS BEADS

Yeast RNA is also efficiently released by disrupting the cells using high-speed mixing in the presence of glass beads and denaturing agents. Proteins are removed by extraction with organic solvents and the RNA is recovered by ethanol precipitation and quantitated by measuring its absorbance at 260 nm. This preparation is suitable for S1, northern hybridization, or primer extension analyses (UNITS 4.6, 4.9, and 4.8, respectively) and can be prepared quickly and easily from a relatively small quantity of yeast cells. Although the RNA isolated by this procedure is contaminated with DNA, the DNA component does not interfere with most analytical studies.

Additional Materials

- RNA buffer
- 25:24:1 phenol/chloroform/isoamyl alcohol (equilibrated with RNA buffer; see support protocol, UNIT 2.1)
- 0.45- to 0.55-mm, chilled, acid-washed glass beads (Sigma)

Prepare the cells

1. Grow and process yeast cells and freeze cell pellet as in steps 1 to 3 of the basic protocol.

If necessary, the samples can now be quick-frozen on dry ice and stored at -70°C . Thaw on ice just before processing.

2. Resuspend pellet in 300 μl RNA buffer.

Disrupt the cells

3. Add a volume of chilled acid-washed glass beads equivalent to ~ 200 μl water.

Prepare acid-washed glass beads by soaking in concentrated nitric acid for 1 hr, washing extensively with deionized water, and drying in a baking oven.

Before use the glass beads should be chilled on ice. Manipulate the beads with a stainless steel spatula that has been dried in a baking oven. Do this carefully, using a spatula or a funnel fashioned out of weighing paper. If beads stick to the lip of the microcentrifuge tube, they will prevent the tube from closing securely.

4. Add 300 μl of 25:24:1 phenol/chloroform/isoamyl alcohol equilibrated with RNA buffer.

A phenol mix previously equilibrated with TE buffer (UNIT 2.1) can be reequilibrated with RNA buffer. Remove the aqueous layer (TE buffer), add a volume of RNA buffer equal to the volume of the organic layer, shake vigorously, and allow the phases to separate. Remove the aqueous layer (RNA buffer), add fresh RNA buffer, mix well, and allow the phases to separate.

5. Close the cap, then invert and shake up and down to ensure that the beads are suspended. Vortex vigorously for 2 min at highest speed.

Hold 2 to 4 tubes on the head of a vortexer for 1 min, place these tubes on ice, and vortex another set. After 1 min with the second set, place on ice, and vortex the first set for another minute. This limits the processing to 8 samples at one time. If a high-speed horizontal shaker is available many samples can be vortexed simultaneously. Use the highest speed setting for 3 min in a cold room.

6. Microcentrifuge 1 min at room temperature. Transfer aqueous (top) layer to a clean microcentrifuge tube.

Avoid the interface by taking only the uppermost 200 to 250 μl from each sample. Taking a fixed amount from each sample results in a more uniform yield of RNA from each sample.

7. Add an equal volume of 25:24:1 phenol/chloroform/isoamyl alcohol (200 to 250 μl). Vortex vigorously 10 sec.

8. Repeat step 6.

Precipitate the RNA

9. Add 3 vol (~600 μl) of ice-cold 100% ethanol. Mix well and place at -20°C for ≥ 30 min or on dry ice for 5 min.
10. Microcentrifuge 2 min at 4°C . Aspirate or pour off the supernatant and wash pellet with ice-cold 70% ethanol.
11. Microcentrifuge 1 min at 4°C . Aspirate or pour off supernatant and dry pellet.
12. Resuspend pellet in 50 μl H_2O . Determine the concentration spectrophotometrically by measuring the A_{260} and A_{280} (UNIT 4.1). Store the RNA at -70°C .

If 2×10^8 cells are used, the RNA concentration of the final solution will be ~2 mg/ml.

PREPARATION OF POLY(A)⁺ RNA

The RNA isolated in the basic and first alternate protocols is also a suitable source of poly(A)⁺ RNA for use in constructing cDNA libraries. For this purpose, larger quantities of RNA can be isolated by simply scaling-up the procedures. For 10¹⁰ *S. cerevisiae* cells, use the following guidelines:

For the hot acidic phenol protocol: Increase volumes of TES and acid phenol solutions to 4 ml each; use 50-ml polypropylene centrifuge tubes for all manipulations. The yield will be ~10 mg of RNA.

For the glass beads protocol: Increase volumes to 15 ml RNA buffer, 10-ml volume glass beads, 15 ml phenol/chloroform/isoamyl alcohol, and 30 ml of 100% ethanol. Perform the procedure in a 50-ml disposable polypropylene tube and centrifuge 10 min, 3000 rpm (1200 × g), 4°C in a fixed-angle or swinging-bucket type rotor at each phenol extraction step. Good recovery of the precipitated nucleic acid can be accomplished by centrifugation under these same conditions. The yield will be ~5 mg total RNA.

Prepare poly(A)⁺ RNA from either method using the protocol presented in *UNIT 4.5*.

REAGENTS AND SOLUTIONS

Acid phenol

Add sufficient water to a bottle of solid phenol such that phenol is water-saturated; pH will be ~5.0. Do not buffer phenol. Store at 4°C, protected from light.

RNA buffer

0.5 M NaCl
200 mM Tris·Cl, pH 7.5
10 mM EDTA
Store indefinitely at room temperature

TES solution

10 mM Tris·Cl, pH 7.5
10 mM EDTA
0.5% SDS
Store indefinitely at room temperature

COMMENTARY

Background Information

Aside from the harsh conditions used to break open yeast cells, the RNA isolation procedures presented here are similar to the phenol/SDS method for isolating RNA from plant cells (*UNIT 4.3*). Both methods take advantage of the fact that phenol extraction is an effective means of inactivating and removing RNases. The hot acidic phenol method is preferable when working with multiple samples; because the number of manipulations and time required for each are reduced, very little sample-to-sample variation is encountered.

The glass bead disruption procedure causes the release of both RNA and DNA, and the absorbance at 260 nm will measure total nucleic acid. For precise determination of RNA con-

centrations, the DNA component can be removed as described in *UNITS 4.1, 4.3, and 4.5*. This is not necessary for routine northern blot, primer extension, and S1 analyses. Refer to *UNITS 4.1-4.5* for further information on the purification and properties of RNA.

Critical Parameters

As with all RNA manipulations, precautions must be taken to prevent RNase contamination. See *UNIT 4.1* for details. In the hot acidic phenol method, the two phenol and one chloroform extractions are critical to obtain clean RNA for analysis.

These protocols are designed to process multiple samples in tandem—for example, when monitoring gene induction over time or

when examining RNA synthesis driven by different promoter constructions. In these cases (where quantitation is critical), detection using probes in northern hybridization, S1 mapping, or primer extension studies should be carried out in parallel (preferably in the same tube or hybridization bag) with a probe for a gene in which transcription does not change over time or in response to inducing conditions. The ratios of signal intensities for the two probes in each sample are then compared.

Anticipated Results

The yield of RNA isolated using the hot acidic phenol protocol is ~300 µg from 2×10^8 . The yield resulting from the glass bead disruption protocol starting with 2×10^8 cells will be ~100 µg of total RNA. Scale-up of either method will produce ~5 to 10 mg total RNA. Ten to twenty micrograms of total RNA isolated by either procedure is sufficient for most northern blot, S1 mapping, or primer extension applications.

Time Considerations

Depending on the organization of the researcher, 12 to 24 samples can be processed conveniently in about 1 hr using the hot acidic phenol method. For the glass bead method, eight samples can be easily processed without using a high-speed shaking apparatus in ~1.5 hr. A second set of eight samples can be processed while the first set is precipitating at -20°C . With a high-speed shaking apparatus 16 samples can be processed in about 1 hr. Both phenol extraction steps can be done on the shaking apparatus.

If RNA synthesis is being monitored over time, samples from individual time points can be frozen at -70°C (see step 3, basic protocol) so that all of the samples can be processed simultaneously.

Preparation of Protein Extracts from Yeast

Three protocols are presented for preparing protein extracts; they differ primarily in the way the cells are broken. In the basic protocol, cells are enzymatically converted to spheroplasts, which are then lysed by a combination of osmotic shock and Dounce homogenization. A support protocol for isolating intact nuclei by differential centrifugation is also presented. An alternate protocol describes mechanical breakage of cells by vortexing in the presence of glass beads. In a second alternate protocol, growing cells are frozen immediately in liquid nitrogen and then lysed by grinding in an industrial-strength blender in the presence of liquid nitrogen. These methods each have advantages and disadvantages; the best choice will depend on the particular application. For all of these procedures, it is advantageous to use protease-deficient strains such as BJ926 or EJ101.

BASIC PROTOCOL

SPHEROPLAST PREPARATION AND LYSIS

Materials

Protease-deficient yeast cells (BJ926, EJ101, or equivalent)

YPD medium (UNIT 13.1)

Zymolyase buffer, room temperature and ice-cold

Zymolyase 100T (ICN Immunobiologicals)

1 M sorbitol (optional)

Lysis buffer

Extraction buffer

Storage buffer

Liquid nitrogen

Sorvall GS-3 or GSA rotor (or equivalent)

Sorvall SS-34 or SA-600 rotor (or equivalent)

Beckman Type 45Ti rotor (or equivalent; large capacity)

30°C shaker platform

Rubber policeman

Dounce homogenizer

Rotating wheel or rocker

Additional reagents and equipment for growing yeast cells (UNITS 13.1 & 13.2), large-volume dialysis (APPENDIX 3), and determining conductivity (UNIT 10.10)

Grow the cells

1. Grow cells to mid-log phase in YPD medium with vigorous shaking or forced aeration.

The OD_{600} can vary with aeration conditions, but should be between 1 and 5. The procedure is appropriate for between 100-ml and 20-liter cultures, although it can be scaled up if necessary.

2. Harvest cells by centrifugation 5 min at $1500 \times g$ (GS-3 or GSA rotor at ~ 3000 rpm), 4°C, in preweighed centrifuge bottles.

Prepare the spheroplasts

3. Determine the wet weight (in grams) of yeast cells in the pellet by the weight increase over that of the preweighed bottle. This is approximately equal to the packed cell volume (in milliliters), and for all subsequent steps will be considered 1 vol.

One liter of BJ926 (a diploid strain) at $OD_{600} = 1.0$ yields a packed cell volume of 2 to 3 ml.

4. Resuspend cells in 2 to 4 vol ice-cold water and immediately centrifuge 5 min at $1500 \times g$ (SS-34 or SA-600 rotor at 3500 rpm), 4°C . Discard the supernatant.
5. Resuspend the cells by adding 1 vol zymolyase buffer containing 30 mM DTT (see note in reagents and solutions), and incubate 15 min at room temperature.

This step facilitates subsequent zymolyase treatment and spheroplast lysis by breaking disulfide bonds.

6. Centrifuge 5 min at $1500 \times g$, 4°C , and resuspend in 3 vol zymolyase buffer. Add 2 mg (200 U) Zymolyase 100T per ml of original packed cell volume to the resuspended cells. Incubate 40 min at 30°C on a shaker platform at ~ 50 rpm.
7. Determine if conversion to spheroplasts has been completed by the lysis in water technique (UNIT 13.7). If spheroplasting is incomplete, continue incubation until complete.

Perform all procedures from this point on at 4°C .

8. Centrifuge spheroplasts 5 min at $1500 \times g$. Decant the supernatant carefully—the spheroplast pellet will not be as tight as the previous cell pellets.

For some procedures (e.g., extracts for in vitro transcription or translation), spheroplasts are resuspended in YPD medium containing 1 M sorbitol and incubated for 30 to 60 min at 30°C to allow metabolic recovery.

9. Wash the spheroplasts by gently resuspending the pellet in 2 vol ice-cold zymolyase buffer and centrifuging 5 min at $1500 \times g$. Repeat this step two more times.

Spheroplasts are sticky and difficult to resuspend. To facilitate resuspension, first resuspend the spheroplasts in a small volume with the aid of a rubber policeman and then add more buffer to achieve the correct final volume.

The washing step is important for removing proteases, phosphatases, and nucleases present in the zymolyase preparation. For some purposes, it may be necessary to carry out additional washes.

Lyse the spheroplasts

10. Gently resuspend the pellet in 2 vol lysis buffer. Do not try to achieve a homogeneous suspension; simply dislodge the pellet from the side of the centrifuge tube and gently swirl 10 to 20 times. Centrifuge spheroplasts 10 min at $1500 \times g$.

Extensive manipulation of the pellet may result in premature osmotic lysis.

11. Thoroughly resuspend spheroplast pellet with 1 vol lysis buffer using a glass rod.

At this point, tubes containing the resuspended spheroplasts can be quick-frozen in liquid nitrogen and stored at -80°C . Thaw frozen spheroplasts overnight on ice before proceeding.

12. Lyse spheroplasts with 15 to 20 strokes of a tight-fitting pestle (clearance 1 to 3 μm) in a Dounce homogenizer.

Extract proteins from lysate

13. Half-fill ultracentrifuge tubes with lysate. Add an equal volume of extraction buffer and seal the tubes. Gently invert tubes on rotating wheel or rocker for 15 to 30 min at 4°C .

The lysate and extraction buffer are not premixed because the resulting solution will immediately become quite viscous and hence difficult to pour if the ionic strength is above ~ 0.5 M.

14. Centrifuge 90 min at $100,000 \times g$ (Type 45Ti rotor at 33,000 rpm), 4°C .
15. Collect supernatant and dialyze 2 to 4 hr against 100 vol storage buffer. Transfer dialysis bag to 100 vol fresh storage buffer; dialyze an additional 2 to 4 hr.

A flocculent precipitate may form during dialysis. These precipitates usually contain negligible amounts of most protein factors and can be discarded.
16. Remove a few microliters of the dialysate, dilute 1:1000 with water, and determine the conductivity (UNIT 10.10). If it is equal to that of similarly diluted storage buffer or below some acceptable value (usually 100 to 250 mM NaCl), proceed to step 17. If not, continue dialysis.
17. Centrifuge dialysate 10 min at $10,000 \times g$ (SS-34 rotor at 9200 rpm or SA-600 rotor at 8500 rpm), 4°C . Collect the supernatant, freeze in small aliquots in liquid nitrogen, and store at -80°C .

This crude extract contains most DNA-binding proteins as well as transcription and replication factors. The pellet contains proteins that can be "salted in" by resuspending in storage buffer containing 0.5 to 1.0 M KCl, if desired.

SUPPORT PROTOCOL

NUCLEI PREPARATION BY DIFFERENTIAL CENTRIFUGATION

Nuclei suitable for chromatin studies and/or nuclear protein extracts are prepared by osmotically lysing spheroplasts in the presence of Ficoll, which preserves nuclear structure and prevents proteins from leaking out of the nucleus, followed by differential centrifugation.

Additional Materials

Ficoll buffer, ice-cold
Teflon pestle tissue homogenizer, motor-driven (optional; Thomas)

1. Perform steps 1 to 9 of basic protocol. Resuspend cells in 0.5 vol zymolyase buffer.
2. Pipet cells drop by drop into a beaker containing 15 to 25 vol ice-cold Ficoll buffer with continuous stirring in an ice bath or cold room.

Alternatively, resuspend cells in several volumes Ficoll buffer and homogenize with 5 to 10 strokes using a motor-driven tissue homogenizer and moderately tight Teflon pestle (clearance 0.15 to 0.23 mm) at medium speed.

3. Transfer the suspension to centrifuge tubes and centrifuge 5 min at $3000 \times g$ (SS-34 rotor at 5000 rpm), 4°C , to pellet cell debris and unlysed spheroplasts.

This step can be skipped if separation of unlysed cells is not critical, or it can be repeated multiple times if it is important to completely remove debris.

4. Transfer supernatant to new centrifuge tubes and centrifuge 20 min at $20,000 \times g$ (SS-34 rotor at 13,000 rpm), 4°C . Decant the supernatant. The pellet contains the nuclei.

The pellet can be difficult to resuspend. If necessary, resuspend as described in step 9 of basic protocol.

For chromatin studies, the nuclei can be suspended in an appropriate buffer and used directly for micrococcal nuclease or DNase I digestion. In some instances, it is useful to wash the nuclei in a buffer equivalent to Ficoll buffer but containing 10% glycerol instead of Ficoll. Nuclei can be stored in this buffer several months at -80°C if the tubes are frozen quickly on dry ice or liquid nitrogen.

5. To obtain nuclear extracts, resuspend the nuclei in 1 vol lysis buffer and perform

steps 12 to 17 of basic protocol.

Alternatively, the nuclei can be washed in buffers containing various types and molarities of salt. The supernatants will contain proteins that have been extracted by the salt.

**ALTERNATE
PROTOCOL**

CELL DISRUPTION USING GLASS BEADS

These procedures are for small-scale preparations using a vortexer, and for large-scale preparations using a Bead Beater.

Additional Materials

Glass bead disruption buffer
Chilled, acid-washed glass beads (0.45- to 0.55-mm; see reagents and solutions)
Bead Beater and vessel (Biospec; optional)

1. Grow and harvest yeast cells as described in steps 1 to 4 of the basic protocol for spheroplast lysis. Determine the packed cell volume.

All subsequent steps should be carried out at 4°C.

2. Resuspend cells in 1 vol glass bead disruption buffer.

The cells can be frozen by slowly pouring this suspension into a plastic beaker filled with liquid nitrogen. Use enough liquid nitrogen to submerge the frozen paste. This frozen "popcorn" can be stored at -80°C. Thaw overnight on ice before proceeding.

3. Mix cell paste with 2 vol glass bead disruption buffer.
4. Add 4 vol of chilled, acid-washed glass beads.

For packed cell volumes of <10 ml:

- 5a. Transfer the cell suspension to an appropriately sized screw-cap centrifuge tube. The suspension should occupy no more than 60% to 70% of the capacity of the tube.
- 6a. Vortex the suspension at maximum speed for 30 to 60 sec at 4°C; place tube on ice for 1 to 2 min. Repeat 3 to 5 more times. Check the amount of cell breakage by visual inspection under a microscope. Proceed to step 7.

Although larger volumes may be processed by using multiple aliquots, it is better to use a Bead Beater as described below.

For packed cell volumes of >10 to 20 ml:

- 5b. Transfer the cell suspension to an appropriately sized Bead Beater vessel (stainless steel is recommended for better heat transfer) and add glass bead disruption buffer to fill the vessel almost to the brim. The volume of buffer required to fill the vessel should not exceed 1 cell-suspension volume. Attach the blade and cap assembly, ensuring that all air is excluded from the vessel.

It is important to exclude air in order to prevent foaming and potential protein denaturation.

- 6b. Grind at high speed for 60 sec, then let sit 1 to 2 min on ice. Repeat 3 to 5 more times.
7. Allow the glass beads to settle out and decant the supernatant.
8. Add 2 to 4 vol glass bead disruption buffer to the glass beads and invert the tube 5 to 10 times. Allow the beads to resettle and decant the supernatant. Pool the supernatants.
9. Centrifuge the pooled supernatants 60 min at 12,000 × g (SS-34 rotor at 10,000 rpm),

***Saccharomyces
cerevisiae***

13.13.4

4°C. Collect the supernatant which represents the crude extract. For long-term storage, aliquot into small tubes, quick-freeze the tubes in liquid nitrogen, and store at -80°C.

**ALTERNATE
PROTOCOL**

CELL DISRUPTION USING LIQUID NITROGEN

This protocol is designed for processing 200 ml to ~20 liters of cells. It can be easily scaled up for processing larger amounts (e.g., from a fermentor), in which case a larger blender and cup must be used.

Additional Materials

Yeast cakes (optional; Red Star)

Liquid nitrogen

60-ml syringe

1-liter plastic beaker (Nalgene or equivalent)

1-liter stainless steel blender cup and blender (Waring or equivalent)

1. Grow cells to mid-log phase in YPD (or selective) medium with vigorous shaking or forced aeration. Centrifuge the culture to harvest cells. Discard supernatant.

Many liters can be processed at one time with this method. Alternatively, commercial yeast cakes can be used in place of the growing cells.

2. Vortex cell pellet to create a thick cell paste. If necessary, add a minimal amount of ice-cold water to allow the paste to be poured or spooned.

NOTE: Keep cell paste on ice in subsequent steps.

If using a yeast cake, mix equal volumes of cells and water and blend into a thick paste.

3. Remove the plunger from a 60-ml syringe. Seal the bottom with a plug or tightly wrapped parafilm. Pour or spoon in 50 ml of the cell paste.

4. Place 400 ml liquid nitrogen into a 1-liter Nalgene beaker.

Avoid contact with liquid nitrogen due to the danger of frostbite. Use insulated gloves when handling containers. Never use glass containers to hold liquid nitrogen as they may break.

5. Hold the syringe over the liquid nitrogen; remove plug or parafilm from bottom, insert plunger, and squeeze the cell paste into the liquid nitrogen. Repeat steps 3 and 5 no more than three times. A maximum of ~200 ml cell paste can be processed at one time when using a 1-liter blender cup.

Long spaghetti-like aggregations of frozen cells should form with a thick cell paste; spherical popcorn-like clumps form with a thinner paste. The frozen cells can be stored indefinitely at -80°C before disruption.

6. Carefully pour the liquid nitrogen with frozen cells into a blender cup that is already attached to the blender and has been thoroughly dried prior to use.

It is preferable to perform the grinding in a cold room with a precooled blender to decrease the rate of evaporation of the liquid nitrogen, but the procedure can be done at room temperature if necessary.

Only industrial-strength blenders and stainless steel blender cups can be used for this protocol (a Waring commercial blender is recommended). Care should be taken that all moving parts of both the blender and blender cup are completely free of moisture in order to avoid freezing when adding the liquid nitrogen.

7. Place the lid on the blender cup, making sure the lid vents are open so that pressure does not build up in cup as liquid nitrogen evaporates. Keeping the lid held down tightly, grind at high speed in three successive 2-min bursts. Between bursts, mix frozen powder and, if necessary, add liquid nitrogen to just cover powder.

Begin grinding as soon as possible after pouring in the liquid nitrogen to avoid freezing the moving parts. Some material will spurt out of the lid vents during grinding; take care not to get in its way. It is advisable to cover the working area with plastic sheeting prior to grinding to ease the clean-up. Pulsed grinding may help avoid the spurting problem, but keep in mind that speed is critical here—the frozen powder should not be allowed to thaw.

8. After grinding, pour the fine frozen yeast powder into a beaker containing twice the original cell-paste volume of ice-cold storage buffer. Mix and then pour the suspension into a centrifuge bottle. Keep bottle on ice.
9. Repeat steps 3 through 8 until all the cell paste has been processed.
10. Centrifuge 15 min at $5000 \times g$ (GSA or GS-3 rotor at 5500 rpm; or SS-34 rotor at 6500 rpm), 4°C . The supernatant contains a crude extract whose concentration should be between 10 and 20 mg protein/ml. It can be used immediately for assays or as a starting point for protein purification. For long-term storage, aliquot the supernatant into plastic tubes, freeze quickly on dry ice, and store at -80°C .

Alternatively, the frozen yeast powder can be resuspended in 1 vol lysis buffer and treated as described in steps 13 to 17 of the basic protocol for spheroplast lysis.

REAGENTS AND SOLUTIONS

Extraction buffer

Lysis buffer (see below)
0.8 M ammonium sulfate
20% glycerol

Ficoll buffer

18% (w/v) Ficoll-400 (Pharmacia)
10 mM Tris-Cl, pH 7.5
20 mM KCl
5 mM MgCl_2
3 mM DTT
1 mM EDTA
1 \times protease inhibitor mix (see below)
1 mM PMSF

Glass bead disruption buffer

20 mM Tris-Cl, pH 7.9
10 mM MgCl_2
1 mM EDTA
5% glycerol
1 mM DTT
0.3 M ammonium sulfate
1 \times protease inhibitor mix (see below)
1 mM PMSF

The concentration of ammonium sulfate in the buffer can be varied between 0.1 and 1.0 M. Final concentrations above 0.25 M strip specific DNA-binding proteins and histones off chromatin and are therefore useful in obtaining factors that interact with nucleic acids. KCl and NaCl can also be added to final concentrations between 0.1 and 2.0 M.

Saccharomyces cerevisiae

13.13.6

Glass beads, chilled and acid-washed, 0.45- to 0.55-mm

Wash the beads by soaking 1 hr in concentrated nitric acid. Rinse thoroughly with water. Dry the beads in a baking oven, cool to room temperature, and store at 4°C until needed.

Lysis buffer

50 mM Tris·Cl, pH 7.5
10 mM MgSO₄
1 mM EDTA
10 mM potassium acetate
1 mM DTT
1× protease inhibitor mix (see below)
1 mM phenylmethylsulfonyl fluoride (PMSF)

100× protease inhibitor mix

Listed below are representative protease inhibitors; different combinations may be more appropriate for individual applications.

10 µg/ml chymostatin
200 µg/ml aprotinin
100 µg/ml pepstatin A
110 µg/ml phosphoramidon
720 µg/ml E-64
50 µg/ml leupeptin
250 µg/ml antipain
10 mM benzamidine
10 mM sodium metabisulfite

Storage buffer

20 mM Tris·Cl, pH 7.5
0.1 mM EDTA
10% glycerol
100 mM KCl
1 mM DTT
1× protease inhibitor mix (see above)
1 mM PMSF

Zymolyase buffer

50 mM Tris·Cl, pH 7.5
10 mM MgCl₂
1 M sorbitol
1 mM *or* 30 mM DTT (see annotation below)

For step 5 of basic protocol use 30 mM DTT in this buffer. For all other applications, use 1 mM DTT.

COMMENTARY

Background Information

The three protocols for preparing protein extracts from yeast differ primarily in the way the cells are broken. Each of these methods has advantages and disadvantages that should be considered when choosing one for a particular application. Most importantly, the extracts made by these different methods may contain different proteins and different levels of protein activity. Thus, it may be

necessary to try different methods to obtain extracts capable of carrying out the *in vitro* reactions of interest.

Spheroplast procedure. Cells are converted to spheroplasts by zymolyase treatment, and then lysed by a combination of osmotic shock and Dounce homogenization. Because this method is the most gentle way to break yeast cells, it is most suitable for preparing extracts that can carry out complex enzymatic

functions (e.g., translation, transcription, DNA replication) and in which the integrity of macromolecular structures (e.g., ribosomes, spliceosomes) has been maintained. It is also useful for isolating intact nuclei that can be used for chromatin studies (Bloom and Carbon, 1982) or for nuclear protein extracts (Lue and Kornberg, 1987). The support protocol described here for isolating nuclei derives primarily from Nelson and Fangman (1979) and is based on differential centrifugation in the presence of high concentrations of Ficoll (a polymer that inhibits leakage of nuclear proteins into the cytoplasm). Another procedure for purifying the nuclei (after release by spheroplast lysis) employs a Percoll gradient (Amati and Gasser, 1988). Although these nuclei are slightly more purified, they seem to be of varying or lower quality than those produced by the differential centrifugation (based on nucleosome ladder integrity). The major disadvantages of the spheroplast lysis procedure are that it is relatively tedious and expensive, especially for large-scale preparations (>10 liters), and the long incubation periods can lead to proteolysis or protein modification.

Liquid nitrogen procedure. Initially described by Sorger and Pelham (1987), cells are frozen immediately in liquid nitrogen and then lysed by grinding in a Waring blender in the presence of liquid nitrogen. The protocol is quick and easy (albeit a bit messy and potentially dangerous to the careless investigator). It can accommodate varying amounts of yeast cells including very large cultures. Its main advantage is that cells are taken immediately from the actively growing state into liquid nitrogen (-135°C), decreasing degradative enzyme activities such as proteases and nucleases as well as activities that modify proteins (e.g., phosphatases and kinases). It is particularly suited for making whole-cell extracts from a single yeast culture for large-scale protein purification. A detailed description of the technique as applied to very large-scale cultures (100 to 400 liters) is given by Sorger et al. (1989). A drawback to the liquid nitrogen protocol is that small samples (i.e., 10- to 100-ml yeast cultures) are not easily processed because there is not enough mass of frozen cell clumps to fracture effectively in the blender. Stainless steel blender cups with very small capacities (10 to 100 ml) can be obtained and may be useful for processing such small amounts. Multiple samples pose another problem for the liquid nitrogen technique because, usually, only one blender is available, making it time-

consuming to process individual samples and to clean the equipment between uses.

Glass bead procedure. This protocol involves mechanically breaking cells by vortexing in the presence of glass beads. It is very flexible because it can be carried out easily on multiple small (10-ml) cultures as well as on very large cultures with appropriate equipment such as a Bead Beater (Klekamp and Weil, 1982). It is particularly useful when making extracts from many different small yeast cultures for assaying purposes rather than for protein purification. Unfortunately, during the glass bead procedure, proteins are treated harshly causing extensive foaming. The amount of cell breakage varies, and proteolysis and modification of the proteins may result from heating the extract above 4°C during the mechanical breakage.

Critical Parameters

For all these procedures, it is advantageous to use protease-deficient strains such as BJ926 or EJ101, but laboratory strains of a desired genotype can be used. In addition, commercial yeast cakes can be used for some applications and have the advantage that limitless quantities of material can be obtained for little cost and no work. The liquid nitrogen method is probably best for processing yeast cakes, while the spheroplast method is unsuitable for this application.

Another crucial factor, even for extracts from protease-deficient strains, is the inclusion of a wide collection of protease inhibitors at all stages during and after lysis. The protease inhibitor mix given in this procedure, along with PMSF and EDTA (to inhibit metalloproteases) should inactivate almost all types of proteases, although other combinations may be more appropriate for particular applications. A final general consideration is to be sure that all solutions coming in contact with the extracted proteins are kept ice cold.

Spheroplast procedure. For this protocol, it is important to handle the spheroplasts gently. The amount of time and zymolyase needed to achieve complete spheroplasting can vary quite a bit between strains, and some adjustments of the amounts given in the protocol may be necessary. Complete spheroplasting is essential for efficient lysis. Only the highest grade Zymolyase 100T should be used. However, because even this grade of zymolyase contains considerable proteolytic activity, it is important to wash the spheroplasts several times prior to lysis.

Liquid nitrogen procedure. For optimal yields of protein, all (or nearly all) the cells should be broken. This should be tested by suspending a small amount of the ground powder in buffer and visually inspecting under the microscope. (Remember to add more liquid nitrogen to the remaining powder to keep it frozen.) If many intact (phase-refractile) cells are seen, further grinding in liquid nitrogen should be performed. Care should be taken to ensure that the liquid nitrogen covering the cells does not evaporate. The frozen yeast powder should always be poured into cold extraction buffer as quickly as possible.

Glass bead procedure. It is crucial that the beads be the correct size. Cell breakage will be inefficient if the wrong size beads are used. As is the case for the liquid nitrogen procedure, the degree of breakage should be examined before proceeding. Finally, it is very important that the temperature of the solution during the breakage remains between 0° and 4°C. Because mechanical disruption generates heat, it is usually necessary to vortex in short bursts so that the solution cools down between intervals. It is also important to minimize foaming during vortexing as this is indicative of protein denaturation which may result in considerable loss of activity. Because the Bead Beater generates much less foaming than vortexing, it is preferred for large-scale preparations.

Anticipated Results

Cell extracts produced by any of these procedures contain ~10 to 30 mg/ml of the total cellular protein. These extracts can be used directly for some purposes, such as mobility shift DNA binding assays (Chapter 12), or can serve as the first step in protein purification (Chapter 10). The extracts will also contain large amounts of nucleic acid, especially RNA. Nuclear extracts will contain significant concentrations of chromosomal DNA.

Time Considerations

After growing the cells, the spheroplast procedure should take between 3 to 12 hr depend-

ing on the amount of yeast cells being processed. The most time-consuming and tedious steps are the resuspensions of the spheroplasts. Isolation of nuclei will take an additional 2 to 4 hr depending on the size of the preparation. For the liquid nitrogen or glass bead procedures, several liters of a single culture sample can be processed in an hour or less; larger cultures require more time.

Overview of *Schizosaccharomyces pombe*

UNIT 13.14

The fission yeast *S. pombe* is a popular model eukaryote that offers complementary strengths to the more familiar budding yeast *S. cerevisiae*. The organisms are evolutionarily distant with an estimated 1000 million years separation. Fission yeast has been dubbed an archaeoscomycete, making it quite separate from common ascomycetes, including *S. cerevisiae* and the filamentous fungi (Hedges, 2002); however, like budding yeast, fission yeast is genetically tractable, and lends itself to easy molecular manipulation. Its increasing popularity in recent years, especially in labs studying mammalian cell biology, has led to the nickname “micromammal.”

Fission yeast was discovered in 1893, but wasn't commonly taken up as a model organism until the 1960s (e.g., see Mitchison, 1990; Egel, 2000; Yanagida, 2002), largely for studies of growth control and differentiation. In the 1970s, Nobel laureate Paul Nurse and his colleagues isolated cell cycle mutants that either blocked the cell division cycle, or accelerated it, making *S. pombe* an important model for cell cycle control (Nurse, 2000). *S. pombe* continues as an important system for studying cell cycle regulation, sexual differentiation, and more recently, chromosome dynamics and polarized cell growth. Other areas were less developed but are now growing as new investigators continue to move into the system. Given its wide divergence from *S. cerevisiae*, *S. pombe* provides a complementary model system, and the compare and contrast approach to problems using both species has proven remarkably fruitful in providing models for biology of larger cell types (e.g., Forsburg, 1999). With a haploid genome size of just 13.8 Mb, distributed amongst 4,824 open reading frames (compared to over 5500 for *S. cerevisiae*), *S. pombe* is the smallest sequenced eukaryote (Wood et al., 2002). Unlike *S. cerevisiae*, there is no evidence of genome-wide duplications in *S. pombe*.

There are ~145 genes in *S. pombe* that have metazoan homologs but are not found in *S. cerevisiae*, and a similar number vice versa (Wood et al., 2002). These genes tend to represent groups of proteins involved in particular cellular functions. For example, *S. pombe* has

three relatively large chromosomes of 5.7, 4.6, and 3.5 Mb. These have features typical of higher eukaryotes, including large diffuse replication origins (~1 kb) and large heterochromatic centromeres (~40 to 100 kb). These elements do not contain short consensus sequences, as in the more numerous small chromosomes of budding yeast, but are defined by activity typical of the same elements in higher cells. Many of the proteins common to *S. pombe* and metazoans that are missing in *S. cerevisiae* are implicated in chromosome functions, including heterochromatin factors such as Swi6/HP1, chromatin modifiers such as the histone methyltransferase Clr4/SuVar2-9, telomere proteins such as Taz1/TRF, centromere proteins such as CENP-B, and components of RNAi apparatus such as Argonaut and Dicer. Not surprisingly, *S. pombe* is proving to be a particularly appropriate model system for studies of mammalian chromosome biology. Similarly, given its distinct rod-shaped morphology and division by medial fission, it is also a good model for polarity and cytokinesis. Other problems are also easily approached.

The choice of system is in part driven by the problem under study, but also by the availability of local expertise. Relatively few U.S. investigators chose fission yeast as a system prior to the explosion of the cell cycle studies in the 1980s, in contrast to its strong popularity in Japan and Europe; however, *S. pombe* is now well represented throughout North America, as well as in its traditional strongholds. In addition, a number of groups with experience in mammalian cell biology have picked up *S. pombe* as their alternative model system, leading to a substantial group of fission yeast researchers who work in labs that do not consider themselves yeast groups. The fission yeast community overall is relatively small by comparison to that of budding yeast but is friendly and international in outlook. It is held together by an international meeting in alternate years, and extensive online resources.

There is a persistent myth suggesting that *S. pombe* cannot be manipulated to the same extent as budding yeast. In practice, working in *S. pombe* is not strikingly different from working in *S. cerevisiae*. Most tools available in *S.*

Yeast

13.14.1

Supplement 64

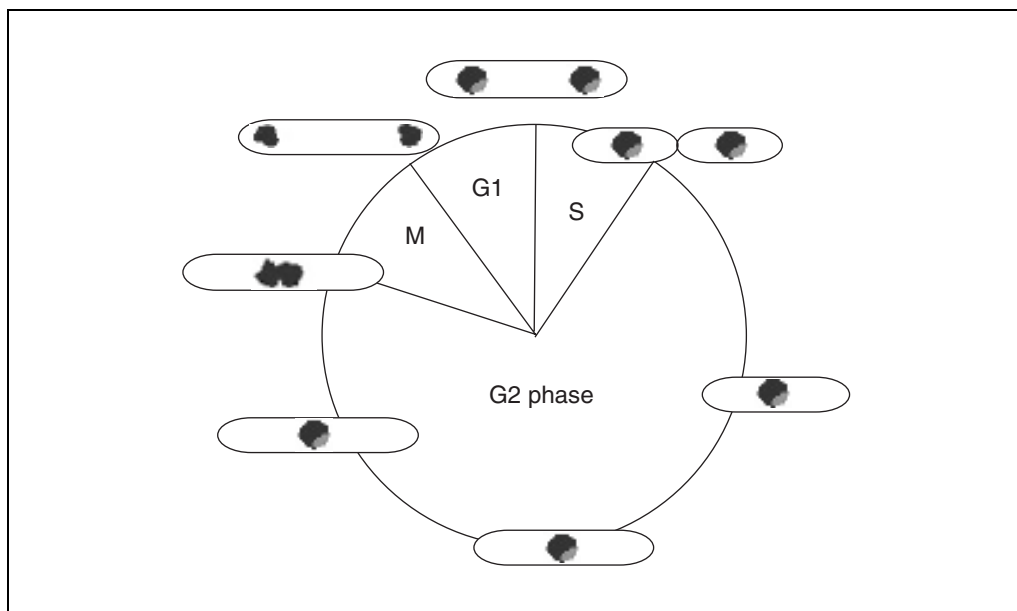

Figure 13.14.1 The fission yeast cell cycle. Rod-shaped cells grow at the ends, maintaining constant diameter. In exponentially growing cells, cytokinesis occurs after daughter nuclei have already entered their next S phase.

cerevisiae are available in *S. pombe* versions that accommodate the distinct biology of the fission yeast, and similar genetic strategies are available for both systems (e.g., Forsburg, 2001). Fission yeast still lacks well developed genomics resources, presumably because its genome sequence was only completed in 2002. Commercial microarrays or oligonucleotide libraries are not widely available, and there is as yet no standard collection of disruptions of all open reading frames. However, other community-wide resources have been developed, including libraries of temperature-sensitive and insertion mutants at FYSSION at the University of Sussex, UK (<http://pombe.biols.susx.ac.uk>), which may be freely screened. A large expression project is underway at the Sanger Centre and the data are freely searchable (http://www.sanger.ac.uk/PostGenomics/S_pombe).

S. pombe cells are rod shaped and grow by increasing length while maintaining a constant diameter. The length of a cell is a sensitive indicator of its position within the cell cycle. They divide by medial fission, producing two essentially identical daughter cells. The nuclear cell cycle is divided into distinct G1 (10%), S (10%), G2 (70%), and M (10%) phases. Following mitosis, the newly replicated nuclei enter the next cell cycle and undergo G1 and S phase prior to completion of the previous cycle's cytokinesis. This quirk means that a single cell particle almost always has a 2C DNA content, either because of the extended G2 phase, or the binucleate G1 or S phase cells (see

Fig. 13.14.1). Fission yeast is generally haploid even in the wild. Following conjugation, newly formed zygotes immediately enter meiosis and sporulation to produce four spores in a linear tetrad ascus. Diploids can be recovered in the laboratory by selection for complementing markers, but are unstable and prone to sporulate even on minimal media. One of the major differences in *S. pombe* and *S. cerevisiae* is in handling mating and diploids (see UNIT 13.16).

Approximately 43% of genes have at least one intron and multiple introns are common; however, the introns are usually short, and most are <100 bp in length (Wood et al., 2002). They do not have the rigid splicing consensus observed in *S. cerevisiae*. TATA boxes and other consensus sequences for transcription are more proximal to the ATG than observed in budding yeast (Russell, 1983). For this reason, it cannot be assumed that fission yeast genes will express appropriately in budding yeast, or vice versa. Thus, for cross-complementation experiments it is best to use a cDNA and a promoter native to the host species. Plasmids and markers for *S. pombe* are conceptually similar to those in *S. cerevisiae*, with the exception of single-copy centromere plasmids. Since the fission yeast centromeres are so large, they cannot be accommodated on a typical episome. While some *S. cerevisiae* plasmids and markers can be maintained in *S. pombe*, and were widely used in the early days of fission yeast molecular biology, they are not optimal and are prone to plasmid loss or rearrangement. Plasmids containing *S.*

pombe-specific replication origins and markers are strongly recommended and a large variety now exist.

Most protocols described in the sections on *S. cerevisiae* are broadly applicable to fission yeast with only minor changes. The author's purpose here is to identify those common *S. pombe*-specific methods that are required by a new investigator but are substantially different from similar protocols in budding yeast, including specific media (UNIT 13.15), crosses and diploids, tetrad analysis, and cell cycle synchronization (UNIT 13.16), and some types of transformation (UNIT 13.17). General handling of the organism, microbial culture, and overall purification of nucleic acid and protein are similar to budding yeast. Generally, an investigator who has handled *E. coli* in the course of performing standard molecular biology manipulations will have no trouble working with yeast of either species. Additional resources for working with *S. pombe* can be found in (Moreno et al., 1991; Alfa et al., 1993; Gould, 2003).

STRAIN MAINTENANCE AND GENERAL GUIDELINES

Growth conditions

The basic methods for yeast culture are the same for both *S. pombe* and *S. cerevisiae* (see UNIT 13.2). The generation time of *S. pombe* is somewhat longer than that of budding yeast, ranging from 2 to 5 hr depending upon the medium, strain, and temperature. The preferred permissive temperature is 32°C, although cells grow well at 30°C. The maximum permissive temperature is 36°C and the minimum is 17°C. Most temperature-sensitive mutants are viable at 25°C.

Determining cell count

As an approximate guide, an OD₆₀₀ of 1.0 equals $\sim 1.5 \times 10^7$ cells/ml, subject to the same caveats described in UNIT 13.2; however, bear in mind that the OD is a measure of overall cell mass, not cell number. A strain arrested by mutation in a cell cycle gene will continue to increase in OD because the cells continue to elongate, even though the cell number is not increasing. Under these conditions, a hemacytometer or Coulter counter should be used to measure cell number.

Diploids

Diploid strains should not be maintained for prolonged periods, but constructed fresh before use (see UNIT 13.16 on mating and mating type testing). The fission yeast diploid is partially induced for meiosis, and prolonged growth leads to selection for mutants that block the meiotic pathway. The exception is diploids that contain an otherwise lethal disruption. It is common for diploids awakened from the freezer to have a high frequency of sporulation-minus segregants; this can be examined by iodine staining, as described below. Similarly, *h*⁺ strains which can revert to *h*⁹⁰ should be tested to verify the mating type. Yeast nomenclature is detailed in Table 13.15.1.

Table 13.15.1 Yeast Nomenclature

Species	Wild type gene name	Recessive mutant	Protein	Disruption
<i>S. pombe</i>	<i>yfg1</i> ⁺	<i>yfg1-1</i>	Yfg1, Yfg1p	$\Delta yfg1::ura4^+$; $\Delta yfg1-D1$; <i>yfg1</i> Δ or $\Delta yfg1$
<i>S. cerevisiae</i>	<i>YFG1</i>	<i>yfg1-1</i>	Yfg1, Yfg1p	$\Delta yfg1::URA3$; <i>yfg1</i> Δ or $\Delta yfg1$

PRESERVING STRAINS BY FREEZING

Strains are typically stored at –70°C in glycerol. Stocks should be cultured to stationary phase (OD₆₀₀ = 1.5) in YES medium (see recipe), then mixed 1:1 either with sterile yellow freezing mix (50% v/v glycerol in YES) or 50% (v/v) sterile glycerol and immediately frozen. For strains that must be maintained under selection (e.g., to maintain a plasmid), the culture should be grown in EMM (see recipe) and frozen by addition of an equal volume of 50% (v/v) glycerol. Phenotypes of strains reawakened from the freezer should be verified by replica plating.

NOTE: Rather than sterile velvets, the authors recommend using two circles of Whatman #1 filter paper, which are sterile straight out of the box.

Yeast

13.15.1

Supplement 64

MEDIA

Fission yeast can be grown on synthetic minimal or rich media (see recipes), depending upon the needs of the experiment. Ideally, investigators should use media optimized for the organism, although *S. pombe* can be maintained on budding yeast media if necessary. Rich media made from yeast extract (YE) is usually supplemented to promote maximum growth and prevent adenine limitation. There are several variations of minimal media, although EMM (see recipe) is the most efficient at suppressing mating or sporulation. There are multiple choices for mating media, including malt extract or SPAS (see recipe). Most fission yeast investigators do not use “drop-out mix,” but add the individual supplements required for their strains; however, this is a result of habit rather than a requirement. Commercially available media mixes are also available from Qbiogene.

The same general rules apply for fission yeast media as for budding yeast media (*UNIT 13.1*), including sources for compounds, autoclaving, and general procedures. Media should not be autoclaved for more than 20 min to prevent caramelization of the glucose.

Rich Medium

YES

<i>Per liter:</i>	<i>Final concentration:</i>
5 g yeast extract	0.5% yeast extract
30 g glucose	3% glucose
225 mg adenine-HCl	1.31 mM adenine
225 mg L-histidine	1.45 mM L-histidine
225 mg L-leucine	1.71 mM L-leucine
225 mg uracil	2.01 mM uracil
225 mg L-lysine-HCl	1.23 mM L-lysine
20 g Difco Bacto Agar	2% agar (solid medium only)

*YES, or YE + supplements, is preferred for general growth when selection is not required; however, when selecting for the kan-MX marker using G418/geneticin resistance (Sigma G-5013), YES is the preferred media. The supplements are added to ensure maximum growth. If the supplements are not added, normal YE is functionally a low-adenine media. Note that YE or YES contains thiamine, so it represses expression from the commonly used *nmt1* (no message in thiamine) promoter.*

Minimal Medium

EMM

<i>Per liter:</i>	<i>Final concentration:</i>
3 g potassium hydrogen phthalate	14.7 mM $C_8H_5KO_4$
2.2 g dibasic sodium phosphate	15.5 mM Na_2HPO_4
5 g ammonium chloride	93.5 mM NH_4Cl
20 g glucose	2% glucose
20 ml 50× salt stock (see recipe)	1× salt
1 ml 1000× vitamin stock (see recipe)	1× vitamins
0.1 ml 10,000× mineral stock (see recipe)	1× minerals

When using Edinburgh minimal medium, required supplements for auxotrophies (e.g., adenine, uracil) are added immediately before use to a final concentration of 225 mg/liter as required. These can be maintained as sterile stock solutions at 7.5 mg/ml in water (3.75 mg/ml for uracil). Low adenine media, which allows the development of a red color in Ade^- strains, reduces the amount of adenine to 7.5 mg/liter. Some protocols use 10 or even 30 mg/liter adenine, and still see satisfactory red color develop.

The *nmt1* promoter, which is the most commonly used promoter for heterologous gene expression (Maundrell, 1990, 1993), is repressed by the addition of 15 μM thiamine (15 μM or 5 $\mu\text{g/ml}$; from filter sterilized stock at 10 mg/ml) immediately prior to use. The levels of expression can also be titrated using intermediate amounts of thiamine (0.05 μM or 0.016 $\mu\text{g/ml}$; Javerzat et al., 1996). SD media, used for budding yeast, contains thiamine and therefore cannot be used for fission yeast when *nmt1* expression is desired.

Variations of EMM media are used for particular purposes. For example, EMM lacking nitrogen (i.e., which leaves out the ammonium chloride; EMM -N) is used to arrest cells in the G1 phase of the cell cycle at 25°C. EMM in which the ammonium chloride is replaced by 1 g/liter L-glutamate is a low nitrogen medium that promotes sexual differentiation in lieu of mating media discussed below. Under conditions where slow growth is desired to allow full expression of a particular phenotype, ammonium chloride is often replaced with a poor nitrogen source, for example 3.8 g/liter glutamate (Ekwall et al., 1996) or 1.2 g/liter proline (Rhind and Russell, 1998). EMM with 0.5% glucose instead of 2% reportedly improves some transformation procedures (Okazaki et al., 1990). EMM that lacks both nitrogen and glucose (EMM -N -G) can be used to arrest cells in the G2 phase of the cell cycle and is also a suitable buffer to maintain spores following random spore analysis (UNIT 13.16). EMM + sorbitol plates are used for plating protoplasts. Add sorbitol to a final concentration of 1.2 M in standard EMM prior to autoclaving.

Stock Solutions

Prepare all stock solutions in water. Filter sterilize and store indefinitely at 4°C.

50× salt stock

<i>Per liter:</i>	<i>Final concentration:</i>
52.5 g magnesium chloride hexahydrate	0.26 M $\text{MgCl}_2 \cdot 6 \text{H}_2\text{O}$
0.735 g calcium chloride dihydrate	5.0 mM $\text{CaCl}_2 \cdot 2 \text{H}_2\text{O}$
50 g potassium chloride	0.67 M KCl
2 g disodium sulfate	4.1 mM Na_2SO_4

1000× vitamin stock

<i>Per liter:</i>	<i>Final concentration:</i>
1 g pantothenic acid	81.2 mM pantothenic acid
10 g nicotinic acid	81.2 mM nicotinic acid
10 g inositol	4.20 mM inositol
10 mg biotin	40.9 μM biotin

10,000× mineral stock

<i>Per liter:</i>	<i>Final concentration:</i>
5 g boric acid	80.9 mM boric acid
4 g magnesium sulfate	33.2 mM MnSO_4
4 g zinc sulfate heptahydrate	13.9 mM $\text{ZnSO}_4 \cdot 7 \text{H}_2\text{O}$
2 g ferric chloride hexahydrate	7.40 mM $\text{FeCl}_2 \cdot 6 \text{H}_2\text{O}$
0.4 g molybdic acid	0.32 mM molybdic acid
1 g potassium iodide	6.02 mM KI
0.4 g cupric sulfate pentahydrate	1.60 mM $\text{CuSO}_4 \cdot 5 \text{H}_2\text{O}$
10 g citric acid	47.6 mM citric acid

Mating Media

ME

<i>Per liter:</i>	<i>Final concentration:</i>
30 g Bacto-malt extract (ME)	3% (w/v) malt extract
30 g glucose	3% glucose
225 mg adenine-HCl	1.31 mM adenine
225 mg L-histidine	1.45 mM L-histidine
225 mg L-leucine	1.71 mM L-leucine
225 mg uracil	2.01 mM uracil
20 g Difco Bacto agar	2% agar (for solid medium only)
Adjust to pH 5.5 with NaOH	

ME is the most common mating media, but may show batch-to-batch variation. More defined media can be used instead, such as SPAS, EMM -N, or EMM with 1 g/liter L-glutamate instead of NH_4Cl .

SPAS

<i>Per liter:</i>	<i>Final concentration:</i>
10 g glucose	1% (w/v) glucose
1 g potassium phosphate monobasic	7.3 mM KH_2PO_4
1 ml 1000 \times vitamin stock	1 \times vitamins
45 mg adenine-HCl	0.26 mM adenine (1/5 normal)
45 mg histidine	0.29 mM histidine (1/5 normal)
45 mg leucine	0.34 mM leucine (1/5 normal)
45 mg uracil	0.40 mM uracil (1/5 normal)
45 mg lysine-HCl	0.25 mM lysine (1/5 normal)
30 g Difco Bacto agar	3% agar (for solid medium only)

Phloxin B

This vital stain is commonly used to determine ploidy and temperature sensitivity of *S. pombe*. It colors solid media vivid pink and the colonies will range in color according to the health of the cells. However, because it is mildly toxic, it should only be used for testing and not for long-term storage. Cells on phloxin B media die rapidly if the plates are refrigerated. Wild-type haploids form pale pink colonies on phloxin B. Diploid colonies are slightly darker. Dying cells form darker colonies or patches, and lethal mutants are often dark red. The color is not apparent at the single cell level (any dead cells will stain vivid pink), but relies on macroscopic examination of colony color.

Phloxin B (Magdala Red; Sigma) is prepared at a final concentration of 5 mg/liter from a stock of 10 g/liter in water. It is then filter sterilized and kept indefinitely at room temperature. Because it is light sensitive, it should be stored in the dark (e.g., a foil-covered tube). Plates should be stored at room temperature, in the dark, for no more than a few weeks. If the plates start to dull or look brownish, they are past their usefulness.

Much of the difference in working with *S. pombe* compared to *S. cerevisiae* comes from two issues. First, *S. pombe* has a G2-oriented cell cycle, spending 70% of its lifecycle in G2—almost completely opposite to the case of *S. cerevisiae*. Second, a wild-type cell is usually haploid, because *S. pombe* cells mate and sporulate only in response to nutrient limitation in a continuous pathway from conjugation through meiosis. This contrasts with wild-type *S. cerevisiae* which will mate whenever an appropriate partner is present, but only sporulates under nutrient limitation. Thus, working with fission yeast diploids in the laboratory requires specific genetic tricks and planning ahead. Moreover, mating type pheromones cannot be used to arrest the cell cycle easily in *S. pombe*, so other methods must be employed. This unit addresses these distinct areas of working with crosses, tetrads, and diploids, as well as analyzing the cell cycle and the products of genetic analysis.

CROSSES, TETRADS, AND DIPLOIDS

Fission yeast has two mating types, h^+ and h^- , which are alleles of the *mat1* locus (*mat1-M* for h^- , *mat1-P* for h^+). Fully wild-type cells switch between h^+ and h^- mating types; these are called h^{90} (because 90% of cells can typically switch). In a culture of h^{90} cells, approximately half of the cells will be functionally h^+ and half h^- because of switching. Laboratory investigators typically use strains with rearrangements of the silent mating loci to provide a stable mating type and prevent switching. These heterothallic strains will only mate if a partner of the opposite mating type is provided to them. Since the silent loci are closely linked to the expressed *mat1* locus, it is convenient (but not quite accurate) to think of mating type in *S. pombe* as having three alleles: h^{90} , h^+ , and h^- . The common h^- is stable, but most laboratory h^+ strains revert to h^{90} at a low frequency ($\sim 10^{-3}$; for review, see Klar, 1992).

The *S. pombe* lifestyle is predominantly haploid, and in contrast to budding yeast, fission yeast haploids must be starved of nitrogen in order to undergo mating. Once they mate, they normally proceed immediately through sporulation, generating a curved, zygotic ascus (Fig. 13.16.1A). Diploids can be recovered in the laboratory by interrupting this process, and can be maintained vegetatively; however, they are prone to sporulate, and when they do, they form a linear, azygotic ascus that is easily distinguished from the zygotic ascus (Fig. 13.16.1A).

In this unit, mating type testing is described (see Basic Protocol 1), crossing strains for tetrad or random spore analysis is covered (see Basic Protocol 2), and instructions for working with diploids are given (see Basic Protocol 3).

TETRAD DISSECTION AND RANDOM SPORE ANALYSIS

Both tetrad dissection and random spore analysis (RSA) are used to construct new strains and for analysis of meiotic products. Because mating and meiosis are linked in *S. pombe*, it is generally not necessary to isolate a diploid prior to characterizing offspring. Instead, the haploid parents are crossed on mating plates and allowed to proceed all the way through sporulation. The only exceptions are generally when very efficient sporulation is required, or when one parent is homothallic (h^{90}), and would otherwise cross with itself.

The logic of tetrad dissection is exactly the same for *S. pombe* as *S. cerevisiae*, and the manipulations are similar. RSA in fission yeast is much simpler than for budding yeast

Yeast

13.16.1

Supplement 64

because vegetative cells are easily killed by the enzyme glusulase (snail gut enzyme), and the spores do not stick to one another, so they are readily dispersed. RSA provides certain advantages because it allows the analysis of a large population of offspring with relatively little labor, and is very commonly used. On the other hand, tetrad dissection uniquely allows the analysis of the products of an individual meiosis, and the unambiguous identification of double mutants. *S. pombe* tetrads are generally somewhat linear in shape, and therefore ordered, but it is seldom possible to dissect the spores in such a way as to maintain the order.

How does one choose which is most useful? For general strain construction in which the desired double mutant can be unambiguously identified, RSA is the method of choice. It is particularly useful if the two mutations are linked (e.g., *leu1* and *his7*), because a large number of offspring can be analyzed to identify a rare event. RSA can be used for linkage analysis in genetic screens, since large numbers of crosses can be processed easily, and it is commonly used to determine recombination frequency in large mapping studies. The only caveats are that all the genotypes must be equally viable and the desired recombinant must be unambiguously identified. In cases where there is some doubt about the genotype of a putative double mutant, the candidates can be backcrossed to each parent to verify linkage. Most common strain construction requirements are satisfied by RSA.

There are two special cases where RSA is particularly helpful. The first is in recovery of spores containing plasmids. Because fission yeast plasmids cannot encompass the very large fission yeast centromere (*UNIT 13.14*), plasmids are meiotically unstable and usually only 10% of spores will contain a plasmid marker. However, using RSA, even this low fraction is sufficient to isolate a plasmid-containing spore or to draw conclusions about plasmid complementation of deletion alleles in cases where plasmid shuffle is not possible.

The second special case is the analysis of lethal mutations in the population during a spore germination experiment. Diploid strains heterozygous for a marked allele are sporulated in batch culture of liquid mating medium to generate large populations of spores. Following digestion with the enzyme, the spores can be inoculated into selective medium so that only cells carrying a desired marker are able to germinate. The rest of the spores are inert so that the phenotype of the germinated mutants may be unambiguously determined.

Tetrad analysis provides an enormous amount of information even in ten tetrads. Linkage trends are usually visible in just a few tetrads (but meaningful numbers for weak linkage may take many more). Most importantly, tetrad analysis allows the unambiguous identification of double mutants and is essential if the phenotype of a double mutant is unknown or potentially lethal. Consider a cross between two viable mutants, $\Delta yfg1::ura4^+$ and $\Delta yfg1::ura4^+$. Since both are marked with *ura4*⁺ and are otherwise indistinguishable, the investigator relies upon isolation of the nonparental ditype tetrad (2 *ura4*⁺:2 *ura4*⁻ spores) to identify unambiguously the double mutant. In this tetrad, the two *ura4*⁺ spores must both be double mutants and their phenotypes and viability can be determined.

Wild-type fission yeast are efficient at germinating on YES plates. Germination is modestly reduced on EMM plates, so unless selection for specific markers is required, YES plates are preferred both for RSA and tetrad dissection.

In this unit, tetrad analysis is described (see Basic Protocol 4). Additional protocols detail RSA (see Alternate Protocol 1), nonsporulating diploids (see Alternate Protocol 2), and endoreduplication (see Alternate Protocol 3).

Cell Cycle Synchronization

In budding yeast, the mating pheromone α factor is sufficient to arrest cells in G1 phase. In wild-type fission yeast, mating pheromone has much weaker effects, and the primary G1 arrest signal is provided by nitrogen starvation. Thus, cells can be arrested in G1 by starving for nitrogen and then releasing by refeeding with complete medium. This leads to a reasonably synchronous cell cycle following a several hour delay (lag phase). Alternative methods for cell synchronization fall into two classes: those that separate small G2 cells on the basis of size by some form of centrifugation and those that rely on cell cycle block and release by starvation, drugs, or mutants. The latter are generally simpler to perform but, since they rely on a perturbation of the cell cycle, they may lead to confusing results. Any meaningful cell cycle variation in phenotype, protein, or RNA levels should be verified using cycling cells unperturbed by arrest.

In these protocols the authors describe methods used for physiological analysis, such as cell cycle dynamics, using small cultures. They can be adjusted for preparative studies of RNA or protein by increasing the culture volume and harvesting larger aliquots at each time point.

To determine cell cycle synchronization during nitrogen starvation, a time course is monitored by sampling cells at each time point and fixing the aliquot for microscopy (see Basic Protocol 5 and Support Protocol). Similar monitoring is used for other synchrony methods, including cell cycle block and release (see Alternate Protocol 4). Size selection of cells via lactose gradients is also described (see Basic Protocol 6). Use of centrifugal elutriation requires a specialized centrifuge and rotor that is not found in most labs; however, should such an instrument be available, a good description of the procedure is found in Alfa et al. (1993).

MATING TYPE TESTING

Unlike *S. cerevisiae*, mating type testing in *S. pombe* relies upon completion of sporulation rather than isolation of complementing diploids. This reflects the relative instability of diploids in the laboratory. Thus, the only markers that are relevant in the strains to be tested are their mating types. When fission yeast cells complete meiosis and sporulation, they produce starch that can be stained easily by exposure to iodine vapor; however, iodine vapor kills the cells, so this method cannot be used if further analysis of the meiotic products is required.

Materials

- Known h^+ and h^- tester strains
- Rich medium plates (e.g., YES plates; *UNIT 13.15*)
- Characterized (positive control) and uncharacterized strains
- Mating plates (ME, SPAS, or EMM -N; *UNIT 13.15*)
- Iodine crystals (Sigma)
- 25°C incubator
- Empty petri dish
- Additional equipment and reagents for replica plating (*UNITS 1.3 & 13.2*)

CAUTION: Iodine is toxic and the vapors from the crystals or the exposed tester plate should not be inhaled.

1. Patch known h^+ and h^- tester strains vertically on rich medium plates, and the uncharacterized strain on a separate plate horizontally (Fig. 13.16.1). Include a characterized strain as a positive control. Incubate at 32° (wild type) or 25°C (ts strains) until both patches are grown up (1 to 2 days).

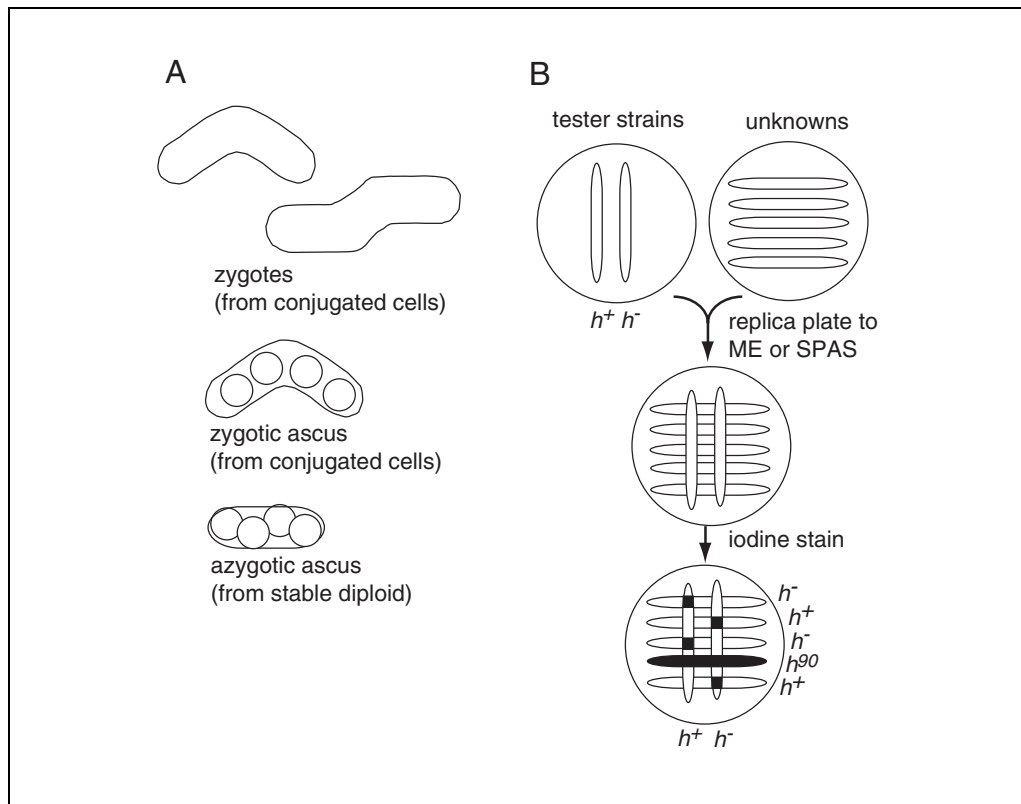

Figure 13.16.1 Fission yeast mating. (A) Zygotes and asci as seen under the microscope. (B) Mating type testing on plates.

2. Replica plate onto mating plates so that they intersect (UNITS 1.3 & 13.2).

Cells mate most efficiently when they are replica plated from freshly grown streaks on rich medium.

3. Incubate 3 to 4 days at 25° to 29°C.

Mating and sporulation are inherently temperature sensitive and should be carried out at 25°C (maximum of 29°C).

4. Prepare an iodine plate by scattering iodine crystals on the bottom or lid of an empty petri dish in a fume hood. Remove the lid of the tester plate and invert over the plate of crystals. Incubate this way until the positive control becomes dark brown where the streak intersects the tester of the opposite mating type (5 to 10 min). Do not allow the crystals to touch the agar or cells.

The plate with crystals can be stored in a sealed plastic container in the fume hood. The crystals will continue to sublime and will need to be refreshed regularly. If the tester plate is left too long, the color can be reduced by removing the plate from the crystals and letting it fade in the hood.

5. Determine the mating type by identifying the junctions in which a strain of known mating type generated a dark patch with the strain being tested (see Fig. 13.16.1B). h^{90} strains will mate with all testers and themselves, generating a continuously dark streak. The dark color does not last, so the results should be recorded immediately.

CROSSING STRAINS FOR TETRAD OR RANDOM SPORE ANALYSIS

Construction of new strains or analysis of meiotic products requires that the parent strains cross efficiently under conditions where the spores are viable. The previous protocol (see Basic Protocol 1) is adequate for assigning mating type, but mating via replica plates is relatively inefficient, and the iodine staining will kill the cells. This protocol provides more efficient mating by improving the mixing of the parent cells, and does not employ iodine. Successful mating can be determined microscopically by determining the formation of zygotes and asci (Fig. 13.16.1A).

Materials

- Strains to be crossed (i.e., strains 1 and 2) growing robustly on YES plates (EMM if selection is required; *UNIT 13.15*)
- Mating plates (ME or SPAS plates; *UNIT 13.15*)
- H₂O, sterile
- Sterile toothpicks
- 25° to 29°C incubator

For single matings

- 1a. Using a sterile toothpick, take a visible glob of cells from strain 1 and make a small patch on a mating plate (~5 mm in diameter). Using a second sterile toothpick, take an equivalent amount of strain 2 and add to the previous patch.
- 2a. Add 5 µl sterile water and mix strains gently on the surface of the agar with a sterile toothpick.

For multiple matings using the same strains

- 1b. Pick a generous amount into 100 µl sterile water.
- 2b. Pipet 5 µl of each onto a patch and use a sterile toothpick to mix each cross gently.
 - Strains growing in liquid medium can be mated, but they must be washed free of the medium or the nitrogen in the medium will suppress mating.*
3. Incubate at 25° to 29°C for 2 to 4 days (2 to 3 for tetrads, 3 to 4 for other assays). Monitor formation of asci microscopically.

Note that iodine staining (see Basic Protocol 1) is lethal and cannot be used if viable asci are required for tetrad dissection, RSA, or spore germination.

Mating and sporulation are inherently temperature sensitive and should be carried out at 25°C (maximum of 29°C). Sterile strains can be forcibly mated using protoplast fusion, a variation of the protoplast protocol used for transformation (see section on transformation in UNIT 13.17). Mating and sporulation can also occur in liquid culture. Equal numbers of both mating types, or previously isolated diploid cells, are washed free of normal growth medium and then inoculated into liquid mating medium. Cultures are incubated with gentle shaking at 25°C and monitored microscopically for the formation of zygotes and/or spores. Generally this is accompanied by substantial flocculation.

WORKING WITH DIPLOIDS

Although fission yeast diploids are unstable, they can be recovered by interrupting the mating process. Diploid strains must be selected by complementation of nutritional markers; however, after they are identified, they should be maintained on YES to suppress sporulation. Diploids are important for many assays and take only a little advance planning to be useful in the laboratory.

A particularly convenient pair of markers for diploid construction is provided by two complementing *ade6* alleles, *ade6-M210* and *ade6-M216*. When present in the same cell, these alleles complement intragenically, leading to an Ade⁺ phenotype. This also provides a color screen: the *ade6*⁺ gene is the ortholog of budding yeast *ADE2*, and mutants cause the accumulation of a pink or red color in the cell in the presence of low adenine (see *UNIT 13.15*). Ade⁺ strains are white. The two *ade6* alleles can be distinguished by their degree of color: *ade6-M210* is usually darker pink than *ade6-M216*. Neither is as dark as a null allele; however, their color can be affected by the strain background, so the marker is frequently misassigned. Assignment can be verified by attempting to make a diploid against a strain with a known *ade6* allele.

If the appropriate *ade6* markers are unavailable, a diploid can be constructed by complementation of any two auxotrophic markers. In this case, the investigator must use care to verify that the strain recovered is diploid, and not a recombinant haploid spore.

Materials

Strains to be crossed (complementing mating types and *ade6* markers) growing robustly on YES plates (EMM if required for selection; *UNIT 13.15*)

EMM plates lacking adenine (*UNIT 13.15*)

YES plates containing phloxin B (*UNIT 13.15*)

YES plates (*UNIT 13.15*)

Mating plates (ME or SPAS; *UNIT 13.15*)

Sterile toothpicks

25° or 32°C incubator

Additional reagents and equipment for mating and testing the mating type of *S. pombe* (see Basic Protocol 1)

1. Follow the steps for mating *S. pombe* (see Basic Protocol 1, steps 1 to 3), using strains with complementing mating types and *ade6* markers growing robustly on YES (or EMM) plates.
2. At 6 hr after mating and again at 12 hr, take a sterile toothpick and pick a swatch of cells. Streak to EMM medium lacking adenine (but containing any other required supplements).
3. Incubate at 32°C (25°C for temperature-sensitive diploids).
Incubation at 36°C, if the diploids are not temperature sensitive, will suppress sporulation.
4. Once clearly white colonies are visible (1 to 2 days), pick and streak several on YES plates containing phloxin B. Incubate 2 to 4 days at 32°C (25°C for temperature-sensitive mutants).

The cells in the middle of a colony on EMM may have sporulated; these will form pale pink haploid colonies when streaked on YES plates containing phloxin B. The darker pink colonies are still diploids. It is useful to streak a known haploid on YES containing phloxin B plates to verify its color. In addition, diploids are longer and wider than haploids when viewed under the microscope.

5. Pick several independent colonies and streak to YES plates. Patch the same colony in an ~5- to 10-mm spot on mating plates (ME or SPAS) and incubate 1 to 2 days at 25°C. Expose the mating plates to iodine vapor as described in mating type testing (see Basic Protocol 1) to verify clones are sporulation competent.

Diploids are stable for 1 to 2 weeks at 4°C if maintained on YES.

Prolonged maintenance selects for sporulation deficient mutants; therefore, diploids should be constructed fresh whenever possible.

TETRAD ANALYSIS

This method is almost identical to that in budding yeast and the apparatus is the same (see *UNIT 13.2*). The significant difference is that fission yeast asci do not require prior digestion with glusulase: they fall apart by themselves. Thus, the investigator must identify a mating plate with ripe asci before they have started to disintegrate, and manipulate the intact asci out to the position as shown in Figure 13.2.1. The plate is incubated for a few hours at room temperature (or overnight at 17°C), during which time the ascus breaks down, and the investigator returns to the plate and completes the dissection of the now freed tetrads. This must be completed before the freed spores enter their first cell division. The disintegration of asci is retarded at low temperatures and accelerated at high temperatures.

In addition, fission yeast spores are not particularly sticky. Thus, a very high quality needle with a completely flat plane is essential, since the spores will not stick to the needle without surface tension. In addition to pulling needles oneself, precut fiber optic needles that fit standard tetrad microscopes are also available (e.g., Singer Instruments; <http://www.singerinstruments.co.uk>).

Materials

Mating/sporulation plate grown for 2 to 3 (haploid) or 1 to 2 (diploid) days
YES plates (*UNIT 13.15*)

Sterile toothpicks
Tetrad dissecting microscope
36°C incubator (optional)
17°C incubator (optional)
25° or 32°C incubator

Additional reagents and equipment for preparation and dissection of tetrads (*UNIT 13.2*)

NOTE: Azygotic asci from previously isolated diploids form more quickly than zygotoc asci from haploids, which must mate first.

1. Under a microscope, examine a mating/sporulation plate which has been grown for 2 to 3 (zygotoc) or 1 to 2 (azygotoc) days at 25° to 29°C to identify ripe asci, which are intact but have clearly distinguished spores. If necessary, spread cells in the mating patch along the agar with a sterile toothpick to make them more apparent.
The mating/sporulation plate can be left in the refrigerator for a day or two to retard ascus breakdown if the investigator cannot immediately dissect the tetrads.
2. Transfer and lay cells across the YES plate upon which dissection will be performed using a sterile toothpick.
3. Upon identification of a ripe intact ascus, use a dissecting needle to manipulate the ascus to a fixed position (a of Fig. 13.2.1) on the plate (see protocol for preparation and dissection of tetrads, *UNIT 13.2*). Place each additional ascus 0.5 cm to one side of the preceding tetrad.
- 4a. *For tetrads identified in the morning:* Incubate the plate a few hours at warmer temperatures (i.e., 32° to 36°C) to stimulate ascus breakdown. If the strain is not temperature sensitive, an hour or two at 36°C can noticeably accelerate the process.
- 4b. *For tetrads identified at the end of the day:* Incubate the plate overnight at room temperature or 17°C.

5. Upon returning the plate to the micromanipulator, identify tetrads that have popped by the four large, round, free spores and sometimes the faint skin of an ascus. Move them down the plate to the b, c, and d positions (Fig. 13.2.1). Repeat steps 3 and 4 throughout the day as needed.
6. Once the plate is completed, incubate it at the appropriate temperature (32°C for wild type, 25°C for temperature-sensitive mutants).

Germination occurs within a few hours and it generally takes 2 to 5 days to observe colonies, depending upon the temperature of incubation.

RANDOM SPORE ANALYSIS

Fission yeast spores do not adhere to one another outside of the ascus; rather, the ascus falls apart over time and the remaining vegetative diploids in a culture are readily killed by glusulase. Thus, random spore analysis is significantly easier in *S. pombe* than in budding yeast. It is the method of choice for many strain constructions, as long as the recombinant strains are viable and easily distinguished from the parents. When used in bulk liquid culture, it allows spore germination experiments to analyze large populations of marked, lethal alleles.

Materials

Mating/sporulation plate

H₂O, sterile

5% glusulase (DuPont NEN) in sterile water

PBS (APPENDIX 2; optional), or EMM –N –G (UNIT 13.15; optional)

YES plates (UNIT 13.15)

Sterile toothpick

Additional reagents and equipment for counting cells using a hemacytometer
(APPENDIX 3F)

1. Using a sterile toothpick, pick cells from a mating/sporulation plate into 100 µl sterile water. Add 10 µl of 5% glusulase and incubate overnight at room temperature.
2. Using a hemacytometer (APPENDIX 3F), count the number of spores in 10 µl of a 1:10 dilution in sterile water. Verify that no complete asci remain.

Typically all the spores in the central 5 × 5 grid area of an improved Neubauer hemacytometer are counted, and the number multiplied by 100 to give the number of spores per milliliter.

3. Dilute in sterile water, PBS, or EMM –N –G and plate 500 spores per plate (assuming all spores are viable). If selecting directly for spores containing particular markers, adjust this number accordingly. If selecting directly for spores containing a plasmid, plate 1000 to 10,000 spores per plate.

Do not use medium containing glucose for the dilutions, because it will induce germination. The dilutions can be stored at 4°C for several days in case replating is required (e.g., if the plates were plated too densely). Alternatively, spores in the original glusulase suspension can be washed free of the enzyme in EMM –N –G and stored at 4°C for many days in case further plating is required.

Colonies will appear in 2 to 5 days, depending on the temperature, and plates can be replica plated to assign markers.

The same procedure can be employed at a larger scale on cultures of sporulated cells in liquid medium, for a spore germination experiment. Following digestion (generally overnight or longer), the spores are washed several times before inoculation into selective medium. Only the fraction of the population containing the selected marker(s) will germinate. Any phenotype associated with the marker(s) can thus unambiguously be distinguished from the inert background of wild-type spores.

NONSPORULATING DIPLOIDS

Given the instability of normal h^+/h^- diploids, it can be useful to work with nonsporulating diploids. Typically, these are either homozygous at the mating locus, or contain a mutation in the h^+ information that prevents sporulation (Egel and Egel-Mitani, 1974; Willer et al., 1995). These can sporulate by providing the missing mating information or by inducing meiosis independent of mating type signaling by inactivating *pat1* kinase. They can also be induced to haploidize using drugs promoting chromosome loss (e.g., Bodi et al., 1991). These strains have specialized uses including mapping genetic loci to chromosomes, assessing the effect of ploidy on mutant phenotypes, or testing rates of chromosome loss.

ALTERNATE
PROTOCOL 2

ENDOREDUPPLICATION

At a low frequency, wild-type fission yeast cells will occasionally skip mitosis and produce a homozygous diploid, a process called endoreduplication. Because such diploids are homozygous at the mating locus, they are incapable of sporulation; however, they are still larger and darker on phloxin B. They can be isolated by screening cells plated on YES containing phloxin B for darker pink colonies, which arise at a frequency of $\sim 10^{-3}$.

ALTERNATE
PROTOCOL 3

Materials

YES plates containing phloxin B (UNIT 13.15)
Liquid culture of strain of interest

1. Plate 500 to 1000 cells per plate on YES plates containing phloxin B.
2. Incubate at 25° or 32°C until colonies form and color develops (generally 2 to 5 days).
3. Pick darker pink colonies and restreak on YES plates containing phloxin B plates. Verify diploid morphology by microscopy and ploidy by flow cytometry.

CELL-CYCLE SYNCHRONIZATION BY NITROGEN STARVATION

At low temperatures (25°C), *S. pombe* cells placed in EMM without nitrogen or supplements will arrest predominantly in G1. This is a temperature-sensitive effect, because at higher temperatures, a larger fraction of the cells will arrest in G2 (Costello et al., 1986). Auxotrophic markers such as *ade6* may retard this arrest slightly, which can be accommodated by arresting the cells in EMM without nitrogen supplemented with 45 mg/liter adenine (1/5 normal). Cells released from nitrogen by refeeding with regular EMM will enter the cell cycle after ~ 2 hr delay (the so-called “lag phase”). Nitrogen starvation cannot be used to synchronize h^{90} or diploid cells, because absence of nitrogen triggers the sexual differentiation process.

BASIC
PROTOCOL 5

Materials

Cells from the strain of interest
EMM and EMM –N (UNIT 13.15)
Complete medium (e.g., EMM with supplements, YES; UNIT 13.15)
25°C incubator
Incubator set at growth temperature (i.e., 32° to 36°C)

1. Grow cells from the strain of interest to mid-late exponential phase (OD = 0.6 to 1.0) in EMM with nitrogen.

The amount of culture will depend upon the purpose of the experiment—i.e., whether it is physiological analysis, in which case 50 ml will do, or synchrony to recover material for protein or RNA analysis, in which case 300 to 500 ml are more appropriate.

Yeast

13.16.9

Figure 13.16.2 Determining septation index for synchronous cultures.

2. Harvest by centrifuging 5 to 10 min at $4000 \times g$, 20°C . Wash twice with an equal volume starvation medium.
3. Resuspend in an equal volume starvation medium (i.e., EMM –N) and incubate 12 hr at 25°C .
4. Add an equal volume prewarmed complete medium, preferably EMM containing any required supplements. Incubate ~ 2 hr at the appropriate growth temperature.

The temperature of the re-fed culture depends upon the purpose of the experiment. For a normal wild-type strain, the cells should be returned to 32°C . For a temperature-sensitive strain under restrictive conditions, the cells should be incubated at 36°C . It will take ~ 2 hr for cells released from nitrogen starvation in G1 to enter S phase.

YES can also be used to re-feed but, because it is a less defined medium subject to batch variations, this is not preferred.

5. Every 20 to 30 min, take an aliquot of cells ($\sim 5 \mu\text{l}$) and place on a slide with a cover slip. Examine under a phase microscope (dark-field illumination may help) and count the percent septated cells (septation index), which corresponds to G1/S phase cells (Fig. 13.16.2). Plot as a function of time.

*The degree of synchrony is determined by the maximum peak of septation; generally 30% for this method and up to 80% for the following method. This is ideally performed on live cells to monitor the time course in real time. Because of the structure of the *S. pombe* cell cycle (Fig. 13.14.1), the peak of septation in wild-type strains is roughly the same as cells in S phase.*

Aliquots may also be fixed in ethanol for FACS or microscopy and the septation index counted from fixed cells if this is more convenient (see Support Protocol). The key to using the septation index is to clearly distinguish cells that have begun division from those that have not (Fig. 13.16.2). Consistency is essential so that in a given experiment, it is best if a single investigator counts all the cultures. Preparative analysis requires larger aliquots; cells can be harvested by centrifugation, the pellets frozen on dry ice, and stored for weeks or longer at -70°C for subsequent analysis.

SUPPORT PROTOCOL

ETHANOL FIXATION

Samples fixed in 70% ethanol may be stored indefinitely at 4°C . This is particularly useful if FACS analysis or DAPI staining will also be performed, as the fixation is identical.

Materials

- Exponentially growing culture
- 70% ethanol, 4°C
- H_2O , sterile
- Mounting medium with stain (see recipe; optional)
- Positively charged microscope slides

1. Harvest 10^7 cells from an exponentially growing culture by centrifuging 5 min at $4000 \times g$, 20°C . Pour off the supernatant.
2. Vortex the tube while adding 1.0 ml cold 70% ethanol. Store at 4°C .
3. To rehydrate the cells, take 0.1 ml and add to 1 ml sterile water in a microcentrifuge tube. Mix and microcentrifuge 5 min. Decant the supernatant and resuspend in 0.1 ml sterile water. If desired, process for septation index as described (see Basic Protocol 5).
4. *Optional:* To visualize the nucleus and/or septa, pipet 5 μl cell suspension onto a cleaned microscope slide. Allow to air dry or place on a heating plate at low temperature until the liquid is just evaporated.

To ensure a monolayer of cells, pretreat the slides with poly-L-lysine (Sigma) or use a positively charged slide.

5. *Optional:* Add 5 μl mounting medium with stain and immediately cover with a cover slip. Examine using epifluorescence.

Samples can be stained with DAPI to visualize the nucleus, with Calcofluor to visualize the septa, or processed for FACS analysis.

CELL CYCLE BLOCK AND RELEASE

Alternative methods of cell cycle synchronization rely upon reversible temperature-sensitive cell cycle mutants, with the *cdc25-22* mutant being the most commonly used. It arrests cells at the G2 phase of the cell cycle at 35.5°C (Russell and Nurse, 1986). Following return to permissive temperature, *cdc25* strains rapidly enter mitosis and proceed through a synchronous cell cycle. The second cell cycle is significantly less synchronous.

The key to temperature arrest is rapid increase and decrease of temperature. All water baths should be prewarmed to the correct temperature. The volume of culture should be low for the size of the flask, to ensure most efficient temperature exchange.

Materials

Temperature-sensitive cell cycle mutants (e.g., *cdc25-22*; ATCC# 90337)
 25° and 36°C water baths
 Thermometer cleaned with ethanol

1. Grow temperature-sensitive cell cycle mutants to early/mid-log phase ($\text{OD}_{600} = 0.2$ to 0.4) at permissive temperature. If necessary, remove an aliquot for an exponentially growing cell time point, which can be processed for the same morphological or molecular tests as the synchronized cells.

The volume taken will depend upon the assay: <1 ml for cell morphology or FACS, >10 ml for protein or RNA preparation.

2. Incubate 4 to 6 hr at 36°C .

A rapid temperature shift is important. Water baths promote the most efficient thermal transfer. If a 36°C water bath is not available, swirl the flask in a 50°C bath or sink until the culture approaches 36°C as described in step 3, then transfer to an air shaker.

3. Take an aliquot for a $t = 0$ time point. Release cells to 25°C by rapidly swirling the flask in ice water and monitoring with a thermometer that has been cleaned with ethanol. Place in 25°C water bath.

ALTERNATE PROTOCOL 4

Yeast

13.16.11

4. To follow synchrony, sample time points every 20 to 30 min for septation index (correlates with S phase). This should approach 60% to 80% for an effective temperature-driven block and release.

Samples can be fixed for simple microscopy, or pellets can be harvested and frozen for RNA or protein analysis. If complex manipulations are required, it is often easier to have two people taking time points.

Because of their pronounced cell elongation, cdc25 mutants often give ambiguous FACS profiles following release to permissive temperature.

LACTOSE GRADIENT CENTRIFUGATION

Because fission yeast cells are very regular in size, size selection to isolate newborn G2 cells is an effective means to synchronize a population. Centrifugal elutriation is a frequent method in fission yeast, but requires an expensive and highly specialized centrifuge rotor, and working with more than one strain at a time is difficult. Lactose gradient centrifugation (e.g., Edwards and Carr, 1997) offers a convenient alternative that can be performed in most laboratories on multiple strains. Both these methods rely on separating cells based on cell size, so the strains must not show elongation or variation in cell morphology. Mutants that have heterogeneous phenotypes or cause elongation are much more difficult to synchronize using size selection methods.

Materials

Cells
70% ethanol
YES (*UNIT 13.15*) with 0%, 10%, and 40% lactose, 32°C
Gradient maker
20- and 50-ml conical tubes

Prepare culture

1. Grow a 125-ml culture overnight so that it is in mid- to late-exponential phase the next day ($OD_{600} = 0.5$ to 0.8).

Prepare gradient

2. Sterilize a gradient maker by passing 70% ethanol through the entire apparatus, being sure to loosen the screw so that both compartments empty into the tube. Place a tiny stir bar in the compartment closest to the exit tube (Fig. 13.16.3), put the gradient maker on a stir plate, and let the solutions drain down into a collection/waste beaker. After the ethanol has run through the gradient maker, rinse with YES containing no lactose.
3. Close the valve between the compartments. Load YES with 10% lactose in the chamber away from the exit tube. Open the central valve briefly to clear any bubbles. Load YES with 40% lactose in the compartment with the stir bar, proximal to the exit tube. Again, clear bubbles. Turn on the stir plate so that the stir-bar in the 40% compartment is mixing (Fig. 13.16.3).
4. Pour 5 ml YES with 40% lactose into a sterile 50-ml conical tube. Open both valves of the gradient maker, allowing the gradient to flow down the sides of the conical tube. Fill to 45 ml.

Once poured, the gradient is stable for an hour. Additional gradients can be poured if required to allow processing of multiple strains.

Figure 13.16.3 Assembling a lactose gradient.

Load culture onto gradient

5. Harvest cells by centrifuging at $3000 \times g$ (~5000 rpm), at 20°C until pelleted (5 to 10 min).
6. Resuspend cells in 0.5 ml YES with no lactose and pipet along the inside of the conical tube just above the gradient solution.
7. Centrifuge the conical tube in a swinging bucket centrifuge 5 min at $228 \times g$ (1000 rpm), room temperature.
8. Collect 5 ml from the top of the gradient in 1-ml aliquots using a pipettor. Examine the cells in each aliquot using the microscope. Pool all aliquots.

When removing the aliquots, the tip of the pipet should barely touch the top of the gradient.

The goal is a uniform population of small G2 cells; no longer cells nor any septated cells should be seen.

9. Spin down the aliquot of cells, wash in YES medium with 0% lactose, and resuspend in 10 ml YES medium. Follow cell progression by septation and FACS.

A maximum septation index of ~40% is expected.
10. *Optional:* If the above separation does not provide sufficient synchrony, or sufficient cell number, repeat the procedure using a larger starting culture (500 ml).

11. *Optional*: Further purify cells as follows:

- a. Add 0.5 ml of 40% lactose in YES to the bottom of a 20-ml conical tube.
- b. Add 10 ml YES/lactose from the gradient maker (step 3) on top of this initial addition.
- c. Layer the 5 ml harvested from the first gradient on the second, and centrifuge 3 min at $228 \times g$ (1000 rpm), room temperature.
- d. Recover six 0.5-ml aliquots, wash into fresh medium, and follow as above.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Calcofluor white, 1 mg/ml

Prepare Calcofluor white (fluorescent brightener 28; Sigma) at a final concentration of 1 mg/ml in 50 mM sodium citrate/100 mM sodium phosphate, pH 6.0 (APPENDIX 2). Store for months in the dark at 4°C.

DAPI stock

Dissolve 1 mg DAPI per milliliter DMSO. Store weeks to months in the dark at -20°C. Discard if the solution turns dark brown.

Mounting medium stock

Dissolve the following in 5 ml PBS (APPENDIX 2):

50 mg *n*-propyl gallate (Sigma)

50 mg *p*-phenylenediamine (PPD; Sigma)

Add glycerol to 50 ml

Aliquot and store for months at -20°C in the dark

Discard if solution darkens

Mounting medium with stain

Staining can be performed with DAPI, Calcofluor white, or both, using the following solutions.

DAPI alone

Dilute 1 μ l of DAPI stock (i.e., 1 mg DAPI/1 ml DMSO; see recipe) per 1.5 ml mounting medium stock (see recipe). Store 1 to 2 days at -20°C in the dark. Discard if the solution turns brown.

Calcofluor white alone

Dilute 1 mg/ml Calcofluor white to 50 μ g/ml in mounting medium stock (see recipe) prior to use. Prepare fresh.

Calcofluor white and DAPI

Prepare a solution of mounting medium stock (see recipe) containing both stains as described for the individual components. Prepare fresh. Note that the concentration of Calcofluor white may need adjustment to prevent overcoming the DAPI signal.

COMMENTARY

Background information

Several important biological differences between *S. pombe* and *S. cerevisiae* are particularly worth noting. First, the fission yeast is generally haploid, and can only be maintained

as a diploid with complementing markers or other genetic tricks. Thus, linkage analysis is often more efficient than complementation to assess whether two mutations affect the same gene. Second, because mating and meiosis are

coupled, it is not necessary to isolate a stable diploid prior to sporulating cells and analyzing meiotic products: haploid strains are crossed and allowed to proceed through meiosis in one process. Third, the ease of random spore analysis in fission yeast makes isolation of even rare meiotic products straightforward and, moreover, facilitates bulk sporulation and germination in liquid culture. The methods described here are sufficient for the basic genetic manipulation of fission yeast in any laboratory.

Individual labs may use slightly different protocols or medium, but in practical terms this makes little difference in assessing mating type, isolating diploids, or analyzing meiotic products by tetrads, RSA, or spore germination. For additional background on the detailed biology of mating type and meiosis, see Egel (2000), Klar (1992), and Yamamoto (1996).

There is considerably more discussion about the relative uses of different methods of cell cycle synchronization (for general reviews of cell cycle control, see MacNeill and Nurse, 1997; Moser and Russell, 2000). Methods that arrest and then release the cell cycle, such as nitrogen starvation (see Basic Protocol 5), cell cycle block and release (see Alternate Protocol 4), or drug treatments (such as hydroxyurea, which arrests early in S phase) allow very high levels of synchronization—i.e., a septation index approaching 65% or more. However, in all cases, there is substantial perturbation of the cell cycle: just because some events are blocked during the arrest, does not mean that all events are blocked. For example, *cdc25* mutants arrested in G2 phase continue to accumulate cyclin to higher than normal levels (Moreno et al., 1989). This is an important caveat that may influence downstream interpretation of the results. Generally, the use of two independent methods of synchronization is recommended to verify that the results reflect normal cell cycle variations, rather than an effect of arrest.

Not all mutants release as well as *cdc25*, but well-behaved alternatives include *cdc10-M17* (temperature sensitive, blocks at G1; Verkade and O'Connell, 1998) and *nda3-KM311* (cold sensitive; blocks in mitosis; Umesono et al., 1983). These may be employed similarly to *cdc25*, although the temperatures are reversed for *nda3*. For conditions where simple cell cycle arrest is sufficient without release, *cdc10*, *cdc25*, and *nda3* mutants may be compared with temperature-sensitive mutants affecting other parts of the cell cycle, including *cdc22* (ribonucleotide reductase; blocks in early S phase; Fernandez Sarabia et al., 1993), *cdc17*

(DNA ligase, blocks late in S phase; Nasmyth, 1977), or *nuc2* (APC component, arrests in mitosis/G1; Hirano et al., 1988).

Size-selection methods of synchrony such as lactose gradients (see Basic Protocol 6) or elutriation (Alfa et al., 1993) do not overtly perturb the cell cycle, but are less synchronous than the arrest-release approaches. The maximum septation index is ~35% to 40%, and the peaks of septation are much broader. As described in *UNIT 13.14*, newly separated fission yeast cells are in G2; therefore, methods that preferentially isolate small cells will enrich the G2 population, the basis for these procedures. The cells may suffer some modest stress from the low-speed centrifugation, but under conditions where temperature-sensitive mutants cannot be employed, or where normal cell cycle responses are particularly important, these are the methods of choice.

The reader is referred elsewhere for fundamentals of molecular analysis (Moreno et al., 1991) and other methods in fission yeast (Alfa et al., 1993; Gould, 2003).

Critical Parameters and Troubleshooting

Mating

The mating type testing protocol (see Basic Protocol 1) is often inefficient because it relies upon relatively low numbers of cells transferred by replica plating. Strains that grow slowly, that have impaired starvation response, or that have defects in mating may not generate sufficient numbers of asci to be observed by iodine staining. Under these conditions, crossing strains for tetrad or random spore analysis (see Basic Protocol 2) can be used and the plates subjected to iodine staining, or monitored for zygote formation by microscopy. If the latter, a sterile toothpick is used to pull the cells out from the mating patch and spread them out on the adjacent area of the plate, or apply them to a microscope slide in 5 μ l sterile water. Zygotes and asci as in Figure 13.16.1A can be observed under these conditions. It is generally a good idea to set up crosses for mating type testing, tetrads, or diploid isolation with a known pair of wild-type strains to confirm that the medium and conditions are suitable for analysis.

Tetrads and RSA

It is a good idea to practice both tetrads and RSA on well-behaved wild-type strains before performing them on mutants of interest. In addition, prior to replica plating, the micro-

scope should be employed, especially on tetrad plates where there are “missing” colonies, to verify that there were actually spores manipulated in the gaps. This also provides evidence of the phenotype prior to replica plating, when single spores or dead cells can be lost.

Diploids

The most common reason for failure to recover a diploid is misassignment of the mating type marker, or the *ade6* marker. These can be distinguished by observing the original mating plate to see whether zygotes and asci formed. If they do, then the likely culprit is the *ade6* allele, which can be tested by setting up crosses with a control strain with the opposite marker.

Stable diploids

Isolation of endoreduplicated strains to create stable homozygous diploids requires a method to verify ploidy in addition to phloxin B staining, because there is frequently a background of more darkly staining colonies that are still haploid in the population. FACS is unambiguous if a known haploid and diploid are used as controls. Isolation of a haploid from the stable homozygous diploid relies upon chromosome loss. If fission yeast diploids lose one chromosome, they will rapidly haploidize and this can be accelerated with certain drugs (e.g., Bodi et al., 1991).

An alternative method to create stable diploids relies upon crossing two strains with complementing markers which are able to mate but not sporulate. The *mat1-P* mating type locus produces two transcripts, one required for mating, and the second for meiosis (Egel and Egel-Mitani, 1974; Willer et al., 1995). A homothallic strain containing the *mat2-102* allele lacks the sporulation-specific P transcript. By itself on mating medium it makes zygotes but no spores. If mated as an h^+ to a wild-type h^- and selected for complementing markers, the resulting diploid is unable to enter meiosis. In contrast, the *mat2-102* strain functions as a normal h^- , so if mated to a wild-type h^+ , the resulting diploid is sporulation-competent. In this way, the *mat2-102* allele can be moved into different backgrounds.

Synchronization

The success of synchronization procedures is heavily influenced by the strain background. Not all mutants will arrest appropriately in G1 phase when starved for nitrogen. Similarly, many mutants cause a heterogeneous size phenotype that precludes use of size-selection

methods. These difficulties are only established by trial and error. The experiment should be performed on small-scale cultures, monitoring septation index and FACS if appropriate, to see if conditions are suitable before scaling up to preparative levels. Often it helps to divide the work between two people (one to harvest and fix cells, one to count septa).

Anticipated Results

Crosses, diploids, and tetrads are the fundamental components of classical genetic analysis. The methods are straightforward and allow determination of synthetic phenotypes or construction of useful strains. Synchronization methods are important because of *S. pombe*'s continuing importance as a model system for cell cycle analysis.

Time Considerations

For cell growth experiments, the limiting factor is growth rate of the individual strain. This varies substantially depending upon the genotype, medium, and temperature. Generation of recombinant strains takes about a week from crossing the haploid parents, to replica plating the germinated spores. Isolation and purification of a diploid strain generally takes about a week. Synchronous cultures generally take all day to perform, not including time for preparative analysis.

Introduction of DNA into *S. pombe* Cells

UNIT 13.17

Transformation is the essential method by which DNA is introduced into a cell, whether it is a plasmid episome or an integration construct. Fission yeast is readily transformed using a variety of methods, but efficiencies, expressed as transformed colonies per microgram plasmid, are generally lower than *S. cerevisiae* (albeit still more than sufficient for plasmid recovery, screening of plasmid libraries, repair of gapped plasmids, and other standard yeast procedures). There are several possible explanations. First, the protocols have not been as carefully optimized. Second, maintenance of episomes may be affected by performance of the replication origin, and the absence of a centromere or other segregation method. Third, mutants affecting DNA dynamics may be harder to transform.

S. pombe is efficient at homologous integration of fragments of DNA, although it is also adept at nonhomologous recombination. For maximum efficiency of integration and minimum background, tracts of homology >300 base pairs are recommended; targeted integration occurs with smaller homology tracts (e.g., 50 base pairs), but generally have substantial background of nonhomologous events which must be screened out (Bähler et al., 1998; Grallert et al., 1993; Keeney and Boeke, 1994). Most plasmids are selected using nutritional markers on EMM plates. However, G418 resistance requires selection on YES plates.

S. pombe can be transformed by lithium acetate (see Basic Protocol and Alternate Protocol 1), electroporation (see Alternate Protocol 2), or protoplast treatment (see Alternate Protocol 3). In addition, protoplasts can be induced to fuse and undergo karyogamy, which provides a means of mating sterile strains (see Support Protocol).

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly.

TRANSFORMATION USING LITHIUM ACETATE

The principles of this method (Okazaki et al., 1990) are similar to *S. cerevisiae*, although maximum efficiency requires that the lithium acetate have a lower pH. Reported transformation frequency is up to 10^5 transformants per microgram DNA. This is a laborious but high-efficiency method; a more rapid version with somewhat reduced efficiency follows (see Alternate Protocol 1).

Materials

- YES medium (UNIT 13.15)
- S. pombe*
- MB medium (see recipe)
- 0.1 M lithium acetate (adjust to pH 4.9 with acetic acid)
- Plasmid DNA
- TE, pH 7.5 (APPENDIX 2)
- 50% (w/v) PEG 4000, 25° or 30°C
- 50% YE medium (see recipe for YES in UNIT 13.15)
- Selective EMM plates (UNITS 13.15)

- 25° or 32°C incubators
- 1-liter flask
- 43°C water bath

- Additional reagents and equipment for culturing yeast (UNIT 13.7)

NOTE: If necessary, a 30° rather than a 32°C incubator can be used.

Yeast

13.17.1

Supplement 64

Prepare cells for transformation

1. Two days before the experiment, inoculate 5 ml YES medium with a single *S. pombe* colony of the strain to be transformed. Grow overnight to saturation at 32°C.

The saturated overnight culture may, if desired, be prepared up to several days in advance of the transformation and stored at 4°C. EMM (UNIT 13.15) should be used if selection is required.

2. The night before transformation, inoculate a 1-liter sterile flask containing 150 ml MB medium with an appropriate amount of the saturated culture and grow overnight at 32°C to an OD₆₀₀ of 0.5. Calculate the volume of starter culture from which to generate a larger overnight culture which is grown up with shaking.

$$\text{vol. inoculated (ml)} = \frac{(Y \times \text{OD}_f) / 2^n}{\text{OD}}$$

where Y is the volume of overnight culture required, n is the expected number of generations in this media during the expected grown period, OD_f refers to the desired OD for the exponential culture (generally 0.5), and OD refers to the OD₆₀₀ of the starter culture.

The expected number of generations when inoculating from a saturated starter culture must take into account a 1-generation lag phase to allow the cells to exit stationary phase and re-enter the cell cycle. For example, for a 12-hr growth period of a strain with a 3-hr doubling time, the total number of possible growth generations is $12/3 = 4$. If diluting from an already growing exponential culture, then $n = 4$. However, if inoculating from a stationary starter culture, there is one lag generation, so the actual growth generations = $4 - 1$, or 3.

The amount of culture to be inoculated depends upon the growth rate of the strain which is influenced by growth temperature, genotype, age of the starter culture, and growth media. A healthy wild-type strain in complete medium (YES or EMM) at 32°C has a generation time of between 2.5 and 3 hr during exponential growth. MB is a stringent minimal medium that has severely reduced growth rate compared to normal EMM; generation time will be ≥ 5 hr. It is not clear why this medium improves efficiency of transformation, but it may affect cell wall permeability.

Strains with particular auxotrophic markers or other mutations may be unable to grow in MB sufficiently well to generate a large working culture. In this case, cells may be grown to mid-exponential phase in EMM ($\text{OD}_{600} = 0.5$) and diluted into MB for two additional generations to gain some of the benefits of growth in MB. Low-glucose EMM can be used in place of MB, but transformation efficiency may be reduced. How much depends upon the individual strain.

3. Harvest the cells 5 min at $228 \times g$ (3000 rpm), room temperature. Wash cells in 40 ml sterile water and centrifuge again.

Transform with lithium acetate

4. Resuspend the cells at 1×10^9 cells/ml (0.5 to 1.5 ml) in 0.1 M lithium acetate, pH 4.9, and dispense 100- μ l aliquots into microcentrifuge tubes. Incubate 60 min at 32°C, or 25°C for temperature-sensitive (ts) mutants.

Cells will sediment at this stage. Cells can be left for up to 120 min without harm. Each tube is sufficient for a single transformation.

5. Add 1 μ g plasmid DNA in 15 μ l TE, pH 7.5 to each tube. Mix by gentle vortexing, completely resuspending cells that sedimented during the incubation. Do not allow the tubes to cool down.

Duplicate transformations using the same plasmid for each tube maximizes total transformants (e.g., screening a library).

6. Add 290 μ l of 50% (w/v) PEG 4000, 32°C (25°C for ts mutants) to each tube. Mix by gentle vortexing and incubate 60 min at 32°C (25°C for ts mutants).
7. Heat shock 15 min in a 43°C water bath or heat block. Cool the tubes and incubate 10 min at room temperature.
8. Microcentrifuge 2 min at 5000 rpm. Carefully remove the supernatant by aspiration.
9. Resuspend each tube in 1 ml of 50% YE medium by pipetting up and down with a 1000- μ l micropipettor.
10. Transfer each tube suspension to a 50-ml flask and dilute with 9 ml of 50% YE. Incubate with shaking at least 60 min at 32°C (25°C for ts mutants).
11. Plate <0.3-ml aliquots onto EMM plates selective for the marker of interest at 32°C (25°C for ts strains). If necessary, centrifuge the cells from a single transformation and resuspend in 1 ml EMM medium to spread more cells on a plate.

Colonies will generally form in 3 days at 32°C for wild-type cells

RAPID LITHIUM ACETATE PROCEDURE

This rapid method (Kanter-Smoler et al., 1994) reports efficiencies of up to 2×10^4 per microgram plasmid DNA. It uses small cultures and does not include a grow-out period for phenotypic expression.

Additional Materials (also see *Basic Protocol*)

Low-glucose EMM with appropriate supplements (*UNIT 13.15*)
 100 mM lithium acetate/1mM EDTA (pH 4.9)
 40% (w/v) PEG 3350/100 mM lithium acetate/1mM EDTA, pH 4.9
 42°C water bath

Additional reagents and equipment for growth of yeast (*UNIT 13.7*)

1. Grow a 10-ml culture of *S. pombe* in low-glucose EMM low to a density of 0.5–1 $\times 10^7$ cells/ml ($OD_{600} = 0.2$ to 0.5) as described above.
2. Wash once with 10 ml sterile water and resuspend in 1 ml sterile water. Transfer to a sterile 1.5-ml microcentrifuge tube and pellet cells by microcentrifuging briefly at 20°C.
3. Wash once with 0.2 ml of 100 mM lithium acetate/1 mM EDTA, pH 4.9, and resuspend in 50 μ l lithium acetate/EDTA.
4. Add 1 μ g DNA in up to 30 μ l water or TE, pH 7.5, and add 300 μ l of 40% (w/v) PEG 3350/100 mM lithium acetate/1mM EDTA, pH 4.9.
5. Incubate 30 min with agitation at 32°C.
6. Heat shock 15 min in a 43°C water bath without agitation.
7. Pellet by microcentrifuging briefly at 20°C. Resuspend in 1 ml TE, pH 7.5, and plate 200- μ l aliquots on EMM plates selective for the plasmid marker.

Colonies will generally form in 3 days at 32°C for wild-type cells.

**ALTERNATE
 PROTOCOL 1**

Yeast

13.17.3

ELECTROPORATION OF *S. POMBE* CELLS

The electroporation protocol for *S. pombe* is similar to that for *S. cerevisiae* (see UNIT 13.7); however, it is not necessary to plate the *S. pombe* cells on sorbitol-containing selection plates and in fact, doing so will actually retard growth. The sorbitol in which cells are suspended following treatment is sufficient for osmotic protection.

PROTOPLAST PROCEDURE

This is a time-consuming protocol that is seldom used any more, although it can be useful for creating diploids between nonmating strains (see Support Protocol for protoplast fusion). Transformation frequency is $\sim 1 \times 10^4$ to 5×10^4 transformants per microgram DNA.

Additional Materials (also see Basic Protocol)

- EMM medium (UNIT 13.15)
- Cit/phos/EDTA (see recipe)
- Cit/phos/sorbitol (see recipe)
- NovoZym 234 (BiosPacific)
- 10 mM Tris·Cl, pH 7.6 (APPENDIX 2)/1.2 M sorbitol
- 10 mM Tris·Cl, pH 7.6 (APPENDIX 2)/10 mM CaCl₂/1.2 M sorbitol
- 10 mM Tris·Cl, pH 7.6 (APPENDIX 2)/10 mM CaCl₂/20% (w/v) PEG 4000
- CaCl₂/sorb/YE (see recipe)
- Selective EMM sorbitol plates (UNIT 13.15)

- 50-ml plastic centrifuge tube
- 37°C incubator
- 29° to 32°C incubator

Additional reagents and equipment for counting cells using a hemacytometer
(APPENDIX 3F)

Prepare cultures

1. Grow a 200-ml culture of *S. pombe* to an OD₆₀₀ of 0.2 to 0.5 (up to 1×10^7 cells/ml) in EMM medium.
2. Harvest cells by centrifuging 5 to 10 min at $4000 \times g$ (5000 rpm), room temperature. Decant the supernatant and resuspend the pellet in 10 ml cit/phos/EDTA. Transfer to 50-ml plastic centrifuge tube.
3. Harvest cells and resuspend each tube in 5 ml cit/phos/sorbitol.

Form protoplasts

4. Add 25 mg NovoZym 234. Immediately incubate 15 to 30 min at 37°C until spheroplasts have formed (check that cells have rounded up under a microscope).

Using different enzymes (e.g., Sigma's lysing enzyme) changes the shape of the cells when protoplasting. This is because different enzymes break different sugar linkages in the cell wall. Depending upon which linkages are broken, sometimes the cells get round, sometimes they stay rodlike, and sometimes they ooze out of their jackets like bright little refractile balloons, leaving ghosts behind. It is possible to check protoplasting efficiency for any morphology by taking a small aliquot (a few microliters) and dropping them on a slide with a large drop of 0.5% to 1% SDS. Protoplasted pombe will lyse in these conditions.

From this point, the protoplasts are extremely fragile, so handle gently.

5. Add 35 ml of 10 mM Tris·Cl, pH 7.6/1.2 M sorbitol and divide between 2 to 4 tubes (no more than 3×10^8 spheroplasts/tube). Centrifuge 5 min at $1000 \times g$ (2000 rpm), 20°C.

It is better to centrifuge at slow speed and repeat than to pellet too vigorously.

6. Resuspend gently in 1 ml Tris·Cl/sorbitol, then add an additional 20 ml and invert several times to wash. Harvest and repeat. After the last resuspension in 1 ml, take a sample and count the number of protoplasts using a hemocytometer (APPENDIX 3F).
7. Resuspend at 2 to 5×10^8 protoplasts/ml in 10 mM Tris·Cl, pH 7.6/10 mM CaCl_2 /1.2 M sorbitol and pool the contents of the tubes.

Transform protoplasts

8. Add 1 to 10 μg plasmid in no more than 10 μl water to 100 μl protoplasts in a microcentrifuge tube. Incubate at room temperature for 15 min.
9. Add 1 ml of 10 mM Tris·Cl, pH 7.6/10 mM CaCl_2 /20% (w/v) PEG 4000 and incubate 15 min at room temperature.
10. Microcentrifuge briefly at 20°C. Drain well and resuspend the protoplasts in 0.2 to 0.5 ml CaCl_2 /sorb/YE. Incubate 30 to 60 min at 30°C.
11. Plate 0.2-ml aliquots onto well-dried, sterile, EMM sorbitol plates. Spread cells very gently with minimum force (e.g., using a spreader derived from a Pasteur pipet). Incubate 2 to 5 days at 29° to 32°C (i.e., until transformants appear).

Protoplasts can be aliquotted and stored in 10 mM Tris·Cl (pH 7.6)/10 mM CaCl_2 /1.2 M sorbitol (see step 7) up to 2 months at -70°C . The frequency of transformation is 1×10^3 transformants per microgram DNA for protoplasts stored in this way.

PROTOPLAST FUSION

This protocol allows creation of a diploid strain using nonmating strains. Cells lacking cell walls stick together in PEG and may fuse to generate a diploid. Recovery of a diploid requires selection for complementing markers in the two starting haploids (e.g., *ade6-M210* and *ade6-M216*, or *ura4⁺* in one parent and *leu1⁺* in the other).

Additional Materials (also see Basic Protocol and Alternate Protocol 3)

Strains with complementary markers

1. Follow protoplast transformation (see Alternate Protocol 3, steps 1 through 6) for each of two strains with complementing markers.

Complementing mating types are not required.

It is not necessary to count in a hemacytometer.

2. Combine 50 μl of each strain in a sterile tube. Incubate 15 min at room temperature.
3. Add 2 ml of 10 mM Tris·Cl (pH 7.6)/10 mM CaCl_2 /20% (w/v) PEG 4000. Incubate 25 min at room temperature.
4. Plate on EMM sorbitol plates selecting for the complementing markers at the appropriate temperature (32°C for wild type). As the cells are extremely fragile, spread gently (e.g., using a spreader from a thin Pasteur pipet).

Growth is reduced on sorbitol plates so it may take a few extra days to see colonies.

SUPPORT PROTOCOL

Yeast

13.17.5

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

CaCl₂/sorb/YE

10 mM CaCl₂
1.2 M sorbitol
0.5 mg/ml yeast extract
5 μg/ml each leu, ura, ade, and his
Sterilize by autoclaving
Store indefinitely at room temperature

Cit/phos/EDTA

2.82 g/liter Na₂HPO₄
4.2 g/liter citric acid
40 mM EDTA pH 8.0
Sterilize by autoclaving
Store indefinitely at room temperature

Cit/phos/sorbitol

7.1 g/liter Na₂HPO₄
11.5 g/liter citric acid
1.2 M sorbitol
Adjust to pH 5.6 with 5 M NaOH
Sterilize by autoclaving
Store indefinitely at room temperature

MB medium

0.5 g KH₂PO₄
0.36 g potassium acetate
0.5 g MgSO₄·7 H₂O
0.1 g NaCl
0.1 g CaCl₂·2 H₂O
5 g (NH₄)₂SO₄
500 μg H₃BO₄
40 μg CuSO₄·5 H₂O
100 μg KI
200 μg FeCl₃·6 H₂O
400 μg MnSO₄·H₂O
200 μg Na₂MoO₄·2 H₂O
400 μg ZnSO₄·7 H₂O
5 g glucose
10 μg biotin
1 mg calcium pantothenate
10 mg nicotinic acid
10 mg myo-inositol
150 mg uracil for *ura4⁻* strains or leucine for *leu1⁻* strains
Adjust volume to 1 liter with water
Sterilize by autoclaving
Store indefinitely at room temperature

COMMENTARY

Background Information

Early attempts to transform fission yeast relied upon *S. cerevisiae* plasmids and methods (Beach and Nurse, 1981). Because most *S. cerevisiae* plasmids and markers are poorly maintained in *S. pombe*, cloning of *S. pombe* specific origins and auxotrophic markers significantly improved efficiencies (for review, Russell, 1989, and Siam et al., 2003). While standard *S. cerevisiae* protocols, most notably electroporation, work to some extent in *S. pombe*, better success with the protoplast and lithium acetate methods is generally observed using *S. pombe*-specific methods.

The choice of method is determined by the equipment and time available. For example, electroporation (see Alternate Protocol 2) is extremely fast and simple to perform, but requires access to an electroporator. Recent studies report improving efficiency following treatment with DTT (Suga and Hatakeyama, 2001) and also describe storage of frozen electrocompetent cells (Suga and Hatakeyama, 2003).

The classic lithium acetate method (see Basic Protocol) is the most efficient technique, but it is also quite time consuming and relies on growth in a stringent minimal medium, as well as a grow-out period for phenotypic expression. A faster method should be suitable for most routine transformations (see Alternate Protocol 1). In addition, lithium acetate has been reported to be more efficient than protoplast treatment (see Alternate Protocol 2) for recovery of homologous integrants (Grallert et al., 1993). Methods have also been reported for preservation of frozen competent cells using this method (Broker, 1993).

Protoplast preparation was the first transformation technique reported for fission yeast (Beach and Nurse, 1981), but has fallen out of favor with the development of other methods. Homologous integration is less effective using this method than lithium acetate, with events skewed towards nonhomologous integration (Grallert et al., 1993), yet protoplast fusion mediated by PEG allows recovery of diploids from strains that are otherwise unable to mate (see Alternate Protocol 3 and Support Protocol). Competent protoplasts can also be preserved in the freezer (Jimenez, 1991).

Further information about transformation methods may be found in Moreno et al. (1991), Alfa et al. (1993), and Gould (2003).

Critical Parameters

The most important variable of any transformation procedure is the growth of the target strain. For all methods, cells in midexponential phase are preferred. Growth in low glucose medium has been reported to enhance transformation efficiency for lithium acetate (Kanter-Smoler et al., 1994; Okazaki et al., 1990), but has not been tested for electroporation. Transformation of mutant strains, especially those defective in genes affecting DNA replication or repair, or temperature-sensitive strains, may have reduced efficiency.

The plasmid or other DNA being used should be of high quality, as nonspecific inhibitors of transformation may be present in crude preparations. The number of transformants obtained per microgram generally decreases with larger amounts of DNA, although total transformants will still increase. Especially for electroporation, DNA should be in a small volume without any excess salt.

Targeted integration of linear plasmids or fragments varies enormously in efficiency, depending upon the actual locus and the amount of homology used to target the event (Grallert et al., 1993; Keeney and Boeke, 1994). A high background of nonhomologous integrants must often be screened to find the desired clone. Increasing the homology generally results in much more efficient targeting. Protoplast transformation is not recommended for homologous integration (Grallert et al., 1993).

Troubleshooting

Transformation is highly variable depending upon the strain, plasmid, and conditions of growth. Mutants defective in DNA replication are particularly difficult to transform, and may be slow to form colonies; however, simply transforming a known plasmid into a strain does not require high efficiency and can be performed without much concern or effort. In contrast, transformation of a plasmid library relies upon efficient recovery of a large number of colonies. In this case, a control plasmid containing the marker of interest should be used to optimize conditions, including temperature of growth before and after transformation, growth stage of the culture (mid- versus late exponential), and method employed.

A special consideration is transformation with a library to complement a temperature-sensitive mutant. Failure to recover any trans-

formants at the restrictive temperature may reflect absence of a complementing clone in the population, or may reflect growth conditions required to establish the plasmid. If direct plating of the transformation to the restrictive temperature doesn't work, it often helps to allow phenotypic expression of the clone at permissive temperature for a day or two before transferring the plates to the restrictive temperature. In some cases, allowing the transformed colonies to develop at permissive temperature and then replica plating to restrictive temperature (e.g., using phloxin B plates to identify the rescuing clones; see UNIT 13.15) may be the best way to proceed.

Anticipated Results

Transformation efficiencies may exceed 10^5 colonies per microgram DNA when the protocols are performed exactly with well-behaved wild-type strains, but are more likely to be in the 10^3 to 10^4 range with some mutants if frozen competent cells are used or if short cuts are taken in the procedures.

Time Considerations

Rapid lithium acetate transformation (see Alternate Protocol 1) and electroporation (see Alternate Protocol 2) require minimal manipulation of the target culture: a few washes, treatment with the DNA, and rapid plating. These can be accomplished within an hour or two. The classic lithium acetate method (see Basic Protocol) and protoplast preparation (see Alternate Protocol 3) are significantly more laborious, including prolonged incubation steps. These will occupy several hours.

CHAPTER 14

In Situ Hybridization and Immunohistochemistry

INTRODUCTION

This chapter presents some commonly used cytological techniques for determining the temporal and spatial expression patterns of both mRNA (in situ hybridization of tissue sections) and protein (immunohistochemistry) in individual cells, tissues, and even whole embryos. The study of gene products using biochemical and molecular techniques often requires tissue samples containing a considerable amount of the target molecule. This presents a difficulty because many developmentally interesting genes are expressed either in a minority of cells in complex tissues or for only brief periods of time during the differentiation of an organism or tissue. This chapter presents some commonly used cytological techniques for determining the temporal and spatial expression patterns of both mRNA (in situ hybridization of tissue sections) and protein (immunohistochemistry) in individual cells. Light microscopy coupled with sensitive detection methods allows the detection of local RNA or protein expression and adds an invaluable tool to the gene product detection repertoire.

The in situ hybridization techniques described here rely upon the hybridization of a specifically labeled nucleic acid probe to the cellular RNA in individual cells or tissue sections. Three areas of technical expertise are required. First, preparation of a suitable nucleic acid probe demands an understanding of the principles of molecular biology (e.g., subcloning, plasmid preparation, and radiolabeling). Successful tissue preparation requires practical experience in the art of histology. Finally, as with all morphological techniques, the correct interpretation of the experimental results requires familiarity with cell biology, anatomy, or embryology.

Although the extent of expertise outlined here may seem overwhelming to some, the reader should realize that the protocols are described in great detail, and that the commentary sections on critical parameters and troubleshooting can be very useful in avoiding or analyzing common mistakes. Of course, it is always reasonable to consult an experienced colleague for advice.

Immunohistochemical localization of cellular molecules exploits the ability of antibodies to bind specific antigens (usually proteins) with high affinity. The technique may be used to localize antigens to subcellular compartments or individual cells within tissues. It is especially powerful when used together with in situ hybridization to localize both the mRNA and protein products of a particular gene.

The chapter begins with a discussion of fixation and sectioning of mouse tissues (although most procedures should be applicable to those of other species). Fixation and sectioning (*UNITS 14.1 & 14.2*), which critically affect the success of both in situ hybridization and immunohistochemistry experiments, must frequently be optimized for each experimental application. Although these parameters are discussed at length, the protocols presented are not complete treatises on these methods and a good histology text and the advice of a trained histologist are highly recommended.

In Situ
Hybridization
and Immuno-
histochemistry

14.0.1

Supplement 64

Pretreatment, in situ hybridization, and washing of cells and tissue sections are discussed in *UNIT 14.3*. In situ hybridization can be performed on either paraffin (*UNIT 14.1*) or frozen sections (cryosections; *UNIT 14.2*). Alternate protocols are given for each case, although with the appropriate modifications either protocol can be used successfully with each type of sectioned material. The advantages of each method are detailed in the commentary of *UNIT 14.3*, but by far the most important reason to choose one method over the other is equipment availability. If a microtome is available there is generally no reason to buy a cryostat and vice versa.

Detection of hybridized probe and the counterstaining and mounting of treated cytological preparations using isotopic (radioactive; *UNITS 14.3-14.5*), non-isotopic (*UNITS 14.7 & 14.8*), and fluorescent (*UNITS 14.10 & 14.11*) probes are described. Radioisotope-labeled hybridization probes have a very high sensitivity and resolution. The hybridization signal can be detected by either film or emulsion autoradiography (*UNIT 14.4*). A number of alternate staining and mounting procedures are presented in *UNIT 14.5*. A method for quantifying radioactive signal produced by in situ hybridization of a radioactive using a phosphorimager is presented in *UNIT 14.12*. Non-isotopic methods for detecting hybridization signals (*UNIT 14.7 & 14.8*) provide an attractive alternative for RNAs expressed at slightly higher levels because they provide increased sensitivity while avoiding the hazards normally associated with the use of radioisotopes. *UNIT 14.7* describes fluorescence in situ hybridization, with methods for amplifying weak signals as well as enzymatic detection methods using horseradish peroxidase or alkaline phosphatase. Two units (*14.10 & 14.11*) deal with technical aspects of fluorescence light microscopy and confocal microscopy. *UNIT 14.10* discusses the basis of fluorescence microscopy, the methodology used to detect the fluorescence emitted from hybridized fluorescent probes. *UNIT 14.11* presents confocal microscopy, which can be used to increase the sensitivity and specificity of in situ hybridization methods. The use of the polymerase chain reaction in conjunction with in situ hybridization, presented in *UNIT 14.8*, allows the specific amplification of low-abundance sequences and can be used with any probe, regardless of label.

In situ hybridization to whole embryos, rather than cells or tissue sections, is a powerful tool for examining RNA expression during early stages of vertebrate development. Whole-mount in situ hybridization, presented in *UNIT 14.9*, can be used to detect patterns of transcription in intact vertebrate embryos, including chicken, mouse, and *Xenopus*.

UNIT 14.6 surveys immunohistochemical techniques for protein localization and focuses on the use of indirect immunofluorescence as the primary detection method. Alternative methods (immunoperoxidase and immunogold labeling), suitable for bright-field microscopy, are described and critically reviewed. An extensive troubleshooting guide with a list of suitable routine controls is also included.

Both in situ hybridization and immunohistochemistry eventually produce images of cells, tissues or whole embryos overlaid with a pattern of RNA or protein. Because most laboratories capture these images digital photography, the images can be manipulated and quantitated using standard digital image analysis tools. Valuable tools for biologic image analyses are described in *UNIT 14.15*.

Fixation, Embedding, and Sectioning of Tissues, Embryos, and Single Cells

UNIT 14.1

This unit describes selected methods for fixing and sectioning various forms of biological materials ranging from tissues to single cells. Sections prepared according to these protocols can then be used to examine cell and tissue morphology and in studies involving in situ hybridization, immunohistochemistry, and enzyme histochemistry. The basic protocol describes how tissues and embryos can be prepared for sectioning by fixing in paraformaldehyde followed by embedding in wax, while the alternate protocol describes fixation of suspended or cultured cells. Two support protocols cover preserving and fixing organs by perfusion of whole animals with paraformaldehyde and a procedure for sectioning wax blocks of fixed tissue, plus the subsequent mounting of sections onto prepared or “subbed” glass slides.

PARAFORMALDEHYDE FIXATION AND PARAFFIN WAX EMBEDDING OF TISSUES AND EMBRYOS

BASIC
PROTOCOL

Samples are fixed for the appropriate time and dehydrated through a graded ethanol series. They are then impregnated in paraffin wax and cast into blocks.

Materials

- 4% paraformaldehyde (PFA) fixative, freshly prepared at 4°C
- Paraffin wax (e.g., Paraplast)
- 50%, 70%, 95%, and 100% ethanol
- Xylenes (Baker)
- Silicone spray
- 20-ml snap-cap glass vials (silanized for small samples; APPENDIX 3)
- 60°C oven and heating block with holes to hold 20-ml glass vials
- Embedding molds and rings (e.g., VWR Scientific)
- Hot forceps or hot Pasteur pipet with end cut off
- Hot Pasteur pipet with end drawn out and sealed

Fix the samples

1. Place dissected organs or embryos in labeled 20-ml snap-cap glass vials (for very small samples use silanized glass vials). Label the caps as well as the vials in case the label is removed by organic solvents. Fill vials with freshly prepared 4% PFA fixative, 4°C. Allow fixation to proceed at 4°C for the desired time.

Optimal fixation time is that which gives good morphology as well as good signal-to-noise ratio after in situ hybridization, and must be determined empirically for each sample. Hence, series of different fixation times, ranging from 15 min to 4 hr, should be tested.

In general, organs dissected from perfused mice have given best results when fixed for 1 to 2 hr (Zeller et al., 1987; Muller et al., 1988). Fixation times for mouse embryos vary greatly depending on age and size of the embryo: isolated gestational day 7 and 8 embryos (where the day of the copulatory plug is designated gestational day 0) should be fixed 15 to 30 min, day 9 and day 10 embryos should be fixed 1 to 2 hr, and older embryos 2 hr or longer (Zeller et al., 1987).

For better and more homogeneous fixation of individual organs, animals should be perfused with fixative prior to harvesting tissues. See support protocol for perfusion.

2. Begin melting paraffin wax in 60°C oven using a sufficient amount to process all the samples (see step 8).

Supplement 7

Dehydrate the samples

3. After fixation is completed, pour off the fixative (be careful not to lose the sample), and replace with 50% ethanol. Immediately change the 50% ethanol to fresh 50% ethanol. Incubate 20 min and change the 50% ethanol again. A total of three changes of ethanol, each followed by a 20-min incubation at room temperature, is done this way.
4. Continue dehydration by incubating three times in 70% ethanol, 20 min each time (room temperature).

At this stage samples can be stored in 70% ethanol for a few days, if desired.

5. Incubate in 95% ethanol for 20 min at room temperature. Repeat two more times.
6. Incubate in 100% ethanol for 20 min at room temperature. Repeat two more times.

Do not reduce these incubation periods. Incomplete dehydration will lead to unusable paraffin blocks.

7. Replace 100% ethanol with xylenes. Immediately change to fresh xylenes and incubate 10 min. Follow with two more xylenes changes and 10-min incubations after each change.

CAUTION: Xylenes are toxic organic solvents—steps 7 and 8 should be carried out in a hood.

Prepare samples for embedding in wax

8. Pour off xylenes and add 5 ml fresh xylenes to each vial (check that samples are still there). Add an equal amount of molten wax using a hot glass pipet.

Transfer of the wax must be very fast to avoid hardening.

9. Mix and leave samples at room temperature overnight. The wax/xylenes mixture will harden, but enough paraffin is dissolved in the xylenes to start impregnation of the samples.

10. Transfer samples to 60°C oven to melt the wax/xylenes mixture.

11. Prepare a 60°C heating block (the 20-ml vials must fit its holes). When the wax/xylenes mix is molten, transfer vials to heating block.

12. Pour off the wax/xylenes mixture from one vial into a waste bottle (be careful to retain the samples). Immediately add fresh molten wax to the vial with a hot glass pipet. Put the vial back into the heat block. Repeat procedure with all the vials.

Work quickly to avoid hardening of the wax. If hardening occurs, melt the wax again at 60°C before initiating the 1-hr incubation (step 13). Otherwise, impregnation of the samples will be poor and sectioning impossible.

13. Return vials to 60°C oven and incubate 1 hr at 60°C.

14. Remove vials from oven and place again into 60°C heating block. Repeat steps 12 to 13 twice for a total of 3 hr of incubation.

Embed samples in wax and prepare blocks

15. The samples are now ready for embedding. Prepare embedding molds according to manufacturer's instructions (e.g., coated with silicone spray) and fill one of the molds with molten paraffin wax using a hot glass pipet.

16. Immediately transfer sample to the wax-filled mold using hot forceps or a hot cut-off Pasteur pipet.

In general, only one to two embryos should be embedded in each block. This facilitates ribboning (see support protocol for sectioning).

17. Place an embedding ring on the mold and fill with paraffin wax. Label the embedding ring to facilitate future identification of samples. Samples can be oriented within the mold using a hot drawn-out and sealed Pasteur pipet.

The embedding ring will be used to attach the sample to the microtome holding clamp (support protocol for sectioning, step 2).

18. Leave cast blocks at room temperature to harden completely.
19. Remove cast blocks from embedding molds and store in a dry place at room temperature. Perform sectioning according to the support protocol in this unit.

Blocks stored this way are stable and can be used successfully for years. Moisture destroys the blocks; dry storage is essential.

FIXATION OF SUSPENDED AND CULTURED CELLS

Cells are fixed to poly-L-lysine-coated slides with 4% PFA, dehydrated, and stored at -70°C until use (Berger, 1986).

Materials

4% paraformaldehyde (PFA) fixative at room temperature
3 \times and 1 \times phosphate-buffered saline (PBS), pH 7.2
50%, 70%, 95%, and 100% ethanol

Poly-L-lysine-coated glass slides (see reagents and solutions)
Moist chamber
Glass staining dishes

1. Pipet 10 μl of cells (2×10^7 cells/ml density) in a drop onto a poly-L-lysine-coated glass slide.

Resuspend cells in serum-free medium if possible.

2. Place slide in a humidified chamber and let cells settle 30 min.
3. Transfer slides into a slide rack and immerse in a glass staining dish filled with 4% PFA fixative. Allow fixation to proceed 20 min at room temperature.

Alternatively, cells can be grown directly on poly-L-lysine-coated cover slips or slides, and processed with 4% PFA fixative for 20 min at room temperature.

4. Transfer slide rack to a new dish filled with 3 \times PBS and incubate 2 min.

This step is necessary to stop the PFA fixation.

5. Transfer to a new dish containing 1 \times PBS and incubate 2 min. Replace PBS with fresh 1 \times PBS and incubate another 2 min.
6. Dehydrate slides through a series of 5-min incubations in 50% ethanol, 70% ethanol, 95% ethanol, and 100% ethanol. All dehydration steps are done in dishes.

The dehydration can be performed efficiently by setting up four glass staining dishes, each having a different ethanol concentration. Slides aligned in a slide rack can be easily dipped into each solution and transferred to the next dish after 5 min.

7. Air dry the slides until they are completely dried.
8. Transfer slides to slide boxes containing desiccant and store at -70°C . Slides must be completely dry before storing in desiccant and freezing; otherwise, freezing artifacts can occur. Slides stored in this manner can be used for several weeks.

ALTERNATE PROTOCOL

In situ Hybridization and Immuno- histochemistry

14.1.3

PERFUSION OF ADULT MICE

Perfusion of animals is essential for achieving good morphology and preservation of brains, kidneys, hearts, and many other organs. For the untrained person the first perfusion might not work—it is therefore advisable to learn this procedure using some control animals first, or to seek the advice of a trained animal pathologist or colleague familiar with this procedure.

The protocol described here for mice (applicable also to most other species) involves first exchanging the animal's blood with phosphate-buffered saline and subsequently exchanging the saline with freshly prepared ice-cold (4°C) 4% paraformaldehyde. This protocol gives reproducibly good results without the necessity of using a pressure-controlled perfusion setup. These more sophisticated setups (available in major Anatomy departments) need to be used if, for example, blood vessels or kidney glomeruli need to be fixed in situ without any possible collapse of capillaries.

Materials

- 1× phosphate-buffered saline (PBS)
- 4% paraformaldehyde (PFA) fixative, freshly prepared at 4°C
- 2 syringes (20- to 30-ml) equipped with 23-G needles
- Container (bag) for mouse and CO₂ gas
- Dissection instruments (scissors, forceps, etc.)

1. Fill one syringe with 1× PBS, and another with 4% PFA fixative, 4°C. Set aside.
2. Kill mouse with CO₂ gas in a bag. Immediately after respiratory arrest, lay mouse on its back and open the thorax carefully to avoid excessive bleeding. Cut carefully through the rib cage and remove the diaphragm for access to the heart.

It is important to work fast, but be careful to get a good perfusion. If the blood clots or the main blood vessels are harmed, perfusion will not work.

3. Carefully insert syringe filled with 1× PBS into the left ventricle. Cut open the right ventricle for drainage, allowing the 1× PBS to be slowly but constantly perfused into the heart (see Fig. 14.1.1).

If the perfusion is working well, blood-rich organs such as liver, spleen, and kidneys will turn grayish-white.

4. After most of the blood has been flushed out, remove the syringe with 1× PBS and insert syringe filled with 4% PFA fixative (4°C) into the same puncture of the left ventricle. Slowly perfuse the mouse with ~20 ml fixative.

The start of the perfusion with 4% PFA is considered the starting point of the fixation process ($t = 0$).

A sign of a good perfusion is a muscle tremor best seen on the limbs and tail. By the end of this procedure the animal should be stiff. If perfusion is unsuccessful, it is not worthwhile continuing at this point (see Commentary).

5. Following perfusion, dissect out organs and tissues, transfer into well labeled glass vials (filled with 4% PFA fixative), and store on ice (4°C). Further fixation and processing is carried out as described in the basic protocol or *UNIT 14.2*.

SECTIONING SAMPLES IN WAX BLOCKS

Sectioning paraffin blocks containing samples is a process requiring experience and should be learned from an experienced individual if at all possible. Some universities and hospitals have service facilities that perform sectioning. If so, provide instructions on the desired thickness of the sections and orientation for mounting on subbed glass slides (see below). The following is an outline of the sectioning protocol. Paraffin blocks are cut into

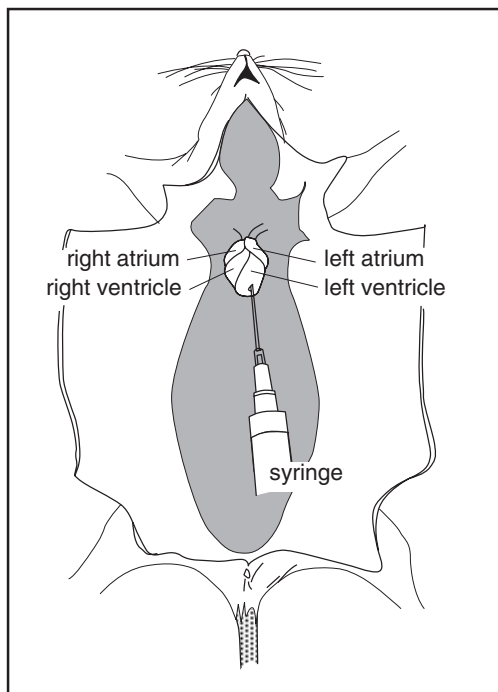

Figure 14.1.1 Perfusion of a mouse. This diagram illustrates the chambers of the heart and the correct positioning of the syringe in the left ventricle for perfusion.

thin (8- μm) tissue sections, which are mounted on subbed slides to be further processed for in situ hybridization (UNIT 14.3).

Materials

- Paraffin wax block(s) containing samples
- 0.2 \times gelatin subbing solution
- Microtome, complete with knives
- Gelatin-subbed glass slides
- Fine brushes
- Slide warmer or heating plate set between 45° and 50°C
- 42°C oven
- Desiccant (e.g., Humicaps, United Desiccants-Gates)

1. Cut a wax block containing samples into a trapezoidal shape using a razor blade. Carefully shave off the extra wax and do not cut too close to the embedded sample. Otherwise the sample might be destroyed or the paraffin wax might shatter.

The trapezoidal shape facilitates ribboning during sectioning (step 2) and allows the placement of sections close together on the slide.

2. Attach the trapezoid block (with the wide edge facing the knife) to the holding clamp of a microtome and begin sectioning (see Fig. 14.2.1c-e). Cut 8- μm sections.

Thinner sections (>1 μm) may be cut, but 8 μm is the standard thickness used. If the block is sectioning well, a ribbon will form.

CAUTION: *Microtome knives are very sharp. For the proper and safe use of the microtome, consult the manufacturer's manual.*

3. Put a drop of 0.2 \times gelatin subbing solution on a gelatin-subbed glass slide (see Fig. 14.1.2, which illustrates steps 3 to 8).
4. Transfer the ribbon of sections (up to 10 sections, depending on sample size) onto the drop on the subbed slide using fine brushes.

Figure 14.1.2 Placement of paraffin sections on gelatin-subbed glass slides. Steps **A** to **E** depicted here correspond to steps 3 to 8 in the support protocol.

5. Transfer the slide onto a slide warmer or heating plate set between 45° and 50°C.
Heat will stretch the sections and remove wrinkles. Do not leave slides on the slide warmer longer than necessary or the sections may be destroyed.
6. After stretching is complete, remove slide from slide warmer and carefully remove the remaining subbing solution using a Pasteur pipet.
7. Dry slide at room temperature.
8. Incubate 1 to 2 days at 42°C to firmly attach sections to subbed slides.
9. Store sections in a slide box with desiccant at –20°C for up to several weeks.
If desired, several different samples can be placed on the same slide. After steps 3 to 7 have been completed for sample 1, sample 2 is sectioned and sections are placed next to those of sample 1. Place sections as close together as possible to minimize the area on the slide that they occupy. The more space on a slide occupied by sections, the more hybridization solution will be needed for in situ hybridization (UNIT 14.3). Do not place sections too close to the edge of the slide.

REAGENTS AND SOLUTIONS

Gelatin-subbed glass slides

Use 25 × 75-mm precleaned Rite-on Microslides from Clay Adams or comparable source and prepare as follows:

1. Wash slides in water with detergent for a few minutes. Use any good soap.
2. Rinse slides in water 30 min. During this rinse, prepare 1× gelatin subbing solution (see below).
3. Place slides in a slide rack and immerse 2 min in a glass staining dish filled with 1× gelatin subbing solution (4°C). Subbing must be done carefully to avoid air bubbles.
4. Remove slide rack from subbing solution and set on its side, with the frosted sides of the slides facing downward, to let excess subbing solution drip off. Dry overnight before use. Slides subbed with gelatin are stable at room temperature for several weeks.

1× and 0.2× gelatin subbing solution

Dissolve gelatin (type Bloom 275) in water at 70°C to make a 0.5% solution. Cool the solution to room temperature, and add $\text{CrK}(\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}$ to 0.05% (chromium potassium sulfate). Cool the solution to 4°C on ice. Use immediately, as gelling occurs after prolonged storage of the solution on ice.

Prepare 0.2× gelatin solution by diluting 1× solution 5-fold with water. It can be used for several days if prepared using sterile water and stored at room temperature. If cloudiness or bacterial growth occurs, discard the solution.

4% paraformaldehyde (PFA) fixative

Heat to 60°C a volume of water equal to slightly less than $\frac{2}{3}$ the desired final volume of fixative. Weigh out a quantity of paraformaldehyde (Baker) that will make a 4% solution and add it with a stir bar to the water. Cover. Transfer to fume hood and maintain on heating plate at 60°C with stirring. Add 1 drop 2 N NaOH with a Pasteur pipet. The solution should become almost clear fairly rapidly, but will still have some fine particles that will not go away. Be careful not to overheat the solution. Remove from heat and add $\frac{1}{3}$ vol 3× PBS. Bring pH of solution to 7.2 with HCl, add water to final volume, and filter using a Millipore or Nalgene filter. Cool to room temperature, or to 4°C on ice.

CAUTION: *Formaldehyde is a carcinogen and may cause allergic reactions.*

3× and 1× phosphate-buffered saline (PBS), pH 7.2

Prepare the following solutions: 390 mM NaCl/30 mM Na_2HPO_4 and 390 mM NaCl/30 mM NaH_2PO_4 . Mix to obtain 3× PBS, pH 7.2, and autoclave or filter sterilize. Prepare 1× PBS by diluting 3× PBS 3-fold with water.

Poly-L-lysine-coated glass slides

Clean glass slides as described for gelatin-subbed glass slides (use slide racks and glass staining dishes). Prepare a sufficient amount of 500 $\mu\text{g}/\text{ml}$ poly-L-lysine (Sigma, MW >150,000) in water. Coat the glass slides by dipping individually into this solution, air dry, and store at 4°C. Use within a week. (A useful small dipping chamber is a plastic cytology slide mailer; see *UNIT 14.4*.)

COMMENTARY

Background Information

The best fixative for in situ hybridization appears to be paraformaldehyde (see Zeller et al., 1987), although other fixatives have been used successfully. Sample fixation is one of the crucial steps of the in situ hybridization protocol (*UNIT 14.3*) and is decisive in determining subsequent success or failure. Underfixation of samples leads to bad morphology and/or loss of signal, whereas overfixation leads to fixation artifacts, loss of signal, and/or increased background (noise) signal. The 4% PFA fixation recommended here has worked very well for mouse embryos as well as on tissues, but other investigators find it imperative to use different fixatives for some species. (A list of references to alternative fixation protocols for other species is given at the end of *UNIT 14.3*.) Homogeneous fixation of large, well vascularized or-

gans, such as brains, hearts, and kidneys, is achieved only by complete perfusion of the animal. On the other hand, it is not necessary to perfuse animals if embryos of pregnant females or poorly vascularized tissues (e.g., mammary tissues) are to be harvested.

Critical Parameters

The use of freshly prepared 4% PFA fixative is essential for good sample fixation. This is in contrast to fixation of tissues to be used for histology examination where commercially available formaldehyde stock solutions are used. Perfusion and fixation are done at 4°C because formaldehyde fixation is progressive over time; lowering the temperature slows the fixation process and provides a more suitable fixation.

Troubleshooting

Fixation. Failure of paraffin blocks to section well can be due to either under- or overfixation. If the sections crumble and disintegrate very easily, or are destroyed during stretching, underfixation or poor dehydration or impregnation with wax are frequently to blame. If the cellular morphology of the section is very poor, and cavities have collapsed, underfixation is again most likely to be at fault. If the block is extremely hard and falls out in one piece during sectioning, overfixation is the reason.

These problems might be partially or completely solved by using longer or shorter fixation times. Optimal fixation, however, may not be the only factor in obtaining a strong hybridization signal and low background. Many of the parameters have to be adjusted empirically by doing a series of test experiments using different fixation times and different hybridization conditions (see *UNIT 14.3*).

Perfusion. Perfect perfusion requires working quickly and methodically. If large areas of grayish-white decolorization are not seen on the liver, spleen, and kidneys of a perfused animal, it is not worthwhile continuing with the procedure. The main causes of a failed perfusion are severing of major blood vessels during opening of the animal, improper insertion of syringe needle into the left ventricle (thereby penetrating into other heart chambers or going all the way through the heart), and slow perfusion, leading to blood clotting.

Sectioning. Problems during sectioning can be caused by blunt or scratched knives or a misadjusted microtome. It is important to sharpen the blades occasionally or arrange for a service check of your microtome. If sections are lost in large quantities from slides during subsequent treatment and hybridization (*UNIT 14.3*), insufficiently subbed slides are most likely to blame. In such cases, make up freshly subbed slides.

Last, but not least, sectioning is a routine which requires experience—if you are inexpe-

rienced, do not expect the first sections to come out perfectly. Get advice from an experienced trained histologist, or let such a person do the sectioning for you. A detailed description is also given in Luna (1968).

Time Considerations

The amount of time needed to complete this procedure varies greatly with experience and the number of samples processed. From the start of fixing tissues until sections can be processed for in situ hybridization, allow at least 4 to 5 days. Approximate times for the individual operations are as follow:

perfusion—5 to 10 min
fixation—15 min to 4 hr
dehydration—5 to 6 hr
impregnation—overnight
embedding—5 to 6 hr
sectioning—≥1 hr, depending on
number of slides and samples
processed
attachment of sections—1 to 2 days.

Cryosectioning

This unit describes sample preparation and sectioning methods for frozen tissue. Sections of this type are used in a variety of light microscopic procedures including in situ hybridization, immunohistochemistry, and enzyme histochemistry.

SPECIMEN PREPARATION AND SECTIONING

Samples are quick-frozen and then sectioned. This protocol produces sections that are particularly suitable for immunohistochemistry and enzyme histochemistry. See commentary for critical parameters on specimen size before freezing tissue.

Materials

- Liquid N₂
- CryoKwik (Damon) or isopentane
- OCT compound (Tissue Tek II, Miles)
- Small Dewar flask or expanded polystyrene box
- Filter paper cut into 1 × 7-cm strips (e.g., Whatman 50)
- Forceps
- Metal rod

- Cryostat and microtome equipped with roll bar or plastic roll plate
- Cutting chuck (metal platform that supports specimen during sectioning)
- Heat sink or CO₂ jet freezer
- Fine brush and ¼-in. brush
- Gelatin- or poly-L-lysine-coated slides (UNIT 14.1), prelabeled with specimen details in pencil

All tools used in the cryosectioning, including the trimming razor blade, should be prechilled within the cryostat chamber. NOTE: The slides should not be chilled.

Freeze tissue specimen and prepare for sectioning

1. Chill a 50-ml Pyrex beaker by immersing in a Dewar flask (or expanded polystyrene box) filled with liquid N₂.
2. Fill beaker with CryoKwik.
3. Label one end of a filter paper strip with pencil and place specimen on the other end with forceps.

Samples prepared as a slurry are best frozen as 200- to 300-μl drops applied to the filter paper strips with a Pasteur pipet. Most tissue samples will stick to the filter paper naturally, but if they will not, it may be necessary to use a little OCT compound between the sample and filter paper.

4. Ensure the CryoKwik is liquid. If necessary, melt the CryoKwik by touching it with a metal rod.
5. Immerse specimen in cold CryoKwik ~1 min. Some of the CryoKwik may solidify on the sample, but this will evaporate in the cryostat.

At this stage specimens may be stored in either liquid N₂ or in a -70°C freezer.

6. Place filter paper strips with tissue specimens in a cryostat chamber and mount on cutting chucks with a thin layer of OCT compound (Fig. 14.2.1).

Do not use excessive OCT compound as this may lead to freezing artifacts; in particular, immersion of tissue in OCT should be avoided, unless small multiple specimens are being sectioned (see commentary).

BASIC PROTOCOL

In situ Hybridization and Immuno- histochemistry

14.2.1

Supplement 7

Figure 14.2.1 Sectioning procedure. **A** to **E** illustrate cryosectioning and correspond to steps 6 to 13 of basic protocol; **C** to **E** also illustrate paraffin wax sectioning and correspond to steps 1 to 4 of support protocol, *UNIT 14.1*.

- Cool the specimen/chuck mount within the cryostat with a precooled heat sink or a CO₂ jet freezer until the OCT compound solidifies.

The specimen block must remain frozen throughout the mounting procedure to avoid formation of cryoartifacts (see Table 14.2.1).

- Leave specimen within the cryostat for >10 min to reach the same temperature as the prechilled microtome.
- Trim specimen block to a trapezoid shape—if it is convenient and does not compromise the morphology—using a prechilled razor blade. Tear off filter paper.

Section specimen block

- Mount the chuck in the microtome with the parallel faces of the trapezoid in line with the knife and the wide edge toward the knife edge.
- Retract the specimen block until it easily clears the knife edge.
- Produce a smooth “face” on the block using the knife at rapid cutting speed (one section/sec).

Choice of section thickness is important as this will have considerable effect on the final resolution at the microscope. Generally, the thickest usable sections are ~10 μm and should not exceed 20 μm, since extremely thick sections will frequently

shatter, rendering the specimen useless. It is best to reduce section thickness until sectioning is only just possible ($\sim 5 \mu\text{m}$) as this will markedly improve quality.

13. Once the specimen block has been cut so that either the structure of interest can be seen within the cut face or the block dimensions are optimal (between 0.5 and 1 cm on a side), sections may be collected.

Collect cryosections

Generally one of two methods is employed to facilitate section collection: the roll-bar method (described in step 14 and Fig. 14.2.2) and the plastic roll-plate method (described in step 15 and Fig. 14.2.3).

14. The roll-bar method (this system is most suitable for large block faces, though not suitable for serial sections):
 - a. Flip the roll bar over such that it lies against the cut face of the specimen block and align it such that it is positioned ~ 1 mm from the edge of the block nearest the knife.
 - b. Cut sections slowly (~ 2 to 3 sec to traverse the cut face).
 - c. As sections are cut, the roll bar should lift onto the knife face, sandwiching the section between it and the knife, thereby preventing the section from rolling up on itself or being lost due to static electricity.
 - d. Proceed with step 16.

Figure 14.2.2 A roll bar (a U-shaped metal bar) is mounted on the rear of a cutting chuck onto which the specimen has been placed. As sections are cut, the roll bar will lift onto the knife face, over the section, and prevent the section from rolling up.

Figure 14.2.3 A plastic roll plate is hinged at the back of the microtome's knife holder and placed parallel to the plane of the knife edge. The plate touches the knife at the leading edge and is tilted up from the knife at the rear so that sections may pass between the knife and the plate.

15. The plastic roll-plate method (this system is the most commonly used as it allows easy serial sectioning, though it is less suitable for large block faces):
 - a. Prior to sectioning, flip the roll plate down such that it touches the knife and lies parallel to the knife edge, though retracted slightly behind the cutting edge of the knife.
 - b. Turn the crank and cut sections, which under these conditions will roll up at the cutting edge of the knife.
 - c. Lift the roll plate and, with a small brush, brush cut sections from the knife edge.
 - d. Drop the roll plate and advance it slightly.
 - e. Repeat steps 15a to 15d until sections pass smoothly between the roll plate and knife (generally when the roll plate leads the knife edge by ~ 0.5 mm) then proceed with step 16.

16. Lift the roll bar or plate and move the cut sections to the rear of the knife with a fine brush.

17. Collect sections by gently touching to a warm prelabeled gelatin- or poly-L-lysine-coated slide (see morphology troubleshooting, Table 14.2.1).

Mounted sections may be left in the microtome until all sectioning is complete. If they will be used for in situ hybridization, treat immediately following the support protocol for the fixation of cryosections for in situ hybridization. If they will be used for immunohistochemistry or enzyme histochemistry, the sections may be stored at -70°C for a limited time (overnight) in an airtight container (see also UNIT 14.6 on air dried sections for immunohistochemical study).

18. After lifting sections onto slide, clear condensed ice from the knife using a thick ($\frac{1}{4}$ -in.) brush.

This brushing may need to be quite vigorous and, therefore, should always be toward the knife edge; otherwise the knife will be rapidly dulled and the brush ruined.

FIXATION OF CRYOSECTIONS FOR IN SITU HYBRIDIZATION

Cryosections used for in situ hybridization must be fixed with paraformaldehyde and then dehydrated.

Materials

4% paraformaldehyde (PFA) fixative (UNIT 14.1), freshly prepared

3× and 1× phosphate-buffered saline (PBS; UNIT 14.1)

30%, 60%, 80%, 95%, and 100% ethanol

Moist chamber (Fig. 14.2.4)

Desiccant (e.g., Humicaps, United Desiccants-Gates)

1. Put slides containing sections in a moist chamber and cover the sections with 4% PFA fixative. Cover the chamber and incubate 20 min at room temperature for previously unfixed tissues or 5 min for fixed tissues.

Fixing and dehydrating the sections in a moist chamber will firmly fix most tissues to the slides throughout the remaining steps. Some tissues, however, may stick to slides better than others, and may be fixed in Coplin jars. This can be determined for the tissue of interest.

2. Aspirate off the fixative and flood the section with 3× PBS from a pipet or squirt bottle. Incubate 5 min.
3. Repeat step 2 twice with ~1× PBS.
4. Remove PBS and flood with ethanol for 2 min at each of the following concentrations: 30%, 60%, 80%, 95%, and 100%.
5. Dry the slides and store with desiccant at -70°C in an airtight box for up to several weeks. Before opening the box to use the slides, bring to room temperature.

Figure 14.2.4 Moist chamber. Take a conveniently sized container with a tight lid (e.g., Tupperware or equivalent) and attach pairs of 5- to 10-ml plastic pipets to bottom so that they support slides at either end. Place pipets so that the maximum number of slides can be set on them. Alternatively, place a stainless steel cake rack in the bottom. Put absorbent paper on the bottom and drench with water or, for in situ hybridization, where incubation times are very long, use a solution of identical osmolarity and formamide concentration to your hybridization buffer (see UNIT 14.3).

TISSUE FIXATION AND SUCROSE INFUSION

Frequently for cryosectioning, morphology is much improved if the tissue is fixed and infused with sucrose prior to sectioning.

Materials

Phosphate-buffered saline (PBS; *UNIT 14.1*)

2% (for immunohistochemistry) or 4% (for in situ hybridization)
paraformaldehyde (PFA) fixative (*UNIT 14.1*; for 2%, make 1:1
dilution in PBS of 4% PFA fixative)

0.5 M sucrose in PBS

1. Fix small tissue samples or isolated embryos (e.g., day 7 or day 8 mouse embryos) in 2% (for immunohistochemistry) or 4% (for in situ hybridization) PFA fixative for 30 min at 4°C.

Larger embryos, and some tissues, may require fixation for up to 4 hr. Larger organs should be fixed in situ within the animal by perfusion (UNIT 14.1) prior to dissection.

2. Following fixation, wash tissue samples twice in PBS.
3. Infuse samples in 0.5 M sucrose in PBS until tissue sinks (~1 to 3 hr).

This infusion may be extended to overnight, but no longer.

Paraformaldehyde fixation is a continuous fixation, as the tissue will become increasingly fixed the longer it is left in the fixative. Therefore, the fixation time should be minimized, as overfixation will result in loss of reactivity for both in situ hybridization or immunohistochemistry. This is particularly important for in situ hybridization (see commentary, UNITS 14.1-14.3).

COMMENTARY

Background Information

Cryosections, which are rapidly and relatively easily prepared, provide a good system for visualizing cellular fine detail. There are currently three main sectioning methodologies available to study the morphology of cells and tissues at the light microscope level: cryosections, paraffin sections (*UNIT 14.1*), and plastic (commonly methacrylate) sections. The latter two methodologies generally present a superior morphology than cryosections and both have been used for in situ hybridization. However, the preparation procedures are more arduous, and neither method can be used reliably for immunohistochemistry or enzyme histochemistry where retention of native protein form and function may be necessary.

Critical Parameters

Fixation

As a general rule, enzyme histochemical methods are most effected by changes in the state of the protein within the sections. For these studies, fixation of any kind should be avoided

as this may impair the functional state of the protein to be studied. For sections to be used in immunohistochemical studies, in which proteins need not be functional, fixation should not proceed to the point at which antigenic activity is lost. This is rarely a problem if only formaldehyde is used as a fixative. In situ hybridization is too new a method to have any golden rules of procedure. Since proteins bound to RNAs must be removed by pronase digestion or denaturation, a mild fixation protocol should be used. Optimization of fixation conditions is critical for the success of the in situ hybridization procedure. For standard histological staining methods, where fixation is not important, the morphology may be optimized. If this type of methodology is the ultimate goal of the technique, paraffin or methacrylate sections may be the preferred methods of preparation, as the storage and handling of these types of specimens are both easy and cheap.

Size of specimens

The size of specimens to be sectioned may vary from groups of cells grown in suspen-

Table 14.2.1 Troubleshooting Guide for Morphological Problems Encountered During Cryosectioning

Problem	Possible cause	Solution
Poor morphological preservation throughout tissue	Inadequate care during dissection or excessive delay between dissection and freezing	Take great care during dissection not to damage tissue by stretching or excessive bending. Freeze tissue soon after dissection to prevent proteolysis by endogenous proteolytic enzymes. This is particularly important for delicate samples (e.g., small embryos or brain) or enzyme-rich tissues (e.g., liver). Fixation and infusion with sucrose may improve morphology considerably (see support protocol).
Holes in tissue	Ice crystal formation in tissue during freezing, or due to thawing of the block and subsequent refreezing and ice crystal formation in the cryostat	Ensure that blocks are frozen in either isopentane or CryoKwik rather than a gas such as nitrogen. The latter will boil on contact with the warm tissue giving a “shell freezing” effect, where the boiling gas insulates the outer layers of the tissue from the cold liquid nitrogen, thereby slowing freezing and allowing ice crystal formation. Ensure that when specimens are mounted in the microtome they are protected from warming by a large precooled heat sink. Ensure that you do not touch the specimens with your fingers or with warm tools.
Morphology appears fuzzy	“Pressure artifact” due to excessive pressure on the back of the slide while picking up the section	Use less pressure when picking up the section. A mixture of warmth and static charge will normally ensure that sections stick to the slide. If this is not the case, the slide is too cold and may be locally warmed by touching a finger to the back of the slide.
Morphology appears smeared	Slide was moved while lifting section	Hold slide against the rear of the knife and use this as a fulcrum while gently rocking the slide down to touch the section, thereby ensuring no lateral motion of the slide.
Sections do not stick to slide, they wash away during labeling	Slides were not adequately coated	Ensure that sections stick to slides by dip-coating them as described in <i>UNIT 14.1</i> .
Sections blow away from knife edge during sectioning	A buildup of static electricity in the cryostat	There is no reliable cure. It is possible to buy polonium brushes which may help. Antistatic guns (such as those designed for record players) have also been used successfully.
Sections have lines running up them and separate into ribbons on knife edge	Knife is dull	Sharpen knife. Generally a knife will cut ~20 to 30 blocks of soft tissue before it needs to be sharpened. If starting with new equipment, a disposable blade system (e.g., Fisher) may be cheaper over the long term.

sion to whole animals—the upper size limit of the specimen is normally defined by the capacity of the standard laboratory cryostat, ~1.5 to 2 cm³. The method of preparation prior to sectioning is important as this will ultimately affect the final image quality.

Small, multiple specimens. This category includes samples ranging in size from cells (e.g., lymphocytes grown in suspension), to small animal samples (e.g., early mouse embryos or small nematodes). With specimens of this type, orientation is generally not possible. Instead, sufficient samples are included at random orientations in each specimen such that most or all orientations are present. Prior to freezing, specimens are mixed as a slurry in an inert supporting media which is easy to section (e.g., OCT compound).

Large specimens. Larger specimens, such as organs or tissue samples, are generally sectioned individually. A factor that should be considered prior to freezing is whether the tissue sample has a homogeneous density, as this will make sectioning much easier. An example of extreme inhomogeneity is whole animal limbs, where skin, muscle, and bone may all be contained within the same sample, making sectioning very difficult; in this case, specific tissues should be dissected out prior to freezing. Small tissue samples, which are easily lost and are not available in large quantities, are best mounted in another tissue, such as in a “liver sandwich,” which frequently serves as a negative control as well as a tissue support.

Another feature which should be considered prior to sectioning is tissue orientation, as this may be indistinguishable in whole frozen tissue. This is important in tissues such as muscle or pieces of brain; here the type of information gathered from the labeled sections will depend entirely on orientation.

Sectioning

The cryostat must be thermally stable prior to sectioning. Fluctuations in temperature make sectioning very difficult as the specimen will either contract away from the knife, or worse still, expand into the knife, usually causing the sample to tear out from the chuck and be ruined. For this reason, it is necessary to allow the cryostat to stabilize for some time (30 min to 1 hr) after the chosen temperature is reached, or after altering the temperature, before proceeding with sectioning. Normal cutting temperatures are between –30° and –20°C. Usually,

softer tissues require colder cutting temperature. As a guide, softer samples (e.g., brain tissue) are cut at –30°C, while harder samples with a defined cytoskeleton (e.g., muscle) are cut at about –20°C. For very hard specimens it may be necessary to raise the temperature to –15°C, although temperatures any warmer than this may lead to excessively soft specimen blocks. It is quite easy to recognize temperature problems. Generally, if the sections appear brittle and crumble, the cryostat is too cold. If the sections wrinkle excessively, the cryostat is too warm.

Morphology

A variety of morphological problems may arise. Refer to Table 14.2.1 for a guide to troubleshooting some of the more common difficulties.

Anticipated Results

Cryosections should show good retention of morphology (Fig. 14.6.2), with no artifacts due to ice crystals and sectioning problems as described in Table 14.2.1. The sections provide an ideal substrate for immunohistochemistry (UNIT 14.6), in situ hybridization (UNIT 14.3), or enzyme histochemistry.

Time Considerations

Specimen preparation. If the specimen is to be fixed and infused with sucrose, this procedure may take several hours; otherwise, freezing the tissues takes only a few minutes.

Sectioning. With practice, this procedure becomes very rapid—<30 min for each specimen. However, it takes time to reach this degree of competence, so in the beginning, allot ≥1 hr for each specimen.

In Situ Hybridization to Cellular RNA

UNIT 14.3

In situ hybridization to cellular RNA is used to determine the cellular localization of specific messages within complex cell populations and tissues. Tissues may either be embedded in paraffin and sectioned on a microtome (see Basic Protocol), or frozen and sectioned in a cryostat (see Alternate Protocol). RNA contained in the specimens is hybridized to a specific radiolabeled probe (see Support Protocols 1 and 2), which is then detected using film autoradiography or emulsion autoradiography (UNIT 14.4).

HYBRIDIZATION USING PARAFFIN SECTIONS AND CELLS

Dewaxed sections and single cells are hydrated, then pretreated to denature the tissue and remove some of the proteins to make the mRNA transcripts more accessible for hybridization. On the second day, specimens are hybridized to [³⁵S]UTP-labeled riboprobe for up to 4 hr. After hybridization, specimens are washed and digested with RNase to remove excess and nonspecifically hybridized probe.

Materials

- Specimens mounted on subbed glass slides (e.g., see UNIT 14.1)
- Dewaxing/rehydration (dehydration) series consisting of 3 staining dishes of xylenes, 2 staining dishes of 100% ethanol, and 1 staining dish each of 95%, 70%, and 50% ethanol
- 0.2 N HCl
- 2× SSC (APPENDIX 2), 70°C
- 1× and 3× phosphate-buffered saline (PBS; UNIT 14.1)
- Predigested pronase solution (optional; see recipe)
- 2 mg/ml glycine in 1× PBS (optional)
- 4% paraformaldehyde (PFA) fixative (UNIT 14.1), freshly prepared at room temperature
- 10 mM dithiothreitol (DTT)/1× PBS (see recipe), freshly prepared at 45°C
- Blocking solution (see recipe), prepared immediately before use at 45°C
- Triethanolamine (TEA) buffer (see recipe), freshly prepared
- Acetic anhydride
- [³⁵S]UTP-labeled riboprobes (see Support Protocol 1)
- S-riboprobe competitor (see recipe)
- 50 mM DTT, sterile
- Hybridization mix A (see recipe)
- Moist chamber solution A (see recipe)
- Wash solutions A, B, and C (see recipes)
- RNase digestion solution (see recipe)
- 50% ethanol/0.3 M ammonium acetate
- 70% ethanol/0.3 M ammonium acetate
- 95% ethanol/0.3 M ammonium acetate
- 100% ethanol
- Two sets of slide racks (one clearly labeled for RNase use only)
- ≥10 glass staining dishes
- 45°, 55°, and 50°C water baths
- Slide box with desiccant (e.g., Humicaps, United Desiccants–Gates)
- 100°C heating block or water bath
- 45°C incubator
- Moist chambers (Fig. A.3E.4; one clearly labeled for RNase use only)
- ≥4 glass staining dishes, clearly labeled for RNase use only

**BASIC
PROTOCOL**

**In situ
Hybridization
and Immuno-
histochemistry**

14.3.1

Additional reagents and equipment for fixation and sectioning of tissues and cells (UNIT 14.1), probe preparation (see Support Protocols 1 and 2), autoradiography (UNIT 14.4), and staining and mounting (UNIT 14.5).

NOTE: All of the following steps are performed by incubating the slides containing specimens (held in a slide rack) in glass staining dishes in the indicated solutions. All solutions are made up fresh and are used only once unless indicated otherwise.

Dewax and rehydrate the specimens

1. Prepare the dewaxing/rehydration series (can be reused several times) and 0.2 N HCl while slides containing specimen sections (kept in slide boxes at -20° or -70°C ; see UNIT 14.1) are warmed to room temperature. Also, start preheating $2\times$ SSC to 70°C (for step 5).
2. Dewax slides by three changes in xylenes, 2 min each (not necessary for slides containing unembedded single cells).
3. Rehydrate through the following regimen:
 - 100% ethanol—twice, 2 min each
 - 95% ethanol—2 min
 - 70% ethanol—2 min
 - 50% ethanol—2 min.

Denature the specimens

4. Denature specimens 20 min at room temperature in 0.2 N HCl.

This step will denature proteins and nick DNA, but will also partially reverse the paraformaldehyde fixation step.
5. Heat denature 15 min at 70°C in $2\times$ SSC.

This step denatures RNA and probably also removes some of the proteins to make RNA in sections or cells more accessible to hybridization.
6. Rinse 2 min in $1\times$ PBS.

Optional step: Under certain circumstances (see Commentary), a pronase digestion step is included here. Specimens are digested 15 min at 37°C with 0.1 to 10 $\mu\text{g}/\text{ml}$ pronase digestion solution. The optimal pronase concentration has to be determined empirically for each tissue, but in general, the highest possible pronase concentration that still gives good cellular morphology is used. Pronase digestion is stopped by rinsing slides 30 sec in 2 mg/ml glycine in $1\times$ PBS.
7. Post-fix specimens 5 min at room temperature in freshly prepared 4% PFA fixative.
8. Block fixation 5 min in $3\times$ PBS.
9. Rinse twice, 30 sec each time, in $1\times$ PBS.

Block the specimens

10. Equilibrate specimens in 10 mM DTT/ $1\times$ PBS for 10 min at 45°C in a water bath.
11. Block specimens with freshly prepared blocking solution 30 min at 45°C in a water bath covered with aluminum foil (iodoacetamide is light sensitive).

CAUTION: Both iodoacetamide and *N*-ethylmaleimide are very toxic substances; handle very carefully.

This step is included to block nonspecific sulfur-binding sites on tissue specimens; it may be omitted if ^3H - or ^{32}P -labeled probes are used for in situ hybridization.

12. Rinse twice, 2 min each time, in 1× PBS at room temperature.
13. Equilibrate specimens 2 min in freshly prepared TEA buffer.
14. Transfer slide rack to fresh TEA buffer and add acetic anhydride to a concentration of 0.25%. Mix quickly and incubate slides 5 min with agitation. Add additional acetic anhydride to reach a final concentration of 0.5% and incubate another 5 min.

This step blocks polar and charged groups on tissue sections, which will cause nonspecific sticking of probes. It is important to add the acetic anhydride immediately before specimens are incubated because the half-life of acetic anhydride in aqueous solutions is very short.

15. Block specimens 5 min in 2× SSC.

Dehydrate the specimens

16. Dehydrate specimens through 50% ethanol, 70% ethanol, 95% ethanol, and 100% ethanol (twice), for 2 min each at room temperature.

For this step, use the same ethanol solutions as in step 3.

17. Air dry specimens (or dry in desiccator), making sure specimens are absolutely dry before proceeding to step 18.
18. Store specimens in a slide box with desiccant at -70°C overnight.

Prepare the probe

19. Spin down the ethanol-precipitated antisense and sense ^{35}S -labeled riboprobes (see Support Protocol 1), as well as the S-ribo probe competitor. Dry pellets. Dissolve each pellet (corresponding to one reaction) in 5 μl of sterile 50 mM DTT. Add 2.5 μl (half a reaction) of S-ribo probe competitor to both antisense and sense riboprobe.

Start probe preparation early in the morning.

20. Heat dissolved probes to 100°C for 3 min in heating block or water bath.
21. Immediately add enough hybridization mix A to obtain a 0.3 $\mu\text{g}/\text{ml}$ final probe concentration (see Support Protocol 1 for details concerning determination of the probe mass synthesized). Mix well and count 1 μl (expected counts $\geq 1 \times 10^5$ cpm/ μl). Place tubes in water bath at 45°C (hybridization temperature).

If antisense and sense probes differ extensively in their counts per μl (e.g., antisense riboprobe has five times more counts per μl than sense riboprobe, or vice versa), make sure it is not due to improper mixing, and recount the samples. If the difference is consistent, dilute the sample that has more counts to get a roughly equal count per μl for both antisense and sense riboprobes. Radiolabeled probes that are substantially less than 10^5 cpm/ μl should not be used. The poor recovery was probably caused by loss during ethanol precipitation.

Hybridize the specimens

22. Set up hybridizations by carefully spreading an appropriate amount of probe on the specimens (e.g., 20 $\mu\text{l}/20$ mm³) using the tip of a pipet (see Fig. 14.3.1).

If background is a problem, a prehybridization step can be included prior to hybridization: Take up one reaction of S-ribo probe competitor in 5 μl of 50 mM DTT, heat 3 min to 100°C , and add 500 μl of hybridization mix A. Spread ≥ 20 μl of this prehybridization mix on the specimens as described in step 22. Incubate 1 to 2 hr at 45°C in a moist chamber. To remove prehybridization mix, tip slides, causing the prehybridization mix to collect at one edge and carefully blot off buffer with Whatman 3MM paper. Then proceed with step 22.

Figure 14.3.1 Application of hybridization mix to slides. Carefully spread hybridization on sections with the tip of a pipet (avoid touching sections). Arrows indicate directions of spreading of hybridization mix A (or B).

23. Place specimens in a moist chamber (see Fig. 14.2.4) containing moist chamber solution A and incubate at 45°C for the appropriate hybridization time. Perform a series of hybridizations ranging from 30 min to 4 hr.

It is crucial that slides are kept level; otherwise the hybridization mix will collect at one side, leading to uneven hybridization. Equilibrate and seal the moist chamber carefully since dried out specimens will result in high background. The osmolarity of the moist chamber solution must equal that of the hybridization mix to prevent its dilution or concentration.

24. During the last hour of hybridization, prepare and preheat wash solutions A, B, and C.

Wash the specimens

25. Start washing slides by dipping one at a time into 100 ml wash solution A at 55°C. Immediately place in a slide rack in a staining dish filled with wash solution A.

The first dip into wash solution A removes much of the radioactivity, and should be disposed of into radioactive liquid waste. For disposal of all other less radioactive liquid wash solutions, follow local guidelines.

Do not allow slides to dry during any of the hybridization and washing steps. Drying causes extremely high background.

26. Incubate twice, 15 min each time, in wash solution A at 55°C.
27. Incubate twice, 15 min each time, in wash solution B at 55°C.
28. Incubate twice, 2 min each time, in wash solution C at room temperature.

Treat specimens with RNase

29. Add 500 µl RNase digestion solution per slide, covering all specimens, and place the slides in a moist chamber (containing water) of the type shown in Figure 14.2.4 (but labeled “RNase”).

NOTE: In steps 29 to 34, use only materials clearly labeled “RNase.” Do not use these materials for any other steps in any of the protocols described in this unit. Cross-contamination with RNases can ruin the experiment.

30. Incubate 15 min at room temperature.
31. Wash slides twice, 30 min each time, in wash solution C at 50°C with gentle shaking.
32. Wash slides twice, 30 min each time, in wash solution A at 50°C with gentle shaking.
33. Wash slides twice, 5 min each time, in 2× SSC at room temperature.

34. Dehydrate through the following regimen (2 min each):

50% ethanol/0.3 M ammonium acetate
70% ethanol/0.3 M ammonium acetate
95% ethanol/0.3 M ammonium acetate
100% ethanol.

35. Air dry the slides.

36. Expose slides at least overnight against film, and then perform emulsion autoradiography (e.g., *UNIT 14.4*).

HYBRIDIZATION USING CRYOSECTIONS

Sections are briefly treated with pronase, acetylated, and hybridized to radiolabeled or digoxigenin-labeled probe. Although the protocol detailed here specifies cryosections, it may also be used successfully with dewaxed and hydrated paraffin sections (see Basic Protocol, steps 1 to 3).

Materials

Specimens mounted on subbed glass slides (*UNIT 14.2*)
Predigested pronase solution (see recipe)
50 mM Tris-Cl, pH 7.5 (*APPENDIX 2*)/5 mM EDTA
2 mg/ml glycine in 1× PBS
1× phosphate-buffered saline (PBS; *UNIT 14.1*)
Triethanolamine (TEA) buffer (see recipe), freshly prepared
Acetic anhydride
2× SSC (*APPENDIX 2*)
30%, 60%, 80%, 95%, and 100% ethanol
Labeled DNA or RNA probe (see Support Protocols 1, 2, and 3)
Hybridization mix B (see recipe)
Deionized formamide (see recipe)
50% dextran sulfate (Amersham Pharmacia Biotech)
3.3 M dithiothreitol (DTT), freshly prepared
Moist chamber solution B (see recipe)
DNA wash solution (see recipe), prewarmed to 37°C
RNA wash solutions I and II (see recipes), prewarmed to 50°C
20 µg/ml boiled ribonuclease A (*UNIT 7.3*) in 0.5 M NaCl/10 mM Tris-Cl, pH 8.0
0.6 M NaCl in 30% ethanol and in 60% ethanol

2 sets of slide racks and jars (one set will be reserved for RNase use only)
50°C water bath
Moist chamber
37° or 42°C incubator (or water bath)

Additional reagents and equipment for fixation and sectioning of tissues (*UNIT 14.2*),
probe preparation (see Support Protocols 1 and 2), autoradiography (*UNIT 14.4*),
and staining and mounting (*UNIT 14.5*).

Pretreat the sections for hybridization

1. Remove box of slides from freezer and allow to come to room temperature before opening.

***ALTERNATE
PROTOCOL***

**In situ
Hybridization
and Immuno-
histochemistry**

14.3.5

2. Place slides in rack and immerse 10 min in predigested and lyophilized pronase in 50 mM Tris·Cl, pH 7.5/5 mM EDTA.

The concentration of pronase required must be determined in a test experiment. If cryosections are used, digestion may sometimes be omitted. However, in this protocol paraffin sections require pronase digestion.

3. Rinse slides 30 sec at room temperature in PBS containing 2 mg/ml glycine, then twice in PBS for 30 sec each time.

This step stops proteolysis.

Acetylate the samples

4. Immerse slides 5 min in freshly prepared TEA buffer.
5. In a beaker, prepare enough TEA buffer to cover slides. Add acetic anhydride to a final concentration of 0.25% and pour on slides as quickly as possible. Agitate rack to mix. Incubate 10 min.
6. Wash slides twice, 5 min each time, in 2× SSC.
7. Dehydrate for 2 min each in 30%, 60%, 80%, 95%, and 100% ethanol. Dry and use immediately for hybridization.

Prepare the probes

8. Precipitate labeled DNA or RNA probes.
9. Determine the percent of label incorporated and estimate the mass of probe synthesized. Calculate the volume of final hybridization mix required to resuspend the pellet at a final concentration of 0.2 µg/ml per kilobase.
10. Resuspend the pellet first in 2 parts hybridization mix B and 2 parts deionized formamide. Subsequently, add 1 part 50% dextran sulfate. Mix thoroughly.

Probe may be prepared the previous day and stored frozen at -80°C.

Hybridize the probes

11. Boil labeled DNA probes 2 min and chill in ice bath, or place heat-labeled RNA probes 30 sec at 80°C and then hold at 50°C.
12. Add 50 mM DTT from a 3.3 M stock solution. Using the tip of a pipet, distribute sufficient probe to cover sections, e.g., 20 µl/20 mm² (see Fig. 14.3.1).

Refer to the support protocols for preparation of DNA and RNA probes.

If using single-stranded probes, several different probes may be heated at once. Double-stranded probes, however, are so concentrated that self-annealing is a problem, so denature only a few slides' worth of probe at a time.

13. Incubate 4 hr in a well-sealed moist chamber containing moist chamber solution B. Incubate DNA probes at 37°C and RNA probes at 42°C.

Wash the slides

- 14a. *DNA probes:* Wash 2 hr at 37°C with 4 to 5 changes of prewarmed DNA wash solution.

- 14b. *RNA probes:*

- a. Wash 15 min at least twice at 50°C in prewarmed RNA wash solution I.
- b. Treat slides 30 min at 37°C with 20 µg/ml boiled ribonuclease A in 0.5 M NaCl and 10 mM Tris·Cl, pH 8.0.

- c. Wash 15 min at least twice at 50°C in prewarmed RNA wash solution I.
- d. Wash 15 min twice at 50°C in prewarmed RNA wash solution II.

This wash temperature may be increased to 60°C, if desired, although morphology may suffer.

IMPORTANT NOTE: *Keep all glassware and racks used for washes and RNase treatment completely separate from glassware used for pretreatment and hybridizations.*

15. Dehydrate through the following regimen (2 min each):

0.6 M NaCl in 30% ethanol
 0.6 M NaCl in 60% ethanol
 80% ethanol
 95% ethanol
 100% ethanol.

The ethanol solutions used in step 7 may be reused here, but discard them after this step in order to avoid later RNase contamination.

16. Air dry the slides and detect hybridized probe by autoradiography (UNIT 14.4) or enzymatic detection (see Support Protocol 3; Haramis and Carrasco, 1996).

SYNTHESIS OF ³⁵S-LABELED RIBOPROBES

Materials

5× transcription buffer (see recipe)
 1 M dithiothreitol (DTT), freshly prepared
 Ribonuclease inhibitor (e.g., Amersham placental ribonuclease inhibitor or Promega Biotec RNasin)
 10 mM CTP, ATP, and GTP (UNIT 3.4)
 1 µg/µl restriction enzyme–digested plasmid (see recipe)
 1000 to 1500 Ci/mmol [³⁵S]UTP (UNIT 3.4)
 SP6 or T7 RNA polymerase (UNIT 3.8)
 10 mg/ml yeast tRNA or mouse poly(A) RNA for carrier
 1 U/µl RNase-free DNase I (e.g., Promega Biotec RQ1; UNITS 4.1 & 4.10)
 3 M sodium acetate
 7.5 M ammonium acetate
 100% and 70% ethanol, –20°C

NOTE: When ³⁵S-labeled probes are prepared, it is very important to add 10 mM DTT to all solutions containing [³⁵S]UTP, particularly after any step that may inactivate DTT (e.g. precipitation, column chromatography, and boiling). In addition, extreme care should be taken to prevent RNase contamination of reagents.

1. Prepare the following reaction mix at room temperature (20 µl total):

4.0 µl 5× transcription buffer
 0.2 µl 1 M DTT
 60 U ribonuclease inhibitor
 1.0 µl each of the three 10 mM NTPs
 1.0 µl digested DNA (1 µg/µl)
 10.0 µl [³⁵S]UTP
 16 U SP6 or T7 RNA polymerase.

2. Incubate 30 min at 37°C. Add 16 U more polymerase and continue incubation at 37°C for 40 min.

SUPPORT PROTOCOL 1

In situ Hybridization and Immuno- histochemistry

14.3.7

3. Add the following to the reaction mix:

60 U ribonuclease inhibitor
2.0 μ l 10 mg/ml carrier RNA
1.0 μ l DNase I.

Incubate 10 min at 37°C to remove template.

4. Add the following to the reaction mix:

0.8 μ l 1 M DTT
63.0 μ l sterile H₂O
10.0 μ l 3 M sodium acetate.

Remove 1 μ l and determine cpm/ μ l by scintillation counting.

5. Make reaction mix 2 M ammonium acetate by adding 36.4 μ l of 7.5 M ammonium acetate. Add 272 μ l of -20°C 100% ethanol, precipitate 10 min on dry ice, pellet, wash with -20°C 70% ethanol, and dry. Repeat if desired. Resuspend in 100 μ l of 10 mM DTT and determine cpm/ μ l.

6. Determine percent incorporation.

Under these conditions 70% to 90% of the label is incorporated, resulting in ~70 to 90 ng labeled RNA.

7. Following synthesis of labeled probe, add 50 to 100 μ g carrier tRNA per 20- to 25- μ l synthesis reaction, add sodium acetate to 0.3 M and DTT to 10 mM, and then ethanol precipitate as in step 5 (adjusting quantities proportionally).

Riboprobes should be used within 2 to 3 days of synthesis.

SUPPORT PROTOCOL 2

SYNTHESIS OF ³⁵S-LABELED DOUBLE-STRANDED DNA PROBES

Radioactive double-stranded DNA probe may be synthesized by nick translation or random oligonucleotide-primed synthesis using [³⁵S]dNTPs. Add 10 mM DTT to the standard reaction mixes (UNIT 3.5) and replace the [³²P]dNTP with two different [³⁵S]dNTPs (specific activity \geq 1000 Ci/mmol) at as high a final molarity as possible, usually 2 to 4 μ M.

Note that since the rate of [³⁵S]dNTP incorporation is slower than that of [³²P]dNTPs, the reaction should be optimized for maximum incorporation and desired DNA length. Incorporation should be as high as 5×10^8 cpm/ μ g.

SUPPORT PROTOCOL 3

SYNTHESIS OF DIGOXIGENIN-LABELED RNA PROBES

Antisense riboprobes are synthesized as run-off transcripts from linearized templates, using bacteriophage polymerases and template DNA consisting of the DNA fragment of interest cloned in a vector containing the promoter appropriate for the RNA polymerase (T3, T7, or SP6). RNA synthesis is carried out in the presence of a digoxigenin-substituted ribonucleotide. Nonradioactive probes have several advantages. They are easily synthesized in large quantities, they are stable for several months, and they can be reused up to three times. An additional advantage of RNA versus DNA probes is that they result in cleaner signals because nonspecifically bound probe is removed during ribonuclease treatment. This protocol is based on Wilkinson (1993).

Materials

Distilled water, sterile
10× transcription buffer: 400 mM Tris-Cl (pH 8.25)/60 mM MgCl₂/20 mM spermidine (Boehringer Mannheim)
0.2 M dithiothreitol (DTT; APPENDIX 2)
Nucleotide mix, pH 8: 10 mM GTP/10 mM ATP/10 mM CTP/6.5 mM UTP/3.5 mM digoxigenin-UTP (Boehringer Mannheim)
1 µg/ml linearized plasmid
100 U/ml placental ribonuclease inhibitor (RNasin, Boehringer Mannheim)
10 U/µl SP6, T3, or T7 RNA polymerase
TBE electrophoresis buffer (see recipe)
RNase-free DNase I
TE buffer, pH 8 (APPENDIX 2), DEPC-treated (UNIT 4.1)
4 M LiCl, DEPC-treated
70% ethanol in DEPC-treated water
100% ethanol
37°C water bath
Additional reagents and equipment for agarose gel electrophoresis (Voytas, 1988)

1. Mix reagents in the following order at room temperature (21 µl total):

13 µl sterile distilled water
2 µl 10× transcription buffer
1 µl 0.2 M DTT
2 µl nucleotide mix
1 µl linearized plasmid
1 µl RNasin
1 µl RNA polymerase.

Incubate 2 hr at 37°C.

Although stock solutions of sensitive reagents should be kept on ice, the reaction mixture should be mixed at room temperature; otherwise the spermidine in the transcription buffer will precipitate the DNA.

2. Remove 1 µl of the reaction and run on an agarose gel in TBE electrophoresis buffer to estimate amount of riboprobe synthesized.

The RNA band should be ~10 times more abundant than the plasmid band, indicating that ~10 µg of riboprobe have been synthesized.

3. Add 2 µl RNase-free DNase I to the reaction mix. Incubate 15 min at 37°C.
4. Add 100 µl TE buffer, 10 µl of 4 M LiCl, and 300 µl of 100% ethanol. Mix and incubate 30 min at -20°C.

LiCl precipitates high-molecular-weight RNA.

5. Microcentrifuge 10 min at maximum speed, 4°C.
6. Wash pellet with 70% ethanol.
7. Air-dry pellet (do not use a Speedvac evaporator). Redissolve pellet in TE buffer to give a concentration of ~0.1 µg/µl. Store at -20°C.

Digoxigenin-labeled riboprobes are stable at least 2 years at -20°C.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Blocking solution

Preheat 400 ml of 1× PBS (see APPENDIX 2) to 45°C. Immediately before use, add the following: 0.617 g DTT, 0.74 g iodoacetamide, and 0.5 g *N*-ethylmaleimide. Mix well and use immediately. Cover with aluminum foil.

CAUTION: *These substances are very toxic—exercise proper precautions during preparation and handle very carefully.*

Deionized formamide

Mix 50 ml of good-quality formamide (e.g., Fluka) and ~5 g of mixed-bed, ion-exchange resin (e.g., Bio-Rad AG 501-X8, 20 to 50 mesh) and stir 30 min at room temperature. Filter through Whatman filter paper, dispense into 1-ml aliquots, and store at –20°C.

DNA wash solution

0.6 M NaCl
10 mM Tris·Cl, pH 7.5 (APPENDIX 2)
1 mM EDTA (APPENDIX 2)
50% formamide (use inexpensive grade, e.g., Fluka, and do not deionize)
0.1% 2-mercaptoethanol

10 mM DTT/1× PBS

Preheat 400 ml of 1× PBS (APPENDIX 2) to 45°C; immediately before use, add 0.617 g dithiothreitol (DTT) and dissolve.

Use highest quality DTT available (Sigma).

Hybridization mix A

50% deionized formamide (see recipe above for deionization)
0.3 M NaCl, sterile
10 mM Tris·Cl, pH 8.0 (APPENDIX 2)
1 mM EDTA (APPENDIX 2)
1× Denhardt's solution (APPENDIX 2)
500 µg/ml yeast tRNA
500 µg/ml poly(A) (Amersham Pharmacia Biotech)
50 mM DTT
10% polyethylene glycol (MW 6000; EM Science)
Store in aliquots at –70°C

Hybridization mix B

1.2 M NaCl
20 mM Tris·Cl, pH 7.5 (APPENDIX 2)
4 mM EDTA (APPENDIX 2)
2× Denhardt's solution (APPENDIX 2)
1 mg/ml yeast tRNA
200 µg/ml poly(A) (Amersham Pharmacia Biotech)
Store in aliquots at –20°C

Moist chamber solution A

50% formamide (inexpensive grade)
0.3 M NaCl
10 mM Tris·Cl, pH 8.0 (APPENDIX 2)
1 mM EDTA (APPENDIX 2)

Moist chamber solution B

50% formamide (inexpensive grade)
0.6 M NaCl
10 mM Tris·Cl, pH 7.5 (*APPENDIX 2*)
2 mM EDTA (*APPENDIX 2*)

Predigested pronase

Predigest pronase by incubating a 40 mg/ml pronase solution in water for 4 hr at 37°C. Lyophilize in aliquots and store in a nondefrosting freezer at –20°C.

Determine the optimal pronase concentration by digesting a series of sections with sequential dilutions of the predigested pronase as follows: resuspend pronase in 50 mM Tris·Cl, pH 7.5/5 mM EDTA (see *APPENDIX 2* for stock solutions). For the Basic Protocol, incubate slides 15 min at 37°C with 0.1 to 10 µg/ml pronase. For the Alternate Protocol, incubate slides 10 min at room temperature with 0.125 to 1 mg/ml pronase. Pretreat experimental sections with the highest possible pronase concentration that allows the retention of adequate cellular morphology.

Restriction enzyme–digested plasmid, 1 µg/µl

Insert gene of interest into a vector containing an SP6 (e.g., pSP64 or pSP65), T3, or T7 promoter. Linearize the plasmid downstream of the coding sequence. Phenol/chloroform extract the DNA (*UNIT 2.1A*), ethanol precipitate, wash pellet in 70% ethanol, dry, and redissolve at 1 µg/µl in sterile water. Alternatively, treat with 0.1% fresh diethylpyrocarbonate (DEPC) for 10 min at room temperature, heat to 65°C for 10 min, and ethanol precipitate as above.

The DNA should be clean and free of salt after the restriction digestion in order to avoid terminating transcription.

RNase digestion solution

40 µg/ml RNase A (Sigma)
2 µg/ml RNase T1 (Sigma)
10 mM Tris·Cl, pH 7.5 (*APPENDIX 2*)
5 mM EDTA (*APPENDIX 2*)
0.3 M NaCl

RNA wash solution I

2× SSC (*APPENDIX 2*)
50% formamide (use inexpensive grade, e.g., Fluka, and do not deionize)
0.1% 2-mercaptoethanol

RNA wash solution II

0.1× SSC (*APPENDIX 2*)
1% 2-mercaptoethanol

S-riboprobe competitor (see Basic Protocol)

S-riboprobe competitor is synthesized using a vector without an insert as template. The [³⁵S]UTP in the transcription reaction (see Support Protocol 1, step 1) is replaced by 100 nM nonradioactive S-UTP (NEN Life Sciences). Half of a reaction of S-riboprobe competitor is required per ³⁵S-labeled riboprobe reaction.

TBE electrophoresis buffer, 10×

108g Tris base (890 mM)
55 g boric acid (890 mM)
960 ml H₂O
40 ml 0.5 M EDTA, pH 8.0 (20 mM final; *APPENDIX 2*)

Transcription buffer, 5×

200 mM Tris·Cl, pH 8.3 (APPENDIX 2)
30 mM MgCl₂
10 mM spermidine·Cl
0.1% Triton X-100
Store at -70°C in aliquots

Triethanolamine (TEA) buffer (0.1 M TEA)

Add 18.57 g triethanolamine·Cl to 900 ml water. Dissolve and adjust pH to 8.0 with NaOH. Adjust to 1 liter with water for 0.1 M solution. Prepare fresh daily.

Wash solution A

50% formamide (inexpensive grade, e.g., Fluka)
2× SSC (APPENDIX 2)
20 mM 2-mercaptoethanol
Preheat half to 55°C and half to 50°C

Wash solution B

50% formamide (inexpensive grade, e.g., Fluka)
2× SSC (APPENDIX 2)
20 mM 2-mercaptoethanol
0.5% Triton X-100
Preheat to 55°C

Wash solution C

2× SSC (APPENDIX 2)
20 mM 2-mercaptoethanol
Preheat to 50°C

COMMENTARY**Background Information**

In situ hybridization was first used to localize specific DNA sequences on chromosomes (Gall and Pardue, 1971). This technique has been modified for the detection and localization of RNAs within tissues from many different organisms. Alternative protocols for in situ hybridization studies using organisms other than mouse are listed below. Early studies described the localization of viral or abundant cellular messages in cultured cells or tissue sections (e.g., Brahic and Haase, 1978; Singer and Ward, 1982). Improved methods allowing detection of moderate to low abundance mRNAs were developed later in order to describe the expression and localization of genes regulating embryonic and larval development in *Drosophila*. The sensitivity of these methods, which utilized double-stranded (Hafen et al., 1983) or single-stranded (Akam, 1983) tritiated DNA probes, has been increased further by the use of single-stranded RNA probes (Cox et al., 1984) and ³⁵S-labeled probes (Awgulewitsch et al., 1986).

Nonradioactive techniques for the detection of cellular messages have also been developed.

Commonly used methods employ digoxigenin- and biotin-conjugated nucleotides to label probes which are then detected by either a fluorescent or an enzymatic system (Singer and Ward, 1982; Singer et al., 1986; Haramis and Carrasco, 1996). Digoxigenin-labeled probes are particularly useful for whole-mount in situ hybridization. Although these methods offer increased resolution and rapid detection while avoiding the safety and disposal problems of radioactive isotopes, they can be less sensitive on sections than autoradiographic techniques.

Successful in situ hybridization to cellular RNA relies on a number of factors. The most suitable cytological fixation procedure should provide adequate cellular morphology, while neither extracting nor changing the location of the RNA. Moreover, fixation must not be so thorough that it inhibits probe access. The most widely used fixative is paraformaldehyde, although many other fixatives have also been used successfully. The length of fixation time and type of fixative should be empirically determined for the tissue of interest and for any other cytological procedures (e.g., immunolo-

calization) required. Limited proteolytic digestion is commonly used to increase probe access to fixed tissues. The degree of proteolysis must be carefully balanced to permit adequate morphology while increasing signal, and often digestion may be unnecessary (Lawrence and Singer, 1985; Pardue, 1985).

The probe may be either DNA or RNA. Randomly sheared double-stranded DNA probes labeled by either nick translation or oligonucleotide-primed labeling may form networks on the cytological hybrid, thereby increasing the hybridization signal. Self-annealing of probe also occurs, however, thus decreasing the effective probe concentration. This problem has been circumvented by synthesizing single-stranded DNA probes from M13 templates (Akam, 1983), but the probes most commonly used today are single-stranded RNA probes transcribed by phage polymerases from plasmids containing SP6 or T7 promoters. These highly specific radioactive probes are easily synthesized in large quantities. RNA probes generally give lower backgrounds than equivalent DNA probes because nonspecifically bound probe is removed by ribonuclease treatment. Several studies have shown that probe length affects hybridization efficiency with probes of about 30 to 300 nucleotides being optimal. DNA probe length may be decreased by DNase I digestion, while RNA probes may be shortened by limited alkaline hydrolysis (Cox et al., 1984). Length of RNA probes does not appear to be as critical as that of DNA probes, and the protocols described here do not involve hydrolysis at all.

Acetylation of tissue preparations is frequently used to decrease background binding of radioactive probe when performing in situ hybridization to chromosomal DNA (Hayashi et al., 1978). This treatment is equally important when hybridizing to cellular mRNAs and is recommended in all cases. In the Basic Protocol an additional step for blocking nonspecific sulfur-binding sites on tissue sections is included (Zeller et al., 1987).

Critical Parameters

Many particularly critical points are noted throughout the hybridization protocol of which the following are noteworthy. The most sensitive parameter, tissue fixation, requires careful optimization in order to maximize the signal-to-noise ratio. Overfixation can entirely obscure weak signals.

It is essential that freshly prepared solutions are used where indicated since many reagents,

blocking agents in particular, are extremely labile. Moreover, be sure to purchase only as much chemical as can be used in a reasonable period of time.

[³⁵S]NTPs, the radionucleotides most commonly used for labeling in situ hybridization probes, are treated in essentially the same way as [³²P]NTPs, with a few important exceptions. In general, any factor that makes a [³²P]NTP reaction slightly substandard will almost abolish [³⁵S]NTP incorporation, presumably because thionucleotides are less easily utilized by the enzymes. Consequently, great care should be taken to use clean restriction endonuclease-digested plasmid DNA, fresh [³⁵S]NTPs (<2 weeks old), and fresh aliquots of cold NTPs. Most importantly, make sure that all solutions contain ≥10 mM DTT and that RNase contamination is eliminated.

The successful in situ hybridization experiment requires thoughtful design and suitable controls. For the initial experiments the following guidelines are helpful: (1) If possible, include a tissue in your experiments which expresses the gene of interest at high levels in a RNase protection or northern assay (UNIT 4.9). (2) Use at least two different fixation time points which have been found to yield high-quality sections (see UNITS 14.1 & 14.2). (3) To optimize the signal-to-noise ratio, use different hybridization times (30 min, 1 hr, 2 hr, 4 hr). (4) Process at least duplicate slides for each fixation and hybridization condition to get two different exposure times by emulsion autoradiography (UNIT 14.4). (5) Initially, the experimenter should be conservative in estimating how many slides can be processed.

The following controls should be done to confirm the spatial distribution pattern: First, and most importantly, hybridize one set of slides to an antisense single-stranded riboprobe (see Support Protocol 1) to detect the specific hybridization to the complementary mRNA, as well as a second set under absolutely identical conditions to a sense riboprobe (synthesized from the same template as the antisense riboprobe in opposite orientation) as a control to detect nonspecific background. It is advisable to determine that there is no transcription of the opposite strand using an RNase protection assay.

As a second control, treat sections with RNase prior to hybridization to the antisense probe in order to reveal signal resulting from binding to non-RNA cell components. Finally, use another portion of the gene, expecting to get the same result (this control is important

Table 14.3.1 Time Parameters for In Situ Hybridization

Step	Paraffin	Cryosections
Fixation and embedding	Day 1—Fix or perfuse tissues in 4% PFA fixative. Dehydrate.	Day 1—Fix or perfuse tissues in 4% PFA fixative. Infuse in sucrose. Orient and embed in OCT compound. Quick freeze and store at -70°C .
Sectioning	Days 3 to 4—Cut sections on microtome and place on slides. Dry on slides for 1 to 2 days at 42°C . Store desiccated ≤ 2 months at -20°C .	Day 2—Make cryostat sections and place on microscope slides. Fix with 4% PFA fixative, dehydrate, and store desiccated ≤ 1 month at -70°C .
Pretreatment	Day 4—Dewax. HCl and heat treat. Treat with blocking agents and acetic anhydride. Dehydrate and store desiccated overnight at -70°C .	Day 3—Pronase digest. Treat with acetic anhydride. Dehydrate and use immediately.
Hybridization	Day 5—Overlay sections with probe and hybridize in moist chamber 1 to 4 hr.	Day 3—Overlay sections with probe and hybridize in moist chamber 1 to 4 hr.
Washes	Day 5—Wash, RNase-treat, and dehydrate.	Day 3—Wash, RNase-treat, and dehydrate.
Detection	Days 5-?—Expose to X-ray film, 1 to 3 days. Estimate exposure time and dip multiple slides in autoradiographic emulsion. Develop and analyze.	Days 3-?—Expose to X-ray film, 1 to 3 days. Estimate exposure time and dip multiple slides in autoradiographic emulsion. Develop and analyze. Alternatively, detect digoxigen-labeled probe enzymatically 1 to 2 days

when the gene is a member of a multigene family), and compare the expression pattern to that of a completely unrelated gene.

Troubleshooting

Sections get lost during procedure

- Slides were subbed or coated improperly.
- Tissue requires more gentle fixation; use a moist chamber throughout fixation, and the first dehydration (cryosections only).

Low signal, high background

- Tissue is overfixed; use shorter fixation time.
- Blocking agents are old; buy small quantities, which can be used up rapidly.
- $[^{35}\text{S}]\text{UTP}$ is oxidized; use a fresh batch, store it properly at -70°C , and check that enough DTT (or 2-mercaptoethanol) is present in all solutions. Keep freezing/thawing to a minimum.

d. Overdigestion with pronase (cryosections only).

e. Certain sequences of some genes are associated with high background; use a different portion of the gene as probe.

Localized high levels of background

Certain cell types are very sticky for ^{35}S -riboprobes. If these cells are a minor component of the tissue of interest, use sense-strand control riboprobe to document that the particular signal is nonspecific. Alternatively, digest sections with higher concentrations of pronase.

Comparison of paraffin and cryosections

Advantages of paraffin wax (Paraplast). Easier to get satisfactory sections and good morphology; routine histology, antigen localization using enzymatic detection, and in situ hybridizations can be performed on serial sections; blocks can be stored indefinitely at room temperature; has been shown to work with

tissues from many different organisms; paraffin sectioning is routine in clinical settings.

Advantages of cryosections. Quicker; coimmunolocalization on the same section is possible; and immunolocalization using fluorescent tags is possible. Finer morphological studies are possible (e.g., electron microscopy) because the tissues are treated more gently.

Anticipated Results

A good in situ hybridization experiment will clearly identify the location of a message within specific cells or tissues with minimal background throughout the remainder of the tissue. Numerous examples of these experiments can be found in the listed references.

Time Considerations

Table 14.3.1 details how long it takes to complete an in situ hybridization experiment, starting with fixing the tissue and finishing with exposure of the hybridized slide. It is advisable that probes be synthesized the day before hybridization is performed.

Detection of Hybridized Probe

UNIT 14.4

Autoradiography is used to detect and quantitate radioactive probe hybridized to cytological preparations. Autoradiographic film is used to detect ^{32}P - or ^{35}S -labeled probe, and can be useful in experiments dealing with large organs or tissues. Emulsion autoradiography is required to obtain resolution at the level of a single cell. For further information on film autoradiography, see *APPENDIX 3*.

FILM AUTORADIOGRAPHY

Tape slides to a backing such as cardboard or an old piece of film. Expose slides to Du Pont Cronex Video Imaging Film (MRF 34 Clear) at 4°C under light pressure. Kodak XRP-1 may also be used.

When using Du Pont Cronex Video Imaging Film make sure that the emulsion side of the film is facing the specimens.

**BASIC
PROTOCOL**

EMULSION AUTORADIOGRAPHY

Single-cell resolution and ^3H detection can be obtained by coating slides with autoradiographic emulsion.

**BASIC
PROTOCOL**

Materials

- Diluted Kodak emulsion (support protocol)
- Kodak D19 developer
- Kodak fixer
- Plastic cytology slide mailer (Curtin Matheson), for use as dipping chamber
- Nonsparking fan or slide dryer (Oncor; optional)
- Kodak safelight filter #2 (optional)
- Black, light-tight slide boxes
- Desiccant (e.g., Humicaps, United Desiccants-Gates)
- 42° to 45°C water bath
- Slide racks and jars, for use in developing and fixing
- 15° to 20°C water bath (a styrofoam box works well)
- Slide rack or wire test-tube rack for drying dipped slides

Steps 1 to 7 must be performed in complete darkness, or ~4 feet from safelight.

1. Melt aliquot of diluted emulsion (prepared according to support protocol) in 42° to 45°C water bath for 10 min. Pour or pipet emulsion into clean slide mailer (dipping chamber).
2. Dip slides slowly and smoothly into slide mailer or dipping chamber. Withdraw slowly and place vertically in a test-tube rack to dry 2 hr.
Alternatively, use a nonsparking fan to decrease drying time, or place in a slide dryer and dry according to manufacturer's instructions. With tissue sections artifacts caused by running of emulsion can be a problem. Prevent this by placing the dipped slides on a cold glass plate for 10 min before drying the slides.
3. Place thoroughly dry slides in a light-tight slide box with desiccant. Seal box with electrician's black tape, cover with foil, and expose at 4°C .

If slides are not completely dry sensitivity is decreased, as humidity causes fading of the latent images in the autoradiographic emulsion.

Do not expose in a refrigerator that is used for storing ^{32}P because even very small quantities of ^{32}P will increase background. Organic solvents will also increase background.

14.4.1

Supplement 7

- Put developer, water, and fixer in slide jars and bring to 15° to 20°C in water bath.

The exact temperature is not critical. Lowering the temperature, however, reduces the silver grain size; 15°C is recommended.

- Take slides out of the refrigerator and allow to warm to same temperature as developing solutions.

Slides and developing solutions should be at the same temperature since drastic temperature changes will cause the emulsion to wrinkle.

- Transfer the slides to slide racks and develop in a light-tight darkroom as follows (monitor time carefully with a timer):

2.5 min in developer
30 sec in water
3 min in fixer.

Kodak does not recommend using an acid stop bath because it may cause formation of microscopic bubbles in the emulsion. Use of rapid (ammonium) fixers may result in the loss of developed silver grains. Do not agitate slides vigorously.

- Rinse slides 10 to 15 min under gently running cool tap water in the light, then once in cool distilled water. While slides are still wet, scrape off emulsion on the back of the slide with a razor, then dry them in a dust-free location.

- Counterstain the slides as desired and mount under clean cover slips (UNIT 14.5).

Developed silver grains are best observed by dark-field microscopy, under which they appear as white dots on a black background.

SUPPORT PROTOCOL

PREPARATION OF DILUTED EMULSION FOR AUTORADIOGRAPHY

This protocol outlines the preparation of a 1:1 (v/v) dilution of Kodak NTB-2 autoradiographic emulsion for use in emulsion autoradiography. *NOTE:* All steps must be performed in complete darkness or ~4 feet from safelight.

Additional Materials

Kodak NTB-2 autoradiographic emulsion

- Heat a 4-oz bottle of Kodak NTB-2 autoradiographic emulsion in a 42° to 45°C water bath 30 min in the dark. At the same time warm an equal volume of water in a 500-ml flask to the same temperature.
- After emulsion has melted, slowly pour it down the side of the flask (which is held at an angle) and mix. Swirling the flask gently once or twice will sufficiently mix the emulsion and water. Avoid creating any bubbles.
- Aliquot diluted emulsion into nylon scintillation vials or plastic slide mailers.

If the scintillation vial caps have cork inserts, remove them because they may release organic compounds that can increase background. If slide mailers are used, the aliquots must be stored vertically in order to prevent leakage before the emulsion solidifies; however, they are convenient because they may be used for dipping directly.

- Wrap each aliquot in aluminum foil or store in a light-tight container in a refrigerator that is never used for storing ³²P or organic chemicals.

Even very small quantities of ³²P will cause an unacceptable background.

- Test diluted emulsion before use by dipping and developing two clean, unused slides (as described in basic protocol for emulsion autoradiography) and visualizing under a 100× lens. If >100 grains per microscope field are observed, the emulsion should be returned to Kodak.

COMMENTARY

Background Information

The final factor affecting hybridization sensitivity is autoradiographic detection. Two forms of autoradiography are used: film (*APPENDIX 3*) and emulsion.

Emulsion autoradiography is performed by dipping previously hybridized slides in liquid nuclear track emulsion, thus producing a thin film of autoradiographic emulsion that adheres closely to the tissue section. The thickness of this film and the type of isotope used directly affect the resulting sensitivity, resolution, and background of this procedure. Very strong β -particle emitters such as ^{32}P (1710 KeV) produce a strong signal that may be detected by ordinary X-ray film, but the long path length of each particle makes fine tissue and cell resolution impossible. Emulsion autoradiography is rarely used to detect this isotope because of this lack of resolution and because many particles escape from the emulsion before decaying. Tritium, a weak β emitter (18.5 KeV), can only be localized by emulsion autoradiography and is ideal for single-cell resolution. Because the approximate path length of each particle is <1 micron, most particles decay within the emulsion above the cytological preparation. The weak signal, however, makes extremely long exposure times necessary. ^{35}S -labeled probes (167 KeV) are a suitable compromise because they afford increased sensitivity combined with adequate cellular resolution.

Film autoradiography may be used to preview quickly the results of hybridization using a ^{35}S label, thus allowing one to estimate subsequent emulsion exposure time and to determine whether or not an experiment worked as expected. In some cases, where large organs or embryos are labeled, this exposure may provide the required information; however, single-cell resolution requires the use of emulsion autoradiography. As an approximate rule of thumb, the exposure time required for an equivalent signal in emulsion is 3- to 5-fold that of film, although multiple slides must always be used in order to obtain the best exposure.

Critical Parameters

Emulsion must be prepared and used either in complete darkness or at a reasonable distance from a safelight (~4 feet).

After exposing slides to emulsion, be sure to dry slides completely before putting them away to expose. Both the slides and the emul-

sion should never be stored in a cold room or refrigerator that is used for storing ^{32}P or organic solvents. Either material can increase background and ruin an experiment.

In preparing and using emulsion, it is important to avoid forming any bubbles, either in the solution itself or along the slides. Any bubbles in the surface will prevent the slides from being smoothly coated with emulsion and interfere with autoradiography.

Anticipated Results

Film autoradiography provides a rapid but low resolution image of hybridized ^{35}S probe. Fine resolution and detection of tritiated probes are obtained with emulsion autoradiography.

Time Considerations

Film autoradiography requires only a few minutes to place film on the specimens, a 1- or 2-day exposure, and ≤ 10 min developing time. Thus film autoradiography is frequently used to preview the results of an experiment before embarking on the time-consuming process of emulsion autoradiography.

Although the time required to emulsion coat and develop slides is brief, lengthy exposure times may be required. Moreover, it is usually necessary to prepare replicate slides for different exposure times. Preparation of emulsion requires 45 to 60 min. Dipping of slides requires 1 to 3 hr, depending on the availability of a fan or slide dryer. Slides hybridized to ^{35}S probes should be exposed to film for 1 to 2 days, then emulsion exposure time is estimated based on the signal observed; emulsion is about 3- to 5-fold slower. Usual exposure times range from days to weeks, while slides hybridized to tritiated probes may require exposure times of up to several months. Developing takes ~1 hr.

Counterstaining and Mounting of Autoradiographed In situ Hybridization Slides

UNIT 14.5

The morphology of specimen sections and the identity of specific areas are defined by lightly counterstaining sections. After staining, slides are dehydrated, mounted with coverslips, hardened, and cleaned for examination under the microscope. In the protocols provided below, Giemsa stains predominantly the nuclei, hematoxylin/eosin stain differentiates both the nuclei and cytoplasm, toluidine blue staining is a simpler procedure that lightly stains both nuclei and cytoplasm, and Hoechst staining of nuclei provides a fast, easy, and effective way to simultaneously view the entire tissue and the regions of hybridization.

NOTE: Carry out all steps at room temperature except where specified otherwise.

GIEMSA STAINING

**BASIC
PROTOCOL**

Materials

Hydrated, developed in situ hybridization slides (UNITS 14.3 & 14.4)

Giemsa stain (Fisher)

10 mM NaPO₄ buffer, pH 6.8 (1:50 dilution of 500 mM stock)

50%, 70%, 95%, and 100% ethanol

Xylenes

Mounting medium: Permout (Fisher) or Gelvatol (now called Airvol, from Air Products and Chemicals)

13 glass staining dishes

Blunted forceps

Whatman 3MM paper chips

42°C incubator

CAUTION: Xylenes are toxic organic solvents. All steps using xylenes must be carried out under a fume hood.

1. Immerse developed slides in a slide rack in a staining dish filled with water.
2. Prepare the following regimen of staining dishes filled with solutions:
 - 1 dish—25-fold dilution of Giemsa stain in 10 mM NaPO₄ buffer, pH 6.8
 - 3 dishes—H₂O
 - Dehydration series (can be reused, or use the series prepared for dewaxing in UNIT 14.3)—3 dishes each filled with 50%, 70%, and 95% ethanol, respectively, and 2 dishes filled with 100% ethanol
 - 3 dishes—xylenes.
3. Stain slides 20 sec in a 25-fold dilution of Giemsa stain.

Depending on staining time, a weak or intense stain can be achieved. Optimal staining times vary from tissue to tissue and should also be adjusted to the strength of the in situ hybridization signal. Perform a test series the first time.

4. Rinse slides in water three times, 2 min each time.
5. Dehydrate slides through the ethanol series, 2 min in each dish. Transfer to xylenes and do three changes, 2 min each time.

It is important to perform the dehydration and equilibration in xylenes carefully because Permout will not mix with water or ethanol.

14.5.1

Supplement 24

- In the hood, mount slides as follows: With blunted forceps (in left hand), remove one slide from the xylenes and hold it flat at its frosted end. Add ~4 drops Permout to the other end (where sections are located). With the right hand, grab a clean coverslip and place it very slowly on the slide as shown in Figure 14.5.1.

Gelvatol is used instead of Permout when the cytological preparation should not be dehydrated, e.g., in the case of immunohistochemistry. Mount slides with Gelvatol as follows: Place a small drop of gelvatol on a coverslip. Carefully set the slide containing the specimen on the drop, avoiding formation of bubbles. Avoid applying pressure as this may squash the specimen. Allow to harden 2 to 4 hr at room temperature. See reagents and solutions for a homemade recipe for Gelvatol.

It is important that the slide does not start to dry before the mounting medium is added and the coverslip is placed on. Otherwise, microbubbles can cause artifacts.

- Remove extra mounting medium/xylenes by blotting carefully around the edges with 3MM paper and by wiping the back of the slide (but not the coverslip).
At this stage, slides cannot be stored upright in slide boxes because the mounting medium has not yet hardened.
- Place slides flat on a cardboard tray and allow to harden ~2 days in a 42°C incubator.
- Remove excess emulsion, stain, and mounting medium from the backs of slides by carefully scraping with a razor blade; remove dust with lens paper or plain tissue.
- Transfer cleaned slides to slide boxes. If necessary, relabel slides properly.
- Slides may now be examined microscopically. For weak signals, dark-field illumination is recommended. For strong signals, transillumination is sufficient.

Figure 14.5.1 Mounting of slides with mounting medium.

ALTERNATE PROTOCOL

HEMATOXYLIN/EOSIN STAINING

Additional Materials

- Hematoxylin stain (Harris modified hematoxylin with acetic acid, mercury-free; Fisher)
- 0.1% ammonium hydroxide
- Eosin stain

- Place developed slides (in slide rack) in a staining dish filled with water.
- Prepare the following regimen of solutions in staining dishes:
 - 1 dish—hematoxylin stain
 - 2 dishes—H₂O

- 1 dish—0.1% NH₄OH
- 2 dishes—H₂O
- 1 dish—eosin stain
- 1 dish—95% ethanol
- 2 dishes—100% ethanol
- 3 dishes—xylenes.

3. Stain slides 20 to 30 sec in hematoxylin.

Again, optimal staining time varies a bit from tissue to tissue, and also among batches of hematoxylin. Do not overstain.

4. Rinse two times in water, 2 min each time.
5. Quickly dip into 0.1% ammonium hydroxide, then rinse in water.

If the dip in 0.1% ammonium hydroxide is too long, autoradiographic emulsion may start to come off the slides.

6. Wash 5 min in water, then eosin stain 20 to 30 sec.

If oversteining with eosin occurs, destaining can be achieved by dipping the slides in 50% ethanol for a short time. Watch the stain diffusing out. If the stain is too weak, restain again.

7. Dip slides eight times in the same 95% ethanol solution, then dip them again eight times in the same 100% ethanol solution.
8. Fully dehydrate 2 min in 100% ethanol.
9. Equilibrate three times, 2 min each, in xylenes.
10. Mount and process as described in steps 6 to 11 of the basic protocol.

TOLUIDINE BLUE STAINING

Additional Materials

Toluidine blue stain

1. Dilute Toluidine blue stain with water.

The dilution should be determined empirically, according to the degree of staining desired. Start at ~1:100.

2. Dip slides briefly in diluted stain solution. Rinse several times with water and mount as desired.

HOECHST STAINING

Additional Materials

1 mg/ml Hoechst stain in dimethyl sulfoxide (Hoechst 33258 dye, bisbenzimidazole; store at -20°C)

Mounting medium: 0.5 g/ml Canada balsam or Gelvatol

Fluorescence microscope with Hoechst or DAPI filter and dark-field optics

CAUTION: Hoechst dye is a carcinogen.

1. Dilute 1 mg/ml Hoechst stain 1:500 with water to 2 µg/ml final.
2. Cover sections with diluted stain or dip slides in diluted stain. Incubate 2 min at room temperature.

**ALTERNATE
PROTOCOL**

**ALTERNATE
PROTOCOL**

**In situ
Hybridization
and Immuno-
histochemistry**

14.5.3

3. Wash slides 2 min in water at room temperature.
4. Air dry slides at room temperature.
5. Bake slides 30 to 60 min in a 42° to 55°C incubator. Remove and bring to room temperature.
6. Mount as in Figure 14.5.1 using 0.5 g/ml Canada balsam and air dry the slides 2 days at room temperature (after mounting).

Do not use Permount because autofluorescence occurs when nuclei are viewed. Canada balsam clears paraffin sections well and does not fluoresce under UV irradiation. Gelvatol may be used for cryosections but should not be used for paraffin sections since it does not clear the tissues.

7. View nuclei using Hoechst epifluorescence optics. Cover the light source with a red filter and view silver grains simultaneously with dark-field illumination.

The silver grains will appear red and contrast well with the fluorescent blue nuclei. To photograph, make a double exposure of the nuclei and the silver grains, optimizing the exposure time required for both nucleus and silver grain visualization.

REAGENTS AND SOLUTIONS

0.5 g/ml Canada balsam

5 g Canada balsam
 10 ml methyl salicylate
 Stir until Canada balsam is dissolved
 Store at room temperature

Eosin stain

12 g Eosin Y (Fisher)
 3 g Phloxine B (Fisher)
 500 ml 70% ethanol

Gelvatol (now called Airvol)

Gelvatol (Air Products and Chemicals) is a water-soluble mounting medium made from polyvinyl alcohol (PVA) and glycerol. The following recipe is a simplification of the original method: Add 5 g PVA 2000 to 100 ml 1× PBS (APPENDIX 2) every hour for 4 hr (total 20 g) while stirring constantly. Keep covered and stir overnight at 4°C. Add 3 more grams PVA 2000 and stir until dissolved. Add a single sodium azide crystal and 50 ml glycerol. Mix thoroughly, aliquot, and store at 4°C in sealed storage vials.

500 mM NaPO₄ buffer, pH 6.8 (stock solution)

35.5 g Na₂HPO₄
 34.5 g NaH₂PO₄
 H₂O to 1 liter
 Adjust pH if necessary

Toluidine blue stain

1.0 g sodium borate
 0.5 g Toluidine blue
 H₂O to 100 ml
 Filter before use

COMMENTARY

Background Information

The histological stains described here are used to differentiate cellular morphology after completing in situ hybridization (UNITS 14.1-14.4) or immunolocalization (UNIT 14.6) procedures. Counterstaining sectioned material is necessary to positively identify the specific structures or cell types in an embryo or tissue expressing the gene of interest. Choice of histological stain depends on several factors. In general, a histological stain that is commonly used in morphological analysis of the particular tissue or cell type is suggested. For adult tissues, hematoxylin/eosin staining is preferred, whereas Giemsa and Toluidine blue stains are mostly used to stain embryos. Hoechst staining of nuclei, combined with dark-field illumination, permits simultaneous visualization of exposed silver grains and nuclei and allows the viewer to determine exactly which cells have hybridized to the probe (Edgar and O'Farrell, 1989).

For more detailed information and the use of other histological stains the reader is referred to Luna (1968), which shows expected results with color plates.

Critical Parameters

For any of the four staining procedures, the optimal staining time will depend upon the tissue as well as the type of stain used, and should be adjusted to the intensity of the hybridization signal.

Thorough exposure to xylenes after dehydration is important because Permount mounting medium will not mix with water or ethanol. When the specimen should not be dehydrated, Gelvatol can be used instead.

Canada balsam or Gelvatol mounting media must be used with Hoechst-stained tissues since Permount autofluoresces. Paraffin sections should be mounted with Canada balsam in order to clear the tissues adequately.

Troubleshooting

If the stains are too weak, sections can be restained by removing Permounted coverslips in xylenes, washing the slides extensively in xylenes, and then rehydrating them as described in UNIT 14.3. Gelvatol-mounted coverslips may be removed by soaking in water.

Overstaining for hematoxylin is irreparable, whereas both Giemsa and eosin stains can be destained in low ethanol concentrations. To avoid under- or overstaining, it is advisable to go through the procedure the first time with very few slides and then to adjust the staining times according to the results obtained.

Anticipated Results

Ideally, histological staining reveals the details of cellular morphology thus allowing identification of the cell types expressing the gene of interest but not interfering with visualization of the grains of the autoradiographic exposure (UNIT 14.4). Certain stains (e.g., hematoxylin/eosin) have the tendency to nonspecifically stain the autoradiographic emulsion, which can obscure the hybridization signal. In general, shorter times are used for staining sections after in situ hybridization or immunolocalization than for conventional histological analysis.

Time Considerations

These staining procedures are very fast and should not take more than 10 to 15 min to complete. Mounting time depends on experience and number of slides processed, although 20 slides should easily be mounted in 30 min. After mounting, several hours (Gelvatol) to 2 days (Permount and Canada balsam) are required for hardening.

Immunohistochemistry

This unit surveys immunohistochemical techniques for protein localization. The first four protocols focus on indirect immunofluorescence which is the easiest and most widely used method of optical detection. In the following protocols alternate methods suitable for bright-field microscopy, such as immunoperoxidase and immunogold labeling, are described and critically reviewed. The commentary contains an extensive troubleshooting guide with a list of suitable routine controls.

The chosen method of tissue or cellular preparation must be suitable to answer the fundamental objective of the protocol (i.e., where the protein is localized within the system). Thus, if cultured cells are being studied, and it is suspected that the protein exists at the cell's surface, it would be pointless to employ a protocol designed to look at cytoplasmic contents and which includes an intrinsic step that may disrupt the cell membrane. Furthermore, the choice of fluorochrome and the method of labeling are also important to optimize the sensitivity of antigen localization. The basic protocol is therefore divided into two sections: (1) cellular preparations (monolayers of adherent cells and cells grown in suspension) and (2) tissue section labeling.

The commentary discusses suitable routine control experiments that should be performed for each experiment. Advantages and disadvantages of monoclonal and polyclonal primary antibodies and secondary labeling methods, including secondary antibody-fluorochrome conjugates, protein A-fluorochrome conjugates, and antibody-biotin/streptavidin-fluorochrome conjugates, are also discussed. It is recommended that the commentary be read before starting any of the labeling protocols.

BASIC PROTOCOL

IMMUNOFLUORESCENT LABELING OF CELLS GROWN AS MONOLAYERS

Immunocytochemical studies are easily performed on adherent cultured cells. Cells are generally grown in culture dishes, on glass cover slips, or in sterile tissue culture chambers on glass slides (see Table 14.6.1 in commentary). Immobilization of the antigen varies depending on whether the antigen is considered to be associated with the cell surface membrane or contained within the cytoplasm. Low concentrations of paraformaldehyde are used to fix surface antigens. This will generally not destroy antigenicity, and will preserve cell morphology. If fixation does remove antigenic activity, one may use the same protocol and eliminate the fixation step, provided that all incubations are performed at 4°C.

When cytoplasmic antigens are to be studied, the membrane must be permeabilized to allow antibodies into the cell. Two methods are provided, in which the lipid bilayer is disrupted and the cytoplasmic protein is fixed, with generally good retention of antigenicity—the dehydration method (using methanol) and the cross-linking/ permeabilization method (using a mixture of paraformaldehyde and Triton X-100).

Materials

- Cells of choice generally grown in a 3- to 5-cm dish (a smaller dish uses less antibody; however, the dish must fit under the microscope objective)
- 4°C phosphate-buffered saline (PBS; APPENDIX 2)
- 2% paraformaldehyde (PFA) fixative (1:1 dilution with PBS of 4% PFA fixative described in UNIT 14.1), 4°C—for cell surface antigens
- 100% methanol, -10° to -20°C (solvent cooled in the ice box of a refrigerator is ideal) or 2% PFA fixative containing 0.1% Triton X-100, 4°C—for cytoplasmic antigens
- Primary antibody, ~5 to 10 µg/ml (see commentary)

Secondary antibody–fluorochrome conjugate specific to the source species of primary antibody (see commentary)

Motorized pump or water pump

1. Cool the cells on ice.

The cells should be confluent (or as close to confluent as possible).

2. Pipet off culture media and wash in 4°C PBS.

All pipetting steps are done with Pasteur pipets attached to a pump.

3. Pipet off PBS. If cell surface antigens are being studied, fix for 30 min in 2% PFA fixative on ice. If cytoplasmic antigens are being studied, fix either 30 min in 2% PFA fixative/0.1% Triton X-100 on ice, or 15 min in 100% methanol in the freezer compartment of a standard refrigerator (–10° to –20°C).

Both methods of cytoplasmic antigen fixation work well; however, the paraformaldehyde/Triton X-100 fix frequently gives a better final morphology.

If methanol fixation is being used, be sure that the cells are washed thoroughly with methanol before putting into freezer, or they will freeze.

4. Pipet off fixative and wash twice in 4°C PBS (5 min/wash).
5. Microcentrifuge diluted primary antibody 2 min at 13,500 × g, 4°C.
6. Layer primary antibody into dish such that cells are just covered and incubate 1 hr at 4°C.
7. Wash four times in 4°C PBS (5 min/wash).
8. Microcentrifuge diluted secondary antibody 2 min at 13,500 × g, 4°C.
9. Layer secondary antibody into dish and incubate 1 hr at 4°C.
10. Wash four times in 4°C PBS. Store cells in PBS. Unless cells are to be observed immediately, cover dishes, wrap in aluminum foil, and refrigerate. It is important to examine preparations of this type within 24 hr as the fluorescence rapidly fades and/or dissociates from the cells.

Do not store cells in water as osmotically competent membrane systems remaining in the cells will be disrupted.

IMMUNOFLUORESCENT LABELING OF SUSPENSION CELLS

Cells may be labeled in suspension, concentrated by centrifugation, and layered onto poly-L-lysine–coated slides prior to observation. The procedure is essentially the same as for monolayer cells, except that the washing steps are replaced by gentle centrifugation, replacement of supernatant, and resuspension of cells. Also, to preserve cellular morphology, the number of centrifugation steps is minimized. Use of PFA/Triton X-100 is the preferred fixation method for cytoplasmic labeling of cells grown in suspension, as methanol fixation frequently renders cells too fragile to be centrifuged reliably.

Additional Materials

5 × 10⁶–10⁷ cells in media in 15-ml Falcon tube

Poly-L-lysine–coated slides (UNIT 14.1)

1. Cool the cells on ice.
2. Centrifuge 5 min at 800 × g, 4°C, in tabletop centrifuge (for lymphocytes).

Speed is adjusted for cell type but must be slow enough to prevent damage. Unless otherwise stated, all centrifuge steps are done under these conditions.

**ALTERNATE
PROTOCOL**

**In situ
Hybridization
and Immuno-
histochemistry**

14.6.2

3. Pipet off culture media and resuspend cells in cold PBS.
All pipetting steps are performed with pipets attached to a pump.
4. Centrifuge to a pellet, pipet off PBS, and fix by resuspending cells (30 min on ice) in 1 to 2 ml of either 2% PFA fixative or 2% PFA fixative/0.1% Triton X-100.
5. Centrifuge to a pellet, pipet off fixative, and resuspend cells in 15 ml of 4°C PBS. Allow to wash 5 min and repeat with a second PBS wash.
A large volume of buffer allows a minimal number of washes.
6. Microcentrifuge primary antibody 2 min at $13,500 \times g$, 4°C. An antibody volume of 250 μ l is adequate for 5×10^6 cells.
7. Centrifuge cells to a pellet, pipet off PBS, resuspend in primary antibody, and incubate 1 hr at 4°C.
8. Dilute cells and antibody to 15 ml with 4°C PBS.
This dilution step serves as an initial wash.
9. Centrifuge to a pellet, pipet off PBS, and resuspend cells in 4°C PBS. Repeat once.
10. Microcentrifuge secondary antibody 2 min at $13,500 \times g$, 4°C. An antibody volume of 250 μ l is adequate for 5×10^6 cells.
11. Pipet off PBS, resuspend cells in secondary antibody, and incubate 1 hr at 4°C.
12. Repeat steps 8 and 9.
13. Unless cells are to be observed immediately, wrap tube in aluminum foil and refrigerate—*prior* to final concentration step below.
It is important to examine preparations of this type within 24 hr as the fluorescence rapidly fades and/or dissociates from the cells.
14. Centrifuge cells to a pellet and resuspend in a small volume of PBS. Pipet onto poly-L-lysine-coated slides, cover with cover slips, and observe immediately if possible.
Do not store in water as osmotically competent membrane systems remaining in the cells will be disrupted.

**BASIC
PROTOCOL**

IMMUNOFLUORESCENT LABELING OF TISSUE SECTIONS

This protocol describes a procedure for fluorescent labeling of frozen sectioned material. Material is prepared and sectioned as detailed in *UNIT 14.2*. Sections are reacted with primary antibody and secondary antibody–fluorochrome conjugate.

Materials

- Specimen tissue cryosections on glass slides (*UNIT 14.2*)
- Phosphate-buffered saline (PBS; *APPENDIX 2*)
- Primary antibody, ~5 to 10 μ g/ml (see commentary)
- Secondary antibody–fluorochrome conjugate specific to the source species of primary antibody (see commentary)
- Mounting medium (e.g., Gelvatol; *UNIT 14.5*)
- Plastic slide box or moist chamber (*UNIT 14.2*)
- Motorized pump or water pump

1. Layer wet paper towels in base of slide box to make a moist chamber, or make a chamber as in *UNIT 14.2*.

2. Remove slides with sections from cryostat or freezer, place across slide box (~6 per side), or place in moist chamber. The slides should not touch one another.
3. Once slides are at room temperature, and before they air dry, layer PBS over sections. Do not flood the slides.
4. Microcentrifuge diluted primary antibody 2 min at $13,500 \times g$, 4°C (40 to 50 μl antibody should cover the sections on each slide).
5. Remove PBS from slides by aspirating at one end of the sections with a Pasteur pipet connected to a pump and introduce antibody at the other end.
6. Close box and incubate 1 hr at room temperature.
7. Wash slides three times in PBS (5 min/wash).

For all washes, introduce new buffer at one end and aspirate off old buffer from opposite end of sections.
8. Microcentrifuge diluted secondary antibody 2 min at $13,500 \times g$, 4°C . Allow 40 to 50 μl antibody per slide.
9. Layer secondary antibody over sections and incubate in moist chamber 1 hr at room temperature (see commentary on choice of antibody).
10. Wash slides three times in PBS (5 min/wash).
11. Lay cover slips on paper towels and place a drop of Gelvatol in the middle of the cover slip.

If Gelvatol is not available, glycerol or PBS may be used for temporary mounting.
12. Invert slides on cover slip.

Do not apply pressure, as this will damage the section; instead let the Gelvatol spread naturally.
13. Leave slides 30 min on bench under aluminum foil to keep out light to allow Gelvatol to harden.
14. Observe under microscope or store at 4°C in closed slide box.

IMMUNOFLUORESCENT LABELING OF TISSUE SECTIONS USING COPLIN JARS

**ALTERNATE
PROTOCOL**

The preceding basic protocol for immunofluorescent staining of tissue sections should work for all antigens. However, the following modifications are appropriate for those antigens which do not lose their antigenicity upon air drying. It employs Coplin jars for the washing steps, and is simpler and quicker than the basic protocol.

Tissue sections are air dried and may be stored in slide boxes at room temperature prior to labeling. Air-dried sections rarely detach from glass slides and therefore may be treated more rigorously than wet sections.

1. Layer wet paper towels in base of slide box to make a moist chamber, or make a chamber as in *UNIT 14.2*.
2. Rehydrate air-dried slides by dipping in a Coplin jar containing enough PBS to cover the sections and dry the area around each section with paper towel.

Drying the area around the sections reduces the amount of antibody used as it stops the antibody from spreading all over slide.

**In situ
Hybridization
and Immuno-
histochemistry**

14.6.4

3. Place slides across slide box (~6 per side) or in moist chamber. The slides should not touch one another.
4. Microcentrifuge diluted primary antibody 2 min at $13,500 \times g$, 4°C . Pipet primary antibody over sections; 40 to 50 μl antibody should cover the sections on each slide. Close box and incubate 1 hr at room temperature.
5. Put slides in Coplin jar containing PBS and wash by changing PBS three times (5 min/wash).

PBS is changed by simply tipping it down the sink and refilling the Coplin jar with fresh buffer.
6. Microcentrifuge diluted secondary antibody 2 min at $13,500 \times g$, 4°C . Allow 40 to 50 μl antibody per slide.
7. Dry slides around sections, layer secondary antibody over sections, and incubate in moist chamber 1 hr at room temperature (see commentary on choice of antibody).
8. Wash slides three times in PBS as in step 5.
9. Follow basic protocol for sectioned material, starting at step 11.

**ALTERNATE
PROTOCOL**

IMMUNOFLUORESCENT LABELING USING STREPTAVIDIN-BIOTIN CONJUGATES

This protocol describes a triple-step reaction technique that increases the sensitivity of the immunohistochemical reaction. This is achieved using a streptavidin–secondary antibody conjugate followed by reaction with a biotin–fluorochrome conjugate (see Fig. 14.6.1d and commentary on choice of secondary antibody).

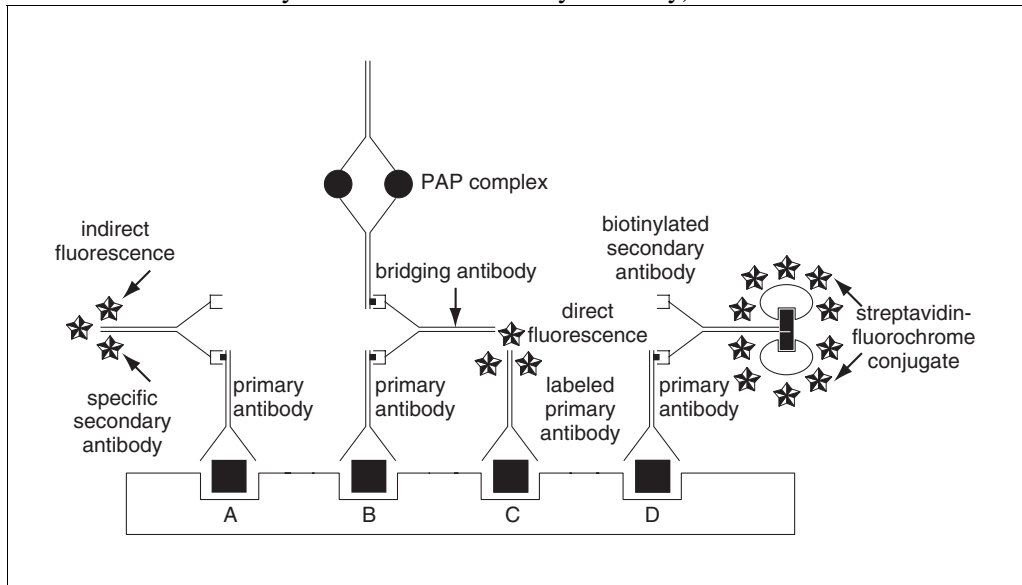

Figure 14.6.1 Various methods of immunohistochemical labeling. **(A)** The primary antibody bound to a specific epitope has been revealed by a secondary antibody conjugated to a fluorochrome. This may then be viewed by fluorescence microscopy. **(B)** The PAP–immunoperoxidase method. The primary antibody is bound to its epitope and has been coupled to PAP complex by a bridging antibody. Following development of the DAB substrate solution, a brown coloration at the epitopic site will be seen by bright-field microscopy. **(C)** The original method of labeling tissue or cells for immunofluorescence employed a primary antibody directly conjugated to a fluorochrome that could then be viewed by fluorescence microscopy. **(D)** The use of streptavidin–biotin conjugates allows considerable amplification of the section so that low-level binding may be clearly seen. The primary antibody has bound specifically to the substrate which is then labeled with biotinylated secondary antibody. This complex is then revealed with a streptavidin fluorochrome.

Additional Materials

Biotinylated secondary antibody (Vector Laboratories)
Fluorochrome-streptavidin conjugate (Vector Laboratories)

Follow steps 1 to 7 of basic protocol on immunofluorescent labeling of tissue sections.

8. Microcentrifuge diluted biotinylated secondary antibody for 2 min at $13,500 \times g$, 4°C (~40 to 50 μl antibody per slide).
9. Lay secondary antibody over sections and incubate in a moist chamber 1 hr at room temperature.
10. Wash slides three times in PBS (15 min/wash). Layer fluorochrome-streptavidin (~40 to 50 μl antibody per slide) over sections and incubate in a moist chamber for 1 hr at room temperature. Wash slides three times in PBS as in step 7 of basic protocol.
11. Follow basic protocol for sectioned material, starting at step 11.

IMMUNOGOLD LABELING OF TISSUE SECTIONS

This parallels the basic protocol on immunofluorescent labeling of tissue sections, except for steps 9 and 14 below. See commentary on silver enhancement method in nonfluorescent marker section.

Additional Materials

Immunogold conjugate (Janssen)

9. Incubate 2 hr in immunogold-conjugated secondary antibody.
14. Observe under microscope or store at room temperature in a closed slide box.

IMMUNOPEROXIDASE LABELING OF TISSUE SECTIONS

This is a very sensitive method. Currently, the most popular immunoperoxidase method is that using horseradish peroxidase–anti-peroxidase (PAP) (Sternberger et al., 1970). Here, a tertiary antibody is used that is directed at, and comes conjugated to, horseradish peroxidase (HRPO). This form of noncovalent linkage assures that the enzyme retains maximum reactivity for the diaminobenzidine (DAB) substrate. The PAP complex is cross-linked to the primary antibody via a “bridging antibody” (Fig. 14.6.1b). The antibody constituting the PAP complex must be of the same type as the primary antibody to be recognized by the bridging antibody.

Additional Materials

0.25% hydrogen peroxide in PBS
Secondary antibody (a bridging antibody recognizing both primary antibody and PAP complex)
Horseradish peroxidase–anti-peroxidase (PAP) complex (from the same source species as the primary antibody)
Diaminobenzidine (DAB) substrate solution

CAUTION: DAB is a carcinogen; handle with great care.

Follow steps 1 to 3 of the basic protocol for immunofluorescent labeling of tissue sections. All pipetting steps are performed with Pasteur pipets attached to a pump.

4. Incubate slides 30 min in 0.25% hydrogen peroxide in PBS at room temperature. Wash three times in PBS.

***ALTERNATE
PROTOCOL***

***ALTERNATE
PROTOCOL***

**In situ
Hybridization
and Immuno-
histochemistry**

14.6.6

5. Follow steps 4 to 7 of basic protocol (immunofluorescent labeling of tissue sections).
6. Incubate slides 1 hr at room temperature in specific secondary bridging antibody. Wash three times in PBS.
7. Incubate slides 1 hr at room temperature in PAP complex.
8. Wash three times in PBS.
9. Develop 2 to 5 min in DAB substrate solution at room temperature.

Developing time is empirical and must be assessed for each experiment.

10. Follow steps 10 to 14 of basic protocol.

Keep slides in the dark in a slide box. It is not necessary to refrigerate them.

**ALTERNATE
PROTOCOL**

**IMMUNOFLUORESCENT DOUBLE-LABELING
OF TISSUE SECTIONS**

Indirect immunofluorescence microscopy allows two or more antigens to be revealed on the same section at any one time. This is done by using fluorochromes which are excited by, and emit light of, different wavelengths. Generally this is limited to two fluorochromes, the most popular combination being rhodamine (excited in green range and emitting red) and fluorescein (excited in blue and emitting green), though more exotic combinations using fluorochromes such as phycoerythrin are possible (see commentary on choice of antibody). However, the following should be observed, regardless of the fluorochrome used:

1. When performing double-labeling experiments, the most important criterion is that the primary antibodies be of different types, such that secondary antibodies can recognize them independently. It is preferable that they originate in different animals; however, if monoclonals are being used, this may not be possible. When monoclonals are used, antibodies of different types such as IgG and IgM may be differentiated reliably, though antibodies of different classes (IgG₁ and IgG₂, for example) cannot generally be differentiated by secondary antibodies.
2. The protocol is the same as the basic protocol for immunofluorescent labeling of tissue sections except that the primary and secondary antibody steps are replaced by *mixtures* of two primary and two secondary antibodies.
3. Prior to attempting a double-labeling experiment, single-labeling experiments should be performed to find optimal dilutions for the different primary and secondary antibodies.

REAGENTS AND SOLUTIONS

Diaminobenzidine (DAB) substrate solution

Dissolve 60 mg 3,3' diaminobenzidine (DAB) in 200 ml phosphate-buffered saline (PBS; APPENDIX 2). Store frozen in 5- to 10-ml aliquots until use. Defrost DAB aliquot and add hydrogen peroxide to a final concentration of 0.1%. (NOTE: concentrated hydrogen peroxide is generally sold as a 30% solution.) Filter through syringe (Millipore) and use immediately.

CAUTION: *DAB is a carcinogen and must be used with great care. Exposure to dry carcinogenic DAB may be minimized by preparing large batches of DAB solution in the fume hood which are stored as frozen aliquots.*

COMMENTARY

Background Information

Nearly 50 years ago, fluorescent markers were employed in the first successful use of immunocytochemical methods to study cellular protein distributions (Coons, 1941). Early studies used direct labeling (Fig. 14.6.1c), where the primary antibody is conjugated directly to the fluorochrome. This methodology was cumbersome as every primary antibody had to be conjugated separately to the fluorescent marker. Indirect methods are more sensitive, as signal amplification occurs when multiple secondary antibodies bind to a single primary antibody (particularly when streptavidin-biotin conjugates are used; see commentary below on choice of antibody). Furthermore, they are much easier to employ, because a single secondary antibody conjugate may be used to label a variety of different primary antibodies from the same source species. Today, commercially available secondary markers have very high specificity, purity, and signal strength, and are available directed against primary antibodies from most animals. In addition, an ever-increasing number of primary antibodies is available (a fairly complete list is compiled annually in *Linscott's Directory*).

A variety of methodologies for immunohistochemical labeling of cells and sections are described in this section. Each method has advantages and disadvantages. For routine labeling of sections, we suggest using the basic protocol for immunofluorescent labeling initially. If this is too laborious, try the alternate protocol, which describes immunofluorescent labeling of sections using Coplin jars.

If the level of labeling seen on the section is inadequate using the basic protocol, it is possible to amplify the perceived signal using the alternate protocol employing streptavidin-biotin conjugates, or to use a bright-field technique such as immunoperoxidase labeling of tissue sections. Of the two bright-field methods discussed—immunogold labeling and immunoperoxidase labeling—the latter is generally considered to be more sensitive than immunofluorescence methods. However, it has some specific disadvantages. These are (1) the reaction product may diffuse away from the site of reaction and hence the antibody locus, (2) it is a lengthy triple-step procedure, (3) the specificity of the reaction may be confused by reactive endogenous peroxidase, (4) the reaction product is light sensitive, and (5) DAB is con-

sidered a carcinogen. These problems may be solved to a degree in that endogenous peroxidase may be blocked by preincubation with hydrogen peroxide and labeled slides may be kept in light-tight boxes. Other modifications are to use alternative substrate reagents (see Polak and Van Noorden, 1983) or to use alkaline phosphatase instead of peroxidase. These latter methods, however, generally give inferior results.

The immunogold labeling methodology, still gaining popularity, is best used in conjunction with silver enhancement of the gold probe (as discussed below).

It is strongly recommended that the critical parameters sections be read carefully prior to attempting any of the methods discussed here.

Critical Parameters

Dilution recommendations in the protocols—both in terms of true protein concentrations and empirical dilutions—are rough guidelines and are presented to serve only as starting points. Whenever a study uses an unknown primary antibody, a dilution series should be performed to assay the optimal dilution for that antibody. Frequently, clear differences in labeling may be seen with quite subtle changes in dilution. For example, an initial dilution series would be 1:10, 1:100, and 1:1000. Once the appropriate range is found, another series should be done, e.g., 1:100, 1:200, 1:400. While this may seem excessively time consuming, it will ensure optimal results and frequently a more economic use of antibody.

Choice of antibody

Primary antibodies. Antibodies are produced in two main forms, polyclonal antibodies and monoclonal antibodies (see Chapter 11). Their critical feature with regard to immunohistochemistry is that polyclonal antisera may contain antibodies to many different epitopes on the antigen, whereas monoclonal antibodies recognize a single epitope. The ramifications of this difference are considerable, as a multivalent polyclonal antibody will recognize many epitopic sites, the resultant signal seen using immunocytochemistry may be greater than that found using a monoclonal antibody. On the other hand, monoclonal antibodies are generally more specific than a polyclonal antiserum. Nonspecific cross-reactivity is generally avoided in polyclonal antibodies by affinity

purification of the antibody before use. Generally, best results are obtained with affinity-purified polyclonal antibodies followed by monoclonal antibodies, and finally antisera.

Monoclonal antibodies (UNITS 11.3-11.11). Monoclonal antibodies are available in three main forms: hybridoma culture supernatant, ascites and purified IgG. The effective concentration of the antibody in monoclonal culture supernatants is generally very low. This antibody should be used either concentrated or at dilutions in the 1:5 to 1:10 range.

Ascites fluid contains a large amount of cellular debris as well as antibody, although as long as it is spun before use (2 min, 13,500 × *g* in microcentrifuge) it will work very well. Both ascites and purified monoclonal immunoglobulins are generally used very dilute (1:1000 to 1:10,000).

It should be noted that monoclonal antibodies are commonly produced as IgM's. As this form of antibody effectively appears as clusters of immunoglobulin, the labeling may appear punctate due to clustering of the secondary antibody.

Polyclonal antibodies (UNITS 11.12 & 11.13) are present in serum and may be used in this form, or after purification from serum or affinity purification. If the antibodies are specific on western blots as antiserum, they will generally work adequately for immunolabeling at the light-microscope level and further purification is unnecessary. As a general rule, polyclonal antisera work well at 1:50 to 1:100 dilution. After affinity purification when the exact protein concentration is known, the working dilution should be 5 to 10 µg/ml.

Secondary markers

A variety of different fluorochromes are available commercially (see below) which are used in conjunction with one of three main second labeling methods as follows.

Secondary antibodies. This is the most common secondary marker and is the recommended choice in this unit. The source species should not compete with other primary antibodies in a double-labeling experiment. They are generally sold in lyophilized form. Following rehydration, the antibody should be spun 5 min at 4°C in a microcentrifuge, and the supernatant quick frozen and stored in 10-µl aliquots at -70°C until use. Antibodies sold as a liquid should also be centrifuged when received, the supernatant quick frozen, and stored at -70°C

in aliquots unless specifically indicated by the manufacturer.

Protein A, protein G. Protein A is generally purified from the cell wall of *Staphylococcus aureus* and binds very strongly, though variably, to the Fc fragment of antibodies from a variety of source animals—in particular, mouse, human, and rabbit antibodies. Protein G is derived from the cell wall of G group streptococci and also binds to the Fc fragment of many antibodies, frequently with greater avidity than protein A. For example, it binds to rat and goat IgG more strongly than protein A. The disadvantage of this method of labeling is that it may bind to other primary or secondary markers (in the case of a double-labeling experiment), or to a blocking antibody, if used, thereby causing increased background or apparent colocalization with another antibody.

Streptavidin-biotin. This method is used primarily as an amplification system (Fig. 14.6.1d). Biotin binds strongly and irreversibly to avidin. Biotinylated secondary antibodies are incubated with a streptavidin-fluorochrome conjugate. Several streptavidin fluorochrome conjugates will bind to each biotinylated antibody.

Fluorochrome

Choice of fluorochrome for most work is simple, although for double- or triple-labeling experiments the combinations may become more exotic. The following is a discussion of each with its potential advantages and disadvantages. See also Table 14.6.1 for troubleshooting the labeling procedure.

Fluorescein isothiocyanate (FITC) is the most commonly used fluorochrome and most fluorescent microscopes will be equipped with the correct filters. It is excited by blue light and emits a bright green fluorescence (ideal filters are Excitor 450 to 490 nm and Barrier 520 to 560 nm). The intensity of label is high and is frequently detected where other fluorochrome such as rhodamine may give a threshold signal. The major disadvantage is that it extinguishes rapidly and irreversibly, so photography must be performed as soon as a positive area is detected. This dye is available conjugated to all the markers described above from a variety of vendors (Cappel, Calbiochem, ICN).

Tetramethyl rhodamine isothiocyanate (TRITC) is a very commonly used fluorochrome, second in popularity to FITC, and again, most microscopes will be equipped

with correct filters. It is excited by green light and emits a red fluorescence (ideal filters are Excitor 510 to 560 nm and Barrier 590 nm lower cutoff). The intensity of label is less than with FITC though the persistence of the signal is longer, thus more careful examination of the label is possible before extinction below usable level occurs. This dye is available conjugated to most of the markers described above from a variety of vendors (Cappel, Calbiochem, ICN), and is commonly used in double-labeling experiments in conjunction with FITC-conjugated markers.

Texas Red is becoming increasingly popular inasmuch as it offers the high emission of FITC in conjunction with the better persistence of TRITC. It is excited and emits in the same range as TRITC, though the emitted signal has a slightly more orange characteristic. Unfortunately, it cannot be reliably distinguished from TRITC and thus cannot be used with this in double labeling work, though it is ideal for use with FITC. We prefer to use this dye as a matter of course, and its increasing popularity means that the range of available immunoconjugates will continue to increase.

Phycoerythrin has been available for some time but is only now becoming popular as a

potential marker. It is excited in the same range as FITC though it emits a more yellow light, which makes it easily distinguishable from FITC. Furthermore, it generally has a longer persistence than FITC. It is discussed here as it is the most plausible third label for triple label studies. The only disadvantage is that the photography must be in color so that FITC and phycoerythrin may be distinguished (marketed by TAGO).

Nonfluorescent markers

The advantages of these methods are that labeled sections have an indefinite shelf life, and morphology and labeling may be examined using the same type of illumination. Further, the immunoperoxidase method is highly sensitive and may be used on paraffin sections if antigenicity remains where fluorescent markers cannot be used since autofluorescence is generally too great in this type of sample.

Immunogold conjugates present as a pink coloration under the light microscope. They have a high mass, and hence, high steric hindrance when compared with fluorescent conjugates, which may decrease labeling intensity. It is possible to increase the optical density of label using silver enhancement, which enlarges

Figure 14.6.2 Immunofluorescent labeling of the protein dystrophin in a cross-section of normal skeletal muscle. The protein is clearly localized at the periphery of the muscle fibers (**A**). No background is apparent within the muscle fibers themselves. The identity of the cells as muscle fibers is confirmed in the phase micrograph of the same field (**B**).
Bar = 10 μ m.

the gold particle by depositing metallic silver on it (Danscher, 1981). This method is difficult inasmuch as the reagents used are generally light sensitive and the reaction is hard to control. Thus, it is strongly recommended that a kit (such as the IntenSE kit marketed by Janssen) be used.

Controls

Because of the variety of problems of background and nonspecific labeling inherent in any immunohistochemical analysis of cells and tissues, the following controls are suggested (see also Table 14.6.1): (1) use of preimmune serum from the antibody-producing animal used at an equivalent dilution, (2) use of secondary antibody alone, (3) use of no antibodies at all, (4) use of an antibody, the antigen for which is not found in the tissue or cells to be studied, (5) use of a known positive antibody (e.g., actin), and

(6) use of a limited dilution series for the primary antibody for each experiment.

Troubleshooting

Refer to Table 14.6.1 for an itemization of the problems commonly encountered when using the procedures in this unit. Possible causes are described and solutions are recommended.

Anticipated Results

Good immunolabeling at the light microscope is characterized by clear definition of a marker within the tissue or cell being studied, with minimal background or nonspecific labeling throughout the remainder of the tissue (see Fig. 14.6.2).

Time Considerations

One advantage of the immunohistochemi-

continued on p. 14.6.13

Table 14.6.1 Troubleshooting Guide for Immunofluorescent Labeling of Specimen Sections

Problem	Possible cause	Solution
Slides appear "faded"	Slides were not kept in the dark and the cold prior to observation	It is extremely important that slides are stored in the cold in the dark
Morphology appears grainy; labeling is grainy or weak	Slide dried out when removed from the cryostat or lyophilized in the cryostat or -80°C freezer	Deal with slides promptly; <i>do not allow slides to dry out at any time</i> , unless the antigen is extremely robust and abundant
Fluorescence is seen even in unlabeled material	Autofluorescence, frequently caused by the use of aldehyde fixatives	Block most autofluorescence by preincubating sections after the first PBS wash for 10 min in 0.5% sodium borohydride (NaBH_4) in water (prepare immediately before use). Frequently, bubbles appear on the section. This is normal, but treatment is rigorous and may cause section loss.
	With monolayer labeling, autofluorescence may be caused by the culture dish; test by examining a new culture dish under the fluorescence microscope	Grow cells on glass cover slips or in sterile culture chambers in glass slides
Fluorescent labeling appears over section—even in the absence of a primary antibody	Secondary antibody is too concentrated	Dilute antibody further. Normally, commercial immunoconjugates work at a 1:100 dilution, although this is a very general starting concentration. For best results, do a dilution series with each batch of secondary antibody.
Bright spots of fluorescence occur nonspecifically across section and slide	Inadequate washing during immunolabeling or a failure to spin unconjugated fluorochrome out of the secondary antibody	Make sure secondary antibodies are spun 5 min in microcentrifuge ($13,500 \times g$) as soon as they are received. This is particularly important for antibodies shipped as lyophilized product. In most cases, a 10- to 20- μl pellet will result, which should be discarded.

continued next page

Table 14.6.1 Troubleshooting Guide for Immunofluorescent Labeling of Specimen Sections (continued)

Problem	Possible cause	Solution
Labeling appears specific, but background is excessive	Nonspecific binding of primary or secondary antibody	Preincubate sections 1 hr in 1% serum (eg., normal goat serum) prior to labeling with primary antibody. Be sure that the blocking antibody is not recognized by the secondary antibody (as this will only compound labeling problems) by blocking with serum from same animal species as that used to make the secondary antibody. It is also possible to dilute all antibodies in 1% to 10% serum, thereby avoiding the blocking step.
Labeling is specific, but not where expected, or mutually exclusive labeling patterns are seen on the same section	Antiserum contains tissue-specific antibodies other than those to the target antigen	Confirm problem by labeling sections with preimmune serum, i.e., serum taken from the antibody-producing animal prior to injection of antigen. Serum should always be taken prior to immunization and should be part of the antibody production process. Avoid nonspecific labeling of this type by affinity purification of the antibody.
No labeling is seen on sections even though clear label is seen on western blots of the same material	The tissue section used does not contain the antigen	Be sure to cut sufficient sections so that all possible structural features of the tissue are sampled
	The antigen is not recognized by the antibody in its native form. This may occur if the antibody was raised against denatured rather than native antigen and happens more frequently with monoclonal than polyclonal antibodies, because the latter include antibodies to a variety of epitopes.	Make new antibody using native antigen
	Tissue processing prior to labeling has rendered the antigen nonreactive	While many antigens may be air dried in sections and still retain strong antigenic reactions (see alternate protocol for immunofluorescent staining using Coplin jars), if labeling is not seen using this protocol, use basic protocol.
Labeling appears blurry and streaked across slide	Overfixation leading to conformational changes in the antigen prior to freezing (<i>UNIT 14.2</i>)	Reduce the fixation time of the sample
	On rare occasions, very soluble antigens may be found which dissolve out of the section during labeling. A more probable cause is smearing of the tissue during sectioning (see sectioning troubleshooting, Table 14.2.1).	Fixation of tissue prior to freezing or fixation of section itself

cal methods described here is their relative speed. It is quite possible to go from the whole animal to labeled sections in one day.

In situ Hybridization and Detection Using Nonisotopic Probes

Nonisotopic in situ hybridization can be used to determine the cellular location and the relative levels of expression of specific transcripts within cells and tissues. RNA in prepared specimens is hybridized with a probe labeled nonisotopically with biotin or digoxigenin. Nonisotopic probes are generally detected by fluorescence or enzymatic methods (Figs. 14.7.1 & 14.7.2). Hybridization and detection of ^{35}S - and ^{32}P -labeled probes are described in UNITS 14.3 & 14.4, respectively.

Fluorescence in situ hybridization (FISH), probably the most widely used method, is described in Basic Protocol 1. Support Protocols 1 and 2 describe techniques for amplification of weak fluorescent signals obtained in FISH. Nonisotopic probes can also be detected by enzymatic reactions using horseradish peroxidase or alkaline phosphatase, as described in Alternate Protocols 1 and 2. Nonisotopic labeling of DNA probes by nick translation or by random oligonucleotide primed synthesis is described in UNIT 3.18.

NOTE: Water should be treated with DEPC and all solutions prepared with DEPC-treated water to inhibit RNase activity. See UNIT 4.1, Reagents and Solutions, for instructions.

CAUTION: DEPC is a suspected carcinogen and should be handled carefully.

FLUORESCENCE IN SITU HYBRIDIZATION

Fluorescence in situ hybridization (FISH) involves hybridization of biotin- or digoxigenin-labeled DNA probes to prepared specimens (cells or tissue sections) and visualization of those probes with fluorochrome-conjugated reagents. The accompanying Support Protocols describe amplification of weak fluorescent signals.

Materials

- Glass slide containing specimen (UNIT 14.1)
- 20 to 150 ng nonisotopically labeled DNA probe (UNIT 3.18)
- Deionized formamide (American Bioanalytical *OR* UNIT 14.3)
- 10 mg/ml sonicated salmon sperm DNA (see recipe)
- Master hybridization mix (see recipe)
- 50% (v/v) formamide (not deionized)/2× SSC (APPENDIX 2)

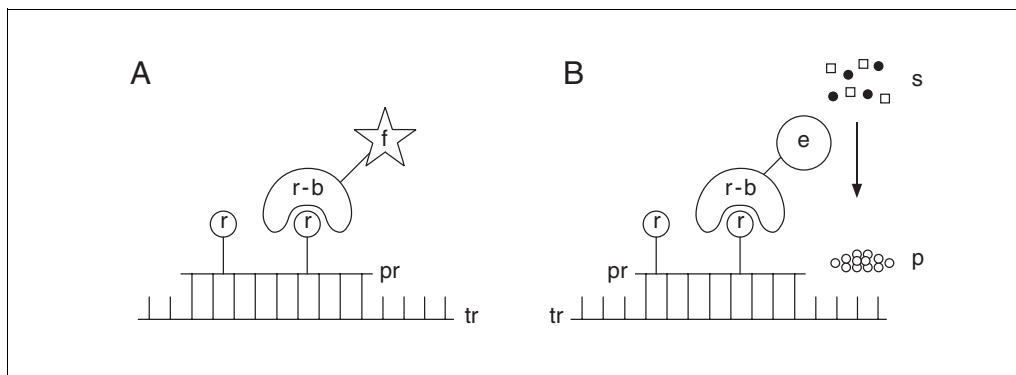

Figure 14.7.1 Detection of hybridized probe. **(A)** Fluorescence in situ hybridization (FISH). **(B)** Enzymatic detection. Abbreviations: e, enzyme (e.g., alkaline phosphatase or horseradish peroxidase); f, fluorochrome (e.g., fluorescein, rhodamine, or Texas red); p, colored precipitate product; pr, probe labeled with reporter molecule; r, reporter molecule (e.g., biotin, digoxigenin); r-b, reporter-binding molecule (e.g., avidin, streptavidin, or digoxigenin antibody); s, soluble substrate; tr, transcript. Arrow indicates reaction catalyzed by enzyme.

BASIC PROTOCOL

In situ Hybridation and Immuno- histochemistry

14.7.1

1×, 2×, and 4× SSC, pH 7.0 (*APPENDIX 2*)
 Biotin detection solution *or* digoxigenin detection solution *or* biotin/digoxigenin detection solution (see recipes)
 0.1% (v/v) Triton X-100/4× SSC
 DAPI *or* propidium iodide staining solution (see recipes)
 Appropriate antifade mounting medium (see recipe)
 39°, 42°, and 72°C water baths
 Phase-contrast microscope
 22-mm² coverslips
 Rubber cement
 Moist chamber (Fig. 14.2.4)
 Slide box with desiccant (Baxter Scientific)
 Nail polish
 Fluorescence microscope with epillumination and filter set(s) appropriate for fluorochrome(s) used including dual-band pass filter (fluorescein/Texas red) or triple-band pass filter (fluorescein/Texas red/DAPI; Omega Optical or Chroma Technology)
 Ektar-1000 *or* Ektachrome-400 color film *or* Technical Pan 2415 black-and-white film (Kodak)

Additional reagents and equipment for preparing paraffin sections or cells for hybridization (*UNIT 14.3*, Basic Protocol, steps 1 to 16) or for preparing cryosections for hybridization (*UNIT 14.3*, Alternate Protocol, steps 1 to 7) and ethanol precipitation of DNA (*UNIT 2.1*)

CAUTION: Formamide, DAPI, and propidium iodide are hazardous; see manufacturer's information for guidelines on handling, storage, and disposal.

Prepare the specimens for hybridization

1a. *For hybridization to paraffin sections or cells:* Prepare slides by dewaxing, rehydrating, blocking, and dehydrating as in *UNIT 14.3*, Basic Protocol steps 1 to 7, finishing with air drying the specimens (or drying in dessicator), followed by storage in a slide box with dessicant overnight at −70°C.

It is essential that the specimens be absolutely dry before they are stored.

1b. *For hybridization to cryosections:* Pretreat sections and acetylate as described in *UNIT 14.3*, Alternate Protocol steps 1 to 7, finishing with dehydration of slides.

It is essential that the specimens be absolutely dry. Slides are now ready for hybridization (step 3), which should be done immediately.

Prepare the probe

2. For each hybridization precipitate 10 to 15 ng of probe in ethanol and dissolve in 10 μl deionized formamide. Add 5 μg (0.5 μl) sonicated salmon sperm DNA. Heat denature the probe 10 min at 70 to 80°C.

*Probe can be labeled with biotin or digoxigenin (*UNIT 3.18*) or with fluorochrome-tagged deoxynucleotides (see Background Information). Quantitation and detection of nonisotopic probes is discussed in the Support Protocol of *UNIT 3.18*.*

Hybridize probe to sample

3. Add 10 μl master hybridization mix to denatured probe (0.1 to 0.5 μg/ml final probe concentration). Mix well, spin briefly at high speed in a microcentrifuge, and transfer onto preparation on slide. Cover with 22-mm² coverslip, remove any large air bubbles with gentle pressure, and incubate 2 to 4 hr in a moist chamber at 37°C.

Hybridizations can also be performed overnight. In this case, seal the coverslip using rubber cement.

When hybridizing with labeled oligonucleotide probes, the optimal hybridization temperature is a function of the melting point of the probe. This must be calculated for each probe (see UNIT 6.4, Basic Protocol 1).

4. During last 30 min of hybridization, warm 50 ml of 50% formamide/2× SSC wash solution and 50 ml of 2× SSC in Coplin jars in a 37°C water bath.
5. Remove slide from moist chamber. Peel off rubber cement (if present) and carefully remove coverslip. Wash hybridized slide 15 min in 37°C 50% formamide/2× SSC, 15 min in 37°C 2× SSC, and 15 min in room temperature 1× SSC.
6. Allow slide to equilibrate 5 min in 4× SSC at room temperature. Remove slide and drain excess buffer. Do not allow slide to dry at any point during the procedure.
7. Add 50 µl biotin detection solution, digoxigenin detection solution, or biotin/digoxigenin detection solution to hybridized preparation on slide and cover with 22-mm² square of Parafilm. Incubate 45 min in an aluminum foil-wrapped moist chamber at 37°C.

Detection reagents and DAPI (step 10) are light sensitive; keep exposure to light to a minimum by wrapping containers in aluminum foil.

8. Soak slide sequentially in aluminum foil-wrapped Coplin jars containing room temperature 4× SSC, 0.1% Triton X-100/4× SSC, and 4× SSC—10 min in each solution.

Counterstain DNA

9. Add 50 µl DAPI or propidium iodide staining solution to preparation on slide, cover with 22-mm² square of Parafilm, and allow to stain 5 min at room temperature. Rinse briefly in 1× SSC in Coplin jar to remove excess stain. Blot slide, but do not dry.

DAPI staining of nuclei can be viewed simultaneously with fluorescein and rhodamine or Texas red. Propidium iodide and fluorescein can be viewed simultaneously, but propidium iodide and rhodamine or Texas red cannot because their emission spectra overlap.

10. Add 7 µl of appropriate antifade mounting medium to stained slide and add a coverslip. Gently squeeze out excess antifade medium, taking care not to damage tissue, and seal with nail polish. Store at -20°C in slide box with desiccant.

The antifade mounting medium chosen depends on the fluorochrome used (see Critical Parameters).

Slide is ready to examine immediately after it is mounted, but it may be stored several weeks at 4° or -20°C with minimal loss of fluorescence.

View and photograph slides

11. Examine slide using a fluorescence microscope with epillumination and filter set appropriate for the fluorochrome used.

A DAPI filter set is used for nuclear identification and a dual-band-pass or a triple-band-pass filter set is used for simultaneous viewing of multiple fluorochromes.

12. Photograph using either Ektar-1000 (for prints) or Ektachrome-400 (for slides) color film.

Exposure times vary with brightness of hybridization signal, but exposures for DAPI are ~2 sec and exposures through dual- or triple-band-pass filter sets are 30 to 90 sec and 3 to 8 sec, respectively. Probes with bright hybridization signals can be photographed with black-and-white film, e.g., Kodak Technical Pan 2415, exposed at ASA 200.

AMPLIFICATION OF HYBRIDIZATION SIGNALS

Signals of both biotin- and digoxigenin-labeled probes can be amplified if necessary (see Fig. 14.7.2). Amplification can be performed at any point after post-hybridization washes, including after viewing, and it may be repeated.

SUPPORT PROTOCOL 1

Amplification of Biotinylated Signals

Slides hybridized with biotinylated probes and exposed to avidin are incubated with a biotin-labeled antibody to avidin. Every avidin molecule contains four biotin-binding sites, so biotin-labeled antibody to avidin can potentially bind the avidin molecule via a biotin-avidin interaction or an antibody interaction. A final application of fluorescein-conjugated avidin results in significant signal amplification. Because the signal-to-noise ratio decreases with successive amplifications, amplification is recommended only when the probe yields weak fluorescence with very little background.

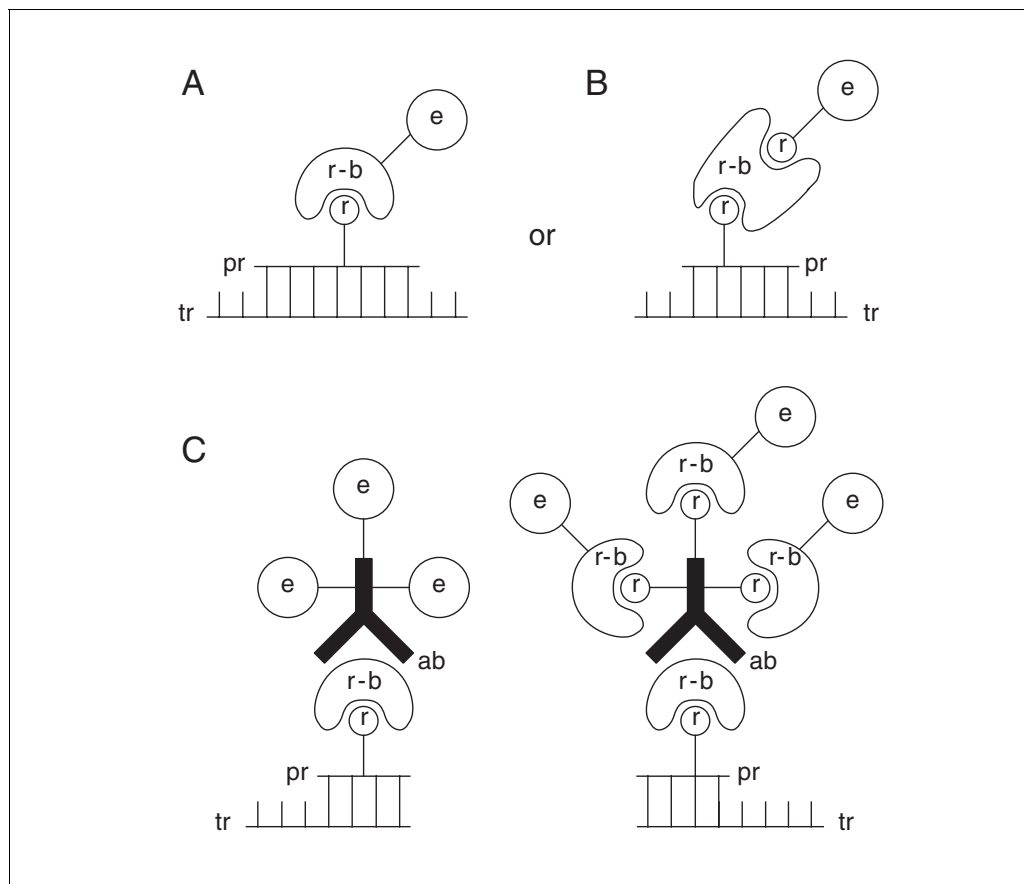

Figure 14.7.2 Enzyme-mediated detection of reporter molecules. **(A)** For direct detection, enzyme is conjugated to reporter-binding molecule. **(B)** For a two-step procedure, reporter-binding molecule is applied first, followed by an incubation with reporter-conjugated enzyme. **(C)** For signal amplification, incubation with reporter-binding molecule is followed by incubation with an antibody to reporter-binding molecule. The antibody may be conjugated with enzyme or reporter molecule. In the latter case an incubation with enzyme-conjugated reporter-binding molecule follows. The final step is addition of substrate (not shown). Fluorochrome can be substituted for enzyme molecule. Abbreviations: ab, antibody to reporter-binding molecule conjugated with enzyme or reporter molecule; e, enzyme (e.g., alkaline phosphatase or horseradish peroxidase); pr, probe labeled with reporter molecule; r, reporter molecule (e.g., biotin or digoxigenin); r-b, reporter-binding molecule (e.g., avidin, streptavidin, or anti-digoxigenin); tr, transcript.

Additional Materials (also see Basic Protocol)

- 1 to 3 µg/ml biotinylated anti-avidin antibodies (Vector Laboratories) in 4× SSC/1% (w/v) BSA (fraction V)
Biotin amplification solution: 2 to 5 µg/ml fluorescein-avidin DCS (Vector Laboratories) in 4× SSC/1% (w/v) BSA (fraction V)

NOTE: This procedure should be performed with minimum exposure to light.

1. Hybridize slide with biotinylated probe, wash, and perform first round of signal detection (see Basic Protocol).

Amplification of the signal from biotinylated probes can be carried out at any time after step 8 of the Basic Protocol.

2. If slide has been mounted and sealed, remove sealed coverslip by breaking the nail polish seal with a needle or scalpel, lifting off the nail polish, and soaking slide 15 min in 0.1% Triton X-100/4× SSC in an aluminum foil-wrapped Coplin jar with gentle agitation. If coverslip is not loose, carefully lift it off. Repeat wash twice.
3. Drain excess wash solution from slide and add 50 µl of 1 to 3 µg/ml biotinylated anti-avidin antibody to slide. Cover with 22-mm² square of Parafilm, place in moist chamber, wrap moist chamber in aluminum foil, and incubate 30 min at 37°C.
4. Remove Parafilm and wash 15 min in 0.1% Triton X-100/4× SSC with gentle agitation.
5. Drain excess solution from slide and add 50 µl biotin amplification solution. Cover with Parafilm, then incubate 30 min at 37°C in a foil-wrapped moist chamber.
6. Remove Parafilm and wash 15 min in 0.1% Triton X-100/4× SSC, then 15 min in 4× SSC, both with gentle agitation.

Multiple layers of avidin-fluorescein and biotinylated anti-avidin can be applied, but background will be significantly increased.

7. Counterstain, mount, and examine slide (see Basic Protocol, steps 9 to 12).

Amplification of Signals from Digoxigenin-Labeled Probes

Improved fluorescence signal for digoxigenin-labeled probes is achieved by “sandwiching” a nonfluorescent Fab fragment of sheep anti-digoxigenin between the digoxigenin-labeled probe and a fluorochrome-labeled rabbit anti-sheep IgG. Because more than one Fab fragment can attach to a single digoxigenin molecule and each of these Fab fragments is recognized by the fluorochrome-conjugated second antibody, this procedure leads to signal amplification.

Additional Materials (also see Basic Protocol)

- 10 µg/ml Fab fragment of sheep anti-digoxigenin (Boehringer Mannheim) in 4× SSC/1% (w/v) BSA (fraction V)
Digoxigenin amplification solution: 3.5 to 7.0 µg/ml fluorescein-conjugated rabbit anti-sheep IgG (Sigma) in 4× SSC/1% (w/v) BSA (fraction V)

NOTE: This procedure should be performed with minimum exposure to light.

1. Hybridize slide with digoxigenin-labeled probe and wash (see Basic Protocol, steps 1 through 6).
2. Add 50 µl of 10 µg/ml Fab fragment of sheep anti-digoxigenin to slide and cover with 22-mm² square of Parafilm. Incubate 30 min at 37°C.

**SUPPORT
PROTOCOL 2**

**In situ
Hybridation
and Immuno-
histochemistry**

14.7.5

3. Remove Parafilm. Wash in 4× SSC, 0.1% Triton X-100/4× SSC, then 4× SSC, 15 min each.
4. Drain excess 4× SSC and add 50 μl digoxigenin amplification solution to slide. Cover with 22-mm² square of Parafilm, place in moist chamber, wrap chamber in aluminum foil, and incubate 30 min at 37°C.
5. Repeat washes as in step 3.
6. Counterstain, mount, and examine slide (see Basic Protocol, steps 9 to 12).

ENZYMATIC DETECTION OF NONISOTOPICALLY LABELED PROBES

Hybridized probes can also be detected by enzymatic reactions that produce a colored precipitate at the site of hybridization (Fig. 14.7.1). The most commonly used enzymes for this application are alkaline phosphatase (AP) and horseradish peroxidase (HRPO). Although these enzymes can be conjugated directly to nucleic acid probes, such enzyme-coupled probes are often inappropriate for in situ hybridization to cellular preparations because probe penetration is hampered by the presence of the conjugated enzyme. Therefore, indirect methods are preferred. As illustrated in Figure 14.7.1, probes labeled by reporter molecules such as biotin or digoxigenin are detected via AP or HRPO conjugated to reporter-binding molecules such as avidin (for biotin) or antibodies (for digoxigenin). To visualize the site of probe hybridization, a slide is incubated with the appropriate enzyme substrate. The substrate is converted by the enzymatic activity to a stable colored precipitate, thus providing a permanent in situ hybridization signal that can be analyzed by phase-contrast microscopy. Because of their stability, such signals are often preferred for diagnostic analysis in routine pathology laboratories.

Table 14.7.1 summarizes the most commonly used combinations of enzyme and substrate for detection of in situ hybridization probes.

Table 14.7.1 Commonly Used Enzyme/Substrate Combinations for Detection of In Situ Hybridized Probes

Enzyme	Substrate ^a	Color ^b
Alkaline phosphatase	5-bromo-4-chloro-3-indolyl phosphate (BCIP) and nitroblue tetrazolium (NBT)	Bluish-purple precipitate
	Naphtol-AS-MX-phosphate and fast red TR	Red precipitate and red fluorescence
	Naphtol-AS-MX-phosphate and fast blue BN (Boehringer)	Blue precipitate
	Naphtol-AS-MX-phosphate and fast green BN (Boehringer)	Green precipitate
	Vector Red	Red precipitate
	Vector Black	Black precipitate
	Vector Blue	Blue precipitate
Horseradish peroxidase	3,3-diaminobenzidine tetrahydrochloride (DAB)	Brown precipitate ^c

^aThe main suppliers for these reagents are Boehringer Mannheim, Life Technologies, Promega, Sigma, and Vector Laboratories, but other suppliers deliver equivalent reagents.

^bThe detection systems listed result in hybridization signals that are generally analyzed by conventional bright-field microscopy. A fluorescence microscope is needed when utilizing the fluorescence signals produced by fast red. Optimization of the fluorescence detection procedure has been reported (Speel et al., 1992).

^cCan be intensified by silver deposition.

Enzymatic Detection Using Horseradish Peroxidase

**ALTERNATE
PROTOCOL 1**

Additional Materials (also see *Basic Protocol*)

Blocking solution: 1% (w/v) BSA in PBS (*APPENDIX 2*)
Streptavidin solution (see recipe)
0.1% (v/v) Tween 20/PBS (*APPENDIX 2*), 42°C
Biotinylated horseradish peroxidase (HRPO) solution (see recipe)
DAB substrate solution: 500 µg/ml 3,3'-diaminobenzidine tetrahydrochloride
(DAB) in PBS (*APPENDIX 2*), prepared fresh
3% H₂O₂
PBS (*APPENDIX 2*)
90% (v/v) glycerol *or* appropriate antifade mounting medium (see recipe)
24 × 60-mm coverslips
42°C shaking water bath

CAUTION: DAB is hazardous; see manufacturer's information for guidelines on handling, storage, and disposal.

NOTE: This procedure must be performed in the dark with minimum exposure to ambient light.

Apply detecting reagents

1. Hybridize slide preparation with biotinylated probe and wash slide (see *Basic Protocol*, steps 1 to 6).
2. Remove slide from 1× SSC. Drain as much buffer as possible, but do not allow slide to dry. Add 200 µl blocking solution to slide, and place 24 × 60-mm coverslip on top of applied solution. Place slide in an aluminum foil-wrapped moist chamber and incubate 30 min at 37°C.
3. Remove slide from chamber, tilt it to let coverslip slide off, and drain off as much blocking solution as possible without allowing slide to dry. Add 200 µl streptavidin solution to slide and place a 24 × 60-mm coverslip on top of applied solution. Place slide in an aluminum foil-wrapped moist chamber and incubate 30 min at 37°C.
4. Remove slide from chamber, tilt it to let the coverslip slide off, and place slide in Coplin jar containing 42°C 0.1% Tween 20/PBS. Place Coplin jar in a 42°C shaking water bath and agitate 5 min. Repeat wash twice with 42°C 0.1% Tween 20/PBS.
5. Remove slide and drain thoroughly without allowing to dry. Add 200 µl biotinylated HRPO solution to slide and place a 24 × 60-mm coverslip on top of applied solution. Incubate slide in an aluminum foil-wrapped moist chamber 30 min at 37°C.

Alternatively, steps 3 to 5 can be accomplished in a single step by incubating the slide with 3 µg/ml streptavidin-conjugated HRPO.

HRPO-conjugated anti-digoxigenin antibody should be used to detect digoxigenin-labeled probes.

6. Repeat wash as in step 4.

Enzymatically detect bound probe

7. Remove slide from wash solution and drain thoroughly without allowing to dry. Add 0.015% H₂O₂ to DAB substrate solution. Immediately add 200 µl DAB substrate solution to slide and place a 24 × 60-mm coverslip on top of applied solution. Incubate slide 10 to 20 min in the dark at room temperature.

**In situ
Hybridization
and Immuno-
histochemistry**

14.7.7

**ALTERNATE
PROTOCOL 2**

8. When the colored precipitate becomes visible to the eye, wash slide 5 min in room temperature PBS to stop the reaction.
9. If desired, apply a fluorescent counterstain to identify nuclei (see Basic Protocol, step 9).
10. Mount slide in 90% glycerol *or* appropriate antifade mounting medium (see Critical Parameters). View and photograph with a phase-contrast microscope.

Enzymatic Detection Using Alkaline Phosphatase

Additional Materials (also see Basic Protocol)

- Blocking solution: 1% (w/v) BSA/PBS (*APPENDIX 2*)
- Streptavidin solution (see recipe)
- 0.1% (v/v) Tween 20/PBS (*APPENDIX 2*), 42°C
- Biotinylated alkaline phosphatase (AP) solution (see recipe)
- Alkaline phosphatase buffer, pH 9.5 (see recipe), 42°C
- NBT/BCIP substrate solution (see recipe)
- PBS (*APPENDIX 2*)
- 90% glycerol *or* appropriate antifade mounting medium (see recipe)
- 24 × 60-mm coverslips
- 42°C shaking water bath

NOTE: This procedure must be performed in the dark with minimum exposure to ambient light.

1. Hybridize slide with biotinylated probe, wash, block, and incubate in streptavidin solution (see Alternate Protocol 1, steps 1 to 4).
2. Remove slide from 0.1% Tween 20/PBS and drain without allowing it to dry. Add 200 µl biotinylated AP solution to slide and place a 24 × 60-mm coverslip on top of applied solution. Incubate slide in an aluminum foil-wrapped moist chamber 30 min at 37°C.

Alternatively, this procedure can be accomplished in a single step by incubating the slide with 3 µg/ml streptavidin-conjugated AP (Life Technologies).

3. Remove slide from chamber, tilt it to let the coverslip slide off, and place slide in Coplin jar containing 42°C 0.1% Tween 20/PBS. Agitate 5 min at 42°C in shaking water bath. Repeat wash twice with 42°C 0.1% Tween 20/PBS.
4. Transfer slide to Coplin jar containing 42°C alkaline phosphatase buffer, pH 9.5. Agitate 5 min at 42°C. Replace buffer and agitate again 5 min at 42°C.
5. Place slide in aluminum foil-wrapped Coplin jar containing 50 ml freshly prepared NBT/BCIP substrate solution. Incubate in dark at 37°C or at room temperature (to slow down reaction) until color development is suitable.

Usually, 15 to 60 min incubation is sufficient. Longer incubation often results in higher background.

6. Wash slide 5 min in PBS at room temperature to stop reaction.
7. If desired, Apply a fluorescent counterstain to identify nuclei (see Basic Protocol, step 9).
8. Mount in 90% glycerol or appropriate antifade mounting medium (see Critical Parameters). View and photograph with a phase-contrast microscope.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Alkaline phosphatase buffer, pH 9.5

0.1 M Tris-Cl, pH 9.5

0.1 M NaCl

50 mM MgCl₂ (add immediately before use)

Store up to 1 year (without MgCl₂) at room temperature

Antifade mounting media

DABCO mounting medium: Dissolve 0.233 g 1,4-diazobicyclo-[2.2.2]octane (Sigma; 0.21 M final) in 800 µl H₂O. Add 200 µl 1 M Tris-Cl, pH 8.0 (0.02 M final) and 9 ml glycerol (90% final). Mix. Store 100-µl aliquots, wrapped in foil, at -20°C. Thaw and use once.

CAUTION: *DABCO is hazardous; see manufacturer's information for guidelines on handling, storage, and disposal.*

Phenylenediamine dihydrochloride: Dissolve 50 mg *p*-phenylenediamine dihydrochloride in 5 ml PBS (9 mM final). Adjust to pH 8 with 0.5 M carbonate/bicarbonate buffer, pH 9.0 (see recipe). Add to 45 ml glycerol (90% final), mix, and filter through 0.22 µm filter. Store in small aliquots in dark at -20°C. Thaw and use at once.

Vectashield: Purchase from Vector Laboratories; follow manufacturer's instructions.

Biotin detection solution

Dilute fluorescein-avidin DCS *or* rhodamine-avidin D (Vector Laboratories) to 2 µg/ml in 4× SSC/1% (w/v) BSA (fraction V). Prepare fresh daily.

Biotin/digoxigenin detection solution

Dilute fluorescein-avidin DCS (Vector Laboratories) and rhodamine-conjugated Fab fragment of sheep anti-digoxigenin (Boehringer Mannheim) to 2 µg/ml each in 4× SSC/1% (w/v) BSA (fraction V). Prepare fresh daily.

Biotinylated alkaline phosphatase solution

PBS (APPENDIX 2) containing:

1% (w/v) BSA

0.1% (v/v) Tween 20

2.5 µg/ml biotinylated alkaline phosphatase

Prepare fresh

Biotinylated horseradish peroxidase solution

PBS (APPENDIX 2) containing:

1% (w/v) BSA

0.1% (v/v) Tween 20

3 µg/ml biotinylated horseradish peroxidase

Prepare fresh

Carbonate/bicarbonate buffer (pH 9.0), 0.5 M

0.42 g NaHCO₃

10 ml H₂O

Adjust pH to 9 with NaOH

Store up to 1 year at room temperature

DAPI staining solution

Stock solution: Dissolve 1 mg 4',6-diamidino-2-phenylindole (DAPI; 0.3 mM final) in 10 ml H₂O. (Add a few drops of methanol before adding H₂O to help dissolve DAPI). Aliquot into aluminum foil–wrapped tubes and store a year or more at –20°C.

Working solution: Dilute stock solution 1/1000 in PBS (APPENDIX 2). Store in aluminum foil–wrapped tubes several weeks at 4°C.

CAUTION: *DAPI is hazardous; see manufacturer's information for guidelines on handling, storage, and disposal.*

Digoxigenin detection solution

2 µg/ml fluorescein *or* rhodamine-conjugated Fab fragment of sheep anti-digoxigenin (Boehringer Mannheim) in 4× SSC/1% (w/v) BSA (fraction V). Prepare fresh daily.

Master hybridization mix

1 ml 20× SSC (APPENDIX 2; 4× final)

0.5 ml 20 mg/ml nuclease-free BSA (2 mg/ml final)

1.5 ml sterile H₂O

2 ml 50% (w/v) dextran sulfate (Pharmacia Biotech, mol. wt. 500,000; autoclaved; 20% final)

Store at 4°C and use up to 6 weeks

NBT/BCIP substrate solution

Add 220 µl nitroblue tetrazolium (NBT) solution (75 mg/ml in dimethylformamide; 330 µg/ml final) to 50 ml alkaline phosphatase buffer, pH 9.5 (see recipe) and mix gently (do not vortex). Add 170 µl 5-bromo-4-chloro-3-indolyl phosphate (BCIP) solution (50 mg/ml in dimethylformamide; 170 µg/ml final) and mix gently again. Prepare fresh each time.

CAUTION: *Dimethylformamide is hazardous; see manufacturer's information for guidelines on handling, storage, and disposal.*

Propidium iodide staining solution

Stock solution: Dissolve 1 mg propidium iodide in 10 ml H₂O (0.15 mM final). Aliquot into aluminum foil–wrapped tubes and store up to 1 year at –20°C.

Working solution: Dilute stock solution 1/1000 in PBS (APPENDIX 2) and store in aluminum foil–wrapped tube up to 6 months at 4°C.

CAUTION: *Propidium iodide is hazardous; see manufacturer's information for guidelines on handling, storage, and disposal.*

Sonicated salmon sperm DNA, 10 mg/ml

Dissolve 10 mg salmon sperm DNA (Worthington) in 1 ml sterile water in a polycarbonate tube. Sonicate five times, 30 sec each time, at maximum power, chilling tube on ice between bursts. Check molecular size of DNA by gel electrophoresis (UNIT 2.5A); it should be 200 to 400 bp. Store in 50-µl aliquots up to 1 year at –20°C.

Streptavidin solution

PBS (APPENDIX 2) containing:

1% (w/v) BSA

0.1% (v/v) Tween 20

3 µg/ml streptavidin

Prepare fresh

COMMENTARY

Background Information

In situ hybridization (ISH) is a powerful technology for examining the expression, processing, and location of specific nucleic acid sequences in single cells or in tissue sections. Historically, ISH has been performed using isotopically labeled probe sequences that are detected by autoradiography (see *UNITS 14.3 & 14.4*; see also Knoll and Lichter, 1995 for a more extensive version of this unit optimized for hybridization to chromosomes and nuclei). This method has been used to identify and localize both repetitive and unique sequences of DNA in chromosomes (Morton et al., 1984; Lawrence et al., 1988) as well as RNA transcripts (Zhang et al., 1994). In recent years, nonisotopic ISH has gained recognition because of technical advances that make its sensitivity comparable to that of isotopic ISH (Lichter et al., 1988, 1990). Nonisotopic techniques can be used in combination with radioactive hybridization and immunohistochemistry as a powerful approach to detect more than one nucleic acid target and antigen in the same section (Trembleau et al., 1993).

The method described in this unit is a modification of methodology previously described for fluorescent detection of single-copy nuclear DNA (Lawrence et al., 1988; Knoll and Lichter, 1995). The approach described here has been adapted to allow direct visualization of specific transcripts. The method has been used most recently to study the sites at which RNA transcription and processing occur—in particular, to localize splicing events and the factors associated with processing nascent transcripts in mammalian nuclei (Zhang et al., 1994).

Results are obtained more rapidly with nonisotopic ISH because there is no need for lengthy autoradiographic exposures. Nonisotopically labeled probes do not require special handling and disposal. With fluorochrome detection using multi-band-pass filters, two or more sequences can be examined simultaneously and distinguished from one another. Isotopic ISH (IISH; *UNITS 14.3 & 14.4*), however, is useful for mapping small sequences that cannot be detected easily by nonisotopic methods.

FISH

The advantages and availability of commercially prepared probes have contributed to widespread application of nonisotopic ISH, especially fluorescence in situ hybridization (FISH), in clinical and research laboratories

(Knoll and Lichter, 1995). Probes are generally labeled by nick translation, but other methods such as random oligonucleotide-primed labeling are also effective. Detailed protocols for both labeling procedures are provided in *UNIT 3.18*. Biotin-labeled and digoxigenin-labeled deoxynucleotides are most frequently used for labeling, but other modified nucleotides, such as direct-labeled fluorescent nucleotides (e.g., fluorescein-12-dUTP; Boehringer Mannheim) are also used (Wiegant et al., 1991). Biotin- and digoxigenin-labeled probes are detected by incubating the hybridized preparation with a fluorochrome- or enzyme-conjugated reporter-binding molecule (Fig. 14.7.1). Digoxigenin detection yields lower background fluorescence than biotin detection because digoxigenin is not a natural component of mammalian cells. Hybridized probe is detected by fluorescent (Lawrence et al., 1989) or enzymatic methods (Lawrence and Singer, 1988) and viewed by transmission, reflection, or epifluorescence microscopy. Analysis may be facilitated by using cameras such as charge-coupled device (CCD) cameras, or for three-dimensional analysis, confocal microscopy.

Enzymatic detection

In this unit, two protocols for enzymatic detection of biotinylated and digoxigenin-labeled probes are described; one uses horseradish peroxidase (HRPO) with diaminobenzidine (DAB) as substrate; the other uses alkaline phosphatase with 5-bromo-4-chloro-3-indolyl phosphate (BCIP) and nitroblue tetrazolium (NBT) as substrates. These procedures were developed in several different laboratories and the protocols described here are based on published work (e.g., Lichter et al., 1988; Emmerich et al., 1989).

Enzyme-mediated detection procedures result in permanent colored precipitates (Figs. 14.7.1 & 14.7.2); therefore, these techniques are often preferred for preparing routine specimens that are to be archived. However, until recently it has been very difficult to simultaneously label different targets in the same specimen, a goal that is achievable using fluorescence methods, because the precipitates produced by HRPO- and AP-mediated reactions were often hard to distinguish in cellular preparations. With the advent of new substrates (see Table 14.7.1) that yield differently colored precipitates, this limitation has been overcome. For a typical dual-color experiment, the bio-

tinylated first probe is detected using AP and a substrate that produces a red precipitate, and the second digoxigenin-labeled probe is detected using HRPO and a substrate that produces a brown precipitate.

Critical Parameters and Troubleshooting

For a detailed discussion of special considerations for in situ hybridization to RNA see *UNIT 14.3*, Commentary.

FISH

To maximize probe hybridization efficiency and signal-to-noise ratio, it is important to have high-quality cytological preparations. For best hybridization results with hypotonically treated and methanol/acetic acid-fixed cells, unstained nuclei should appear dark gray when examined with a phase-contrast microscope. They should not appear black and refractile or light gray and almost invisible. In addition, there should be minimal extracellular debris in the preparations. Avidin nonspecifically binds to extracellular debris and increases background. Pretreatment—e.g., with pepsin or pronase—is recommended when there is too much debris (*UNIT 14.3*).

Probe hybridization efficiency and background are also influenced by the size of the labeled probe. Optimal probe size is 100 to 500 bp; background increases significantly when this size is exceeded. If the probe extends beyond 800 bp, additional nick translation is suggested. If the DNA is difficult to nick to smaller sizes (i.e., it contains inhibiting contaminants), fresh probe DNA should be prepared. An additional phenol/chloroform extraction and ethanol precipitation of the unlabeled probe DNA is often sufficient to prepare clean DNA for subsequent nick translations. Biotin- and digoxigenin-labeled DNA should not be subjected to phenol/chloroform extraction because it will partition to the interface.

If the hybridization signal is not visible or is difficult to see, it is possible that the target is too small, the level of nucleotide incorporation is inadequate, the concentration of probe utilized is too low, or denaturation is not optimal. The level of incorporation of labeled nucleotide should be checked and the concentration of probe utilized for hybridization should be increased, if necessary (see *UNIT 3.18*). Amplification of the signal may improve fluorescence intensity. Additionally, the optimal antifade mounting medium for the fluorochrome de-

tected should be used. DABCO (1,4-diazobicyclo-[2.2.2]octane) permits optimal green fluorescence of fluorescein (Johnson et al., 1982); *p*-phenylenediamine dihydrochloride (Johnson and de C. Nogueira Araujo, 1981) and Vectashield (Vector) permit optimal red fluorescence of rhodamine and Texas red. Fluorescein fluorescence is less bright with *p*-phenylenediamine dihydrochloride and Vectashield but is still very good. Vectashield does not readily discolor and therefore does not obscure a less intense signal, as may occur with *p*-phenylenediamine. Digital imaging systems (e.g., CCD cameras and confocal microscopes) are also useful to detect small or weak hybridization signals (see Lichter et al., 1991, for an overview of digital imaging systems). These systems, however, are expensive and not accessible to many laboratories.

Image shifting as filter sets are changed is a potential problem in orienting sequences that are physically close, or in localizing a hybridization signal with precision. This problem is solved for practical applications by simultaneous viewing of multiple-color fluorescence through a dual- or triple-band-pass filter set, instead of viewing each color through a separate filter set.

Enzymatic detection

In general, enzymatic detection can be carried out in two ways, as illustrated in Figure 14.7.2. The reporter-binding molecule can be coupled directly to the enzyme, as in Figure 14.7.2A, requiring only one incubation with detection reagents prior to the enzyme reaction. However, these conjugates are often large and do not always penetrate into cytological preparations as well as the individual reporter-binding and enzyme molecules. Therefore, a two-step application of detection reagents, as outlined in Figure 14.7.2B and described in the protocols, may be preferred. Weak signals can be amplified as indicated in Figure 14.7.2C.

An important parameter of AP-mediated detection is the accurate adjustment of pH in the alkaline phosphatase buffer to pH 9.5. Another extremely important critical parameter is the time period of the color reaction described in the protocol. The reaction can continue for hours. Although longer reaction times may result in an increase of detection sensitivity, in general they also tend to result in a considerable increase in background. In contrast, HRPO-mediated detection using DAB/H₂O₂ is substrate-inactivated. Therefore, longer incuba-

tion times do not improve signal intensity, but can still increase background.

Silver intensification increases the optical density of the colored precipitate, facilitating the use of enzyme-mediated procedures for electron microscopy. Applications of silver-intensified DAB products have been reported (Manuelidis and Ward, 1984).

Anticipated Results

Detection of RNAs either in the nucleus or cytoplasm is dependent upon the size of the RNA target, its abundance, and its distribution. Generally, molecules smaller than a few kilobases are not easily visible without the use of amplification procedures, which may tend to enhance background. Examples of results of these experiments are described and illustrated in many of the references cited here (e.g., Lawrence et al., 1988; Zhang et al., 1994).

This FISH protocol has allowed detection of cDNA probes as small as 1.8 kb without use of signal amplification or digital imaging.

The sensitivity of enzymatic detection is less than that of FISH so this method is not suitable for probes of cosmid size or smaller. However, many diagnostic probes are highly complex and the colorimetric signals obtained with enzymatic detection are permanent, so enzymatic detection protocols are often preferred in clinical laboratories.

Time Considerations

Denaturation and hybridization of probe and cellular DNA require ≥ 4 hr with a repetitive probe, and hybridization can be performed in a few hours or overnight. Post-hybridization washing, signal detection, and counterstaining require a total of 3 to 4 hr. An additional 2 to 3 hr are required if signal amplification is performed. After mounting in antifade medium, preparations from cDNA can be stored at -20°C for ~ 2 weeks.

The time required for enzyme-mediated detection is not significantly longer than that required for fluorescence detection.

In situ Polymerase Chain Reaction and Hybridization to Detect Low-Abundance Nucleic Acid Targets

This unit presents a novel approach for detecting low-abundance nucleic acid targets in nuclear and cytoplasmic regions by amplification of specific target sequences using an in situ polymerase chain reaction (ISPCR). If the target sequence is RNA, ISPCR is preceded by in situ reverse transcription. Following ISPCR, in situ hybridization is performed. The Strategic Planning section discusses specific considerations for the overall approach, including selection and design of primers, determination of annealing temperatures for reverse transcription and amplification, design of controls, and validation of experiments. Basic Protocol 1 describes ISPCR amplification of DNA or RNA targets. An Alternate Protocol describes a variant in situ method for simultaneously reverse transcribing and amplifying RNA transcripts using recombinant *Thermos thermophilus* (*rTth*) polymerase. Basic Protocol 2 describes in situ hybridization and detection of amplified targets.

Two specific variations on the standard in situ hybridization protocols (in *UNITS 14.1 & 14.3*) are recommended for this particular application. The first is the use of slides subbed with 3-aminopropyltriethoxysilane (AES) in place of gelatin-subbed slides (see recipe in *UNIT 14.1*). Support Protocol 1 describes preparation of AES-subbed slides. Support Protocol 2 outlines methods for attaching tissue sections and cells to AEC-subbed slides in preparation for ISPCR. The second variation is the use of ³³P-labeled oligonucleotide probes instead of ³⁵S-labeled riboprobes for in situ hybridization. Support Protocol 3 describes radiolabeling of oligonucleotide probes using ³³P.

STRATEGIC PLANNING

Figure 14.8.1 outlines the major steps for in situ amplification and hybridization. It is essential that appropriate planning and consideration be given to each aspect of the project—including design of primers, amplification parameters, detection and fixation conditions, and validation and controls—before proceeding with the actual protocols. These considerations and the corresponding procedural variations, which are discussed below, must be defined and optimized for each system. For further details on optimization of various aspects of the protocols, see Critical Parameters.

Design of Primers to Reverse Transcribe and Amplify Target

The design of primers for amplification reactions in general requires careful planning (see *UNIT 15.1*); for in situ amplification, the design of the primer set is even more critical. In the authors' laboratory, antisense downstream primers for the gene of interest are used, as the authors already know the sequence of most genes that they study. However, it is equally possible to use oligo(dT) primers to convert all mRNA populations into cDNA, and then perform the in situ amplification for a specific cDNA. This technique may be useful when several different gene transcripts are being amplified at the same time in a single cell. For example, if attempting to detect expression of various cytokines in a cell or tissue section, it is possible to use an oligo(dT) primer to reverse transcribe all of the mRNA copies in the specimen. More than one type of cytokine cDNA can then be amplified, and the various types can be detected with differentially labeled probes (see Commentary for discussion of detecting multiple signals in individual cells).

There are two possible choices in designing a specific method to detect expression of a particular RNA. The more elegant method is to use primer pairs that are complementary to the sequence spanning spliced sequences of mRNA, as these particular sequences will

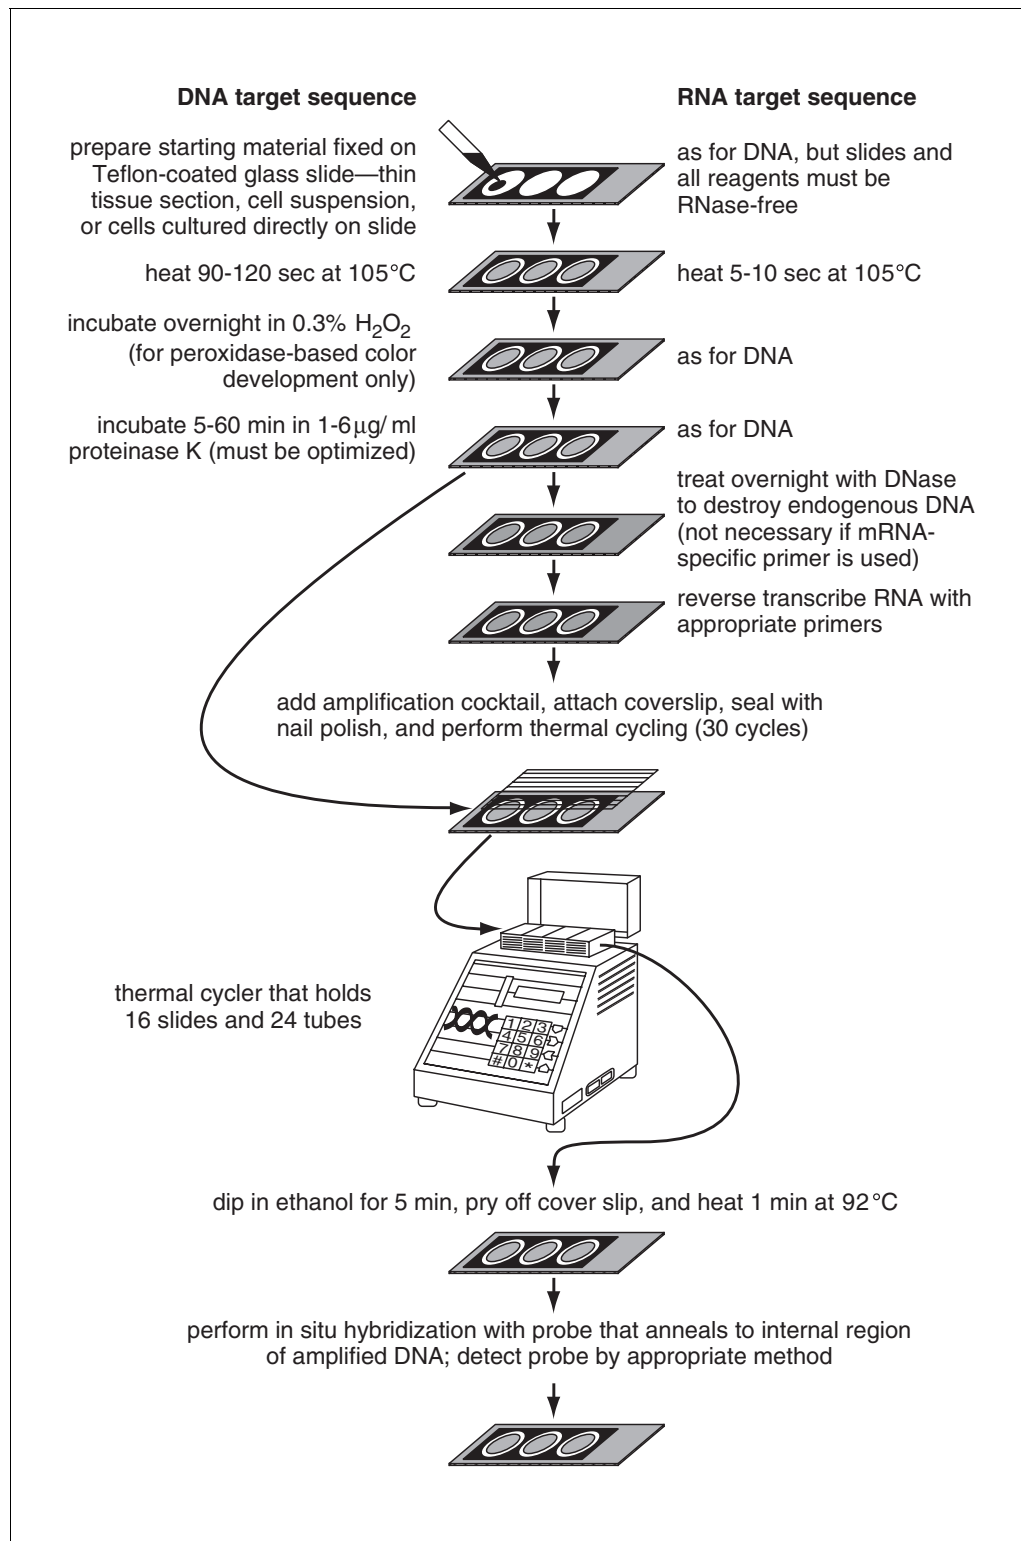

Figure 14.8.1 Flow chart for in situ amplification/hybridization.

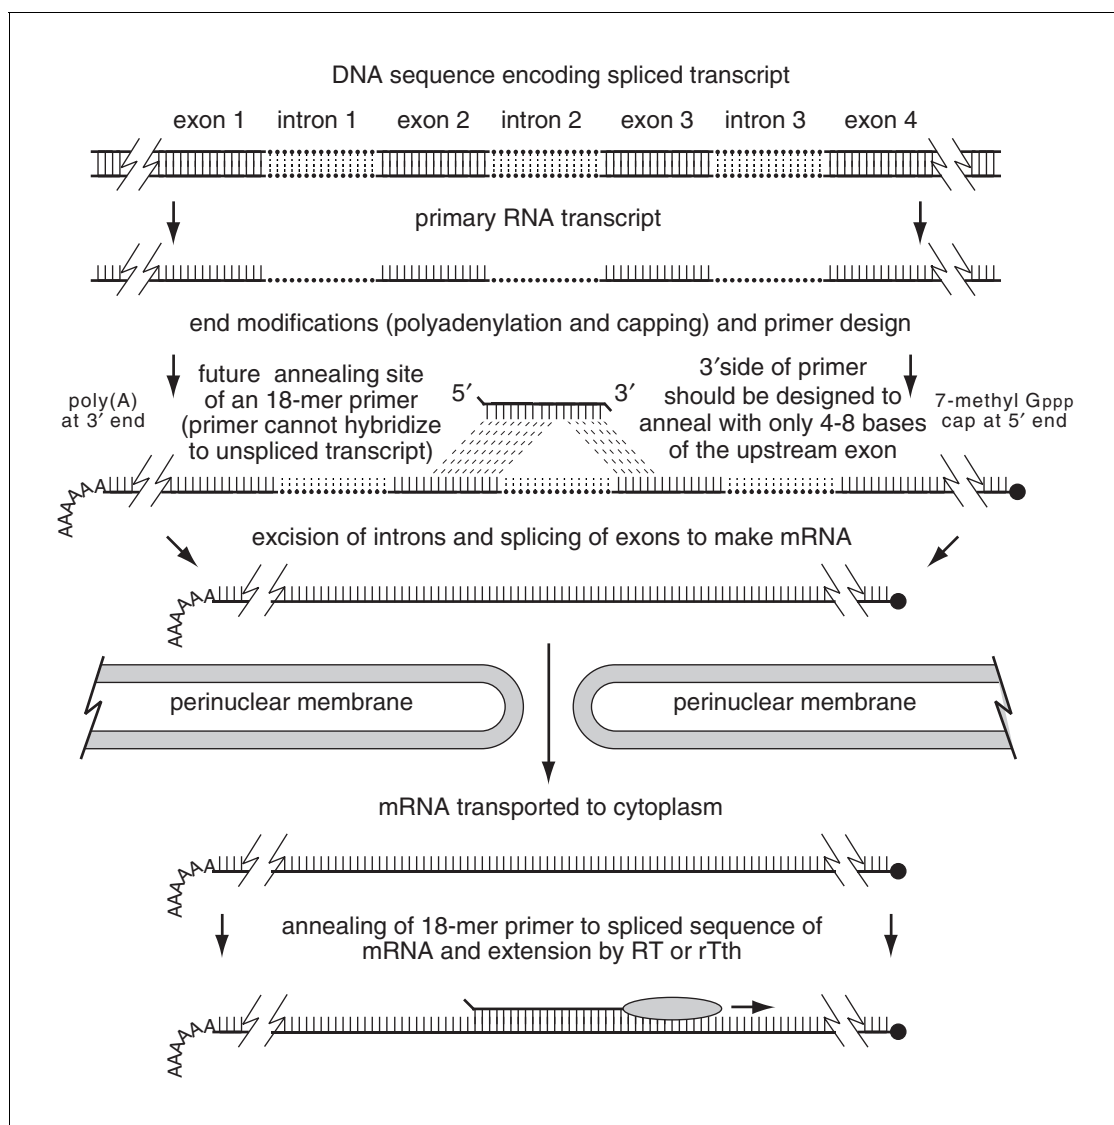

Figure 14.8.2 Design of primers to amplify mRNA without interference from DNA. Primers are designed so that their sequences span the splice junction where two exon sequences are joined. The resulting sequence thus exists only in mRNA, not in the encoding DNA. Use of such primers allows DNase treatment to be omitted and facilitates simultaneous amplification of RNA and DNA signals.

be found only in spliced mRNA and will not fully hybridize to the encoding sequence in DNA (see Fig. 14.8.2). Thus, by using these primers, it is possible to omit the DNase treatment (to destroy endogenous DNA) and proceed directly to reverse transcription. The more brute-force, yet often necessary, approach is to treat the cells or tissue with DNase subsequent to the proteinase K digestion. This step destroys all of the endogenous DNA in the cells so that only RNA survives for amplification and subsequent detection.

In all reverse transcription reactions, it is advantageous to reverse transcribe only relatively small fragments of mRNA (<1500 bp). Larger fragments may not be completely reverse transcribed due, for example, to the presence of secondary structures. Furthermore, the reverse transcriptase enzymes—avian myeloblastosis (AMV) reverse transcriptase and Moloney murine leukemia virus (MoMuLV) reverse transcriptase, at least—are not very efficient in transcribing long mRNAs. However, this size restriction does not apply to DNA amplification; DNA target lengths up to 5000 bp are routinely amplified in situ in the authors' laboratory. Several new recombinant enzymes and buffer systems

have been described that allow efficient amplifications of much larger fragments (up to 10 kb) of DNA or cDNA (Lundberg et al., 1991; Barnes, 1994). An alternative approach is to create a multiple primer set, choosing primers positioned 200 to 300 nucleotides apart along the sequence to be amplified (see Haase et al., 1990).

Several additional points should be kept in mind when designing primers for ISPCR and reverse transcription: (1) the length for both sense and antisense primers should be 18 to 22 bp; (2) at the 3' ends, primers should contain at least one GC-type dinucleotide (i.e., GG, CC, GC, or CG) to facilitate complementary-strand formation (as two GC-type base pairs will provide six hydrogen bonds as compared to four with two AT-type base pairs); (3) the preferred GC content of the primers is 45% to 55%; (4) primers should be designed so that they do not form intra- or interstrand base pairs; (5) the 3' ends of the primers should not be complementary to each other, or they will form primer-dimers; and (6) reverse transcription primers should be designed so that they do not contain secondary structures (see Pallansch et al., 1990)

Determining Optimal Annealing Temperature

The optimal primer annealing temperature for reverse transcription and DNA amplification is usually 2°C above the T_m of the primer, which is calculated according to the formula:

$$T_m \text{ of the primers} = 81.5^\circ\text{C} + 16.6 (\text{Log } M) + 0.41 (\%GC) - 500/n$$

where T_m is the melting temperature of the primer, n is the length of the primer, and M is the molarity of the salt in the buffer (usually 0.047 M for DNA reactions and 0.070 M for reverse transcription reactions)

If using AMV reverse transcriptase, the value of the melting temperature will be lower according to the following formula:

$$T_m \text{ of the primers} = 62.3^\circ\text{C} + 0.41 (\%GC) - 500/n$$

These formulas provide only an approximate temperature for annealing, because base stacking, near-neighbor effect, and buffering capacity may play a significant role in determining the annealing temperature of a particular primer.

The logic of determining the correct annealing temperature for ISPCR is that during amplification, spurious products often appear in addition to those desired. Even if the cells do not contain DNA homologous to the primer sequences, many artifactual bands may appear as a result of false priming, which will occur if the determined melting temperature (T_m) between primer and template is not accurate. Annealing at a temperature too far above the T_m will yield no products, and annealing at a temperature too far below the T_m will often give unwanted products resulting from false priming.

Recently, MJ Research has devised a thermal cycler (the PTC-100) that has the capacity to perform in situ gene amplification on slides and solution-based amplification in tubes simultaneously in the same block. This kind of thermal cycler can be very useful in determining optimal amplification conditions for a gene of interest. Many methods for eliminating high background resulting from false priming in PCR have appeared in the literature, including hot-start PCR (Nuovo et al., 1992, 1994a) as well as use of DMSO, formamide, and anti-Taq DNA polymerase antibodies (e.g., TaqStart from Clontech; Nuovo, 1994a). These variations and modifications are discussed in *UNIT 15.1*.

The annealing temperature should be optimized with solution-based reactions before the corresponding in situ reactions are attempted, as in situ reactions are simply not as robust as solution-based ones (O'Leary et al., 1994). One hypothesis is that this is due to primers

not having easy access to DNA templates inside cells and tissues; the numerous membranes, folds, and other small structures can prevent primers from binding complementary sites as readily as they do in solution. In solution-based PCR, determining the appropriate optimal annealing temperature may not be as critical as in ISPCR, because primers in solution may anneal at the correct temperatures while temperatures are changing during thermal cycling. For example, if the optimal annealing temperature is empirically calculated to be 48°C but in reality is 52°C, freely moving primers may anneal at the proper temperature as the temperature cycles on the downward slope from the denaturation to the calculated annealing temperature of 48°C. For ISPCR, determining the optimal annealing temperature is more critical because primers do not move as freely as a result of partial hindrance by intracellular organelles, multiple layers of membranes, and numerous subcompartments. Two additional ways to determine the real annealing temperature in situ are to use “touchdown PCR” (Don et al., 1991), or to utilize a thermal cycler designed for determining actual annealing temperature (e.g., Robocycler from Stratagene).

Validation and Controls

The validity of in situ amplification/hybridization should be examined in every run. Attention is especially necessary in laboratories that are using the technique for the first time, because occasional technical pitfalls lie on the path to mastery. Even in an experienced laboratory, it is necessary to continuously validate the procedure and to confirm the efficiency of amplification. In the authors’ laboratory, two or three sets of experiments are run simultaneously in multiwell slides. This is done not only to validate the amplification, but also to confirm the subsequent hybridization/detection steps.

The authors frequently use ISPCR in working with HIV-1. A common validation procedure used in the authors’ laboratory is to mix HIV-1-infected cells and uninfected cells in a known proportion (e.g. 1:10 or 1:100), then to confirm that the results are appropriately proportional. To examine the efficiency of amplification, the authors use a cell line that carries a single copy or two copies of cloned HIV-1 virus, then check that proper amplification and hybridization have occurred. In all amplification procedures, the authors use one slide in which the amplified cells are hybridized with an unrelated probe as a control for nonspecific binding. The authors also use HLA-DQ α probes and primers with human peripheral blood mononuclear cells (PBMCs) as positive controls to check various parameters of the system. If tissue sections are used, a cell suspension lacking the gene of interest can be used as a control. These cells can be added on top of the tissue section, then retrieved after the amplification procedure and analyzed with the specific probe to see if the signal from the tissue leaked out and entered the cells floating above.

It is suggested that researchers carefully design and employ appropriate positive and negative controls for their specific experiments. In the case of reverse transcription/in situ amplification, RNAs for β -actin or HLA-DQ α , or other abundant endogenous RNAs may be used as the positive markers. Of course, a reverse-transcription-negative control should always be used for reverse transcription/in situ amplification, as well as DNase-treated and non-DNase-treated controls. Controls without DNA polymerase should always be included, with and without primers.

**IN SITU PCR (ISPCR) AMPLIFICATION OF DNA AND RNA TARGETS
WITH IN SITU REVERSE TRANSCRIPTION FOR RNA**

The first steps of the protocol comprise the basic preparatory work that must be done before performing any in situ amplification/hybridization procedures; subsequent steps describe separate methods for amplifying DNA or RNA targets. For optimal results, use of slides subbed with AES (see Support Protocol 1) is recommended. Slides with fixed tissue specimens are pretreated with proteinase K to optimize resolution and reduce background during subsequent reactions. For RNA, the target transcript is reverse transcribed to make DNA copies suitable for amplification. The last several steps of the protocol give the details of the ISPCR amplification process.

Materials

Slides containing fixed specimens (see Support Protocol 2)
0.3% H₂O₂ in PBS (prepare fresh)
PBS (APPENDIX 2)
1 mg/ml proteinase K (Sigma; store in aliquots at -20°C)
RNase-free DNase solution (see recipe)
Rinse buffer: RNase-free DNase solution (see recipe) without DNase
DEPC-treated H₂O (UNIT 4.1)
10× AMV/MoMuLV reaction buffer (see recipe)
10 mM 4dNTP mix: 10 mM each dNTP in TE buffer, pH 7.5 (see APPENDIX 2 for TE buffer; store 4dNTP mix at -20°C)
40 U/μl RNasin (Promega)
20 μM downstream primer (for reverse transcription; see Strategic Planning)
20 U/μl avian myeloblastosis virus (AMV) or Moloney murine leukemia virus (MoMuLV) reverse transcriptase *or* 20 U/μl SuperScript II (with 5× reaction buffer; Life Technologies)
0.1 M DTT
25 μM forward and reverse primers (for PCR; see Strategic Planning and UNIT 15.1)
1 M Tris·Cl, pH 8.3 (APPENDIX 2)
1 M KCl (APPENDIX 2)
100 mM MgCl₂
0.01% (w/v) gelatin
5 U/μl *Taq* DNA polymerase
100% ethanol
2× SSC (APPENDIX 2)
55°C (optional), 92°C, 95°C, and 105°C heating blocks accommodating glass slides
Moist chamber (UNIT 14.2)
42°C incubator (optional)
20 × 60-mm glass coverslips
Clear nail polish or varnish (see Critical Parameters)
Thermal cycler accommodating glass slides (see Critical Parameters)

NOTE: Where the target sequence is RNA, all reagents should be prepared with DEPC-treated water (UNIT 4.1). In addition, the AES-subbed glass slides and all glassware should be RNase free; in the authors' laboratory this is ensured by baking overnight in an oven usually set at 250° to 300°C.

Pretreat samples with peroxide and proteinase K

1. Incubate slide with fixed specimens 5 to 120 sec on a 105°C heating block.

This step serves to stabilize the cells or tissue on the glass surface of the slide. The time is absolutely critical, and it may be necessary to experiment with different time

periods in order to optimize for specific tissues. The authors' laboratory routinely uses 90 sec for DNA target sequences, and 5 to 10 sec for RNA sequences. The shorter incubation is recommended for RNA targets because certain mRNAs may be unstable at high temperature.

2. Incubate slide overnight at 37°C or room temperature in 0.3% H₂O₂ in PBS, then wash once with PBS.

This treatment will inactivate any endogenous peroxidase activity that may interfere with subsequent assays; it is required only where peroxidase-based color development (see Basic Protocol 2) will be used for hybridization/detection.

3. Dilute 1 ml of 1 mg/ml proteinase K in 150 ml PBS (6 µg/ml final). Immerse slide in this solution and incubate at room temperature. After 5 min, examine cells under microscope at 400×; if the majority of cells of interest exhibit small round “bubbles,” “blobs,” or “peppery dots” (as in Fig. 14.8.4), proceed immediately to step 4. Otherwise, continue incubation up to 60 min, examining the slide at 400× at 5 min intervals and proceeding immediately to step 4 at the point where cell surface bubbles appear.

Performing this treatment properly is absolutely critical. The time and temperature of incubation should be optimized carefully for each cell line or tissue-section type (see Critical Parameters). If development of “peppery dots” takes >2 hr at room temperature, digestion may be performed at 48° or 55°C to speed up the process. Examination for dots should be done with an ordinary bright-field microscope with light adjusted for optimal visualization. Too much digestion will either cause membranes to deteriorate during repeated denaturation or (in the worst case) cause signals to leak out of the cells. In the former case, cells will not contain the signal and high background will result. In the latter case, many cells will show pericytoplasmic staining, representing the leaked signals contaminating other cells (see Basic Protocol 2). Attention to detail at this step can often mean the difference between success and failure, and this procedure should be practiced rigorously with extra samples before proceeding to the amplification steps.

Figure 14.8.3 shows typical cytoplasmic membranes before proteinase K treatment. Figure 14.8.4 shows membranes exhibiting “bubbles” after treatment.

4. Heat slide 2 min in a 95°C heating block to inactivate the proteinase K, then rinse 10 sec in PBS and 10 sec in water. Allow slide to air dry.

To reverse transcribe RNA targets, proceed with step 5, except if primer pairs are to be used that are complementary to the sequence joining spliced sequences of mRNA (to specifically amplify mRNA; see Strategic Planning, discussion of design of primers to reverse transcribe and amplify target), in which case proceed to step 7. To amplify DNA targets, proceed to step 10.

Treat slides with DNase (RNA samples only)

5. Add 10 µl RNase-free DNase solution to each well of slide. Incubate overnight at 37°C in a moist chamber.

For liver tissue, this incubation should be extended an additional 18 to 24 hr.

6. Rinse slide once with rinse solution, then twice with DEPC-treated water and allow to air dry.

Figure 14.8.3 Lymphocytes before proteinase K treatment. Cells have been subjected to heat treatment and fixation. Note the smooth cytoplasmic membranes without “bubbles”, “peppery dots,” or “salt and pepper dots” on the cell surface.

Figure 14.8.4 Lymphocytes after proteinase K treatment. Note the minute cell surface “bubbles,” which are presumably the result of partial digestion of transmembrane proteins. The “bubbles” should appear uniform and be fairly evenly distributed.

Reverse transcribe RNA

If using AMV or MoMuLV reverse transcriptase:

7a. Make up the following reverse transcription cocktail (20 μ l total volume):

- 2 μ l 10 \times AMV/MoMuLV RT buffer
- 2 μ l 10 mM 4dNTP mix
- 0.5 μ l 40 U/ μ l RNasin
- 1.0 μ l 20 μ M downstream primer
- 0.5 μ l 20 U/ μ l AMV or MoMuLV reverse transcriptase
- 8 μ l DEPC-treated H₂O.

Avian myeloblastosis virus (AMV) reverse transcriptase and Moloney murine leukemia virus (MoMuLV) reverse transcriptase give comparable results in the authors' laboratory. Other reverse transcriptase enzymes will probably work also. However, it is important to read the manufacturer's descriptions of the reverse transcriptase enzyme and to make certain that the proper buffer is used. An alternative reverse transcriptase enzyme, SuperScript II (Life Technologies), has significantly reduced RNase H activity and is therefore suitable for reverse transcription of long mRNAs. It is also suitable for routine reverse transcription, and in our laboratory has proven to be more efficient than the two enzymes described above.

If using SuperScript II reverse transcriptase:

7b. Make up the following reverse transcription cocktail (20 μ l total volume):

- 4 μ l 5 \times reaction buffer (supplied with enzyme)
- 2 μ l 10 mM 4dNTP mix
- 0.5 μ l 4 U/ μ l RNasin
- 1.0 μ l 20 μ M downstream primer
- 0.5 μ l 20 U/ μ l SuperScript II
- 1.2 μ l 0.1 M dTT
- 4.8 μ l DEPC-treated H₂O.

RNasin inhibits ribosomal RNases and should be included for optimal yields.

8. Add 10 μ l reverse transcription cocktail to each well of slide and carefully cover each well with a 20 \times 60-mm glass coverslip. Incubate 1 hr at 42°C or 37°C in a moist chamber.
9. Incubate slides 2 min at on a 92°C heating block. Remove coverslips and wash slides twice with water.

Perform ISPCR amplification

10. Make up the following amplification cocktail (100 μ l total volume):

- 5 μ l 25 μ M forward primer (1.25 μ M final)
- 5 μ l 25 μ M reverse primer (1.25 μ M final)
- 2.5 μ l 10 mM 4dNTP mix (200 μ M each dNTP final)
- 1.0 μ l 1.0 M Tris-Cl, pH 8.3 (10 mM final)
- 5.0 μ l 1.0 M KCl (50 mM final)
- 2.5 μ l 100 mM MgCl₂ (2.5 mM final)
- 10 μ l 0.01% gelatin (0.001% final)
- 2 μ l 5 U/ μ l Taq DNA polymerase (0.1 U/ μ l final)
- 66 μ l H₂O.

Appropriate primers for HIV-1 are SK 38 (forward) and SK 39 (reverse). Thermostable DNA polymerases other than Taq DNA polymerase have also been used quite successfully.

11. Layer 8 μl (if using 3-well slide) or 12 to 20 μl (if using single-well slide) ISPCR amplification cocktail onto each well using a 20 μl micropipettor, so that the whole surface of the well is covered with the solution.

Be careful not to touch the surface of the slide with the tip of the micropipettor.

12. Place a 20 \times 60-mm glass coverslip over each slide and carefully seal the edge of the coverslip to the slide with clear nail polish or varnish.

If using tissue sections, use a second slide instead of a cover slip. Be certain to carefully paint the polish around the entire periphery of the coverslip or the edges of the dual slide, as the polish must completely seal the coverslip/slide assembly in order to form a small reaction chamber that can contain the water vapor during thermal cycling (see Critical Parameters).

13. Incubate slide 90 sec on a 92°C heating block, then transfer to thermal cycler. See Critical Parameters for discussion of thermal cyclers.

14. Carry out PCR using the following amplification cycles:

30 cycles:	30 sec	94°C (denaturation)
	1 min	~45°C (annealing)
	1 min	72°C (extension)
Final step:	indefinitely	4°C (hold).

These times and temperatures will likely require optimization for the specific materials and thermal cycler being used. Furthermore, the annealing temperature should be optimized (see Strategic Planning discussion of optimization of annealing temperature). These particular incubation parameters work well with SK38 and SK39 primers for the HIV-1 gag sequence, amplified in an MJ Research PTC-100-60 or PTC-100-16MS thermal cycler.

Mount slides

15. Remove slide from thermal cycler and soak in 100% ethanol \geq 5 min to dissolve nail polish. Pry off coverslip using a razor blade or other fine blade. Scratch off any remaining nail polish so that fresh coverslips can be placed evenly in the hybridization/detection steps (Basic Protocol 2).

16. Incubate slide 1 min on a 92°C heating block, then soak 5 min in 2 \times SSC at room temperature.

The 92°C incubation helps immobilize the intracellular signals. The amplification protocol is now complete and the slide is ready for hybridization (see Basic Protocol 2). If not to be used immediately, slides can be stored 2 to 3 weeks at 4°C.

ALTERNATE PROTOCOL

ONE-STEP REVERSE TRANSCRIPTION AND AMPLIFICATION

This method uses a single, recombinant enzyme—*rTth* DNA polymerase—which performs both reverse transcription and DNA amplification at once in a single reaction, thus avoiding the need for two different buffer systems as required in Basic Protocol 1.

Additional Materials (also see Basic Protocol 1)

3 mM 4dNTP mix: 3 mM each dNTP in TE buffer, pH 7.5 (see APPENDIX 2 for TE buffer; store 4dNTP mix at -20°C)

10 mM MnCl₂

25 mM MgCl₂

10 \times *rTth* transcription buffer: 100 mM Tris·Cl, pH 8.3 (APPENDIX 2)/900 mM KCl

10 \times chelating buffer (see recipe)

1.7 mg/ml BSA

2.5 U/ μl *rTth* DNA polymerase (Perkin-Elmer or Life Technologies)

1. Pretreat slides with peroxidase, proteinase K, and DNase (see Basic Protocol 1, steps 1 to 6).
2. Make up the following single-step reaction cocktail (100 μ l total volume):
 - 0.5 μ l 100 μ M forward primer
 - 0.5 μ l 100 μ M reverse primer
 - 6 μ l 3 mM 4dNTP mix
 - 2 μ l 10 mM MnCl₂
 - 10 μ l 25 mM MgCl₂
 - 2 μ l 10 \times r*Tth* transcription buffer
 - 8 μ l 10 \times chelating buffer
 - 10 μ l 1.7 mg/ml BSA
 - 2 μ l 2.5 U/ml r*Tth*
 - 59 μ l DEPC-treated H₂O.
3. Carry out steps 11 to 13 of Basic Protocol 1, using the single-step reaction cocktail from step 2 in place of the ISPCR reaction cocktail.
4. Carry out the following thermal cycling program for reverse transcription:

1 cycle:	15 min	70°C
	3 min	92°C
	15 min	70°C
	3 min	92°C
	15 min	70°C
5. Carry out the following thermal cycling program for ISPCR:

29 cycles:	1 min	93°C	(denaturation)
	1 min	53°C	(annealing)
	1 min	72°C	(extension).
Final step:	indefinitely	4°C	(hold).
6. Carry out steps 15 and 16 of Basic Protocol 1.

HYBRIDIZATION AND DETECTION OF ISPCR-AMPLIFIED TARGET MATERIAL

Amplified target nucleic acid from the Basic Protocol 1 or the Alternate Protocol is detected using an adaptation of standard in situ hybridization procedures (also see *UNIT 14.3*, *UNIT 14.4* & *UNIT 14.7*). Hybridized specimens are detected using a method suitable for the particular labeled probe employed in the hybridization reaction and slides are subsequently counterstained and mounted for visualization and analysis. Alternative steps are provided for detection of ³³P-labeled probes (by emulsion autoradiography) and biotin- or digoxigenin-labeled probes (by peroxidase- or alkaline phosphatase-based methods). More detail concerning in situ hybridization and detection can be found in *UNITS 14.3* & *14.7*.

Materials

- 200 pM probe, ³³P-labeled (see Support Protocol 3) or biotin- or digoxigenin-labeled (*UNIT 3.18*)
- Deionized formamide
- 20 \times and 2 \times SSC (*APPENDIX 2*)
- 100 \times Denhardt solution (*APPENDIX 2*)
- 10 mg/ml sonicated salmon sperm DNA (*UNIT 2.10*; denature 10 min at 94°C before adding to hybridization mix)

**BASIC
PROTOCOL 2**

**In situ
Hybridization
and Immuno-
histochemistry**

14.8.11

10% (w/v) SDS
Slide containing ISPCR-amplified nucleic acids (see Basic Protocol 1 or see Alternate Protocol)
Diluted Kodak emulsion (UNIT 14.4)
Kodak D19 developer
Kodak Unifix fixer
2% Gills hematoxylin (Sigma)
PBS (APPENDIX 2)
Streptavidin-peroxidase conjugate working solution (see recipe)
AEC working solution (see recipe)
Blocking solution (see recipe)
Streptavidin-alkaline phosphatase conjugate working solution (see recipe)
100 mM Tris·Cl, pH 7.5 (APPENDIX 2)/150 mM NaCl
Alkaline phosphatase substrate buffer (see recipe)
75 mg/ml nitroblue tetrazolium (NBT) in 70% (v/v) dimethylformamide
50 mg/ml 5-bromo-4-chloro-3-indolyl phosphate (BCIP) in 100% dimethylformamide
Nuclear fast red stain (Sigma)
50%, 70%, 90%, and 100% (v/v) ethanol
50% (v/v) glycerol in PBS
Mounting medium, water-based (e.g., CrystalMount; Stephens Scientific or GelMount; Biomed) or organic-based (e.g., Permount; Fisher)
20 × 60-mm glass coverslips
95°C heating block accommodating glass slides
48°C incubator
Moist chamber (UNIT 14.2)
Light-tight slide box
Dessicant
Coplin jars or glass staining dishes

NOTE: All washes and incubations are performed at room temperature unless otherwise noted.

1. Prepare the following hybridization mix:
 - 2 μ l 200 pM probe (20 pM final)
 - 50 μ l deionized formamide (50% final)
 - 10 μ l 20 \times SSC (2 \times final)
 - 10 μ l 100 \times Denhardt solution (10 \times final)
 - 10 μ l 10 mg/ml sonicated salmon sperm DNA (1 mg/ml final)
 - 1 μ l 10% SDS (1% final)
 - 7 H₂O.
2. Add 10 μ l hybridization mix to each well of slide containing ISPCR-amplified nucleic acids. Cover wells with coverslips and heat slide 5 min on a 95°C heating block.
3. Incubate slides 2 to 4 hr at 48°C in a moist chamber.

The optimal hybridization temperature is a function of the T_m (melting temperature) of the probe, which must be calculated for each probe. See Strategic Planning, discussion of optimization of annealing temperature. However, the hybridization temperatures used should not be too high. If it is necessary to use a very high hybridization temperature, 40% formamide should be substituted for 50% formamide in the hybridization mix in step 1 (see UNIT 14.3, Commentary).

For ³³P-labeled probe

- 4a. Remove coverslips and wash slide in 2× SSC for 5 min.
- 5a. Dip slides in diluted Kodak emulsion.
- 6a. Air dry slides, then incubate 3 to 10 days in light-tight slide box with a dessicant.
- 7a. Develop slides in darkroom as follows:
 - 3 min in Kodak D19 developer
 - 30 sec rinse in H₂O
 - 3 min in Kodak Unifix fixer.
- 8a. Counterstain slide by incubating 2 to 3 min in 2% Gills hematoxylin in a Coplin jar at room temperature.

The slide is now ready for viewing; omit steps 9 to 11.

For peroxidase-based detection of biotin- or digoxigenin-labeled probe:

- 4b. Remove coverslips and wash slide twice in PBS, immersing for 5 min each time.
- 5b. Add 10 μl 100 μg/ml streptavidin-peroxidase to each well of slide. Gently cover wells with new coverslips and incubate 1 hr at 37°C.
- 6b. Remove coverslip and wash slides twice in PBS, immersing 5 min each time .
- 7b. In the dark, add 100 μl AEC working solution to each well of slide. Incubate 10 min at 37°C, then observe slides under microscope; if color is not strong, develop another 10 min.
- 8b. Rinse slide with tap water, then allow to dry.

Positive cells will appear brownish-red under the microscope.

For alkaline phosphatase-based detection of biotin- or digoxigenin-labeled probe

- 4c. Remove coverslips and wash slides twice in 2× SSC, immersing 15 min each time at room temperature, then cover surface of each well with 100 μl blocking solution. Place slide flat in moist chamber and incubate 15 min at room temperature.
- 5c. For each well to be developed, mix 10 μl of 40 μg/ml streptavidin-alkaline phosphatase conjugate with 90 μl conjugate dilution buffer.
- 6c. Remove blocking solution by touching absorbent paper to edge of slide. Cover surface of each well with 100 μl of the diluted conjugate solution prepared in step 5c. Place slide flat in moist chamber and incubate in 15 min at room temperature.

Do not allow the tissue sample to dry after adding the conjugate.

- 7c. Wash slides twice in 100 mM Tris-Cl, pH 7.5/150 mM NaCl, 15 min each time at room temperature, then wash once more in alkaline phosphatase substrate buffer, 5 min at room temperature.
- 8c. Prewarm 50 ml alkaline phosphatase substrate buffer to 37°C in a Coplin jar. Add 200 μl 75 mg/ml NBT and 166 μl of 50 mg/ml BCIP. Mix well, then incubate slides at 37°C in this solution at 37°C until desired level of signal is achieved (usually 10 min to 2 hr; check color development periodically by removing slide from solution and examining under 10× objective without allowing slide to dry), then stop reaction by rinsing slides in several changes of deionized water.

Be careful not to allow specimen to dry when removing slides to check color development.

Counterstain and mount slide (for nonisotopic probes only)

9. Stain slide for 5 min at room temperature in either 0.2% Gills hematoxylin (if peroxidase-based color development was used) or in 1% nuclear fast red stain (if alkaline phosphatase-based color development was used). Rinse slide in several changes of tap water.
10. Dehydrate slide by incubating 1 min at room temperature successively in 50%, 70%, 90%, and 100% ethanol. Air dry at room temperature.
11. Mount slide by applying one drop mounting medium per well and covering with a coverslip. View immediately, taking care not to disrupt the coverslip, or allow mounting medium to dry overnight at room temperature.

**SUPPORT
PROTOCOL 1**

PREPARATION OF AES-SUBBED SLIDES

Teflon-coated glass slides with wells are treated with 3-aminopropyltriethoxysilane (AES), rinsed extensively, and dried before use. The Teflon coating serves to form distinct wells, each of which serves as a small reaction chamber for in situ PCR (Basic Protocol 1) when covered with a coverslip and sealed with nail polish. The Teflon coating also helps to keep the nail polish from entering the reaction chamber. Use of slides with multiple wells allows for both a positive and negative control on the same slide. See Critical Parameters for further considerations regarding choice of slides.

Materials

Teflon-coated glass slides with three 10-, 12-, or 14-mm wells for cell suspensions or single oval well for tissue sections (Cel-Line Associates and Erie Scientific)
2% (v/v) 3-aminopropyltriethoxysilane (AES; Sigma) in acetone (prepare in Coplin jar or glass staining dish immediately before use)
DEPC-treated H₂O (UNIT 4.1)

Coplin jars or glass staining dishes
Vessel accommodating 1000 ml of liquid

1. Dip Teflon-coated glass slides in 2% AES for 5 min, then allow to dry 10 to 15 min at room temperature.
2. Dip slides for five min in a separate vessel containing 1000 ml of DEPC-treated water.
3. Repeat step 2 three times using three changes of DEPC-treated water, then air dry in laminar-flow hood overnight.

Slides should be used within 15 days of subbing.

**SUPPORT
PROTOCOL 2**

PREPARATION OF SPECIMENS ON SLIDES FOR ISPCR

Paraffin-Fixed Tissue

Routinely prepared paraffin-fixed tissue sections (UNIT 14.1) can be amplified quite successfully, permitting evaluation of individual cells in the tissue for the presence of a specific RNA or DNA sequence (Greer et al., 1991a,b). Specially designed slides that have single wells and that have been subbed with 3-aminopropyltriethoxysilane are used for this purpose (see Support Protocol 1). The authors routinely use sections of placental, CNS, cardiac, and similar tissues that have been sliced to a 3- to 5- μ m thickness. Other laboratories prefer to use sections up to 10- μ m thickness, but in the authors' experience, amplification is often less successful with thicker sections as multiple cell layers can often lead to difficult interpretation resulting from superposition of cells. However, if tissues that contain particularly large cells are being studied—e.g., ovarian follicles—thicker

sections may be appropriate and even desirable.

Plastic Sections

In situ amplification can be performed successfully on plastic sections (see Pereira et al., 1995 for plastic section technique). First, plastic-sectioned tissue must be deplasticized to remove methyl methacrylate by incubating in four successive baths of fresh methyl celuloacetate ether (MCA; Sigma) for 15 min each time, then in three successive baths of fresh acetone for 10 min each time, and then in multiple baths of xylene up to 4 hr each time. After this, the tissue is fixed in 4% paraformaldehyde (*UNIT 14.1*), and the in situ procedure is performed as with other tissue preparations (R. Boyce, pers. comm.).

Frozen Sections

It is possible to use frozen sections for in situ amplification, but the morphology of the tissue following the amplification process is generally not as good as with paraffin sections (see above). It seems that the freezing of the tissue, combined with the lack of paraffin substrate during slicing, compromises the integrity of the tissue. Usually, thicker slices must be made, and the tissue “chatters” in the microtome. As any clinical pathologist will relate, definitive diagnoses are made from paraffin sections, and this rule of thumb seems to apply to ISPCR as well. The exception to the rule is when immunohistochemical techniques are to be used for detecting additional signals in the cells (see Background Information) as certain immunohistochemical techniques require frozen sections.

To use frozen sections, the first step is to freeze the tissue properly (*UNIT 14.2*). For this purpose cut a 1 × 1–mm piece of styrofoam from a sheet (or a cup if a sheet is not available). Cut a piece of tissue about the same size (1 × 1–mm; 0.2- to 0.3-mm thickness), attach it to the styrofoam with ~2 to 4 ml of OCT solution (*UNIT 14.2*) and immerse the whole specimen attached to the styrofoam in liquid nitrogen in an insulated vessel. The tissue will freeze in few seconds. The frozen tissue can then be mounted in a cryostat and cut with a microtome (*UNIT 14.2*) or frozen at –70°C for future use. This method prevents the formation of icicles in the tissues and preserves the morphology much better than simply storing the tissue in a deep freeze. If liquid nitrogen is not available, the tissue (with styrofoam and OCT) may be wrapped in aluminum foil and placed on dry ice for 10 to 15 min before being stored in the deep freeze. As thin a slice as possible (3 to 4 μm) should be cut during sectioning. This is then applied to an AEC-subbed slide (see Support Protocol 1), dehydrated for 10 min in 100% methanol, and air dried in a laminar-flow hood.

Cell Cultures

ISPCR has been successfully performed by the authors on cells cultured on either 4 or 8-well Nunc slides (VWR Scientific) or AES-subbed Teflon ISPCR slides (see Support Protocol 1). If Nunc slides are used, 4- or 8-well slides with a glass base should be selected because plastic-base slides will melt during thermal cycling. This type of slide has a rubber gasket that should be left on, but the coverslip will not fit unless some protruding portions of the gasket are shaved off. Also, in the author’s laboratory, the stability of these gaskets is reinforced by applying a layer of nail polish at the junction of the gasket and the glass base. Aside from these modifications, the Nunc slides can be processed like the Teflon slides (they need not be AES-subbed, but can be subjected to thermal cycling in the PTC-100 thermal cycler). It should be noted that occasional leakage occurs in these slides. AES-subbed Teflon slides may also be used for tissue culture. They should be sterilized after silanization by incubating 30 min in 70% ethanol. Cells can be then placed on these slides and cultured overnight in a sterile humidified box. After this, the cells may be fixed as in *UNIT 14.1* and subjected to ISPCR.

LABELING OLIGONUCLEOTIDE PROBES USING ³³P

³³P-labeled probes are preferable for isotopic in situ hybridization (ISPCR) to avoid possible contamination of the thermal cycler with the more hazardous ³²P. Oligonucleotides are easily labeled with ³³P using polynucleotide kinase.

Materials

- 2 μM oligonucleotide probe (see Strategic Planning)
- 10× T4 polynucleotide kinase buffer (*UNIT 3.4*)
- 10 μCi/μl [γ -³³P]ATP (10 Ci/mmol; Amersham)
- 10 U/μl T4 polynucleotide kinase
- 0.8-ml Sephadex G-50 column (e.g., QuickSpin, Boehringer Mannheim)
- TE buffer, pH 7.4 (*APPENDIX 2*)

Additional reagents and equipment for labeling with T4 polynucleotide kinase (*UNITS 3.4 & 3.10*)

1. Make up the following reaction mix in a microcentrifuge tube (20 μl total volume):
 - 1.0 μl 2 μM oligonucleotide probe
 - 2 μl 10× polynucleotide kinase buffer
 - 1.0 μl 10 μCi/μl [γ -³³P]ATP
 - 15 μl H₂O
 - 1 μl 10 U/μl T4 polynucleotide kinase.

Incubate 30 min at 37°C.

2. Apply reaction mix to an 0.8-ml Sephadex G-50 column. Elute with TE buffer, and collect fractions at the following volumes:

Fraction 1	300 μl
Fraction 2	100 μl
Fraction 3	100 μl
Fraction 4	100 μl
Fraction 5	100 μl
Fraction 6	100 μl.

3. Count radioactivity in 1.0 μl of each fraction and identify those containing the labeled probe.

The labeled probe should be contained in fractions 2 through 4.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Acetate buffer, 50 mM (pH 5.0)

Add 74 ml of 0.2 M acetic acid (11.55 ml glacial acetic acid/liter) and 176 ml of 0.2 M sodium acetate (27.2 g sodium acetate trihydrate in 1 liter) to 1 liter of deionized water and mix.

AEC solution

Stock solution: Dissolve one tablet (20 mg) of 3-amino-9-ethylcarbazole (AEC; Sigma) in 2.5 ml *N,N* dimethylformamide. Store at 4°C in the dark up to 6 months.

Working solution: Add 250 μl stock solution to 5 ml of 50 mM acetate buffer, pH 5 (see recipe), then add 25 μl 30% H₂O₂. Make fresh before each use; keep solution in the dark.

Alkaline phosphatase substrate buffer

100 mM Tris·Cl, pH 9.5 (APPENDIX 2)
150 mM NaCl
50 mM MgCl₂
Store at 4°C up to 3 months

AMV/MoMuLV reaction buffer, 10×

100 mM Tris·Cl, pH 8.3 (APPENDIX 2)
500 mM KCl
15 mM MgCl₂
Prepare fresh

Blocking solution

100 mM Tris·Cl, pH 7.8 (APPENDIX 2)
150 mM NaCl
50 mg/ml BSA
0.2 mg/ml sodium azide
Prepare fresh

Chelating buffer, 10×

100 mM Tris·Cl, pH 8.3
1 M KCl
7.5 mM EGTA
0.5% Tween 20
50% (v/v) glycerol

Conjugate dilution buffer

100 mM Tris·Cl, pH 7.3 (APPENDIX 2)
150 mM MgCl₂
10 mg/ml BSA
0.2 mg/ml sodium azide
Prepare fresh

RNase-free DNase solution

40 mM Tris·Cl, pH 7.4 (APPENDIX 2)
6 mM MgCl₂
2 mM CaCl₂
1 U/μl RNase-free DNase (e.g., RQ1, Promega)
Prepare fresh

For use with cells that are particularly rich in RNase, add 1000 U/ml placental ribonuclease inhibitor (e.g., RNasin, Promega) and 1 mM DTT to the above solution.

Streptavidin–alkaline phosphatase conjugate solution

Stock solution: 40 μg/ml streptavidin–alkaline phosphatase conjugate (e.g., Life Technologies). Store at 4°C up to 8 months.

Working solution: For each well to be developed, dilute 10 μl stock solution with 90 μl conjugate dilution buffer (see recipe) immediately before use.

Streptavidin–peroxidase conjugate solution

Stock solution: 1 mg/ml streptavidin–horseradish peroxidase conjugate (e.g., Life Technologies) in PBS, pH 7.2 (APPENDIX 2). Store at 4°C.

Working solution: When stock solution is fresh (i.e., stored <1 month), dilute 1:100 in PBS, pH 7.2, to prepare working solution. Because the activity of the solution declines with prolonged storage, dilute 1:80 after 1 month of storage, 1:50 after 2 months of storage, and 1:30 after 3 months of storage. Discard after 4 months of storage.

COMMENTARY

Background Information

In situ hybridization, described in *UNIT 14.3* & *UNIT 14.7*, provides a critical and powerful means of determining the level of gene expression in individual cells and tissues, thereby allowing the investigator to assess and compare varying levels of gene expression within a population. A serious limitation of in situ hybridization, however, has been its inability to detect and quantitate target nucleic acid sequences present at levels below which the signal can be clearly distinguished from background. Use of the polymerase chain reaction (PCR) in conjunction with in situ hybridization (in situ PCR or ISPCR) has allowed specific amplification of previously undetectable sequences (Haase et al., 1990; Nuovo et al., 1991; Nuovo, 1994b; Bagasra et al., 1992, 1993a; Embretson et al., 1993a). Over the past several years, ISPCR has been used successfully by a number of research groups to identify the presence of targets that fall below the threshold of detection of traditional in situ hybridization. Thus, in situ amplification technology has been exploited to confirm the presence in specific cells of various subfamilies of retroviruses, including lentivirus (Haase et al., 1990) and HIV-1 (Bagasra et al., 1992; 1993b, Patterson et al., 1993, Nuovo et al., 1994). ISPCR has also been used to study elements involved in shifting an integrated virus from a latent to an infectious state (Chieu et al., 1992, Embretson et al., 1993a,b; Winslow et al., 1993; Bagasra and Pomerantz, 1993; Guatelli et al., 1994). Other applications of ISPCR include the detection of transcripts to facilitate the study of rearrangement of immunoglobulin heavy and light chain V-genes (Embleton et al., 1992), the variation in expression of cellular EGF receptor (Heniford et al., 1993; Patel et al., 1994), the expression of surfactant protein A and estrogen-receptor mRNA (Bibbo et al., in press), the expression of platelet factor XI mRNA (Hsu et al., 1994), and the localization of human and viral cDNAs (Nuovo et al., 1992; Mankowski et al., 1994).

Application of ISPCR in conjunction with electron microscopy (EM)

The authors' group at Thomas Jefferson University and another group at Uppsala University in Sweden have been developing techniques that make it possible to observe the results of ISPCR under an electron microscope. The procedure used by the authors is a simple modification of the immunogold EM

technique (Hacker et al., 1994). First, in situ amplification is carried out in solution rather than with the cells or tissue attached to a glass slide. The cells or tissue that have been subjected to ISPCR are then fixed in 4% paraformaldehyde for 4 hr (see *UNIT 14.1*), washed in PBS, and treated with proteinase K (see Basic Protocol 1). As in Basic Protocol 1, the cells are observed under an optical microscope for the development of "bubbles" or "peppery dots" (Fig. 14.8.3). Amplification of DNA or RNA is then carried out as described in Basic Protocol 1. To check the results, a small aliquot of the cells is sampled and placed on a slide, then in situ hybridization is performed with the specific biotinylated probe and an unrelated biotinylated probe as a negative control. Color is developed with streptavidin-peroxidase or streptavidin-alkaline phosphatase. If color develops with the specific probe but not the non-specific control, immunolabeling can be performed with the remaining cells. To do this, cells are first hybridized with biotinylated probe(s) and then labeled with streptavidin-immunogold conjugate. After 1 hr of incubation at 37°C, the cells are washed extensively to remove unbound conjugate, then pelleted by centrifugation. The cell pellet is incubated with freshly prepared 2.5% glutaraldehyde and processed for EM work. EM grids can also be used as the substrate for the cells or tissues. If used, the grid is placed between two slides and in situ amplification is performed as described above. Labeling with biotin/streptavidin-immunogold is then carried out. In the authors' laboratory, it has been found that the harsh treatment inflicted by repeated denaturation tends to destroy the internal organelles of cells. However, clear signals can be detected in the perinuclear areas.

Application of ISPCR in conjunction with immunohistochemistry

Immunohistochemistry to detect proteins (e.g., surface antigens) and in situ amplification to detect corresponding DNA sequences and RNA transcripts can be performed simultaneously in a single cell. In the authors' laboratory, cells or frozen sections of tissue, already attached to slides, are fixed with 100% methanol for 10 min and washed in PBS. Labeling of surface antigen(s) can then be carried out by standard immunohistochemical methods—i.e., the cells are incubated with unconjugated antibody for 1 hr at 37°C, washed, and fixed in

4% paraformaldehyde for 2 hr (see UNIT 14.6). To further facilitate these analyses, immunohistochemistry panels have been compiled tabulating specific surface antigens that will still bind specific FITC-conjugated monoclonal antibodies even after treatment with 10% formalin and similar reagents used in histopathology laboratories. It is possible, therefore, to use routinely prepared paraffin sections for the detection of such cellular antigens. In addition to the immunohistochemical detection of the antigens, in situ amplification is carried out as described in Basic Protocol 1. The amplified product is hybridized and detected as in Basic Protocol 2. At this point, secondary antibody conjugated with FITC, rhodamine, or another appropriate label may be applied. After a 1 hr incubation, the slides are washed and the cells or tissue are viewed under UV and visible light in an alternate fashion, to detect both the immunohistochemical and ISPCR/hybridization signals in a single cell.

Detection of multiple signals and multiple labels in individual cells

DNA, mRNA, and protein can all be detected simultaneously in individual cells. As described above, it is possible to label proteins with FITC-labeled antibodies, then perform in situ amplification of both RNA and DNA in the cells. If primers are used for spliced mRNA, which will not bind any sequences in DNA (see Strategic Planning), then both DNA amplification by ISPCR and RNA amplification by in situ reverse transcription/amplification can be carried out simultaneously. Subsequently, the products can be detected by hybridizing with differentially labeled probes that result in different-color signals (Komminoth et al., 1992). For example, proteins can show a rhodamine signal, mRNA can show a fluorescent FITC (20 colors of rhodamine-conjugated probe are available), and DNA can be labeled with a biotinylated probe and detected with peroxidase or phosphatase as in Basic Protocol 2. Each label will show a different signal within an individual cell.

Direct incorporation of nonisotopically labeled nucleotides into amplification products

Several nonisotopically labeled nucleotides are available from various sources—e.g., dCTP-biotin and digoxigenin-11-dUTP. By incorporating them into the ISPCR cocktail (see Basic Protocol 1) these nucleotides can be used to directly label amplification products—as an

alternative to the in situ hybridization steps (see Basic Protocol 2). The proper secondary reagents and chromogens can then be used to detect the directly labeled in situ amplification products. However, in the opinion of the authors—as well as in the opinion of several other investigators—the greatest specificity is achieved only by conducting amplification followed by subsequent in situ hybridization with the specific probe or probes. In the protocols used for labeling with nonisotopically labeled nucleotides, nonspecific incorporation can be significant, and even if this incorporation is minor, it still leads to false-positive signals similar to nonspecific bands that appear in gel electrophoresis following solution-based DNA amplification or RNA reverse transcription/amplification. Therefore, direct incorporation of labeled nucleotides as part of an in situ amplification protocol is strongly discouraged.

The only exception to this recommendation is when a large number of primer pairs is being screened for optimization of a specific assay. In that case, direct incorporation of labeled nucleotides may be useful. To perform such screenings, 4.3 μM labeled nucleotide—either biotin-14-dCTP, biotin-14-dATP, or digoxigenin-11-dUTP—is added along with the non-labeled 4dNTPs to achieve a 0.14 mM total nucleotide concentration.

Critical Parameters and Troubleshooting

Choice and treatment of slides

Choice and treatment of slides is critical to the success of the protocol (also see Support Protocol 1). Glass slides that are partially covered by a Teflon coating should always be used. Not only does glass withstand the stress of thermal cycling, but it also presents the right chemical surface—silicon oxide—needed for proper silanization. Slides with special Teflon coatings that form individual wells are useful because vapor-tight reaction chambers can be formed on the surface of the slides when coverslips are attached with coatings of nail polish around the periphery. These reaction chambers are necessary because within them, proper tonicity and ion concentrations can be maintained in aqueous solution during thermal cycling—conditions that are vital for proper amplification. The Teflon coating serves a dual purpose in this regard. First, the Teflon helps keep the glass surfaces of the slide and coverslip slightly separated, allowing reaction chambers ~20- μm in height to form in between. Second,

the Teflon border helps keep the nail polish from entering the reaction chambers when being applied. This is important because any leakage of nail polish into a reaction chamber can compromise results.

Normally, glass slides are silanized to make the slide surface hydrophobic. However, AES treatment (see Support Protocol 1) has a very different surface effect. This silicon compound imparts a strong, persistent, positive electrical charge to the slide by forming an aminopropyl derivative of glass at the surface of the slide. The resulting positive charge—and electrostatic attraction—causes the cells or tissues to adhere with great tenacity throughout the amplification/hybridization procedure. Experiments have been conducted using slides coated with alternative adhesives including white glue, albumin, chrome-gelatin, and poly-L-lysine. For slides prepared using alternative subbing techniques, however, the authors have found that slides treated with AES result in superior tissue adhesion and lower background with all tissue types tested, including mixed-cell suspensions, paraffin sections, and frozen sections. The authors hypothesize that this adhesion occurs because the negatively charged molecules on membrane surfaces bond ionically to the positively charged surface of the glass when the cells or tissues are initially placed on the slide. However, the limited positive charge is probably lost rather quickly, so later in the procedure, when solutions containing additional negatively-charged molecules are added, the new molecules float freely without becoming bound to the slide surface.

Optimizing proteinase K digestion

In the authors' laboratory, proper proteinase K digestion parameters (also see Basic Protocol 1) vary considerably with tissue type. Typically, lymphocytes require 5 to 10 min at 25°C or room temperature, CNS tissue requires 12 to 18 min at room temperature, and paraffin-fixed tissue requires between 15 to 30 min at room temperature. However, these time periods can vary widely and the appearance of the "salt and pepper dots" (see Fig. 14.8.3 and Fig. 14.8.4) is the important factor. Unfortunately, the appearance of the "salt and pepper dots" is less prominent in paraffin sections. Representative examples of "salt and pepper dots" on lymphocytes are illustrated in Figure 14.8.4. The critical importance of these dots should not be underestimated, as an extra 2 to 3 min of treatment after the appearance of dots will result in

leakage of signals. An alternative to the observation of "dots" is to select a constant time and treat slides with varying amounts of proteinase K—15 min using a range of from 1 to 6 µg/ml proteinase K.

The authors have also experimented with the use of other proteinases—e.g., amylase, trypsin, pronase, pepsinogen, and pepsin—instead of proteinase K. This has proven successful in many circumstances—e.g., incubation of slides for with 1 mg/ml pepsinogen for 10 min at pH 2.0. However, proteinase K has almost always been found to give better overall results.

Considerations for amplification

Attaching coverslip (or top slide). To ensure that a small, completely closed reaction chamber is formed to contain water vapor during thermal cycling, nail polish must be evenly distributed around the periphery of the coverslip or edges of the slide. For effective sealing, do not use colored nail polish or polish that is especially "runny"—the authors prefer to use "Wet & Wild" clear nail polish (Procter & Gamble). Proper sealing is very important in keeping reaction concentrations consistent through the thermal cycling procedure, which is critical to proper amplification. However, it is necessary to apply the nail polish very carefully so that none gets into the actual chamber where the cells or tissues reside. If any nail polish does enter the chamber, that slide should be discarded as the results will be questionable. Sealing the coverslip with nail polish is truly a learned skill; therefore, it is strongly recommended that researchers practice this procedure several times with mock slides before attempting an experiment. Where tissue sections are used for ISPCR, it is best to use another, identical blank slide to cover the specimen instead of a coverslip. This is done by applying the amplification cocktail to the appropriate well of the blank slide (a modification to Basic Protocol 1, step 11), placing the inverted tissue-containing slide (prepared as in Basic Protocol 1, steps 1 to 9) atop the blank slide, and sealing the edges with nail polish as described in Basic Protocol 1, step 12. The slide is then inverted once again so that the tissue-containing slide is on the bottom. A videotape illustrating this procedure is available from TAO Biomedical.

Hot-start PCR. There is much debate as to whether a "hot start" (see UNIT 15.1) helps to improve the specificity and sensitivity of ISPCR amplification reactions. In the authors'

Figure 14.8.5 In situ reverse transcription/polymerase chain reaction using FITC-labeled (*tat-rev*) probes for HIV-1 expression in lymphocyte cell line chronically infected with HIV-1. Note cytoplasmic staining showing HIV-1 mRNA expression.

Figure 14.8.6 DNA-ISPCR of HIV-1-infected microvascular endothelial cell line. HIV-1 provirus gag sequence is amplified with an SK-38/39 primer pair and hybridized with a biotinylated SK-19 probe. Color was developed with AEC (see Basic Protocol 2) resulting in a red color.

laboratory this variation has been found to add no advantage; rather, it adds only technical difficulty to the practice of ISPCR. Recently, however, a variation of the hot-start method has been reported (Nuovo, 1994b) that essentially serves the same function without its difficulties. In this procedure, anti-*Taq* DNA polymerase antibody is used in the PCR cocktail to block *Taq* DNA polymerase activity until the first cycle of 94°C, at which temperature the antibody becomes denatured and full *Taq* DNA

polymerase activity is restored.

Thermal cyclers. Various types of thermal cyclers will work in this application; however, some work much better than others. The authors use two types: a standard, block-type thermal cycler that normally holds 60 0.5-ml tubes, but which can be adapted to hold 4 to 6 slides by use of aluminum foil, paper towels, and a weight. The authors also use dedicated thermocyclers that are specifically designed to hold 16 slides. Other laboratories have used

stirred-air, oven-type thermal cyclers quite successfully; however, problems with the cracking of glass slides during cycling have been reported. Thermal cyclers dedicated to glass slides are now available from several vendors, including Barnstead Thermolyne of Iowa, Coy Corporation of Minnesota, Hybaid of England, and MJ Research of Massachusetts. The authors' laboratory has used an MJ Research PTC-100-16MS quite successfully.

Several manufacturers of thermal cyclers, as well as suppliers of labeled nucleotides, have reported contamination problems associated with a chemical breakdown product from ^{35}S -labeled nucleotides. It is hypothesized that when these particular compounds are subjected to high temperatures, a gaseous, radioactive breakdown product forms—possibly $\text{H}_2[^{35}\text{S}]$ —which leaks from the sample vessel. This can lead to contamination of the incubating device and possibly the air in the laboratory. Therefore, for labeling probes, use of nucleotides labeled with the newer phosphorus isotope, ^{33}P , rather than ^{35}S is recommended. Biotin or digoxigenin labeling is another alternative.

It is suggested that the manufacturer's instructions on the use of a particular thermal cycler be followed, and that several additional points be kept in mind. First, glass does not easily make good thermal contact with the surface on which it rests. Therefore, a weight to press down the slides and/or a thin layer of mineral oil to fill in the space between the bottom of the slide and the heating surface will help thermal conduction. If mineral oil is used, the oil should be well-smearred over the bottom surface of the slide so that it is not merely floating on air bubbles beneath it. Second, the top surfaces of slides lose heat quite rapidly through radiation and convection; therefore, a thermal cycler should be selected that envelops the slide in an enclosed chamber (as in some dedicated instruments), or else the tops of the slides should be insulated in some manner. Insulation is particularly critical when using a weight on top of the slides because the weight can serve as an unwanted heat sink if it is in direct contact with the slides. Third, good thermal uniformity is imperative for good results—poor uniformity or irregular thermal change can result in cracked slides, uneven amplification, or completely failed reactions. If adapting a thermocycler that normally holds plastic tubes, a layer of aluminum foil should be used to spread out the heat.

In the authors' laboratory it has been ob-

served that most dedicated thermal cyclers do not transfer heat in an even manner to all parts of the thermal cycler block. The authors therefore recommend use of either the PTC-100-16MS or the newly designed "DNA Engine" (PTC-200 with slide block), both from MJ Research.

Anticipated Results

Amplification products can be detected and identified in the cytoplasm and in nuclear regions using fluorescent, colorimetric, or isotopic probes. Figure 14.8.5 shows results of *in situ* reverse transcription and amplification using FITC-labeled probes to detect HIV-1 expression in lymphocytes. Figure 14.8.6 confirms the presence of HIV-1 sequences in microvascular epithelial cells (MVEC) as determined by DNA ISPCR.

Time Considerations

The time required for preparing slides of tissue samples is as described in *UNITS 14.1 & 14.2*. Basic Protocol 1 requires ~8 hr of laboratory work in addition to the time required for thermal cycling, which is performed overnight. After amplification and hybridization, detection and visualization of the products requires ~1.5 hr of laboratory work. More time, up to 12 hr, is required for detection of a radiolabeled probe.

Hybridization (Basic Protocol 2) takes 4 to 18 hr. AES-subbing of slides and preparation of probes (Support Protocols 1 and 3) should take 1 hr each.

Whole-Mount In Situ Hybridization and Detection of RNAs in Vertebrate Embryos and Isolated Organs

The spatial and temporal distribution of transcripts (e.g., during embryogenesis) provides important clues to possible functions of the encoded gene products and/or possible interactions with other genes.

The whole-mount in situ hybridization method, first introduced by Tautz and Pfeifle (1989) and applied to *Drosophila* embryos, has been extended to vertebrate embryos: *Xenopus* (Harland, 1991; Franco et al., 1999), zebrafish (Schulte-Merker, 1993), and mouse and chicken (Wilkinson, 1993). Given the complex anatomy of embryos, the method simplifies detection and interpretation of gene expression patterns, especially for genes with graded or dynamic distribution. This method circumvents the tedious detection of RNA hybrids by emulsion autoradiography (UNIT 14.4) and subsequent reconstruction of their three-dimensional distribution.

Whole-mount in situ hybridization using digoxigenin-labeled riboprobes is probably the most commonly used method to detect RNA transcripts in intact embryos or isolated organs (see Basic Protocol 1 and Alternate Protocol 1). The hybrids are subsequently detected with anti-digoxigenin antisera conjugated to alkaline phosphatase and immune complexes are visualized by an enzymatic reaction of alkaline phosphatase with a chromogenic substrate (see Basic Protocols 2 and 4 and Figs. 14.9.1, 14.9.2, and 14.9.3).

The methods described in this unit are based on procedures by Riddle et al. (1993) and Wilkinson (1993). They have been used successfully for the detection of mRNAs in mouse and chicken embryos. The methods are also applicable to experimentally manipulated embryos—e.g., for detection of transcripts in mouse tissue grafted to chicken embryos (Haramis et al., 1995).

Whole-mount in situ hybridization of *Xenopus* embryos requires different pretreatment, hybridization, and detection conditions because these embryos are yolk-rich and prone to high background (see Basic Protocols 3 and 4). Both hybridizations use digoxigenin-labeled antisense RNA probes (riboprobes; see Support Protocol 2), and hybridizations with mouse and chicken embryos use anti-digoxigenin antibody that will be preabsorbed with embryonic powder to reduce nonspecific binding of the detecting antibody to embryonic tissue (see Support Protocol 1).

CAUTION: Paraformaldehyde, formaldehyde, methanol, hydrogen peroxide, glutaraldehyde, formamide, NBT, BCIP, and DEPC are hazardous. Please consult manufacturer's guidelines for their proper handling and disposal.

NOTE: All solutions should be treated with diethylpyrocarbonate (DEPC, see UNIT 4.1) and autoclaved to inhibit RNase activity.

NOTE: The samples should always be kept covered with liquid to avoid drying, which causes high levels of background staining. Therefore, when exchanging solutions, always leave the sample covered by a small quantity of liquid. This also prevents physical damage or loss of samples.

WHOLE-MOUNT IN SITU HYBRIDIZATION WITH MOUSE OR CHICKEN EMBRYOS AND ORGANS

Mouse or chicken embryos or organs are isolated and fixed to preserve their morphology, then pretreated to make the target transcripts accessible to the riboprobe. The pretreatments and prehybridization block nonspecific binding sites, thus reducing nonspecific hybridization of riboprobes and background staining during enzymatic detection of RNA hybrids. Finally, the sample is hybridized to digoxigenin-labeled riboprobe (see Support Protocol 1) and visualized using an enzyme-conjugated antibody to digoxigenin.

Materials

Mouse or chicken embryos or organs
PBS (APPENDIX 2), ice-cold
4% (w/v) paraformaldehyde in PBS (4% PFA; UNIT 14.1), 4°C
PBT (also see recipe): 0.1% or 1% (v/v) Tween 20 in PBS, 4°C and room temperature
25%, 50%, and 75% methanol in PBT (methanol/PBT)
100% methanol
6% (v/v) hydrogen peroxide (H₂O₂; Aldrich) in PBT (optional)
10 µg/ml proteinase K in PBT, not predigested
2 mg/ml glycine (Merck) in PBT, freshly prepared
0.2% (v/v) glutaraldehyde (EM grade, Sigma)/4% (w/v) paraformaldehyde in PBT, freshly prepared
Hybridization solution (see recipe)
Hybridization solution containing 1 µg/ml digoxigenin-labeled riboprobe previously denatured (see Support Protocol 1)
Dissecting tools (e.g., scissors and forceps), wiped with 70% ethanol
Dissecting microscope
6-well culture plate with polycarbonate membrane inserts
1.5- to 2-ml microcentrifuge tubes
Heating block with adapter to hold 2-ml microcentrifuge tubes
Rocker platform

NOTE: All washes are carried out in 10 ml (6-well culture plates with polycarbonate membrane insert) or 1.5 to 2 ml (2-ml microcentrifuge tubes) of solution at room temperature with gentle agitation, unless stated otherwise. Solutions should be warmed to the indicated temperature before use.

Fix sample

1. Dissect mouse or chicken embryo in ice-cold PBS using appropriate dissecting tools and a dissecting microscope, if necessary. Completely remove the extraembryonic membranes and the amnion. Open cavities.

Riboprobes and antibodies that are trapped in embryonic cavities are one of the major causes of nonspecific signals. Therefore, it is important to open (i.e., pierce) cavities such as heart chambers and brain ventricles before or after fixation; this is particularly necessary for mouse embryos older than embryonic day 10 or chicken embryos older than embryonic stage 20. For advanced embryos (i.e., mouse embryos from embryonic day 14 or later) or postnatal stages, it is necessary to isolate the organs or tissues of interest to achieve best results.

Extraembryonic membranes can be stored up to 6 months at -80°C and used for preparation of genomic DNA (UNIT 2.2). DNA is used to genotype embryos by PCR (UNIT 15.1) or Southern blot hybridization (UNITS 2.9 & 2.10).

2. Transfer the sample into a 6-well culture plate containing ~10 ml of cold 4% PFA. Fix 4 hr to overnight at 4°C.

If desired, it is possible to fix several samples in one well of a 6-well culture plate with an excess of fixative. In general, fixation time (from 4 hr to overnight) is not critical and does not affect signal strength.

The 4% PFA can be prepared (UNIT 14.1) and stored frozen in aliquots at -20°C. Each aliquot should be thawed and used once.

3. Wash sample two times in PBT at 4°C.

For mouse embryos, it is recommended that all solutions contain 1% Tween 20 rather than 0.1%. Tween 20 is routinely used at 0.1% for the chick protocol.

It is advisable to perform the dehydration, rehydration, and bleaching steps (steps 4 to 8) even if the embryos are to be used immediately and not stored. The authors have found that these steps improve permeabilization of the tissues and increase the sensitivity of the method. Alternatively, the embryos can be stored in 1% PFA at 4°C for several weeks, and processed directly from step 8 onwards.

4. Dehydrate sample by successive washes in 25%, 50%, and 75% methanol/PBT at room temperature for 5 min each. Finally, wash two times in 100% methanol.

The samples can be stored in 100% methanol up to 6 months at -20°C. Alternatively, the samples can be processed to step 14 and then stored at -20°C.

Pretreat sample

5. Rehydrate sample using a reverse order of the methanol/PBT series from step 4 and wash two times in PBT at room temperature for 5 min.

6. Bleach sample with 6% hydrogen peroxide in PBT for 1 hr at room temperature.

See Critical Parameters and Troubleshooting for further discussion.

7. Wash sample three times in PBT for 5 min each.

Treat with proteinase K

Proteinase K digestion removes proteins, unmasks the target RNA, and helps to permeabilize the tissues, allowing the riboprobe to access its target mRNAs during hybridization (step 15). Two parameters can be manipulated: the concentration of proteinase K and/or the length of treatment. Use the following information as a guideline.

- 8a. *For chick embryos:* Digestion conditions indicate stage, concentration of proteinase K, and incubation time:

<10	1 to 3 µg/ml	15 min
10 to 18	10 µg/ml	15 min
18 to 24	10 µg/ml	20 to 25 min
26 to 29	10 µg/ml	up to 40 min

- 8b. *For embryos at stage 26 and older:* Increase the concentration of proteinase K while keeping the incubation time constant at 15 min:

26 to 27	20 µg/ml
28 to 29	30 µg/ml
30 to 31	40 µg/ml
32 and older	50 µg/ml

These conditions are an alternative treatment to step 8a. They may be used for late-stage embryos that are very difficult to permeabilize. A higher proteinase K concentration reduces the incubation time, which at these stages, should be >1 hr.

8c. *For mouse embryos:* Incubate in 10 µg/ml proteinase K. Modify the incubation time as embryo age in day post-coitum (dpc) increases, as follows:

6.5 dpc	4 min
7.5 dpc	4 to 5 min
8.5 dpc	6 min
9.5 dpc	10 min
10.5 dpc	15 min
11.5 to 12.5 dpc	20 min
13.5 to 14.5 dpc	30 min

9. Stop digestion by washing 10 min in freshly prepared 2 mg/ml glycine in PBT.

10. Wash two times for 5 min each in PBT.

Postfix and hybridize sample

11. Postfix sample with freshly prepared 0.2% glutaraldehyde/4% paraformaldehyde in PBT for 20 min at room temperature.

It is important that the 4% PFA used for this step is freshly prepared. Inclusion of 0.2% glutaraldehyde in the fixative is optional but seems to enhance the signal-to-noise ratio.

12. Wash three times in PBT for 5 min each.

For mouse embryos, a slow equilibration in hybridization solution is suggested. This approach has not been routinely used for chick embryos, but it could probably be used successfully.

13. Transfer the sample to a 1.5- to 2-ml microcentrifuge tube containing 1.5 ml of a 1:1 mixture of hybridization solution/PBT. Wash for 10 min at room temperature.

A small spoon or spatula can be used to transfer embryos.

Depending on sample size, more than one sample can be hybridized in a tube provided that the samples are completely submerged in solution. This facilitates direct comparative analysis of different samples.

14. Wash 10 min in hybridization solution.

The samples can be stored up to 6 months in hybridization solution at -20°C either before or after completing this step.

15. Incubate at 70°C in prewarmed hybridization solution for ≥1 to 3 hr.

16. Replace the hybridization solution with fresh hybridization solution containing 1 µg/ml digoxigenin-labeled riboprobe (previously denatured). Hybridize overnight at 70°C.

See Critical Parameters and Troubleshooting for suggestions on recommended hybridization temperatures.

Denatured probe in hybridization solution can be stored at -20°C and reused up to three times. Because the probe in the hybridization solution can be reused, the authors recommend that the samples be completely submerged in the microcentrifuge tubes to avoid any drying of the samples during the hybridization step.

BASIC PROTOCOL 2

ISH and Detection of RNAs in Vertebrate Embryos

14.9.4

ENZYMATIC DETECTION OF RNA HYBRIDS IN MOUSE AND CHICKEN EMBRYOS AND ORGANS

The antibody detection reaction can take 30 min for abundant messages, 3 to 4 hr for less abundant messages, or overnight to several days for rare messages. The reaction can be carried out at room temperature, in a 37°C warm room, or at 4°C. Each temperature will speed up (warm) or slow down (cold) the reaction as desired. To avoid background, do not overstain embryos. This protocol is preferred over Alternate Protocol 2 because it

contains fewer steps, which decreases the probability of damaging the samples. This protocol has been successfully used for most of the probes. Basic Protocol 2 may be used with Alternate Protocol 1.

Materials

Hybridized samples (see Basic Protocol 1)
Solution I (see recipe), 70°C
Solution II (see recipe), 65°C
TBST (also see recipe): 0.1% (chick) or 1% (mouse) (v/v) Tween 20 in TBS (see recipe for TBS)
Blocking solution for chick: 10% heat-inactivated sheep serum (see recipe) in TBST
Blocking solution for mouse: 10% heat-inactivated sheep serum (see recipe), 0.1% blocking reagent (see recipe) in TBST
Alkaline phosphatase–conjugated Fab fragments of anti-digoxigenin antibodies (Boehringer Mannheim), 4°C
Alkaline phosphatase buffer, pH 9.5 (NTMT; see recipe), freshly prepared
Reaction mix: 125 µg/ml BCIP and 250 µg/ml NBT in NTMT, pH 9.5
PBT buffer: 0.1% (chick) or 1% (mouse) Tween 20 in PBS
4% (w/v) paraformaldehyde in PBS (4% PFA; UNIT 14.1) with 0.1% glutaraldehyde
PBS (APPENDIX 2)
20%, 50%, and 80% glycerol/PBS solution
Rocker platform
Aluminum foil
6-well culture plate with polycarbonate membrane inserts

Perform post-hybridization washes, blocking, and antibody incubation

1. Hybridize samples (see Basic Protocol 1). Remove and keep (recycle) the hybridization solution containing the riboprobe. Prewarm solution I to 70°C and solution II to 65°C.

This riboprobe solution can be used up to three times and is stable for up to 2 years if kept at –20°C.

2. Wash embryos three times for 30 min each at 70°C with prewarmed solution I.
3. Wash embryos three times for 30 min each at 65°C with prewarmed solution II.
4. Wash three times with fresh TBST for 5 min each at room temperature.
5. For chick embryos, block with 10% heat-inactivated sheep serum in TBST for at least 1 hr at room temperature. For mouse embryos, block embryos by incubating at room temperature for 60 to 90 min in 10% heat-inactivated sheep serum and 0.1% blocking reagent in TBST.

Blocking solution for mouse takes a long time to solubilize. Prepare it early in the morning and heat at 37°C to help the dissolution.

6. Remove blocking solution from samples and add diluted (1:2000 to 1:10,000) alkaline phosphatase–conjugated Fab fragments of anti-digoxigenin antibody in 1% sheep serum/TBST solution. Incubate overnight at 4°C.
7. Remove and keep (recycle) the TBST solution containing the antibody.

Keep the antibody/TBST solution at 4°C, this antibody solution can be used up to three times.

8. Perform post-antibody washes by washing three times, 10 min each, in TBST at room temperature, then wash five times, 1 to 1.5 hr each, in TBST at room temperature. Finally, wash overnight in TBST at 4°C with gentle rocking on a platform rocker.

The purpose of the washes is to remove excess and nonspecifically bound antibody from the tissues to prevent nonspecific reaction with chromogenic substrate. For this step the samples can be transferred into a 6-well culture plate with polycarbonate membrane inserts. This will increase the volume of solution used for the washes and allow for better results.

The second group of five washes can be done over 2 days at 4°C—e.g., one wash in the morning and one wash at night each day with ice-cold TBST. The authors have found that longer washes result in less background during development.

Detect antibody

9. Wash hybridized samples three times for at least 10 min each (up to 1 hr) in 10 ml NTMT, pH 9.5.
10. Remove NTMT and add reaction mix. Allow the reaction to develop at the chosen temperature with gentle rocking. Throughout the development reaction, keep samples covered with aluminum foil to protect from light and periodically check to monitor progress of the reaction.

Do not hesitate to change the staining solution when it becomes purple.

11. When the reaction is judged to be complete, wash at least three times, 10 min each, in PBT buffer.

The reaction is judged to be complete when the appearance of a specific pattern of staining is observed.

An optional additional wash with TBST can be performed overnight (protected from light) at 4°C, if necessary, to reduce background.

12. Post-fix the samples in 10 ml of 4% PFA in PBS with 0.1% glutaraldehyde solution for at least 1 hr at room temperature (the reaction can go overnight at 4°C, if necessary).
13. Wash briefly 5 min in 10 ml PBS at room temperature.
14. (Optional) To clarify samples to clearly distinguish the specific staining from the background, incubate in increasing concentrations of glycerol solutions at room temperature as follows:

20% glycerol/PBS solution for at least 15 min

50% glycerol/PBS solution for at least 15 min

80% glycerol/PBS solution for at least 15 min

All the unstained tissue will become clear, allowing easier detection of the specific staining. The samples can now be analyzed prior to storage at 4°C.

ALTERNATE PROTOCOL 1

WHOLE-MOUNT IN SITU HYBRIDIZATION WITH MOUSE OR CHICKEN EMBRYOS AND ORGANS

This protocol is used for very high background probes and for the detection of very rare transcripts by modification of the hybridization and washing conditions.

Materials

Mouse or chicken embryos or organs

PBS (APPENDIX 2), ice cold

4% (w/v) paraformaldehyde in PBS (4% PFA; UNIT 14.1), 4°C

PBT (also see recipe): 0.1% (v/v) Tween 20 in PBS, 4°C and room temperature

25%, 50%, and 75% methanol in PBT (methanol/PBT)

100% methanol
6% (v/v) hydrogen peroxide (H₂O₂; Aldrich) in PBT (optional)
10 µg/ml proteinase K in PBT, not predigested
2 mg/ml glycine (Merck) in PBT, freshly prepared
0.2% (v/v) glutaraldehyde (EM grade, Sigma)/4% (w/v) paraformaldehyde in PBT, freshly prepared
Prehybridization solution A (see recipe), 65°C
Hybridization solution A: prehybridization solution A (see recipe) containing 1 µg/ml digoxigenin-labeled riboprobe (see Support Protocol 1)

Dissecting tools (e.g., scissors and forceps), wiped with 70% ethanol
Dissecting microscope
20-ml snap-cap glass vials
Heating block with adapter to hold 2-ml microcentrifuge tubes
Platform rocker

NOTE: All washes are carried out in 5 to 10 ml (20-ml glass vials) or 1.5 to 2 ml (2-ml microcentrifuge tubes) of solution for 5 min at room temperature with gentle agitation, unless stated otherwise. Solutions should be warmed to the indicated temperature before use.

Fix sample

1. Dissect mouse or chicken embryo in ice-cold PBS using appropriate dissecting tools and a dissecting microscope, if necessary. Completely remove the extraembryonic membranes and the amnion and open cavities.

See Basic Protocol 1, step 1 annotation, for information about the dissection.

2. Transfer sample into a 20-ml snap-cap glass vial containing ~10 ml of cold 4% PFA. Fix 4 hr to overnight at 4°C.

If desired, it is possible to fix several samples in one glass vial with an excess of fixative.

3. Wash sample two times in PBT at 4°C.
4. Dehydrate sample by successive washes, 5 min each wash, in 25%, 50%, and 75% methanol/PBT at room temperature. Finally, wash two times in 100% methanol.
5. Rehydrate sample using the methanol/PBT series from step 4 in reverse order and wash two times in PBT at room temperature.

Pretreat sample

6. (Optional) Bleach sample with 6% hydrogen peroxide in PBT for 15 min at room temperature.

See Critical Parameters and Troubleshooting for further discussion.

7. Wash the sample three times in PBT at room temperature.
8. Digest sample with 10 µg/ml proteinase K in PBT for 15 min at room temperature.

The samples are very fragile during this step.

The length of treatment and/or concentration of proteinase K needs to be optimized. For example, if the distribution of RNAs in embryonic ectodermal structures is studied, proteinase K digestion must be reduced to 4 µg/ml for 5 min or 10 µg/ml for 2 min to keep the ectoderm intact (Crossley and Martin, 1995). Alternatively, detergent permeabilization (Rosen and Beddington, 1993) can be substituted for proteinase K digestion.

9. Stop digestion by washing in freshly prepared 2 mg/ml glycine in PBT.
10. Wash two times in PBT.

Postfix and hybridize sample

11. Postfix sample with freshly prepared 0.2% glutaraldehyde/4% paraformaldehyde in PBT for 20 min at room temperature.
12. Wash three times in PBT.
13. Add 1 ml prewarmed (65°C) prehybridization solution A to the glass vial and transfer the sample to a 2-ml microcentrifuge tube.

A small spoon or spatula can be used to transfer embryos. Alternatively, the sample with prehybridization solution A can be carefully poured into the microcentrifuge tube.

Depending on sample size, more than one sample can be hybridized in a tube provided that the samples are completely submerged in solution. This facilitates direct comparative analysis of different samples.

14. Remove the solution and add 2 ml fresh prewarmed prehybridization solution A. Close the microcentrifuge tube, place it in a 65°C heating block, and secure it. Place the heating block sideways on a platform rocker. Prehybridize the sample 3 hr at 65°C.

This setup enables optimal and gentle mixing of the prehybridization solution, and is used for hybridization and all subsequent washes not carried out at room temperature. Alternatively, a shaking water bath may be used.

The samples can be stored up to 6 months in prehybridization solution A at -20°C either before or after completing step 14.

15. Replace prehybridization solution with 1 ml hybridization solution A containing 1 µg/ml digoxigenin-labeled riboprobe and hybridize overnight at 70°C.

See Critical Parameters and Troubleshooting for suggestions on recommended hybridization temperatures. Prehybridization and hybridization solutions can be stored at -20°C and reused up to three times.

One milliliter of hybridization solution is sufficient for three day-10.5 mouse embryos, two day-11.5 mouse embryos, or five stage-17 chicken embryos.

16. Proceed with enzymatic detection of RNA hybrids (see Alternate Protocol 2).

ALTERNATE PROTOCOL 2

ENZYMATIC DETECTION OF RNA HYBRIDS IN MOUSE AND CHICKEN EMBRYOS AND ORGANS

After hybridization (see Alternate Protocol 1) nonspecifically bound riboprobes are removed by extensive washes and RNase A digestion. Subsequently, digoxigenin-labeled RNA hybrids are detected immunologically using preabsorbed alkaline phosphatase-conjugated Fab fragments of anti-digoxigenin antibodies (see Support Protocol 2). Immune complexes are detected by an alkaline phosphatase color reaction.

This protocol is preferred to Basic Protocol 2 when there is high background. The steps with RNase, maleic acid buffer, and the preabsorption of the antibody may help to decrease unspecific staining.

Materials

Hybridized mouse or chicken embryo or organ sample in hybridization solution A (see Alternate Protocol 1)

Prehybridization solution A (see recipe), 70°C

2× SSC, pH 4.5 (see recipe for 20× SSC), 70°C

0.1% (v/v) CHAPS (3-[(3-cholamidopropyl)dimethylammonio]-1-propane-sulfonate)/2× SSC, 70°C

20 µg/ml RNase A (Boehringer Mannheim) in 0.1% CHAPS/2× SSC, 37°C
Maleic acid buffer (MAB; see recipe), 70°C and room temperature
PBS (APPENDIX 2)
PBT (also see recipe): 0.1% (v/v) Tween 20 in PBS
Blocking solution (see recipe)
Alkaline phosphatase–conjugated Fab fragments of anti-digoxigenin antibodies
(Boehringer Mannheim), preabsorbed (see Support Protocol 2), 4°C
0.1% (w/v) BSA in PBT
Alkaline phosphatase buffer, pH 9.5 (NTMT; see recipe), freshly prepared
2 mM levamisole (Sigma) in NTMT (optional)
NBT/BCIP substrate solution (UNIT 14.7) or BM purple AP substrate (Boehringer
Mannheim)

Plastic Pasteur pipets
70°C heating block with adapter for 2-ml microcentrifuge tubes
Rocker platform
37° and 70°C water bath (optional)
20-ml snap-cap glass vials
Aluminum foil
Dissecting microscope equipped with a camera

CAUTION: Formamide and DEPC are hazardous; see manufacturer's guidelines for handling, storage, and disposal.

NOTE: All incubations and washes are carried out at the temperatures indicated and with gentle rocking (see Basic Protocol 1, step 14). Solutions should be warmed to the indicated temperature before use.

Wash hybridized sample

1. Remove hybridization solution from hybridized mouse or chicken embryo or organ sample and add 800 µl prewarmed prehybridization solution A. Wash 5 min at 70°C.

The riboprobe in the hybridization solution is stable up to 2 years at –20°C and can be reused up to three times.

2. Add 400 µl of 2× SSC, pH 4.5, to the tube without removing prehybridization solution. Wash 5 min at 70°C. Repeat the addition of 2× SSC and wash two additional times.

Successive additions of 2× SSC to the prehybridization solution produce a stepwise dilution to 25% prehybridization solution/75% 2× SSC.

At high hybridization temperatures (e.g., 70°C), low pH (4.5) stabilizes the negative charges of the riboprobe and facilitates hybridization.

3. Remove the mix and wash two times, 30 min each wash, in 0.1% CHAPS/2× SSC at 70°C.
4. Digest sample with 20 µg/ml RNase A in 0.1% CHAPS/2× SSC for 1 hr at 37°C.

The conditions of RNase A digestion may need to be adjusted (see Critical Parameters and Troubleshooting).

5. Wash two times, 10 min each wash, in MAB at room temperature. Wash two times, 30 min each wash, in MAB at 70°C.

These washes significantly decrease nonspecific hybridization signals by blocking nonspecific antibody binding sites.

6. Wash two times, 10 min each wash, in PBS at room temperature.
7. Wash 5 min in PBT at room temperature.

Incubate with antibody

8. Incubate samples 2 to 3 hr in blocking solution at room temperature.
This step blocks nonspecific antibody-binding sites. The Fab fragments can be conveniently preabsorbed during step 8 (see Support Protocol 2).
9. Replace the blocking solution with 2 ml preabsorbed alkaline phosphatase-conjugated Fab fragments of anti-digoxigenin antibodies. Incubate overnight at 4°C with gentle agitation.
The Fab fragment solution can be reused up to three times within ~6 weeks. Store the solution at 4°C and check for possible contaminations before use.
The purpose of the subsequent washes is to remove excess and nonspecifically bound antibody from the tissues to prevent nonspecific reaction with chromogenic substrate.
10. Replace the Fab fragment solution with 0.1% BSA in PBT and transfer the sample to a 20-ml snap-cap glass vial.
For all subsequent steps, ~10 ml solution is used and all washes are carried out with gentle rocking at room temperature.
11. Wash five times, 45 min each wash, in 0.1% BSA in PBT.
12. Wash two times, 30 min each wash, in PBT.
13. Wash three times, 10 min each wash, in NTMT buffer.

Levamisole (2 mM final) may be included in the NTMT buffer to inhibit endogenous alkaline phosphatases.

If the Boehringer Mannheim BM Purple AP substrate is used, wash two times in NTMT buffer.

Visualize hybrids

14. Incubate in 3 ml NBT/BCIP substrate solution or BM Purple substrate solution. Cover glass vial with aluminium foil and gently rock the vial for the first 20 min of the development.
The sample must be completely submerged in substrate solution.
The NBT/BCIP substrate solution is light sensitive, and it is therefore important to keep the samples in the dark. Monitor progression of staining with minimal exposure to light.
BM Purple substrate solution is stabilized and presents superior signal-to-noise ratios. It produces clean signals with minimum background, even after overnight incubations. It is recommended for use when long developing times (overnight to 3 to 4 days) are required.
15. Monitor staining by eye or using a dissecting microscope. After the signal has developed to the desired extent, stop the staining reaction by washing the samples at least six times with PBT.

The stained samples can be stored ~2 to 3 months in PBT containing 100 mM EDTA at 4°C without significant effects on signal strength.

Signal strength depends on abundance of the target RNA, hybridization conditions, and additional factors (see Critical Parameters and Troubleshooting). Development times of up to 48 hr are required for some RNAs, whereas other probes yield strong signals after only 20 min. However, for most probes, incubation times of ~2 hr are required to obtain convincing results. The substrate solution should be replaced for overnight incubations.

It is possible to restain samples by repeating the procedure from steps 13 to 15.

16. (Optional) Fix sample overnight in 4% PFA in PBT at 4°C. Wash several times and store in PBT at 4°C.

This step fixes the signal, but may affect overall morphology. Furthermore, sample cannot be restained after fixation.

17. Photograph samples submerged in PBT in a petri dish.

Results should be documented as soon as possible. Samples are photographed submerged to avoid reflections and drying artifacts. It is best to illuminate the sample from the top or side using glass-fiber optics, and to use tungsten slide film or black-and-white negative film.

PREABSORPTION OF Fab FRAGMENTS WITH EMBRYONIC POWDER

To reduce nonspecific binding of the detecting antibody to embryonic tissue, it is important to preabsorb the antibody against an acetone powder prepared from the embryo or organ under study. The embryonic acetone powder (prepared as described in Wilkinson, 1993) is heat-inactivated and incubated with the alkaline phosphatase-conjugated Fab fragments of anti-digoxigenin antibody. The preabsorbed antibody is then ready for use in enzymatic detection of RNA hybrids in Basic Protocol 2 and Alternate Protocol 2. However, recent studies suggest that the preabsorption may be optional (A. Pizard, pers. comm.). The authors have obtained good results using Basic Protocols 1 and 2 without preabsorption when the antibody is used at a dilution of 1:2000 to 1:10,000.

Materials

Embryos or organs under study (e.g., embryonic day-10 to -12 mouse embryos or stage-24 to -26 chicken embryos)

Liquid nitrogen

Acetone, ice cold

PBT (also see recipe): 0.1% Tween 20 in PBS (*APPENDIX 2* for PBS)

BSA

Sheep serum (see recipe), heat-inactivated

Alkaline phosphatase-conjugated Fab fragment of anti-digoxigenin antibody (Boehringer Mannheim)

Blocking solution (see recipe)

Mortar and pestle

50-ml centrifuge tubes

Beckman TJ-6 centrifuge or equivalent, 4°C

Filter paper

Air-tight microcentrifuge tubes

Rocker platform

Prepare embryonic powder

1. Collect mouse embryos of embryonic day 10 to 12. Remove the extraembryonic tissues. Freeze the embryos in liquid nitrogen and store at -70°C until needed.

The frozen embryos may be stored up to 12 months at -70°C.

To produce 1 ml of embryo powder, use ~20 mouse embryos of embryonic day 11. For a high yield of chicken embryonic powder, use ~10 chicken embryos of stage 24 to 26.

2. Using a mortar and pestle, homogenize the embryos in liquid nitrogen to make a fine powder. Transfer the powder to a 50-ml centrifuge tube.
3. Evaporate the liquid nitrogen. Add 4 vol ice-cold acetone and mix well. Incubate 30 min on ice.

4. Centrifuge 10 min at $2500 \times g$ (4000 rpm in TJ-6 centrifuge), 4°C . Remove supernatant.
5. Wash pellet with ice-cold acetone and centrifuge again 10 min at $2500 \times g$, 4°C .
6. Spread the pellet on a sheet of filter paper and grind it to a fine powder. Allow to air dry and store in an air-tight microcentrifuge tube at -20°C .

The powder is stable for several months at -20°C .

7. Weigh out 3 mg embryo powder. Add 1 ml PBT and heat-inactivate 30 min at 70°C .

Each 3-mg embryo powder is sufficient to prepare 2 ml preabsorbed antibody at the appropriate dilution.

Preabsorb antibody

8. Cool the solution on ice. Add BSA to 1% (w/v) final concentration, heat-inactivated sheep serum to 10% (v/v) final concentration, and $1 \mu\text{l}$ alkaline phosphatase-conjugated Fab fragment of anti-digoxigenin antibody. Incubate 2 to 3 hr on a rocker platform at 4°C .
9. Centrifuge 10 min at $2500 \times g$, 4°C .
10. Dilute the supernatant to 2 ml with blocking solution to produce a final 1:2000 dilution of antibody.

Preabsorbed antibody may be stored up to 6 weeks at 4°C .

BASIC PROTOCOL 3

WHOLE-MOUNT IN SITU HYBRIDIZATION WITH *XENOPUS* EMBRYOS

Xenopus embryos are fixed to preserve morphology, then subjected to pretreatment to prepare the sample for hybridization with digoxigenin-labeled riboprobes. The authors have found that background can be substantially reduced by including a high concentration (1 mg/ml) of denatured salmon sperm DNA in the hybridization solution. Proteinase K treatment significantly increases the sensitivity of the method. This protocol is based on Harland (1991) with some modifications (Franco et al., 1999; López et al., 2003).

Materials

- Albino *Xenopus laevis* embryos
- 2% (w/v) cysteine, pH 7.8
- MEMFA buffer (see recipe)
- PBS (APPENDIX 2)
- 50% and 75% ethanol in sterile distilled water
- 100% ethanol
- 25% methanol/PBT
- PBT (also see recipe): 0.1% (v/v) Tween 20 in PBS, pH 7.8
- 2.5 $\mu\text{g/ml}$ proteinase K in PBT
- 0.1 M triethanolamine (TEA) buffer in PBT, pH 7.8 (UNIT 14.3, except use PBT), prepared fresh
- Acetic anhydride (Sigma)
- 4% formaldehyde in PBT
- Prehybridization solution B (see recipe)
- Hybridization solution B: prehybridization solution B (see recipe) containing 1 $\mu\text{g/ml}$ digoxigenin-labeled riboprobe (see Support Protocol 2)
- 2-ml screw-cap plastic conical tubes
- 37° and 60°C shaking water bath

CAUTION: All solutions should be treated with diethylpyrocarbonate (DEPC; see *UNIT 4.1*) and autoclaved to inhibit RNase activity. DEPC is a suspected carcinogen and should be handled carefully.

NOTE: The samples should always be kept covered with liquid to avoid drying, which causes high levels of background staining. Therefore, when exchanging solutions, always leave the sample covered by a small quantity of liquid. This also prevents physical damage or loss of samples.

NOTE: It is important that the embryos be kept in suspension during the early fixation steps, otherwise they will flatten.

Fix embryos

1. Incubate albino *Xenopus laevis* embryos in 2% cysteine, pH 7.8, for 3 to 5 min at room temperature to remove the jelly coat.
2. Transfer the embryos to a small petri dish and let the embryos settle. Remove most of the liquid and fill the vial with MEMFA buffer. Incubate 60 min at room temperature with gentle agitation to fix.
3. Replace the MEMFA buffer with PBS and wash three times, 10 min each wash, at room temperature.
4. Dehydrate gradually by incubating sample successively in 50% ethanol, 70% ethanol, and 100% ethanol, 10 min each, at room temperature.
5. Wash three times, 10 min each, in 100% ethanol, at room temperature. Store sample at -20°C .

Embryos can be stored for months in 100% ethanol at -20°C .

6. Rehydrate samples by incubating successively in 1 ml of 75% methanol, 50% methanol, and 25% methanol/PBT, 5 min each, at room temperature.
7. Wash three times, 5 min each, in PBT at room temperature.
8. Incubate embryos 10 min at room temperature in 2.5 $\mu\text{g/ml}$ proteinase K in PBT.

Skip this step if immunohistochemistry is to be performed after in situ hybridization, to preserve the antigenic structure.

Pretreat embryos

9. Wash two times, 5 min each, in 500 μl of 0.1 M TEA buffer in PBT, pH 7.8.
10. Add 1.25 μl acetic anhydride. Rock tubes 5 min at room temperature. Add an additional 1.25 μl acetic anhydride and rock for another 5 min.

*Tissues are acetylated to decrease background binding of probe. See *UNIT 14.3* (see *Background Information*) for a discussion of the rationale for the use of acetic anhydride and special considerations.*

11. Wash two times, 5 min each, in 1 ml PBT.
12. If proteinase K digestion was performed, refix embryos for 20 min with 4% formaldehyde in PBT, if not, skip steps 12 and 13.
13. Wash five times, 5 min each wash, in PBT.
14. Wash 10 min at room temperature in 1 ml fresh PBT and 250 μl prehybridization solution B.

15. Once embryos have settled through the solution, prehybridize them with 500 μ l fresh prehybridization solution B. Incubate 10 min in a 60°C shaking water bath.

A 500- μ l quantity of solution is sufficient for ten tadpoles.

16. Replace prehybridization solution B with a fresh 500- μ l aliquot. Prehybridize 3 hr at 60° to 65°C.

Hybridize

17. Replace prehybridization solution B with 500 μ l hybridization solution B containing 1 μ g/ml digoxigenin-labeled riboprobe. Hybridize overnight at 60° to 65°C.

18. Proceed with enzymatic detection of RNA hybrids (see Basic Protocol 4).

BASIC PROTOCOL 4

DETECTION OF RNA HYBRIDS IN *XENOPUS* EMBRYOS BY ANTI-DIGOXIGENIN ANTIBODIES

After hybridization (see Basic Protocol 3), nonspecifically bound probe is removed by a series of washes, and RNA hybrids are detected by anti-digoxigenin antibodies. For this protocol, maleic acid is included in antibody blocking and incubation steps and post-antibody washes (as recommended in the DIG system manual of Boehringer Mannheim and in Sive et al., 1994). It has been reported that several specific batches of antibody to digoxigenin have produced high backgrounds. This problem can be alleviated by replacing phosphate buffer with 2% blocking reagent (Boehringer Mannheim) in maleic acid buffer (MAB) for antibody washes and incubation (Lamb et al., 1993). Furthermore, the authors have found that extensive washing in maleic acid buffer before and after the antibody incubation result in clean signals with minimum background (Franco et al., 1999).

Materials

Hybridized *Xenopus laevis* embryos (see Basic Protocol 3)

Prehybridization solution B (see recipe), 60°C

2 \times and 0.2 \times SSC (see recipe for 20 \times), 60°C and room temperature

2 \times SSC containing 20 μ g/ml RNase A and 10 U/ml RNase T1 (see recipes)

0.1 (v/v) DEPC

Maleic acid buffer (MAB; see recipe)

2% (w/v) blocking reagent (see recipe) in MAB

Alkaline phosphatase-conjugated Fab fragments of anti-digoxigenin antibody (Boehringer Mannheim) diluted 1:2000 in 2% blocking reagent (see Support Protocol 1)

Alkaline phosphatase buffer, pH 9.5 (NTMT; see recipe) containing 5 mM levamisole (Sigma), filtered

NBT/BCIP substrate solution (UNIT 14.7) or BM purple AP substrate (Boehringer Mannheim)

Ethanol

4% (w/v) formaldehyde in PBT

37° and 60°C shaking water baths

Aluminum foil

Dissecting microscope equipped with a camera

CAUTION: Dimethylformamide and DEPC are hazardous; see manufacturer's guidelines for handling, storage, and disposal.

NOTE: All solutions should be treated with diethylpyrocarbonate (DEPC; see UNIT 4.1) and autoclaved to inhibit RNase activity.

NOTE: The samples should always be kept covered with liquid to avoid drying, which causes high levels of background staining. Therefore, when exchanging solutions, always leave the sample covered by a small quantity of liquid. This also prevents physical damage or loss of samples.

Wash embryos

1. Remove hybridization solution from hybridized *Xenopus laevis* embryos and add 500 μ l prehybridization solution B. Incubate 10 min at 60°C.
2. Wash three times, 20 min each wash, in 2 \times SSC at 60°C.
3. Remove 2 \times SSC and incubate in 2 \times SSC containing 20 μ g/ml RNaseA and 10 U/ml RNase T1. Incubate 30 min at 37°C.

RNases A and T1 have different specificities. Both are used to guarantee complete degradation of unhybridized probe and reduce background.

4. Wash 10 min in 2 \times SSC at room temperature.
5. Wash two times, 30 min each wash, in 0.2 \times SSC at 60°C. Add 0.1% fresh DEPC to each wash.
6. Wash two times, 15 min each wash, in MAB at room temperature.
7. Wash in 2% blocking reagent 15 min at room temperature.
8. Replace with fresh blocking reagent and incubate 1 hr at room temperature.

Detect RNA hybrids

9. Replace blocking reagent with 500 μ l alkaline phosphatase-conjugated Fab fragments of anti-digoxigenin antibody in 2% blocking reagent. Incubate 4 hr at room temperature with very gentle agitation.
10. Wash sample three times, 15 min each and leave overnight at 4°C in MAB with very gentle agitation.
11. Wash two times, 5 min each, in filtered NTMT buffer containing 5 mM levamisole at room temperature.
12. Replace last wash with NBT/BCIP substrate solution, and then wrap the container in aluminum foil. Incubate 5 min to 1 day at 37°C until the colored reaction product is visible.
13. After the signal has developed to the desired extent, stop the staining reaction by incubating in 100% methanol 30 min at room temperature.

This step is crucial to remove background.

14. Rehydrate embryos using 75% methanol/PBS; 50% methanol/PBS; PBS alone and then wash two times in PBS at room temperature.
15. Store embryos in 4% formaldehyde in PBS at 4°C.

SYNTHESIS OF DIGOXIGENIN-LABELED RNA PROBES

Antisense riboprobes are synthesized as run-off transcripts from linearized templates, using bacteriophage polymerases and template DNA consisting of the DNA fragment of interest cloned in a vector containing the promoter appropriate for the RNA polymerase (T3, T7, or SP6). RNA synthesis is carried out in the presence of a digoxigenin-substituted ribonucleotide. Nonradioactive probes have several advantages. They are easily synthe-

Hybridization
and Immuno-
histochemistry**

14.9.15

sized in large quantities and are stable for several months. An additional advantage of RNA versus DNA probes is that they result in cleaner signals because nonspecifically bound probe is removed during ribonuclease treatment. See *UNIT 4.6* and the Commentary in *UNIT 14.3* for a discussion of RNA synthesis. This protocol is based on Wilkinson (1993). Also see Paganelli et al. (2001).

Materials

Distilled water, sterile
10× transcription buffer: 400 mM Tris·Cl (pH 8.25)/60 mM MgCl₂/20 mM spermidine (Boehringer Mannheim)
Nucleotide mix (pH 8): 10 mM GTP/10 mM ATP/10 mM CTP/6.5 mM UTP/ 3.5 mM digoxigenin-UTP (Boehringer Mannheim)
1 μg/ml linearized plasmid (*UNIT 4.7*)
40 U/ml placental ribonuclease inhibitor (RNasin, Boehringer Mannheim)
20 U/μl SP6, T3, or T7 RNA polymerase
RNase-free DNase I (*UNIT 4.1*)
TE buffer, pH 8 (*APPENDIX 2*) containing 0.1% SDS, DEPC-treated
Sephadex G-25 (coarse)
100% ethanol
3 M sodium acetate, pH 5.2 (*APPENDIX 2*)
70% ethanol in DEPC-treated water (see *UNIT 4.1*)
RNA loading buffer (see recipe)
37°C water bath
1-ml syringe
Additional reagents and equipment for agarose gel electrophoresis (*UNIT 2.5A*)

1. Mix reagents in the following order at room temperature (20 μl total):

13 μl sterile distilled water
2 μl 10× transcription buffer
2 μl nucleotide mix
1 μl 1 μg/ml linearized plasmid
1 μl 40 U/ml RNasin
1 μl 20 U/μl RNA polymerase

Incubate 2 hr at 37°C.

Although stock solutions of sensitive reagents should be kept on ice, the reaction mixture should be mixed at room temperature; otherwise the spermidine in the transcription buffer will precipitate the DNA.

2. Add 2 μl RNase-free DNase I to the reaction mix. Incubate 15 min at 37°C.

Purify the probes

3. Add 80 μl TE buffer containing 0.1% SDS to the reaction mix.
4. Prepare the spin column filling a 1-ml syringe with Sephadex G25 (coarse) in TE buffer/0.1% SDS.
5. Eluate the sample by centrifuging 2 min at 1500 × g, room temperature.
6. Add 200 μl of 100% ethanol and 10 μl of 3 M sodium acetate, pH 5.2.
7. Mix and incubate overnight at -20°C.
8. Microcentrifuge 20 min at maximum speed, 4°C.

9. Wash pellet with 70% ethanol.
10. Air-dry pellet (do not use a Speedvac evaporator). Redissolve pellet in 20 μ l DEPC-treated water and store at -70°C .

Digoxigenin-labeled riboprobes are stable at least 2 years at -70°C .

Check the riboprobe

11. Mix 2 μ l of the probe with 23 μ l of RNA loading buffer.
12. Incubate 15 min at 65°C and then place 5 min on ice.
13. Run on 1% agarose gel in TBE buffer (*UNIT 2.5A*).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Alkaline phosphatase buffer (NTMT), pH 9.5

- 100 mM NaCl
- 100 mM Tris-Cl, pH 9.5 (*APPENDIX 2*)
- 50 mM MgCl_2
- 0.1% (v/v) Tween 20

Prepare fresh on the day of use to avoid decrease in pH during storage caused by absorption of carbon dioxide (Wilkinson, 1993).

*Levamisole (Sigma) is added to NTMT to block the activity of endogenous alkaline phosphatases. It should be added, just before use, to 5 mM for mouse and chicken embryos and 5 mM for *Xenopus* embryos.*

*It is necessary to filter the solution before use with *Xenopus* embryos.*

Blocking reagent, 2% (w/v)

Dissolve blocking powder (Boehringer Mannheim) in MAB (see recipe) by autoclaving 20 min, 1 atm, to give a 2% final concentration. Store at -20°C in aliquots.

Blocking solution

- 10% (v/v) heat-inactivated sheep serum (see recipe)
 - 1% (w/v) BSA
 - 0.1% (v/v) Tween 20
 - PBS (*APPENDIX 2*)
- Prepare fresh on the day of use

Hybridization solution

- 50% (v/v) deionized formamide (*UNIT 14.3*)
 - 5 \times SSC, pH 4.5 (see recipe for 20 \times)
 - 1% SDS
 - 50 μ g/ml yeast RNA
 - 50 μ g/ml heparin
- Store 25-ml aliquots up to 1 year at -20°C

Maleic acid buffer (MAB)

- 100 mM maleic acid (Sigma)
 - 150 mM NaCl
- Adjust pH to 7.5 with HCl
Autoclave
Prepare fresh on day on use

MEMFA buffer

0.1 M 3-(*N*-morpholino)propanesulfonic acid (MOPS), pH 7.4
2 mM EGTA
1 mM MgSO₄
3.7% (w/v) formaldehyde
Prepare fresh

PBT buffer

1× PBS (*APPENDIX 2*), DEPC-treated (*UNIT 4.1*)
0.1% or 1% (v/v) Tween 20
Store up to 6 months at 4°C

Prehybridization solution A

50% (v/v) deionized formamide (*UNIT 14.3*)
5× SSC, pH 4.5 (see recipe for 20×)
2% (w/v) blocking reagent (see recipe)
0.1% (v/v) Tween 20
0.5% (v/v) 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate (CHAPS)
50 µg/ml yeast RNA
5 mM EDTA
50 µg/ml heparin
Store 25-ml aliquots up to 1 year at –20°C

Add CHAPS from a 2% stock solution prepared in distilled sterile water (do not autoclave this solution). Add yeast RNA and heparin from 10 mg/ml stock solutions prepared in sterile distilled water.

Prehybridization solution B

50% (v/v) deionized formamide (*UNIT 14.3*)
5× SSC (see recipe for 20×)
1 mg/ml torula RNA (see recipe)
100 µg/ml heparin
1× Denhardt solution (*APPENDIX 2*)
0.1% (v/v) Tween 20
0.1% (v/v) 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate (CHAPS)
10 mM EDTA
1 mg/ml salmon sperm DNA (*UNIT 14.7*), denatured 10 min at 95°C
Adjust volume with DEPC-treated H₂O (*UNIT 4.1*)
Prepare fresh on day of use

RNA loading buffer

55% (v/v) formamide
20% (v/v) formaldehyde
22 mM 3-(*N*-morpholino) propanesulfonic acid (MOPS)
5.5 mM sodium acetate, pH 5.2 (*APPENDIX 2*)
0.5 mM EDTA, pH 8.0 (*APPENDIX 2*)
22% (v/v) glycerol solution: 30% (v/v) glycerol in water containing 0.25% (w/v) bromophenol blue
17 µg/ml ethidium bromide
Store up to 6 months at –20°C

RNase A

Dissolve RNase A (Sigma) to a concentration of 10 mg/ml in 10 mM Tris·Cl, pH 7.5/15 mM NaCl. Boil 10 min. Store in 100- μ l aliquots up to 12 months at -20°C .

RNase T1

Dissolve RNase T1 (Sigma) to a concentration of 10,000 U/ml in 0.1 M sodium acetate buffer, pH 5.5 (*APPENDIX 2*). Boil 10 min. Store 100- μ l aliquots at -20°C .

Keep a working stock of RNase at 4°C to avoid repeated freezing and thawing. It is stable for several months.

Sheep serum

Thaw sheep serum (Sigma-Aldrich) in a 37°C water bath. Heat inactivate the liquid serum 30 min at 70°C . Divide into 30-ml aliquots and centrifuge 15 min at $2500 \times g$ (4000 rpm in Beckman TJ-1 centrifuge), 4°C . Prepare 2-ml aliquots from the supernatant. Store 2-ml aliquots up to 1 year at -20°C ; do not refreeze aliquots once thawed.

Solution I

50% formamide
5 \times SSC, pH 4.5 (see recipe for 20 \times)
1% SDS
Store up to 6 months at room temperature

Solution II

50% formamide
2 \times SSC, pH 4.5 (see recipe for 20 \times)
0.1% (chick embryos older than stage 4 to stage 9) or 1% (mouse) Tween 20
Store up to 6 months at room temperature

SSC, pH 4.5, 20 \times

Prepare SSC as described in *APPENDIX 2*. Adjust pH to 4.5 with citric acid. Autoclave, then store at room temperature (stable for months).

TBS, 10 \times

1.4 M NaCl
27 mM KCl
250 mM Tris·Cl, pH 7.5 (*APPENDIX 2*)
Store up to 6 months at room temperature

TBST

1 \times TBS (see recipe for 10 \times) plus 0.1/1% Tween 20
2 mM 0.5 mg/ml Levamisole
Add Tween 20 on day of experiment

NOTE: *Most no longer add levamisole to TBST.*

Torula yeast RNA, 10 mg/ml

Dissolve torula yeast RNA (Sigma) in water at a concentration of 20 mg/ml. Heat to 60°C and sonicate until completely resuspended. Extract with 25:24 (v/v) phenol/chloroform and precipitate with 2 vol ethanol. Resuspend pellet in DEPC-treated water (*UNIT 4.1*) to a final concentration of 10 mg/ml. Store 100- μ l aliquots up to 12 months at -20°C .

Torula yeast RNA is less expensive than yeast tRNA.

COMMENTARY

Background Information

Nonisotopic in situ hybridization using intact embryos or organs is a widely used method that enables fast determination of RNA spatial distributions. Large numbers of samples can be analyzed simultaneously, which permits direct comparison of different developmental stages and/or genotypes. Furthermore, the sensitivity and reproducibility of whole-mount in situ hybridization facilitates the analysis of genes expressed in restricted patterns, i.e., in small structures easily overlooked when using serial sections (UNITS 14.1-14.5). In addition, the opportunity for inspecting histological details is not lost because the embryos can be sectioned after staining. Therefore, whole-mount in situ hybridization is often the method of choice to determine the expression patterns of novel gene products (Rosen and Beddington, 1993).

Protocols enabling simultaneous detection of two different transcripts by whole-mount in situ hybridization have been developed. Probes labeled with digoxigenin and fluorescein can be detected differentially by antibodies coupled to different enzymatic detection systems

(Hauptmann and Gerster, 1994; Jowett and Lettice, 1994). The methods described here can also be used for detecting multiple gene products using digoxigenin-labeled riboprobes, provided the target transcripts are localized in distinct structures or cell types of the embryo.

Critical Parameters and Troubleshooting

The methods described in this unit have been used to localize different types of transcripts in mouse, chicken, and *Xenopus laevis* embryos (e.g., Haramis et al., 1995; Figs. 14.9.1, 14.9.2, and 14.9.3). However, the parameters discussed in the following paragraphs may require optimization depending on particular tissues and target mRNAs. Furthermore, controls are suggested that should aid in the adaptation of these protocols to “difficult” tissues or probes. In general, it is important to assure that the target RNAs remain intact during fixation and subsequent manipulation of samples. Therefore, embryos or organs should be isolated at 4°C and fixed as fast as possible. It is also important to use RNase-free solutions to avoid possible

Figure 14.9.1 Whole mount ISH of *Xenopus* embryo. Detection of *X-delta-1* mRNA in *Xenopus laevis* whole-mounted gastrula (stage 11) using digoxigenin-labeled RNA antisense probe. Magnification at ~200 \times . (Contributed by Carrasco et al.)

Figure 14.9.2 Whole mount ISH of *Xenopus* tadpole. Detection of sonic hedgehog (*X-shh*) mRNA in *Xenopus laevis* whole-mounted tadpole (stage 30) using digoxigenin-labeled RNA antisense probe. Magnification at ~100 \times . (Contributed by Carrasco et al.)

Figure 14.9.3 Whole mount ISH of *Xenopus* embryo. Detection of *hairy 2A* mRNA in *Xenopus laevis* transversal section of whole-mounted neurula (stage 14) using digoxigenin-labeled RNA antisense probe. Magnification at ~200 \times . (Contributed by Carrasco et al.)

degradation of target RNAs, so solutions should be autoclaved or treated with diethylpyrocarbonate (DEPC; see *UNIT 4.1*). During initial experiments, it is advisable to perform the procedure exactly as described and to complete it without intermediate storage. Furthermore, a probe with a known distribution in the tissue(s) of interest should be included as a positive control. Samples from which the riboprobe and/or anti-digoxigenin Fab fragments have been omitted serve as negative controls for nonspecific labeling and/or activity of endogenous alkaline phosphatases. Alternatively, a sense-strand digoxigenin-labeled riboprobe

can be synthesized and used as a negative control.

Fixation

Fixation of embryos and organs for whole-mount in situ hybridization is less critical than when using ^{35}S -labeled riboprobes on histological sections (Carrasco and Malacinski, 1987; Franco et al., 1999).

Bleaching with hydrogen peroxide

In the case of pigmented *Xenopus* embryos, extensive treatment may be required to bleach pigment granules. However, embryos of an

Table 14.9.1 Troubleshooting Guide for Whole-Mount In Situ Hybridization

Problem	Cause	Solution
Low or no hybridization signal	Low abundance or degradation of target RNA	Optimize fixation time. Optimize concentration of enzyme and duration of proteinase K digestion.
	Problems with riboprobe	Lower hybridization temperature, e.g., to 55°C. Increase concentration of riboprobe.
	Overdigestion with RNase	Use lower concentration of enzyme or shorter digestion time, e.g., 30 minutes. Perform digestion at room temperature.
High levels of nonspecific signal	Hybridization conditions not stringent enough	Increase stringency of hybridization and washes (temperature, ionic strength, or incubation time). For <i>Xenopus</i> , increase concentration of salmon sperm DNA.
	Incomplete RNase digestion	Increase RNase to 100 (µg/ml).
	Nonspecific binding of Fab fragments of antibody	Preabsorb antibody with tissue of interest. Extend preabsorption to overnight at 4°C.
	Residual endogenous alkaline phosphatase activity	Add levamisole to NTMT buffer just before use (2 mM for mouse/chicken, 5 mM for <i>Xenopus</i>).
Loss of morphology	Chromogenic substrate too old	Use fresh substrate or stabilized BM Purple Substrate Solution (Boehringer Mannheim).
	Damage to sample during handling	Handle samples carefully and check for damage at each transfer step.
	Insufficient fixation or postfixation after proteinase K digestion	Increase fixation or postfixation time.
	Overtreatment with hydrogen peroxide	Decrease treatment time.

albino mutant strain are used to circumvent the necessity of bleaching.

Proteinase K digestion

Proteinase K digestion permeabilizes the tissues, unmask target RNAs by removing proteins, and inactivates endogenous ribonucleases. It is important to establish optimal proteinase K digestion conditions for each sample. Optimal conditions might vary depending on the batch and/or supplier of the enzyme. Conditions are determined empirically in pilot experiments using varying concentrations of proteinase K. Short, nonoptimal digestion may reduce signals and increase background levels, whereas overdigestion will cause degradation of sensitive structures, especially when very young embryos are studied. The amount of enzyme, the duration of digestion, or both may be varied to optimize proteinase K digestions (see Basic Protocols 1 and 3). Postfixation of samples after proteinase K digestion is essential to retain unmasked RNAs and preserve morphology during subsequent hybridization. Proteinase K digestion must be omitted when an immunohistochemistry procedure is performed to preserve the antigenic structure.

Selection of riboprobe and hybridization conditions

Before attempting to study the distribution of RNAs of interest in a particular tissue, it is important to establish their abundance and temporal distribution by northern blot hybridization (UNIT 4.9) and/or an RNase protection assay (UNIT 4.7). RNase protection assays should be used to select possible probes for subsequent whole-mount in situ hybridization (also see UNIT 14.3, Background Information). Several parameters affect the strength of the hybridization signal and signal-to-noise ratio. Both GC- and AT-rich sequences should be avoided. The best probes are often derived from coding regions. However, when analyzing expression of members of highly conserved gene families, the probes must be derived from the least conserved regions to ensure detection of specific RNAs. Sensitivity of detection and signal-to-noise ratios depend on probe length and concentration. However, probe length seems less critical when using digoxigenin (or other haptens) than when using ³³S-labeled riboprobes (UNIT 14.3). Riboprobes up to 2.5 kb long have been used successfully without previous alkali hydrolysis (Franco et al., 1999).

RNase A digestion

RNase A digestion eliminates nonspecifically hybridized riboprobes and is essential to obtaining the best signal-to-noise ratios. Specifically hybridized RNA hybrids are stable, but RNase concentrations may have to be lowered or digestion omitted when detecting heterologous or rare mRNAs. Pilot experiments using varying RNase concentrations and/or digestion times are necessary to establish optimal conditions.

Troubleshooting

Table 14.9.1 is a guide to troubleshooting problems associated with whole-mount in situ hybridization.

Anticipated Results

A successful experiment will reveal the spatial distribution of target RNAs in the samples of interest. Good examples for the analysis of expression patterns by whole-mount in situ hybridization can be easily found in the references listed and in major scientific journals (Franco et al., 1999; Paganelli et al., 2001; López et al., 2003). Representative examples of experiments carried out using the methods described in this unit are illustrated in Figures 14.9.1, 14.9.2, and 14.9.3.

Time Considerations

Before starting whole-mount in situ hybridizations, large amounts of tissue must be collected for preparation of the embryonic acetone powder. Also, riboprobes should be tested by northern blot hybridization (UNIT 4.9) or RNase protection assays (UNIT 4.7). In general, three overnight steps are required during the procedure (fixation, hybridization, and antibody incubation). Linearization of the template DNA can be done overnight during the fixation step. Preparation of riboprobes requires 4 to 5 hr. Pretreatment of samples before hybridization requires 4 hr of hands-on work and an additional 3 hr for prehybridization. Posthybridization washes and blocking prior to antibody treatment require a total of 8 hr. Post-antibody washes require ~6 hr. Signal detection requires a minimum of 2 hr and can extend overnight. If different samples are to be collected over a period of time and analyzed at one time, they may be stored at -20°C either after fixation in 100% ethanol or after prehybridization or in prehybridization buffer.

Principles and Application of Fluorescence Microscopy

Fluorescence is the luminescent emission that results from absorption of photons. Fluorescence is distinguished from its counterpart, a longer-lasting afterglow called phosphorescence, by the magnitude of the decay time. Fluorescent emission ceases abruptly when the exciting energy is shut off. The decay time, or afterglow, of the emission is on the order of 10^{-8} sec and results in a negative frequency-shifted emission. In contrast, the decay in phosphorescence takes place in milliseconds to seconds.

The fluorescent effect is used in a number of spectroscopy techniques, and it is particularly useful for fluorescence microscopy. The principal use of fluorescence microscopy is to examine specimens that have been treated with special fluorescent reagents. These reagents are able to absorb light of a certain wavelength and emit light at a longer wavelength slightly shifted toward the red end of the spectrum from the absorbed light. If, for example, blue light is absorbed, green light will be emitted. Green is shifted to yellow, yellow to red, and invisible UV light to visible blue light. This phenomenon

is termed the Stokes shift and is defined as the separation of the spectral maxima of excitation and emission (see Fig. 14.10.1).

The λ_{\max} of the spectrum is typically ~20 to 50 nm longer than that of the absorbed exciting light. The Stokes shift, however, can range from <10 to >100 nm (see Fig. 14.10.2). Each fluorochrome exhibits its own very specific absorption and emission spectra, depending on the structure of the molecules and sometimes also on their surroundings.

Fluorescence microscopy allows selective examination of a particular component of a complex biomolecular assembly. A specimen labeled with fluorescent dye(s) is illuminated with filtered light of the absorbing wavelength and is viewed using a barrier filter that is opaque to the absorbing wavelength but which transmits the longer wavelength of the emitted light. The structures marked with the fluorescent molecules will light up against the black background. Additional experimental information can be derived from the combination of optical and biochemical responses exhibited by the

Figure 14.10.1 Absorption and emission spectra of Hoechst 33342 (Molecular Probes) bound to DNA. The dye solution is excited with a fixed-wavelength monochromatic light (typically the λ_{\max} of the absorption spectrum) and the emission measured with a spectrofluorometer. Spectra have been normalized, and relative intensities are plotted to illustrate the peak shift from absorbed to emitted light termed the “Stokes shift.” Spectra courtesy of Molecular Probes.

fluorescent probe.

The growing importance in biology of fluorescence microscopy is due to (1) the extraordinary development of new fluorescent molecular probes and (2) the development of improved low-light-level imaging systems and confocal microscopy techniques (see *UNIT 14.11*).

FLUORESCENT MOLECULAR PROBES

Fluorescent dyes or fluorochromes can be linked to specific antibodies or to other specific molecular probes. Many such fluorescent molecular probes are commercially available (e.g., from Amersham, Calbiochem-Novabiochem, Molecular Probes, and Sigma). Fluorescent probes are identified and quantitated by their absorption and fluorescence emission wavelengths and intensities. Some examples are shown in Figure 14.10.2.

An important experimental consideration is separation of the fluorescence emission signal from the scattered excitation light. This is facilitated by choosing a fluorescent probe with a large Stokes shift. Maximization of the spectral separation can be achieved by choosing

fluorophores with narrow spectral peaks.

During excitation of a fluorescent reagent only some of the absorbed photons result in fluorescent emission. "Quantum yield" is a term that describes the ratio of emitted to absorbed photons. Good fluorescent reagents have a high quantum yield. Additional optical signals may be due to endogenous background fluorescence or to an analytically useful second emitting species.

Fluorescence detection is compromised by background signals. Many biological molecules fluoresce when illuminated with ultraviolet light. This effect is called autofluorescence. The fluorescent amino acid tryptophan, for instance, occurs in a large number of proteins. This molecule is of limited value in cell biology because of the lack of selectivity. Fortunately, autofluorescence of cells and biological tissues and fluids can be minimized by using probes that can be excited at >500 nm.

FILTERS AND FILTER SETS

Filters for fluorescence microscopy (available, e.g., from Omega Optical, Chroma Technology, and microscope manufacturers) must

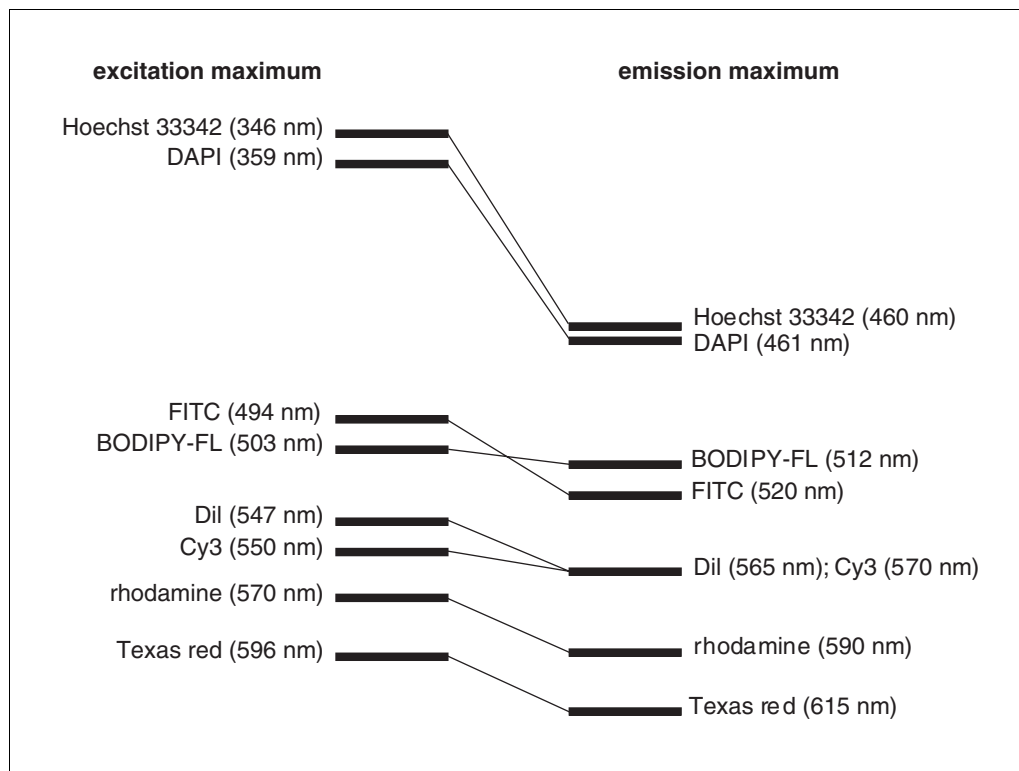

Figure 14.10.2 Excitation and emission maxima for commonly used fluorophores. transmit light of the required wavelengths and block other light as completely as possible. This is difficult to do, because the excitation light intensity is many times higher than that of the emission light. Ideally, light at the excitation wavelength is blocked from the microscopic image, while the emitted light arrives with minimal attenuation.

In practice, a narrow optical bandwidth (<20 nm) is usually used for fluorescence excitation, whereas the fluorescence detection bandwidth is variable, ranging from full spectrum for maximal sensitivity to narrow band (~20 nm) for maximal resolution.

Early types of filters consisted of simple colored glass or the combination of two filters to form so-called band-pass filters. They were made by combining a filter passing long wavelengths with one passing short wavelengths, giving a band-pass where the transmission curves overlap. Contemporary interference filters can achieve much sharper cutoffs with high transmission in the selected region. They consist of a sheet of glass coated with several thin layers of transparent materials of different refractive indices. Light partially reflected at each boundary between layers combines to interfere constructively for some wavelengths and destructively for others. Such interference filters can be used for reflection as well as for transmission, and they can be tailor-made to meet the spectral requirements for a particular fluorescent dye. Figure 14.10.3 shows an example of both an excitation and an emission scan of FITC along with transmission spectra of filters

optimized for FITC spectra. The resulting unfiltered signals overlap significantly, but the filtered signals are discrete.

Fluorescence microscopy is implemented using epiillumination whereby the specimen is illuminated by light passing through the objective. Since epifluorescence microscopy requires the use of a high-intensity light source, a main advantage of this arrangement over transillumination is the safety afforded to the retina. The optical paths of excitation and emission light are shown in Figure 14.10.4. The excitation filter allows only a narrow band of monochromatic light to project on the surface of the dichroic mirror (a chromatic beam splitter, sometimes referred to as a “dichroic”). The dichroic, inclined 45° to the incident light, reflects short-wavelength radiation and transmits longer wavelengths. It reflects the excitation radiation (and any back-scatter from the specimen) and transmits to the observer all of the fluorescent radiation above the cutoff wavelength. Above the beam splitter, the emission light and the remainder of the excitation light hit the emission (barrier) filter where only the emission light can pass to form the fluorescence image of the specimen against a black background (see Fig. 14.10.5).

MULTIBAND FILTERS AND MULTIDYE FLUORESCENCE

The combined use of two or three different dyes simultaneously is becoming increasingly prevalent. Different structures light up in different colors that can be viewed separately, or

Figure 14.10.3 Transmission spectra of excitation and emission (barrier) filters. Filter characteristics are optimized to match the excitation and emission spectra of fluorescein isothiocyanate (FITC; rolling slopes). Spectra are normalized for comparison. Note the sharp drop-off of the filter spectra in relation to the FITC spectra. (For a pure sample, the absorption and excitation spectra are superimposable.) Courtesy of Omega Optical.

Individual microtubules and bundles can be visualized within the complex structure of the cytoplasm.

simultaneously, using special filter sets. Most microscopes have reflector sliders that permit up to three or four sets of filters to be mounted for different fluorescent markers, making the changeover easy.

Since the mid 1980s, multidye fluorescence filter sets have been used more frequently. The sets have the same general components as single-color filter sets, i.e., an excitation filter, a beam splitter, and an emission filter. In each component, there are two or more regions of controlled reflection and transmission. Such an assembly allows the simultaneous imaging of at least two fluorescent labels.

Several standard dual-dye sets are available from some of the major microscope and filter manufacturers (e.g., Zeiss, Leica, Nikon, Olympus, Chroma Technology, and Omega Optical). Omega Optical specializes in producing not only standard multidye sets but also custom-made multidye filter sets including triple (see Fig. 14.10.6) and quadruple dye sets.

Figure 14.10.7 shows an example of three-color staining using cultured endothelial cells labeled with three different fluorescent markers.

The most common use of multiband filters is to investigate the relative spatial localization of two antigens. This is typically done with red and green dyes which form a yellow image from spectral summation when the antibodies colocalize. Colocalization of antigens on organelles as small as stress fibers and vesicles can be detected. Multidye filter sets with more than two-color capability are useful for illuminating intracellular organization of organelles and organization of cells within a tissue. To this end, nucleic acid dyes that stain the nucleus blue, such as DAPI and Hoechst 33342, are among the most commonly used dyes to complement red and green. Use of four or more dyes simultaneously is technically possible and has been accomplished for artistic views of cellular architecture. The use of more than three dyes at once, however, has not yet proved to have the

Figure 14.10.6 Spectra for a triple-dye filter set for blue, green, and red dyes. E₁ to E₃, excitation filters; B₁ to B₃, emission filters. Courtesy of Omega Optical.

analytical value of simple double labeling. The reason for this is undoubtedly linked to the difficulty of optimizing the conditions required for color balance that are encountered in sample preparation, data acquisition, and final image reproduction.

LIGHT SOURCES

Lamps illuminated by filaments are not suitable as light sources in fluorescence microscopy, because the glowing metal filaments convert most of the electrical energy into red or even invisible infrared light. The light source must provide a large amount of excitation energy in very narrow ranges of the spectrum, typically 10 to 50 nm. For this purpose, so-called line emitters, usually high-pressure mercury lamps, are used. The high-pressure mercury lamp uses the gas discharge principle and features a discrete light spectrum. Figure 14.10.8 shows the line spectrum of a mercury arc lamp with its characteristic emission peaks.

The ability to choose absorption and emission filters that take advantage of the intensity lines and the weak spectral ranges is a major benefit of this line emitter. Excitation can be made with a single line, and, because of the Stokes shift, the fluorescence can be viewed at a wavelength at which the light of the illuminator causes minimal disturbance.

Light from a mercury arc lamp radiates from ionizing gases in an arc between discrete points on the anode and cathode. A 2-hr “burning-in”

period should be allowed after lamp replacement before adjusting the optics. After that, the points at which the arc contacts the surfaces of the electrodes stabilize, and readjustment is required only occasionally to maintain uniform illumination of the field. Although an arc lamp may remain stable for 6 months to a year, it should be checked for even illumination with each use. The simplest way is to move the specimen stage and verify that the intensity of a brightly labeled cell or organelle does not vary within the field. In this way, a novice, but conscientious, user can visually detect most alignment problems that stem either from tampering, curious hands, or a spontaneously occurring change in the position of the arc on the surface of the lamp electrodes. Alignment procedures are not complex and are well documented in operators manuals. Additionally, most manufacturers have technical specialists who are able to assist users either by telephone or through courtesy visits. In making adjustments, note that fluorescence filters are sensitive to the heat emitted by the illuminator, so the heat protection filter should never be removed.

Lamps are expensive, and the time to install and align them is costly as well. Short on-off cycling times should be avoided since this necessitates more frequent realignments or lamp replacement. The life of a mercury arc lamp can be extended by planning imaging sessions for >1 hr whenever possible. Check with other users before turning off the lamp, and try to

Figure 14.10.7 Three-color staining observed simultaneously with a multidy fluorescence filter set. Cultured endothelial cells were labeled with Mito Tracker Red CMXRos, BODIPY-FL phalloidin, and DAPI. The slide, which was purchased from Molecular Probes, is an excellent diagnostic and teaching tool, showing red fluorescent mitochondria, green fluorescent actin filaments, and blue fluorescent nuclei. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to <http://www.currentprotocols.com/colorfigures>*

schedule experimental sessions so that the lamp does not need to be turned off between users (<1 hr between users).

MICROSCOPE OBJECTIVES

The fluorescence emission from the excited specimen is radiated in all directions. The objective must gather as much of this radiation as possible. High-NA objectives are the most effective for this purpose. If the objective aperture is doubled, approximately four times more fluorescent light is gathered. Moreover, the use of immersion oil eliminates the loss of light caused by reflection on the surface of the objective front lens.

The best general-purpose microscope objectives offer optimum image corrections. This is achieved by using many individual lenses. However, objectives for fluorescence should provide high transmission values into the UV range. This is achieved by minimizing the number of individual lenses. Therefore, there is always a trade-off between image correction and high transmission. An additional problem is that some lenses and immersion liquids autofluoresce, producing a brightened background and low contrast.

IMAGE RESOLUTION AND THE POINT-SPREAD FUNCTION (PSF)

A fluorescence microscope maps the light emitting from structures in the microscope plane of focus to a two-dimensional image in the microscope image plane. By changing the focus of the microscope, one can map the three-dimensional structures of a specimen to a volume image that is constructed from a stack of two-dimensional images. Thus, the relationship between the image and the actual structure

of the specimen depends on how the microscope is used.

From wave optics, it follows that light emitted from a point on the specimen is not focused to an infinitely small point in the image plane. Rather, passing through the objective lens, the light waves converge and interfere around the image plane to produce a three-dimensional diffraction pattern.

Microscope resolution is limited by the diffraction effects of the finite aperture of the objective. For a well-corrected microscope objective lens, the three-dimensional diffraction pattern is symmetrical about the optical axis. When the three-dimensional diffraction pattern is sectioned in the focal plane, it is observed as the two-dimensional diffraction pattern, or Airy disk. Every point in the microscope is therefore represented by an Airy disk, rather than by a simple small point.

A point-spread function (PSF) is a mathematical representation of the image of a point source. For a diffraction-limited optical system operating in the absence of aberration, the PSF is the Airy disk (see Fig. 14.10.9).

The resolving power of an objective lens can be determined by examining the size of the Airy disk formed by that lens. The size of the Airy disk is a function of the NA of the objective lens and of the wavelength of light. Therefore, both lateral resolution and depth of field (resolution along the axis of observation) are a function of the NA of the objective lens. For a wavelength of light of 546 nm and a 0.65-NA dry lens objective, the depth of field is $\sim 1.3 \mu\text{m}$. For a 1.4-NA oil immersion objective, the depth of field is $\sim 0.29 \mu\text{m}$ (Francon, 1961; Spencer, 1982).

Careful alignment and adjustment are required for high-precision imaging with fluores-

cent probes, particularly when imaging multiple probes simultaneously or when performing three-dimensional reconstruction studies. Fluorescent microspheres, microscope point sources, and image intensity calibration standards are available from Molecular Probes. With video cameras, the shallow focal plane of the camera, the high contrast achievable at high-NA objectives, and the high magnification of the picture displayed contribute to an improved optical section resolution and critically define the focal level of a given structure in the specimen.

Digital image analysis systems, consisting of a microscope fitted with a charge-coupled device (CCD) camera and a video digitizer card installed on a personal computer, are commonly sold as packages from specialized companies (e.g., Scanalytics, Universal Imaging) or from the major microscope companies (e.g., Leica, Nikon, Olympus and Zeiss). An excellent, widely used image analysis software package, NIH Image, is available over the Internet at <ftp://zippy.nimh.nih.gov/pub/nih-image>. The reader is also directed to the Confocal Microscopy Resources on the WWW directory (http://www.pharm.arizona.edu/centers/tox_center/swehsc/exp_path/conf_www.html). The microscope stage can be controlled manually by a stepper motor or by a piezoelectric device, and its position automatically controlled by the computer. Such systems can automatically take stacks of images from parallel planes in the specimen and digitally reconstruct the three-dimensional organization of the specimen. Figure 14.10.10 shows the result of digital reconstruction of a blurry microscope image (a labeled smooth muscle cell) to a sharp image using deconvolution computer algorithms.

FLUORESCENCE MICROSCOPY OF LIVING CELLS

A variety of biologically inert fluorescent probes have been developed to be used as tracers of cell morphology or location. They have been used to investigate neuronal cell connectivity, to study dye translocation through gap junctions, and to track movements of cells in culture, tissue, or intact organisms.

Some fluorescent dyes are able to permeate living cells. Others, like fluorescein, permeate cells selectively. This property has been exploited, for example, in the study of primary sensory neurons of *Caenorhabditis elegans* (Perkins et al., 1986). Still other dyes, like the calcium indicator Fluo-3, are excluded by cells. A common method of conferring plasma membrane permeability to fluorescent dyes and other cell biology reagents is to covalently couple them to hydrophobic groups, the acetoxymethyl (AM) moiety, for example, through an ester linkage. The AM groups are cleaved by endogenous phosphodiesterases, effectively trapping the dye in the cell.

Some dyes are too polar to diffuse passively through cell membranes and require special methods for loading such as microinjection or transient permeabilization techniques. Some dyes, when injected into or applied to cells, produce subtle or sometimes quite apparent changes in cellular organization. An extensive array of literature is available and should be consulted to find procedures suitable for each experiment. A useful handbook of fluorescent reagents and applications is available from Molecular Probes (Haugland et al., 1996).

Photostability is an important concern when using fluorescent probes for imaging or for making fluorescence measurements. Under

Figure 14.10.9 Orthogonal view of a point-spread function (PSF). A 0.2- μm fluorescent microsphere was embedded in a thin gel, and a stack of images in the x,y plane was collected. The microsphere and surrounding Airy disk were reconstructed in three dimensions. The figure shows the intensity pattern in the x,z plane that passes through the center of the microsphere. The PSF shows how a simple microsphere is mapped to a three-dimensional complex volume image. The PSF is strongly influenced by how the microscope is used. Significant distortions can arise from intrinsic limitations such as the finite aperture of the objective and from extraneous imperfections in the microscope optics. Courtesy of Scanalytics. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to <http://www.currentprotocols.com/colorfigures>*

some conditions, fluorescent dyes become very sensitive to photobleaching. Moreover, stability varies significantly among dyes. Exposure to light can cause photobleaching. Therefore, one should avoid illuminating the specimen when not observing or recording a signal, and one should maximize collection of the fluorescence by using high-NA objectives, low-magnification, high-quality optical filters optimal for the spectral properties of the fluorophore, and high-speed film or sensitive video cameras. Antifade reagents added to the mounting medium (see discussion of Immunolabeling, section on Mounting) can help reduce photobleaching on fixed cell preparations but are not compatible with living cells.

IMMUNOLABELING: GENERAL STEPS FOR LABELING FIXED CELLS AND TISSUES

Several excellent reference books are devoted to immunocytochemistry. The most often cited, and still quite applicable, is Sternberger (1979). Other sources include Pawley (1995) and Rost (1992). All too often, contemporary texts focus on technological aspects of imaging and image processing and not on sample preparation. Therefore, a very basic discussion is included here. This discussion also complements UNIT 14.6, which provides a thorough discussion of immunohistochemistry techniques.

Commercial Antibody Selection

Linscott's Directory of Immunological and Biological Reagents (see Literature Cited), updated quarterly, is a useful database of commercial sources of monoclonal and polyclonal antibodies with 40,000 different products and reagents. Printed and floppy disk versions are available. This resource is an invaluable aid in the face of the growing number of large and small companies that supply antibodies.

Selection and Preparation of Starting Material

Fluorescence microscopy is a useful tool for the study of living tissues, of isolated living cells, and of fixed material, including cells, tissues, and living organisms. Preparation and fixation steps can be as diverse as nature itself. This section is focused on fluorescence microscopy of cultured animal cells, which constitutes the vast majority of applications in the literature. After fixation, subsequent steps for labeling and visualization are essentially the same as might be used for any fixed specimen.

For tissue culture applications, cells are generally grown on glass coverslips. In a sterile hood, coverslips are sterilized with 70% (v/v) ethanol and flame. Cells may be grown directly on the glass or on glass coated with extracellular matrix proteins. The most popular coating agents are collagen, fibronectin, and laminin. References and protocols for the coating of

Figure 14.10.10 Image of a smooth muscle cell labeled with antibodies against vinculin, before and after digital reconstruction. On the basis of the PSF digital image, restoration microscopy techniques use deconvolution computer algorithms to reassign locations for out-of-focus photons to produce a sharp image of the object (Carrington et al., 1995). The computer initially learns how the microscope optics transform a pointlike bead into the complex PSF, and then during normal imaging operation it reassigns all out-of-focus photons to their correct xyz points of origin. Courtesy of Scanalytics. Image acquired and processed by Dr. Edwin Moore, Biomedical Imaging Center, University of Massachusetts Medical School, Worcester.

coverslips may be readily obtained from suppliers (e.g., Life Technologies, Sigma).

Rinsing Cells (for Tissue Culture)

The rinsing step removes debris and serum components that may mask certain epitopes as a result of fixation. For many antigens, elimination of this step is possible without consequence. Most protocols use phosphate-buffered saline (PBS) at 37°C for rinsing. Dulbecco's PBS (Dulbecco and Vogt, 1954) with added calcium (Life Technologies) is a sensible choice for two reasons. First, calcium stabilizes cell-cell contact and membrane structure. Second, Dulbecco's PBS mimics extracellular fluid and various culture media more closely in the ionic composition of electrolytes than does PBS. Alternatives are fresh medium for debris removal and serum-free medium when serum proteins may interfere with antigenicity. To preserve cell morphology, it is important to follow temperature constraints, as microtubules may rapidly depolymerize at temperatures lower than cell culture conditions.

Fixation

The choice of fixation method will depend on the structure or protein being labeled. A common practice with tissue culture is to use 2% to 4% (w/v) formaldehyde in PBS. The fixative is warmed to 37°C and applied to coverslips immediately after rinsing. Usual incubation conditions are 10 min at room temperature. A stock formaldehyde solution may be prepared from the crystalline polymer paraformaldehyde as an 8% (w/v) aqueous solution

and stored at 4°C for up to 1 week. (**CAUTION:** Formaldehyde vapors are toxic. Preparation of formaldehyde stock solutions is discouraged unless large volumes are needed—e.g., for cardiac perfusion. Paraformaldehyde is insoluble in water at room temperature. Preparation requires heating to 80°C in a fume hood, tedious pH adjustment with solid sodium hydroxide pellets, and filtering.) For fixation of tissue culture cells and local perfusion of tissues, readily available commercial 16% (w/v) formaldehyde solutions are recommended. As an alternative fixation procedure, rinsed coverslips may be quickly immersed in -20° to -30°C acetone or methanol with 1% to 2% (w/v) formaldehyde. This fixative is especially useful when the question of artifactual reorganization of soluble antigen pools is being considered. Acetone and methanol fixatives are prepared by adding the appropriate volume of a 16% (w/v) aqueous formaldehyde stock to the organic solvent. Most protocols specify the use of this fixative at -20°C. In practice, it is easy to achieve -30°C by setting 10-ml glass coverslip containers on the surface of dry ice.

Wash

After fixation, further manipulations are carried out at room temperature. Three washes in PBS are normally performed to remove fixative and to rehydrate samples fixed in organic solvents.

Permeabilization

Permeabilization may be done as a separate step following fixation or by combining deter-

**In situ
Hybridization
and Immuno-
histochemistry**

14.10.9

gent with an aqueous fixation step. Omission of a detergent permeabilization step is often used to assess whether an epitope is located within a cell or on the extracellular surface. Usually 0.3% to 1% (v/v) Triton X-100 is used. For tissues, the authors suggest the use of 1% (v/v) Triton X-100 in PBS for a 30-min incubation followed by three 10-min washes in PBS. For monolayers of tissue culture cells fixed with formaldehyde in PBS, 0.3% (v/v) Triton X-100 is included with the fixative. For cells fixed with organic solvents, no further permeabilization is required because the solvent extracts lipids from the bilayer of the plasma membrane.

Blocking

Nonspecific binding can be blocked using either bovine serum albumin (BSA) or serum. The authors conservatively use both 2% (w/v) BSA and 5% (v/v) goat serum for 1 hr at room temperature or overnight at 4°C.

Primary Antibody

Primary antibodies are diluted in blocking solution and used to probe tissues and cells. The appropriate dilution depends on antibodies and antigens. If a supplier recommends a particular dilution, say, 1:200, then it is best to initiate experiments by bracketing that dilution (i.e., 1:100, 1:200, and 1:1000). To remove aggregates, solutions are centrifuged 10 min at $14,000 \times g$ just before use. For tissue culture cells, one can typically place coverslips in a moist chamber, face up, on Parafilm. The Parafilm helps to keep primary and secondary antibody solutions on the coverslip and aids in transferring coverslips to six-well dishes for washing. A 22×22 -mm coverslip can be covered with 150 μ l of antibody solution. Incubation times vary from 1 to 3 hr. Alternatively, coverslips may be placed, face down, on Parafilm on 30- to 50- μ l droplets. The surface tensions that develop in this procedure are very large. Thus, although this method results in satisfactory images for most antibodies, its use should be limited to cases of extreme shortage of antibody.

Wash

The intermediate wash step is more critical than previous ones. For high-quality images, use five 10-min washes in PBS. For routine screening of monoclonal antibodies, for example, this step can be reduced to three 5-min washes.

Secondary Antibody

Secondary antibodies coupled to fluorophores must be screened for titer with each new batch or lot. Dilutions are made in blocking serum, followed by centrifugation. Centrifugation is especially important for fluorescein isothiocyanate (FITC)-coupled antibodies to reduce particulate background. Conditions for centrifugation are the same as for primary antibody. The supernatant should be carefully transferred to a fresh tube without disturbing the pellet. Titers can usually be adjusted for a 1-hr room temperature incubation.

Final Wash

The final wash step is as critical as the previous wash. The same considerations apply.

Mounting

A number of antifade mounting solutions can be made at the bench or purchased. One that is particularly easy to prepare and use is made by mixing 10 mg *p*-phenylenediamine (Sigma) with 1 ml PBS and 9 ml glycerol. Store the solution in aliquots at -20°C in the dark. Discontinue using when a ruby red color develops. Four dots of nail polish, one at each corner of the coverslip, or four dots of High Vacuum Grease (Dow Chemical), one under each corner, will suffice to hold the coverslip in place. The silicone-based grease may be loaded into a syringe equipped with a wide-bore needle for easy application.

Many other solutions are available to delay fading of fluorescent dyes. The commercial mounting medium ProLong (Molecular Probes) is recommended. In addition to an antifade reagent, the product contains a hardening agent that circumvents the need for nail polish or grease. It works well with cells or tissue. It requires a final water wash and more careful handling. However, ProLong gives results that are noticeably superior to phenylenediamine/glycerol solutions.

Double Labeling

Two basic methods may be used for double labeling. The two primary antibodies are typically generated in mouse and rabbit. They may, however, be from any two distinct host species, so long as there is no cross-reaction of respective secondary antibodies. In the first method, the processing of the first primary antibody and its respective secondary antibody is completed, and then the second primary antibody and its respective secondary antibody are processed separately. The time for the complete operation

is effectively doubled. This method offers the advantage that interactions between the two primary antibodies are avoided. By the same logic, it is absolutely necessary to prepare controls to ensure that the pattern of labeling is not dependent on the order of binding of the two primary antibodies.

An alternative method is to mix the two primary antibodies and two secondary antibodies together. This method produces satisfactory results for many pairs of antibodies and offers significant time savings. Additionally, it provides an opportunity to test for specificity in preadsorption controls (see below). Because of the possibilities of steric hindrance or other interactions in the binding of antibodies to closely situated epitopes, any double-labeling experiments must always be accompanied by controls using each primary antibody separately. This is especially important when one of the antibodies is monoclonal, a typical situation.

Controls

Mixing antigen, in the form of protein or synthetic peptide, with primary antibody provides the best control for specificity. This so-called preadsorption control may also be accomplished in the solid phase by coupling antigen to chromatography resins or by blotting large amounts of antigen on nitrocellulose. Solid-phase adsorption controls are especially useful with antigens such as myosins that normally require high salt concentrations for solubilization. Some protocols call for overnight incubation. However, complete blocking may be obtained after a 1-hr incubation of anti-peptide antibodies with 1 mg/ml immunizing peptide, whereas the same concentration of irrelevant peptide has no effect. A good way to implement this control is to titrate the antibody with antigen and combine the fluorescence microscopy results with immunoblotting. If titration is not performed, it is still important to show that the antigen is not so concentrated that it is blocking sample labeling by nonspecific mechanisms. This may be accomplished by performing double labeling with two primary antibodies simultaneously. The requirement is

that the antigen specifically block labeling by the appropriate antibody only. Other control conditions introduced at this step are the use of preimmune serum, serum from the same host, or blocking solution alone.

Confocal microscopy produces sharp images of structures within relatively thick specimens (up to several hundred microns). It is particularly useful for examining fluorescent specimens. Thick fluorescent specimens viewed with a conventional widefield fluorescent microscope appear blurry and lack contrast because fluorophores throughout the entire depth of the specimen are illuminated and fluorescence signals are collected not only from the plane of focus but also from areas above and below. Confocal microscopes selectively collect light from thin (~1- μm) optical sections representing single focal planes within the specimen. Structures within the focal plane appear more sharply defined than they would with a conventional microscope because there is essentially no flare of light from out-of-focus areas. A three-dimensional view of the specimen can be reconstructed from a series of optical sections at different depths.

The confocal microscope is the instrument of choice for examining fluorescence-stained cells in tissue slices or small, intact organisms such as *Drosophila* (Fig. 14.11.1A,B) and zebrafish embryos. It is also useful for localizing fluorescent-tagged molecules in dissociated cells (Fig. 14.11.1C,D). Its sensitivity even allows fluorescence in living specimens to be monitored, making it feasible to follow the movements in living cells of fluorescent probes such as the green fluorescent protein (GFP; Fig. 14.11.1D). In addition, some types of confocal microscopes can be configured to perform photobleach experiments (Fig. 14.11.1D) and to photoactivate “caged” molecules (molecules that are inactive until released with UV illumination).

Biologists use confocal microscopy in a number of creative ways that are beyond the scope of this article. The information presented herein is intended to provide background and practical tips needed to get started with confocal microscopy. An excellent source of theoretical and technical information is the *Handbook of Biological Confocal Microscopy* (1995; edited by J. Pawley). Also recommended are *Cell Biological Applications of Confocal Microscopy* (1993; edited by B. Matsumoto), a good source of practical information; *Confocal Microscopy* (1990; edited by T. Wilson), for theoretical background; and *Video Microscopy* (1997; Inoue and Spring) for fundamentals of microscopy.

THE BASIS OF OPTICAL SECTIONING

Confocal microscopes accomplish optical sectioning by scanning the specimen with a focused beam of light and collecting the fluorescence signal from each spot via a spatial filter (generally a pinhole aperture) that blocks signals from out-of-focus areas of the specimen. The physical basis of optical sectioning in fluorescence confocal microscopy is illustrated in Figure 14.11.2. A point light source (typically a laser) evenly illuminates the back focal plane of the objective, which focuses the light to a diffraction-limited spot in the specimen. The irradiation is most intense at the focal spot, although areas of the specimen above and below the focal spot also are illuminated. Fluorescent molecules excited by the incident light emit fluorescence in all directions. The fluorescence collected by the objective comes to focus in the image plane, which is conjugate (confocal) with the focal plane in the specimen. A pinhole aperture in the image plane allows fluorescence from the illuminated spot in the specimen to pass to the detector but blocks light from out-of-focus areas.

The diameter of the pinhole determines how much of the fluorescence emitted by the illuminated spot in the specimen is detected, and the thickness of the optical section. From wave optics we know that a point light source in the plane of focus of an objective produces a three-dimensional diffraction pattern in the image plane. The cross section at the image plane is an Airy disk (see Fig. 14.10.9), a circular diffraction pattern with a bright central region. The radius of the bright central region of the Airy disk in the reference frame of the specimen is given by

$$R_{\text{Airy}} = 0.61\lambda/\text{NA}$$

where λ is the emission wavelength and NA is the numerical aperture of the objective (see UNIT 14.10 for a discussion of NA). At the image plane (the location of the pinhole aperture), the radius of the central region is R_{Airy} multiplied by the magnification at that plane (for a more complete explanation see Wilson, 1995).

Adjustment of the pinhole to a diameter slightly less than the diameter of the central region of the Airy disk allows most of the light from the focal point to reach the detector and reduces the background from out-of-focus areas by ~1000-fold relative to widefield micros-

Figure 14.11.1 Applications of laser scanning microscopy. (A,B) (From W. Oldenwald; see Kamabadur et al., 1998.) 3-D analysis of thick specimens. Different neuronal populations of an $\sim 250\text{-}\mu\text{m}$ -thick *Drosophila* embryo were immunolabeled with antibodies against three transcription factors. A, $\sim 2.5\text{-}\mu\text{m}$ optical section collected with $25\times$, 0.8-NA objective using a detector pinhole diameter of ~ 1.3 Airy units. Labeled neurons in the plane of focus appear sharply defined, while those outside it are not visualized. B, projection (superimposition) of 65 optical sections collected at $2\text{-}\mu\text{m}$ intervals in the z axis. Neurons at different focal planes appear to overlap in this flattened image, but are distinct in a 3-D reconstruction. (C) Localization of intracellular structures. Dissociated rat fibroblasts were immunolabeled with anti-tubulin antibodies to visualize microtubules (green) and stained with fluorescent probes for mitochondria (Mitotracker, red) and DNA (DAPI, blue). The image is a projection of 20 optical sections collected at $0.3\text{-}\mu\text{m}$ intervals in the z axis with $100\times$, 1.4-NA objective. (D) Measuring molecular motility. In a living fibroblast expressing a Golgi membrane protein (galactosyltransferase) fused to GFP (S65T-GFP), GFP fluorescence (green) localized to the Golgi complex, shown superimposed on a DIC image of the cell. After the first image was collected, the boxed region (yellow) was scanned with full laser power; this photobleached the GFP in the boxed area as shown in the second image collected ~ 2 sec later. The rate of fluorescence recovery into the photobleached zone (not illustrated) indicated that GFP-galactosyltransferase fusion is highly mobile in Golgi membranes. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to <http://www.currentprotocols.com/colorfigures>*

copy (Sandison et al., 1995). The separation of the in-focus signal from the out-of-focus background achieved by a properly adjusted pinhole is the principle advantage of confocal microscopy for examination of thick specimens (see Fig. 14.11.1A,B).

Point illumination and the presence of a pinhole in the detection light path also produces improved lateral and axial resolution relative to conventional microscopy (Table 14.11.1). The actual extent of improvement depends on the size of the pinhole. Near-maximal axial resolution is obtained with a pinhole radius $\sim 0.7 \times R_{\text{Airy}}$ whereas optimal lateral resolution is obtained with a pinhole less than $0.3 \times R_{\text{Airy}}$ (Wilson, 1995). However, a pinhole smaller than $\sim 0.7 \times R_{\text{Airy}}$ significantly reduces the total signal, a sacrifice that may not be worth the gain in resolution, especially when imaging dim samples. In fluorescence imaging, resolution also is influenced by the emission and excitation wavelengths (Table 14.11.1).

TYPES OF CONFOCAL MICROSCOPES

Several types of confocal microscopes are available, each having unique features and advantages. The types most commonly used for examining fluorescence specimens are laser-scanning confocal microscopes. These microscopes, as their name implies, use lasers as light sources and collect images by scanning the laser beam across the specimen.

Lasers provide intense illumination within a narrow range of wavelengths. The emission wavelengths of several types of lasers, together with the excitation spectra of familiar fluorophores, are illustrated in Figure 14.11.3. Mixed krypton-argon gas lasers are popular for multi-wavelength confocal microscopy because they emit at three well-separated wavelengths (488, 568, and 647 nm) that can be used to simultaneously image two or three fluorophores (e.g., FITC, lissamine rhodamine, and Cy5). The disadvantage of krypton-argon lasers is that

Figure 14.11.2 The basis of optical sectioning in confocal epifluorescence microscopy. Illumination from the point light source is reflected by the dichroic mirror and focused by the objective lens to a diffraction-limited spot within the specimen. Fluorophores within the focal spot as well as in the cone of light above and below it are excited, emitting fluorescence at a longer wavelength than the incident light. The fluorescence captured by the objective passes through the dichroic mirror because of its longer wavelength. The confocal pinhole allows fluorescence from the plane of focus in the specimen to reach the photodetector but blocks fluorescence from areas above and below the plane of focus. Redrawn from Shotton (1993).

Figure 14.11.3 Comparison of the emission wavelengths of various lasers and the excitation spectra of representative fluorophores. The lasers most commonly used for laser-scanning confocal microscopy are air-cooled argon (488 and 514 nm), krypton-argon, and helium-neon lasers. UV argon lasers generally require water cooling and are more expensive. They may be configured to provide only UV wavelengths (351 nm and 364 nm) or both UV and longer wavelengths. Data for the excitation spectra of Cascade blue, fluorescein (FITC), tetramethylrhodamine (TRITC), lisamine rhodamine (LRSC), and cyanine 5.18 (Cy5.18) are from Wessendorf and Brelje (1993) and were downloaded from the web page of Aryeh Weiss, <http://optics.jct.ac.il/~aryeh/Spectra>. Modified from Brelje et al. (1993).

their life spans are short (~2000 hr). Another way to achieve multiwavelength excitation is to combine the outputs of two or more lasers.

Several methods have been devised for scanning the sample with the laser beam to illuminate different positions in the specimen. The most common method employs a pair of galvanometer mirrors to both scan the laser beam across the specimen and collect the fluorescence emitted from the specimen (Fig. 14.11.4). One galvanometer mirror scans sequential spots along the *x* axis, and the second mirror moves from line to line in the *y* axis. The fluorescence emission is separated from the illuminating beam by a dichroic beam splitter and is directed to a photomultiplier tube which collects the fluorescence produced as each spot in the specimen is illuminated. The photodetector output is converted to a digital image that can be displayed on a monitor and stored as a digital image file for later analysis. Most laser-scanning confocal microscopes have 8-bit digi-

tizers that encode 256 gray levels, although some recent models have 12- or 16-bit digitizers. Collection of a full-size image (typically 1024×1024 pixels) takes ~2 sec. Laser-scanning microscopes that employ galvanometer mirror scanners sometimes are called “slow-scan” microscopes because of their relatively slow image acquisition rates. Slow-scan microscopes are available from several sources (Bio-Rad, Zeiss, Leica, Olympus, Nikon, Molecular Dynamics, and Meridian; see APPENDIX 4).

The movements of the galvanometer mirrors in laser-scanning microscopes are under the control of a computer, providing flexibility in the scanning pattern. For example, it is possible to “zoom” a region of interest (visualize it at higher magnification) by reducing the scan area and the distances between sample points. In addition, many laser-scanning microscopes have the ability to repetitively scan a single line or to “park” the scanner to monitor fluorescence at a single spot. The latter technique is

Figure 14.11.4 The light path of a laser-scanning confocal microscope set up for simultaneous imaging of FITC and lissamine rhodamine. The 488-nm and 568-nm lines of a krypton-argon laser are reflected by dichroic beam splitter 1 into the optical axis of the microscope. The scanner contains two galvanometer mirrors, which generate the *x* and *y* axis movements of the beam. The beam is reflected by a mirror into the objective which focuses the beam onto the specimen. The specimen is scanned line by line in a raster pattern. Fluorescence emitted by the specimen as each spot is illuminated travels the reverse path through the scanning system. The FITC fluorescence (peak at 520 nm) and lissamine rhodamine fluorescence (peak at 590 nm) pass through dichroic beam splitter 1 to dichroic beam splitter 2, which transmits the lissamine rhodamine fluorescence to photomultiplier tube 1 and reflects the FITC fluorescence to photomultiplier tube 2. A variable pinhole in front of each photodetector blocks light from out-of-focus areas of the specimen while allowing light from the illuminated spot to reach the detector.

particularly useful for studying rapidly changing fluorescence signals, such as those produced by a Ca²⁺ indicator in an active neuron.

Laser-scanning microscopes are available (from Norau, Life Sciences Resources, and Meridian; see APPENDIX 4) that can collect images at video rates (30 frames/sec) or faster. Several methods for achieving rapid scanning rates have been employed, such as acousto-optical deflection devices, rotating mirrors, or resonating mirrors (reviewed by Art and Goodman, 1993; Tsien and Bacsikai, 1995). The gain in imaging speed always comes at a cost, however. For example, rapid-scan confocal microscopes do not provide the degree of control over the scan pattern offered by top-of-the-line slow-scan microscopes, and some video-rate confocal microscopes are incapable of multiwavelength illumination. Video-rate microscopes that rely on slit apertures rather than pinhole apertures have slightly poorer lateral and axial resolution.

A type of rapid-scan confocal microscope that deserves mention because of its lower cost (among other reasons) uses a spinning disk with multiple pinholes (~200,000) to simultaneously illuminate and detect emission from many spots in the specimen. The light source can be a laser or a broad-spectrum lamp like that used for conventional epifluorescence microscopy. The principle advantage of this type of confocal microscope is that it is capable of collecting images very rapidly (up to 700 frames/sec at 5000 lines resolution; Kino, 1995). The images can be examined directly by eye or captured with a sensitive camera. The main disadvantage is that the disk transmits only ~1% of the available light because the holes in the spinning disk need to be widely spaced. A new type of spinning-disk confocal microscopy has recently become available that uses "microlenses" to improve optical throughput and achieve high-speed confocal imaging with better sensitivity (Ultra View; Life Sciences Resources; see APPENDIX 4).

Another form of laser-scanning microscopy that promises to be of great value uses two-photon (and three-photon) excitation to induce fluorescence emission (Denk et al., 1995). Two-photon excitation occurs when a fluorophore absorbs two photons, each having half the energy needed to raise the fluorophore to the excited state. The light intensities required for simultaneous absorption occur only at the focal point, so only fluorophores at the focal point are excited. Therefore, two-photon excitation allows optical sectioning without a spa-

tial filter in front of the detector. Moreover, since fluorophores outside the focal point are not excited, the specimen is less subject to photobleaching than in a conventional laser-scanning microscope. The wavelengths needed to excite standard visible light fluorophores by two-photon absorption are longer and penetrate tissue better than the wavelengths used for one-photon excitation, making it possible to look deeper into a specimen. In addition, UV fluorophores can be imaged without many of the problems that arise when UV wavelengths are used in conventional laser-scanning microscopes. A current drawback of two-photon confocal microscopy is the high cost of an appropriate laser (~\$100,000). Two-photon scanning microscopes are now available from commercial sources (Bio-Rad, Leica; see APPENDIX 4).

PRACTICAL GUIDELINES

Sample Preparation: Immunofluorescence in Fixed Specimens

Additional guidelines for sample preparation are discussed in UNITS 14.6 & 14.10.

Fixation

The best fixative is one that accurately preserves the three-dimensional geometry of the specimen. The standard fixative for fluorescence microscopy (2% to 4% formaldehyde in PBS) is not ideal because it can cause blebbing of the plasma membrane, vesiculation of intracellular membrane compartments, and other alterations in cellular morphology. Moreover, some commercial preparations of formaldehyde contain methanol, which shrinks cells. Techniques for optimizing formaldehyde fixation are described by Bacallao et al. (1995; also see UNITS 14.6 & 14.10). The buffer should be chosen to match the osmolality and pH of the specimen. Fixatives containing 0.125% to 0.25% glutaraldehyde in addition to formaldehyde preserve cellular morphology better than those containing formaldehyde alone. Some investigators avoid using glutaraldehyde for fluorescence microscopy because it induces autofluorescence. However, autofluorescence can be reduced by treating the sample after fixation with NaBH₄ (1 mg/ml in PBS, pH 8.0, using two treatments of 5 min each for dissociated cells, longer for thicker samples). A more serious drawback of glutaraldehyde for immunofluorescence studies is that it destroys the antibody recognition sites of some antigens. An alternative fixation technique that preserves tissue

better than chemical fixation is rapid freezing followed by freeze substitution (Bridgman and Reese, 1984).

Choices of fluorophores

Criteria to consider in selecting fluorophores for fluorescence microscopy are described in *UNITS 14.6 & 14.10*. The only additional consideration for confocal microscopy is to choose fluorophores that can be excited by the wavelengths provided by the available lasers. However, it is not essential for the excitation spectrum peak to precisely match the laser wavelength because the lasers on most microscopes are sufficiently powerful to maximally excite fluorophores at off-peak wavelengths. For experiments that depend on imaging two fluorophores, it is best to select fluorophores whose excitation and emission spectra have minimal overlap. Good choices for multiwavelength imaging with a krypton-argon laser are: FITC/Oregon green/Alexa 488 (Molecular Probes) for excitation at 488 nm; lisamine rhodamine/Cy3/Texas red/Alexa 568 (Molecular Probes) for excitation at 568 nm; and Cy5 for excitation at 647 nm. UV fluorophores also are good for multicolor imaging (with absorption at 350 to 390 nm; some of the best dyes for DNA are UV fluorophores).

Control samples

Confocal microscopes rely on electronic image enhancement techniques that can make even a dim autofluorescence signal or nonspecific background staining look bright. In order to be able to distinguish a real signal from background it is essential to prepare appropriate control samples. For immunofluorescence experiments with one primary antibody, the appropriate control samples are unstained specimens and specimens treated with the secondary antibody but no primary antibody. Experiments with two primary and secondary antibodies require additional controls to test whether the secondary antibodies cross-react with the “wrong” primary antibody. Other control experiments may be required to verify the specificity of labeling (see *UNIT 14.10*).

Mounting the specimen

The mounting medium should preserve the three-dimensional structure of the specimen. PBS (*APPENDIX 2*) or a mounting medium consisting of 50% glycerol/50% PBS preserves the shapes of cells quite well, but Mowiol and gelvatol cause a 10% decrease in height (Bacallao et al., 1995). Adding an antioxidant to

the mounting medium helps to alleviate photobleaching. One of the best antioxidants is 100 mg/ml 1,4-diazabicyclo[2,2,2]octane (DABCO; Sigma; Bacallao et al., 1995). *n*-propyl gallate (Giloh and Sedat, 1982) and *p*-phenylenediamine (PPD; Johnson et al., 1982) also are effective antibleaching agents, but the former may cause dimming of the fluorescence while the latter may damage the specimen (Bacallao et al., 1995).

The choice of mounting medium should take into account the type of microscope objective that will be used to observe the specimen. In order for an objective to perform optimally, the mounting medium should have the same refractive index as the objective immersion medium. Table 14.11.2 gives the refractive indexes of standard objective immersion media and mounting media. Mismatches in the refractive indexes produce spherical aberration leading to loss of light at the detector, as well as decreased *z* axis resolution and incorrect depth discrimination. Image deterioration caused by spherical aberration increases with depth into the specimen. Significant losses of signal intensity and axial resolution are apparent at distances of just 5 to 10 μm when an oil immersion objective is used to examine a specimen in an aqueous medium (Keller, 1995).

Most microscope objectives are designed for viewing specimens through a glass coverslip of a specific thickness (typically 0.17 μm , a no. 1½ coverslip). Correct coverslip thickness is especially critical for high-NA (>0.5) dry objectives and water immersion objectives (Keller, 1995). Use of a coverslip that differs from the intended thickness by only 5% causes significant spherical aberration. High-NA dry and water immersion objectives typically have an adjustable collar to correct for small variations in coverslip thickness.

The specimen should be mounted as close to the coverslip as possible, especially for observation with immersion objectives, which have short working distances (~100 to 250 μm , depending on the type of objective). This also helps to avoid image deterioration due to spherical aberration. Fragile specimens should be protected by supporting the coverslip; for example, using a thin layer of nail polish, strips of coverslips, or a gasket made from a sheet of silicon rubber (Reiss; see *APPENDIX 4*). Sealing the edges of the coverslip—with nail polish or silicon vacuum grease (Dow Corning; see *APPENDIX 4*)—helps to prevent specimen desiccation and movement.

Table 14.11.2 Refractive Indexes of Common Immersion and Mounting Media

Medium	Refractive index (RI)
<i>Immersion media</i>	
Air	1.00
Water	1.338
Glycerol	1.47
Immersion oil	1.518
<i>Mounting media</i>	
50% glycerol/PBS/DABCO	1.416 ^a

^cRI for liquid medium (RI for solidified medium will be higher).

Living Specimens

Confocal microscopy of living preparations is challenging for several reasons. The specimen must be mounted in a chamber that keeps it healthy and immobile while at the same time providing access for the objective. For high-resolution transmitted-light imaging (e.g., by laser-scanning differential interference contrast microscopy), the chamber must be thin enough to accommodate a high-NA (oil immersion) condenser. Fluorescence signals in living specimens generally are weak and the illumination levels needed to detect them can be damaging to the specimen. Photobleaching inevitably is a problem for experiments that require collecting many images. Temperature fluctuations in specimens kept at nonambient temperatures make it difficult to maintain accurate focus.

A simple chamber for culture preparations grown on glass coverslips can be made by forming a well on a glass slide with a gasket cut from a sheet of silicon rubber or a plastic ruler. To prevent the well from leaking, it should be sealed with silicon vacuum grease, a mixture of melted paraffin and petroleum jelly, or Sylgard (Dow Corning; see APPENDIX 4). The well is filled with medium and then the coverslip with attached cells is placed, cell side down, on top of the well. The preparation can be kept warm during obser-

vation on the microscope with a heated air blower—e.g., a hair dryer with variable power source or a commercial air-stream incubator (e.g., Neutek; see APPENDIX 4)—or with infrared lamps. More elaborate chambers, some of which have built-in heaters and ports for changing solutions, are available from commercial sources (see Terasaki and Dailey, 1995, for a partial listing of manufacturers). An important factor to consider in choosing a chamber is whether it maintains the desired temperature while in contact with an immersion objective that acts as a heat sink. One solution to this problem is to heat the objective as well as the chamber. A heated chamber and objective warmer designed for microscopy with a high-NA objective and condenser are available from Bioprotechs (see APPENDIX 4).

Addition of an oxygen quencher to the medium can help to alleviate photobleaching of the fluorophores. Photobleaching not only leads to dimming of the signal but also to generation of oxygen radicals that can damage cells. Several oxygen quenchers have been reported to be effective, including oxyrase (0.3 U/ml; Oxyrase [see APPENDIX 4]; Waterman-Storer et al., 1993); ascorbic acid (0.1 to 3.0 mg/ml; Sigma; Terasaki and Dailey, 1995); a mixture of Trolox (10 μM; Aldrich) and *N*-acetylcysteine (50 μM; Sigma; M. Burack and G.

Banker, pers. comm.); and crocetin (Tsien and Waggoner, 1995).

Optimizing Imaging Parameters

Choice of objectives

High-NA objectives generally are preferable for fluorescence microscopy because they collect more light than low-NA objectives (brightness is proportional to NA^4). Most high-quality high-NA objectives have >80% transmission at visible wavelengths, but some have low transmission at UV wavelengths (Keller, 1995).

Water immersion objectives are the best choice for visualizing specimens in aqueous solutions (e.g., living specimens). Several microscope manufacturers recently have introduced high-NA water immersion objectives specifically designed for confocal microscopy of biological specimens. These objectives differ from previously available types of water immersion objectives in that they are intended for viewing specimens mounted under a coverslip. They have working distances of $\sim 250 \mu\text{m}$.

Oil immersion objectives can have higher NAs than water immersion objectives. Most have fairly short working distances ($\sim 100 \mu\text{m}$) although some recently introduced oil objectives have working distances of $\sim 200 \mu\text{m}$. A long-working-distance oil objective will be useful only if the specimen is mounted in a medium that matches the refractive index of immersion oil ($\eta = 1.518$). If an aqueous mounting medium is used, images from depths at more than $\sim 20 \mu\text{m}$ into the specimen will be noticeably degraded by spherical aberration. Also, distance measurements in the z axis will need to be corrected. The actual movement of the focal plane in the specimen (d_s) produced by a movement of the objective (d_{obj}) depends on the ratio of the refractive indexes of the specimen and immersion medium. A reasonable approximation (Majilof and Forsgren, 1993) of the relationship is given by:

$$d_s/d_{\text{obj}} = \eta_s/\eta_{\text{obj}}$$

Pinhole size

As was explained above (see Basis of Optical Sectioning), the size of the pinhole has a critical influence on image quality. A pinhole with a radius equal to the radius of the first minimum of the Airy disk—which is approximately equivalent to the diameter at half maximal intensity (Amos, 1995)—will let most of the light from the plane of focus reach the

detector, while blocking most of the out-of-focus flare. The lateral resolution will be $\sim 20\%$ better than that obtainable by conventional microscopy with the same optics (Centonze and Pawley, 1995), although not as good as can be achieved with a smaller pinhole. Lateral resolution continues to improve as pinhole radius is decreased down to a pinhole size of $\sim 0.2 \times$ Airy disk radius, but a pinhole this small excludes $\sim 95\%$ of the signal (Wilson, 1995). Axial resolution improves as pinhole size decreases, down to $\sim 0.7 \times$ Airy disk radius, then levels off. The best trade-off between signal intensity and resolution will depend on the characteristics of the sample and aims of the experiment.

Zoom factor

The zoom setting on a confocal microscope determines the size of the scan region and the apparent magnification of the image. A zoom factor of 2 will scan an area half as long and wide as a zoom factor of 1. Images are made up of the same number of samples (points along the horizontal axis, lines along the vertical axis) and are displayed on the image monitor by a fixed number of pixels regardless of the zoom factor. Therefore, the pixels in a zoom-2 image will represent areas within the specimen half as large in each dimension as the areas represented by the pixels at zoom 1. If the pixel size for an objective at zoom 1 represents $0.25 \mu\text{m} \times 0.25 \mu\text{m}$, then the pixel size at zoom 2 will be $0.125 \times 0.125 \mu\text{m}$. The pixel dimensions (referring to the specimen) are inversely related to the zoom setting.

For each objective, there is an optimal zoom setting which yields pixel dimensions small enough to take advantage of the full resolution of the objective but large enough to avoid oversampling. In order for the minimum resolvable entity to be visible on the display monitor, the pixel dimensions need to be smaller than (less than one-half) the optical resolution. However, if the pixel size is made too small by using a higher-than-optimal zoom factor, the specimen is subjected to more irradiation than necessary with an increased risk of photobleaching. The rate of photobleaching increases proportionally to the square of the zoom factor (Centonze and Pawley, 1995). A guideline for selecting an appropriate zoom factor derived from information theory (the Nyquist Sampling Theorem) states that the pixel dimensions should be equal to the optical resolution divided by 2.3 (see Webb and Dorey, 1995). However, pixel dimensions smaller than this may produce more informative images.

Z axis sectioning interval

In order to study the three-dimensional structure of a specimen, images are collected at a series of focal levels at intervals determined by the commands sent to the focus motor. The most straightforward way to ensure that the reconstructed images have correct proportions in the *x*, *y*, and *z* axes is to collect optical sections at *z* axis intervals equal to the *x*, *y* pixel dimension. However, the interfocal plane interval needed to adequately sample the specimen in the *z* axis is not as small as the *x*, *y* pixel dimension because the axial resolution is poorer than the lateral resolution (see Table 14.11.1). The optimal interfocal plane interval (according to the Nyquist Sampling Theorem) is equal to the axial resolution divided by 2.3. Collecting images at shorter intervals results in oversampling with an increased risk of photobleaching.

Illumination intensity

Fluorescence emission increases linearly with illumination intensity up to a level at which emission saturates. Optimal signal-to-background and signal-to-noise ratios are obtained with illumination levels well below saturation (Tsien and Waggoner, 1995). The illumination intensity on a laser-scanning microscope can be adjusted by inserting neutral-density filters into the light path and/or by operating the laser at submaximal power. In general, the best images are obtained with illumination levels that are as high as possible without producing unacceptable rates of photobleaching.

PMT black level and gain

The contrast and information content of confocal images are influenced by the black level and gain of the photomultiplier tube (PMT) amplifiers. To obtain maximal information, the black level and gain should be adjusted to take advantage of the full dynamic range of the PMTs. The appropriate black level setting can be found by scanning while the light path to the PMT is blocked. The image that appears on the display monitor should be just barely brighter than the background, which is black (gray level = 0). To set the gain, scan the specimen and adjust the gain so that the brightest pixel in the image is slightly below white (gray level = 255). Selecting black level and gain settings which ensure that all signals fall within the dynamic range of the PMT is important for quantitative imaging experiments. The software provided with many confocal microscopes includes a pseudocolor image display mode that facilitates selection of appropriate

black level and gain settings by highlighting pixels with intensity values near absolute black and absolute white.

Averaging

Confocal images of dimly fluorescent specimens captured at typical scan rates (1 to 2 sec/frame for a slow-scan confocal microscope) appear noisy because of the small numbers of photons collected from each spot. In some instances, it may be possible to improve the signal-to-noise ratio by scanning the specimen at slower rates. Another way to obtain a better image is by summing and averaging the signals obtained in multiple scans (frame averaging). Some confocal microscopes provide a second averaging method (line averaging), in which individual lines are repeatedly scanned and averaged. Line averaging generally produces sharper images than frame averaging (which averages full frames) because there is less risk of blurring due to movements or changes in the specimen.

Image display

Commercial confocal microscope packages provide software for some types of image enhancement and display. The display options for three-dimensional datasets typically include “*z* projections” (see Fig. 14.11.1B), which are two-dimensional displays formed by superimposition of stacks of optical sections, and stereoscopic views, which are made by combining two image stacks, one aligned in the *z* axis and the other with a displacement between successive images. Many systems also have the capability to compute cross-sections and projections of the specimen from varying angles. Computed projections for a sequence of view angles can be played as a movie in which the specimen appears to rotate around an axis. Such movies give the viewer a striking impression of the three-dimensional geometry of the specimen. Additional display options are available in various integrated software/hardware packages specifically designed for visualization and analysis of three-dimensional images.

Anticipated Results

Fluorescence in fixed specimens protected with an antifade agent is often sufficiently bright and resistant to photobleaching to make it possible to reconstruct three-dimensional images using imaging parameters that provide optimal resolution. Superb three-dimensional views may be obtained of structures as small and complex as a cell's cytoskeleton or the

terminal arbor of an axon. The maximum depth in the specimen at which adequate images can be obtained depends on a number of factors (e.g., the match in refractive indexes of the immersion and mounting media, the wavelength of light, and the extent of scattering and absorption by the specimen). Under optimal conditions, it may be possible to image structures at depths near the limit allowed by the working distance of the objective; in practice, image quality usually deteriorates at depths in the range of a few hundred micrometers or less.

Although confocal microscopy on living cells is more difficult and damage to the tissue may preclude extensive three-dimensional reconstruction, the added time dimension and confidence in the reality of the images makes it well worth the effort. In addition, it is possible to study dynamic processes lasting for hours by collecting sequences of time-lapse images. Robust fluorophores such as certain variants of GFP (S65T, EGFP) can be imaged repeatedly with minimal loss of fluorescence (see, for example, Ellenberg et al., 1997). In addition, modern laser-scanning confocal microscopes provide a versatile optical bench and sophisticated specimen positioner which permit a wide range of experiments with the controlled application of laser light to living tissues. Current examples of these approaches are photobleaching (Cole et al., 1996; Wedekind et al., 1996) and release of caged compounds (Callaway and Katz, 1993; Svoboda et al., 1996). These are only the harbingers of many future applications of light probe physiology made possible by the versatility of the confocal microscope.

Resources Available via Internet

NIH Image, a powerful image analysis program for Macintosh computers developed by W. Rasband (Research Services Branch, National Institute of Mental Health, NIH), has many useful tools for analysis of confocal images. It can be downloaded from <http://rsb.info.nih.gov/nih-image/> or obtained via FTP from zippy.nimh.nih.gov. A version of NIH Image modified for operation under Windows also is available. Much information about fluorescent probes can be obtained from the Molecular Probes Web Site at <http://www.probes.com/>.

Many topics of interest to confocal microscopists are discussed on the confocal e-mail listserver network. To subscribe to the list, send the message "subscribe confocal<your name>" to listserv@ubvm.cc.buffalo.edu.

Measurement of In Situ Hybridization

UNIT 14.12

Hybridization of labeled specific molecular probes to nucleic acids in tissues allows geometric and functional location of gene expression or of foreign genome sequences. Estimates of amounts and location of target nucleic acid sequence can be made with phosphor storage imaging and molecular controls (see Basic Protocol). A reference material for the procedure may be prepared from RNA, DNA, or virus particles (see Support Protocol).

DETERMINING THE DISTRIBUTION OF RADIOLABELED HETERODUPLEXES IN IN SITU HYBRIDIZATIONS BY PHOSPHOR STORAGE IMAGING

**BASIC
PROTOCOL**

This protocol describes the application of phosphor storage imaging to determining the distribution of radiolabeled heteroduplexes in in situ hybridizations of cells and tissues on microscope slides. The slides and relevant controls and reference materials (labeled with β -emitting isotopes) are exposed on phosphor image storage plates. The resulting signals are nearly linear with respect to radioactivity; they may be digitized and the pixels can be used for quantitative measurements. Alternatively the images so produced may be analyzed by software to determine geometric distribution of label. Inclusion of suitable reference standards allows calculation of relative specific activities at a resolution of 25 μm . Digital results can be confirmed by autoradiography of the slides after imaging.

Materials

- Reference standards (clots; see Support Protocol) hybridized with the same radiolabeled probe used for in situ hybridization
- Radiation standards consisting of ^{14}C embedded in plastic (suitable for ^{35}S or ^{33}P ; may be purchased on a microscope slide from American Radiolabeled Chemicals; <http://www.arc-inc.com>)
- Hybridized slides from in situ hybridization (Chapter 14)
- Phosphor storage imager (e.g., Fuji BAS 5000) with phosphor plates
- Light box or high-intensity light for erasing phosphor plates
- Manila folders
- Double-sided adhesive tape (Scotch brand)
- Plastic wrap (e.g., Saran wrap)
- Image processing software: NIH Image (available for free from the NIH website; <http://rsb.info.nih.gov/nih-image/Default.html>) or MCID (Imaging Research)

Prepare slides for phosphor imaging

1. Assemble reference standards and dry hybridized slides. Erase the phosphor plate completely by exposure to visible light.

Manufacturers provide light boxes that will accomplish erasure, or a high-intensity light may be purchased from the Sun Box (<http://www.sunboxco.com/>).

2. Using double-sided tape, attach slides, with the sections facing up, to a manila folder. Cover this array of slides with a piece of plastic wrap, securing the plastic in place with tape (do not use plastic wrap for ^3H -labeled slides).

Select plastic wrap brands that are as thin as possible. Some brands have plasticizers that may be removed from the slides by washing them in 95% ethanol; Saran wrap, however, is recommended since it does not present this problem.

**In situ
Hybridization
and Immuno-
histochemistry**

3. Place the array of slides in the plate holder, face down on the phosphor plate (be very careful with the imaging plate). Seal the plate holder and store at room temperature in a desiccating cabinet for the requisite exposure time.

Storage plate quality deteriorates if the plate is exposed to moisture; therefore sections should be dry and the plates should be stored in a desiccating cabinet. The authors do not advise attaching slides to the tray with rubber cement, since the solvent in the cement may have an adverse effect on the plate or its properties.

4. Following exposure, working in the dark, take the manila folder with attached slides out of the holder. Take the plate, in the plate holder, to the instrument. Remove the plate from the holder, and in the case of the Fuji BAS 5000, insert it into the machine with the lights out.

The machine is instructed to "read" by the software. The Fuji BAS 5000 instrument reads at a resolution of 25 μm and produces a data file of 160 Mb. This is best handled by a computer with at least 220 Mb RAM, an external storage system with at least 1 Gb capacity, a CD read-only recorder, and a hard disk with 2 Gb storage. After reading the plate, the data is transferred to an external storage system. Up to four data files may be archived on a CD-ROM 650 MB recorder disc.

In contrast to many other instruments used for measuring radioactive decay, storage phosphor images record derivatives of radiation by detecting ionizing radiation from β and γ emitters. The energy is captured by phosphors in the detection screen. The detection screen is swept with a laser light source and visible light is emitted from the phosphorescent screen. This visible light is registered on a photomultiplier and assembled into an image by the computer (Fig. 14.12.1). The signal is linear with respect to radioactivity over several orders of magnitude.

5. Once the plate has been read and the image verified, prepare the slides for autoradiography (UNIT 14.4).

This is an important step since the image on the radiogram may be used to verify events seen on the imaging plate and to assist in the measuring process.

Figure 14.12.1 Phosphor storage imaging.

Evaluate results

6. Extract specific information from the image and to confirm the validity of the information. Keep the following in mind.
 - a. The data from the plate will appear in the computer memory as an image file. Details will vary among instruments and with the computer platform but such files can be very large and appropriate RAM memory should be available.
 - b. On the image of the plate there should be outlines of the slides and of the radiolabeled material. The ^{14}C reference slide should show a progressive gradation of density or, if converted to color, an increase in color from the lookup table.
 - c. The phosphor units should be linear. If they are not, there may be problems with the screens or the hardware.
 - d. A typical experiment is diagrammed in Figure 14.12.2, panels A and B. Mouse fetuses were hybridized with a probe pair and the images were captured on the same plate.
7. Analyze the images using software supplied by the phosphor image manufacturer, or export them to other image processing software such as NIH Image or MCID. When importing files into NIH image, set the width and height of the image in pixels in the custom import menu and then bring in the image as a 16-bit unsigned image on a fixed scale of 0 to 65535.

Figure 14.12.2 (A) Storage phosphor image of a mouse fetus labeled with ^{35}S antisense riboprobe. (B) ^{35}S sense riboprobe hybridized with mouse fetus.

See *Critical Parameters* for interpretation of hybridized control slides.

Although manufacturers report a detection limit as low as 0.9 dpm/mm²/hr; for ¹⁴C (and presumably ³⁵S and ³³P) the time of exposure can vary considerably. With the high-resolution plate, the exposure time may extend to 4 days without overexposure. Other plates will have a satisfactory image after only a few hours.

Estimate amounts of hybridization

- Determine the activity of the ¹⁴C plastic standards per mm² using the instrument's software.

These values can be plotted by the software or by use of a statistical program. The values should be linear or nearly linear with respect to radioactivity. Occasionally, a second-order polynomial will provide a statistically better correlation. Always include the ¹⁴C reference in each exposure.

- Determine the activity per mm² of the RNA clot reference slide. If the distribution of RNA is inhomogeneous, either prepare more reference clots (see Support Protocol) with greater attention to mixing, or, if the clot area is large enough, measure several 1-mm sites and take the mean.

At this point there should be several images on the exposure plate (Fig. 14.12.3). One is the radiation reference slide with multiple rectangles of radioactive plastic standards. Another is the image of the hybridization "standards" from the plasma clots probed with antisense probes accompanied by sections from the sense control and the nonsense control.

The clot hybridized with the sense probe may be used as a molecular control for antisense probe and in addition, a nonsense clot may be used to subtract background from the activity of the antisense probes.

Signals from nucleic acid hybridization are seldom as directly proportional as other chemical processes. There are a number of physical states for both the probe and the target nucleic acids in hybridization reactions that are highly variable. These may preclude conventional stoichiometric measurements. With that understanding, it is only possible to estimate the amounts of hybridization by constructing references such as the plasma clot containing known amounts of RNA. It is unknown what size of RNA will diffuse out of the clot and affect results. The relative amounts of probe hybridization for each experiment can be compared by reference to the permanent ¹⁴C objects, allowing a reasonable reliability of the process.

Figure 14.12.3 Estimating phosphor images.

10. Using the software provided with the imager, determine the phosphor values for the reference ^{14}C sections per mm^2 . If desired, a correction factor can be used to adjust for the differences in decay energy between the ^{14}C standard and the isotope used.
11. Determine the activity of the RNA clot, preferably at several 1-mm locations. Do the same for the sense and nonsense clot sections.

The authors prefer to use the nonsense sections for subtraction as a blank and reserve the sense section as a technique control. The test slides may be compared to a sense or nonsense control. It is assumed that the sections are infinitely thin and that self-absorption is constant. The thickness of the sections is assumed to be $6\ \mu\text{m}$, although microtome sections are subject to a number of variations.

There are several methods for estimating amounts of RNA or virion particles. One is to express values in pCi based on the radiation standards. Another is to convert the concentration of RNA in the corrected clot to phosphor units. This may be done either on the basis of molar concentrations in the clot or “viral genome equivalents” based on the amounts of RNA within the viral particles. Each investigator should develop experience with either of these possibilities.

PRODUCING A REFERENCE SYSTEM

Well characterized suspensions of a variety of viral particles are available from Advanced Biotechnologies. These preparations contain a known number of virions per ml. A quantity of RNA or DNA may also be made using a standard transcription system (*UNIT 14.8*) and assayed for concentration. The authors strongly recommend that a “nonsense” RNA be made as a control. Most suppliers of transcription reagents have a control DNA that can be transcribed to yield a nonsense probe that is irrelevant to the target gene or any other likely to be found. In situ hybridization using radiolabeled riboprobes may be conducted using established protocols (*UNIT 14.3* or Fox and Cottler-Fox, 1993). No special alterations in technique are required. The isotope used may be ^{33}P , ^{35}S , or ^3H . Tritium requires special screens for the phosphorimager. To test for linearity, a series of dilutions may be made of the calibration reference.

For a reference system, the following items are required: (1) radiation standards consisting of ^{14}C embedded in plastic are suitable for ^{35}S or ^{33}P ; these may be purchased on a microscope slide from American Radiolabeled Chemicals—and (2) an artificial tissue (Cottler-Fox and Fox, 1991), which is generated in this protocol using fibrinogen and thrombin and then hybridized with the same radiolabeled probe used in the in situ hybridization.

Materials

Radiolabeled standards: sample of RNA, DNA, or virion suspension (see recipe)
Fibrin glue (see recipe)
Thrombin, USP (see recipe; dilute to 10,000 U/ml)
1.3 M formaldehyde solution without buffers or salt (see recipe)
70% ethanol

1. Combine the fibrin glue with sample standard material in a ratio of 2 parts glue to 1 part standard (e.g., 1 ml glue to 0.5 ml). If the Tisseel system is used, add the standard suspension directly to the fibrinogen diluent used to reconstitute the lyophilized fibrinogen.

The quantities can be varied as long as the fibrinogen glue solution is not diluted >2:1.

CAUTION: *The fibrinogen is of human origin, and suitable biohazard precautions should be used.*

SUPPORT PROTOCOL

In situ Hybridization and Immuno- histochemistry

14.12.5

2. Coagulate the fibrinogen mixture by one of the following methods.
 - a. *If the Tisseel system is used:* Mix using the convenient dispenser provided with the kit, which has two paired syringes connected by a plastic valve allowing both solutions to be expelled and mixed simultaneously. Remove the hypodermic needle from the dispenser assembly for faster mixing. Expel the two solutions simultaneously and vigorously, which will cause a clot to be formed almost instantaneously.
The thrombin solution may be prepared at double strength if necessary.
 - b. *If the Tisseel system is not used:* Mix the fibrinogen solution thoroughly with the test (reference) solution (step 1) and add thrombin solution while the tube containing the mixture is rotated on a vortex mixer. Allow the clot to harden for 3 min.
3. Remove the clot from the tube with a very thin spatula or a broken applicator stick. Place the clot in 20 vol of formaldehyde solution at room temperature. Allow the clot to fix for 24 hr on a slowly (15 rpm) rotating shaker. Transfer the clot to a 70% ethanol solution and process as ordinary tissue (UNIT 14.1).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Fibrin glue

Available in some departments of transfusion medicine or may be obtained in a convenient pharmaceutical grade product kit as the Tisseel system (Baxter or Hyland-Immuno).

Fibrin glue is a concentrated fibrinogen solution made from human plasma and is used in surgery to reduce oozing of wounds.

Formaldehyde solution without buffers or salt, 1.3 M

Prepare by depolymerizing paraformaldehyde (Fluka-Sigma. See UNIT 14.1 for procedure, substituting water for saline).

IMPORTANT NOTE: *Do not use 37% commercial formaldehyde and do not add saline.*

CAUTION: *Formaldehyde is a putative carcinogen.*

Sample of standard material

RNA, DNA, or a virion suspension may be used. Concentration of the RNA and DNA varies considerably. It is a function of the length of the polymer and must be determined empirically. The concentration of the viral suspension should be $\sim 1 \times 10^{12}$ particles per ml.

Thrombin, USP

Topical bovine thrombin manufactured by GenTrac is a convenient product since it comes with diluent and is in a stable lyophilized form that may be stored at room temperature.

COMMENTARY

Background Information

In situ hybridization was first used by Gall and his students for genetic studies (Gall and Pardue, 1971). Since that time, a variety of strategies have been developed for using specific nucleic acid polymers (probes) for hybridizing with target sequences in cell and tissues (see Chapter 14 introduction). There are, however, serious problems in applying the basic principles of Southern or northern hybridization to the inhomogeneous and tortuous compartments of cellular DNA and RNA in tissues. The problem is further compounded by tissue fixation, probe accessibility, stringency of washes, and the enormous variety of biological structures that compromise routine or general protocols.

The functional principles of in situ hybridization in cells and tissues can be briefly stated as follows. The longer a sequence represented in the probe, the greater the sensitivity of target detection. Smaller probes require proportionately more target copies. If riboprobes are to be synthesized, the maximum length of insert should not exceed the capacity of the polymerase used, often 2 to 3 kb. These products should be truncated by hydrolysis to a more practical length. Since hybridization does not involve establishing covalent products and because of the vagaries of microenvironment reaction kinetics, stoichiometry is problematic. Probes based on nonradioactive chromogens are infinitely more difficult to measure than radiolabeled ones. Finally, it is important to remember that negative results in a well tuned and controlled in situ hybridization procedure are important results as well.

Critical Parameters

To estimate the amount of target molecules in tissue specimens, it is first necessary to have a functioning and well proven in situ technique and considerable experience with the plethora of problems in the procedure. The authors have chosen to adapt a protocol (Fox and Cottler-Fox, 1993) to formaldehyde-fixed tissues and test objects, since most archival tissue is available in paraffin blocks.

The expectations of the investigator must be carefully reasoned. If a simple estimate of the total amount of probe hybridized to a tissue section is all that is required, liquid scintillation counting, the use of ^{32}P for probe labeling, or estimations from γ counting of ring-labeled ^{125}I probes will suffice. For more sophisticated

studies, it may be necessary to determine the total number of copies in a particular cell, tissue, or organ, or to estimate the numbers of infected cells in viral diseases. It may also be desirable to determine the size or volume of tissues and targets by image analysis.

Slides that bear sense hybridization specimens should show marked differences from antisense hybridized slides, of at least one to two orders of magnitude. If levels of signal are the same in both sense and antisense, there are serious problems. Common difficulties include probe misidentification, incomplete washing, or, in the case of probe cocktails, the inclusion of an antisense fragment in the sense probe. A theoretical consideration is translation of the opposite strand of DNA resulting in the accumulation of antisense strands. Obviously these are technical details inherent in any in situ hybridization. Further cursory inspection of the image should show a gradient of signals from the ^{14}C control slide.

The principles of phosphor storage imaging were developed in Japan (Miyahara, 1989) and have revolutionized radiation measurement. The authors applied the phosphor imaging principle to measuring virus in tissues some time ago (Fox et al., 1994). Equipment that can be used (other than that used for in situ hybridization) is rather simple. Molds for constructing standards may be adapted from existing laboratory supplies. Imaging equipment is produced by a number of companies. We have chosen the FUJI BAS 5000 for its 25 μm resolution and dual Macintosh/PC compatibility. Other manufacturers, such as Packard Instruments, produce instruments at a lower price with only slightly less resolution and their own variety of software programs. Imaging screens also vary in resolution and sensitivity.

Troubleshooting

Some common hybridization problems are presented in Table 14.12.1.

Anticipated Results

Although manufacturers report a detection limit as low as 0.9 dpm/mm²/hr, for ^{14}C (and presumably ^{35}S and ^{33}P), the time of exposure can vary considerably. With the high-resolution plate, the exposure time may extend to four days without overexposure. Other plates will have a satisfactory image after only a few hours.

An example of how amounts of HIV in a tissue section are estimated is shown in Figure

Table 14.12.1 Troubleshooting

Problem	Possible cause	Solution
High signal in sense or nonsense specimen	Inadequate washing	Increase stringency of SSC washes, increase wash times
	Mislabeled	Repeat procedure
No signal in antisense specimen	Ribonucleases	Improve hygiene
No labeling	No labeling	Remake probe
	Low expression	Consider whether ISH is appropriate. Use higher-energy isotope.
Streaking of image	Inadequate washing	Refer to autoradiogram to see if it occurs in both images
Poor resolution	Defective screens or instrument	Purchase new screens. Service instrument.
Nonlinear measurements of clot controls	Poor mixing, or ribonucleases in fibrinogen	Recast clot
	Loss of RNA through diffusion	Add RNase inhibitors, fix clot promptly, increase fibrinogen, or use longer transcripts

Figure 14.12.4 Quantitative anatomy of an HIV lymph node from phosphor imaging with antisense probe.

14.12.4. The measurement unit is in PSL, a term coined by Fuji for their radiation unit (Photo Stimulated Luminescence). The results are shown in PSL converted to viral genome equivalents. The image demonstrates the possibility of estimating viral expression on a single-cell basis.

Time Considerations

Time considerations are not especially critical. In general, a typical experiment runs as follows.

- a. Preparing probes: 1 day with 3 hr net time.
- b. Processing tissues and microtomy: 2 days, 3 hr net.
- c. Preparing reference: 2 days, 3 hr net.
- d. In situ hybridization of tissue and reference slides: 2 days, 8 hr net.
- e. Exposure of plate: 1 to 7 days, 3 days for the highest sensitivity/resolution.
- f. Scanning plate: 15 to 30 min.
- g. Analysis of results: 1 hr per section.

Morphological, Biochemical, and Flow Cytometric Assays of Apoptosis

UNIT 14.13

As programmed cell death (PCD) or apoptosis has emerged as an important regulator of development and homeostasis in multicellular organisms, methods to quantify apoptosis and to distinguish it from necrosis have been developed. This unit presents a set of assays for these purposes, many of which are technically very simple. Necrosis refers to the morphology usually associated with accidental cell death, while apoptosis is seen when cell death is programmed or physiologically regulated. Loss of viability, whether the result of a necrotic or apoptotic process, is often defined experimentally as the loss of membrane integrity. The determination of whether a cell dies by apoptosis as opposed to necrosis is best made on the basis of (1) alterations in the cell membrane and cytoplasm and (2) changes in the cell's chromatin, both of which occur prior to the lysis of the membrane. The latter changes include extensive condensation of the chromatin as assessed by light or electron microscopy, and DNA fragmentation as detected by sedimentation assays, gel electrophoresis, or end labeling of the DNA fragments. Other apoptotic changes include membrane boiling or blebbing, which can only be appreciated microscopically, and the display of phosphatidylserine on the cell surface, which can be detected by flow cytometry. Loss of membrane integrity is conveniently measured by uptake of certain dyes such as trypan blue, eosin, ethidium bromide, or propidium iodide, or by the release of lactate dehydrogenase or radioactive chromium.

Basic Protocol 1 allows the qualitative and quantitative assessment of apoptosis in lymphocyte cell cultures using light or fluorescent microscopy. Using vital or DNA-binding fluorescent dyes, this method provides an easy way to determine the percentage of cells undergoing apoptosis and/or dying in a given population.

Next is a technique that quantitates apoptotic cells using flow cytometry. Basic Protocol 2 quantitatively detects DNA fragmentation in apoptotic cells based on the observation that apoptotic cells fixed with ethanol and stained with DNA binding dyes display an increased sub-G₀/G₁ peak in the flow histogram of DNA content.

Nucleotide end-labeling to detect DNA fragmentation is another technique for identifying apoptotic cells. Basic Protocols 3 and 4 describe TdT-mediated dUTP-biotin nick end-labeling (TUNEL) methods, which detect apoptotic cells by using terminal deoxynucleotidyl transferase (TdT) to directly label the ends of broken DNA strands. This approach is suitable for both qualitative and quantitative analysis. Basic Protocol 3 outlines the flow cytometric quantitation of apoptotic cells using TUNEL and Basic Protocol 4 describes TUNEL staining of tissue sections to identify apoptotic cells.

A great deal has been learned about the biochemical events and specific families of molecules that regulate the apoptotic process. However, much remains incompletely understood about the molecular pathways of programmed death, and it is probably best to perform more than one of the basic protocols to confirm an observation of apoptotic cell death.

NOTE: Unless the cells are to be used for flow cytometry or other processes that will require no further in vitro cultivation of the cells, all solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly.

histochemistry

**MICROSCOPIC QUANTITATION OF APOPTOTIC INDEX AND CELL
VIABILITY USING VITAL AND FLUORESCENT DYES**

Perhaps the simplest and most accurate means to assess apoptosis is by careful microscopic inspection. By examining cells in the culture dish using a low-power inverted microscope, a qualitative diagnosis of apoptosis can often be made immediately. The tell-tale signs of apoptosis include a condensed nucleus, a blebbing cell membrane, and clear cytoplasm. With extensive cell death *in vitro*, a prominent feature is the accumulation of a large amount of debris. This is because phagocytosis, which normally efficiently removes early apoptotic cells *in vivo*, does not occur *in vitro*. This allows apoptosis to progress to full cellular disintegration and even secondary necrosis.

To easily quantify cell death, hemacytometer counting can be performed (*APPENDIX 3F*). An aliquot of cell suspension is mixed with an equal volume of 0.01% trypan blue and loaded into the trough of a standard hemacytometer. Usually three major morphologies are apparent: (1) healthy, live cells, which are clear white disks that have excluded trypan blue; (2) early apoptotic cells, which are white due to trypan blue exclusion but have an irregular shape (like a wad of crumpled paper) or a shrunken nucleus due to early apoptosis; and (3) cells in end-stage apoptosis or secondary necrosis, which are irregular, blue-stained shells or remnants of dead cells. Both live (white) and dead (apoptotic-appearing or blue) cells can be counted. However, the live cell number is more accurate, since the dead cells disintegrate and can be over- or underestimated depending on the timing of the culture and the nature of the debris that has formed. Although light microscopic examination can be time-consuming for a large number of samples, it is relatively easy and is the most direct means to evaluate apoptosis qualitatively and quantitatively for many biologists. Though this is beyond the scope of this unit, the characteristic changes in nuclear chromatin during apoptosis can also be readily visualized by electron microscopy.

For investigators with ready access to a fluorescent microscope, a more elaborate method can be used. This procedure gives slightly better distinction between apoptotic and necrotic cells.

In this protocol, a cell suspension is mixed with fluorescent DNA-binding dyes and examined by fluorescence microscopy to visualize and count cells with aberrant chromatin organization. Acridine orange is used to determine how many cells within a given population have undergone apoptosis, but it cannot differentiate between viable and nonviable cells. To do this, a mixture of acridine orange and ethidium bromide is used. The differential uptake of these two dyes allows for the identification of viable and nonviable cells (Mishell et al., 1980).

Any fluorescent DNA-binding dye capable of permeating viable cells (e.g., Hoechst 33342 or DAPI) may be used in place of acridine orange; however, these dyes require UV excitation wavelengths of <350 nm, which may not be available on standard fluorescence microscopes.

CAUTION: Acridine orange and ethidium bromide have been found by the Ames test to be highly mutagenic and should be handled with care.

Materials

Dye mix: 0.01% trypan blue (Life Technologies), 100 µg/ml acridine orange (Sigma), *or* 100 µg/ml acridine orange + 100 µg/ml ethidium bromide (Sigma), all prepared in PBS (*APPENDIX 2*)

Cell suspension at $\sim 5 \times 10^5$ to 5×10^6 cells/ml (Table 14.13.1) in complete RPMI 1640 medium (*APPENDIX 3F*)

12 × 75-mm glass tube
 Microscope slide and 22-mm² coverslip (no. 1 thickness; VWR Scientific)
 Fluorescence microscope (e.g., Zeiss or equivalent) equipped with a fluorescein filter set
 Additional reagents and equipment for counting cells (*APPENDIX 3F*)

Trypan blue staining:

- 1a. Place 10 to 20 μl trypan blue solution in the bottom of a 12 × 75-mm glass tube. Add an equal amount of a well-mixed cell suspension and gently mix by hand.

Sometimes cells loosely adhere to the bottom of the flask and may require liberation by gently scraping with a rubber policeman.

- 2a. Load 10 μl of the mixture into the trough of a standard hemacytometer. Examine with a 40× to 60× dry objective of a brightfield microscope.

- 3a. Count a minimum of 200 total cells and record the number of normal versus apoptotic or dead cells.

Cells in early apoptosis may appear white due to trypan blue exclusion, but they will have an irregular shape or shrunken nucleus.

- 4a. Calculate the percentage of apoptotic cells (apoptotic index) as follows:

$$\% \text{ apoptotic cells} = \frac{(\text{total no. of cells counted}) - (\text{total no. of live cells})}{\text{total no. of cells counted}} \times 100$$

This calculation is based on the number of live cells counted, as the dead cell count is less accurate.

Acridine orange staining:

- 1b. Place 1 μl of the dye mix in the bottom of a 12 × 75-mm glass tube. Add 25 μl of the cell suspension and mix gently by hand.

- 2b. Place 10 μl of this mixture on a clean microscope slide and cover with a 22-mm² coverslip. Examine with a 40× to 60× dry objective using epiillumination and a filter combination suitable for observing fluorescein.

Table 14.13.1 Stimulation of Apoptosis in Cultured Cells^a

Cell type	Treatment	Assay time (hr) ^b	Apoptotic index ^c	Protein synthesis required ^d
Thymocytes	100 nM dexamethasone	24	80-100	Yes
	600 rad γ-irradiation	24	80-100	Yes
D011.10 T hybridoma	Anti-CD3	24	80	Yes
P815 mastocytoma	Cytotoxic T cells	4	50-100	No
Raji B cells	Cytotoxic T cells	4	10-20	No

^aSee Background Information for a further description of the cell types and treatments employed in these studies.

^bApproximate time until the cells are assessed for apoptosis.

^cApoptotic index refers to the expected values for the percent of apoptotic/dead cells at the indicated times as quantified according to Basic Protocol 1.

^dRequirement of protein synthesis refers to whether inhibitors of RNA (e.g., actinomycin D) or protein (e.g., cycloheximide, emetine, and pactamycin) synthesis prevent apoptosis (nuclear damage as well as cell lysis).

A hemacytometer may be used for visualization (APPENDIX 3F). However, the ordinary slide/cover slip combination results in a greater flattening of the cells than can be obtained with the rigid coverslip used with hemacytometers, making apoptosis more readily apparent.

- 3b. Count a minimum of 200 total cells and record the number of normal versus apoptotic nuclei.

Acridine orange intercalates into DNA and makes it appear green. It also binds to RNA, but because it cannot intercalate, the RNA stains red-orange. Thus a stained cell will have a green nucleus and may have a red-orange cytoplasm.

It is extremely important to acquaint oneself with normal chromatin distribution in the cell line being investigated (see Commentary). Both live and dead nonapoptotic cell nuclei will fluoresce green and have "structure;" variations in fluorescent intensity reflect the distribution of euchromatin and heterochromatin. Apoptotic nuclei, in contrast, have highly of condensed crescents around the periphery of the nucleus; alternatively, the entire nucleus can be present as one or a group of featureless, bright spherical beads. In advanced apoptosis, the cell will have lost DNA or become fragmented into "apoptotic bodies" and the overall brightness will be less than that of a normal cell.

- 4b. Calculate the percentage of apoptotic cells (apoptotic index) as follows:

$$\% \text{ apoptotic cells} = \frac{\text{total no. of cells with apoptotic nuclei}}{\text{total no. cells counted}} \times 100$$

Acridine orange/ethidium bromide staining:

- 1c. Place 1 μl of the dye mix in the bottom of a 12 \times 75-mm glass tube. Add 25 μl of the cell suspension and mix gently by hand.
- 2c. Place 10 μl of this mixture on a clean microscope slide and cover with a 22-mm² coverslip. Examine with a 40 \times to 60 \times dry objective using epiillumination and a filter combination suitable for observing fluorescein.

A hemacytometer may be used for visualization (APPENDIX 3F). However, the ordinary slide/cover slip combination results in a greater flattening of the cells than can be obtained with the rigid coverslip used with hemacytometers, making apoptosis more readily apparent.

- 3c. Count a minimum of 200 total cells, recording the number of each of the following four cellular states: (1) viable cells with normal nuclei (VN; bright green chromatin with organized structure); (2) viable cells with apoptotic nuclei (VA; bright green chromatin which is highly condensed or fragmented); (3) nonviable cells with normal nuclei (NVN; bright orange chromatin with organized structure); (4) nonviable cells with apoptotic nuclei (NVA; bright orange chromatin which is highly condensed or fragmented).

As noted in step 3b, both live and dead cells take up acridine orange. It intercalates into DNA, making it appear green, and binds to RNA, staining it red. Thus a viable cell will have bright green chromatin in its nucleus and red-orange cytoplasm. Ethidium bromide is only taken up by nonviable cells. It intercalates into DNA, making it appear orange, but binds only weakly to RNA, which may appear slightly red. Thus a dead cell will have bright orange chromatin (the ethidium overwhelms the acridine) and its cytoplasm, if it has any contents remaining, will appear dark red. Cells that have undergone necrosis will have the fluorescent features of nonviable cells but will not have apoptotic nuclear morphology. A similar effect can be obtained with the membrane-impermeant dye propidium iodide, which will stain the cytoplasm and nucleus of necrotic cells orange.

Using this method, both normal or apoptotic nuclei in live cells will fluoresce bright green. In striking contrast, normal or apoptotic nuclei in dead cells will fluoresce bright orange.

- 4c. Calculate the percentage of apoptotic cells (apoptotic index) and percentage of necrotic cells.

$$\% \text{ apoptotic cells} = \frac{VA + NVA}{VN + VA + NVN + NVA} \times 100$$

$$\% \text{ necrotic cells} = \frac{NVN}{VN + VA + NVN + NVA} \times 100$$

$$\% \text{ dead cells} = \frac{NVN + NVA}{VN + VA + NVN + NVA} \times 100$$

If the cells have been undergoing programmed cell death for some time, or have fragmented into apoptotic bodies, they may have lost so much chromatin as to render accurate determination of cell viability impossible. "Viable" apoptotic (VA) cells are included in the numerator of the fraction of dead cells since "viability" refers to membrane integrity, not cell fate, and the appearance of apoptotic changes in the nucleus is always associated with cellular demise.

DETERMINATION OF APOPTOSIS USING SUB-G₀/G₁ DNA PEAK

This protocol depends on the observation that apoptotic cells have reduced or hypodiploid DNA fluorescence using conventional cell cycle profile analysis (see Telford et al., 1994). Like the other protocols using flow cytometry, this protocol allows for the quantitative analysis of intact cells.

Materials

Cells to be analyzed, in FACS buffer (see recipe; 10⁵ to 10⁶ total)
FACS buffer (see recipe)
Ice-cold 100% ethanol (70% if cells are to be antibody-labeled)
1 mg/ml RNase A
50 µg/ml propidium iodide (PI) in PBS (APPENDIX 2)

1. Pellet cells to be analyzed from culture following stimulus for apoptosis (see Table 14.13.1 for examples of stimuli). Also pellet cells from an untreated control culture. Resuspend in 3 ml cold FACS buffer, then pellet the cells by centrifuging 5 min at 300 × g. Resuspend pellets by gently flicking the tube.

It is imperative to prepare an untreated control in order to measure the sub-G₀/G₁ region.

If the cells are to be simultaneously stained for surface expression of other markers, this should be done prior to the fixation step.

- 2a. *If the cells have not been stained with other fluorochrome-labeled antibodies:* Fix the cells by resuspending the cells in FACS buffer, and gently adding 1 vol ice-cold 100% ethanol while vortexing. Incubate the cells for 30 min at room temperature.
- 2b. *If the cells have been stained with other fluorochrome-labeled antibodies:* Fix the cells by resuspending them in 500 to 1000 µl FACS buffer and adding 3 vol of 70% ice-cold ethanol while gently vortexing. Incubate cells ≤1 hr at 4°C.

The use of ethanol as a fixative is crucial. Other fixatives such as glutaraldehyde or formaldehyde do not consistently give the hypodiploid peak possibly due to chromatin cross-linking. Although the mechanism is not clear for obtaining the sub-G₀/G₁ peak, it is

BASIC PROTOCOL 2

In situ
Hybridization
and Immuno-
histochemistry

14.13.5

thought to be due to changes in the chromatin accessibility to dye (possibly from increased nuclear condensation from the ethanol) or the actual loss of DNA from the cells.

3. Pellet the cells. Resuspend in 3 ml cold FACS buffer, then pellet the cells by centrifuging 5 min at $300 \times g$. Resuspend the cells in 250 to 500 μl FACS buffer with 40 $\mu\text{g}/\text{ml}$ RNase A and 50 $\mu\text{g}/\text{ml}$ propidium iodide. Incubate ≤ 30 min in the dark at room temperature.

This step allows for the fragmented soluble DNA to leak out of the fixed cells, while simultaneously preventing nonspecific staining of RNA. Other DNA-binding dyes, including ethidium bromide, acridine orange, and anthracyclines, can be used for fixed cell analysis. This allows for greater flexibility when performing multicolor staining.

4. Analyze the cells using flow cytometry (FL2 or FL3) in a linear mode (Holmes and Fowlkes, 1991). The apoptotic fraction of cells can be measured by gating on the cells staining in the region below the large G_0/G_1 peak.

BASIC PROTOCOL 3

FLOW CYTOMETRIC QUANTITATION OF APOPTOTIC CELLS USING TUNEL

Terminal deoxynucleotidyl transferase-mediated dUTP-biotin nick end labeling (TUNEL) is a method for detecting apoptotic cells that exhibit DNA fragmentation. TUNEL (Gavrieli et al., 1992; Gorczyca et al., 1993) involves end-labeling the broken ends of the double-stranded DNA with biotin-conjugated dUTP using the enzyme terminal deoxynucleotidyl transferase (TdT). This protocol outlines a method for quantitating TUNEL-stained apoptotic cells by flow cytometric analysis. It allows apoptotic cells to be analyzed individually on a flow cytometer and is compatible with cell-surface staining, which permits the quantitation of cell death in specific subpopulations of cells that are discernible only by means of multicolor flow cytometric analysis (Kishimoto et al., 1995). If desired, this TUNEL procedure can be performed immediately following (but not before) cell-surface marker staining (Holmes and Fowlkes, 1991).

Materials

- Cells for analysis
- PBS (APPENDIX 2)
- 95% ethanol (not 100% ethanol), ice cold
- Paraformaldehyde fixative solution (see recipe)
- TdT reaction buffer (see recipe)
- TdT/biotin-dUTP mix (see recipe)
- Fluorescein isothiocyanate (FITC)-conjugated streptavidin (Jackson Immunoresearch; follow manufacturer's instructions for appropriate dilution)
- 12 \times 75-mm round-bottom centrifuge tubes
- IEC 6R6000 centrifuge with model 269 rotor (or equivalent)
- Additional reagents and equipment for immunofluorescence staining (optional; Holmes and Fowlkes, 1991) and flow cytometric analysis (Otten et al., 1995)

- 1a. *For multicolor analysis:* Perform immunofluorescence staining (Holmes and Fowlkes, 1991). Resuspend stained cells in PBS and transfer an aliquot containing 5×10^5 cells to a 12 \times 75-mm round-bottom centrifuge tube.

If this step is performed, it must be done prior to the TUNEL procedure. The final wash should be performed in PBS (instead of the staining buffer used in Holmes and Fowlkes, 1991) in 12 \times 75-mm round-bottom centrifuge tubes and the cells should not be treated with propidium iodide. It is essential that the fluorochromes used for multicolor staining not be destroyed by the fixation steps used in the TUNEL procedure. FITC, PE, and Texas

red are not affected. The duochromes (conjugates of PE and Texas red—e.g., Red 613) are not affected either, but allophycocyanin (APC) is destroyed by the fixation.

1b. *For TUNEL detection alone:* Transfer an aliquot containing 5×10^5 cells to a 12×75 -mm round-bottom centrifuge tube.

2. Add 1 to 2 ml PBS, then centrifuge cells 5 min at $300 \times g$ (1200 rpm in an IEC model 269 rotor), 4°C , and decant supernatant. Resuspend pellet in 250 μl PBS, then add 750 μl ice-cold 95% ethanol dropwise over a period of 5 to 10 sec while gently vortexing. Incubate 20 min at 4°C .

Gradually adding ethanol while gently vortexing reduces clumping during this fixation step.

3. Wash cells by adding 2 ml PBS and centrifuging 5 min at $400 \times g$ (1500 rpm in an IEC model 269 rotor), 4°C . Decant supernatant.

Higher centrifugation speed is required for fixed cells than for unfixed cells, because ethanol fixation causes cell shrinkage.

4. Flick the tube to resuspend cells in residual buffer, and add 1 ml paraformaldehyde fixative dropwise over a period of 5 to 10 sec while gently vortexing cells. Incubate 30 min at room temperature.

Paraformaldehyde fixation makes the intracellular constituents more accessible and greatly increases the sensitivity of TUNEL staining.

5. Wash cells with PBS as in step 3.

The washed cells can be stored for a few days at 4°C in the dark.

6. Wash cells as in step 3, using 0.5 ml TdT reaction buffer in place of PBS. Remove as much supernatant as possible by touching the lip of the inverted tube on absorbent paper immediately after decanting the supernatant.

7. Add 50 μl TdT/biotin-dUTP mix to cell pellet. Incubate 45 min at 37°C .

8. Wash cells with PBS as in step 3, then add 10 μl FITC-conjugated streptavidin (at the dilution recommended by the manufacturer). Incubate 30 min at room temperature, then wash again with PBS as in step 3.

The best staining is obtained with FITC-conjugated streptavidin. Other fluorochromes—e.g., PE and the “duochromes”—give much weaker staining.

9. Perform flow cytometric analysis (Otten et al., 1995).

See Anticipated Results for representative histograms obtained from flow cytometry using the TUNEL method.

IN SITU DETECTION OF APOPTOTIC CELLS IN TISSUE SECTIONS BY TUNEL

The TUNEL method of detecting cells that exhibit DNA fragmentation can also be performed on tissue sections to locate apoptotic cells in situ (Gavrieli et al., 1992). This can be done by end labeling with biotinylated dUTP and detecting with enzyme-conjugated streptavidin, but more sensitive staining is obtained by end labeling with digoxigenin-conjugated dUTP and detecting with two layers of antibodies, the last of which is conjugated to an enzyme that permits colorimetric detection (Surh and Sprent, 1994). An additional advantage of this approach is that it circumvents background staining from endogenous biotin. The TUNEL method described here, which uses digoxigenin-conjugated dUTP, is for frozen sections but can also be performed on paraffin sections. See

BASIC PROTOCOL 4

**In situ
Hybridization
and Immuno-
histochemistry**

14.13.7

UNITS 14.1 & 14.2 for relevant information on preparation and handling of frozen and paraffin sections. It should also be noted that there are now commercially available kits that eliminate one step through the use of enzymatically conjugated dUTP.

Materials

Fresh tissues for analysis
1% (w/v) paraformaldehyde in PBS (dissolve by stirring with low heat overnight and filter before use)
Tris-buffered saline (TBS; APPENDIX 2)
0.1% (v/v) H₂O₂ in TBS
TdT reaction buffer (see recipe)
TdT/digoxigenin-dUTP mix (see recipe)
2% (v/v) horse serum or FBS in TBS
Sheep anti-digoxigenin primary antibody solution (see recipe)
HRPO-conjugated anti-sheep secondary antibody solution (see recipe)
AEC substrate working solution (see recipe)
Mayer's hematoxylin (Sigma)
Crystal Mount mounting medium (Fisher)
Hydrophobic-barrier slide marker (e.g., PAP Pen; Research Products International)
Coplin jars or staining trays
Humidified container (see recipe)
Additional reagents and equipment for preparing frozen sections (as in immunoperoxidase staining; UNIT 14.2 & 14.6)

Prepare and fix sections

1. Prepare 5- to 8- μ m frozen sections (see UNIT 14.2), drying slides overnight at room temperature.

Slides can be stored 2 to 3 weeks at 4°C or a few months at -70°C. This prolonged storage is possible because DNA is fairly stable. Paraffin sections may also be used; these should be prepared, rehydrated, and air dried.

2. Draw a hydrophobic boundary on the glass around each section with a PAP Pen.

A tight boundary is critical because each section must be covered with a small volume of TdT reaction buffer (see step 7).

3. Generously cover the entire section with 1% paraformaldehyde and incubate 30 min at room temperature in a closed container.

A closed container is necessary to prevent evaporation but a humidified container is not required.

Sections can be fixed with acetone instead of paraformaldehyde for 5 min at room temperature. Acetone-fixed sections tend to stain with better resolution, but such staining is generally weaker and tends to have a higher background. If the sections are to be acetone fixed, draw the boundaries with the PAP Pen after the acetone has completely evaporated.

Carry out TUNEL reaction

4. Pour off the paraformaldehyde and wash the slide by incubating 5 min at room temperature in a Coplin jar or staining tray containing TBS, dipping the slide in and out of the solution three to four times during the course of the incubation.

This step is not required for acetone-fixed sections.

5. Cover section with 0.1% H₂O₂ in TBS. Incubate 30 min at room temperature in a closed container to quench endogenous peroxidase activity.

For acetone-fixed sections use 0.01% H₂O₂.

6. Wash with TBS as in step 4, then cover section with TdT reaction buffer to rinse out TBS.

This step is critical because the TdT reaction is highly sensitive to buffer conditions.

7. Remove as much reaction buffer as possible and add 25 µl TdT/digoxigenin-dUTP mix. Incubate 45 to 60 min at 37°C in a humidified container.

Carry out detection reaction

8. Wash slide once with TBS, then once with 2% horse serum or FBS in TBS, each time using the washing technique described in step 4.
9. Cover section with sheep anti-digoxigenin primary antibody solution and incubate 1 hr at room temperature in a closed container.
10. Wash slide as in step 8, then cover section with HRPO-conjugated anti-sheep secondary antibody solution and incubate 1 hr at room temperature in a closed container.

Develop color and mount slide

11. Wash slide as in step 8, then cover section with AEC substrate working solution and incubate 10 to 20 min at room temperature.

The intensity of color development can be visually monitored by low-power light microscopy. Develop until positive staining is strong with a minimal background.

Diaminobenzidine (DAB) may be used as a substrate in place of HRPO (see UNIT 14.6). This helps avert one critical drawback in using AEC—i.e., that the color precipitate starts to fade slowly within a few weeks. Although fading is not a problem with DAB, sections developed with this substrate have lower resolution because DAB tends to diffuse.

12. Wash slide as in step 8, then counterstain by incubating 0.5 to 1 min in Mayer's hematoxylin, then washing 5 min with tap water in a Coplin jar.

This step is optional; omitting it greatly reduces the fading problem with AEC staining. Where sections are not counterstained, the AEC-stained slide (from step 11) should be washed as in step 8; the coverslip should then be mounted as in step 13.

13. Wipe excess water from around the section and mount coverslip with Crystal Mount.

See Anticipated Results for representative stainings obtained using in situ TUNEL.

Because of the fading problem with AEC, sections developed with this reagent should be photographed within a few days after staining.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

AEC substrate solution

AEC stock solution:

Prepare 4 mg/ml 3-amino-9-ethylcarbazole (AEC; Sigma) in DMSO. Store up to 2 to 3 weeks in the dark at room temperature.

Working solution:

1 ml 0.17 M sodium acetate, pH 5.2 (APPENDIX 2)

25 µl AEC stock solution

1 µl 30% H₂O₂

Prepare immediately before use

FACS buffer

PBS (APPENDIX 2)

1% BSA (fraction IV, protease free; e.g., Sigma)

0.01% (w/v) sodium azide

Store indefinitely at 4°C if not contaminated

HRPO-conjugated anti-sheep secondary antibody solution

TBS (APPENDIX 2) containing:

2% (v/v) horse serum or FBS

5 µg/ml horseradish peroxidase (HRPO)-conjugated F(ab')₂ fragment of donkey anti-sheep IgG (Jackson Immunoresearch)

Prepare immediately before use

Humidified container (moist chamber; Fig. 14.2.4)

A moist chamber is constructed from any convenient-sized container with a tight lid (e.g., Tupperware or equivalent). Slide supports are made by attaching pairs of 5- or 10-ml pipets to the bottom, spaced so they support slides at both ends, or by using a stainless steel cake rack or equivalent. The bottom is lined with absorbent paper soaked with water or buffer. For use with light-sensitive reagents, the moist chamber is wrapped in aluminum foil, painted black, constructed from a black container, or shielded from ambient light.

Paraformaldehyde solution

Dissolve 1% (w/v) paraformaldehyde and 0.01% (v/v) Tween 20 in PBS. Stir at low heat (70°C) to dissolve paraformaldehyde. Store up to 6 months at room temperature. Filter through a 0.2-µm filter before use.

Sheep anti-digoxigenin primary antibody solution

TBS (APPENDIX 2) containing:

2% (v/v) horse serum or FBS

5 µg/ml sheep anti-digoxigenin Fab (Boehringer Mannheim)

Prepare immediately before use

TdT/biotin-dUTP mix

TdT reaction buffer (see recipe) containing:

0.5 to 1 µM biotin-dUTP (Boehringer Mannheim or Clontech)

2 to 4 U TdT (Promega or Boehringer Mannheim)

Prepare immediately before use

The TdT and biotin-conjugated dUTP should be titrated; the optimal concentrations should be near the indicated ranges. The best-quality biotin-dUTP preparation is the 1 mM biotin-16-dUTP from Boehringer Mannheim; the most economical is the 10 mM biotin-21-dUTP from Clontech (sold in 100 µl portions).

TdT/digoxigenin-dUTP mix

TdT reaction buffer (see recipe) containing:

1 to 2 µM digoxigenin-11-dUTP (Boehringer Mannheim)

2 to 4 U TdT (Promega or Boehringer Mannheim)

Prepare immediately before use

TdT and digoxigenin-conjugated dUTP should be titrated; the optimal concentrations should be near the indicated ranges. For acetone-fixed sections, a higher concentration of TdT (5 to 10 U) is required.

TdT reaction buffer

0.5 M cacodylic acid, sodium salt, pH 6.8

1 mM CoCl₂

0.5 mM DTT

0.05% (w/v) BSA

0.15 M NaCl

Store at room temperature or 4°C; stable several months

COMMENTARY

Background Information

Cell death in multicellular organisms has been classified into two broad but distinct categories—necrosis and apoptosis (Kerr et al., 1972; Duvall and Wyllie, 1986). Necrosis, also called accidental or pathological cell death, occurs when cells are exposed to conditions that vary significantly from physiological conditions. In contrast, apoptosis takes place under normal physiological conditions. Determination of whether cell death is necrotic or apoptotic is based on a number of morphological and biochemical criteria, with morphology being the first described (Kerr et al., 1972). In this brief discussion, apoptotic cell death will be delineated in terms of morphology, molecular biology, and biochemistry, and its importance in the immune system will be summarized. It is now clear that there are both positive and negative regulators of apoptosis that have important roles in immunoregulation (Vaux et al., 1988; Watanabe-Fukunaga et al., 1992). For more comprehensive discussions of apoptosis, consult Vaux and Strasser (1996), Lenardo (1996), and Chinnaiyan and Dixit (1997).

Necrotic cell death occurs in circumstances of wide departure from physiological conditions. Examples include the pathological death associated with hypoxia, inhibition of oxidative phosphorylation, glycolysis, or Krebs cycle enzymes, extreme hyperthermia, and excessive membrane damage due to toxins or complement activation. Necrosis results in an inflammatory response, oftentimes with additional tissue damage as a result of the inflammation. Apoptosis, in contrast, is a mode of cell death that occurs under normal and abnormal physiological conditions. However, unlike cells undergoing necrosis, apoptotic cells maintain the stability of important (“vital”) cellular machinery that enables it to actively participate its own demise. Importantly, apoptotic cell death does not lead to an inflammatory response, as dying cells are phagocytized prior to the release of pro-inflammatory intracellular contents.

Apoptosis has been best understood in terms of embryogenesis, metamorphosis, normal tissue turnover, and the homeostasis of lymphocytes in the immune system. Work over the past few decades has demonstrated the importance of apoptosis in the formation of the overall body plan of multicellular organisms. More recently apoptosis has been demonstrated to be involved in the precise regulation of cell number (Hengartner et al., 1992; Raff et al., 1993). In the immune system, apoptosis is involved in the removal of potentially harmful cells; self-reactive lymphocytes, tumor cells, and virally infected cells have all been shown to be removed through apoptosis. The role of apoptosis in maintaining homeostasis during immune responses is now well-established (Lenardo, 1991, 1996; Nagata and Golstein, 1995).

The morphological and biochemical changes associated with apoptosis (see below) are highly conserved in various cell types and systems. Apoptosis and the apoptotic machinery have been studied in phylogenetically distant organisms reflecting the evolutionary importance of this process. Studies in invertebrates, including genetic and biochemical studies in the nematode *C. elegans* by Horvitz et al. (Hengartner and Horvitz, 1994), have provided knowledge about families of molecules involved in regulating apoptosis. Much work in murine and human systems has provided an understanding of signaling pathways that regulate apoptosis, as well as the role of apoptosis in the immune system. There is a preponderance of evidence that an evolutionarily conserved cell death program exists in all cells, and that it can be activated under the appropriate conditions (Vaux et al., 1992). Although incompletely understood at present, it also seems likely that this common death pathway can be dysregulated leading to pathological conditions common in a variety of human diseases. Recently, a clearcut association between deficient apoptosis, lymphocyte accumulation, and autoimmunity has been elucidated in the human Autoimmune/Lymphoproliferative Syn-

drome (ALPS), which is associated with inherited mutations in Fas/CD95 (Fisher et al., 1995).

The cell death program

It is now apparent that there are several stages in the apoptotic process. In the first stage, a healthy functioning cell receives a stimulus to initiate the cell death program. This signal can come in the form of an active extracellular signal, such as that through the surface receptor APO-1/Fas/CD95 or the TNF receptor, or through a passive extracellular signal, such as the withdrawal of survival factors (e.g., IL-2 for cycling lymphocytes). Alternatively, a cell might initiate the death program via an intracellular signal such as that caused by a drug or radiation that activates p53. Intracellular signals can also affect the expression of death receptor-ligand systems (Hueber et al., 1997; Rehemtulla et al., 1997). The second stage involves the transduction of the death stimulus into the cell, which entails the activation of the effector arm. The effectors of apoptosis have been studied extensively and include the growing family of proteases known as caspases which have the unique ability to cleave directly following an aspartate residue in target proteins (for a more complete review of caspases, see Miller, 1997). The *C. elegans* genes *ced-3*, *ced-4*, and *ced-9*, and the corresponding mammalian families of genes that have been detected (see discussion below), are involved in the effector stage of the death program. During the effector stage of apoptosis, many biochemical changes occur to prepare a cell for engulfment and degradation by phagocytes, which is the final stage of apoptosis. A number of changes in the surface receptor and phospholipid composition occur, allowing for the selective removal of cells. A similar number of intracellular changes also occur, including drastic alterations in nuclear chromatin (Skalka et al., 1976), that presumably prepare a cell for degradation. Temporal aspects of the cell death program (i.e., which events occur early versus late during the apoptotic program) are poorly understood at the present time, although it is likely that many of the events occur simultaneously following activation of the protease cascade.

Morphological changes in apoptotic and necrotic cells

The initiating event in necrosis appears to involve an impairment of the cell's ability to maintain homeostasis, leading to an influx of

water and extracellular ions. Intracellular organelles, most notably the mitochondria, and eventually the entire cell, swell and rupture. The structure of the nucleus is relatively unchanged and the DNA is randomly degraded. In vivo, necrotic cell death is often associated with extensive tissue damage resulting in an intense inflammatory response.

Cells undergoing apoptosis do not swell, but show a progressive contraction of cell volume, with preservation of the integrity of cytoplasmic organelles (Wyllie, 1981). A decrease in cell volume results in the cells becoming more dense, thereby allowing apoptotic cells to be separated from normal cells by Percoll density gradient centrifugation (Wyllie and Morris, 1982). The reason for this shrinkage is not known, although it is likely that certain key structural molecules, including cytoskeletal proteins, are cleaved following the activation of proteases (see below).

While cell contraction during apoptotic cell death is impressive, widespread changes in nuclear morphology also occur (Kerr et al., 1972; Wyllie, 1981). These changes involve compaction of the nuclear chromatin into sharply circumscribed, uniformly dense masses aligned with the nuclear envelope. As described in Basic Protocol 1, condensation of chromatin is readily discerned and quantified by light microscopy, but is most dramatically observed with the electron microscope.

Late in the apoptotic process, the cells break apart into a number of membrane-bound apoptotic bodies containing one or more fragments of the nucleus. In vivo, these apoptotic bodies are rapidly phagocytosed and digested before they actually lyse. Phagocytosis presumably protects the adjoining cells and tissues from the damaging effects of the release of the intracellular contents of the dying cell which could elicit an inflammatory response. Thus, in contrast to necrosis, apoptosis is often remarkably inconspicuous histologically, making in vivo studies of the biochemical events difficult. This phenomenon is dramatically demonstrated in the thymus, where the vast majority of thymocytes undergo apoptosis during differentiation and selection, yet there are few apoptotic cells detectable.

Biochemical events in apoptosis

Early work in understanding the biochemical events that occur during programmed cell death focused on DNA degradation. DNA from apoptotic cells, when analyzed by agarose gel electrophoresis, is cleaved into a distinctive

ladder pattern consisting of multiples of an ~180-bp subunit (Wyllie, 1980). These chromatin fragments do not co-sediment with intact chromatin when the apoptotic cells are lysed and subjected to centrifugation. The temporal appearance of DNA cleavage correlates with chromatin condensation, suggesting that DNA fragmentation is responsible for the changes in nuclear morphology. The ladder pattern of DNA fragmentation is identical to that obtained when isolated nuclei are exposed to micrococcal nuclease, suggesting that DNA cleavage in apoptosis is the result of activation of an endonuclease that cleaves the DNA in the linker regions between nucleosome cores (Cohen and Duke, 1983). Very recently a protein (DFF) has been identified that is capable of triggering DNA fragmentation following its activation by the caspase family of proteases (Liu et al., 1997).

An important advance in understanding biochemical events that occur during apoptosis resulted from genetic studies in the nematode *Caenorhabditis elegans* (Hengartner et al., 1992; Hengartner and Horvitz, 1994). A large number of genes were identified that, when mutated, affected the highly regulated developmental pattern by altering the number of surviving cells. Two of these genes, *ced-3* and *ced-4* (*ced* standing for cell death defective), are required for cell death to occur, while a third gene, *ced-9*, protects cells that are not normally destined to die. Both *ced-3* and *ced-9* have mammalian homologues that have helped to define different functional families of molecules in the apoptotic pathway. Interleukin-1 converting enzyme (ICE), a previously described cysteine protease (see below) that has the unique ability to cleave following aspartic acid residues (X-D), was the original member of an expanding family of mammalian genes shown to be homologous to *ced-3*. Similarly *ced-9* is homologous in structure and function to an expanding family of mammalian genes that are named after the original member Bcl-2. The role for *ced-4* in apoptosis has been difficult to establish, and only recently has a mammalian homologue for this gene been discovered (Zou et al., 1997). Recent work suggests an adaptor/inhibitor function for *ced-4* whereby it physically interacts with both the *ced-9* and *ced-3* family members (Chinnaiyan et al., 1997; Spector et al., 1997; Wu et al., 1997).

The role of cysteine proteases in apoptosis is evident from studies in a number of systems. These proteases are all part of a specific family

of hydrolytic enzymes termed caspases (for cystinyl-aspartate-requiring proteases). *ced-3* mutants lack all somatic cell death. Transient overexpression of a number of the caspases leads to apoptosis in mammalian cells. Both viral genes and chemical substrates are capable of inhibiting caspases (Shen and Shen, 1995; Bertin et al., 1997); both can competitively inhibit by binding at the active site, and can protect cells from apoptosis in response to a number of stimuli (Ray et al, 1992; Clem and Miller, 1994). Owing to the large number of family members there is thought to be some redundancy in the function of the caspases. Targeted deletion of other cysteine proteases in mice will likely shed much light on their function and regulation.

The number of substrate molecules identified that are specifically cleaved by cysteine proteases during apoptosis has increased in the past 3 years. These intracellular substrates include a number of inactive cysteine proteases themselves, structural molecules (including nuclear lamins, actin, and non-erythroid spectrin), molecules involved in DNA repair [poly-(ADP ribose) polymerase, DNA-dependent protein kinase catalytic subunit], inactive transcription factors (steroid response element binding protein, or SREBP), and signalling molecules, such as Ly-GDI. Presently it remains to be formally demonstrated whether the cleavage of individual molecules has any causal role in the apoptotic process, whether the cleavage itself prepares the cell for further stages of programmed cell death, or whether they simply reflect downstream effects of the activation of proteases.

Initially it was thought that nuclear events were required for the apoptotic program, based on experiments showing that RNA or protein synthesis inhibitors could suppress apoptosis. However, it has become clear that the apoptotic machinery is present in the cytoplasm. This is seen most compellingly in studies involving anucleated “cytoplasts” that can assume the characteristic apoptotic morphology upon appropriate stimulation (Jacobson et al., 1994). This study makes it clear that the pre-existing machinery is present in the cytoplasm and can be triggered by apoptotic stimuli.

Detection of apoptosis using flow cytometry

Flow cytometry (also see Coligan et al., 2000) is a powerful tool that can be used to classify individual cells according to a number of different parameters including light diffraction—i.e., forward scatter (FSC) and side scat-

ter (SSC)—and uptake of fluorescent dyes—e.g., fluorescein isothiocyanate (FITC), phycoerythrin (PE), CyChrome/RED613, and propidium iodide (PI). For use in flow cytometry, FITC, PE, and CyChrome fluorochromes are conjugated to antibodies that bind epitopes on the cell surface. PI is a vital dye that is excluded by live cells, which have intact plasma membranes; however, it enters dead cells and intercalates into DNA, thereby making it possible to distinguish live cells from dead cells and to quantitate the number of live cells in a particular sample (Boehme and Lenardo, 1993a; Martin and Lenardo, 1998). Apoptosis can be distinguished from necrosis using FSC and SSC scatter profiles as cells undergo condensation and shrinkage prior to the loss of membrane integrity (Dive et al., 1992; Ormerod et al., 1995). Flow cytometry with PI staining is particularly valuable when coupled with staining by fluorochrome-conjugated antibodies (see Martin and Lenardo, 1998), because the combination provides a means of quantitating live cells that have a certain surface phenotype within a heterogeneous cell population (Boehme and Lenardo, 1993b; Critchfield et al., 1994). The PI emission spectrum, however, overlaps the FL2 channel, making dual staining with fluorochromes in the FL2 channel difficult, and there are a number of recently developed nucleic acid dyes that have a tighter emission spectra (Frey, 1995). Recently, the expression of the algal green fluorescent protein in mammalian cells has added a new dimension to fluorescence labeling of cells for flow cytometry, although it cannot replace antibody-linked fluorochromes.

One application of this combination of techniques is in experiments where activated, non-transformed T cells and T cell hybridomas undergo apoptotic cell death upon stimulation with antigen-presenting cells (APCs) and antigen (Ashwell et al., 1987; Lenardo, 1991; Wang et al., 1993; Martin and Lenardo, 1998). The activated T cells can be distinguished from the APCs by a number of parameters. Because irradiated APCs degenerate in culture, their size and FSC profile decreases and their PI-uptake profile increases in comparison to viable cells, making it possible to quantitate them according to these flow cytometry parameters. Also, the live cells can be further subdivided on the basis of antibody staining. Thus, by labeling the T cells with anti-clonotypic antibodies (e.g., anti-V β 8 or anti-V α 11) or T cell-specific antibodies (e.g., against Thy-1 or the TCR/CD3 complex, if the APCs have been depleted of T cells),

the number of live T cells of a particular phenotype can be quantitated despite the presence of APCs in the culture.

Another advantage of using the FACScan to quantitate the number of live cells is that it avoids inaccuracies inherent in determining cell loss on the basis of the number of dead cells. Cells undergoing programmed death fragment into multiple apoptotic bodies with variable size and dye uptake properties. This fragmentation makes accurate quantitation of cell loss through quantitation of dead cells extremely difficult, particularly if cell loss is measured late in the death program. Quantitation of apoptotic cells on the basis of DNA content (i.e., $<2n$) as determined by DNA-binding dyes has the same shortcoming, resulting from the fact that apoptotic cells eventually disintegrate. Furthermore, if antibody staining is to be used to determine the level of cell loss in a subpopulation of cells (see Alternate Protocol 2), only live cells can be clearly enumerated. Antibodies may bind nonspecifically to dead cells, thereby creating artifacts.

The major disadvantage of quantitating cell loss on the basis of the number of live cells is that this method does not provide strong evidence that cell death was due to apoptosis. The method outlined in Basic Protocol 2 should therefore be used in conjunction with other techniques (e.g., agarose gel analysis of DNA; *UNIT 2.5A*; see Martin and Lenardo, 1998) to demonstrate DNA fragmentation. Quantitation of cell loss based on the number of live cells also fails to determine definitively whether cell loss was due to actual cell death resulting from the apoptotic stimulus or to a cell-cycle blockade. If apoptosis has occurred, an increase in the number of dead cells as determined by flow cytometric analysis (i.e., cells that stain with PI and have a smaller FSC profile than live cells) should become apparent (see Fig. 14.13.1, upper left quadrant of panel B, for appearance of dead cells in a contour plot). Other methods that reveal dead cells (e.g., microscopy) can also be used to distinguish cell death from cell-cycle blockade. Furthermore, [3 H]TdR or BrdU uptake of cells that survive the apoptosis-inducing stimulus can be measured to determine if these cells are progressing through the S phase of the cell cycle.

Basic Protocol 2 is specifically designed to quantify cell death that occurs in activated mature T cells and T cell hybridomas upon TCR stimulation. This assay, however, can easily be applied to cell death occurring in other cell types under a wide range of conditions (see

Table 14.13.1), provided that various controls are maintained—i.e., resuspending each sample in a constant volume and collecting data for each sample over an equal length of time. Other applications of these protocols include quantitating cell death in primary B cells (Nemazee and Burki, 1989; Goodnow, 1992), in the murine B cell lymphoma WEHI-231 upon membrane Ig cross-linking (De Franco et al., 1987), and in hematopoietic cells cultured in the absence of growth factors such as IL-2, IL-3, and erythropoietin (Duke and Cohen, 1986; Koury and Bondurant, 1990). The authors have compared the quantitation of live cells by trypan blue dye exclusion and by flow cytometric analysis as detailed in this unit (Boehme and Lenardo, 1993a). These studies revealed that the relationship between these two methods is

linear (R value = 0.97); however, further comparison of the methods may be required in different cell systems.

TUNEL

By labeling the ends of DNA strand breaks, the TUNEL method detects apoptotic cells that are undergoing DNA fragmentation (Gavrieli et al., 1992; Gorczyca et al., 1993). There are several advantages to methods that employ TUNEL. First, because the end labeling is performed inside the cells, TUNEL is by far the most direct method for analyzing cells in which DNA fragmentation is occurring. Second, because DNA fragmentation is one of the earliest events in apoptosis, cells undergoing programmed cell death are detected at a very early stage in the process. Third, by using flow cy-

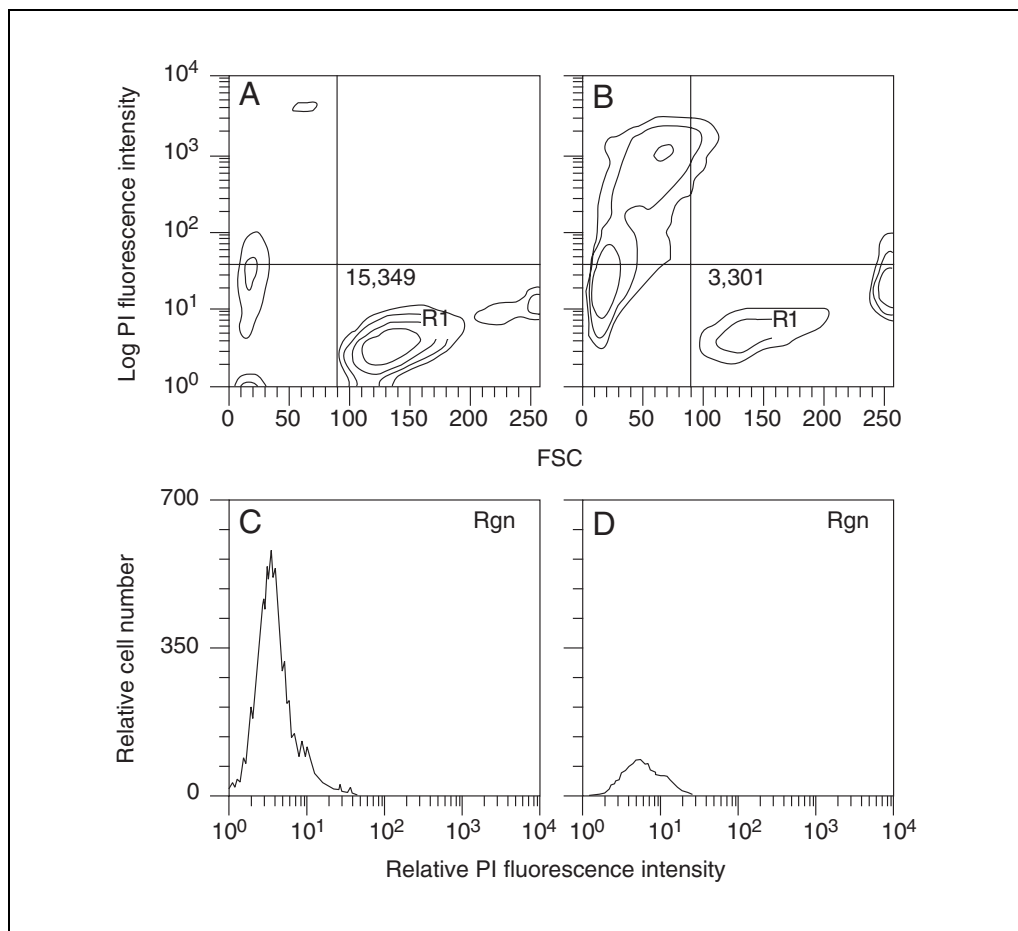

Figure 14.13.1 Dual-parameter FACS contour plots illustrating live and apoptotic cells, with corresponding histograms. **(A)** IL-2 stimulated T cell clone (A.E7) cultured 48 hr in medium alone. Note larger percentage of live cells (i.e., cells that exclude PI and have a large FSC profile) in the lower right quadrant and smaller percentage of apoptotic cells (i.e., cells that stain with PI and have a reduced FSC profile) in the upper left quadrant. **(B)** Same T cell clone cultured 48 hr with plate-bound anti-CD3 MAb. Note smaller percentage of live cells in the lower right quadrant and larger percentage of apoptotic cells in the upper left quadrant. **(C)** Histogram derived from the gated live cells in the lower right quadrant of panel A. **(D)** Histogram derived from gated live cells in the lower right quadrant of panel B. See *UNIT 5.2* for detailed discussion of contour plots and histograms.

tometry, the end-labeled cells can be individually analyzed to accurately quantitate apoptotic cells. Fourth, the TUNEL method is more sensitive than methods using vital dyes such as propidium iodide (PI); hence DNA fragmentation may be detected by TUNEL 4 to 6 hr before cell lysis (Sellins and Cohen, 1987; Kishimoto et al., 1995). Fifth, TUNEL staining is compatible with multiple-color cell-surface staining; cells can be stained for multiple surface markers with various fluorochromes prior to the TUNEL assay, thus allowing definition of the cell-surface phenotype of apoptotic cells (Kishimoto et al., 1995). As noted above, multicolor staining is also possible with vital dyes—e.g., PI or acridine orange—but because the vital dyes have a wide spectrum of emission, they cannot be used together with fluorochromes such as phycoerythrin (PE) and Red 613 unless they are used solely to “gate out” dead cells. Finally, the TUNEL method is suitable for staining apoptotic cells in tissue sections, thus allowing in situ visualization of dying cells with low-power microscopy (Gavrieli et al., 1992; Surh and Sprent, 1994).

The major disadvantage of the TUNEL method is that the reagents required for end labeling (dUTP and TdT) are expensive, probably making this the most costly means of detecting apoptotic cells. Other potential problems with the procedure apply generally to methods that detect apoptotic cells on the basis of DNA fragmentation. For example, TUNEL will not stain apoptotic cells that do not undergo typical double-stranded DNA strand breaks but instead undergo single-strand nicks or no DNA degradation at all (see above). Again, it is stressed that other methods of identifying apoptotic cells should be used in conjunction with this one to verify that cell death is due to apoptosis per se.

Critical Parameters and Troubleshooting

Fluorescence microscopy

Morphological appearance of the cells is the single most important criterion in apoptosis studies and it is important to include proper controls. These should include untreated cells and, if it is not manifestly apparent whether the cells of interest are undergoing apoptosis or necrosis, cells killed by regimens that should cause necrosis (e.g., 43°C for ≥2 hr; Harmon et al., 1990; Sellins and Cohen, 1991). It is extremely important to acquaint oneself with normal chromatin distribution in the cell line being

investigated; different cell types (e.g., normal thymocytes versus tumor cells) may present strikingly different patterns of “normal” chromatin organization. Similarly, it is a good idea to obtain experience in recognizing apoptotic nuclei in one of the systems that has been characterized (see Table 14.13.1).

Flow cytometry

Sample preparation. Each sample must be resuspended in the same volume of FACS buffer/propidium iodide (PI) and analyzed for the identical period of time for comparable results to be obtained. Therefore the FACS buffer and PI should be pipetted using a well-calibrated micropipettor for accuracy. The method also assumes that the FACScan flow rate is identical from sample to sample. This should be stringently tested by measuring the time that it takes for the FACScan to take up a certain volume from various samples with different cell concentrations.

Data acquisition. It is critical to acquire data on the basis of a constant collection time for all samples rather than a constant number of events. This is because a comparison will be made between samples on the basis of the actual number of live cells acquired over time rather than on the basis of the percentage of live cells in each sample. Using a constant flow rate, an absolute cell count per unit volume is obtained for each sample. To acquire data on the basis of collection time, the Time collection mode on the FACScan (found under the Protocol heading) is activated and the number of events collected at the upper limit (100,000; also found under the Protocol heading) is set. The length of time for collection should be chosen so that a statistically significant number of events is measured in the apoptotic cultures, but also so that the total number of events does not exceed the upper limit allowed (i.e., 100,000). Data should be acquired in the List-Mode storage setting (under the Protocol heading). This is done by activating the Auto-Save mode and giving each sample a file name. In the List Output Parameters file, the resolution for all parameters to be analyzed is adjusted to “256.” Parameters that will not be used for analyzing the samples, such as side scatter and FL1 or FL2, may be turned off to save data-storage space. Be sure not to change the flow-rate pressure setting between samples, because this will invalidate the comparison between samples. Do not gate any populations during this collection, although the FSC threshold may be raised (to a setting of 100 to 200 PMT volts) to

exclude very small particles, which will be numerous if significant cell death has occurred.

TUNEL with flow cytometry. When analyzing cells *ex vivo* immediately after preparation or after a period of incubation, the cells should be put into suspension using the gentlest method possible; this helps prevent induction of apoptosis during manipulation. For example, thymocytes should be obtained by gently teasing the thymus lobes with needles instead of by grinding them in a tissue grinder or through a steel screen. Best results are obtained when cells are fixed with ethanol followed by paraformaldehyde. Because both the ethanol and paraformaldehyde fixation steps can result in cell clumping, it is strongly recommended that the fixative be added slowly to cells as they are gently vortexed. As ethanol fixation shrinks cells, higher centrifugation speed is needed to produce a pellet at this stage than before fixation (i.e., $400 \times g$ instead of $300 \times g$). The final ethanol concentration used for fixation should

be 60% to 70%, as cells will shrink excessively with higher ethanol concentrations, making it impossible to obtain a pellet by low-speed centrifugation. When acquiring data by flow cytometry, the PMT voltage for FSC must be set higher to account for cell shrinkage, although the relative positions at which clumps and debris appear in the plot will not change. Total cell counts are also critical for the overall assessment of cell death. It is thus advisable to obtain relative cell counts prior to staining or when cells are acquired in flow cytometry. This can be done by resuspending the cells at constant volume and collecting them for a constant time period (see discussion of flow cytometry, above). Again, it is important that small particles, including debris and apoptotic bodies, be excluded to obtain accurate cell counts.

TUNEL in tissue sections. Tissues should be frozen while still as fresh as possible to reduce apoptosis induced during the handling period. Sections must be completely dried prior to

Figure 14.13.2 Detection of apoptotic cells by the TUNEL method using flow cytometric analysis. Thymocytes from 6-week-old C57BL/6 mice were stained for apoptotic cells with FITC by the TUNEL method before and after an 18-hr incubation in RPMI 1640/10% FBS at 37°C. **(A)** Dot plot depicting FSC versus SSC profile of cells after incubation. The bulk of thymocytes (in the gate R1) are easily distinguished from smaller cellular debris (low FSC) and larger cell clumps (high FSC). **(B)** Dot plot depicting profile of FITC fluorescence versus FSC for cells after incubation. Most of the TUNEL-stained apoptotic cells are slightly smaller than unstained live cells. **(C)** Histogram depicting cells before incubation in the gate R1. Very few apoptotic cells are detected. **(D)** Histogram depicting cells after incubation in the gate R1. Apoptotic cells (brightly stained by TUNEL) are detected.

Figure 14.13.3 In situ detection of apoptotic cells in thymus sections by the TUNEL technique. Sections were counterstained with hematoxylin and photomicrographed at $200\times$ magnification (also see Anticipated Results). **(A)** Thymus from 5-week-old I-E⁺/V β 5 transgenic mouse. Small apoptotic cells are scattered in the cortex (cor) but are unusually prominent in the medulla (med) as large aggregates. **(B)** Thymus from 5-week-old I-E⁻/V β 5 transgenic mouse. This is similar to the normal mouse thymus; apoptotic cells are apparent in the cortex but rare in the medulla.

staining (i.e., at least overnight at room temperature). Sections can be stored for 2 to 3 weeks at 4°C. Paraformaldehyde fixation results in better staining than acetone fixation, probably because much higher proportions of low-molecular-weight DNA fragments are retained inside apoptotic cells with paraformaldehyde fixation. However, in sections from tissues with unusually large numbers of apoptotic cells, such as irradiated thymus, acetone fixation is adequate as apoptotic cells are easier to label.

Anticipated Results

Results of typical apoptosis studies are outlined in Table 14.13.1. There are no universal inducers of apoptosis available at the present time, so entirely new systems must be empirically studied.

As shown in Figure 14.13.1, flow cytometric analysis can distinguish live cells from apoptotic cells and quantitate live cells on the basis of FSC and PI uptake properties. Live cells should have a large FSC profile and be negative for propidium iodide uptake (as illustrated in Fig. 14.13.1, lower right quadrants of panels A and B). By contrast, apoptotic cells should have a smaller FSC profile, which results from a decrease in cell volume. They should also stain positive for propidium iodide if analyzed late in the death program when membrane viability has been lost (as illustrated in Fig. 14.13.1, upper right and left quadrants of panels A and B). The number of cells with decreased FSC profile that fail to exclude PI gives an impression of the number of dead cells; however, it

would be erroneous to calculate an exact number of dead cells on the basis of this parameter, because apoptotic cells fragment into multiple apoptotic bodies during the course of the cell-death process. Cellular debris and apoptotic bodies should have a very small FSC profile and may or may not take up propidium iodide (as illustrated in Fig. 14.13.1, upper and lower left quadrants of panel B). This analysis can be further used to measure the number of live cells of a subpopulation based on antibody binding.

Results from a typical flow cytometric analysis using TUNEL staining are shown in Figure 14.13.2. Freshly prepared normal mouse thymocytes contain very few detectable apoptotic cells (0.6%; see panel C). In contrast, incubation of the same cells in normal medium with FBS for 18 hr at 37°C causes considerable apoptosis (~33%; see panels A, B, and D). The apoptotic cells are slightly smaller than normal thymocytes but are difficult to distinguish on the basis of cell size alone (see panels A and B). Note that in panel A, which shows FSC/SSC profiles, both cell debris (consisting of particles much smaller than the bulk of thymocytes) and cell clumps (which are much larger) can be easily gated out from the analysis.

Photomicrographic results from in situ detection of spontaneously occurring apoptotic cells by the TUNEL method are shown in Figure 14.13.3. In this example, panel A depicts a section of thymus from a transgenic mouse strain produced by a cross between TCR V 5 and I-E⁺ mice. Apoptotic cells are visible in the cortex as scattered small cells, and are prominent in the medulla as large aggregates. The

apoptotic cells in the medulla reflect negative selection to endogenous mammary tumor virus antigens (Mtv 8,9) associated with I-E molecules. Panel B depicts a section of thymus from a transgenic mouse strain produced by a cross between V β 5 and I-E⁻ mice. Apoptotic cells are spread throughout the cortex but are largely absent in the medulla—a pattern of apoptosis that is also observed in normal mouse thymus (Surh and Sprent, 1994). The apoptotic cells in the cortex reflect lack of positive selection, as similar numbers of apoptotic cells are detected in the thymic cortex of MHC-deficient mice (Surh and Sprent, 1994). These data indicate that the TUNEL method is able to detect apoptosis occurring under in vivo physiological conditions.

Time Considerations

Determination of the apoptotic index using acridine orange and/or ethidium bromide staining takes ~2 to 3 min/sample. Separation of fragmented DNA from intact chromatin takes ~30 min. Isolation of DNA for agarose gel electrophoresis takes 2 to 48 hr depending on how much and how large the DNA in the sample is. Agarose gel electrophoresis requires 2 to 4 hr to perform. It takes ~1 hr to harvest 15 samples (in 45 wells including duplicates and controls; number will vary with each experiment) from a 96-well plate for flow cytometric analysis. Each sample takes ~1 to 2 min to run on the FACScan depending upon the amount of time for collection, so that an additional 1 to 1.5 hr are required for collection and data analysis.

In both the flow cytometric and in situ protocols, TUNEL staining takes 4 to 6 hr to complete once the cells or tissue sections are prepared. This estimate does not including the time required for flow cytometric analysis.

Whole-Mount Histochemical Detection of β -Galactosidase Activity

UNIT 14.14

Seminal studies on the *lac* operon led to the isolation of β -galactosidase activity and the use of the *E. coli lacZ* gene as a fusion protein and reporter in bacteria (for review see Silhavy and Beckwith, 1985). Its first use as a reporter gene to determine the spatial and temporal expression in a more complex organism was in *Drosophila* (Lis et al., 1983). Subsequently, numerous reports documented its use in diverse experimental applications in all model organisms.

The combination of direct detection of endogenous gene expression by whole-mount in situ hybridization (UNIT 14.9) and the use of a reporter gene in regulatory sequence analyses using transgenics and chimeric studies results in a better understanding of the potential domain of function of a particular gene or cell lineage. Whole-mount in situ histochemical β -galactosidase activity staining is a relatively simple and highly sensitive method that yields a three-dimensional representation of gene expression. If the analysis is performed at different stages (e.g., during embryogenesis), the dynamic nature of endogenous gene expression, implicating possible function, and tissue- and region-specific promoters, may be visualized in a spatial and temporal manner.

The main procedure (see Basic Protocol) describes fixation and staining for β -galactosidase activity. It is based on Beddington and Lawson (1990), and has been successfully used on vertebrate embryos and tissue explants (some recent examples include: Collignon et al., 1996; Martineau et al., 1997; Wang et al., 1998; Pereira et al., 1999). To help achieve consistent results with larger samples, an Alternate Protocol details preparation of thick sections. Support Protocol 1 describes clearing of tissues for better resolution and Support Protocol 2 describes paraffin-embedding the whole embryo.

CAUTION: Glutaraldehyde, formaldehyde, sodium deoxycholate, potassium ferrocyanide and ferricyanide, dimethylformamide, Histoclear, benzyl benzoate and benzyl alcohol, and Permount are hazardous. Please consult manufacturer's guidelines for their proper handling and disposal; also see APPENDIX 1H.

WHOLE-MOUNT STAINING AND HISTOCHEMICAL DETECTION OF β -GALACTOSIDASE ACTIVITY

BASIC
PROTOCOL

Mouse and chicken embryos, tissues, or explants are isolated, partially fixed so as to not inactivate the β -galactosidase enzyme, washed extensively to remove fixative, thick sectioned if necessary (Alternate Protocol), and stained in the presence of a chromogenic substrate. Following photography of whole-mount stained tissues, samples may be embedded and sectioned to reveal cell and tissue-specific expression of the reporter (Support Protocol 2). It is strongly recommended that pilot studies be performed to assess and standardize optimal conditions for the particular experiment and tissue (see Critical Parameters and Troubleshooting).

Materials

- Mouse or chicken whole embryos, tissues, or explants
- Phosphate-buffered saline (PBS; APPENDIX 2), ice-cold
- β -galactosidase fixative (see recipe)
- β -galactosidase wash buffer (see recipe)
- β -galactosidase staining solution (see recipe)

14.14.1

Supplement 50

5-ml or 10-ml polystyrene or polypropylene capped tubes *or* 1.5- to 2-ml microcentrifuge tubes
Platform rocker
Sealable container for staining
Depression slides with coverslips or chamber slides
Dissecting microscope with fiber-optic lighting
Photomicrography equipment

NOTE: All steps are performed in 5-ml, 10-ml polystyrene or polypropylene capped tubes or in 1.5- to 2-ml microcentrifuge tubes in solutions (20:1 v/v reagent-to-tissue ratio) with gentle end-to-end rocking unless stated otherwise.

1. Dissect embryos or tissues in ice-cold PBS. Place in β -galactosidase fixative for appropriate length of time at room temperature.

Fixation time for tissues will depend on size, type, and whether the animal had been perfused with the β -galactosidase fixative. Whole-animal heart perfusion (see UNIT 14.1) should be performed on postnatal-to-adult animals prior to isolation of specific tissues for further fixation.

Since it is critical that tissues not be overfixed while other samples are being dissected, maintain small groups of embryos or tissues (5 to 10) in 100 mM sodium phosphate buffer, pH 8.0 (APPENDIX 2), until ready to process.

The following are some guidelines for fixation of mouse embryos and tissues: 5 to 10 min for explants and E6.5 to E7.5 embryos; 15 to 30 min for E8 to E9.5 embryos or tail cuts; 30 min to 1.5 hr for E10 to E12.5 embryos; and 2 hr for E13 to 14.5 embryos. E15.5 and larger tissues need to be dissected out or cut in half and fixed for 2 hr. Perfusion of newborn pups and older mice is required prior to dissection of particular tissues for staining.

2. Wash three times in β -galactosidase wash buffer for 15 min each time (for small embryos or tail cuts) or for 30 min each time (for E11 embryos and large tissues) at room temperature, with gentle end-to-end rocking.

It is critical to wash out the fixative sufficiently to allow the enzyme to function. Insufficient washing typically results in surface staining with minimal internal β -galactosidase staining.

3. Incubate tissues in β -galactosidase staining solution (at room temperature, 30°C, or 37°C depending on abundance of β -galactosidase expression) in a 5- or 10-ml capped tube or 1.5 to 2-ml microcentrifuge tube to prevent evaporation. Monitor staining by eye or using a dissecting microscope.

Xgal is the most popular substrate; however, Red-gal (6-chloro-3-indoyl- β -D-galactopyranoside; Research Organics) and Bluo-gal (halogenated indoyl- β -D-galactosidase; Life Technologies) have also been used successfully.

Signal strength depends on the abundance of β -galactosidase expression and appropriate fixation, washing, and buffer conditions. Development times of up to 48 hr are sometimes required, whereas abundant expression may be evident within 1 hr. If staining overnight, place at room temperature or 27° to 30°C to prevent excessive evaporation and possible crystal deposits. Crystals may form in the staining solution or on tissues if the phosphate buffer is incorrectly made. Optimal conditions will have to be determined in preliminary experiments.

*Use of pH 8.0 buffer minimizes the endogenous microsomal β -galactosidase activity, which has a pH optimum of 3 to 6 (MacGregor et al., 1987). Such activity is observed, if the pH drops, in E10 hindbrain, E14 and larger intestines, and kidneys. Use of the optimal pH of 7 to 7.4 for the *E. coli* enzyme is possible if the expected expression is not being investigated in tissues with significant microsomal activity. In addition, timely monitoring of staining*

and the use of nuclear lacZ (β -galactosidase containing a nuclear localization sequence) allows better discrimination of specific and nonspecific activity.

4. After desired signal-to-background is achieved, wash the tissues three times, each time for 30 min, in PBS.

A yellow discoloration may result if tissues are left in staining solution. Samples may be photographed at this stage. See Support Protocol 1 for long-term storage.

5. View and photograph the whole-mount, stained tissues through a dissecting microscope, using low-power objectives and fiber-optic lighting from the sides and top. For best results, place tissues in a depression slide with a coverslip, or a chamber slide, with sufficient PBS to just cover the tissue.

This eliminates reflections from overhead illumination.

PREPARING THICK SECTIONS OF LARGE TISSUES FOR β -GALACTOSIDASE STAINING

**ALTERNATE
PROTOCOL**

Use of thick vibratome sections (<1 mm) for activity staining is sometimes desirable. This step standardizes the protocol for routine and consistent analysis, especially of diffuse staining, in large embryos and tissues (such as adult mouse brain). Use of a cryostat to make frozen sections is possible (UNIT 14.2), but the ease and speed of the vibratome makes it the method of choice. Also, simply cutting the tissues into blocks with a sharp scalpel, for better penetration of solutions, is possible. This cutting would be done at the midpoint of the fixation period (see Basic Protocol, step 1). In the case of vibratome sectioning, one would immediately proceed with β -galactosidase staining (see Basic Protocol, step 3) after sectioning.

Additional Materials (also see Basic Protocol)

4% agarose (see recipe)
Cyanoacrylate glue (e.g., Superglue)
100 mM sodium phosphate buffer, pH 8 (APPENDIX 2)
Vibratome (e.g., model VT1000S; Leica)

1. Fix and wash tissues (see Basic Protocol, steps 1 and 2).
2. Place tissue in a 100-ml beaker and gently aspirate most of the wash buffer with a pipet. Add sufficient 4% intermediate-strength agarose to cover the tissue (when beaker is tilted to its side) at 37° to 40°C.

To avoid air gaps that can get trapped between the tissue and agarose, swirl the beaker to mix and coat the tissue well.

3. Place the beaker at a 45° angle at room temperature until the agarose has hardened (~10 min).
4. Trim the agarose block with a razor blade to square off the sides, leaving 2 to 3 mm on each side.
5. Using cyanoacrylate glue, affix the agarose block, in the appropriate orientation (e.g., for coronal sectioning), to the vibratome specimen-holder plate. Place the specimen-holder plate in the vibratome and fill the bath with 100 mM sodium phosphate buffer, pH 8.
6. Section at ≤ 1 mm (consult vibratome manual for specifics). Carefully remove slices from the vibratome bath and place in β -galactosidase wash buffer until ready to stain. Proceed to stain tissues (see Basic Protocol, step 3).

After staining, the thick, 1-mm sections may be resectioned in the vibratome, at 40 to 100 μ m, to reveal more subtle expression of the reporter. Alternatively, for cellular detail,

**In situ
Hybridization
and Immuno-
histochemistry**

14.14.3

samples may be secured in 3% agarose, and processed for paraffin and microtome sectioning at 10 μ m (see Support Protocol 2, step 1). View and photograph the stained thick sections (see Basic Protocol, step 5).

SUPPORT PROTOCOL 1

STORAGE AND TISSUE CLEARING

For analysis at a later time point, whole-mount stained samples (see Basic Protocol) should be fixed in formaldehyde for storage (up to 1 year). Samples may also be cleared to reveal β -galactosidase expression within internal structures. However, with thick tissues or embryos with bilateral expression, this may complicate the three-dimensional picture. In these situations, confocal microscopy would be valuable to give a better three-dimensional view.

Materials

Stained samples (see Basic and Alternate Protocol)
3.7% formaldehyde: dilute 37% formaldehyde 1:10 with PBS
Phosphate-buffered saline (PBS; APPENDIX 2)
50%, 70%, 80%, 95%, and 100% methanol
2:1 (v/v) benzyl benzoate/benzyl alcohol

1. Post-fix sample by soaking in 3.7% formaldehyde at 4°C (1 hr to overnight).
2. Wash several times in PBS and store at 4°C.

This procedure results in no appreciable loss of stain. Samples can be photographed (see Basic Protocol, step 5) prior to post-fixation, but post-fixation is recommended for long-term storage.

3. *Optional:* To clear tissue, dehydrate samples successively for 15 to 30 min each in 50%, 70%, 95%, and 100% methanol. Finally, place samples in 2:1 benzyl benzoate/benzyl alcohol in a polypropylene tube or glass vial (polystyrene will dissolve in the clearing agent). Allow the tissue to clear with gentle rocking (10 to 30 min). Proceed with photography (Basic Protocol, step 5).

Clearing can be performed any time after samples have been fixed, but the sample should first be photographed once, just in case the three-dimensional picture is too complicated.

Rehydration of the tissue (through a descending graded series of methanols to PBS) and storage in PBS or processing for sectioning is possible (see Support Protocol 2). Do not store in clearing solution since it dissolves the precipitate over time.

Alternatively, samples may be dehydrated and cleared in 1:1 glycerol/alcohol, but it is not as effective as the above solution.

SUPPORT PROTOCOL 2

PARAFFIN EMBEDDING, SECTIONING, AND COUNTER-STAINING

The cellular detail of β -galactosidase expression can be determined upon microsectioning the whole-mount stained tissues (see Basic Protocol and Alternate Protocol). This is often informative for revealing expression within internal structures such as the endothelium of blood vessels (Fig. 14.14.1, panel B) or in post-mitotic neurons of the brain (Fig. 14.14.1, panel C) which are not readily seen in whole-mount view.

Materials

Whole-mount stained embryos (see Basic Protocol)
3% agarose (see recipe)
Histoclear (National Diagnostics)
70%, 95%, and 100% ethanol

**Whole-Mount
Histochemical
Detection of
 β -Galactosidase
Activity**

14.14.4

Figure 14.14.1 (A) Whole-mount view of an E13 embryo stained for β -galactosidase activity, driven by a neuronal enhancer, in peripheral nerves (Eric Nemoz-Gaillard, unpub. observ.). (B) Frontal section of *Tie1-lacZ* expression in endothelial cells of an E9.5 embryo (for detailed expression see Pereira et al., 1999, and Partanen et al., 1996). (C) Section through the midbrain of an E9.5 embryo showing β -galactosidase activity, expressed from the *BETA2/NeuroD* locus, marking post-mitotic neurons (for detailed expression see Naya et al., 1997). *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to <http://www.currentprotocols.com/colorfigures>*

0.1% (w/v) nuclear fast red in 5% (w/v) aqueous aluminum sulfate: (Kernechtrot; Poly Scientific)

Permunt or aqueous mounting medium

Microtome

Subbed microscope slides (e.g., Superfrost Plus, Fisher)

42°C and 65°C ovens

Coplin jars or staining dishes

Photomicrography equipment

Additional reagents and equipment for paraffin embedding (UNIT 14.1)

Embed and section tissue

1. For tissue explants and embryos <E10.5: Embed in 3% agarose by placing tissues in a petri dish, removing excess solution, covering tissue with 3% agarose that has been cooled to 37° to 40°C, and allowing to harden. Trim the agarose for easy handling of these small samples. Carefully mark one corner with a small cut for easy orientation when embedding in paraffin.
2. To maintain tissue morphology, follow the paraffin embedding protocol (UNIT 14.1) to process and embed the stained samples, but substitute HistoClear for xylene in all appropriate steps.

HistoClear is preferred since it does not dissolve the Xgal precipitate as effectively as does xylene.

**In situ
Hybridization
and Immuno-
histochemistry**

14.14.5

Do not dehydrate samples to be cleared until ready to process and embed, since the precipitate is slightly soluble in ethanol.

3. Section tissue on a microtome at 10 μm or thicker. Place in a 42°C water bath and pick sections up onto subbed slides (e.g., Superfrost Plus; Fisher). Allow to dry.

Strong β -galactosidase expression can be readily visualized in 7- μm sections, but diffuse staining may require 10- to 15- μm or thicker sections prepared using a vibratome.

Dewax, coverslip, and examine

4. Place slides at 65°C for 30 to 60 min to completely dehydrate and fix tissue to slides.

Since sections are very thick, allow sufficient time for all steps.

5. Dewax three times, 5 min each time, in HistoClear.
6. For counterstaining, rehydrate through alcohols in Coplin jars or staining dishes as follows:

three times, 1 min each, in 100% ethanol
once, 1 min, in 95% ethanol
twice, 5 min each, in 70% ethanol
five dips in water.

If expression is weak or diffuse, no counterstaining is necessary and the tissue is simply coverslipped and viewed.

7. Counterstain 1 min in 0.1% nuclear fast red staining solution.
8. Remove excess stain with several changes of water.
9. Dehydrate slides as follows:

3 to 5 min in 70% ethanol
1 min in 95% ethanol
three times, 1 min each, in 100% ethanol.

10. Pass slides through HistoClear twice, 1 min each.
11. Coverslip with Permount or aqueous mounting media and dry ≥ 30 min before viewing.
12. Photograph and analyze the samples.

Analysis and photography of sections are optimal when using differential interference contrast or Nomarski microscopy but is satisfactory using bright-field microscopy (deep blue precipitate) or dark-field microscopy (pink precipitate).

REAGENTS AND SOLUTIONS

Agarose, 3% or 4% (w/v)

Melt intermediate-strength agarose (MetaPhor agarose; FMC Bioproducts) in 100 mM sodium phosphate buffer, pH 8 (APPENDIX 2) by heating in a microwave oven. Heat for intervals of 30 sec with gentle swirling to mix solution between intervals, until dissolved (melting temperature is $\leq 75^\circ\text{C}$). Cool to 37° to 40°C (gelling temperature is $\leq 35^\circ\text{C}$) in a water bath before use.

β-galactosidase fixative

0.2% (v/v) glutaraldehyde (from 25% stock; EM grade)
1.5% (v/v) formaldehyde (from 37% stock)
5 mM EGTA (from 100 mM stock, pH 8.0)
2 mM MgCl₂ (from 1 M stock)
100 mM sodium phosphate, pH 8.0 (*APPENDIX 2*)
Prepare fresh on day of use

β-galactosidase staining solution

Prepare the following stock solutions:

25 mg/ml 5-bromo-4-chloro-3-indoyl-β-D-galactopyranoside (Xgal) in dimethylformamide (store up to 1 year in dark at -20°C)

100 mM potassium ferrocyanide [K₄Fe(CN)₆] in 100 mM sodium phosphate buffer, pH 8.0 (see *APPENDIX 2* for buffer; store up to 1 year in dark at 4°C)

100 mM potassium ferricyanide [K₃Fe(CN)₆] in 100 mM sodium phosphate buffer, pH 8.0 (see *APPENDIX 2* for buffer; store up to 1 year in dark at 4°C)

At time of use, dilute the above stocks in β-galactosidase wash buffer (see recipe) to yield the following final concentrations:

1 mg/ml Xgal

5 mM K₄Fe(CN)₆

5 mM K₃Fe(CN)₆

Unused portions may be filtered, stored at 4°C, and reused for up to a week.

β-galactosidase wash buffer

2 mM MgCl₂ (from 1 M stock)
0.01% (w/v) sodium deoxycholate (from 1% w/v stock)
0.02% (v/v) Nonidet P-40 (from 10% stock)
100 mM phosphate buffer, pH 8.0 (*APPENDIX 2*)

COMMENTARY

Background Information

Reporter genes have been used to detect chimeric fusion proteins in transgenics and in tissue explants. The *E. coli lacZ* gene has proven to be an excellent reporter gene for many applications—from cell-lineage mapping to enhancer and promoter analyses to gene-trap analysis—in many systems (Hogan et al., 1994; Sullivan and Lo, 1997). The combination of ease of cloning (the first 26 amino acids are dispensable for activity; Muller-Hill and Kania, 1974), cytoplasmic or nuclear localization (Bonnerot et al., 1987), stability of and lack of deleterious effects of the β-galactosidase enzyme in vivo (Sanes et al., 1986), and the variety of substrates available, has resulted in high sensitivity and reproducibility of detection. The β-galactosidase expression reports, in situ, on the spatial, temporal, and tissue-specific expression. This reporter has proven indispensable in many cases for whole-animal or tissue analyses. Some recent examples are the analysis of EphB2 expression in arteries but not veins (Wang et al., 1998), asym-

metric nodal expression around the mouse node (Collignon et al., 1996), and ROSA26 cells to mark gonadal lineages in chimeric aggregates (Martineau et al., 1997).

Critical Parameters and Troubleshooting

There are a number of possible reasons for failure to observe staining. Pilot studies should be performed to standardize the procedure for the particular experiment and tissue. A standard rule of thumb is to use a 20:1 ratio of reagent to tissue, which helps to avoid minor procedural errors. If different samples are to be collected over an extended period, one should work with small batches and keep tissues in sodium phosphate buffer so as not to overfix the tissues prior to staining. If the β-galactosidase expression is weak, using pH 7 to 7.4 (optimal for bacterial β-galactosidase) will enhance the staining, but it is important to pay attention to specific signal in tissues (e.g., kidney and gut), to differentiate from background endogenous microsomal staining. Some protocols use 20 mM Tris-Cl,

pH 7.3, to stabilize the pH, which may also help to avoid crystal formation after overnight staining. Large tissues should be cut (hemi-sect or vibratome thick sections) to allow penetration of reagents. To avoid dissolution of weak staining, do not store in alcohols.

Anticipated Results

Strong expression will be visible within an hour with typical results (panel A in Figure 14.14.1) yielding a robust deep blue to magenta stain. Weak or diffuse staining appears light blue and may only be visible upon close examination using a dissecting microscope and appropriate lighting. Upon sectioning, cellular detail is evident (panels B and C in Figure 14.14.1) but some strong nuclear staining may leach in to the cytoplasm or diffuse into the surrounding interstitial space. In summary, β -galactosidase is a proven reporter enzyme that is highly specific, sensitive, and useful in many applications from lineage tracing to gene regulatory sequence analysis.

Time Considerations

Processing of tissues from dissection through fixation and washing to staining (Basic and Alternate Protocol) can be performed within 5 to 7 hr, but the staining time varies depending on the strength of the promoter driving the *lacZ* gene. Staining times of 48 hr or more may be necessary for weak promoters/enhancers. Paraffin embedding, sectioning, and counterstaining sections of the whole-mount stained tissues will take at least a couple of days. In all, a result may be obtained within 2 to 3 days from isolation of tissues to viewing the whole-mount stained tissues. Another 2 to 3 days will be required for processing and microsectioning the tissues to view cellular detail of expression.

Overview of Image Analysis, Image Importing, and Image Processing Using Freeware

UNIT 14.15

Quantitative image analysis turns microscopic data that might otherwise be merely descriptive into reliable mechanistic information. Such reliable structural information is a significant part of any biological investigation. "Structural information" refers to the patterns, shapes, contours, and relationships of objects made visible by their mass, as by staining, or by an electronic/computational technique applied to a biological specimen. Reliability of interpretation often depends on the statistical analysis of multiple images of the same structure. Great strides have been made in recent years in the ability to analyze multiple images quantitatively, due to the ease of acquiring images in digital formats and exporting them to various software packages. The types of analysis most often used involve: (1) elimination of background noise; (2) averaging of multiple specimens by superimposition to determine structural regions in common; (3) morphometric analysis of common measurable features obtained from many similar specimens of the same structure; (4) analysis of expression patterns of gene products over time or after an experimental treatment; (5) subcellular or tissue localization of gene products; and (6) quantitative measurements of rates of movements of cells or subcellular structures or molecules. Image analysis is also used to compare various quantitative aspects of biochemical data when such data are obtained in a visual format, such as a gel or blot. While this unit will focus on the analysis of microscopic material, some of the same tools and programs can also be useful when applied to images of biochemical data. The Commentary section of this unit will present an overview of the types of analysis that have been useful in the past as well as comments on emerging applications (see Background Information).

To maintain the value of the unit for a wide variety of investigations, the focus will be on basic techniques common to all biological applications for extracting reliable information from digital images, rather than on the equipment and software used to do this. Brief step-by-step protocols for importing data and for the first steps of data manipulation in the most common analytical applications, using two different freeware applications, NIH image (see Basic Protocol) and ImageJ (see Alternate Protocol), are provided.

IMAGE PROCESSING USING NIH IMAGE 1.62

The following is a protocol to import and process digital images for analysis or for production of figures using NIH Image 1.62, a freeware application available from the NIH at <http://rsb.info.nih.gov/nih-image/>. NIH Image is an image-processing program in the public domain designed for Macintosh computers. Digital images acquired in any format can be imported into NIH Image 1.62 if they are saved in a TIFF format. Once imported, NIH Image can be used to measure area, mean, centroid, and perimeter of user-defined regions of interest. The program includes tools for automated particle analysis and for measuring particle path lengths and angles. Density calibrations as compared to standards with user-specified units are also possible. Analyses can be printed, exported to text files, or copied to the clipboard for export to other compatible software.

NIH Image is most useful for black-and-white images. It can also be used to process such images by averaging to reduce background, by adjusting contrast and brightness, by smoothing pixelation, and by cutting and pasting to arrange a gallery of similar specimens for comparisons. NIH Image provides useful tools for editing and transforming digital

14.15.1

Supplement 63

video images in black and white obtained from confocal microscopy. NIH Image can also be used to transform analog video to digital sequences for archiving. Some of these applications require additional hardware, including the appropriate computer ports to plug in the analog device.

This protocol covers the step-by-step process used to import various types of digital data into NIH Image to process and edit video sequences. NIH Image is capable of many other processes, and detailed instructions for these can be obtained from the NIH Image Manual at <http://rsb.info.nih.gov/nih-image/manual/>.

Materials

Color-capable Macintosh computer with ≥ 2 Mb of free RAM and the following programs:

MacOS v. 7 or later, or OS X capable of running programs in Classic mode
Web browser, e.g., Netscape or MS Internet Explorer
Stuffit Expander
Adobe Photoshop

Digital images and image sequences: these can be translated from a wide variety of file types, although TIFF formats are easiest to work with; importing from many other document types is handled through an Input-Output Macro that downloads with NIH Image

Download freeware

1. Go to the Web site <http://rsb.info.nih.gov/nih-image/>, download NIH Image 1.62, and decompress (“Unstuff”) the file onto the desktop.
2. Restart the computer.
3. On the desktop, highlight the icon for NIH Image application (a black microscope).
4. Under the File menu, select Get Info, then select Memory from the submenu which appears. Set Minimum Size to 75,000, and set Preferred Size to 100,000.

Smaller memory allocations will work for images that use less RAM, but the author of this unit has found that some operations can fail, incomplete loading of digital sequences can occur, or sequences can be loaded in the wrong order. For very large digital sequences, even more memory may be needed.

5. Open the application by double-clicking on the icon.

Import or open the image to process or analyze

To open Bio-Rad confocal files, electron micrographs from a scanner and some other specific formats

- 6a. Use the Input/Output Macro as follows. Choose Special from the menu bar at the top, then select Load Macros from the resulting submenu from the NIH Image folder. When the dialog box appears, open the Macros folder that downloaded automatically when NIH Image was loaded and which will be found inside the NIH Image folder. Scroll down within the Macros folder and highlight Input/Output macros.

Under Special, a list of file types that can be imported will now be seen. These include TIFF files, electron-microscopic images from Siemens, and confocal files from Bio-Rad.

- 7a. To import Bio-Rad confocal digital sequences or single frames, select Import BioRad 600 Z Series. In the dialog box, select the folder containing the Bio-Rad image sequence to be opened and scroll down in the window to find the specific file. Select Custom 512 and “8-bit” (the Bio-Rad will give a single icon for the entire image sequence).

- 8a. To import files from a different confocal, e.g., Zeiss images saved as TIFF sequences, select Open All; in this case, all the images in a sequence must be placed into a single folder.

To open TIFF files

- 6b. First, attempt to open the file by selecting Open from the File menu.
- 7b. If the file cannot be opened as in step 6b, select Import from the File menu. In the pop-up menu that appears, select TIFF and Custom 512 × 512 (or other image pixel size as necessary under the Set button).

It is possible to open all the files in a folder by selecting Open All.

- 8b. To work with Metamorph or Zeiss images, save them in the TIFF format in the Zeiss LSM program by selecting Export from the File menu in that program. Open the saved TIFF as in step 6b or 7b, above.

It is also possible to download the program Browser for free from the Zeiss Web site. This smaller program has only some of the applications included in the full Zeiss LSM program, but can help with saving images in alternative formats.

For images captured in two or more channels, it is better to save each channel separately and then work with them in ImageJ (see Alternate Protocol).

Manipulate the images

9. Upon opening the file, allow the image sequence to load onto the screen.
10. To play through the sequence, open the Stacks menu and select Animate. Click the mouse on the image to stop the playback. To toggle through the images in the forward direction, click on the “greater-than” key (>) without pressing the Shift key. To toggle through in the reverse direction, click on the “less-than” key (<) without pressing the Shift key.

The keyboard numbers can control the speed, with 1 being the slowest and 9 being the fastest.

11. To work with individual frames, open the Stacks menu and select Stacks to Windows, which will cause the images in the sequence to be posted on the screen individually.

Using this view, it is possible to delete an image or process any image in the stack.

IMPORTANT NOTE: *Be careful to put the images back in order on the screen before making them into a stack (see step 12).*

12. To put a series of individual images into a sequence, open the Stacks menu and select Windows to Stacks. Make the sequence as short as desired by deleting images. Add letters/arrows to the first image in a sequence, or to each image in the windows.

13. To crop or process an entire sequence, load the macro Stacks (Special>Load Macros) menu and select Stacks from the Macro folder in the popup window; a new set of commands appears in the scroll-down menu under Special.

Most of these are self-explanatory. The Crop command is one of the most useful, as it will make it possible to crop all images in the stack to exactly the same size.

14. To create a series of cropped images to present as still frames for publication as a figure, or for analysis of a printout, use the rectangular tool from the tool bar and draw the region of interest (ROI) on each frame of the sequence when it is in the stack mode on the screen. For example, if every sixth image is desired, draw the square on the first image, copy the ROI and paste into a new file (typically, at this stage, the author uses Adobe Photoshop to create the new file to paste in the copied image). Without moving the rectangular tool, toggle five frames, and copy the same ROI from

the sixth frame. Continue until all images in the series have been pasted into the new still-frame document.

Most digital cameras and confocals produce images with 72-bit resolution. This does not produce attractive images for publication. To improve the bit mapping in Photoshop, open the Image menu and select Image Size. A resolution of 400 is usually more than enough to produce a smooth figure. Photoshop's Gaussian Blur option (selected by opening the Filter menu and selecting Gaussian from the Blur submenu that appears) equalizes pixels at a radius that can be selected by the user. This will smooth the sharp edges of adjacent pixels where they differ by large contrast in gray scale between pixel edges.

15. Perform frame averaging by merging digital images.

Background subtraction is best performed during image capture. However, some frame averaging can be done by merging digital images. Frame averaging decreases random variations in pixel intensities.

Merging digital images after capture is time-consuming. The author uses Adobe Photoshop; in that program, open two or more frames to be averaged. Paste one image on top of the other. Open the Layers palette by selecting Show Layers from the Window menu. In the Layers palette, set opacity at 50% for each of two images, 25% for each of four images, etc. One can adjust the opacity levels to check that overlay is exact. It is best to align a stable object common to all frames. Select Merge Visible from the Layer menu at the top of the screen to compile the image.

16. Save the new sequence in NIH Image with a different name by opening the File menu and selecting Save As.

If the QuickTime radio button is selected in the Save As dialog box, encoded information may be lost when transporting back into TIFF. QuickTime format is very useful as it can be linked into Powerpoint for presentations or posted on the Web. In the Save As QuickTime pop-up menu, select Video and Color under Compressor, and High or better on the Image Quality slider bar. The optimum speed depends on how many images are in the stack and how fast the change is of the object under study. Generally, a 10- to 100-fold increase in the speed of capture is useful. For images captured every 10 sec, the author uses 6 to 10 frames/sec. Marking the video with a "keyframe" at regular intervals allows one to do manipulations of the sequence in Adobe Premiere, a movie-editing software package, or in Flash by Dreamweaver. Every 10 frames is often a useful frequency.

**ALTERNATE
PROTOCOL**

IMAGE PROCESSING USING ImageJ

ImageJ is a more sophisticated image processing system than NIH Image (see Basic Protocol) and can handle color images and superimposition of digital sequences. ImageJ can be downloaded from the NIH Web site at <http://rsb.info.nih.gov/ij/>.

ImageJ has additional capture macros that can accept data directly from a camera, such as the Hamamatsu Orca 12-bit camera, and from Scine frame grabbers. It also has TWAIN for direct download from most image scanners. It can calculate surface area and line distances, measure angles, and obtain radial profile plots. ImageJ can identify edges and measure changes in the Analyze>Measure descriptors menu. Useful macros include Combine Images to Create Mosaic, which allows digital background subtraction, and Image Calculator Plus, which can combine images of different sizes in different formats.

The ImageJ Web site lists a number of other sites where additional image processing freeware is available. An interesting site is <http://bigwww.epfl.ch/thevenaz/differentials/>. The Image Differentials plug-in available at that site allows one to perform several differentiation operations on images seen as continuous functions, even though they are stored as discrete pixels. The general principle is to construct the continuously defined function

$$f(x,y) = \sum_{k,l} c[k,l]\phi(x-k, y-l)$$

As for NIH Image (see Basic Protocol), memory has to be set at a high value (at least 100,000) if digital sequences of 100 or more frames are to be processed. A caveat is that Java allocates memory from the Systems heap, which means that too much memory allocated to ImageJ can reduce the amount of memory available for loading images, but without enough memory, one can run into error messages when processing QuickTime image series. It is therefore necessary to monitor memory under the Apple menu when running ImageJ and make alterations as necessary according to the computer and image sequence with which one is working.

Materials

Color-capable Macintosh computer or PC with 64 Mb (256 Mb recommended) of free RAM and the following programs:

MacOS v. 7.6 or higher or Windows 95 or higher with Java Runtime Environment 1.1.3

MRJ 2.1 (download from <http://www.apple.com/java/>)

QuickTime for Java (installed with Mac OS 9.04 or higher, or can be installed from QuickTime 1 "custom" Install menu)

1. Once ImageJ is loaded, open the application and open files from within it. If images have been saved as QuickTime files from the original sequences, open by selecting Import from the File menu. To open sequences saved as TIFF, first put all the images into one folder, then open from inside ImageJ by selecting Import from the File menu, then selecting Image Sequence and opening a file within the folder, which will in turn open the whole sequence.
2. Become familiar with the most commonly used image processing procedures in ImageJ (main menu items listed first, then submenus):

Image > Adjust > Brightness/Contrast

Process > Subtract Background (this requires loading of a background image that is devoid of any structures of interest)

Process > Filters > Gaussian Blur

Analyze > Measure

3. Rotate digital sequences by selecting Rotate from the Image menu for export to QuickTime, which can then be played in Powerpoint presentations or uploaded onto the Web in the orientation that makes most sense in comparison to other image sequences or to a model/diagram.

In ImageJ, if a processing routine is applied to a digital sequence, one will be stuck with the results (i.e., this is destructive editing). Therefore, one should always keep a file of the original data separate from the sequence being processed, and save often to preserve desired changes in case subsequent processing is not useful.

4. Save the new image sequences by selecting Save As from the File menu. For a TIFF series, select Image Sequence from the submenu that appears. For QuickTime, select options from the popup menu:

Compressor: Video

Color

Quality: Medium to High

Timing: Frames per Second 6-10

Keyframe every 10

Further processing and analysis can be performed in ever increasingly complex software applications.

COMMENTARY

Background Information

Image analysis to determine the structure of molecules and particles

Prior to the advent of digital image processing, various manual manipulations were required to extract quantitative information from structural data. The term “structural data” in this context refers to photographic or digital images of biological specimens, ranging from whole animals to tiny single molecules. For example, diffraction patterns can be obtained by passing laser light through film containing images of subcellular structures displaying repetitive patterns resembling crystalline arrays, such as the catalase crystal in the peroxisome (Bearer and Orci, 1986), the acetylcholine receptor channel (Unwin, 2002), and the protein coat of viruses (DeRosier and Klug, 1972). Reconstruction of the “ideal” crystalline structure is obtained by solving the diffraction pattern in reciprocal space. Another approach superimposes multiple electron microscopic images of the same structure, which “averages” the image, decreasing the intensity of nonrepeating structures, including those of unrelated background particles or of the movable parts within a fluid region of the structure. This technique has commonly been used in the analysis of electron micrographs. Multiple exposures of the same photographic paper with different images or rotations of the same image superimposed upon itself identifies repeating structures and internal symmetries within a structure. This technique was used to discover the eight-fold symmetry of the endothelial fenestral diaphragm, responsible for the passage of nutrients from blood to tissue in human organs (Bearer and Orci, 1985).

Statistical analysis of biological specimens, also known as “morphometrics,” involves compiling measurements of multiple specimens of the same structure and then mathematically deriving the average size and other statistical values such as standard deviation within the population studied. Such mathematical compilations rely on the acquisition of a large number of measurements from multiple specimens, which until very recently was performed by hand. However, only relatively small sample sizes are easily analyzed by hand, since this requires a large time investment.

Recent advances in structural determination of complex cellular components not amenable to crystallization include tomographic recon-

struction of electron-microscopic images. In this approach, images are captured from thick sections of biological specimens embedded in either plastic or vitreous ice using an intermediate-voltage electron microscope. The section is photographed at various angles of tilt, and the 3-D structure assembled digitally. The structure of the neuronal synapse is yielding to this approach (Harlow et al., 1998), which was recently cited as one of the ten top scientific advances in 2002 by the journal *Science* (News and Editorial Staff, 2002).

New technology exploiting digital image processing includes laser scanning and two-photon confocal microscopy, which allows elimination of the out-of-focus light from fluorescently labeled specimens. Confocal microscopy allows optical sectioning and thereby the acquisition of sharp images of objects deep within thick specimens (White et al., 1987). In confocal microscopy, the image is filtered before capture. Confocal microscopy relies on monochromatic laser excitation of fluorescent tags, and collects only in-focus emission using a pinhole to block out-of-focus emitted light. In two-photon confocal imaging, a recent advance, excitation and collection occurs only from the same optical section of interest, thus prolonging the length of time that a living biological specimen can be observed without laser damage (Kaeck et al., 2001; Meyer et al., 2003). New computational approaches (Meta and Multi-Tracker options in the Zeiss 510 LSM package) narrow the bandwidth of detected emitted light, thus providing the possibility of imaging multiple fluorochromes with the same excitation and even only slightly differing emission spectra in the same specimen. An alternative way to eliminate out-of-focus light is deconvolution, which involves digital processing of a series of images obtained by focusing up and down in the same microscopic field. In this approach, out-of-focus light is eliminated digitally after image capture (Hiraoka et al., 1990). Deconvolution requires a motorized stage to collect a series of images in the *z*-plane (Kam et al., 2001). These images are then processed digitally to extract in-focus structure and detail and eliminate fuzz from out-of-focus or autofluorescent emissions. The equipment is less costly than that used for confocal, but collection times are longer, and thus deconvolution is not as suitable for living specimens undergoing rapid changes. Both of these approaches allow visualization of struc-

tures by fluorescence microscopy that would not be resolved by conventional microscopy. Useful texts on microscopy include Matsumoto (1993) and Inoué and Spring (1997). Microscopy courses at the Marine Biological Laboratory in Woods Hole, Massachusetts (<http://www.mbl.edu>) are also excellent for viewing demonstrations of the latest equipment.

Video microscopy, pioneered by Robert Allen in the late 1970s using Nomarski optics (differential interference contrast or DIC), is capable of detecting structures that are theoretically below the resolution of the light microscope if lenses with high numerical apertures are used (Allen et al., 1979; Hayden and Allen, 1984; Brady et al., 1985). Such lenses have narrow focal planes, and often have short working distances as well; thus, they have not yet proven useful for imaging objects deep within thick specimens. However, like confocal microscopy, video imaging with either DIC or fluorescent tags can be performed on live specimens. Analysis of such sequence data can provide information about structural changes over time, such as the rates of changes in cellular surface contours (Zhang et al., 2002), the velocities of movement of intracellular particles such as viruses (Bearer et al., 2000), and even the dynamic behavior of purified cytoskeletal filaments during interactions with motors or severing factors (Vale et al., 1985; Bearer, 1991). In this case, microscopy becomes an assay for enzymatic activity.

An Open Microscopy Environment (OME) is being developed as an informatics solution for storage and analysis of optical microscope data (Swerdlow et al., 2003). This public resource hopes to provide image analysis automation, modeling tools, and large sets of data for mining biological material. The goal is for data to be stored as an XML-encoded standard file which can be uploaded and processed by any software. The URL for this project <http://www.openmicroscopy.org>.

Image analysis to determine clues of function from subcellular location and behavior

In addition to providing information about the exact measurements of the “ideal” for a particular structure, image analysis is also useful to discover expression patterns, location within cells, and dynamic behaviors of molecules both large (proteins and RNA) and small (ATP and calcium ions). The expression patterns and behaviors of proteins inside cells

detected by microscopy complement those detected by biochemical and molecular approaches, and readily provide functional information about a protein or gene product.

Because the genome projects have identified a large number of novel genes whose function is not easily predicted from DNA sequence, functional clues derived from structural analysis have become increasingly fashionable. Morphological data are being collected in high-throughput screening assays to identify key proteins from large data sets. Such key proteins can then be selected for analysis by more time-consuming approaches in subsequent experiments.

Strategies using localization to derive functional information about individual proteins and thereby select interesting proteins from large data sets were originally developed using antibodies to localize the protein (Bearer and Alberts, 1988; Miller et al., 1989). Antibody staining provides evidence concerning the type of cell within a tissue that expresses the protein and the subcellular location of that protein in cells. In conjunction with other stains, including antibodies, against other cellular proteins whose function is known, the contribution of the unknown protein to a particular aspect of cellular behavior can be inferred.

In addition to antibody staining, several other methods have been developed to detect gene expression. In situ hybridization (ISH) to detect mRNA expression speeds up the analysis because it uses the DNA as a probe and bypasses antibody production, which is time-consuming and not always reliable. However, results from ISH do not produce information about protein function, only about relative expression between cells in a tissue.

Another method, transfection and overexpression of fusions of the target protein with tags such as green fluorescent protein (GFP), allows observation of the dynamic behavior of a protein in the living cell. This method has most commonly been applied to individual proteins once they are determined to be of interest and is not a commonly used screen, as construction of the GFP fusion takes time. Another powerful approach is to label a protein whose function is known with GFP and then observe the effect of overexpression, deletion, or mutation of the unknown protein on the GFP-labeled structures. Finally, labeling of a protein within a larger complex of proteins allows microscopic tracking of the complex within cells, a strategy used to study the movement of viruses within cells (Bearer et al., 2000).

Questions that microscopic analyses usually address include: (1) the timing of expression changes after stimulation, (2) the types of cells within a multicellular tissue in which the gene product is expressed, and (3) the location of the gene product within the cell and its association with other cellular structures of known function. The function of an unknown protein or small molecule can be assessed using substrate cells that are transfected with some other protein whose function is already known, and monitoring the effect of the novel protein on the behavior of the known protein. This approach has proven very useful in identifying proteins whose function affects the secretory pathway, such as Golgi markers (Lippincott-Schwartz, 2001; Kreitzer et al., 2003) or the actin cytoskeleton (Westphal et al., 1997; Fischer et al., 1998).

While all of these types of structural expression analysis have in common the use of the microscope to obtain images for further analysis, the exact method and interpretation of results differ depending on the question being addressed. Microscope assays can be divided into two subsets: those acquired from living specimens in real time or by time lapse, and those acquired from fixed specimens. These assays use a variety of different microscope technologies and experimental methods. This is a fast-moving area of research, and specific applications and equipment are likely to have evolved between the writing of this unit and its appearance in print.

Critical Parameters

Image analysis is only as good as the images being analyzed. It is often a fruitless waste of time to use digital image processing to improve poor images. Therefore, before embarking on an analytical or processing project, images should be carefully scrutinized for: (1) focus; (2) good signal-to-noise ratios; (3) reproducibility; and (4) background contamination. Artifacts to be avoided are those from: (1) laser or other light damage; (2) aggregation of fluorochrome marker; (3) nonphysiologic localizations of fusion proteins; (4) movement of the stage during collection of video images; and (5) other effects of the experiment on the cell that might damage it or perturb its normal processes.

Scientists engaged in monitor-based digital processing tasks should ensure that the monitor's colors, brightness, and contrast are set appropriately. Instructions for this come with the Adobe Photoshop package, and must be

tailored to the individual monitor being used. Printing of processed images requires that the printer be coordinated with the monitor as well. This is dependent on the manufacturer's specifications for the particular printer and monitor being used. Monitor-based processing requires a low-light work area and a maximum-resolution screen.

Time Considerations

Digital image processing and analysis are usually more time-consuming than expected. The better the original image(s), the less time is required for processing. The type of data being extracted also define the length of time that must be invested. If software routines are available, then applying them can be fast once a sequence of steps is defined. It usually takes a graduate student a week to learn a routine, then a half-day to a day to make a processed QuickTime movie from a preselected, excellent series of images.

Three-Dimensional Reconstruction of Tissues

UNIT 14.16

**BASIC
PROTOCOL**

Three-dimensional (3-D) tissue reconstruction relies on the acquisition of three-dimensional data followed by the assembly of the data into a 3-D data block from which information can then be extracted. This unit provides a protocol for performing serial microscopy for acquiring the data, reconstructing the data into data blocks, and extracting cross-sectional areas of some features of the tissue. Because of the wide range of tissues that can be processed by serial microscopy and the reconstruction of the data into data blocks, and because each investigator will focus on different parameters of interest, the last section of the protocol is limited to high-contrast areas.

Three-dimensional imaging is advancing at a rapid rate. However, most 3-D histological techniques rely on expensive instrumentation, often with extensive custom assembly. As a result, this unit will focus on a protocol that requires standard histology and fluorescence microscopy equipment. The protocol outline starts with a brief guide to labeling and histological processing, followed by detailed steps for imaging and post-processing of the images to reconstruct 3-D data. The end result is a series of images that are merged from multiple images from each histological slide, aligned with each other for purposes of reconstruction. This data is useful because the user can display a much larger field of view than what the microscope camera is capable of acquiring, and because the user can follow features in three dimensions with alignment much more easily.

This protocol was written with the assumption that the user is competent with anesthesia, harvesting and processing of tissue, and euthanasia in the desired organism, as well as with fluorescence microscopy, including knowledge of the objectives, filters, cameras, and image output. For post-processing, experience with Matlab or adapting Matlab coding to another programming language is highly encouraged. Although the code provided for this protocol can run without the user knowing Matlab, the most effective use of the coding will require user interaction. Thus, at least minimal knowledge of Matlab is highly recommended for this protocol.

Labeling and histology. To make full use of the protocol and avoid multiple repetitions, it is essential to carefully plan the labels to be used ahead of time. Specifically, interference in wavelengths, the use of bright-field versus fluorescence labels, the expected number and distribution of the components being labeled, and the orientation of the tissue in the paraffin block should be carefully considered in advance of the experiment in order to make the study most fruitful. A few general guidelines that may be helpful include the following:

1. Fluorescence emission wavelengths tend to bleed into higher wavelengths, i.e., a blue dye will leak into green, but a green dye is unlikely to leak into blue. Thus, the smaller, dimmer, and more diffuse components should be labeled with the shorter (closer to blue) wavelengths and filtered appropriately.
2. Some light-based dyes will quench fluorescent labels. While both bright-field and fluorescent dyes can be used, and this can theoretically increase the amount of information acquired, interference and photobleaching must be considered. It is important to test combinations on sample tissues prior to experimentation on the real specimens.

**In Situ
Hybridization
and Immuno-
histochemistry**

3. The tissue should be oriented in the paraffin block (or other cutting block) in such a way that slices yield the information desired with minimal error. The errors in z (the direction perpendicular to each slice) are generally higher than in the plane of the slice (x - y), due both to cutting and to limitations of the optics.
4. With any 3-D reconstruction technique, it will be most difficult to identify the ends of features (cells, vessels) unambiguously in the direction with the least resolution. This will generally be the z direction.
5. The images being acquired should be the same size (the use of different binning for images to be stitched should be avoided), and should be arranged in a rectangular array (2 by 1, 5 by 3, and so on). One should avoid moving samples diagonally.

Materials

Labeled tissue, or animal to be labeled and appropriate anesthesia
 Labeling compounds (e.g., Invitrogen): 10 mg/ml Hoechst stain; 5 mg/136 μ l Texas red maleimide in DMEM; 500 μ g/ml Alexa Fluor 488 in PBS with Ca^{2+} and Mg^{2+} ; or other label of interest
 Fixative (e.g., 4% paraformaldehyde)
 70% ethanol
 Paraffin
 1-ml or smaller syringes
 Small-gauge needle
 Microtome
 Glass slides and coverslips
 Fluorescence microscope with appropriate objectives, filters, cameras, and acquisition software
 Computer (minimum requirements are Pentium 4 with 1 GHz or faster processor, 512 MB or higher RAM, and hard drive of 100-GB capacity or greater, depending on size and number of image files, running MacOS X or Windows 2000)
 Mathematical processing package (e.g., MatLab, Mathworks)
 Additional reagents and equipment for fixation, embedding and sectioning of tissues (e.g., *UNIT 14.1*)

NOTE: Using other programming languages, such as Visual C, requires having the appropriate compiler and knowledge of the programming syntax, which is not provided here. For the code presented in this protocol (available for download at <http://vascular.bwh.harvard.edu/cpmb3d/cpmb3d.html>), Matlab 7.0 or higher with Image Processing and Curve Fitting toolboxes is required.

Label tissue of interest

If the tissue is already labeled ex vivo and embedded in some blocking medium, proceed to step 8. Steps 1 to 7 describe intravital fluorescence labeling of an entire mouse.

1. Anesthetize the animal.
2. Using a 1-ml or smaller syringe, inject the appropriate amounts of the labeling compounds into the tail vein. For example:

50 μ l Hoechst stain for nuclear labeling (stock 10 mg/ml)
 20 μ l Texas red maleimide for matrix labeling (5 mg/136 μ l DMEM)
 50 ml Alexa Fluor 488 isolectin stain for endothelial labeling (500 μ g/ml PBS with Ca^{2+} and Mg^{2+}).

3. Keep the animal under anesthesia for 15 min to 1 hr to allow intravital staining.

4. Sacrifice the animal and harvest/fix the tissue by removing the organs and fixing in 4% paraformaldehyde overnight (UNIT 14.1).
5. Take the tissue from the 4% paraformaldehyde solution and place in 70% ethanol overnight (may be extended up to 1 week).
6. Embed the tissue in paraffin using standard histological protocols (UNIT 14.1).
7. *Optional:* In each block, puncture the paraffin around the tissue using a small-gauge needle (those used for insulin injections are usually adequate). Do not puncture the tissue itself, but place the punctures as close as possible to the tissue to avoid having to acquire extraneous data.

These holes can be used to help perform gross alignment once the images have been registered. This is especially useful for homogeneous tissue.

Section tissue

8. *Optional:* Notch the corner of the block through the entire height of the block, so that the notch will be visible in each slice.

This will help orient the tissue, and should be done if the tissue does not have gross features for orientation purposes.

9. Using a microtome (UNIT 14.1), slice 50 to 100 consecutive times and plate the samples on glass slides (coverslips are optional).

Multiple sections may be placed on the same slide as long as the order is preserved.

Each slice should be 5 to 20 μm thick, although this can be adjusted depending on the nature of the tissue and the features being examined. In general, the thickness of each slice should be selected to give $\sim 1/10$ the resolution of the features of interest, and the number of slices should be chosen to span roughly two to three times the size of the features. For example, if the features of interest are individual cardiac myocytes (expected length of 100 to 150 μm , expected diameter 10 to 30 μm), and the myocytes are being cut in cross-section, slice thicknesses of 10 to 15 μm should be used, and at least 30 consecutive slices should be acquired. If the myocyte is being cut longitudinally (along its long axis) then at least 60 slices of 1 to 2 μm should be acquired.

10. Examine two to three random slides to ensure that the labels are intact and that the notches and holes from steps 7 and 8, if any, are visible.

Image tissue

11. Using a fluorescence microscope, place one slide on the stage and acquire images from the first section in the region of interest. If holes were made in step 7, also acquire adjacent images that include at least two holes in the paraffin.

It is vital that all images have some overlap with each other. This can be done manually using visual landmarks, or by using a properly calibrated automated stage. The images should also form one large rectangular array to be assembled later. For ease of post-processing, the images should be acquired top-to-bottom (the y direction in plane, not the z direction through the section) and then left-to-right. After completion of imaging from one section, the acquired images should fit together to form one large image without separations. Small gaps in the images where there is no useful information are acceptable, but stand-alone islands are unacceptable. For each section, it is recommended that the same number and arrangement of images be acquired.

12. Acquire images from the other sections in sequence, using the same template of images as in the first section from step 11. That is, acquire images from all sections in a similar fashion, so that they encompass the area of interest and the holes, and so that they form the same-sized rectangular array.

Figure 14.16.1 Flowchart of the post-processing for extraction of 3-D data from serial slices.

It is useful to have the file names follow a standard convention so that post-processing will be easier. For example, a file from a heart sample can be labeled heart_3_s6.tif to indicate that it is the third image of section 6.

For processing, the image files must be the same size and dimensions. Thus, binning or cropping should be avoided. If they are necessary, image processing should be performed using software to ensure the images are identical in size, resolution, and format before proceeding to the next step.

The flowchart in Figure 14.16.1 depicts the outline of the rest of the protocol. Images will be registered in-plane, then assembled in the z direction, and then features will be isolated.

Perform two-dimensional post-processing

13. Copy the images to the computer for image processing with the mathematical image analysis software. Make sure the images are in the Matlab root directory (for Matlab Version 7 Release 14 on a PC, this would default to C:\MATLAB701\work).

Figure 14.16.2 Two-dimensional registration of images. (A) Two images to be registered. Notice that the images overlap horizontally but are shifted slightly vertically. (B) Registered image.

14. Load images from a single plane (multiple images from a single slice in the rectangular array) into Matlab for viewing purposes. To do this, type

```
>> imshow filename.tif
```

at the Matlab command prompt, where `filename.tif` is the image file to be displayed. Examine the images to ensure the overlap is visible by looking for common features on the edges of the images. For example, in the images shown in Figure 14.16.2A, the white arrows point to a section of strong labeling that is common to both images.

After beginning this step, do not type 'clear' at the Matlab command prompt because some of the values are needed to execute subsequent commands. Any clearing that has to be done will be in the corresponding code.

15. Register the images in a single plane. Perform registration by cross-correlation using the Matlab codes named `plane_register.m`, with functions `TBreg.m` and `RLreg.m`, if downloaded (for codes, go to <http://vascular.bwh.harvard.edu/cpmb3d/cpmb3d.html>). If manually entering the code, type the contents of the code into separate notepad files and save as `plane_register.m`, `TBreg.m`, and `RLreg.m` in the Matlab directory. If the files have `.txt` appended to them, highlight the files one at a time and press F2 to rename the files without the `.txt` extension. Launch Matlab and type

```
>> plane_register
```

at the Matlab command prompt to run the script.

- a. A dialog box will open asking for the Overlay Pattern. Depending on how the images are designed to fit together, the input should consist of two numbers separated by a space. The first number is the number of rows (vertical number of images), and the second number is the number of columns (horizontal number of images). For the images in Figure 14.16.2A, one would enter 1 2 and then click OK.
- b. Enter the percent overlap of the images. For the images in Figure 14.16.2A, a good initial overlap would be 25%, although this can be adjusted if the program does not obtain a satisfactory result. For automated stages, once one overlap is figured, the rest should be nearly identical. Note that the percent should be entered as a true percentage (and not a fraction). Thus for Figure 14.16.2A, one would enter 25 and then click on OK.
- c. An open file dialog will now open for each image, up to the number of images based on the input in step a. Thus, if the input into step a is 2 3, a total of 6 files will be requested. These must be opened in the order of the image acquisition top to bottom, then left to right. For example:

```
1 3 5
2 4 6
```

would be the order of the images for a 2 by 3 array of images.

- d. The program will then run and register the images into one big image. At the end, a large image will appear of the registered image with some black space used for buffer space. It is recommended that the black space not be removed if z-registration is to be performed immediately.
16. Save the displayed registered images as a single large image. This can be done using the Matlab command `imwrite.m`. At the Matlab command prompt, type:

```
>> imwrite(final_image, 'desired_name.tif', 'tif')
```

where `'desired_name.tif'` can be custom (`'heart001.tif'` for example).

This will save the registered image as a TIFF file. Do not save by using the menu option File/Save As. Make sure the file type is of a suitable format (TIFF is recommended). It is recommended that each registered slice be assigned a slice number for z-registration (heart001.tif being the first slice, heart002.tif being the second, and so on) for easier recall later. Figure 14.16.2B depicts the images from panel A, now in register.

17. Repeat steps 15 and 16 for all the slices (e.g., 50 to 100) that were imaged.

Perform three-dimensional reconstruction

18. Close all images in the workspace to clear memory. Close the figure window or type

```
>> close all
```

at the Matlab command prompt.

19. Open two consecutive (big) images of the slice (saved in step 17) by typing at the Matlab command prompt:

```
>> cpselect('image1name.tif', 'image2name.tif')
```

where `image1name.tif` and `image2name.tif` are the filenames of the images.

A new window will open with four windows (ignore the legend). The bottom two windows display the images in total, while the upper portion displays magnified images of the areas in the white-bordered rectangle in the bottom images. Using the scroll bars in the upper

images, it is possible to move around the whole image. The rectangle in the lower image will move to show the region being magnified in the upper image.

20. Identify several (at least three) morphological features that appear in the same location in both images (e.g., tears, dark spots, a cell with particularly odd morphology, or, failing that, the holes punctured in the paraffin from step 7). Left-click on one feature in the upper left image, followed by the corresponding feature in the upper right image (lower images are for reference). Repeat for at least three pairs of points.
21. Under the menu option File, select Save control points to workspace. Use default checkboxes and click OK.
22. *Optional:* Save the coordinates to a file for future reference by typing at the Matlab command prompt:

```
>> csvwrite('filename.csv', [input_points base_points])
```

where `filename.csv` is a comma-separated value file with a filename of one's choice.

The output is four columns of x and y coordinates of the features in the left-hand image followed by the coordinates of the same features in the right-hand image. The number of rows should be the same as the number of features selected in step 20.

23. Perform least-squares fitting to determine the best orientation and translation of the second image with respect to the first. Use the code `rotate_second_image.m` from download or by typing/saving as a new M-file. Execute the code by typing at the Matlab command prompt:

```
>> rotate_second_image
```

When the open file dialog box appears, choose the name of the second image in the stack to be rotated and shifted in reference to the first, which was done in steps 19 and 20. Once the program has completed its run, save the image by entering the following at the Matlab command prompt:

```
>> imwrite(transformed, 'desired_name.tif', 'tif')
```

where `desired_name.tif` is the filename of the image to be saved.

24. Repeat steps 17 to 23 for the second and third images, then for the third and fourth images, and so on.
25. Once completed, display a data block of the corrected scan volume as individual images or as a movie if the images are stitched together.

Isolate features

This section of the protocol calculates the cross-sectional area of a feature that is dark and bordered by a bright zone. If the image in question is reversed, use an image processing program to invert the image.

26. *Optional:* Open the two consecutive (big and corrected) images aligned from the three-dimensional reconstruction (i.e., ending at step 25). Open the images so that they are the same size and take up the same position in the window when they are active.

This may help with identification of features or landmarks in successive sections. It is best to open images from the center of the stack (images 25 and 26 in a stack of 50 images or 50 and 51 in a stack of 100 images).

27. Run the script `feature_extract.m`, with the two functions `image_mask.m` and `bwcfind.m` (again, type each script/function into separate files and save, or download). Open the image at the top of the z-stack when prompted by the dialog box. Set threshold at the desired value (25 is default; lower means dimmer signal gets included, higher means brighter signals get excluded) and click OK. Drag the mouse to select a region containing the cells or features of interest (click once and hold the mouse button to start dragging, once the area has been selected, release the button). Two images will display, one with the cropped original image and one entitled 'water,' which has a watershed and edge-detected segmentation of the cropped image. Save the water image if desired, otherwise continue to step 28 with the cropped original image and ignore the water image.
28. Identify a cell or feature of interest for which the cross-sectional area is desired by clicking in the middle of the cell/feature. Repeat for as many cells/features as desired, then click the middle mouse button/scroll wheel (if using a PC) to end. If the mouse does not have a center button, hit Enter, and type at the Matlab command prompt:

```
>> Areas
```

The cross-sectional areas (in pixels) will be displayed in the order the cells/features were selected.
29. *Optional:* Save the images for future reference. Use the `imwrite` command as previously described (File/Save As is possible but not recommended). Make sure the desired file format is selected (TIFF is recommended).
30. Repeat steps 27 to 29 for subsequent images and identify the same cell or feature. This can be accomplished using several landmarks:
 - a. The cell is in the same location and overlaps significantly with the first.
 - b. The cell is fluorescently labeled and the ones near it are unlabeled or labeled differently.
 - c. The morphology of the cell is distinctive and the same distinctiveness shows up in the second image.

In general, method b is best for clear identification, but is most difficult to attain.
31. To identify the ends of the cell, use one or more of the following landmarks:
 - a. The cell is fluorescently labeled and the ones adjacent to it are not. When the fluorescence ends, so does the cell.
 - b. The location of the cell is no longer taken up by a cell but by non-cell features. Alternatively, if a cell overlaps with previous cells by a large percentage, then suddenly no cells overlap by the same amount, that is an indication that the cell has ended.
 - c. If a nuclear stain was used, and the number of nuclei in the cells is known, locations between the nuclei of a single cell where the cell visibly shrinks are likely to represent a partition.
 - d. Use the image stack in 3-D, and extract a perpendicular section. Use the perpendicular section to identify the ends of the cells.

In general, method a is best, although method d permits similar analysis without requiring additional staining.
32. Once the complete cell is identified, calculate the volume by adding the cross-sectional areas of each slice containing the cell and multiplying by the thickness of the slices. Convert from pixels to microns according to the microscope/camera setup,

Figure 14.16.3 Example of extracted cell with various planes showing part of a cardiac myocyte. This processing was performed using Amira.

using a Ronchi ruling or similar, if desired. Calculate the surface area by adding the perimeter of each cross-sectional area multiplied by distance between slices.

The image stack can also be imported for use in other 3-D packages, such as Amira (Fig. 14.16.3).

COMMENTARY

Background Information

Three-dimensional (3-D) image processing of tissue data is a powerful tool that can provide clear visualization of the tissue properties and enhance quantization of relevant morphology. This unit refers to any reconstruction and analysis requiring all three dimensions, regardless of the thickness of the specimen. For example, a globe of the Earth is three-dimensional, despite the fact that the information on the globe has no theoretical thickness, because simple attempts to flatten the map will induce distortions or introduce discontinuities. Thus, all three dimensions are necessary.

From a visualization perspective, being able to see and rotate a solid model in space has advantages over two-dimensional (2-D) representations. For example, consider explaining the structure of coronary arteries using a 3-D surface map versus one where a movie of serial slices is shown and the audience is expected to mentally construct the map. The 3-D

map is much less likely to create confusion. Additionally, once a 3-D data block has been acquired, the tissue can be sectioned in any desired plane. Having 3-D data also obviates problems that might arise when determining the length, breadth, and width of the same cell using classic 2-D techniques.

Quantitatively, there are numerous advantages to using 3-D analysis compared to 2-D. Determination of volumes, surface areas, and spatial orientation is facilitated with 3-D data. Statistical advantages exist as well. Due to heterogeneity in some tissues, 2-D data reflect not only the inherent variability of the cells in the tissue but also the variability resulting from cutting. This weakens statistical analysis, resulting in changes of significance or increasing the number of specimens required to make a significant finding. To clarify this point, consider sampling a number of cylinders with varying cross-sectional areas. If one has the 3-D image of each cylinder, the cross-sectional

area determined by a caliper-type program would reflect the variability in the cylinders themselves (along with measurement errors). However, if one were to cut the cylinders at various angles, the variances in cross-sectional areas will generally be increased, artificially inflating the values and the variance itself.

Despite the advantages of 3-D analysis, few studies have focused on developing techniques and even fewer studies have involved 3-D analysis on tissues. Some reasons for this include the expense and difficulty in use of the necessary instrumentation, difficulty of post-processing, large amounts of data storage and processing required, and increased time required for analysis.

With the advent of commercial confocal and two-photon microscopes and improved computation, more studies are relying upon three-dimensional analysis. Confocal microscopy uses standard fluorescence illumination (laser or lamp based) and then filters out-of-plane signals using a pinhole (see, for example, Periasamy, 2001). Depending on the illumination source, the scanner/pinhole setup, and the objective, the expected z signal can be narrowed down to an $\sim 0.5\text{-}\mu\text{m}$ -thick plane. Studies using confocal microscopy show improved image quality in relatively thin planes as well as in deep scanning. Disadvantages of confocal microscopy include the cost of a laser-scanning system (typically \$200,000 USD and above), limited penetration depths (especially for shorter wavelengths), and photobleaching when taking volumetric data over an extended time. Despite these disadvantages, the signal clarity and rejection of out-of-plane noise provide sufficient advantages that several studies in three-dimensional cell and tissue structure rely on confocal microscopy and post-imaging reconstruction (Roeder et al., 2004; Sun et al., 2004; Sugawara et al., 2005; Tobita et al., 2005).

Two-photon microscopy typically uses a red-to-infrared ($>700\text{-nm}$) laser to generate an excitation volume confined to the area of maximal focus after the objective (Denk et al., 1990, 1991; Williams et al., 1994). Because the excitation relies on two photons exciting the same molecule nearly simultaneously, only the focal region has sufficient photon density to generate a fluorescent signal. The practical result is that the signal received by the camera or photomultiplier tube is emanated from a small volume, with a z -plane thickness of $\sim 1\ \mu\text{m}$ (depending on the objective used). There is subsequently no need for a pinhole/scanner arrangement, although this can be added to fur-

ther clarify the signal. Two-photon microscopy has two main advantages: (1) the limitation of excitation to a small volume, which reduces overall photobleaching and out-of-plane noise, and (2) the use of long wavelengths that have greater penetration depth into tissues, allowing scanning of optically favorable tissues of up to several hundred microns. Disadvantages of two-photon microscopy include heat damage to the specimen, expense of laser and microscope maintenance, and, in some cases, loss of resolution and difficulty in locating the feature of interest due to the scanning nature of the majority of two-photon microscopes. Two-photon microscopy is well-suited for deep scanning of tissues and for performing three-dimensional cell and tissue scanning, in part because of its penetration depth.

When using standard epifluorescence (sometimes called wide-field fluorescence), the out-of-plane noise is generally unavoidable. However, software programs can perform deconvolution on acquired data, assuming that information regarding the optical setup is known. There are several types of deconvolution, and the technique most suitable for a given application depends on the equipment, the tissue sample, and the desired outcome. In general, deconvolution can greatly improve epifluorescence images but not to the extent of confocal image acquisition. However, the combined cost of a standard fluorescence microscope and deconvolution software is much lower than the cost of a confocal system. Deconvolution has been used to clarify three-dimensional images of cells mainly, but also of some tissues (see, for example, Maierhofer et al., 2003; Mudry et al., 2003; Segretain et al., 2003; Carreno et al., 2004; Bick et al., 2005). The technique described in this unit does not rely on deconvolution. The out-of-plane noise is eliminated simply by imaging only the thin section that is desired, and then the 3-D reconstruction is performed by using cross-correlation algorithms to find a match to splice the images together; finally, a least-squares fit is applied to the spliced images to perform the alignment in z . While some commercial microscope and imaging processing packages can perform the in-plane registration automatically when coupled with an automated stage, the protocol described in this unit does not require an automated stage and can do alignment in the vertical direction based on serial slices.

Three-dimensional tissue scanning has been applied to an increasing number of tissue types and sizes. Certain new techniques

such as optical projection tomography permit the acquisition of larger and increasingly complex specimens (Sharpe et al., 2002; Sharpe, 2003). The addition of a lateral microtome to remove scanned sections on confocal or two-photon microscopes allows theoretically unlimited scanning (Young et al., 1998; Ewald et al., 2002; Ragan et al., 2003; LeGrice et al., 2004). Laser ablation (the burning away of scanned tissues using a second laser) has been used in a similar manner (Tsai et al., 2003). Certain other techniques—such as MRI, ultrasound, and, more recently, optical coherence tomography—allow fairly deep (millimeters to tens of centimeters), nondestructive scanning but are limited in resolution and feature extraction. Current challenges include increasing the speed of image acquisition, performing high-resolution non-invasive scans, labeling of specific tissue and cell components (at the organ level or above), and storage and post-processing of data.

Critical Parameters

In performing 3-D analysis using the method described here, it is vital that potential errors associated with the method be understood.

The sections to be imaged must be cut with a microtome with care so that distortion is minimized and all or almost all slices can be saved. This is not a major issue if the reconstruction is meant to be a rough estimate or if the slices are extremely thin (1 to 3 μm), but for most purposes, dropping slices leads to missing volumes that might contain the end of a cell or other feature that is important.

The programs offered in this protocol allow the user to register (in x - y) and assemble (in z) stacks of slices in order to obtain a three-dimensional tissue stack. However, it cannot be overemphasized that the user must check each step to make sure the alignments are realistic. Even with guides and cross-correlations, it is possible for the program to settle on a fit that is rotated, shifted entirely out of view, or matched to incorrect features. The old adage of GIGO (garbage in, garbage out) is especially applicable in three-dimensions, where one needs to look at successive images to see if the construct makes sense.

When locating features of interest, it is useful to check a few slices in z ahead of where the current slice is located to see whether the feature will be useful. Good features (1) persist for several slices instead of just one or two, (2) do not apparently change in shape or position much, if at all, (3) are unique in some

way, and are therefore unambiguously identifiable from slice to slice, and (4) are small or have small features that are uniform. Small size permits the coordinates of the features to have the smallest error from slice to slice.

Finally, for statistical analyses or analyses involving differential determinations, it is important that the person performing the registration and extraction be blind to the experimental groups for the specimens being analyzed. The user of the programs can unintentionally distort the size and shape of the features. Use of more advanced technologies, such as the lateral microtome or laser ablation techniques, might alleviate user bias.

Troubleshooting

Poor registration can be a result of several issues. If the image does not have sufficient resolution for feature alignment, then the imaging setup might need to be examined. In particular, the illumination, exposure time, objective, focus, and amount of overlap may need to be adjusted for each specimen.

Incorrect image registration usually results from input error. First, make sure the images are the correct ones being registered. It may be helpful when acquiring the images to tag filenames consistently with a code so that the slice and position can be determined. Overlap should be visible on opening the images. The user should attempt to input as accurate an overlap percentage as possible. Input of a 60% overlap when the images only overlap 20% will increase the chances of registering incorrectly due to mathematical noise; in contrast, attempting a 10% overlap when the images have a 20% overlap will almost never yield correct results. The overlap percentage should be slightly greater than the actual overlap, but not by too much. During imaging, overlaps of 20% to 40% are optimal for most cases.

Registering images may present the following error: Matrix index must be positive or logical. This occurs when Matlab is creating the final image and either an image below the first input image has an offset >200 pixels to the left, or an image to the right has an offset >200 pixels above of the first image. If this occurs, two options are accessible without editing the programs. The first one is to reexamine and retake the images of the section with lower (diagonal) shifts. The second option is to crop the images to a smaller size using Matlab or another image processing package, making certain that all the images in the layer are of the same dimensions.

Tissue distortion may result in a poor 3-D stack. If this is the case, the sample preparation needs to be adjusted. For example, the thickness of the cut can be adjusted (keeping in mind not to increase the thickness far beyond 1/10 the useful resolution), the tissue fixation can be adjusted (i.e., by increasing or decreasing the length of fixation), and/or the embedding medium can be adjusted from the standard paraffin (e.g., with frozen sections in specialty media, or epoxy resins).

If the ends of cells are difficult to identify (this is a common problem), then selective labeling should be used to highlight the cells of interest. Some examples include transfecting or infecting cells of the organ with a fluorescent reporter, using dyes such as Cell-Tracker (Invitrogen), labeling the nuclei (using Hoechst, for example, which will help identify the number of expected cells if the cells are known to have exactly one nucleus), sectioning in a perpendicular direction, or using thinner slices, which may help expose the ends of the cells.

If there is a lack of features for z alignment, for example, because the tissue is extremely homogeneous under a microscope, then one can introduce artificial features by puncturing the paraffin surrounding the tissue, puncturing the tissue itself, or cutting the tissue block into a rectangular piece so that the overall geometry is easily identified. Puncturing the tissue is not recommended, since this will likely cause tears in the tissue during sectioning and may introduce distortions into the tissue directly.

During segmentation, too little or too much segmentation may occur (i.e., the area selected may be much larger or much smaller than the region that should be segmented). In this case, change the threshold value parameter depending on the contrast of the image to obtain appropriate segmentation. The default value is 25; a lower value will generally yield larger areas of segmentation while a higher value will yield a smaller area. If possible, increase the contrast of the image prior to segmentation by using an image processing package or the Matlab command:

```
>> imadjust('filename.tif')
```

Occasionally, Matlab will not write an image using `imwrite` after many registrations have been performed and the images written to files using `imwrite`. This generally occurs because the computer memory is full. If this happens, type at the Matlab command prompt:

```
>> pack; dumpmemex;
```

or alternatively, exit and restart Matlab. The last program may need to be rerun.

Anticipated Results

By following this method, the user should obtain 3-D data of individual cells that can be quantitatively analyzed. Extraction of cell data and information includes cell volume, length, and surface visual representation. Location of inner features such as nuclei can be made. Depending on the quality of the slices, the entire image section may have usable data; however, due to shifts in overlap and expected distortions, not all of the cells will be usable.

As an illustration, for a section that is $\sim 1400 \times 1000$ pixels from a single image, combining six images together with 40% overlap will yield one large image that is 3000×1600 pixels. At $20\times$ magnification, with $1 \mu\text{m}$ per pixel, the field is therefore $3 \times 1.6 \text{ mm}$. Given that a cardiac myocyte is $\sim 500 \mu\text{m}^2$ in cross-section, one might expect there to be nearly 10,000 usable cells. However, not all of the area will have cells, not all of the area will have correct overlap (and portions outside the overlap region cannot be used), not all of the cells will be complete in the z direction, and not all of the cells will have identifiable ends.

Time Considerations

Registration in x - y should take 6 hr for a stack of 50 slices, each slice having six images with image dimensions of 1392×1040 with 40% overlap (using a 2.2 GHz Pentium 4, with 1 GB of RAM, running Matlab 7 Release 14 under Windows XP). Registration in z should take 1 to 2 hr for a stack of 50 images (same configuration as above). Identifying a single cell should take 6 to 10 min with practice.

A single data set (50 slices, all aligned and pre-processing files deleted) should require 4 to 10 GB of HDD space, post-processing. While this information is not strictly a time consideration, it is presented here because copying, backing up, and/or moving the files can take substantial time even at high transfer rates. For example, data transfer of a 10 GB set of files at 100 KB/sec (Ethernet speed) would take over 24 hr.

CHAPTER 15

The Polymerase Chain Reaction

INTRODUCTION

The polymerase chain reaction (PCR) is a rapid procedure for *in vitro* enzymatic amplification of a specific segment of DNA. Like molecular cloning, PCR has spawned a multitude of experiments that were previously impossible. The number of applications of PCR seems infinite—and is still growing. They include direct cloning from genomic DNA or cDNA, *in vitro* mutagenesis and engineering of DNA, genetic fingerprinting of forensic samples, assays for the presence of infectious agents, prenatal diagnosis of genetic diseases, analysis of allelic sequence variations, analysis of RNA transcript structure, genomic footprinting, and direct nucleotide sequencing of genomic DNA and cDNA.

The theoretical basis of PCR is outlined in Figure 15.0.1. There are three nucleic acid segments: the segment of double-stranded DNA to be amplified and two single-stranded oligonucleotide primers flanking it. Additionally, there is a protein component (a DNA polymerase), appropriate deoxyribonucleoside triphosphates (dNTPs), a buffer, and salts.

Figure 15.0.1 The polymerase chain reaction. DNA to be amplified is denatured by heating the sample. In the presence of DNA polymerase and excess dNTPs, oligonucleotides that hybridize specifically to the target sequence can prime new DNA synthesis. The first cycle is characterized by a product of indeterminate length; however, the second cycle produces the discrete “short product” which accumulates exponentially with each successive round of amplification. This can lead to the many million-fold amplification of the discrete fragment over the course of 20 to 30 cycles.

The primers are added in vast excess compared to the DNA to be amplified. They hybridize to opposite strands of the DNA and are oriented with their 3' ends facing each other so that synthesis by DNA polymerase (which catalyzes growth of new strands 5'→3') extends across the segment of DNA between them. One round of synthesis results in new strands of indeterminate length which, like the parental strands, can hybridize to the primers upon denaturation and annealing. These products accumulate only arithmetically with each subsequent cycle of denaturation, annealing to primers, and synthesis.

However, the second cycle of denaturation, annealing, and synthesis produces two single-stranded products that together compose a discrete double-stranded product which is exactly the length between the primer ends. Each strand of this discrete product is complementary to one of the two primers and can therefore participate as a template in subsequent cycles. The amount of this product doubles with every subsequent cycle of synthesis, denaturation, and annealing, accumulating exponentially so that 30 cycles should result in a 2^{28} -fold (270 million-fold) amplification of the discrete product.

This chapter consists of protocols that cover some of the more common applications of PCR. For many applications, the first step is simply to get PCR working with a known segment of DNA and a set of primers. Therefore, *UNIT 15.1* presents a basic PCR protocol and ways to optimize it for the sequence of interest.

PCR permits direct sequencing of nucleic acids without requiring cloning, thus avoiding cloning difficulties and artifacts. Several different protocols for preparing PCR products for sequencing using either dideoxy (Sanger) sequencing methods or chemical (Maxam-Gilbert) methods are presented in *UNIT 15.2*. This unit should permit the practitioner to choose a protocol best suited to the problem at hand and to his or her taste.

Several PCR methods have been developed that require knowledge of only a small stretch of sequence (30-40 bases) and add sequence to the ends of amplified molecules to facilitate analyses. One of these, ligation-mediated PCR (*UNIT 15.3*) has broad applications including genomic footprinting and sequencing.

PCR can be used to help clone and manipulate sequences. Various methods for generating suitable ends to facilitate the direct cloning of PCR products are detailed in *UNIT 15.4*. Other protocols for cloning and mutagenesis of DNA using PCR can be found in *UNIT 3.7* and *UNIT 8.5*.

An important application of PCR is to detect RNA transcripts, analyze their structure, and amplify their sequences to permit cloning and/or sequencing. *UNIT 15.5* presents procedures that adapt PCR to RNA templates, via production of a cDNA copy of the RNA by reverse transcriptase (RT-PCR). Anchored PCR, which, like ligation-mediated PCR, requires little knowledge of sequence and makes use of the ends of nucleic acids, is applied in *UNIT 15.6* to analysis of mRNAs.

PCR is frequently used because it is the most sensitive assay for rare sequences. A protocol that not only detects rare DNAs but quantitates them as well is presented in *UNIT 15.7*. The downside of sensitivity is contamination by infinitesimal amounts of unwanted exogenous sequences. Procedures designed to avoid contamination with undesired DNA sequences are emphasized in this unit.

In Supplement 56, we have rearranged the order of the units and have updated some of them. Further updates and new units, especially on quantitative approaches to PCR, are forthcoming. We have also moved one unit, formerly 15.8, which describes a powerful application of PCR called differential display to Chapter 25, "Discovery and analysis of differentially expressed genes in single cells and cell populations", where it is now *UNIT*

25B.3. Chapter 25 includes other PCR-based protocols as well. Of course, as PCR has become an invaluable tool for nearly every branch of molecular biology, applications of PCR can be found in many other chapters of *Current Protocols in Molecular Biology* including Chapters 3, 7, 8, 12-14, 16, 21, 22, and 24.

Enzymatic Amplification of DNA by PCR: Standard Procedures and Optimization

UNIT 15.1

**BASIC
PROTOCOL**

This unit describes a method for amplifying DNA enzymatically by the polymerase chain reaction (PCR), including procedures to quickly determine conditions for successful amplification of the sequence and primer sets of interest, and to optimize for specificity, sensitivity, and yield. The first step of PCR simply entails mixing template DNA, two appropriate oligonucleotide primers, *Taq* or other thermostable DNA polymerases, deoxyribonucleoside triphosphates (dNTPs), and a buffer. Once assembled, the mixture is cycled many times (usually 30) through temperatures that permit denaturation, annealing, and synthesis to exponentially amplify a product of specific size and sequence. The PCR products are then displayed on an appropriate gel and examined for yield and specificity.

Many important variables can influence the outcome of PCR. Careful titration of the MgCl_2 concentration is critical. Additives that promote polymerase stability and processivity or increase hybridization stringency, and strategies that reduce nonspecific primer-template interactions, especially prior to the critical first cycle, generally improve amplification efficiency. This protocol, using *Taq* DNA polymerase (see UNIT 3.5), is designed to optimize the reaction components and conditions in one or two stages. The first stage (steps 1 to 7) determines the optimal MgCl_2 concentration and screens several enhancing additives. Most suppliers (of which there are many) of *Taq* and other thermostable DNA polymerases provide a unique optimized MgCl_2 -free buffer with MgCl_2 in a separate vial for user titration. The second stage (steps 8 to 13) compares methods for preventing pre-PCR low-stringency primer extension, which can generate nonspecific products. This has come to be known as “hot start,” whether one omits an essential reaction component prior to the first denaturing-temperature step or adds a reversible inhibitor of polymerase. Hot-start methods can greatly improve specificity, sensitivity, and yield. Use of any one of the hot-start approaches is strongly recommended if primer-dimers or other nonspecific products are generated, or if relatively rare template DNA is contained in a complex mixture, such as viral nucleic acids in cell or tissue preparations. This protocol suggests some relatively inexpensive methods to achieve hot start, and lists several commercial hot-start options which may be more convenient, but of course more expensive.

NOTE: Use only molecular biology-grade water (i.e., DNase, RNase, and nucleic acid free) in all steps and solutions.

Materials

- 10× MgCl_2 -free PCR buffer (see recipe)
- 50 μM oligonucleotide primer 1: 50 pmol/ μl in sterile H_2O (store at -20°C)
- 50 μM oligonucleotide primer 2: 50 pmol/ μl in sterile H_2O (store at -20°C)
- Template DNA: 1 μg mammalian genomic DNA or 1.0 to 100.0 pg of plasmid DNA (UNIT 2.1-2.4)
- 25 mM 4dNTP mix (see recipe)
- 5 U/ μl *Taq* DNA polymerase (native or recombinant)
- Enhancer agents (optional; see recipe)
- 15 mM (L), 30 mM (M), and 45 mM (H) MgCl_2
- Mineral oil
- TaqStart Antibody (Clontech)
- Ficoll 400 (optional): prepare as 10× stock; store indefinitely at room temperature
- Tartrazine dye (optional): prepare as 10× stock; store indefinitely at room temperature

**The Polymerase
Chain Reaction**

15.1.1

Table 15.1.1 Master Mixes for Optimizing Reaction Components

Components	Final concentration	Per reaction	Master mix ^a (μl)			
			I	II	III	IV
10× MgCl ₂ -free PCR buffer	1×	10 μl	40.0	40.0	40.0	40.0
Primer 1	0.5 μM	1 μl	4.0	4.0	4.0	4.0
Primer 2	0.5 μM	1 μl	4.0	4.0	4.0	4.0
Template DNA ^b	Undiluted	1 vol	4 vol	4 vol	4 vol	4 vol
25 mM 4dNTP mix ^c	0.2 mM	0.8 μl	3.2	3.2	3.2	3.2
<i>Taq</i> polymerase	2.5 U	0.5 μl	2.0	2.0	2.0	2.0
DMSO ^d (20×)	5%	5 μl	—	20.0	—	—
Glycerol ^d (10×)	10%	10 μl	—	—	40.0	—
PMPE ^d (100×)	1%	1 μl	—	—	—	4.0
H ₂ O	—	To 90 μl	To 360	To 360	To 360	To 360

^aTotal volume = 360 μl (i.e., enough for $n + 1$ reactions).

^bTemplate DNA volume (“vol”) is generally 1 to 10 μl.

^cIf 2 mM 4dNTP mix is preferred, use 10 μl per reaction, or 40 μl for each master mix; adjust the volume of water accordingly.

^dSubstitute with other enhancer agents (see recipe in Reagents and Solutions) as available.

0.5 ml thin-walled PCR tubes
Automated thermal cycler

Additional reagents and equipment for DNA preparation (UNIT 2.1-2.4, agarose gel electrophoresis (UNIT 2.5A), nondenaturing PAGE (UNIT 2.7), or sieving agarose gel electrophoresis (UNIT 2.8), restriction endonuclease digestion (UNIT 3.1), and Southern blotting and hybridization (UNITS 2.9 & 6.4)

NOTE: Do not use DEPC to treat water, reagents, or glassware.

NOTE: Reagents should be prepared in sterile, disposable labware, taken directly from its packaging, or in glassware that has been soaked in 10% bleach, thoroughly rinsed in tap water followed by distilled water, and if available, exposed to UV irradiation for ~10 min. Multiple small volumes of each reagent should be stored in screw-cap tubes. This will then serve as the user’s own optimization “kit.” Thin-walled PCR tubes are recommended.

Optimize reaction components

1. Prepare four reaction master mixes according to the recipes given in Table 15.1.1.

Enhancing agents probably work by different mechanisms, such as protecting enzyme activity and decreasing nonspecific primer binding. However, their effects cannot be readily predicted—what improves amplification efficiency for one primer pair may decrease the amplification efficiency for another. Thus it is best to check a panel of enhancers during development of a new assay.

2. Aliquot 90 μl master mix I into each of three 0.5-ml thin-walled PCR tubes labeled I-L, I-M, and I-H. Similarly, aliquot mixes II through IV into appropriately labeled tubes. Add 10 μl of 15 mM MgCl₂ into one tube of each master mix (labeled L; 1.5 mM final). Similarly, aliquot 10 μl of 30 mM and 45 mM MgCl₂ to separate tubes of each master mix (labeled M and H, respectively; 3.0 and 4.5 mM final concentrations respectively).

It is helpful to set the tubes up in a three-by-four array to simplify aliquotting. Each of the three Mg²⁺ concentrations is combined with each of the four master mixes.

3. Overlay the reaction mixture with 50 to 100 μ l mineral oil (2 to 3 drops).

To include hot start in the first step, overlay reaction mixes with oil before adding the MgCl₂, heat the samples to 95°C in the thermal cycler or other heating block, and add the MgCl₂ once the elevated temperature is reached. Once the MgCl₂ has been added, do not allow the samples to cool below the optimum annealing temperature prior to performing PCR.

Alternatives to mineral oil include silicone oil and paraffin beads. Additionally, certain cyclers feature heated lids that are designed to obviate the need for an oil overlay.

Choose cycling parameters

4. Using the following guidelines, program the automated thermal cycler according to the manufacturer's instructions.

30 cycles: 30 sec	94°C	(denaturation)
30 sec	55° (GC content \leq 50%) or	
	60°C (GC content $>$ 50%)	(annealing)
~60 sec/kb		
product sequence	72°C	(extension)

Cycling parameters are dependent upon the sequence and length of the template DNA, the sequence and percent complementarity of the primers, and the ramp times of the thermal cycler used. Thoughtful primer design will reduce potential problems (see Commentary). Denaturation, annealing, and extension are each quite rapid at the optimal temperatures. The time it takes to achieve the desired temperature inside the reaction tube (i.e., the ramp time) is usually longer than either denaturation or primer annealing. Thus, ramp time is a crucial cycling parameter. Manufacturers of the various thermal cyclers on the market provide ramp time specifications for their instruments. Ramp times are lower with thin-walled reaction tubes. The optimal extension time also depends on the length of the target sequence. Allow ~1 min/kb for this step for target sequences $>$ 1 kb, and as little as a 2-sec pause for targets $<$ 100 bases in length.

The number of cycles depends on both the efficiency of the reaction and the amount of template DNA in the reaction. Starting with as little as 100 ng of mammalian genomic DNA ($\sim 10^4$ cell equivalents), after 30 cycles, 10% of the reaction should produce a band that is readily visible on an ethidium bromide-stained gel as a single predominant band. With more template, fewer cycles may suffice. With much less template, further optimization is recommended rather than increasing the cycle number. Greater cycle numbers (e.g., $>$ 40) can reduce the polymerase specific activity, increase nonspecific amplification, and deplete substrate (nucleotides). Many investigators lengthen the time for the last extension step—to 7 min, for example—to try to ensure that all the PCR products are full length.

These guidelines are appropriate for most commercially available thermal cyclers. For rapid cyclers, consult the manufacturers' protocols.

Analyze the product

5. Electrophorese 10 μ l from each reaction on an agarose (UNIT 2.5A), nondenaturing polyacrylamide (UNIT 2.7), or sieving agarose gel (UNIT 2.8) appropriate for the PCR product size expected. Stain with ethidium bromide.

For resolution of PCR products between 100 and 1000 bp, an alternative to nondenaturing polyacrylamide gels or sieving agarose is a composite 3% (w/v) NuSieve (FMC Bioproducts) agarose/1% (w/v) SeaKem (FMC Bioproducts) agarose gel. SeaKem increases the mechanical strength of the gel without decreasing resolution.

An alternative to ethidium bromide, SYBR Gold Nucleic Acid Gel Stain (Molecular Probes), is 25 to 100 times more sensitive than ethidium bromide, is more convenient to use, and permits optimization of 10- to 100-fold lower starting template copy number.

Table 15.1.2 Master Mixes for Optimizing First-Cycle Reactions

Components	Final concentration	Master mix (μl)			
		A	B	C	D
10 \times PCR buffer	1 \times	10	10	10	10
MgCl ₂ (L, M, or H)	Optimal	10	10	10	10
Primer 1	0.5 μM	1.0	1.0	1.0	1.0
Primer 2	0.5 μM	1.0	1.0	1.0	1.0
Additive	Optimal	V ^a	V ^a	V ^a	V ^a
Template DNA	— ^b	V ^a	V ^a	V ^a	V ^a
25 mM 4dNTP mix ^b	0.2 mM	0.8	0.8	0.8	0.8
<i>Taq</i> polymerase	2.5 U	0.5	0.5	—	—
<i>Taq</i> pol + <i>Taq</i> Start	2.5 U	—	—	—	1.0
H ₂ O	To 100 μl	V ^a	V ^a	V ^a	V ^a
Preparation temperature		Room temperature	Ice slurry	Room temperature	Room temperature

^aV, variable amount (total volume should be 100 μl).

^bUse undiluted or diluted template DNA based on results obtained in step 6.

- Examine the stained gel to determine which condition resulted in the greatest amount of product.

Minor, nonspecific products may be present even under optimal conditions.

- To ensure that the major product is the correct one, digest an aliquot of the reaction with a restriction endonuclease known to cut within the PCR product. Check buffer compatibility for the restriction endonuclease of choice. If necessary, add Na⁺ or precipitate in ethanol (*UNIT 2.1A*) and resuspend in the appropriate buffer. Electrophore the digestion product on a gel to verify that the resulting fragments have the expected sizes.

Alternatively, transfer the PCR products to a nitrocellulose or nylon filter and hybridize with an oligonucleotide derived from the sequence internal to the primers (UNITS 2.9 & 6.4). With appropriately stringent hybridization and washing conditions, only the correct product (and possibly some minor related products) should hybridize.

Optimize the first cycle

These optional steps optimize initial hybridization and may improve efficiency and yield. They are used when primer-dimers and other nonspecific products are detected, when there is only a very small amount of starting template, or when a rare sequence is to be amplified from a complex mixture. For an optimal reaction, polymerization during the initial denaturation and annealing steps should be prevented. *Taq* DNA polymerase activity can be inhibited by temperature (reaction B), physical separation (reaction C), or reversible antibody binding (reaction D). PCR without hot start is performed for comparison (reaction A).

- Prepare four reaction mixtures using the optimal MgCl₂ concentration and additive requirement determined in step 6. Prepare the mixes according to the recipes in Table 15.1.2. Use the following variations for addition of *Taq* polymerase.
 - Prepare reactions A and C at room temperature.
 - Chill all components of reaction B in an ice slurry before they are combined.

- c. For reaction D, combine 1.0 μl TaqStart antibody with 4.0 μl of the dilution buffer provided with the antibody, add 1.0 μl *Taq* DNA polymerase (for 1:4:1 mixture of these components), mix, and incubate 5 to 10 min at room temperature before adding to reaction mixture D (glycerol and PMPE are compatible with TaqStart antibody but DMSO will interfere with antibody binding).

To ensure that the reaction does not plateau and thereby obfuscate the results, use the smallest amount of template DNA necessary for visualization of the PCR product by ethidium bromide staining. Use the results from step 6 to decide how much template to use. If the desired product stains intensely, dilute the starting material as much as 1/100. If only a faint signal is apparent, use undiluted sample.

9. Overlay each reaction mixture with 50 to 100 μl mineral oil.
10. Heat all reactions 5 min at 94°C.

It is most convenient to use the automated thermal cycler for this step and then initiate the cycling program directly.

11. Cool the reactions to the appropriate annealing temperature as determined in step 4. Add 0.5 μl *Taq* DNA polymerase to reaction C, making sure the pipet tip is inserted through the layer of mineral oil into the reaction mix.

*Time is also an important factor in this step. If the temperature drops below the annealing temperature and is allowed to remain low, nonspecific annealing will occur. *Taq* DNA polymerase retains some activity even at room temperature.*

12. Begin amplification of all four reactions at once, using the same cycling parameters as before.
13. Analyze the PCR products on an agarose gel and evaluate the results as in steps 5 and 6.
14. Prepare a batch of the optimized reaction mixture, but omit *Taq* DNA polymerase, TaqStart antibody, PMPE, and 4dNTP mix—these ingredients should be added fresh just prior to use. If desired, add Ficoll 400 to a final concentration of 0.5% to 1% (v/v) and tartrazine to a final concentration of 1 mM.

Adding Ficoll 400 and tartrazine dye to the reaction mix precludes the need for a gel loading buffer and permits direct application of PCR products to agarose or acrylamide gels. At these concentrations, Ficoll 400 and tartrazine do not decrease PCR efficiency and do not interfere with PMPE or TaqStart antibodies. Other dyes, such as bromphenol blue and xylene cyanol, do inhibit PCR. Tartrazine is a yellow dye and is not as easily visualized as other dyes; this may make gel loading more difficult.

Ficoll 400 and tartrazine dye may be prepared as 10 \times stocks and stored indefinitely at room temperature.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Enhancer agents

For a discussion of how to select enhancer agents, see Commentary.

5 \times stocks:

25% acetamide (20 μl /reaction; 5% final)

5 M *N,N,N*-trimethylglycine (betaine; 20 μl /reaction; 1 M final)

40% polyethylene glycol (PEG) 8000 (20 μl /reaction; 8% final)

10× stocks:

Glycerol (concentrated; 10 µl/reaction; 10% final)

20× stocks:

Dimethylsulfoxide (DMSO; concentrated; 5 µl/reaction; 5% final)

Formamide (concentrated; 5 µl/reaction; 5% final)

100× stocks:

1 U/µl Perfect Match Polymerase Enhancer (Stratagene; 1 µl/reaction; 1 U final)

10 mg/ml acetylated bovine serum albumin (BSA) or gelatin (1 µl/reaction; 10 µg/ml final)

1 to 5 U/µl thermostable pyrophosphatase (PPase; Roche Diagnostics; ; 1 µl/reaction; 1 to 5 U final)

5 M tetramethylammonium chloride (TMAC; betaine hydrochloride; 1 µl/reaction; 50 mM final)

0.5 mg/ml *E. coli* single-stranded DNA-binding protein (SSB; Sigma; 1 µl/reaction; 5 µg/ml final)

0.5 mg/ml Gene 32 protein (Amersham Pharmacia Biotech; 1 µl/reaction; 5 µg/ml final)

10% Tween 20, Triton X-100, or Nonidet P-40 (1 µl/reaction; 0.1% final)

1 M (NH₄)₂SO₄ (1 µl/reaction; 10 mM final; use with thermostable DNA polymerases other than *Taq*)

MgCl₂-free PCR buffer, 10×

500 mM KCl

100 mM Tris·Cl, pH 9.0 (at 25°C; see APPENDIX 2)

0.1% Triton X-100

Store indefinitely at –20°C

This buffer can be obtained from Promega; it is supplied with Taq DNA polymerase.

4dNTP mix

For 2 mM 4dNTP mix: Prepare 2 mM each dNTP in TE buffer, pH 7.5 (APPENDIX 2). Store up to 1 year at –20°C in 1-ml aliquots.

For 25 mM 4dNTP mix: Combine equal volumes of 100 mM dNTPs (Promega). Store indefinitely at –20°C in 1-ml aliquots.

COMMENTARY

Background Information

The theoretical basis of the polymerase chain reaction (PCR; see chapter introduction) was probably first described in a paper by Kleppe et al. (1971). However, this technique did not excite general interest until the mid-1980s, when Kary Mullis and co-workers at Cetus developed PCR into a technique that could be used to generate large amounts of single-copy genes from genomic DNA (Saiki et al., 1985, 1986; Mullis et al., 1986; Embury et al., 1987).

The initial procedure entailed adding a fresh aliquot of the Klenow fragment of *E. coli* DNA polymerase I during each cycle because this enzyme was inactivated during the subsequent denaturation step. The introduction of thermostable *Taq* DNA polymerase from *Thermus*

aquaticus (Saiki et al., 1988) alleviated this tedium and facilitated automation of the thermal cycling portion of the procedure. *Taq* DNA polymerase also permitted the use of higher temperatures for annealing and extension, which improved the stringency of primer–template hybridization and thus the specificity of the products. This also served to increase the yield of the desired product.

All applications of PCR depend upon an optimized PCR. The basic protocol in this unit optimizes PCR for several variables, including MgCl₂ concentration, enhancing additives—dimethyl sulfoxide (DMSO), glycerol, or Perfect Match Polymerase Enhancer (PMPE)—and prevention of pre-PCR mispriming. These and other parameters can be extremely impor-

tant, as every element of PCR can affect the outcome (see Critical Parameters and Troubleshooting for discussion of individual parameters).

There are several PCR optimization kits and proprietary enhancers on the market (Table 15.1.3). Optimization kits generally provide a panel of buffers in which the pH, buffer, non-ionic detergents, and addition of $(\text{NH}_4)_2\text{SO}_4$ are varied, MgCl_2 may be added at several concentrations, and enhancers (e.g., DMSO, glycerol, formamide, betaine, and/or proprietary compounds) may be chosen. The protocol presented here is aimed at keeping the costs low and the options broad.

Critical Parameters and Troubleshooting

MgCl₂ concentration

Determining the optimum MgCl_2 concentration, which can vary even for different primers from the same region of a given template (Saiki, 1989), can have an enormous influence on PCR success. In this protocol three concentrations are tested—1.5 mM (L), 3.0 mM (M), and 4.5 mM (H)—against three enhancers. Enhancers tend to broaden the MgCl_2 optimal range, contributing to the success of the PCR at one of these concentrations. A 10× buffer optimized for a given enzyme and a separate vial of MgCl_2 are typically provided with the polymerase, so that the user may titrate the MgCl_2 concentration for their unique primer-template set.

Reagent purity

For applications that amplify rare templates, reagent purity is the most important parameter, and avoiding contamination at every step is critical.

To maintain purity, store multiple small volumes of each reagent in screw-cap tubes.

For many applications, simply using high-quality reagents and avoiding nuclease contamination is sufficient; however, avoid one common reagent used to inactivate nucleases, diethylpyrocarbonate (DEPC). Even tiny amounts of chemical left after treatment of water by autoclaving are enough to ruin a PCR.

Primer selection

This is the factor that is least predictable and most difficult to troubleshoot. Simply put, some primers just do not work. To maximize the probability that a given primer pair will

work, pay attention to the following parameters.

General considerations. An optimal primer set should hybridize efficiently to the sequence of interest with negligible hybridization to other sequences present in the sample. If there are reasonable amounts of template available, hybridization specificity can be tested by performing oligonucleotide hybridization as described in UNIT 6.4. The distance between the primers is rather flexible, ranging up to 10 kb. There can be, however, a considerable drop-off in synthesis efficiency with distances >3 kb (Jeffreys et al., 1988). Small distances between primers, however, lessen the ability to obtain much sequence information or to reamplify with nested internal oligonucleotides, should that be necessary.

Design primers to allow demonstration of the specificity of the PCR product. Be sure that there are diagnostic restriction endonuclease sites between the primers or that an oligonucleotide can detect the PCR product specifically by hybridization.

Several computer programs can assist in primer design (see Internet Resources at end of unit). These are most useful for avoiding primer sets with intra- and intermolecular complementarity, which can dramatically raise the effective T_m . Given the abundance of primers relative to template, this can preclude template priming. Computer primer design is not foolproof. If possible, start with a primer or primer set known to efficiently prime extensions. In addition, manufacturers' Web sites offer technical help with primer design.

Complementarity to template. For many applications, primers are designed to be exactly complementary to the template. For others, however, such as engineering of mutations or new restriction endonuclease sites, or for efforts to clone or detect gene homologs where sequence information is lacking, base-pair mismatches will be intentionally or unavoidably created. It is best to have mismatches (e.g., in a restriction endonuclease linker) at the 5' end of the primer. The closer a mismatch is to the 3' end of the primer, the more likely it is to prevent extension.

The use of degenerate oligonucleotide primers to clone genes where only protein sequence is available, or to fish out gene homologs in other species, has sometimes been successful, but it has also failed an untold (and unpublished) number of times. When the reaction works it can be extremely valuable, but it can

Table 15.1.3 PCR Optimization Products

Optimization goal	Supplier	Product
Optimization support	Perkin-Elmer	Technical information in appendix to catalog
Optimization support	Promega	PCR troubleshooting program on the Internet: http://www.promega.com/amplification/assistant
Optimization kits	Boehringer-Mannheim, Invitrogen, Stratagene, Sigma, Epicentre Technologies, Life Technologies	Several buffers, Mg ²⁺ , and enhancers which may include DMSO, glycerol, formamide, (NH ₄) ₂ SO ₄ , and other unspecified or proprietary agents
Quick startup	Amersham Pharmacia Biotech	Ready-To-Go Beads “optimized for standard PCR” and Ready-To-Go RAPD Analysis Beads (buffer, nucleotides, <i>Taq</i> DNA polymerase)
Quick startup	Fisher	EasyStart PCR Mix-in-a-Tube—tubes prepackaged with wax beads containing buffer, MgCl ₂ , nucleotides, <i>Taq</i> DNA polymerase
Quick startup	Life Technologies	PCR SuperMix—1.1× conc.—premix containing buffer, MgCl ₂ , nucleotides, <i>Taq</i> DNA polymerase
Quick startup	Marsh Biomedical	Advanced Biochemicals Red Hot DNA Polymerase—a new rival for <i>Taq</i> polymerase with convenience features
Hot-start/physical barrier	Fisher, Life Technologies	Molecular Bio-Products HotStart Storage and Reaction Tubes—preadhered wax bead in each tube; requires manual addition of one component at high temperature
Hot-start/separate MgCl ₂	Invitrogen	HotWax Mg ²⁺ beads—wax beads contain preformulated MgCl ₂ which is released at first elevated-temperature step
Hot-start/separate MgCl ₂	Stratagene	StrataSphere Magnesium Wax Beads—wax beads containing preformulated Mg ²⁺
Hot Start/separate polymerase	Promega	TaqBead Hot Start Polymerase—wax beads encapsulating <i>Taq</i> DNA polymerase which is released at first elevated-temperature step
Hot-start/reversible inactivation of polymerase by antibody binding	Clontech	TaqStart Antibody, TthStart Antibody—reversibly inactivate <i>Taq</i> and <i>Tth</i> DNA polymerases until first denaturation at 95°C
Hot-start/antibody binding	Life Technologies	PlatinumTaq—contains PlatinumTaq antibody
Hot-start/antibody binding	Sigma	JumpStart Taq—contains TaqStart antibody
Hot-start/reversible chemical modification	Perkin-Elmer	AmpliTaq Gold—activated at high temperature
Hot-start/reversible chemical modification	Qiagen	HotStarTaq DNA Polymerase—activated at high temperature
Enhancer	Boehringer Mannheim, New England Biolabs	<i>Tth</i> pyrophosphatase, thermostable
Enhancer	Clontech	GC-Melt (in Advantage-GC Kits)—proprietary
Enhancer	CPG	Taq-FORCE Amplification System and MIGHTY Buffer—proprietary
Enhancer	Fisher	Eppendorf MasterTaq Kit with TaqMaster Enhancer—proprietary
Enhancer	Life Technologies	PCRx Enhancer System—proprietary
Enhancer	Promega	<i>E.coli</i> Single Stranded Binding Protein (SSB)
Enhancer	Qiagen	Q-Solution—proprietary
Enhancer	Stratagene	Perfect Match Polymerase Enhancer—proprietary
Enhancer	Stratagene	TaqExtender PCR Additive—proprietary

15.1.8

also generate seemingly specific products that require much labor to identify and yield no useful information. The less degenerate the oligonucleotides, especially at the 3' end, the better. Caveat emptor.

Primer length. A primer should be 20 to 30 bases in length. It is unlikely that longer primers will help increase specificity significantly.

Primer sequence. Design primers with a GC content similar to that of the template. Avoid primers with unusual sequence distributions, such as stretches of polypurines or polypyrimidines, as their secondary structure can be disastrous. It is worthwhile to check for potential secondary structure using one of the appropriate computer programs that are available.

"Primer-dimers." Primer-dimers are a common artifact most frequently observed when small amounts of template are taken through many amplification cycles. They form when the 3' end of one primer anneals to the 3' end of the other primer, and polymerase then extends each primer to the end of the other. The ensuing product can compete very effectively against the PCR product of interest. Primer-dimers can best be avoided by using primers without complementarity, especially in their 3' ends. Should they occur, optimizing the MgCl₂ concentration may minimize their abundance relative to that of the product of interest.

Template

Aside from standard methods for preparing DNA (UNIT 2.1-2.4), a number of simple and rapid procedures have been developed for particular tissues (Higuchi, 1989). Even relatively degraded DNA preparations can serve as useful templates for generation of moderate-sized PCR products. The two main concerns regarding template are purity and amount.

A number of contaminants found in DNA preparations can decrease the efficiency of PCR. These include urea, the detergent SDS (whose inhibitory action can be reversed by nonionic detergents), sodium acetate, and, sometimes, components carried over in purifying DNA from agarose gels (Gelfand, 1989; Gyllenstein, 1989; K. Hicks and D. Coen, unpub. observ.). Additional organic extractions, ethanol precipitation from 2.5 M ammonium acetate, and/or gel purification on polyacrylamide rather than agarose, can all be beneficial in minimizing such contamination if the simplest method (precipitating the sample with ethanol and repeatedly washing the pellet with 70% ethanol) is not sufficient.

Clearly the amount of template must be sufficient to be able to visualize PCR products using ethidium bromide. Usually 100 ng of genomic DNA is sufficient to detect a PCR product from a single-copy mammalian gene. Using too much template is not advisable when optimizing for MgCl₂ or other parameters, as it may obscure differences in amplification efficiency. Moreover, too much template may decrease efficiency due to contaminants in the DNA preparation.

Amount of template, especially in terms of the amount of target sequence versus nonspecific sequences, can have a major effect on the yield of nonspecific products. With less target sequence, it is more likely that nonspecific products will be seen. For some applications, such as certain DNA sequencing protocols where it is important to have a single product, gel purification of the specific PCR product and reamplification are advisable.

Taq and other thermostable DNA polymerases

Among the advantages conferred by the thermostability of *Taq* DNA polymerase is its ability to withstand the repeated heating and cooling inherent in PCR and to synthesize DNA at high temperatures that melt out mismatched primers and regions of local secondary structure. The enzyme, however, is not infinitely resistant to heat, and for greatest efficiency it should not be put through unnecessary denaturation steps. Indeed, some protocols (e.g., UNIT 15.7 and the "hot start" method described here) recommend adding it after the first denaturation step.

Increasing the amount of *Taq* DNA polymerase beyond 2.5 U/reaction can sometimes increase PCR efficiency, but only up to a point. Adding more enzyme can sometimes increase the yield of nonspecific PCR products at the expense of the product of interest. Moreover, *Taq* DNA polymerase is not inexpensive.

A very important property of *Taq* DNA polymerase is its error rate, which was initially estimated at 2×10^{-4} nucleotides/cycle (Saiki et al., 1988). The purified enzyme supplied by manufacturers lacks a proofreading 3'→5' exonuclease activity, which lowers error rates of other polymerases such as the Klenow fragment of *E. coli* DNA polymerase I. For many applications, this does not present any difficulties. However, for sequencing clones derived from PCR, or when starting with very few templates, this can lead to major problems. Direct sequencing of PCR products (UNIT 15.2),

sequencing numerous PCR-generated clones, and/or the use of appropriate negative controls can help overcome these problems. Alternatively, changing reaction conditions (Eckert and Kunkel, 1990) or changing to a non-*Taq* DNA polymerase (with greater fidelity) may be useful.

Another important property of *Taq* DNA polymerase is its propensity for adding nontemplated nucleotides to the 3' ends of DNA chains. This can be especially problematic in cloning PCR products. It is frequently necessary to "polish" PCR products with enzymes such as other DNA polymerases before adding linkers or proceeding to blunt-end cloning. Conversely, addition of a nontemplated A by *Taq* DNA polymerase can be advantageous in cloning (UNIT 15.4).

Certain PCR protocols may work better with one thermostable polymerase rather than another. Table 15.1.4 lists currently available thermostable DNA polymerases by generic and trade names, the original source of native and recombinant enzymes, the supplier, the end generated (3'A addition versus blunt), and associated exonuclease activities. A 3' to 5' exonuclease activity is proofreading. Removal of the 5' to 3' exonuclease activity of *Taq* DNA polymerase (N-terminal deletion) is reported to produce a higher yield. A 5' to 3' exonuclease activity may degrade the primers somewhat. Proofreading enzymes synthesize DNA with higher fidelity and can generate longer products than *Taq*, but tend to generate low yields. Enzyme blends (Table 15.1.5) have been optimized for increased fidelity and length along with sensitivity and yield.

Hot start

What happens prior to thermal cycling is critical to the success of PCR. *Taq* DNA polymerase retains some activity even at room temperature. Therefore, under nonstringent annealing conditions, such as at room temperature, products can be generated from annealing of primers to target DNA at locations of low complementarity or having complementarity of just a few nucleotides at the 3' ends. The latter would in effect create new templates "tagged" with the primer sequences. Subsequent cycles amplify these tagged sequences in abundance, both generating nonspecific products and possibly reducing amplification efficiency of specific products by competition for substrates or polymerase. Thus conditions preventing polymerization prior to the first temperature-controlled steps are desirable. In this protocol, three

methods of inhibiting polymerization prior to the temperature-controlled step are compared. These include physical separation of an essential reaction component prior to the first denaturation step, cooling reagents to 0°C, and reversibly blocking enzymatic activity with an antibody.

Denaturation of the template before *Taq* polymerase or MgCl₂ is added to the reaction provides a dramatic improvement in specificity and sensitivity in many cases (Chou et al., 1992). The main drawback of this method is that it requires opening the reaction tubes a second time to add the essential missing component. This creates both an inconvenience and an increase in the risk of contamination, an important consideration when testing for the presence of a given sequence in experimental or clinical samples.

Cooling all components of the reaction mixture to 0°C prior to mixing is more convenient and the least expensive method but is also the least reliable. Transferring the PCR reaction tubes from the ice slurry to a 95°C preheated thermocycler block may improve the chance of success.

Reversible inhibition of *Taq* DNA polymerase by TaqStart antibody (Clontech) is the most convenient method and very effective (Kellogg et al., 1994). Complete reactions can be set up, overlaid with oil, and stored at 4°C for up to several hours prior to thermal cycling with no loss of sensitivity or specificity compared to the other hot start methods (M.F. Kramer and D.M. Coen, unpub. observ.). Cycling is initiated immediately following 5-min denaturation of the antibody at 94°C. DMSO inhibits antibody binding and should not be used with TaqStart.

Several hot-start products are now commercially available (Table 15.1.3). Success with each may depend on strict adherence to the manufacturer's protocols, even on a specific thermocycler. Wax barrier and reversible antibody binding methods are more forgiving, while chemical modifications have more stringent activation temperature requirements.

Deoxyribonucleoside triphosphates

In an effort to increase efficiency of PCR, it may be tempting to increase the concentration of dNTPs. Don't! When each dNTP is 200 mM, there is enough to synthesize 12.5 mg of DNA when half the dNTPs are incorporated. dNTPs chelate magnesium and thereby change the effective optimal magnesium concentration. Moreover, dNTP concentrations >200

Table 15.1.4 Thermostable DNA Polymerases

^aNo information at this time.

mM each increase the error rate of the polymerase. Millimolar concentrations of dNTPs actually inhibit *Taq* DNA polymerase (Gelfand, 1989).

The protocol in this unit calls for preparing 4dNTPs in 10 mM Tris·Cl/1 mM EDTA (TE buffer), pH 7.4 to 7.5. This is easier and less prone to disaster than neutralization with sodium hydroxide. However, EDTA also chelates magnesium, and this should be taken into account if stocks of dNTPs are changed. Alternatively, to lower the risk of contamination, a 4dNTP mix can be made by combining equal volumes of commercially prepared stocks.

Enhancers

Enhancers are used to increase yield and specificity and to overcome difficulties encountered with high GC content or long templates. Nonionic detergents (Triton X-100, Tween 20, or Nonidet P-40) neutralize charges of ionic detergents often used in template preparation, and should be used in the basic reaction mixture, rather than as optional enhancers. Higher yields can be achieved by stabilizing/enhancing the polymerase activity with enzyme-stabilizing proteins (BSA or gelatin), enzyme-stabilizing solutes such as betaine or betaine-HCl (TMAC), enzyme-stabilizing solvents (glycerol), solubility-enhancing sol-

vents (DMSO or acetamide), molecular crowding solvents (PEG), and polymerase salt preferences [(NH₄)SO₄ is recommended for polymerases other than *Taq*]. Greater specificity can be achieved by lowering the T_M of dsDNA (using formamide), destabilizing mismatched-primer annealing (using PMPE or hot-start strategies), and stabilizing ssDNA (using *E. coli* SSB or T4 Gene 32 Protein). Amplification of high-GC-content templates can be improved by decreasing the base pair composition dependence of the T_M of dsDNA (with betaine; Rees et al., 1993). Betaine is an osmolyte widely distributed in plants and animals and is nontoxic, a feature that recommends it for convenience in handling, storage, and disposal. Betaine may be the proprietary ingredient in various commercial formulations. For long templates, a higher pH is recommended (pH 9.0). The pH of Tris buffer decreases at high temperatures, long-template PCR requires

more time at high temperatures, and increased time at lower pH may cause some depurination of the template, resulting in reduced yield of specific product. Inorganic phosphate (PPi), a product of DNA synthesis, may accumulate with amplification of long products to levels that may favor reversal of polymerization. Accumulation of PPi may be prevented by addition of thermostable PPase. When large numbers of samples are being analyzed, the convenience of adding PCR products directly to a gel represents a significant time savings. Some companies combine their thermostable polymerase with a red dye and a high density component to facilitate loading of reaction products onto gels without further addition of loading buffer.

Thermal cycling parameters

Each step in the cycle requires a minimal amount of time to be effective, while too much

time can be both wasteful and deleterious to the DNA polymerase. If the amount of time in each step can be reduced, so much the better.

Denaturation. It is critical that complete strand separation occur during the denaturation step. This is a unimolecular reaction which, in itself, is very fast. The suggested 30-sec denaturation used in the protocol ensures that the tube contents reach 94°C. If PCR is not working, it is well worth checking the temperature inside a control tube containing 100 µl water. If GC content is extremely high, higher denaturation temperatures may be necessary; however, *Taq* DNA polymerase activity falls off quickly at higher temperatures (Gelfand, 1989). To amplify a long sequence (>3 kb), minimize the denaturation time to protect the target DNA from possible effects, such as depurination, of lowered pH of the Tris buffer at elevated temperatures.

Annealing. It is critical that the primers anneal stably to the template. Primers with relatively low GC content (<50%) may require temperatures lower than 55°C for full annealing. On the other hand, this may also increase the quantity of nonspecific products. For primers with high GC content, higher annealing temperatures may be necessary. It can be worthwhile, although time-consuming, to experiment with this parameter. Some manufacturers have thermal cyclers on the market which are capable of forming a temperature gradient across the heating units, thus permitting annealing temperature optimization in one run. As with denaturation, the time for this step is based mainly on the time it takes to reach the proper temperature, because the primers are in such excess that the annealing reaction occurs very quickly.

Extension. The extension temperature of 72°C is close to the optimal temperature for *Taq* DNA polymerase (~75°C), yet prevents the primers from falling off. Indeed, primer extension begins during annealing, because *Taq* DNA polymerase is partially active at 55°C and even lower temperatures (Gelfand, 1989).

The duration of extension depends mainly on the length of the sequence to be amplified. A duration of 1 min per kb product length is usually sufficient.

Certain protocols, including others in this chapter, end the PCR with a long final extension time in an attempt to try to make products as complete as possible.

Ramp time. Ramp time refers to the time it takes to change from one temperature to another. Using water baths and moving samples

manually from temperature to temperature probably gives the shortest ramp times, which are mainly the time required for the tube's contents to change temperature. Different thermal cyclers have different ramp times; basically, the shorter the better.

The Stratagene Robocycler uses a robotic arm to move samples from one constant-temperature block to another, virtually eliminating block ramp time, but a ramp time for tube contents must be calculated (~1 sec/°C) and added to denaturation, annealing, and extension times. Rapid cyclers that utilize positive-displacement pipet tips or capillary tubes for the PCR reactions dramatically reduce the ramp times.

Generally, the more "high-performance" thermal cyclers with short ramp times are proportionally more costly. There are many new thermal cyclers on the market priced below \$5000, which perform quite well (Beck, 1998).

Anticipated Results

Starting with ≥100 ng mammalian DNA (≥10⁴ molecules), the basic protocol can be used to determine which MgCl₂ concentration, enhancing additive, and initial conditions will yield a predominant PCR product from a single-copy sequence that is readily visible on an ethidium bromide-stained gel. It is possible that other minor products will also be visible.

Time Considerations

The basic protocol can be completed in a single day. Assembly of the reaction mixtures should take ~1 hr. Cycling should take less than 3 hr. Preparing, running, and staining the gel should take another few hours. Further checks on specificity of the product such as restriction endonuclease digestion or Southern blot hybridization will take another few hours or days, respectively.

Direct DNA Sequencing of PCR Products

UNIT 15.2

This unit describes two basic approaches for direct DNA sequencing of polymerase chain reaction (PCR) products. Either approach permits the rapid characterization of sequences of interest, without the need for library construction or screening.

PCR products can be sequenced using either the dideoxy (Sanger) approach or the chemical (Maxam-Gilbert) approach. Dideoxy sequencing methods are presented in Basic Protocol 1 and Alternate Protocols 1 to 4. In Basic Protocol 1 and Alternate Protocol 1, the target sequence is amplified and an excess of one strand of the target sequence (relative to its complement) is then generated by “asymmetric PCR,” where one primer is present in vast excess over the other. This single-stranded product serves as the template for conventional dideoxy sequencing methods (UNIT 7.4). The Alternate Protocol 2 describes how PCR products can be prepared so that they will be suitable templates for double-stranded dideoxy sequencing methods (UNIT 7.4). The Alternate Protocol 3 uses λ exonuclease to generate single-stranded template from double-stranded PCR products. Alternate Protocol 4 describes a one-step purification procedure that renders the PCR products suitable for direct sequencing.

Chemical sequencing methods are presented in Basic Protocol 2, where an end-labeled product is used, and in Alternate Protocol 5, where an unlabeled product is characterized using the genomic sequencing approach. The dideoxy method is somewhat simpler, and can be used for most applications, especially where short stretches of sequence are being characterized. The chemical sequencing method, although requiring more steps, is well suited for larger-scale sequencing projects where a number of separate sequences need to be amplified and determined, as in “multiplex sequencing” (Church and Kieffer-Higgins, 1988; see Commentary).

GENERATING SINGLE-STRANDED PRODUCTS FOR DIDEOXY SEQUENCING BY ASYMMETRIC PCR

BASIC
PROTOCOL 1

In this approach, an excess of one amplified strand (relative to its complement) is generated by the addition of one primer in vast excess over the other. The resulting excess of single-stranded product is then used as a template for the production of the dideoxy-terminated chains from which the sequence is derived.

Materials

- Oligonucleotide primers 1 and 2
- ^{32}P -labeled dNTPs (optional; UNIT 3.4)
- 10 M ammonium acetate (APPENDIX 2)
- 100% and 70% ethanol, room temperature
- 0.1 \times TE buffer, pH 8.0 (APPENDIX 2)
- Centricon 30 or 100 column (optional; Amicon)

Additional reagents and equipment for PCR (UNIT 15.1), electrophoresis using agarose gels (UNIT 2.5A) or nondenaturing polyacrylamide gels (UNIT 2.7), Southern blotting and hybridization (UNITS 2.9 & 6.4), ethanol precipitation (UNIT 2.1A), and dideoxy sequencing (UNIT 7.4)

1. Assemble a PCR with optimized components (UNIT 15.1) but use ~100:1 ratio of the two oligonucleotide primers.

The ideal amounts of the primers should be determined empirically, but will generally range from 0.2 to 1 pmol for the limiting primer, and from 10 to 30 pmol for the

Supplement 56

primer present in excess. Because the primers are present in substantial excess under standard PCR conditions (~50 pmol of each primer), the limiting primer must be exhausted prior to the completion of PCR in order to produce an excess of one strand. Empirically, this means that one primer concentration must be kept below 1 pmol/100- μ l reaction.

2. Carry out PCR using optimized times and temperatures (UNIT 15.1) for 40 to 45 cycles, ending with a long extension step. Analyze an aliquot to confirm the presence of one predominant single-stranded product, proceeding to step 3 only upon verification.

The limiting primer is generally exhausted by the 25th cycle. Thereafter, amplification proceeds by the arithmetic accumulation of a single strand, initiated by the nonlimiting primer. The yield of single-stranded DNA can be verified by the addition of a small amount (0.1% of cold dNTP concentration) of [³²P]dNTPs, or of 0.001 to 0.1 pmol of [³²P] “nonlimiting” primer, during the final 3 to 5 rounds of amplification. In this way, amplified products can be directly visualized by autoradiography of an agarose or nondenaturing polyacrylamide gel. The single- and double-stranded products exhibit different electrophoretic mobilities. Include double-stranded DNA size markers to aid the analysis.

Alternatively, 2% to 5% of the unlabeled PCR products can be electrophoresed on an agarose or nondenaturing polyacrylamide gel. The agarose or polyacrylamide gel is then blotted using capillary or electroblotting methods (UNIT 2.9), and the resulting blots hybridized to a labeled oligonucleotide complementary to the 3' end of the single-stranded product.

If a single predominant product is not found, see Critical Parameters and Troubleshooting and consider performing one of the Alternate Protocols.

3. After the final long extension, and verification of single-stranded DNA product, bring the reaction slowly to room temperature and remove the mineral oil with a Pasteur pipet.
4. Precipitate by adding 10 M ammonium acetate to a final concentration of 2.5 M, followed by 1 vol of room temperature 100% ethanol. Leave the sample 5 min at room temperature. Microcentrifuge 5 min at room temperature, maximum speed, then wash pellet with room-temperature 70% ethanol and dry under vacuum. Resuspend pellet in 50 μ l water or 50 μ l of 0.1 \times TE buffer, pH 8.0.

This precipitation should result in the clean, amplified product, free of amplification buffer components and of most of the unincorporated PCR primers. Alternatively, the products can be purified by spin-dialyzing through a Centricon 30 or 100 column (according to manufacturer's instructions), depending on the size of the amplified fragment. If products are to be sequenced using Taq DNA polymerase (UNIT 7.4), this purification step may be omitted, because PCR and Taq sequencing buffers are compatible.

5. Carry out dideoxy sequencing (UNIT 7.4) using the asymmetric PCR-generated single-stranded templates.

The sequencing primer can be either the PCR-limiting oligonucleotide primer or any complementary sequence internal to the 3' end of the single-stranded template.

ALTERNATE PROTOCOL 1

GENERATING SINGLE-STRANDED TEMPLATE FOR DIDEOXY SEQUENCING BY SINGLE-PRIMER REAMPLIFICATION

The use of asymmetric primer ratios does not always result in reproducible high yields of single-stranded product. An alternate method entails isolation of double-stranded PCR products, followed by reamplification—this time in the presence of a single primer. This method of asymmetric reamplification supplies sufficient single-stranded template for a full set of dideoxy sequencing reactions.

For materials, see Basic Protocol 1.

1. Carry out 25 to 40 cycles of PCR under optimized conditions (*UNIT 15.1*), using equimolar amounts (20 to 50 pmol) of each primer, and ending with a long extension step.
2. Remove the mineral oil with a Pasteur pipet.
3. Precipitate, wash, and dry amplified products (see Basic Protocol 1, step 4). Resuspend the pellet in 30 μ l of 0.1 \times TE buffer, pH 8.0.

Because the double-stranded PCR product is to be reamplified in the presence of only a single primer, it is important to remove all excess primer remaining in this first amplification. The precipitation conditions described ensure the recovery of the double-stranded amplified product, but leave the unincorporated primers in solution.

4. Use 1 μ l of the resuspended double-stranded product as template for a new *asymmetric* PCR amplification. Add 20 to 40 pmol of *one* of the two primers, and carry out 20 cycles of PCR under the same conditions as in step 1.

Determine the yield and quality of the single-stranded product before sequencing it. Add 0.5 to 1 pmol of 32 P-labeled PCR primer (in addition to the cold primer) to the asymmetric reamplification (step 4). When PCR is completed, electrophore 5% to 10% of the product on a non-denaturing agarose or polyacrylamide gel, dry the gel, and expose to X-ray film.

Alternatively, the labeled primer can be omitted, and the unlabeled products from the asymmetric PCR can be electrophoresed on a non-denaturing agarose or polyacrylamide gel. Southern or electroblotted without denaturing the gel or filter (thus ensuring that only single-stranded products are targeted by the probe), and the filter probed with a labeled oligonucleotide complementary to the 3' end of the single-stranded product.

In both cases, a single band corresponding to the single-stranded product should be visible (a band corresponding to the double-stranded product may occasionally appear, but should be much fainter than the single-strand band). Although the single-stranded product increases only arithmetically with each cycle, 15 to 20 asymmetric PCR cycles generally produce sufficient single-stranded product for 6 to 12 sequencing reactions. If a single predominant product is not found, see Critical Parameters and Troubleshooting and consider performing one of the Alternate Protocols.

5. Precipitate amplified products (see Basic Protocol 1, step 4). Dry pellet under vacuum.

*This step may not be necessary if Taq DNA polymerase is used to sequence (*UNIT 7.4*).*

6. Carry out dideoxy sequencing using the PCR-generated single-stranded template (*UNIT 7.4*).

*The sequencing primer can be either the PCR primer (the primer **not** used in the asymmetric reamplification) or any complementary sequence internal to the 3' end of the single-stranded template.*

PREPARING DOUBLE-STRANDED PCR PRODUCTS FOR DIDEOXY SEQUENCING

Although double-stranded, closed circular DNA templates can be alkaline-denatured and sequenced using dideoxy methods (*UNITS 7.3 & 7.4*), this method of template preparation gives poor results with linear PCR products. A modified method suitable for dideoxy sequencing of PCR-generated double-stranded DNA is presented in this protocol. Amplified DNA is purified, freed of oligonucleotide primers, then heat-denatured and snap-cooled. Primers used for the PCR amplification or other internal primers can then be used in the sequencing reaction.

ALTERNATE PROTOCOL 2

The Polymerase Chain Reaction

15.2.3

Additional Materials (also see *Basic Protocol 1*)

PEG/NaCl solution (see recipe)
70% ethanol, cold
1 pmol (2 to 5 ng) sequencing primer
5× annealing buffer (see recipe)

Additional reagents and equipment for phenol/chloroform extractions (*UNIT 2.1A*)

1. Carry out PCR under optimized conditions (*UNIT 15.1*), using 50 pmol of each oligonucleotide primer, ending with a long extension step.

Use enough template DNA and perform a sufficient number of PCR cycles to yield enough products for several sequencing reactions. For mammalian genomic DNA, 1 μg and 30 cycles should be sufficient. Yield should be checked on a gel (step 2) and PCR conditions altered as necessary.

2. Analyze a 5-μl aliquot of the PCR product by electrophoresis in agarose, nondenaturing polyacrylamide, or sieving agarose gels appropriate for the PCR product size expected, and stain with ethidium bromide.

*Identification and determination of purity of the PCR product is important for deciding which method to use for the purification. If the desired PCR product is the predominant species, proceed with steps 3 and 4. If more than one PCR product is observed, the desired product can be purified on a low gelling/melting temperature agarose gel (*UNIT 2.6*) before denaturation (step 5).*

3. Remove the mineral oil from the PCR sample with a Pasteur pipet. Extract DNA with phenol/chloroform and then chloroform (*UNIT 2.1A*). Transfer the aqueous phase to a fresh tube.
4. Add 0.6 vol PEG/NaCl solution to DNA and incubate 10 min at 37°C. Microcentrifuge 10 min at top speed to collect the precipitate. Wash pellet with cold 70% ethanol and dry under vacuum. Resuspend at a concentration of ≥ 0.1 pmol/μl (60 ng/μl of 1-kbp fragment) in 0.1× TE buffer, pH 8.0.

This precipitation should remove the excess oligonucleotide primers and free nucleotides.

5. Pipet ~0.1 pmol of purified PCR product (i.e., ~1 μl of ~60 ng/μl of 1-kbp fragment) into a microcentrifuge tube. Adjust volume to 9 μl with 0.1× TE buffer, pH 8.0. Denature template by heating 2 min at 95°C, then quickly cool 1 min in a dry ice/ethanol bath. Proceed immediately to step 6.

Only ~0.1 pmol of template is required for a clear autoradiographic signal from a sequencing gel after an overnight exposure.

6. Quickly add 1 μl sequencing primer and 2 μl of 5× annealing buffer to the frozen DNA sample. Microcentrifuge tube briefly at room temperature to thaw and mix the reaction.

A 5-fold molar excess of primer over template is recommended. However, each primer should be tested for its optimal concentration.

7. Incubate template and primer 30 min at room temperature.
8. Carry out dideoxy sequencing reactions (*UNIT 7.4A & B*).

GENERATING SINGLE-STRANDED TEMPLATE FOR DIDEOXY SEQUENCING BY λ EXONUCLEASE DIGESTION OF DOUBLE-STRANDED PCR PRODUCTS

ALTERNATE
PROTOCOL 3

An alternative approach for generating single-stranded products does not require the use of unequal primer concentrations (Higuchi and Ochman, 1989). This method involves the selective digestion of one of the two strands of the amplified product by the action of λ exonuclease. This enzyme is a double-strand-specific 5'→3' exonuclease, but is only active if a phosphate is present at the 5' position (UNIT 3.11). If only one of two PCR primers is phosphorylated, only the strand flanked by that primer will be degraded.

Additional Materials (also see Basic Protocol 1)

- T4 polynucleotide kinase (UNIT 3.10) and 1× buffer (UNIT 3.4)
- 3 M sodium acetate, pH 5.2 (APPENDIX 2)
- λ exonuclease (UNIT 3.11) and 1× buffer (UNIT 3.4)

1. Phosphorylate 10 to 50 pmol of either PCR oligonucleotide primer 1 or 2 (*but not both*) with T4 polynucleotide kinase, using unlabeled ATP (UNIT 3.10).
2. Ethanol precipitate the phosphorylated primer following addition of 3 M sodium acetate to 0.3 M final concentration, using 2.5 vol cold 100% ethanol. Place 1 hr at -70°C, microcentrifuge 20 min at 4°C, and wash pellet once (carefully) with 70% ethanol. Dry pellet briefly under vacuum.

If the phosphorylation was carried out in a volume of ≤ 10 μ l, the entire reaction can be incubated 5 min at 65°C to inactivate the polynucleotide kinase, then added directly to the 100- μ l PCR mix in step 3.

3. Carry out PCR under optimized conditions (UNIT 15.1) with equimolar amounts (10 to 100 pmol) of both the phosphorylated and nonphosphorylated PCR oligonucleotide primers.
4. Phenol extract the PCR products (UNIT 2.1), then ethanol precipitate, wash, and dry (see Basic Protocol 1, step 4).
5. Resuspend the pellet in 50 to 100 μ l of 1× λ exonuclease buffer. Add 5 U λ exonuclease and incubate 15 to 30 min at 37°C.

The yield and quality of the template may be verified before sequencing, as in step 4 of the second alternate protocol.

6. Phenol extract twice, then ethanol precipitate, wash, dry, and resuspend the single-stranded product (see Basic Protocol 1, step 4).
7. Carry out dideoxy sequencing (UNIT 7.4) with the PCR- and λ exonuclease-generated single-stranded templates.

ONE-STEP ENZYMATIC PURIFICATION OF PCR PRODUCTS FOR DIRECT SEQUENCING

ALTERNATE
PROTOCOL 4

This protocol offers convenient enzymatic purification of PCR products for direct sequencing without the need for further subcloning, precipitation, or column purification. All reactions may be done in 96-well PCR plates and are compatible with large-scale sequencing. This method is designed to be convenient and rapid. The enzymatic purification and subsequent sequencing reaction may be done in the same PCR tubes or wells, eliminating the decreased yield associated with multiple sample transfers. The principal elements of a PCR reaction that interfere with conventional sequencing reactions are primers and dNTPs. Exonuclease I (Exo I), which preferentially hydrolyzes single-

The Polymerase
Chain Reaction

15.2.5

stranded DNA, is used to degrade the primers. Shrimp alkaline phosphatase (ShrAP) is used to dephosphorylate the remaining deoxynucleotides. A mixture of the above enzymes is added in one pipetting step to a small aliquot of PCR product. The samples are then placed in a thermal cycler for incubation and subsequent heat inactivation. The resulting product is then ready for direct sequencing. Commercial chromatography columns can be used as an alternative to the following protocol. However, purification columns may decrease yield and are significantly more expensive, especially when sequencing is performed on a large scale.

The following purification approach is suitable for a variety of PCR templates, including plasmid, lambda, and genomic DNA. This protocol is even compatible with PCR products from direct bacterial and yeast colony PCR.

Materials

PCR product to be sequenced (*UNIT 15.1*), 25 to 250 ng/μl
1 U/μl shrimp alkaline phosphatase (ShrAP; e.g., USB)
10 U/μl exonuclease I (Exo I; e.g., USB)
50 mM Tris-Cl, pH 8.0 (*APPENDIX 2*)

PCR tubes or 96-well PCR plate
Thermal cycler to accommodate tubes or 96-well plates

Additional reagents and equipment for agarose gel electrophoresis (*UNIT 2.5A*)

1. Run a small sample of a PCR product on an agarose gel (*UNIT 2.5*). Use an appropriate DNA molecular size marker to estimate DNA concentration.

The presence of a single clear PCR product should be confirmed.

The DNA concentration should be in the range of 25 to 250 ng/μl. One of the principal requirements for high-quality sequences is the careful titration of DNA template used in the cycle sequencing reaction. The most common mistake is to use an excess of template, which causes early termination of the sequencing reactions. Keep in mind that there will be no loss of PCR template during this purification.

2. Mix together the enzyme cocktail as follows:

0.1 μl 1 U/μl ShrAP
0.1 μl 10 U/μl Exo I
1.8 μl 50 mM Tris-Cl, pH 8.0.

This mixture should be scaled up according to the number of PCR products being purified.

3. Add a 2-μl aliquot of enzyme cocktail into each PCR tube or well of a 96-well PCR plate.

When executing large-scale reactions using 96-well PCR plates, it is often helpful to use a multichannel pipettor that can dispense small volumes (1 to 10 μl).

4. Add 2 μl PCR product to the enzyme cocktail and mix by gently pipetting a few times.

Remember that there should be no loss of DNA template during this purification process. To minimize intervening pipetting steps, it is best to titrate the amount of PCR product used prior to enzymatic treatment. This would allow subsequent sequencing reactions to be done in the same PCR tubes or wells. Most sequencing reactions will require ~50 to 500 ng DNA template. Optimization of the amount of DNA template will depend upon the specific sequencing protocol and facility. Often, the direct pipetting of 2 μl PCR product will give satisfactory results. However, some contemporary automated sequencing facilities will require the PCR product to be diluted prior to treatment with the enzyme cocktail, as undiluted PCR product sometimes has too much DNA template for the sequencing reaction.

To optimize DNA concentration, a good starting point is the undiluted PCR product, with subsequent dilutions made using 50 mM Tris·Cl, pH 8.0.

There is usually enough magnesium in a typical PCR reaction to support enzymatic treatment by *ShrAP* and *Exo I*, even with a 3-fold dilution. If PCR products are diluted ≥ 4 -fold, the authors suggest using 50 mM Tris·Cl (pH 8.0)/100 mM MgCl₂ for dilutions. This buffer should provide the divalent cations that might otherwise be lost with higher dilutions of the PCR product.

5. Briefly centrifuge the product to bring down any residual fluid along the sides of the tube or well.

This step is optional, but relatively small amounts of residual primer or dNTPs are capable of interfering with the sequencing reactions. Therefore, it is important that all of the PCR product be in contact with the enzyme cocktail.

6. Place the PCR tube or plate into a thermal cycler and run using the following conditions:

15 min	37°C	(enzyme incubation)
15 min	80°C	(heat inactivation of enzymes)
Indefinitely	4°C	(hold).

The samples may be stored for several days at 4°C or frozen for several weeks at -20°C until sequencing.

7. Carry out dideoxy sequencing (UNITS 7.4A & 7.4B).

Cycle sequencing reactions may be performed in the very same PCR tubes or wells using 4 pmol sequencing primer. (The amount of sequencing primer may vary with the sequencing PCR conditions optimized for a given facility.) One of the primers used in the original PCR reaction may be used successfully as the sequencing primer. However, a nested sequencing primer may give improved results.

The purified products from this protocol are suitable for use with typical dye-terminator sequencing (e.g., UNIT 7.4B). The resulting sequencing extension products may be analyzed on a typical sequencing gel (e.g., ABI 377 DNA Sequencer; Applied Biosystems) or a polymer-based multicapillary sequencer (e.g., UNIT 7.6; ABI 3700 DNA Analyzer; Applied Biosystems).

LABELING PCR PRODUCTS FOR CHEMICAL SEQUENCING

One of the two PCR oligonucleotide primers is radioactively 5' end-labeled with polynucleotide kinase and then used in PCR. This results in the production of a double-stranded amplified product containing one labeled and one unlabeled strand. The double-stranded product is then used for chemical sequencing.

Materials

5 to 10 pmol oligonucleotide primer 1 (to be end-labeled)
T4 polynucleotide kinase (UNIT 3.10) and 1× buffer (UNIT 3.4)
[γ -³²P]ATP, specific activity 6000 Ci/mmol
20 to 40 pmol oligonucleotide primer 2
10× PCR amplification buffer (UNIT 15.1)
2 mM 4dNTP mix (UNIT 15.1)
DNA template (20 to 1000 ng for eukaryotic DNA; 10 to 100 ng for bacterial DNA; 1 to 20 ng for cloned DNA inserts)
Taq DNA polymerase (UNIT 15.1)
Mineral oil

BASIC PROTOCOL 2

The Polymerase Chain Reaction

15.2.7

Disposable columns or dialysis cartridges for DNA purification (optional; NACS prepack cartridge, Life Technologies; Centricon 30 column, Amicon; or Select 6L column, 5 Prime→3 Prime)

Additional reagents and equipment for PCR (*UNIT 15.1*), end-labeling with T4 polynucleotide kinase (Table 3.4.1 & *UNIT 3.10*), electrophoresis using agarose gels (*UNIT 2.5A*) or nondenaturing polyacrylamide gels (*UNIT 2.7*), autoradiography (*APPENDIX 3A*), electroelution from agarose gels (*UNIT 2.6*), phenol extraction and ethanol precipitation (*UNIT 2.1A*), sequencing by the chemical method (*UNIT 7.5*), and sequencing gels (*7.6*)

1. In a volume of 10 μ l, radioactively end-label 5 to 10 pmol oligonucleotide primer 1 for 30 min using T4 polynucleotide kinase. Heat-inactivate kinase by incubating 10 min at 65°C.

[γ -³²P]ATP with a specific activity of 6000 Ci/mmol is recommended. Use lower specific-activity label if longer autoradiograph exposures (>48 hr) are acceptable.

2. Prepare a microcentrifuge tube for PCR containing the following:

10 μ l 10 \times amplification buffer (optimized as in *UNIT 15.1*)
10 μ l 2 mM 4dNTP mix
20 to 40 pmol oligonucleotide primer 2 (not labeled in step 1)
DNA template
1.5 to 2.5 U *Taq* DNA polymerase
10 μ l kinase reaction (step 1)
H₂O to 100 μ l.

Overlay with 100 μ l mineral oil. Carry out PCR under optimized conditions for 5 to 10 cycles (see *UNIT 15.1*, steps 6 to 8). Complete PCR with a final long extension step of 5 to 7 min.

The final extension ensures that all PCR products are complete and blunt-ended. If the DNA template is a single band from a previous PCR reaction that has been cut out and extracted from a gel, >10 cycles of PCR may be necessary. Similarly, if only a small amount of initial template is present, 20 to 25 cycles of PCR may be necessary to generate sufficient labeled product.

3. Remove the mineral oil with a Pasteur pipet.
4. Separate the labeled PCR product from the unincorporated labeled primer and the unincorporated labeled nucleotides by electrophoresis on an agarose or nondenaturing polyacrylamide gel. Using the characteristic mobilities of the loading dyes (bromphenol blue and/or xylene cyanol) as guideposts (*UNITS 2.5A & 2.7*), run the gel until the unincorporated primers and nucleotides migrate off the gel and into the lower buffer chamber. Visualize the labeled PCR products by autoradiography for 10 to 60 min.

Be conservative in running the gel. Avoid running the PCR products off the gel.

5. Cut and isolate the desired labeled PCR product from the gel, using one of the described protocols for fragment purification (*UNITS 2.5A, 2.6, or 2.7*).

*A preparative gel confirms the presence of the desired amplified product. However, amplified DNA can be also be purified using disposable columns, which yield clean double-stranded DNA. Chemical sequencing can also be carried out without gel or column purification. In such cases, the PCR sample should be phenol extracted and ethanol precipitated in the presence of 0.3 M sodium acetate and 2.5 vol cold 100% ethanol (*UNIT 2.1A*). The resulting pellet should be washed with 70% ethanol.*

The columns and extraction procedures described above should not be used instead of a preparative gel unless it is known that only a single, homogeneous product has been amplified during PCR.

6. Resuspend the labeled PCR product in 30 to 50 μ l water.
7. Carry out chemical sequencing using 8% to 10% of the product for each sequencing reaction (UNIT 7.5).
8. Resolve sequencing products on a sequencing gel (UNIT 7.6). Wrap gel in plastic wrap and autoradiograph at -20°C for 2 to 48 hr. Read sequence as described in UNIT 7.5.

The gel may be dried, but it is generally not necessary to do so.

GENOMIC SEQUENCING OF PCR PRODUCTS

This method combines the PCR amplification method with the genomic sequencing technique (Church and Gilbert, 1984). Following PCR, the amplified DNA is chemically sequenced, transferred by electroblotting, and covalently bound by UV crosslinking onto a nylon filter that can be repeatedly probed with short, sequence-specific oligonucleotides. This method is ideally suited to situations where large amounts of sequence are sought, or where more than one region is being amplified. Several amplified fragments can be mixed, simultaneously sequenced, run out on a single set of lanes, and the sequence of the different fragments successively visualized by the use of appropriate probes.

Materials

Filter paper (Schleicher & Schuell #410), precut to gel size

Additional reagents and equipment for phenol extraction and ethanol precipitation (UNIT 2.1A); transfer by electroblotting, UV cross-linking, and hybridization (UNITS 2.9, 6.3, & 6.4); and labeling with terminal deoxynucleotidyltransferase (UNIT 3.6)

1. Carry out PCR under optimized conditions, ending with a final long extension step (UNIT 15.1).

The template concentrations that yield optimum amplifications must be empirically determined. These concentrations range from 20 to 1000 ng for eukaryotic genomic DNA, 10 to 100 ng for bacterial DNA, and 1 to 20 ng for cloned DNA inserts.

2. After the final long extension step, remove the mineral oil with a Pasteur pipet.
3. Phenol extract the amplified product (UNIT 2.1A). Precipitate with 0.1 vol of 3 M sodium acetate, pH 5.2, and 2.5 vol of 100% ethanol for 20 min in a dry ice/ethanol bath. Microcentrifuge 5 min at top speed, 4°C . Wash the pellet twice with 70% ethanol and dry under vacuum (UNIT 2.1A).
4. Resuspend the pellet in 30 to 50 μ l water. Electrophorese 5% to 10% of the PCR sample on an agarose or nondenaturing polyacrylamide gel to determine the yield and purity of the amplified product.

Because every double-stranded product generated by PCR will give rise to a sequence ladder when chemically sequenced, the homogeneity of the amplified product is critical. If amplification yields at least 2 bands of similar intensity, a gel separation prior to sequencing is necessary, unless the different products can be separately visualized by using different oligonucleotide probes. The use of internal probes (3' of the PCR primers) to visualize the sequence will prevent spurious amplification product sequences from appearing, but will not allow sequencing of the entire amplified fragment. The presence of short products ("primer-dimers") will generally not interfere with the majority of the sequence, but will obscure the bottom section of the sequencing gel.

**ALTERNATE
PROTOCOL 5**

**The Polymerase
Chain Reaction**

15.2.9

5. Carry out chemical sequencing using 8% to 10% of the amplified product for each sequencing reaction (UNIT 7.5).
6. Electrophorese the sequenced samples on a denaturing polyacrylamide sequencing gel (UNIT 7.6).

The number of resolvable base pairs can be increased by using a gradient or wedge gel, performing multiple loadings of the sequenced sample, and/or using longer gel plates (≤ 1 meter; UNIT 7.6).

7. Carefully remove one of the glass gel plates. Place the sheet of filter paper carefully on the gel, making sure not to trap air bubbles between the filter paper and gel. Lift the gel (adhered to the filter paper) onto the appropriate transfer apparatus.
8. Wet the gel with a thin layer of TBE electrophoresis buffer and place the nylon filter over the gel, again being careful not to trap air bubbles between the gel and membrane. Transfer the DNA onto the filter membrane by electroblotting (UNIT 2.9).

It is necessary to use a large electroblotting apparatus for this purpose.

9. UV cross-link the DNA onto the filter (UNIT 2.9).
10. Hybridize the filter with the appropriate probe.

The filter can now be probed, visualized, stripped, and reprobed as many as 40 times.

Best results are obtained by probing with the PCR oligonucleotide primers, ensuring that only completed PCR products are visualized. Degenerate probes or probes internal to the amplified fragment can also be used. A high-specific-activity probe can be obtained by "tailing" 3 to 6 pmol of probe using terminal deoxynucleotidyltransferase.

REAGENTS AND SOLUTIONS

Annealing buffer, 5 \times

200 mM Tris·Cl, pH 7.5
100 mM MgCl₂
250 mM NaCl
Store at -20°C

PEG/NaCl solution

20%(w/v) polyethylene glycol (PEG) 6000
2.5 M NaCl
Store at room temperature

COMMENTARY

Background Information

The methods presented in this unit permit rapid sequencing of PCR-amplified DNA. Although the cloning of amplified DNA is relatively straightforward, direct DNA sequencing of PCR products facilitates and speeds the acquisition of sequence information. As long as the PCR reaction produces a single amplified product (or a set of discrete products that can be conveniently separated), such products are amenable to direct sequencing.

In contrast to methods where the PCR product is cloned and a single clone sequenced, the

direct sequencing of "bulk" PCR product is generally unaffected by the comparatively high error rate of *Taq* DNA polymerase. Unless a certain feature of the template causes consistent misincorporation at the same point in the sequence, errors are likely to be stochastically distributed throughout the molecule—thus, the overwhelming majority of the amplified product consists of the correct sequence. The only exceptions to this rule may be those cases where only a very small number of template molecules (<5) are present at the outset of the reaction. In such cases, an error occurring in the first cycle

of amplification may be geometrically amplified.

Both the dideoxy and the chemical sequencing approaches can be used to characterize PCR products directly. The general advantages and shortcomings of the two sequencing approaches are discussed in the introduction to Chapter 7, but those specific to PCR products are emphasized here.

The dideoxy method involves fewer steps than chemical sequencing. Where *Taq* DNA polymerase is used for sequencing reactions, the same buffer will serve for the amplification and sequencing steps, and products do not have to be cleaned and isolated repeatedly.

The technology and procedures used in dideoxy sequencing are by now well standardized. A number of commercially available dideoxy “kits” yield good results. Provided that good yields of high-quality single-stranded template can be obtained, the dideoxy methods described here and elsewhere (UNIT 7.4A & B) permit rapid sequencing of amplified products. The limitations on the maximum amount of sequence obtainable by dideoxy sequencing can frequently be overcome by the use of an internal sequencing primer to generate additional sequence ladder.

The genomic sequencing method (for chemically sequenced PCR products) offers the advantage of a permanent matrix onto which the amplification product(s) can be bound. This method has proven particularly useful for sequencing large regions (>1000 bp). In such cases, the sequences of interest can be amplified simultaneously in a single PCR reaction, or separately, as a set of discrete adjacent or overlapping fragments. The fragments can then be mixed, simultaneously sequenced, electrophoresed on gels, and transferred onto nylon filters. Each fragment can be successively visualized by probing with the appropriate labeled oligonucleotide. In addition, sequences from both strands can be derived from a single filter, with a consequent increase in sequence accuracy. This “multiplex” approach, however, requires the additional blotting and hybridization steps. The direct chemical sequencing of a labeled strand is a fast alternative if only a single product (and a single strand) is being sequenced. The utility of this direct approach is thus limited to those cases when the PCR yields a single DNA species or when the product of interest can be readily gel purified.

Several excellent papers dealing with direct DNA sequencing of PCR products have been published. Detailed discussions of dideoxy se-

quencing approaches can be found in Wrischnik et al. (1987), Gyllensten and Erlich (1988), Innis et al. (1988), Kreitman and Landweber (1989), and Gyllensten (1989). Chemical sequencing of PCR products is described in DiMarzo et al. (1988) and Ohara et al. (1989).

Purification methods commonly used to purify PCR products involve extractions and precipitations, the use of commercial filtration or chromatography columns, or enzymatic clean-up. The protocols used for column purification benefit from their simplicity. However, enzymatic purification (Alternate Protocol 4) is as fast as column purification. This method, developed by Hanke and Wink (1994) and Werle et al. (1994), requires relatively little hands-on time and results in a negligible loss of template, as all steps are performed in the very same PCR tube or well. In addition, the principal advantage of enzymatic purification is the relative ease with which it can be scaled up to high-throughput capacity at a mere fraction of the cost.

Critical Parameters and Troubleshooting

The majority of problems that may hinder direct DNA sequencing of PCR products are described in the units on dideoxy and chemical sequencing (UNITS 7.4 & 7.5) and in the unit pertaining to optimization of PCR amplification (UNIT 15.1).

Regardless of the source of DNA or the sequencing methods employed, the quality of a DNA sequence depends critically on the quality of the starting material. In the case of PCR products, it is imperative (before sequencing) to optimize the reaction conditions (UNIT 15.1) in order to obtain a homogeneous amplification product. For this reason, a final long extension step must be included in any PCR reaction. In certain cases, no amount of optimization will produce a single amplified product, and individual products must be purified by gel electrophoresis. In general, gel purification is sufficient to generate a homogeneous product. On occasion, even a single isolated band contains more than one amplified product (as revealed by the sequence), and more sophisticated methods, such as denaturing gel gradient electrophoresis (Myers et al., 1988), or reamplification with a set of nested internal primers (Ohara et al., 1989), must be used.

Because PCR is normally carried out under conditions strongly favoring synthesis (high concentrations of enzyme, primers, and nucleotides), artifact sequences are easily generated.

This is a particular risk when amplifying in the presence of only one primer. In such cases, DNA synthesis is not bounded by a second primer, and a heterogeneous collection of molecules, including “hybrid” or “artificial” molecules, can easily arise. In addition, snap-back synthesis can take place, again resulting in artificial amplified molecules. Whenever possible, the identity of amplified fragments should be confirmed prior to sequencing by probing of Southern blots, preferably with specific sequences internal to the amplified region (UNIT 2.9), or by restriction endonuclease digestion analyses of amplified products to confirm the expected restriction sites (UNIT 3.1).

Conditions for obtaining single-stranded template must be optimized empirically before undertaking dideoxy sequencing. Alternatively, the alternate protocol described here for sequencing double-stranded PCR products can be employed. Many difficulties with the dideoxy method are caused by the secondary structure of the template strand. The inclusion of nucleotide analogs, coupled with the use of a thermostable polymerase (e.g., *Taq* DNA polymerase) for chain extension, can reduce or resolve many of these problems.

In sequencing double-stranded PCR products, the crucial point is to prevent reannealing of the template strands that compete with binding of the sequencing primer. This can be overcome by two critical manipulations—heat denaturation of the template and quick addition of the primer to the template.

For the one-step procedure (Alternate Protocol 4), titration of the amount of DNA template used for the cycle sequencing reaction is critical to sequence quality. Most polymerase-based capillary sequencers require ~50 to 500 ng DNA per sequencing reaction. Insufficient DNA will result in low-amplitude peaks on the sequencing chromatograms. Excessive DNA, which is more often the case, will result in the rapid depletion of the fluorophore-dNTPs in the cycle sequencing reaction. The sequencing chromatogram will appear to have extremely high-amplitude peaks that burn out relatively early, resulting in a very short region of usable sequence data. Often, the direct pipetting of undiluted PCR product will result in satisfactory sequences. However, optimal sequence lengths may require dilution of the PCR product prior to enzymatic purification.

The shrimp alkaline phosphatase (ShrAP) should be screened for contaminating endonuclease or exonuclease activity. The ShrAP from USB has undetectable or negligible levels of

the above contaminating activities. Exonuclease I (Exo I) preferentially hydrolyzes single-stranded DNA. However, Exo I does have some detectable double-stranded DNA exonuclease activity. Therefore, prolonged incubation with this enzyme may result in minor hydrolysis at the ends of the double-stranded DNA template. For this reason, using a nested primer for sequencing may give improved sequence data over the use of one of the original PCR primers. However, using one of the original PCR primers as the sequencing primer often gives satisfactory results. Further, the enzyme incubation time should be kept to a minimum (i.e., 15 min) prior to heat inactivation.

The amount of hydrolyzing enzyme used in this protocol has been titrated as low as possible without sacrificing sequencing quality. There are two reasons for using minimal enzyme quantities. First, large amounts of protein contaminants have been suspected to cause precipitation within the capillary arrays of ABI 3700 analyzers. The small amounts of enzyme used in this protocol have not caused any increased wear on capillary sequencers to date. Second, using less enzyme results in cost savings for high-throughput sequencing efforts.

Anticipated Results

These protocols capitalize on the efficiency and specificity of PCR and streamline the process of DNA sequencing. From 150 to 300 bp of sequence can routinely be obtained from overnight exposures of either dideoxy or chemical (or genomic) sequencing gels, provided oligonucleotides or strands have been labeled with ³²P. Longer exposures (24 to 72 hr) may be needed when using ³⁵S as a label. With appropriate modifications, including multiple loadings, repeated probings, or a series of sequencing primers, the yield of legible sequence can be substantially increased.

Rapid purification of PCR products can be achieved within one PCR tube or well, which can directly proceed to cycle sequencing using conventional dye-terminator reactions. The sequence quality should be comparable to or better than that achieved through column purification or ethanol precipitation. Further, this protocol can be easily scaled for high-throughput use.

Time Considerations

Each protocol described here can be completed in a single day or less, with additional time required for sequencing reactions and analysis.

Ligation-Mediated PCR for Genomic Sequencing and Footprinting

The polymerase chain reaction (PCR) can be used to exponentially amplify segments of DNA located between two specified primer hybridization sites. This unit describes a single-sided PCR method that initially requires specification of only one primer hybridization site; the second is defined by the ligation-based addition of a unique DNA linker. This linker, together with the flanking gene-specific primer, allows exponential amplification of any fragment of DNA. Because a defined, discrete-length sequence is added to every fragment, complex populations of DNA such as sequence ladders can be amplified intact with retention of single-base resolution.

Although it is also suitable for other applications, the ligation-based protocol (see Basic Protocol) was specifically designed for genomic footprinting and direct sequencing reactions, and is described in this context. The starting material is genomic DNA that has been cleaved so that it retains a 5' phosphate at the cleavage site. In the schematic of the protocol (Fig. 15.3.1), only one cleavage product is shown for clarity; in practice, there would be a population of fragments resulting from the partial cleavage of DNA during footprinting or sequencing reactions. Preparation of DNA for footprinting analysis and genomic sequencing is described in the support protocols. Support Protocol 1 details *in vivo* and *in vitro* dimethyl sulfate (DMS) treatment and isolation of DNA from monolayer cells and its subsequent piperidine cleavage. Support Protocol 2 describes *in vivo* DMS treatment and harvesting of DNA from suspension cells. Support Protocol 3 describes how control DNA generated in the first two support protocols can be prepared for genomic sequencing.

NOTE: It is essential that fresh, high-quality reagents be used throughout this unit. In addition, all solutions should be prepared with glass-distilled water.

LIGATION-MEDIATED SINGLE-SIDED PCR

In this protocol, cleaved DNA is denatured and a gene-specific primer (primer 1) is annealed to the region of interest. In the first-strand synthesis, this primer is extended with a processive polymerase (Vent DNA polymerase) to the cleavage site to create a blunt end. DNA ligase catalyzes the attachment of a unidirectional (staggered) linker to this blunt end. The 3' end of the longer strand of the linker is ligated to the 5' end of the genomic DNA. The shorter strand of the linker lacks a 5' phosphate and therefore is not ligated to the extension product of the gene-specific primer. The DNA is denatured and a second gene-specific primer (primer 2) is annealed to the genomic DNA and extended by Vent DNA polymerase through the ligated linker region. (In theory, the first gene-specific primer could be used here, but in practice substituting a second primer greatly reduces background.) The extended product is now a suitable substrate for a PCR reaction; on one end (left in Fig. 15.3.1) there is a linker sequence to which a linker primer can anneal and on the other end (right in Fig. 15.3.1) there is a genomic sequence to which a gene-specific primer can anneal. Only molecules that have both sequences will be exponentially amplified during the subsequent PCR reaction; molecules with only one of the sequences will be linearly amplified. For the last extension, a third gene-specific primer (primer 3) that overlaps the second is used to label the DNA indirectly. These end-labeled extension products are visualized on a sequencing gel.

High-quality, reproducible footprinting or sequencing reactions can be obtained starting from 6×10^5 genomes (3×10^5 diploid nuclei). This corresponds to 2 μg of mouse (mammalian) genomic DNA. For other species, the recommended minimum number of

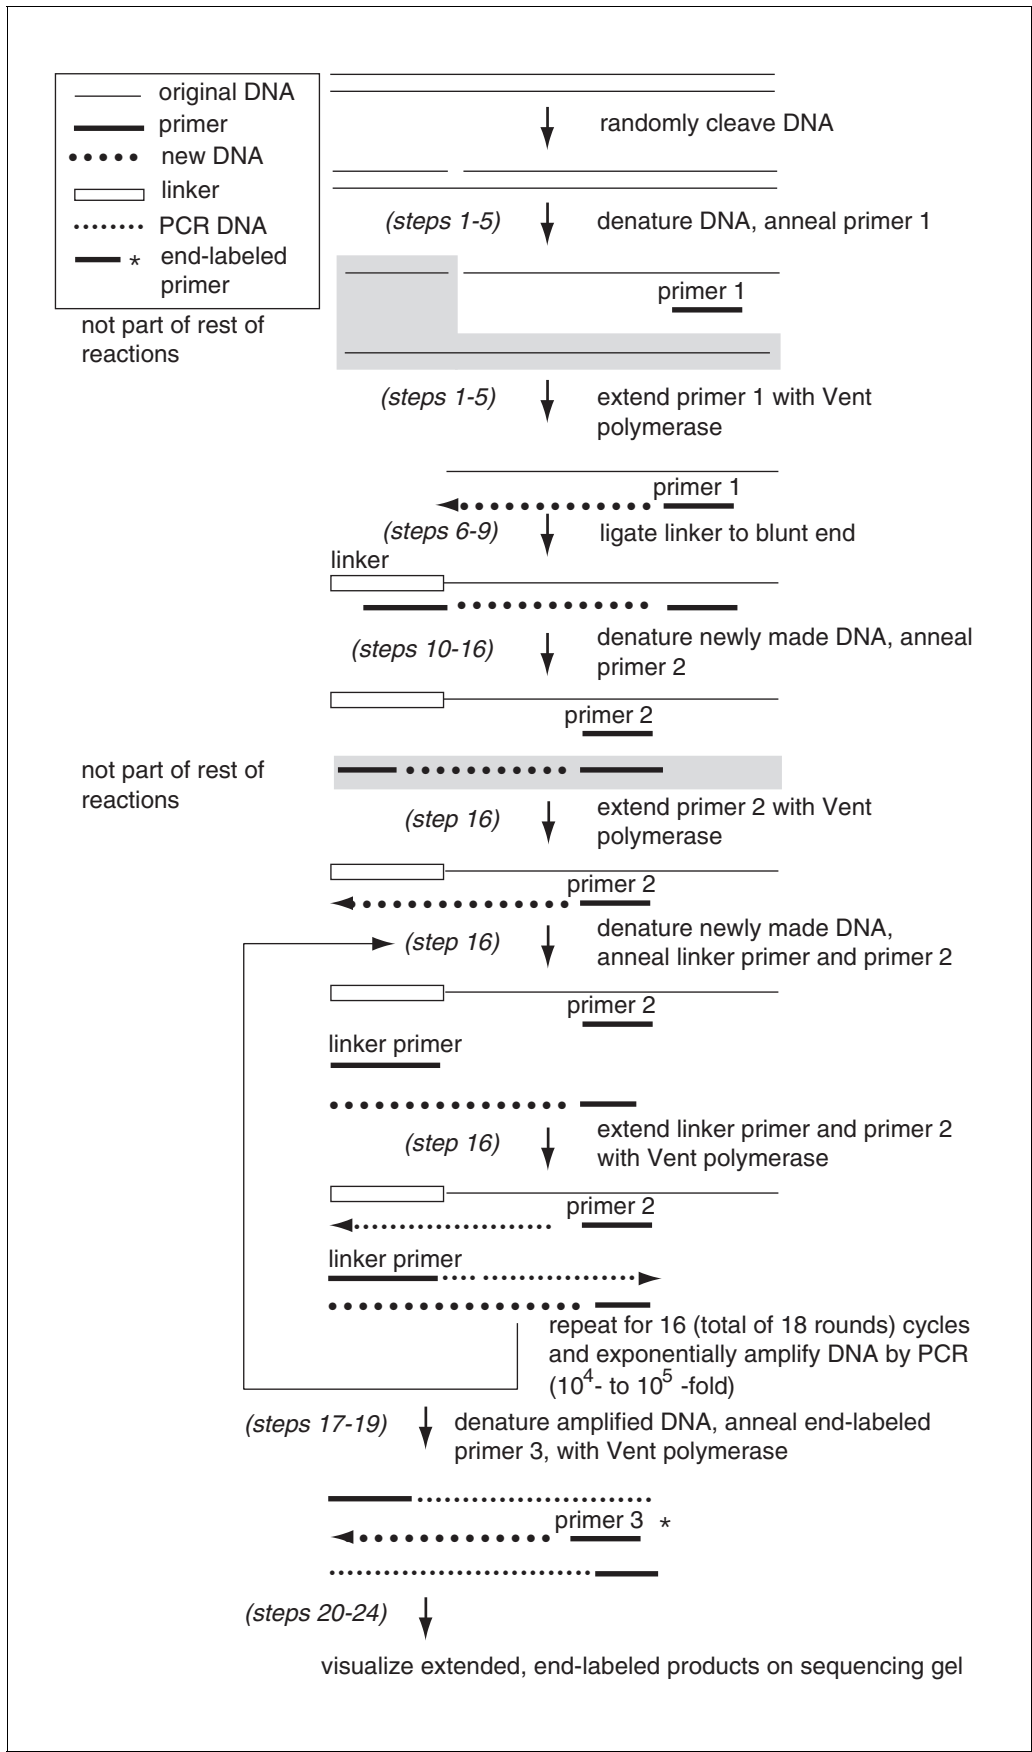

Figure 15.3.1 Flowchart of ligation-mediated PCR protocol (see text for details). The steps correspond to those listed in the Basic Protocol.

haploid genomes remains 6×10^5 , but different genome sizes lead to corresponding differences in the absolute mass of DNA.

Materials

- 0.4 $\mu\text{g}/\mu\text{l}$ cleaved genomic DNA in TE buffer, pH 7.5 (Support Protocol 1, 2, or 3)
- First-strand synthesis mix (see recipe), containing oligonucleotide primer 1 (Figs. 15.3.1 and 15.3.2; also see Critical Parameters)
- 20 μM unidirectional linker mix (see recipe)
- Ligase dilution solution (see recipe)
- Ligase mix (see recipe)
- 2000 to 3000 “Weiss” U/ml T4 DNA ligase (*UNIT 3.14*; Promega or Pharmacia Biotech)
- Precipitation salt mix (see recipe)
- 100% ethanol, ice-cold and room temperature
- 75% ethanol, room temperature
- Amplification mix (see recipe), containing linker primer and primer 2
- 2 U/ μl Vent DNA polymerase mix (see recipe; also see *UNIT 7.4*)
- Mineral oil
- End-labeling mix (see recipe), containing end-labeled primer 3 (Fig. 15.3.3)
- Vent DNA polymerase stop solution (see recipe)
- 25:24:1 (v/v/v) phenol/chloroform/isoamyl alcohol (see recipe)
- Loading buffer (see recipe)
- 1.5-ml microcentrifuge tubes, silanized (*APPENDIX 3*) and with Lid-Loks (optional; Intermountain Scientific)
- 4° and 17°C water baths
- Automated thermal cycler *or* water baths at 95°, 60°, 76°, and 60° to 70°C
- Additional reagents and equipment for PCR (*UNIT 15.1*), denaturing gel electrophoresis for DNA sequencing (*UNIT 7.6*), and autoradiography (*APPENDIX 3A*)

Carry out first-strand synthesis

1. Transfer 5 μl (2 μg) cleaved genomic DNA to a silanized 1.5-ml microcentrifuge tube and chill several minutes in an ice-water bath.
The cleaved DNA sample must be clean; contaminants left in the DNA (e.g., piperidine) will interfere with the reaction.
2. Prepare first-strand synthesis mix containing primer 1 and chill several minutes in an ice-water bath. Add 25 μl to DNA sample, gently mix with a pipettor, and return sample to the ice-water bath. Place Lid-Loks on sample to prevent tube from popping open during denaturation.

Figure 15.3.2 Two possible arrangements of gene-specific primers (see Critical Parameters).

Figure 15.3.3 Staggered linker used in ligation-mediated PCR (LMPCR). This staggered linker is made by annealing the oligonucleotides LMPCR.1 and LMPCR.2 to each other. LMPCR.1 has 25 bases and a GC content of 60%, whereas LMPCR.2 has 11 bases and a GC content of 36%. Other oligonucleotides could be used in place of these as long as they meet the criteria defined in text. Note the lack of 5' phosphates on oligonucleotides (i.e., 5' OH instead) and the unconventional orientation of LMPCR.2 (3' to 5') in the figure.

When mixing with the pipettor, three or four careful strokes are usually sufficient. Try to avoid splashing the sample while mixing; if this occurs, microcentrifuge tubes briefly at 4°C to collect droplets.

- Denature DNA 5 min at 95°C, anneal primer 30 min at 60°C, and extend 10 min at 76°C. As first-strand synthesis proceeds, prepare solutions in step 4.

First-strand synthesis is most easily performed in an automated thermal cycler, but can be performed manually by transferring the tubes to different temperature water baths. It is important that the DNA be completely denatured so the primer can anneal. For this reason it is a good idea to check the calibration of the thermal cycler. The authors have found that some machines must be set to 96° or 97°C to actually obtain 95°C. Furthermore, if a thermal cycler is used, put the samples in the machine only after it is close to the denaturation temperature. This will minimize polymerase activity prior to the initial denaturation step. Most thermal cyclers have a “hold” function that allows sample addition followed by continuation of the program for the full denaturation time. If this reaction is performed manually using water baths, covering the tubes with a styrofoam block during denaturation and annealing minimizes condensation.

The extension step creates a blunt-end substrate for the subsequent ligation reaction (see Fig. 15.3.1); therefore, success at this step is absolutely crucial because it determines the molecules that will ultimately be amplified (see Critical Parameters).

- Thaw 20 μM unidirectional linker mix in ice-water bath. Prepare ligase dilution solution and partially prepare ligase mix (minus unidirectional linker and T4 DNA ligase; see reagents and solutions). Chill both in ice-water bath.

Do not add unidirectional linker mix and T4 DNA ligase to ligase mix until step 6.

- When extension in step 3 is complete, immediately transfer sample to the ice-water bath. Microcentrifuge tube briefly at 4°C to collect condensation, then return to ice-water bath.

The samples should be kept cold during steps 6, 7, and 8 to minimize Vent polymerase activity (see Critical Parameters).

Carry out ligation

- Finish preparing ice-cold ligase mix from step 4 by adding unidirectional linker mix, mixing, adding T4 DNA ligase, mixing, and keeping in ice-water bath.

This order of addition is important because the unidirectional linker is prepared in 250 mM Tris·Cl, pH 7.7, which is required by the ligase.

- Add 20 μl ice-cold ligase dilution solution from step 4 to sample, gently mix with a pipettor, and return sample to the ice-water bath. Add 25 μl ice-cold ligase mix from step 6 to sample, gently mix with a pipettor, and return to the ice-water bath.

Microcentrifuge tube briefly at 4°C and incubate overnight in a 17°C water bath (see critical parameters).

Addition of ligase dilution solution makes the first-strand synthesis mix into a buffer compatible with T4 DNA ligase (the NaCl concentration and, more importantly, the pH, are reduced). Addition of ligase mix provides a convenient way to add ligase and linker to each sample.

8. Prepare sample for precipitation by placing in the ice-water bath for several minutes. Microcentrifuge tube briefly at 4°C, then return to ice-water bath.

Placing samples in the ice-water bath is a convenient way of transferring them from the 17°C bath to the 4°C microcentrifuge without warming them.

9. Prepare and chill precipitation salt mix. Add 9.4 µl ice-cold precipitation salt mix and 220 µl of ice-cold 100% ethanol to the sample. Mix thoroughly by inversion and chill ≥2 hr at -20°C.

If desired, the experiment may be stopped at this point. Samples under ethanol are stable for weeks at -20°C.

Carry out PCR

10. Microcentrifuge precipitated ligation reaction 15 min at 4°C and discard supernatant.

11. Add 500 µl of room-temperature 75% ethanol and invert several times to wash pellet and walls of tube. Microcentrifuge sample ~5 min at room temperature and discard supernatant. Remove last traces of ethanol with a pipettor and allow any remaining ethanol to evaporate by air drying or by using a Speedvac evaporator.

The precipitated pellet will be rather large and will spread up the side of the tube.

12. Add 70 µl water and leave sample at room temperature to dissolve pellet. Vortex tube occasionally to assist dissolution, and after each vortexing, collect droplets by microcentrifuging 2 to 3 sec. When pellet is dissolved (usually ≤30 min), chill sample in ice-water bath. While pellet is dissolving, prepare and chill amplification mix containing linker primer and primer 2.

13. Add 30 µl ice-cold amplification mix to sample, gently mix with a pipettor, and return sample to the ice-water bath.

14. Add 3 µl (1 U) Vent DNA polymerase mix to sample and mix carefully with pipettor. Return sample to the ice-water bath.

The reaction is very sensitive to the amount of Vent DNA polymerase used; excess polymerase results in high background. Surprisingly, this effect has been observed when the amount of Vent polymerase is merely double the optimal level. The basis for the empirically observed threshold for this background is not known. Different lots of Vent polymerase may need to be titrated (see Critical Parameters).

15. Cover sample with 90 µl mineral oil, microcentrifuge briefly at 4°C, and return to the ice-water bath.

If the PCR reaction is performed manually using water baths, a Lid-Lock should be used to prevent the tube from popping open during denaturation.

16. Carry out 18 cycles of PCR. Perform first denaturation for 3 to 4 min at 95°C, and subsequent ones for 1 min. Anneal primers 2 min at a temperature 0° to 2°C above the calculated T_m s (if primer 2 and linker primer have different T_m s, use the lower T_m ; see critical parameters for T_m calculations). Extend 3 min at 76°C; for every cycle, add an extra 5 sec to the extension step. Allow final extension to proceed 10 min.

Transfer sample to ice-water bath, remove Lid-Lock (if applicable), and microcentrifuge briefly at 4°C to collect any condensation. Keep sample in ice-water bath.

In this procedure, 18 rounds of amplification yield highly reproducible sequence ladders that can be visualized (after the radiolabeling step) following an overnight exposure without an intensifying screen. Performing additional rounds of amplification could reduce the exposure time required, but this has not been tested exhaustively. A theoretical concern is that if too many amplification cycles are carried out, some reagents (e.g., polymerase, primers, or dNTPs) may become limiting, leading to undesirable lane-to-lane variability (18 rounds of amplification do not show variability).

An important parameter in this step is the temperature of denaturation. If it is too low, no signal or shortened sequence ladders will be seen; if it is too high, the polymerase will be destroyed. This may be a “hidden” problem because some automatic thermal cycling machines and thermometers do not accurately measure the denaturation temperature (see Critical Parameters).

Carry out end-labeling

17. Prepare end-labeling mix containing labeled primer 3 and chill several minutes in the ice-water bath. Add 5 µl to the sample. Mix aqueous phase by gently pipetting up and down, keeping the sample on ice as much as possible. Microcentrifuge briefly at 4°C and return to ice-water bath.

CAUTION: The label mix contains a significant amount of ³²P. Appropriate care should be taken in handling and disposal of mix and samples to which it is added.

18. Carry out two rounds of PCR to label the DNA. Perform first denaturation 3 to 4 min at 95°C; the second for 1 min. Anneal end-labeled primer 3 for 2 min at a temperature 0° to 2°C above its calculated T_m . Extend 10 min at 76°C. When second extension is complete, transfer sample to ice-water bath.

Although it is rare, in a few experimental situations, having two cycles of PCR during the end-labeling step has led to increased background and/or unusual primer artifacts such as primer-dimer products. It is best to try two cycles of end-labeling, cutting back to one cycle if this problem is encountered. It is also possible to label the amplification products using a filter-blotting procedure (Pfeifer et al., 1989).

If this reaction is performed manually using water baths, a Lid-Lock should be used to prevent the tube from popping open during denaturation.

19. Place sample at room temperature and immediately add 295 µl Vent DNA polymerase stop solution. Mix by vortexing. Microcentrifuge briefly to collect radioactive droplets from top and sides of tube. Add 500 µl phenol/chloroform/isoamyl alcohol and mix either by vigorous shaking or vortexing. Microcentrifuge 3 to 5 min at room temperature. Transfer upper aqueous layer (~400 µl; avoid interface if any) to a clean, silanized 1.5-ml microcentrifuge tube, and thoroughly mix. Microcentrifuge briefly to collect droplets from sides of tube.

EDTA in the Vent DNA polymerase stop solution chelates the magnesium required by Vent polymerase. The organic extraction removes proteins before precipitation and, more importantly, removes the mineral oil (there should be little or no interface). Transferring the aqueous layer to a new tube and mixing it ensures the reaction products will be equally aliquoted for multiple loadings on the sequencing gel (step 20).

20. Set up four clean, silanized 1.5-ml microcentrifuge tubes and add 235 µl of room-temperature 100% ethanol to each tube. Transfer 94 µl of the aqueous layer into each tube, thoroughly mix by vortexing, and chill ≥2 hr at -20°C. Discard any remaining aqueous layer.

This yields enough material for four samples of each reaction to be run on a sequencing gel. This accommodates multiple loadings to maximize the number of bases that can be read and provides extra samples for use in case a gel problem is encountered. If desired, this precipitation step can be a stopping point. Samples under ethanol are stable for several weeks at -20°C ; however, the specific activity of the product decreases with time.

21. Microcentrifuge precipitated samples 15 min at 4°C and discard supernatants.
22. Add 500 μl of room temperature 75% ethanol, vortex, microcentrifuge samples 5 min at room temperature, and discard supernatants. Remove last traces of ethanol by using a pipettor and allow any remaining ethanol to evaporate by air drying or by using a Speedvac evaporator.
23. Add 7 μl loading buffer to each tube and leave at room temperature while pellets are dissolving. Vortex occasionally to assist pellets in dissolving and to recover any of the DNA pellet that is on the side of the tube. After each vortexing, collect droplets by microcentrifuging 2 to 3 sec. Samples usually resuspend rapidly (within 5 min). Check resuspension by removing the sample from the tube with a pipet and using a Geiger counter to ensure that the radioactivity is in the sample and not left behind in the tube. Return sample to same tube. If $>10\%$ of the total radioactivity has remained in the tube, vortex, microcentrifuge, and repeat the resuspension check.

Do not let the samples sit longer than necessary in loading buffer, as this may result in smeared background and poor band resolution.

Run and analyze sequencing gel

24. Denature samples 5 min at 85° to 90°C . Load entire content of each tube on a 6% sequencing gel. At the completion of the run, fix and dry gel, then autoradiograph 6 to 24 hr without an intensifying screen.

The exposure time varies and is dependent upon several factors, including the gene being amplified, the number of amplification and labeling cycles, and the specific activity of primer 3. The ladder will appear 25 bases longer than the original footprinting or sequencing products due to the addition of the 25-base linker. Because a large amount of material is being applied to the gel, use of the usual 0.2-mm-thick sequencing gels may result in smeared bands; therefore, results are usually better if a relatively thick gel (0.35 to 0.56 mm) is used instead. The first readable sequence band will run at ~ 50 nucleotides, depending on the length of the labeling primer used. Therefore, to read as much sequence as possible, multiple loadings on 80-cm gels are recommended (60-cm gels also work well if an electrolyte gradient is used; UNIT 7.6), and any fragments shorter than 50 nucleotides are run into the bottom buffer tank. This means that the bottom buffer tank will contain a significant amount of radioactive ^{32}P in the form of unused primer 3; thus, disposal guidelines must be rigorously applied.

PREPARATION OF GENOMIC DNA FROM MONOLAYER CELLS FOR DMS FOOTPRINTING

This protocol describes the preparation of in vivo and in vitro dimethyl sulfate (DMS)-treated genomic DNA from monolayer cells for use in conjunction with ligation-mediated PCR. Figure 15.3.4 outlines the parallel processing of duplicate sets of cultured cells: one set is left untreated (control) and the second is treated with DMS (in vivo treatment). Both cultures are lysed and their DNA harvested. The control-cell DNA is then treated with DMS (in vitro treatment). Both in vivo and in vitro DMS-treated DNA are cleaved with piperidine before use in the ligation-mediated PCR assay (Basic Protocol). The protocol can be modified to prepare DNA from suspension cells (Support Protocol 2). The deproteinized control DNA (not treated with DMS) is of high quality and thus can also be used for genomic sequencing as described in Support Protocol 3.

SUPPORT PROTOCOL 1

The Polymerase Chain Reaction

15.3.7

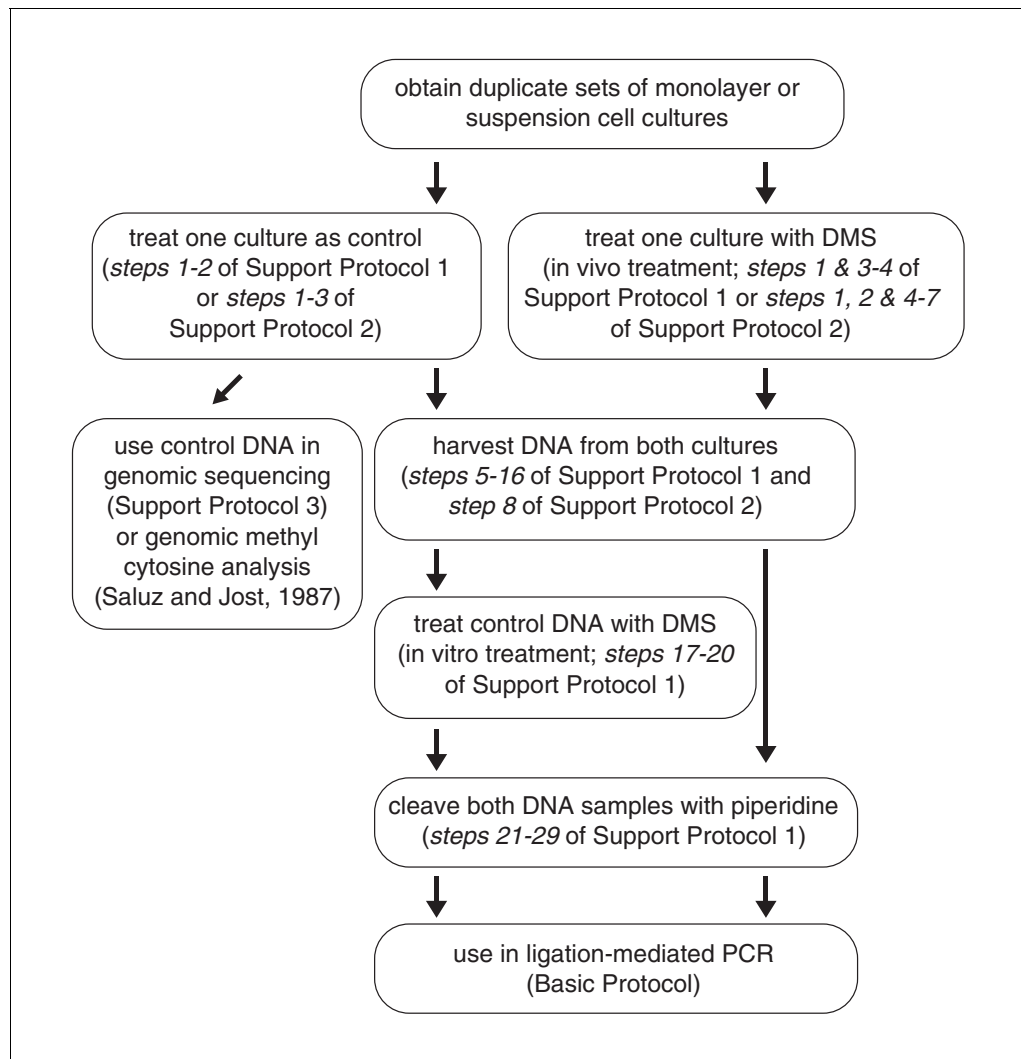

Figure 15.3.4 Flow chart of preparation of DMS-footprinted genomic DNA for use in ligation-mediated PCR.

DMS methylates guanine residues at the N7 position, rendering them susceptible to subsequent cleavage with piperidine. DMS is commonly used for *in vivo* footprinting analysis because cellular membranes are freely and rapidly permeable to it. Treatment of both control (*in vitro*-treated) and experimental (*in vivo* treated) samples with DMS is limited so that only ~1 in 150 guanines is methylated. On the other hand, piperidine treatment is quantitative so that all of the methylated guanines are cleaved. The extraction and purification of the DNA must be thorough so that all proteins and reagents are removed before the DNA is used in ligation-mediated PCR (Basic Protocol).

This procedure works well with $\sim 5 \times 10^7$ cells/set (i.e., one 15-cm plate at ~70% confluence for many fibroblasts), although more cells can be used by scaling up the extractions and $< 10^7$ cells/set will work if extra precautions are taken in precipitating and handling the DNA. The cells should be healthy and adhere well to the plate (see critical parameters).

Materials

- Phosphate-buffered saline (PBS; APPENDIX 2)
- Tissue culture medium appropriate for sample cells
- Lysis solution (see recipe)
- Duplicate 15-cm plates of cells in monolayer culture (see Critical Parameters)

100% dimethyl sulfate (DMS; Aldrich)
 Equilibrated buffered phenol (UNIT 2.1A)
 25:24:1 (v:v:v) phenol/chloroform/isoamyl alcohol (see recipe)
 24:1 (v/v) chloroform/isoamyl alcohol
 Ethyl ether
 Isopropanol
 TE buffer, pH 7.5 (APPENDIX 2)
 3 M sodium acetate, pH 7.0
 100% ethanol, room temperature and chilled on dry ice
 75% ethanol, room temperature
 DMS stop buffer (UNIT 7.5), ice-cold
 Piperidine (Aldrich)
 8 M ammonium acetate

 50- and 15-ml disposable polypropylene screw-cap tubes (e.g., Corning)
 Aspirator attached to waste flask
 Disposable cell scraper
 Tabletop centrifuge (e.g., IEC Centra-7R)
 1.5-ml microcentrifuge tubes, silanized (APPENDIX 3) and with Lid-Loks
 (Intermountain Scientific)
 Sealed Pasteur pipet or thin glass rod

 Additional reagents and equipment for quantitation of DNA (APPENDIX 3)

CAUTION: DMS and concentrated piperidine are extremely toxic. All manipulations that use DMS or piperidine should be performed in a properly functioning fume hood. Before starting this procedure, review precautions for working with and disposing of DMS and piperidine in UNIT 7.5.

Treat monolayer cells with DMS (in vivo treatment)

1. Prepare the following solutions before beginning the procedure: Prewarm PBS (~75 ml/15-cm plate) to 37°C in a water bath inside a fume hood. Aliquot 24 ml tissue culture medium into a 50-ml disposable polypropylene screw-cap tube and prewarm to 37°C as for PBS. Prepare lysis solution.

It is convenient to have the 37°C water bath in or near the fume hood.

2. *For control (untreated) cells:* Remove and discard medium from cells on one 15-cm tissue culture plate, and immediately add ~25 ml prewarmed PBS. Gently swirl plate a few times and remove and discard PBS. Immediately proceed to step 5.
3. *For in vivo DMS-treated cells:* Remove and discard medium from cells on the second 15-cm tissue culture plate. Add 24 µl of 100% DMS to aliquot of prewarmed medium (0.1% DMS final). Screw on cap, mix by inversion, and gently pour entire contents onto tissue culture plate. Leave this 0.1% DMS medium on cells exactly 2 min.

Do not add DMS to the medium until immediately before it is needed; the water in the medium quickly inactivates it. The high heat capacity of the liquid medium should keep the temperature of the reaction at ~37°C for the 2-min incubation, but this can be controlled more effectively by placing a styrofoam sheet (prewarmed to 37°C) under the plate to insulate it.

The incubation time and DMS concentration listed here are good starting conditions; it may be necessary to modify them to get an optimal DMS footprint. Typically, DMS treatment is done at the temperature at which cells are grown (e.g., 37°C for most mammalian cells); if the treatment is done at a different temperature, it is necessary to modify the incubation time or DMS concentration by empirical determination to achieve similar levels of alkylation.

4. Remove and discard the 0.1% DMS medium using an aspirator attached to a flask to hold the DMS waste. Pour ~25 ml prewarmed PBS gently on the cells. Gently swirl plate a few times and aspirate PBS. Wash plate three times with prewarmed PBS, allowing PBS to sit on cells ~30 sec each wash.

The first wash quickly removes most of the remaining DMS from the medium; subsequent washes allow the intracellular DMS to diffuse from the cell. After the last wash, the plate may be removed from the fume hood. When pouring PBS, be very careful not to dislodge the cells; they may be less adherent after DMS treatment.

5. For both untreated and treated cells: After removing as much PBS as possible, pipet 1.5 ml lysis solution onto cells. Gently tip and rock plate to spread solution evenly over cells, then let plate sit at room temperature ~5 min.

The cells should lyse within seconds of contact with the lysis solution. This will be apparent from the viscosity of the DNA/cell lysis mixture.

6. Tilt plate and scrape DNA/lysed-cell slurry to one side with a disposable cell scraper. Slowly remove as much of slurry as possible with a pipet and transfer to 15-ml polypropylene tube.

The DNA/lysed-cell slurry from up to two identically treated plates can be combined in one 15-ml polypropylene tube. If additional plates are used, the slurry may be combined in one or more 50-ml polypropylene tubes. The in vivo DMS-treated DNA must be kept separate from the untreated DNA.

Polypropylene tubes can withstand the organic solvents used in the DNA preparation. Do not use polystyrene tubes.

Harvest the DNA

7. Incubate lysed-cell slurry 3 to 5 hr at 37°C. Mix by inversion every 30 to 60 min.

During this incubation, proteinase K is digesting cellular proteins. After incubation, samples may be stored at -20°C indefinitely. They should be thawed and warmed to room temperature before proceeding with the protocol.

8. Add 1.25 vol buffered phenol, mix thoroughly by gently inverting ~30 times, and centrifuge in a tabletop centrifuge 10 min at 1300 × g (2500 rpm in an IEC Centra-7R), room temperature. Slowly remove phenol (bottom layer) from underneath by inserting a 9-in. Pasteur pipet through the aqueous layer and interface to the bottom of the tube. If the viscous DNA begins to trail along into the organic layer, it can be freed by blowing a few bubbles of air through the pipet using a pipet bulb. Do not remove the interface; much of the DNA may be trapped in it. Repeat phenol extraction once.

For this protocol, it is convenient to remove the organic layer rather than the aqueous layer. All extractions should be performed at room temperature and mixing should be by gentle inversion to avoid shearing the DNA.

Do not be alarmed if there is a large interface and a cloudy aqueous layer after the first extraction; this will clear during subsequent extractions. Both the interface and the aqueous layer will be quite viscous—this is desirable because it means the DNA has not been degraded or sheared, but it can make separating the phases a challenge. It is acceptable to leave some phenol behind, as it will be removed in subsequent extractions.

9. Add 1 vol phenol/chloroform/isoamyl alcohol, mix thoroughly by gently inverting ~30 times, and centrifuge 10 min at 500 × g (1500 rpm in an IEC Centra-7R), room temperature. Remove phenol/chloroform/isoamyl alcohol (bottom layer) from underneath with a 9-in. Pasteur pipet as in step 8. Leave the interface, if any, behind. Repeat this extraction once.

By this point the interface should be disappearing or be gone and the aqueous layer should be clear but still quite viscous. It is acceptable to leave some phenol/chloroform/isoamyl alcohol behind, as it will be removed in the next step.

10. Add 1 vol of chloroform/isoamyl alcohol, mix thoroughly by gently inverting ~30 times, and centrifuge 5 min at $200 \times g$ (1000 rpm in an IEC Centra-7R), room temperature. Remove chloroform/isoamyl alcohol (bottom layer) from underneath with a 9-in. Pasteur pipet as in step 8.

There should be little or no interface; any interface still present should be removed with the organic layer. Remove the entire organic layer at this point.

11. Add 1 vol ethyl ether, mix thoroughly by gently inverting ~30 times, and allow phases to separate by gravity (~1 min). Remove ethyl ether (top layer) with a Pasteur pipet; evaporate any remaining ether in a fume hood (~5 min).

CAUTION: Ethyl ether is highly flammable; use appropriate caution and work in a fume hood.

This extraction will remove small amounts of remaining phenol or chloroform (see UNIT 2.1A). Try to evaporate as much ether as possible; if a small amount remains after evaporation, it will be removed during the precipitations.

12. Add 1 vol isopropanol and mix thoroughly by gently inverting ~30 times.

DNA should instantly precipitate and be visible as a stringy white precipitate.

If $\leq 10^7$ cells were used as starting material, there may not be an instant precipitate. If this is the case, the DNA will need to be recovered by centrifugation (UNIT 2.1A); be careful not to allow it to dry out.

13. Spool the stringy DNA precipitate around the end of a sealed 9-in. Pasteur pipet or thin glass rod. Carefully lift the spooled DNA out of the isopropanol solution, and gently touch the DNA to the inside of the tube to remove excess liquid.

Seal the end of the Pasteur pipet in the flame of a Bunsen burner; allow the hot glass to cool before retrieving the DNA. There is no need to remove all of the liquid from the spooled DNA; never allow the DNA to dry out or it will be impossible to resuspend.

14. Unspool the DNA in 3 ml TE buffer, pH 7.5. Redissolve by gently rocking the sample several hours to overnight at room temperature.

The DNA may be released from the pipet tip by gently shaking and twisting the pipet in the TE buffer. Genomic DNA is difficult to resuspend, but the process should not be forced by vortexing as this will shear the DNA.

15. Add 330 μ l of 3 M sodium acetate and 6.7 ml of ice-cold 100% ethanol; mix thoroughly by gently inverting ~30 times. Reprecipitate and spool DNA as in steps 12 and 13.

16. Unspool DNA in 200 to 500 μ l TE buffer, pH 7.5. Redissolve DNA by storing it overnight at room temperature or for several days at 4°C, inverting tube gently a few times during the process. Quantitate DNA using a spectrophotometer and adjust concentration to 0.5 to 1 mg/ml.

The DNA is stable for years at 4°C. The solution will probably contain a significant amount of RNA—at least as great as the amount of DNA; this will be removed by the piperidine treatment.

The control DNA (not treated with DMS) is of high quality, and at this point can also be used for genomic sequencing (Support Protocol 3) and genomic methyl cytosine analysis (Garrity and Wold, 1992).

Treat control DNA with DMS (in vitro treatment)

17. Put ~75 to 175 μg control DNA in a silanized 1.5-ml microcentrifuge tube. Add TE buffer to bring the volume to 175 μl .

The DNA will be quite viscous, so care should be exercised in pipetting and aliquoting it. It is helpful to use a wider-bore pipet tip (1000- μl pipettor tip or 200- μl pipettor tip with the end cut off).

18. Make a 1% DMS solution by adding 5 μl of 100% DMS to 495 μl water. Mix thoroughly by vortexing 25 sec and microcentrifuge briefly to collect droplets.

Several concentrations of DMS may have to be tested to find conditions that will perfectly match the in vivo conditions used in steps 3 and 4 (see Critical Parameters). Once the 1% DMS solution is made it should be used promptly, as DMS is rapidly inactivated by water. It is useful to have a microcentrifuge near or in the fume hood at this point.

19. Add 25 μl of 1% DMS solution to the control DNA and mix thoroughly by vortexing gently ~25 sec. Avoid getting the DMS solution on the lid; microcentrifuge briefly if it does. Incubate exactly 2 min at room temperature, then add 50 μl ice-cold DMS stop buffer. Immediately add 750 μl of 100% ethanol prechilled on dry ice, mix by vigorously shaking, and plunge tube into powdered dry ice. Leave sample in dry ice for ~30 min.

The combination of DMS stop solution and low temperature (-70°C) ends the reaction and precipitates the DNA. Once the ethanol is added and mixed, the lid of the microcentrifuge tube will have a tendency to pop open; this can be avoided by using a finger to maintain pressure on the lid until the tube is in the dry ice.

20. Prepare in vivo-treated DNA for piperidine treatment in parallel with the in vitro-treated DMS samples. Mix 200 μl DNA (from step 16) with 50 μl ice-cold DMS stop buffer and vortex briefly (3 sec). Add 750 μl of ice-cold 100% ethanol, mix by vigorously shaking, and plunge tube into dry ice. Leave sample in dry ice ~30 min.

Cleave in vivo and in vitro DMS-treated DNA with piperidine

21. Microcentrifuge the two precipitated DNA samples (from steps 19 and 20) for 10 min at 4°C . Remove and discard supernatants, add 1 ml room-temperature 75% ethanol to the DNA pellets, and vortex briefly (~5 sec) until each pellet is dislodged. Microcentrifuge 10 min at 4°C , then remove and discard supernatants.

It is acceptable to leave some of the 75% ethanol wash (i.e., a few microliters) with the pellets. Do not allow the DNA pellets to dry out.

22. Dilute piperidine 1:10 in water (to obtain 1 M final) and add 200 μl to each DNA pellet. Resuspend DNA by incubating at room temperature with intermittent vortexing; pellets usually dissolve in ~15 min.

CAUTION: Aliquot piperidine in a fume hood.

Carefully examine the samples to ensure that the DNA is dissolved; an undissolved pellet will appear as a clear, floating lens in the 1 M piperidine.

23. When pellets are completely dissolved, microcentrifuge briefly to collect droplets and place Lid-Loks on tubes. Heat 30 min at 90°C in the fume hood.

Lid-Loks prevent the tubes from popping open during the heating step, which keeps the volatile piperidine from escaping. Heat treatment with piperidine cleaves the genomic DNA at the methylated guanines, denatures the DNA, and destroys contaminating RNA.

24. Remove Lid-Loks and briefly microcentrifuge tubes to collect condensation. Chill samples on dry ice for 10 min, then evaporate piperidine in a Speedvac evaporator for 1 to 2 hr at room temperature.

Chilling the samples on dry ice will facilitate evaporation of piperidine and will minimize its vaporization during loading into the Speedvac evaporator.

25. Resuspend pellets in 360 μ l TE buffer, pH 7.5, add 40 μ l of 3 M sodium acetate, pH 7.0, and mix by vortexing. Add 1 ml of ice-cold 100% ethanol. Shake vigorously to mix and chill at -20°C for ≥ 2 hr.

Because the DNA is cleaved and single-stranded, it will resuspend easily. The two precipitations in steps 25 to 27 remove piperidine and degraded RNA.

26. Microcentrifuge samples 15 min at 4°C and discard supernatant. Resuspend pellets in 500 μ l TE buffer, pH 7.5, and add 170 μ l of 8 M ammonium acetate. Mix by vortexing. Add 670 μ l isopropanol, shake vigorously to mix, and chill at -20°C for ≥ 2 hr.
27. Microcentrifuge samples 15 min at 4°C and discard supernatant. Add 500 μ l room-temperature 75% ethanol, vortex, and microcentrifuge samples 15 min at 4°C . Remove and discard supernatants, and remove the last traces of ethanol with a pipettor.
28. Resuspend pellets in 50 μ l water and dry ~ 1 hr in a Speedvac evaporator. Resuspend pellets in TE buffer such that the final DNA concentration is ~ 1 $\mu\text{g}/\mu\text{l}$.

This step removes any remaining traces of piperidine.

29. Microcentrifuge samples 10 min at room temperature. Transfer supernatants to a fresh silanized 1.5-ml microcentrifuge tube; discard gelatinous pellet if present. Quantitate DNA with a spectrophotometer and adjust concentration to 0.4 $\mu\text{g}/\mu\text{l}$ with TE buffer, pH 7.5.

The samples are now ready for ligation-mediated PCR.

This centrifuge step removes insoluble matter that has been carried through the procedure; not all DNA preparations will have this. At this point, most of the DNA will be single-stranded because of the piperidine treatment, so it can be assumed that an A_{260} of 1.0 = 40 $\mu\text{g}/\text{ml}$ DNA. The DNA is stable for years at 4°C .

PREPARATION OF GENOMIC DNA FROM SUSPENSION CELLS FOR DMS FOOTPRINTING

Many cell types do not adhere well to tissue culture substrates and/or grow better in suspension culture. This protocol describes *in vivo* treatment of suspension cells with DMS. It works well with $0.5\text{--}1 \times 10^8$ cells, although $<10^7$ cells will suffice if extra precautions are taken to prevent losses during later steps in DNA preparation and handling. The remaining steps of the DNA footprinting procedure (DNA harvest, *in vivo* control treatment, and piperidine treatment) required to prepare DNA for the ligation-mediated PCR assay (Basic Protocol) are detailed in Support Protocol 1.

Materials

- Cells in suspension culture
- Phosphate-buffered saline (PBS; APPENDIX 2)
- Lysis solution (see recipe)
- 100% dimethyl sulfate (DMS; Aldrich)
- 100% ethanol, room-temperature
- 50-ml polypropylene screw-cap tubes (e.g., Corning)
- Tabletop centrifuge (IEC Centra-7R or equivalent)

CAUTION: DMS is extremely toxic. All manipulations that use DMS should be performed in a properly functioning fume hood. Before starting this procedure, review precautions for working with and disposing of DMS in UNIT 7.5.

SUPPORT PROTOCOL 2

1. Prepare three 49-ml aliquots of PBS in 50-ml polypropylene screw-cap tubes and chill at least 30 min on ice prior to use. Make lysis solution and prepare three 2.7-ml aliquots in 15-ml polypropylene screw-cap tubes.
2. Transfer duplicate aliquots of medium containing $0.5\text{--}1 \times 10^8$ cells to 50-ml polypropylene tubes. Centrifuge cells 5 min in a tabletop centrifuge at $500 \times g$ (1500 rpm in IEC Centra-7R), room temperature. Aspirate and discard supernatant, leaving behind sufficient tissue culture medium to resuspend cell pellet in a final volume of 1 ml. Resuspend cells by gently flicking the bottom of the tube with a finger or by gently pipetting up and down.

Different suspension-cell cultures may require adjustments in centrifugation to optimize cell recovery and pellet resuspension without cell damage. These conditions were worked out for EL4 T lymphocytes.

3. *For control (untreated) suspension cells:* Transfer 1 ml resuspended cells to one ice-cold 49-ml PBS aliquot, mix by gentle inversion, and centrifuge 5 min at $500 \times g$, 4°C . Proceed to step 8.
4. *For DMS-treated suspension cells:* Transfer 1 ml resuspended cells to a 1.5-ml microcentrifuge tube and place in 37°C water bath inside a fume hood.
5. Make 10% DMS solution by adding 10 μl of room-temperature 100% DMS to 90 μl of 100% ethanol. Mix thoroughly by vortexing ~ 25 sec, and microcentrifuge briefly to collect droplets.

The 10% DMS solution is made in ethanol because DMS is not soluble in water at this concentration, and it should be used as soon as it is made. It is useful to have a microcentrifuge near or in the fume hood at this point.

6. Add 10 μl of 10% DMS solution to the warmed cells, mix by gentle inversion, and incubate 1 min at 37°C . Immediately transfer cells to the second ice-cold 49-ml PBS aliquot, mix by gentle inversion, and centrifuge 5 min at $500 \times g$, 4°C .

The incubation time and amount of DMS used in the treatment listed here are good starting conditions; it may be necessary to modify them to get an optimal DMS footprint. Typically, the DMS treatment is carried out at the same temperature that the cells are grown (i.e., 37°C); if the treatment is carried out at a different temperature, it will be necessary to modify the incubation time or DMS concentration to achieve similar levels of alkylation.

7. Aspirate and discard supernatant. Quickly resuspend cells with gentle pipetting in 1 to 5 ml ice-cold PBS from the third aliquot. Immediately add ice-cold PBS to fill the 50-ml tube, mix by gentle inversion, and centrifuge 5 min at $500 \times g$, 4°C .
8. *For both control and treated cells:* Aspirate and discard supernatant. Resuspend cells in 300 μl ice-cold PBS and transfer to separate 2.7-ml aliquots of lysis solution. Mix by gentle inversion. Continue with DNA harvesting, in vitro DMS treatment of the control DNA, and piperidine cleavage as in steps 7 through 29 of Support Protocol 1.

When lysis solution is added to the cells, the solution should become quite viscous.

SUPPORT PROTOCOL 3

PREPARATION OF GENOMIC DNA FOR CHEMICAL SEQUENCING

This protocol describes the preparation of genomic DNA for LMPCR-aided direct genomic sequencing (i.e., sequencing without intermediate cloning or amplification steps). For this application genomic DNA, prepared as described in the accompanying protocol, is sequenced using a modification of the chemical strategy described in detail in *UNIT 7.5* (this method also reveals in vivo cytosine methylation, as cytosines methylated at the C5 position do not participate in the C+T and C reactions).

Ligation- Mediated PCR

15.3.14

After the base-specific modification reaction, the DNA is cleaved with piperidine before use in the ligation-mediated PCR assay (Basic Protocol).

Materials

- 0.5 to 1.0 µg/µl untreated genomic DNA in TE buffer, pH 7.5 (control DNA from steps 1 to 16 in Support Protocols 1 and 2)
- TE buffer, pH 7.5 (*APPENDIX 2*)
- 3 M sodium acetate, pH 7.0 (*APPENDIX 2*)
- 100% ethanol, room temperature and chilled on dry ice
- 75% ethanol, room temperature
- 88% formic acid (Fisher Chemical)
- G+A stop solution (see recipe)
- Hydrazine, 98% anhydrous (Aldrich #21,515-5)
- C+T/C stop solution (see recipe)
- 5 M sodium chloride (*APPENDIX 2*)

CAUTION: DMS, formic acid, and hydrazine are toxic. All manipulations using these chemicals should be performed in a properly functioning fume hood. Before starting this procedure, review precautions for working with and disposing of DMS and hydrazine in *UNIT 7.5*.

Prepare G>A reaction

1. Place ~50 to 175 µg control DNA in a 1.5-ml microcentrifuge tube. Add sufficient TE buffer, pH 7.5, to bring the total volume to 175 µl. Label this tube G>A.

The DNA will be quite viscous, so pipet and aliquot it carefully.

2. Treat with DMS as described in Support Protocol 1, steps 18 and 19. Proceed to step 9.

Prepare G+A, C+T, and C reactions

3. Place 20 to 40 µg control DNA in each of three 1.5-ml microcentrifuge tubes. Add sufficient TE buffer to bring the total volume in each to 100 µl. Label one tube G+A, one tube C+T, and one tube C.

The DNA will be quite viscous, so carefully pipet and aliquot it.

4. Add 11 µl of 3 M sodium acetate and 222 µl of room-temperature 100% ethanol to each tube. Mix thoroughly by gently inverting a few times.

The DNA should precipitate immediately.

5. Microcentrifuge precipitated samples 5 min at maximum speed, room temperature, then remove and discard supernatants. Add 500 µl of room-temperature 75% ethanol to each pellet and mix by inversion until pellets are dislodged. Microcentrifuge 3 min at maximum speed, room temperature, then remove and discard supernatants.

Try to remove as much of the 75% ethanol as possible with a pipettor, but do not allow the DNA pellets to dry out. Do not use a Speedvac evaporator, as it will be impossible to resuspend the DNA once it is dried.

6. Redissolve samples in water as follows: add 18 µl to G+A tube, 40 µl to C+T tube, and 10 µl to C tube. Incubate overnight at 4°C. Warm redissolved DNA to room temperature.

Uncleaved genomic DNA redissolves slowly at these concentrations. Gentle mixing by flicking the tube with a finger a few times during the resuspension can help speed this process. Overnight incubation is usually sufficient to allow resuspension. A small amount of insoluble material is occasionally seen at this step. It does not interfere with subsequent

reactions and can be ignored; it will be discarded after the piperidine cleavage reaction in step 9.

For the G+A sample:

- 7a. Add 54 μl of 88% formic acid, mix thoroughly by vortexing 25 sec, and microcentrifuge briefly to collect droplets. Incubate 7 min at room temperature.
- 8a. Add 164 μl ice-cold G+A stop solution and vortex briefly (3 sec). Add 750 μl of 100% ethanol prechilled on dry ice, mix by vigorously shaking, and plunge tube into powdered dry ice. Leave samples in dry ice for \sim 30 min, then proceed to step 9.

The 7-min incubation time used here is a good starting condition. The extent of reaction can be changed by varying the incubation time; the average size of the final product after piperidine cleavage will decrease as incubation time is increased.

For the C+T sample:

- 7b. Add 60 μl hydrazine, mix thoroughly by vortexing 25 sec, and microcentrifuge briefly to collect droplets. Incubate 3 min at room temperature.
- 8b. Add 150 μl ice-cold C+T/C stop solution and vortex briefly (3 sec). Add 750 μl of 100% ethanol prechilled on dry ice, mix by vigorously shaking, and plunge tube into powdered dry ice. Leave samples in dry ice for \sim 30 min, then proceed to step 9.

The 3-min incubation time used here is a good starting condition. The extent of reaction can be changed by varying the incubation time, as described in step 8a.

For the C sample:

- 7c. Add 30 μl of 5 M sodium chloride, mix thoroughly by vortexing 25 sec, and microcentrifuge briefly to collect droplets. Add 60 μl hydrazine, mix thoroughly by vortexing 25 sec, and microcentrifuge briefly to collect droplets. Incubate 3 min at room temperature.
- 8c. Add 150 μl ice-cold C+T/C stop solution and vortex briefly (3 sec). Add 750 μl of 100% ethanol prechilled on dry ice, mix by vigorously shaking, and plunge tube into powdered dry ice. Leave samples in dry ice for \sim 30 min, then proceed to step 9.

The 3-min incubation time used here is a good starting condition. The extent of reaction can be changed by varying the incubation time, as described in step 8a.

Carry out cleavage and sequencing

9. Cleave DNA from each of the four reactions with piperidine as described in Support Protocol 1, steps 21 to 29. Proceed to ligation-mediated PCR (Basic Protocol).

REAGENTS AND SOLUTIONS

4dNTP mix, pH 7.0, 25mM

Prepare as in UNIT 3.4. Alternatively, purchase as individual 100-mM stock solutions from Pharmacia Biotech and combine equal amounts of dATP, dCTP, dGTP, and dTTP to obtain the 25 mM 4dNTP mix. Store at -20°C .

Amplification buffer, 5 \times

200 mM NaCl
100 mM Tris·Cl, pH 8.9 (APPENDIX 2), room temperature
25 mM MgSO₄
0.05% gelatin (from bovine skin; Sigma)
0.5% Triton X-100
Store at -20°C

Amplification mix, per reaction (30 μ l):

- 20.0 μ l 5 \times amplification buffer (see recipe)
- 1.0 μ l 10 pmol/ μ l oligonucleotide LMPCR.1 (linker primer; Fig. 15.3.3)
- 1.0 μ l 10 pmol/ μ l oligonucleotide primer 2 (Figs. 15.3.1 & 15.3.2)
- 0.8 μ l 25 mM 4dNTP mix, pH 7.0 (see recipe)
- 7.2 μ l H₂O

Prepare immediately before use and chill on ice

Addition of LMPCR.1 may not be required, but this has not been tested.

C+T/C stop solution

- 400 mM sodium acetate, pH 7.5
 - 0.14 mM EDTA, pH 8.0 (APPENDIX 2)
- Prepare fresh and chill on ice before use

End-labeling mix, per reaction (5 μ l):

- 1.0 μ l 5 \times amplification buffer (see recipe)
- 2.3 μ l 1 pmol/ μ l end-labeled primer 3 (Fig. 15.3.3)
- 0.4 μ l 25 mM 4dNTP mix, pH 7.0 (see recipe)
- 0.8 μ l H₂O
- 0.5 μ l 2 U/ μ l *Thermococcus litoralis* DNA polymerase (Vent; New England Biolabs)

Prepare immediately before use. Mix first four components and chill on ice before adding Vent DNA polymerase and chill on ice. Then add polymerase and keep on ice.

5' end-labeled primer 3 can be prepared as in UNIT 3.10 (forward reaction) with the following modifications: end-label 20 to 100 pmol of primer 3 with labeling-grade (i.e., less expensive) [γ -³²P] ATP (~6000 Ci/mmol); incubate at 37°C for 30 min instead of 60 min. Remove unincorporated ³²P by gel purification (UNIT 2.12) or by using a Nensorb-20 nucleic acid purification cartridge (Du Pont NEN)—elute primer with 50% ethanol instead of 50% methanol. Resuspend primer 3 in TE buffer, pH 7.5, so that its concentration is 1 pmol/ μ l; the specific activity should be 4–9 \times 10⁶ cpm/pmol.

First-strand buffer, 5 \times

- 200 mM NaCl
 - 50 mM Tris-Cl, pH 8.9 (APPENDIX 2) room temperature
 - 25 mM MgSO₄
 - 0.05% gelatin (from bovine skin; Sigma)
- Store at –20°C

First-strand synthesis mix, per reaction (25 μ l):

- 6.0 μ l 5 \times first-strand buffer (see recipe)
- 0.3 μ l 1 pmol/ μ l oligonucleotide primer 1
- 0.24 μ l 25 mM 4dNTP mix, pH 7.0 (see recipe)
- 18.21 μ l H₂O
- 0.25 μ l 2 U/ μ l *Thermococcus litoralis* DNA polymerase (Vent; New England Biolabs #254L)

Prepare immediately before use. Mix all components except Vent DNA polymerase and chill on ice. Then add polymerase and keep on ice.

Primer 1 should be stored in a silanized tube at a concentration \geq 10 pmol, then diluted in TE buffer, pH 7.5, immediately before use. This will minimize primer loss due to sticking to the tube walls.

G+A stop solution

360 mM sodium acetate, pH 7.5
0.14 mM EDTA, pH 8.0 (*APPENDIX 2*)
Prepare fresh and chill on ice before use

Ligase dilution solution, per reaction (20 μ l):

2.2 μ l 1 M Tris-Cl, pH 7.5, at room temperature (*APPENDIX 2*; 110 mM final)
0.35 μ l 1 M MgCl₂ (17.5 mM final)
1.0 μ l 1 M DTT (50 mM final)
0.25 μ l 10 mg/ml BSA (DNase-free; Pharmacia Biotech; 125 μ g/ml final)
16.2 μ l H₂O
Prepare immediately before use and chill on ice

Ligase mix, per reaction (25.0 μ l):

0.25 μ l 1 M MgCl₂ (*APPENDIX 2*; 10 mM final)
0.50 μ l 1 M DTT (*APPENDIX 2*; 20 mM final)
0.75 μ l 100 mM ATP, pH 7.0 (Pharmacia Biotech; 3 mM final)
0.125 μ l 10 mg/ml BSA (DNase-free; Pharmacia Biotech; 50 μ g/ml final)
17.375 μ l H₂O
5.0 μ l 20 μ M unidirectional linker mix (see recipe; 4 μ M linker and 50 mM Tris-Cl, pH 7.7, final)
1.0 μ l 3 “Weiss” U/ μ l T4 DNA ligase (*UNIT 3.14*; 3 U final)
Prepare immediately before use. First mix MgCl₂, DTT, rATP, BSA, and H₂O and chill on ice. Next add ice-cold unidirectional linker mix and T4 DNA ligase.
Tris-Cl added in the linker mix is 50 mM, pH 7.7, at final concentration.

Loading buffer

80% (v/v) formamide, deionized (see *UNIT 14.3*)
45 mM Tris base
45 mM boric acid
1 mM EDTA
0.05% (w/v) bromphenol blue
0.05% (w/v) xylene cyanol
Store in aliquots at -20°C and discard after 3 months

Lysis solution

300 mM NaCl
50 mM Tris-Cl, pH 8.0 (*APPENDIX 2*), room temperature
25 mM EDTA, pH 8.0 (*APPENDIX 2*)
0.2% (v/v) SDS (prepare fresh; add just before use)
0.2 mg/ml proteinase K (prepare fresh; add just before use)
Lysis solution without SDS and proteinase K can be stored indefinitely at room temperature. Immediately before use, add 10 μ l of 20% SDS and 10 μ l of 20 mg/ml proteinase K per milliliter lysis solution.

Phenol/chloroform/isoamyl alcohol

Mix 25 parts phenol (equilibrated in 150 mM NaCl/50 mM Tris-Cl (pH 7.5)/1 mM EDTA) with 24 parts chloroform and 1 part isoamyl alcohol. Add 8-hydroxyquinoline to 0.1%. Store in aliquots at -20°C and discard after 6 months.

Precipitation salt mix, per reaction (9.4 μ l):

8.4 μ l 3 M sodium acetate, pH 7.0 (2.7 M final)
1.0 μ l 10 mg/ml yeast tRNA (~1 mg/ml final)
Prepare immediately before use

Unidirectional linker mix, 20 μ M

20 μ M oligonucleotide LMPCR.1 (Fig. 15.3.3)

20 μ M oligonucleotide LMPCR.2 (Fig. 15.3.3)

250 mM Tris·Cl, pH 7.7 (APPENDIX 2)

Prepare this mix in advance as follows: (1) purify the oligonucleotides on denaturing polyacrylamide gels (UNIT 2.12), (2) combine the two oligonucleotides and Tris·Cl and heat 5 min at 95°C, (3) transfer to 70°C and gradually cool ~1 hr to room temperature, (4) leave ~1 hr at room temperature and then gradually cool ~1 hr to 4°C, and (5) leave ~12 hr at 4°C and store in aliquots at –20°C. Thaw linker on ice before use.

Hybridization of the linker undoubtedly takes place more rapidly than allowed for in this procedure, but this has reproducibly worked well. Because the monovalent salts (e.g., NaCl) more traditionally used to raise ionic concentration inhibit T4 DNA ligase, and Tris·Cl is required by the ligase in any case, Tris·Cl is used as the salt in this hybridization reaction. Consequently, it is difficult to calculate the kinetics of oligonucleotide annealing, and so the question of timing has not been studied in detail.

Vent DNA polymerase mix, per reaction (3.0 μ l)

Mix 0.6 μ l of 5 \times amplification buffer (see recipe) with 1.9 μ l H₂O and chill several minutes in an ice-water bath. Add 0.5 μ l (1 U) *Thermococcus litoralis* DNA polymerase (Vent; New England Biolabs), gently mix, and return to ice-water bath. Prepare just before use.

Vent DNA polymerase stop solution, per reaction (295 μ l):

25 μ l 3 M sodium acetate, pH 7.0 (260 mM final)

266 μ l TE buffer, pH 7.5 (APPENDIX 2; 10 mM Tris·Cl, pH 7.5, final)

2 μ l 0.5 M EDTA, pH 8.0 (APPENDIX 2; ~4 mM final)

2 μ l 10 mg/ml yeast tRNA (68 μ g/ml final)

Prepare immediately before use

COMMENTARY

Background Information

Ligation-mediated PCR was originally developed to study in vivo protein-DNA interactions at regions of genes important for transcriptional control of expression. Several genomic sequencing strategies have been previously applied to in vivo footprinting. These relied on the principles of Southern blotting (Church and Gilbert, 1984), solution hybridization (Jackson and Felsenfeld, 1985), or primer extension (Huibregtse and Engelke, 1986). Unfortunately, with these strategies, in vivo footprinting of a single-copy regulatory region in large genomes (e.g., mammalian) is technically challenging, requires large cell numbers, and often produces results with unacceptable signal-to-noise ratios.

The polymerase chain reaction (Saiki et al., 1988; White et al., 1989) is used to amplify specific fragments of single-copy genes (see Chapter 15 introduction and UNIT 15.1). It relies on two primers that flank the specific fragment of DNA to be amplified and uses repeated

cycles of template denaturation, primer annealing, and extension by a thermally stable DNA polymerase to exponentially amplify that fragment. PCR is not immediately applicable to sequencing or footprinting because it requires that every fragment of DNA have two defined ends (a sequence ladder is composed of a population of related DNA fragments that differ in length; they all have one end in common but the other end varies depending on the sequence). The Basic Protocol in this unit circumvents this problem by attaching a common sequence to the variable end of every fragment, thus creating substrates suitable for PCR and resulting in exponential amplification of each representative of the sequence ladder. One end of every fragment is primed with a gene-specific primer and the other is primed with the common attached sequence. Footprint and sequence information contained in the original sample of genomic DNA is amplified by an additional 10⁴ to 10⁵ copies. When visualized on a sequencing gel, each band in the ladder is

shifted to a higher position that corresponds to the length of attached sequence. In practical terms, starting with as little as 2 μg of mammalian DNA (equivalent to 3×10^5 cells), a genomic sequence ladder of a single-copy gene can be seen following overnight exposure without an intensifying screen.

Ligation-mediated PCR differs significantly from another single-sided PCR procedure that uses terminal transferase to add a homopolymeric tail of guanines or adenines to one end of the substrate DNA (Frohman et al., 1988; Loh et al., 1989; Ohara et al., 1989). This tail is added nonspecifically to all DNA and is expected to be somewhat variable in length. In contrast, ligation-mediated PCR results in the blunt-end ligation-based addition of a sequence of defined length and composition. The blunt end is generated by the extension of a gene-specific primer. The initial hybridization of this primer selects a small subset of specific gene fragments (to be modified in later steps) from the original complex DNA sample. This level of selection is unique to ligation-mediated single-sided PCR. These features, together with the use of multiple gene-specific primers, greatly reduce nonspecific background and provide the single-base resolution required for genomic footprinting, sequencing genomic DNA (Pfeifer et al., 1989; Garrity and Wold, 1992), studying *in vivo* methylation patterns of cytosine residues (Pfeifer et al., 1989, 1990; Rideout et al., 1990; Garrity and Wold, 1992), and cloning promoter elements from restriction-digested genomic DNA (Fors et al., 1990). This last adaptation uses gene-specific primers selected from known sequences located at the 5' end of an mRNA to clone the corresponding unknown promoter region.

Support Protocols 1, 2, and 3 describe methods for the preparation of genomic DNA for genomic DMS footprinting and genomic sequencing. Both of these methods are based on the Maxam-Gilbert chemistry described in *UNIT 7.5*. In addition, DNA cleaved randomly by a nuclease such as DNase I (*UNIT 12.4*; Tanguay et al., 1990; Rigaud et al., 1991), or site-specifically by a restriction endonuclease (*UNIT 3.1*) can also in principle be utilized in ligation-mediated PCR. In any case, the cleaved DNA must contain a 5' phosphate to participate in the ligation reaction.

Critical Parameters

Several important parameters are discussed in this section, but two underlying technical

points deserve emphasis at the outset. First, in order to keep background to a minimum, the hybridizations and extensions should be performed at the highest possible temperatures. Hybridizations are incubated at or 2°C above the calculated melting temperature (T_m) of the primers, and extensions are performed at 76°C with Vent DNA polymerase. (In specific cases, these temperatures may need to be adjusted, but they have worked with all combinations of primers tested to date). Second, background can be greatly reduced by using multiple primers, each primer having an end that extends 3' to the previous one. This produces a level of specificity that cannot be obtained with a single 25-base primer.

It is recommended that a test experiment be done before any footprinting or sequencing experiments are undertaken. This should include several identical samples that are processed in parallel. When visualized on a sequencing gel, these samples should appear identical. In addition, this is a convenient way to test for any problems in the operation of the automated thermal cycler or in the execution of ligation-mediated PCR. Whenever possible, prepare solutions as a reaction cocktail; this will minimize sample variation. Oligonucleotides should be gel-purified (*UNIT 2.12*) to remove contaminants and stored in TE buffer, pH 7.5, at ≥ 10 pmol/ μl and at -20°C .

Gene-specific primers

Primer position. Figure 15.3.2 shows possible arrangements for gene-specific primers. Several different primer combinations have been tested and the following operating rules were derived (P.R.M. and B.W., unpub. observ.). Primers 1 and 2 may or may not overlap but the extending end of primer 2 must be 3' to primer 1. If they do overlap, the overlap should be less than half their length. On the other hand, primer 3 can completely overlap primer 2 and extend a few extra bases 3' to it (Fig. 15.3.2A), and it must be positioned with an overlap of at least half the length of primer 2 (Fig. 15.3.2B). If primers 2 and 3 do not overlap, the labeling extension will not be successful, because it is necessary for these primers to compete for the same binding site. The basis of this phenomenon is not known. It may be caused by the premature extension product of primer 2 excluding the hybridization of primer 3. The hybridization temperatures used during the annealing phase of the labeling cycle(s) are close to the optimal temperature for Vent DNA po-

lymerase. This is done to minimize background, but probably results in the immediate extension of any primer following its binding.

Primer composition and melting temperature. Elevated temperatures minimize the formation of imperfect duplexes between genomic DNA and primers. Thus, to minimize background, hybridizations and reactions should be carried out under temperature conditions that demand as much as much specificity as possible. For hybridizations, the optimal temperature is at or even above the calculated T_m of the primer (see below for calculation). This principle is also used to favor the binding of the labeling primer (primer 3) over the amplification primer (primer 2). In general, the T_m of the primers should increase in the order primer 1 < primer 2 < primer 3. Thus, the binding of the first-strand synthesis primer (primer 1) will be less stable under amplification conditions and the binding of the amplification primer (primer 2) will be less stable under labeling conditions. In practice, this doesn't appear to be essential, but it would probably be unwise to have the relative T_m of the primers reversed.

The T_m of the primers can be adjusted by choosing sequences with differing GC content and/or length (see below). The first-strand synthesis primer (primer 1) should have a T_m of $\geq 60^\circ\text{C}$; primers of 20 (~60% GC content) to 25 bases (~50% GC content) work well. If the T_m of the primer is below 60°C , it may be necessary to reduce the hybridization temperature below the suggested 60°C (see Basic Protocol, step 3). The amplification primer (primer 2) should have a T_m equal to or higher than that of primer 1, and should closely match the T_m of the linker primer; a primer of 25 bases with a GC content of ~60% works well. The labeling primer (primer 3) should have an even higher T_m . During the labeling extension, the linker primer does not need to extend, and the labeling primer can better compete with the amplification primer for occupancy if it has a higher T_m (recall that the amplification primer and labeling primer must overlap or the labeling primer will be excluded).

Overall, the exact GC content or length of the primers is probably not very important. What is important is their relationship to each other and to the temperature of the reactions. Primers must be long enough to be specific to the gene of interest, but they should not be excessively long or have a T_m greater than $\sim 76^\circ\text{C}$ (this may lead to nonspecific binding). The following formula (Wahl et al., 1987) may be used to approximate the T_m of primers:

$$T_m = 81.5 + 16.6(\log M) + 0.41(\%GC) - (500/n)$$

where n = length of primer and M = molarity of the salt in the buffer. To determine the molarity, ignore the contribution of Mg^{2+} and multiply the Tris concentration by 0.67 (N. Davidson, pers. comm.). Therefore, for the amplification buffer, the molarity would be $0.040(\text{NaCl}) + 0.67 \times 0.020(\text{Tris}) = 0.053 \text{ M}$ salt. Hybridizations work best if done at or 2°C above this calculated T_m . As an example, the T_m calculation for a 25-base primer with a 60% GC content is as follows: $81.5 + 16.6(\log 0.053) + .41(60) - (500/25) = 65^\circ\text{C}$. Hybridization with this primer should be carried out between 65° and 67°C . This is only an approximation, and base stacking and near-neighbor effects may be significant for particular primers. Therefore, it may be necessary to determine empirically the optimal hybridization temperatures for each primer.

Unidirectional linker

The staggered design of the oligonucleotide linker is important because it assures that the ligation event is directional (see Fig. 15.3.3). The 3' hydroxyl of the long oligonucleotide (LMPCR.1) will be ligated to the 5' phosphate of the genomic DNA. For cloning purposes, LMPCR.1 contains restriction sites for *Bst*EII, *Sma*I, *Bgl*II, and *Eco*RI; however, these are not used in sequencing or footprinting experiments. This oligonucleotide will also function as the linker primer in the PCR amplification. On the other hand, the short oligonucleotide (LMPCR.2) functions only in a structural role. When it is hybridized to the long oligonucleotide, it creates a blunt-end duplex at the 3' end of LMPCR.1. This enables T4 DNA ligase to attach LMPCR.1 to the blunt-end duplex of the genomic DNA. By making the short oligonucleotide small and low in GC content, it is possible to make it unable to serve as a primer in subsequent Vent DNA polymerase reactions that are carried out far above its T_m . To prevent linker self-ligation, neither oligonucleotide has a 5' phosphate. By default, this prevents LMPCR.2 from ligating to the first-strand synthesis extension products, but this is not an essential design feature (see Fig. 15.3.1).

The exact sequence, GC content, length, and type of restriction endonuclease sites in this linker are not thought to be important for the function of the linker. The crucial properties for the linker are that (1) it contain no 5' phosphates and be staggered to eliminate self-ligation and assure unidirectionality, (2) it be a ligatable

structure, (3) the duplex between the two oligonucleotides be stable during ligation conditions but not during PCR conditions, and (4) the long oligonucleotide have a T_m in Vent DNA polymerase buffer comparable to that of primer 2.

Ligation

Most products of the first-strand synthesis reaction appear to be ligated after 45 min at 15°C. However, particular bands in some ladders require longer incubation times to reach full intensity (Mueller and Wold, 1991). For this reason, an overnight (6 to 15 hr) ligation at 15° to 17°C is suggested. Although a higher ligation temperature might decrease the time required for complete ligation, this could inadvertently permit undesirable Vent DNA polymerase activity. Prior to ligation, no attempt is made to destroy the Vent DNA polymerase used during the first-strand synthesis. A possible concern is that if the polymerase is active during the ligation, it may extend the short oligonucleotide of the staggered linker (this would compromise the unidirectionality of the linker addition). With ligation at 15° to 17°C, this does not appear to be a problem, but it may be unwise to attempt higher temperatures unless the polymerase is inactivated.

Vent DNA polymerase

Earlier versions of ligation-mediated PCR used a combination of Sequenase and *Taq* DNA polymerase for the first-strand synthesis and amplification/labeling reactions, respectively. Both of these enzymes have been replaced by *Thermococcus litoralis* DNA polymerase (Vent DNA polymerase). Vent DNA polymerase virtually eliminates the unequal representation of some members of a sequence ladder and occasional spurious bands that were previously observed with Sequenase/*Taq* polymerase-based ligation-mediated PCR. It also provides an approximate three-fold increase in signal strength to all members of the sequence ladder (Garrity and Wold, 1992).

A very important procedural point is that ligation-mediated PCR is very sensitive to the amount of Vent DNA polymerase activity. A small (e.g., two-fold) increase in polymerase can result in an unacceptable background level. The reason for this threshold response to the amount of Vent DNA polymerase activity is unknown, but it does mean that this polymerase must be used carefully. If high background is a problem (or suddenly becomes one), the polymerase should be titrated. Normally it is not necessary to titrate each lot of Vent DNA po-

lymerase, but a change in manufacturing at New England Biolabs occurred between early lots (i.e., prior to the fall of 1991), which were less active, and more recent ones. Thus, originally 1 U of Vent DNA polymerase was needed in the first-strand synthesis and 3 U were needed at the amplification step (Garrity and Wold, 1992), but now 0.5 U in the first-strand synthesis and 1.0 U at the amplification step appears to be the ideal amount (P.G. and B.W., unpub. observ.). The 1.0 U added at the labeling step does not need to be altered. The “exonuclease-minus” version of Vent DNA polymerase has not been tested in this procedure.

The buffers recommended here for use with Vent DNA polymerase in ligation-mediated PCR have been developed through empirical testing and differ from the one recommended by the manufacturer (P.G. and B.W., unpub. observ.). KCl has been replaced by NaCl, which gives better extension through certain guanine-rich regions. BSA has been replaced by gelatin, because this reduces the interface formed after the organic extraction. $(\text{NH}_4)_2\text{SO}_4$ has been eliminated, because this reduces background and the amount of excess salt deposited in the ethanol-precipitation pellets. Finally, the concentration of MgSO_4 has been increased, because this increases signal strength. These conditions may need to be adjusted in specific cases, but so far they have worked with all combinations of primers tested. The first-strand synthesis buffer differs slightly from the amplification/labeling buffer (i.e., there is less Tris and no Triton X-100). This change facilitates the conversion of first-strand buffer to ligation buffer without affecting polymerase activity for the single round of extension.

Vent DNA polymerase is added last to each sample and then only after the sample has been chilled on ice. This is to minimize the single- and double-stranded exonuclease activities reported by the manufacturer that are inhibited by cold and by the presence of dNTPs.

Efficiency and statistical limitations (founder effects)

In this procedure, exponential amplification is so effective that the minimum amount of starting DNA needed is not dictated by signal strength; instead statistical considerations become important. Conventional PCR can be successfully performed using the DNA of a single genome (White et al., 1989). Obviously, footprinting or sequencing reactions require much more material than this, but determining exactly how much more is needed is not straight-

forward (UNITS 7.5 & 12.4). It is useful to first estimate the number of starting genomes or founder molecules that would be required in an idealized case in which all steps in the procedure were 100% efficient. To generate a proper sequence ladder, all “rungs” must be represented at least once (i.e., by at least one starting chromosome). Limited cleavage is used to generate DNA fragments that are, on average, ~600 bases long (UNITS 7.5 & 12.4), and each of these can be used to generate a rung on the ladder. In the specific case of a DMS/piperidine guanine ladder, there are ~150 possible cleavage sites (guanine residues) in an average 600-nucleotide fragment. Therefore, ≥ 150 chromosomes are required to generate all of the rungs in a ladder. However, because cleavage is random, ≥ 10 representatives (on average) must be generated to ensure that each rung is derived at least once. Furthermore, in footprinting, quantitative differences in the intensity of individual bands is important, and the maximum acceptable variation in band intensity due to sampling considerations should be $< 10\%$. This level of certainty could be expected with 100 representatives for each rung. Therefore in theory, 15,000 genomes or founder molecules will be required to generate a footprint ladder (150 genomes per rung \times 100 representatives per rung).

This idealized example assumes that it is possible to cleave and represent all fragments equally. This is not the case in experimental practice. The intensity of any particular band on a sequencing gel is influenced by several parameters. For example, some bases are not as easily cleaved as others and the first-strand synthesis and blunt-end ligation steps of ligation-mediated PCR are not 100% efficient. If these variables combine to cause up to a 20-fold reduction in the frequency of the least prevalent fragments, then the weakest bands may require 20-fold more genomes than in the ideal case to be represented adequately. Therefore, by this estimation, 3.0×10^5 ($20 \times 15,000$) genomes or founder molecules will be required to generate a reliable footprint ladder. Anything that reduces the generation (cleavage conditions) or utilization (first-strand synthesis and linker ligation) of founder molecules will further increase the number of required starting genomes.

This crude calculation highlights an important point: if too small a number of genomes are used as starting material, the results may be subject to artifacts caused by founder effects. Empirically, footprinting experiments on multiple genes indicate that 6×10^5 genomes ($3 \times$

10^5 diploid cells) are sufficient to eliminate any apparent founder effects (P.R.M. and B.W., unpub. observ.). Using fewer genomes may result in missing bands or fluctuation in band intensity. Of course, the amount of starting material required will depend on the application. Founder effects must be kept to a minimum in a quantitative footprinting experiment, whereas a sequencing experiment will be more tolerant of band-intensity fluctuation as long as each band is still visible. Cloning applications of ligation-mediated PCR are much less subject to this problem and will tolerate use of substantially less starting material.

DMS footprinting

Genomic DMS footprinting is a comparison between the DMS sensitivity of DNA bound by cellular proteins inside the cell (in vivo DNA) with DMS sensitivity of deproteinized DNA outside the cell (in vitro or “naked” DNA). This requires high-quality in vitro and in vivo DNA samples that are carefully matched as to genotype, cell type, cleavage condition, and concentration. This can be achieved by using the same cell preparation for both in vitro and in vivo DNA and by processing the samples in parallel. DMS and piperidine should be of high quality and be replaced 9 to 12 months after they are opened. The final preparation of DNA must be free of all contaminants (especially piperidine), and its concentration must be determined accurately.

The DNA preparation procedure outlined in the Support Protocol 1 has been used successfully to isolate DNA from fibroblasts and a number of other cultured cell types. Cells should be healthy and adhere well to the plate. If the cell line does not adhere well, consider precoating the plate with collagen or polylysine-fibronectin or using suspension cells (Support Protocol 2). Some cell types may require more rigorous treatment of the DNA to remove impurities. In these cases, additional extractions or the use of chaotropic agents such as guanidinium in the DNA preparation may be necessary. The physiological status of the cell source for genomic DNA is important; specifically, the gene(s) to be footprinted should be uniformly expressed within the cell population. A heterogeneous background of expressing and nonexpressing cells will result in weak or confusing footprints.

Troubleshooting

In cases where comparison between multiple reactions is required (e.g., footprinting), it

is important that the samples be prepared and processed in parallel. Cocktails of reagents and enzyme solutions should be used whenever applicable. A potential problem associated with the use of an automated thermal cycler is well-to-well variability in the temperature cycling parameters (Linz, 1990). This could potentially lead to lane-to-lane variability in the footprint ladder, although this has not been a widely observed problem.

As previously mentioned, it is important that the highest-quality reagents available be used. In chemical footprinting and sequencing reactions, it is very important to use fresh DMS and piperidine, as old stocks give high levels of background. Moreover, all traces of piperidine must be removed from the DNA before any enzymatic step (Saluz and Jost, 1987). This can be accomplished through use of a Speedvac evaporator and doing at least two ethanol and isopropanol precipitations (UNIT 2.1). The precipitations will also remove the ribonucleotides and small oligoribonucleotides generated by piperidine degradation of contaminating RNA. (Unless the genomic DNA preparation was previously treated with RNase or base/heat, it will contain RNA. The heating in the presence of base performed as part of the piperidine treatment conveniently destroys this RNA, but the resulting RNA fragments must be removed to get an accurate determination of the DNA concentration.)

The primer and linker oligonucleotides should be gel purified on polyacrylamide gels and unincorporated ^{32}P should be removed from the end-labeled primer by gel purification or with a Nensorb-20 nucleic acid purification cartridge. Gel reagents (e.g., loading dye and polyacrylamide) must also be fairly fresh, as old stocks may cause high background and fuzzy bands.

If reagents and starting material are good, but results are still less than optimal, it may be necessary to modify the protocol. The first thing to check is the amount of Vent DNA polymerase being used, as even a small excess in polymerase activity will lead to high background. Alternatively, background can sometimes be reduced by increasing the annealing temperatures during the polymerase reactions. Changing primers can also improve results. As has been observed in other PCR procedures, some primers just do not work (UNIT 15.1). Unfortunately, it is not always simple to predict which primers will fail or succeed. A problem that has occurred on multiple occasions is that the published sequence of a gene does not always

match the sequence in the experimental genome, either because of polymorphisms or sequencing errors. Because high annealing and extension temperatures are used in ligation-mediated PCR, even single-base sequence mismatches can lead to failure. It is important to test the primers by conventional PCR on the experimental DNA sample.

Anticipated Results

Two points need to be considered when discussing anticipated results: the first is sensitivity (how long an exposure should be required to visualize the footprint or sequence ladder) and the second is appearance (how that ladder should look). The exposure time will depend largely on the number of input genomes and the numbers of amplification and labeling cycles performed. However, in general, starting with 6×10^5 genomes of cellular DNA (i.e., 2 μg of mammalian DNA), a sequence or footprint ladder should be visible in 6 to 24 hr using Kodak XAR-P film without an intensifying screen.

The quality of the footprint and sequence ladders is a more critical measure of the success of the experiment. The ladder should extend ≥ 500 bases and with a double loading on an 80-cm, 6% polyacrylamide sequencing gel, it should be possible to resolve footprints or sequences to ~ 300 bases. Except for the expected differences in footprint or sequence reactions (i.e., when different base-specific cleavage reactions are performed or when cytosine methylation is present), the lanes should appear identical. For example, in a genomic footprinting experiment, it is crucial that the *in vitro* and *in vivo* levels of DMS alkylation match (Mueller et al., 1988). If they don't, footprints may be incorrectly assigned. Variations in background, weak signals, and unexpected banding patterns are all signs of problems, which in most cases can be traced to the quality of the starting material.

The DNA yield varies, but $\sim 5 \times 10^7$ mammalian cells should yield ~ 300 to 600 μg nucleic acid (DNA and RNA) before piperidine treatment. During the piperidine treatment, RNA is destroyed (and removed by the precipitations) so ~ 40 to 60% of the input nucleic acid recovered will be DNA.

For additional comments on results, see Critical Parameters for discussion of efficiency and statistics.

Time Considerations

Although ligation-mediated PCR is a relatively complex, time-intensive procedure, it can

routinely yield high-quality, reproducible results. Organization of time simplifies the procedure and markedly improves the chance of success.

A good approach is to split the experiment into a 3- or 4-day procedure, depending on the availability of an automated thermal cycler. Late in the day on day 1, perform the first-strand synthesis and ligation reactions, allowing the ligation incubation to proceed overnight. On day 2, stop the ligation reactions and do the exponential amplification and labeling. Allow at least one day to load and run the sequencing gel. If the PCR reactions are carried out in an automated thermal cycler, a sequencing gel can be prepared while the amplification is performed. This gel can be loaded with the first loading late on day 2, run overnight, loaded with the second loading on the following morning, and run through day 3. Alternatively, a gel can be prepared and loaded with the first loading on the morning of day 3, run all day, loaded with the second loading late in the day, and stopped on the next morning.

For DMS footprinting, on day one, the *in vivo* DMS treatment and DNA harvest from several sets of cultured cells can be completed in ≤ 2 hr including set-up time. The lysed-cell slurry is then incubated for 3 to 5 hr. At this point the lysates can be frozen at -20°C overnight. DNA purification by multiple organic extractions followed by precipitation is carried out on day 2 and will take from 3 to 6 hr depending on sample number. The DNA is allowed to resuspend overnight. On day 3, a second precipitation can be performed in ≤ 1 hr and the DNA allowed to resuspend at least overnight. On day 4, the concentration of resuspended DNA can be determined spectrophotometrically in ~ 1 hr. The *in vitro* DMS and piperidine treatments can be carried out up to the precipitation in step 26 in ~ 7 hr. The samples can be recovered from the precipitation in step 27, dried from water in step 28 and finally resuspended in step 29 in ~ 2 to 3 hr. The DNA is allowed to redissolve overnight, and the concentration determined spectrophotometrically in ~ 1 hr on day 5. The DNA is now ready for LMPCR.

Molecular Cloning of PCR Products

UNIT 15.4

It is often desirable to clone PCR products to establish a permanent source of cloned DNA for hybridization studies, to obtain high-quality DNA sequencing results, or to separate products when PCR amplification yields a complex mixture. The efficiency of direct cloning of PCR products can be improved by generating suitable ends on the amplified fragments. In the first protocol presented (see Basic Protocol), the A residue added to the 3' end of DNA by *Taq* DNA polymerase serves as a one-base overhang that facilitates ligation when the complementary T base is added to the cloning vector. In the first alternate protocol (see Alternate Protocol 1), three bases that are part of a restriction endonuclease site are synthesized as part of the PCR primers, and are thus added to the 5' end of the DNA fragments during amplification. The one-base A overhang left by the *Taq* DNA polymerase is removed and the fragments are ligated into long concatemers, generating full restriction sites at the ligated junctions. Subsequent digestion renders these fragments suitable for subcloning into appropriate vectors. These protocols are not exclusive—i.e., a T-A overhang can be used for one end of a fragment and a synthetic restriction site can be on the other end. An alternate method for creating restriction sites is presented in UNIT 8.5, and other variations are discussed in the Commentary of this unit. In the second alternate protocol (see Alternate Protocol 2), uracil DNA glycosylase (UDG) is used to generate a PCR product with specific 3' overhangs and to clone this product into a specially prepared UDG cloning vector. An accompanying protocol (see Support Protocol) discusses the design and use of specific dU-containing primers both to construct one's own UDG cloning vector and to prepare a PCR product suitable for cloning in the vector.

GENERATION OF T-A OVERHANGS

Taq DNA polymerase normally adds a single nontemplated nucleotide (nearly always A) to the 3' ends of all duplex DNA strands, making direct blunt-ended cloning of PCR fragments inefficient. This extra A may be removed using Klenow fragment or T4 DNA polymerase (UNIT 3.5) followed by direct cloning of the resulting blunt-ended fragment (UNIT 3.16), but it is simpler and more efficient to use the extra A as a one-base overhang. In the presence of dTTP alone, *Taq* DNA polymerase will add a single T to the “blunt ends” of a vector, generating the necessary complementary one-base overhang. This procedure is summarized in Figure 15.4.1.

Materials

- 5 μ g vector DNA—e.g., pUC19 (UNIT 1.5) or M13mp18 (UNIT 1.14)
- TE buffer, pH 8.0 (APPENDIX 2)
- 10 \times PCR buffer (with optimized Mg²⁺ concentration, see UNIT 15.1)
- 5 mM dTTP (UNIT 3.4)
- 5 U/ μ l *Taq* DNA polymerase
- Target DNA

Additional reagents and equipment for restriction endonuclease digestion (UNIT 3.1), agarose gel electrophoresis (UNIT 2.5A), purification of DNA (UNIT 2.1A), PCR (UNIT 15.1), and subcloning DNA fragments (UNIT 3.16)

1. Digest 5 μ g vector DNA with a restriction endonuclease that yields blunt ends (UNIT 3.1). Check that digestion is complete by electrophoresing 50 ng on an agarose minigel (UNIT 2.5A). Extract the DNA with phenol/chloroform and precipitate with ethanol (UNIT 2.1A). Microcentrifuge 5 min at top speed, 4°C, and resuspend pellet in 25 μ l TE buffer, pH 8.0.

In the example in Figure 15.4.1, EcoRV is used to generate the blunt ends of the vector.

**BASIC
PROTOCOL**

**The Polymerase
Chain Reaction**

15.4.1

Figure 15.4.1 T-A overhang cloning. A single T is added to the 3' ends of blunt-cut vector DNA using *Taq* DNA polymerase and dTTP. A normal PCR reaction produces a fragment with a single A added to each 3' end. The As and Ts form complementary 1-base overhangs, facilitating ligation of insert to vector.

2. Set up the following T-addition reaction:

5 μ g blunt-ended vector DNA
 10 μ l 10 \times PCR amplification buffer
 20 μ l 5mM dTTP
 1 μ l (5 U) *Taq* DNA polymerase
 H₂O to 100 μ l final.

Incubate 2 hr at 75°C.

For this reaction, the Mg²⁺ should be 2 to 5 mM.

This yields sufficient T-tailed vector for many cloning procedures.

3. Carry out PCR (UNIT 15.1) to amplify the desired target DNA under optimized conditions (UNIT 15.1), ending the reaction with an extra 5- to 15-min extension at 70° to 75°C to be sure all fragments are A-tailed.

The number of amplification cycles needed can vary from 15 to 40, depending on the input DNA. Overcycling can result in amplification artifacts.

4. Recover and subclone the PCR fragments, beginning with step 6 of the Basic Protocol in *UNIT 3.16*.

The first time any preparation of T-tailed vector is used for cloning, a full set of controls should be performed as described in the Commentary.

GENERATION OF HALF-SITES

A second strategy for generating “sticky ends” on PCR products is to add to the 5′ end of each primer three bases, carefully chosen to create a full restriction site when the PCR products are concatemerized by blunt-end ligation. This procedure is summarized in Figure 15.4.2.

Additional Materials (also see Basic Protocol)

T4 DNA ligase (*UNIT 3.14*) and 10× buffer (*UNIT 3.4*)

1 mM ATP (*UNIT 3.4*)

2 mM 4dNTP mix (*UNIT 15.1*)

Klenow fragment of *E. coli* DNA polymerase I (*UNIT 3.5*)

T4 polynucleotide kinase (*UNIT 3.10*)

Additional reagents and equipment for oligonucleotide synthesis (*UNIT 2.11*) and quantitation of DNA (*APPENDIX 3D*)

1. Design and synthesize a pair of oligonucleotide primers with the three 3′ nucleotides of a palindromic six-base restriction site joined to the 5′ end of each specific primer (*UNIT 2.11*).

In the example in Figure 15.4.2, the last three bases of a BamHI site—TCC—are added to the 5′ end of the primers.

2. Anneal primers to desired DNA sequences and carry out PCR under optimized conditions (*UNIT 15.1*). Analyze a 5- μ l aliquot by agarose gel electrophoresis to verify amplification and quantitate yield (*UNIT 2.5A*). Remove the mineral oil with a pipettor. Extract DNA with phenol/chloroform and precipitate with ethanol (*UNIT 2.1A*).

Optimization of amplification conditions may be necessary because of the decreased specificity inherent in the specially designed primers (see Commentary and UNIT 15.1).

3. Resuspend the DNA in TE buffer, pH 8.0, at a concentration of 0.2 μ g/ μ l. Set up the following ligation reaction:

5 μ l (1 μ g) DNA

1 μ l 10× T4 DNA ligase buffer

1 μ l 1 mM ATP

1 μ l 4dNTP mix

1 U Klenow fragment

1 U T4 polynucleotide kinase

500 U (cohesive end) T4 DNA ligase

H₂O to 10 μ l.

Incubate \geq 2 hr at 15°C. Analyze a 1- μ l aliquot by agarose gel electrophoresis to verify ligation (*UNIT 2.5A*).

For convenience, the incubation may be extended up to 24 hr.

Klenow fragment removes the one-base overhang left by the Taq DNA polymerase, T4 polynucleotide kinase phosphorylates the ends, and T4 DNA ligase joins the DNA into long concatemers, generating restriction sites from the half-sites at the ends (see Fig. 15.4.2).

4. Subclone fragments into appropriate vectors, beginning with step 1 of the Basic Protocol in *UNIT 3.16*.

**ALTERNATE
PROTOCOL 1**

**The Polymerase
Chain Reaction**

15.4.3

Figure 15.4.2 Restriction enzyme half-sites. Fragments are generated by a normal PCR using oligonucleotide primers containing the three 3' nucleotides of a 6-base recognition site at their 5' ends. In a single step, the nontemplated A is removed by Klenow fragment, and the fragments are phosphorylated at their 5' ends by T4 polynucleotide kinase and ligated into concatemers. The ligation generates the 6-base recognition sequence, which can then be cleaved with the appropriate restriction enzyme. The resulting fragments can be easily cloned.

CLONING PCR PRODUCTS WITH URACIL DNA GLYCOSYLASE

Cloning of PCR products with uracil DNA glycosylase (UDG) may be utilized to clone any PCR-generated DNA rapidly and efficiently. This method requires synthesis of oligonucleotide primers containing twelve specific deoxynucleotides at the 5' end. Four of the additional twelve nucleotides are dU, and these are distributed evenly throughout the 12-base sequence. (e.g., 5'-CUACUACUACUA-template specific sequence-3'). These primer sequences are incorporated into the PCR product during amplification; the four dU residues provide substrates for UDG at the 5' ends of the PCR product. Excision of dU residues by UDG results in the generation of 3' overhangs on PCR products that are complementary to sequences at the ends of UDG cloning vectors (Fig. 15.4.3). Annealing of PCR products to the vector after UDG treatment yields circular molecules that can transform competent *E. coli* cells. A number of UDG cloning vectors that allow unidirectional as well as bidirectional cloning of PCR-amplified DNA have been described and are commercially available (see Table 15.4.1; Nisson et al., 1991; Rashtchian et al., 1992a). Steps for constructing one's own UDG cloning vector and for preparing PCR products suitable for UDG cloning are described elsewhere (see Support Protocol).

Cloning with UDG is a rapid and efficient method for cloning PCR-amplified DNA. Advantages of the UDG-cloning method are: (1) ease of cloning—no restriction endonuclease digestions or ligations are required and the reaction is completed in 30 min; (2) efficiency of cloning— 1×10^7 clones/ μg DNA are routinely obtained; (3) the PCR product is used directly for cloning without the need for purification from primers and nucleotides or for buffer exchange; and (4) vector background is extremely low and virtually all transformants contain an insert.

Additional Materials (also see *Basic Protocol*)

PCR product amplified using dU-containing primers (see Support Protocol)
25 ng/ μl linearized UDG cloning vector (see Support Protocol)
5 \times PCR buffer (with optimized Mg^{2+} concentration; see *UNIT 15.1*)
1 U/ μl uracil DNA glycosylase (UDG)

Additional reagents and equipment for introduction of DNA into cells (*UNIT 1.8*), screening transformants (*UNIT 1.4*), mapping by restriction endonuclease digestion (*UNIT 3.2 & 3.3*)

1. Set up reaction to generate single-stranded 3'-overhang ends and anneal PCR product and vector by adding the following to a microcentrifuge tube:

1 to 2 μl (100 ng) PCR product amplified using dU-containing primers
2 μl 25 $\mu\text{g}/\text{ml}$ UDG cloning vector
1 μl 10 \times PCR buffer
1 μl 1 U/ μl UDG
H₂O to 10 μl final.

Mix and incubate 30 min at 37°C.

The 12-base sticky ends obviate the requirement for ligase.

2. Transform 100 μl competent *E. coli* cells with 5 μl of the annealing reaction (from step 1; *UNIT 1.8*) and plate on appropriate medium for screening and selection (e.g., LB/ampicillin plates containing Xgal and IPTG). Incubate 16 hr at 37°C.
3. Pick individual transformants and analyze for the presence of insert by screening (e.g., on Xgal; *UNIT 1.4*), mapping by restriction endonuclease digestion (*UNIT 3.2 & 3.3*), or PCR (*UNIT 15.1*).

DESIGNING PRIMER SETS FOR AMPLIFICATION AND CONSTRUCTION OF UDG CLONING VECTORS

The following Support Protocol is designed to enable the amplification of PCR products using dU-containing primers. Although UDG cloning vectors are commercially available (Life Technologies) it may be desirable to generate one's own. In theory, virtually any vector of the appropriate size can be adapted for UDG cloning with careful consideration and design of complementary primer sets for the vector and for the sequence to be cloned.

Preparation of a cloning vector for use in UDG cloning can be achieved in one of two ways: either by PCR amplification of the vector sequence using dU-containing primers, or by ligation of the dU-containing sequence to the ends of a linearized vector. In the first approach outlined in the steps below, the design of a primer set to be used to amplify a vector generally should include a 12-base sequence at the 5' end of the primer that contains at least four dU residues distributed evenly throughout the sequence (for example, see Table 15.4.1 and Figure 15.4.3), followed by another 12- to 16-base sequence complementary to the sequences flanking the site of insertion (cloning site) of the vector. In this approach, the pair of dU-containing primers is combined with vector DNA, linearized at the site of insertion, to amplify the entire vector sequence. This method has been used successfully to amplify the entire sequence of pUC19: dU-containing tails were incorporated into the primer set (5'-UAGUAGUAGUAGACCATCGTCGACCTGCAG-3' and 5'-UAGUAGUAGUAGACCATCGGATCCCCGGGT-3') to create a UDG cloning vector (for details, see Nisson et al., 1991; Table 15.4.1).

Alternatively, the UDG cloning vector can be prepared by ligating specific adaptor sequences encoding 12-base dU-containing sequences to the linearized vector DNA, using the methods described in *UNIT 3.16*. In this case, the specific adaptor oligonucleotides must be designed to accommodate the restriction endonuclease site(s) used for cloning inserts into the vector (for details, see Rashtchian et al., 1992a).

In either case, directional cloning can be facilitated by incorporating discrete or nonidentical dU-containing sequences at the 5' end of each primer. Table 15.4.1 lists a series of commercially available vectors that were constructed from the commonly used cloning vectors pUC18, pUC19, and pSPORT1 using these approaches.

Table 15.7.1 Characteristics of Various UDG Cloning Vectors

Plasmid	Cloning	Cloning sequence used	Remarks
pAMP1	Directional	Upstream Primer (sense, or 5'): 5'-CAUCAUCAUCAU...-3' Downstream Primer (antisense, or 3'): 5'-CUACUACUACUA...-3'	Derived from pSport 1, T7 and SP6 promoters, F1 <i>ori</i> , Amp ^r
pAMP10	Non-directional	Upstream Primer (sense, or 5'): 5'-CUACUACUACUA...-3' Downstream Primer (antisense, or 3'): 5'-CUACUACUACUA...-3'	Derived from pSPORT 1, T7 and SP6 promoters, F1 <i>ori</i> , Amp ^r
pAMP18	Directional	Upstream Primer (sense, or 5'): 5'-ACGCGUACUAGU...-3' Downstream Primer (antisense, or 3'): 5'-AUGGAGAUCUCU...-3'	Derived from pUC18
pAMP19	Directional	Upstream Primer (sense, or 5'): 5'-AUGGAGAUCUCU...-3' Downstream Primer (antisense, or 3'): 5'-ACGCGUACUAGU...-3'	Derived from pUC19

For UDG cloning vectors constructed using either of these approaches, the primer sequences incorporated at the ends of the vector must be used to design a complementary primer set for PCR amplification of the DNA sequence to be cloned. This secondary primer set will encode a 5' 12-base dU-containing sequence that is complementary to the corresponding primer sequence used to amplify the vector, followed by sequences complementary to the ends of the fragment to be amplified. Amplification of a DNA fragment or a clone containing the fragment of interest using the secondary primers results in a PCR product suitable for use with the appropriate vector in UDG cloning (see Alternate Protocol 2).

Materials

Vector DNA linearized at appropriate cloning or insertion site
DNA sequence to be amplified

Additional reagents and equipment for synthesis of oligonucleotides (UNIT 2.11),
PCR (UNIT 15.1), and agarose gel electrophoresis (UNIT 2.5A)

1. Design and synthesize a primary oligonucleotide primer pair (UNITS 2.11 & 15.1).

Each primer should begin with a 5' tail of 12 bases containing at least 4 dU residues distributed evenly throughout, followed by 12 to 16 bases complementary to one end of the vector sequence to be amplified (one primer for each end; see Fig. 15.4.3 and Table 15.4.1 for examples).

2. Design and synthesize a secondary oligonucleotide primer pair (UNITS 2.11 & 15.1).

The 5' 12-base sequence of each of these primers should be complementary to that of one of the primary primers synthesized in step 1, and should be followed by 12 to 16 bases complementary to one end of the DNA sequence to be amplified.

3. Anneal the primary oligonucleotide primers to linearized vector DNA and carry out PCR under optimized conditions (see UNIT 15.1).

Amplify 1 ng linearized vector DNA.

4. In a separate tube, anneal the secondary oligonucleotide primers to the desired insert DNA and carry out PCR under optimized conditions using the hot-start protocol (see UNIT 15.1).

5. Analyze the PCR products by agarose gel electrophoresis (UNIT 2.5A) to verify amplification and quantitate yield.

6. Clone amplified DNA into the prepared vector as described in Alternate Protocol 2.

COMMENTARY

Background Information

T-A cloning

The surprising finding that *Taq* DNA polymerase adds a single nontemplated nucleotide to the 3' end of double-stranded DNA (Clark, 1988) explains why direct blunt-end cloning of PCR fragments is inefficient. At the same time, it affords a new means of direct cloning. The nontemplated nucleotide is almost always A, so a complementary vector with 3' T overhangs allows the fragments to be cloned unmodified. An added advantage is that inefficient blunt-end ligations are avoided.

Several groups have constructed special vectors for T-A overhang cloning that produce single T 3' overhangs when cut with *XcmI* or *HphI* (e.g., Kovalic et al., 1991). Such vectors, which are commercially available, can be used in the Basic Protocol (starting at step 3), but they do not offer the generality that tailing any blunt-end cut vector can offer. When no dATP is present, *Taq* DNA polymerase will add any of the other bases to the end of a strand (Clark, 1988). Thus *Taq* DNA polymerase can be used to add a single T to a blunt site, allowing PCR fragments to be cloned into any blunt site in any vector (Marchuk et al., 1991). The Basic Protocol is not limited, of course, to PCR frag-

ments, and can be used to transform most blunt-end ligations into sticky-end ligations.

Generation of restriction sites

There are three ways in which restriction sites can be used for cloning PCR fragments. The first and simplest way is to employ natural sites within the target DNA. Depending on the target sequence and the intended application, such natural sites can often be found in suitable positions. The other two ways, detailed below, involve using PCR to change the DNA sequence so as to introduce a new restriction endonuclease site. Any method that changes DNA sequence involves unpaired bases in a primer oligonucleotide and therefore may decrease the specificity of the PCR reaction (see Critical Parameters). Cryptic sites require one to two unpaired bases; half-sites use three, and full sites need eight to ten.

In random DNA, a site for a particular enzyme with a 6-base recognition site is found on average every 4 kb. But a cryptic site with a $5/6$ -base match to the recognition site is found every 170 bases. Some computer DNA-analysis packages (e.g., the Map program, GCG package; *UNIT 7.7*) can find cryptic sites automatically. Because the polylinker in a typical cloning vector has ten or more 6-base sites that generate overhangs, useful cryptic sites can be found frequently. Thus, even in special cases (e.g., when the encoded amino acid sequence cannot be changed), it may well be possible to take advantage of cryptic sites by using site-directed mutagenesis of PCR products. The procedure is based on the protocols in *UNIT 8.5* for introducing point mutations, except that the PCR product is digested and subcloned directly. In designing oligonucleotide primers to change cryptic sites to real sites, three unchanged bases must be left at the 3' end, and at least three bases must be left 5' to the restriction site (see Critical Parameters). The resulting fragments can be easily cloned by following the procedures in *UNIT 3.16*.

Finally, restriction sites may be added directly to the 5' ends of oligonucleotide primers during synthesis. A technique for adding full restriction sites to the ends of fragments is discussed in *UNIT 8.5*. In the protocol for half-site generation (see Alternate Protocol 1), half of a restriction site is added to the 5' end of each primer to be used in the amplification reaction. When the reaction is complete, the products are made blunt-ended by removing the 3' A overhang with Klenow fragment, then kinased and concatemerized by ligation; all of these reac-

tions can be performed conveniently in a single buffer. Ligation generates the complete restriction site at each junction (Kaufman and Evans, 1990). The concatemers can then be cut, yielding the full-length fragment with overhangs.

Advantages of the half-site method include lower expense as well as better quality of shorter oligonucleotides and a smaller loss of specificity caused by extra bases in the primers (see Critical Parameters). The major disadvantage is loss of efficiency caused by the blunt-end ligation step. Advantages of the full-site method include the possibility of directional cloning (using a different restriction site at each end) and the flexibility to use each primer independently; a disadvantage is the inherent loss of specificity that may be prohibitive in critical applications.

Cloning PCR products with UDG

Rapid cloning of PCR products is facilitated by the use of PCR primers containing dU residues and using uracil DNA glycosylase (UDG; Nisson et al., 1991). The incorporation of dU-containing primers into the ends of PCR products and into the ends of the cloning vector results in the selective placement of dUMP residues in place of dTMP at the 5' ends of these molecules. UDG is an important part of the uracil excision pathway in many organisms; it cleaves the N-glycosidic bond between the deoxyribose moiety and uracil in single- and double-stranded DNA. The cleavage reaction results in the formation of abasic sites that destabilize base pairing in double-stranded DNA. Thus, treatment of dU-containing DNA with UDG disrupts base pairing at these sites and generates 3' overhanging ends (Fig. 15.4.3). The plasmid vector is amplified with primers whose ends are complementary to the sequences incorporated into the ends of the product to be cloned. Because the vector has identical tails (noncomplementary with respect to one another), the probability of circularization of vector without insert is extremely unlikely, as is suggested by the extremely low background of nonrecombinant transformants. Furthermore, the use of long (12-base) ends permits formation of relatively stable duplexes between these cohesive tails on insert and vector, thus eliminating the need for an *in vitro* ligation step (Aslandis and de Jong, 1990). Subsequent annealing of the 3' protruding termini of the PCR products to the complementary 3' ends of the vector results in products that can be conveniently transformed directly with high efficiency and without ligation or purification.

This method allows joining of PCR-amplified DNA fragments at virtually any point in the DNA without the need for restriction endonuclease sites. A number of UDG cloning vectors using a variety of dU-containing sequences have been developed recently (Table 15.4.1; Buchman et al., 1992, 1993).

UDG cloning has been utilized for creating novel gene constructs (Booth et al., 1994) and for site-directed mutagenesis (Rashtchian et al., 1992b; Owen et al., 1994). These applications are accomplished simply by designing two overlapping primers in which dU residues have been substituted for T residues in the overlap region. The overlap regions in PCR products amplified with such primers can specifically anneal to each other after excision of dU residues with UDG and be cloned into an appropriate UDG cloning vector. This methodology has provided a convenient and rapid approach for ordered assembly of various PCR fragments to construct recombinant genes (Rashtchian, 1995).

Critical Parameters

An extensive discussion of critical parameters for cloning DNA fragments—with examples of various cloning applications—is found in *UNIT 3.16*. Critical parameters for PCR are discussed in *UNIT 15.1*.

A point to emphasize here is that the specificity of an oligonucleotide primer depends on the number of base pairs needed to form a stable duplex between the primer and the target at the annealing temperature used. When extra bases are added to a primer, they may contribute to the necessary base pairing and thus cause the primer to hybridize in unintended places. In noncritical applications, such as amplification from cloned DNA (*UNIT 8.5*), loss of specificity is inconsequential and bases may be added with impunity. However, in stringent applications such as the use of very short or degenerate primers on genomic DNA or cDNA, extra bases should be added only with great caution. Higher annealing temperatures, up to 65° or 70°C, may help compensate for decreased specificity.

The UDG protocol in this unit requires that all reaction components except *Taq* DNA polymerase be heated 5 min at 94°C before adding *Taq* DNA polymerase; this “hot start” procedure improves the productivity of the reaction.

The secondary PCR primers illustrated in Figure 15.4.3 each contain twelve nucleotides (CAUCAUCAU) at the 5′ end that allow the PCR products to be cloned using uracil DNA glycosylase (Alternate Protocol 2). Only

portions of secondary PCR primers hybridize specifically to the template (for example, 5′-CTGAGGAGTGAATTGGTTCG-3′; and 5′-GTGAACTGCACTGTGACAAGCTGC-3′).

The primers can also be modified to allow PCR products to be cloned by other methods—e.g., by adding nucleotides at 5′ ends to install specific restriction endonuclease sites for cloning.

The significant error rate of *Taq* DNA polymerase should also be kept in mind (see *UNIT 15.1*). It is a good idea to sequence all clones derived from PCR.

Troubleshooting

The vast majority of DNA amplification failures can be attributed to oligonucleotides of incorrect sequence or poor quality. Oligonucleotide sequence can be incorrect because of errors in the target sequence (even in published sequences), in transcription, or in synthesis; the synthesis can fail, yielding no full-length product; or oligos can degrade with time. In cases of persistent failure, oligos should be checked on a gel (*UNIT 2.12*) to see if they are full length, and resynthesized if necessary. Because the percentage of full-length product decreases exponentially with the length of the oligo (*UNIT 2.11*), primers should routinely be made as short as is practical.

For T-A overhang cloning, it is essential that the nontemplated T be added to a high fraction of vector ends; otherwise, the vector will recircularize readily, giving a background of clones without inserts. This underscores the need for transfection controls as detailed in Critical Parameters of *UNIT 3.16*.

For the Basic Protocol and Alternate Protocol 1, vectors encoding the α fragment of *lacZ* are preferred, so that blue/white screening can be done if necessary (*UNIT 1.4*). Each new batch of vector should be tested by setting up parallel ligations containing: (1) gel-purified blunt-ended vector; (2) gel-purified T-tailed vector; and (3) gel-purified T-tailed vector and gel-purified PCR product. Some of each ligation mix should be transformed into an appropriate host strain and plated for blue/white screening. Ligation 1 should yield many colonies, most of them blue. Ligation 2 should yield a much smaller number of colonies, mostly white. The insert in ligation 3 should give a large boost in the number of colonies, which are usually white. A large number of blue colonies from ligation 2 indicates incomplete tailing. If this occurs, the tailing reaction should be repeated using fresh dTTP.

Although PCR products with unphosphorylated ends can be T-A cloned, yield may be improved by starting with 5' phosphorylated oligonucleotide primers (UNIT 3.10) or including 1 U of T4 polynucleotide kinase in the ligation reaction. It is unnecessary, even counterproductive, to dephosphorylate the ends of the vector—the T tails prevent self-ligation.

For UDG cloning, the success of the cloning procedure can be assessed by setting up three sets of parallel transformations containing (1) amplified, UDG-treated insert alone, (2) amplified, UDG-treated vector alone, and (3) amplified UDG-treated mixture of vector and insert. In the first two cases, the background should be extremely low or nonexistent. The third case should yield a substantial number of transformants at a frequency of 10^5 to 10^6 recombinants per microgram DNA, which occur predominantly as white colonies if the *lacZ α* -complementation screening is used.

Additional troubleshooting procedures for cloning and PCR amplification are found in UNITS 3.16 & 15.1.

Anticipated Results

A single small-scale (20 μ l) PCR reaction should yield many clones, most of which should have inserts. For example, in UDG cloning (without screening) approximately 90% to 95% of transformants will carry the appropriate insert. The efficiency of transformation depends on the method used (see UNIT 3.16, Commentary, for guidelines).

Time Considerations

Preparation of vector and insert can be completed in one day except for the half-site method which requires an extra ligation reaction often performed overnight. Ligation of vector to insert is also often performed overnight, and growth of bacterial colonies takes 10 to 12 hr. Until bacterial transformation, the procedure can be safely paused at the end of any step by freezing the sample at -20°C .

Enzymatic Amplification of RNA by PCR (RT-PCR)

UNIT 15.5

This unit describes methods for enzymatic amplification of RNA by the polymerase chain reaction (PCR). The essential method (see Basic Protocol) is especially useful for rare RNAs because all steps (annealing, reverse transcription, and amplification) are performed under optimal conditions, thereby maximizing efficiency and recovery. These are also important considerations when amplifying heterogeneous RNA populations or large RNAs.

In the Basic Protocol, an oligonucleotide primer is coprecipitated with the RNA to maximize the efficiency of their annealing to each other. Following annealing, cDNA is synthesized using reverse transcriptase (RT). Enzymatic amplification of this cDNA is then performed by PCR. Alternate Protocols 1 and 2 provide modifications to save time and effort when the optimal conditions in the Basic Protocol are not required. The Support Protocol describes an easy method for making crude RNA preparations suitable for amplification by PCR.

Investigators may also wish to consider the use of commercially available kits for performing RT-PCR reactions. Several are available which offer advantages of convenience and speed, although at some sacrifice in terms of cost and one's ability to customize the reaction conditions for specific target RNAs.

PCR AMPLIFICATION OF RNA UNDER OPTIMAL CONDITIONS

**BASIC
PROTOCOL**

Materials

- Poly(A)⁺ (UNIT 4.5) or crude RNA (see Support Protocol)
- 25 µg/ml cDNA primer in H₂O
- 3 M sodium acetate, pH 5.5 (APPENDIX 2)
- 100% and 70% ethanol
- 400 mM Tris·Cl, pH 8.3 (APPENDIX 2)
- 400 mM KCl (APPENDIX 2)
- Reverse transcriptase buffer (see recipe)
- 32 U/µl AMV reverse transcriptase (UNIT 3.7; Boehringer-Mannheim)
- 10 mM Tris·Cl/10 mM EDTA, pH 7.5
- Phenol buffered with 10 mM Tris·Cl/10 mM EDTA, pH 7.5 (store at room temperature)
- 24:1 chloroform/isoamyl alcohol (UNIT 2.1A)
- ~150 µg/ml amplification primers in H₂O (~20 µM each)
- 5 mM 4dNTP mix (5 mM each dNTP in H₂O; UNIT 3.4)
- 10× PCR amplification buffer (UNIT 15.1)
- Taq DNA polymerase (UNIT 15.1)
- Mineral oil
- Additional reagents and equipment for PCR, (UNIT 15.1), preparation of poly (A)⁺ RNA (UNIT 4.5), total RNA (UNITS 4.2-4.4), or cytoplasmic RNA (UNIT 4.1), and for agarose or nondenaturing polyacrylamide gel electrophoresis (UNITS 2.5A & 2.7)

NOTE: Reagents and solutions used for RNA procedures should be prepared using standard methods for handling RNA (UNIT 4.1).

**The Polymerase
Chain Reaction**

15.5.1

Anneal the primer to the RNA

1. Coprecipitate RNA and cDNA primer by adding the following ingredients to a microcentrifuge tube:

2 μg poly(A)⁺ RNA
25 ng (3 pmol) cDNA primer
H₂O to 90 μl .

Mix and add 10 μl of 3 M sodium acetate, pH 5.5, and 200 μl of 100% ethanol. Mix and incubate overnight at -20°C or 15 min at -70°C .

This coprecipitation step maximizes the efficiency of annealing. The template source can also be total RNA or crude RNA (see Support Protocol). Less than 2 μg can be used, depending upon the abundance of the RNA within the sample. The cDNA primer is frequently the same as one of the amplification primers (see commentary).

2. Microcentrifuge 15 min at high speed, 4°C , and discard supernatant.
3. Add 200 μl of 70% ethanol and mix gently by inversion. Microcentrifuge 5 min at high speed, room temperature, and discard supernatant. Dry pellet briefly in a desiccator under vacuum or in a Speedvac evaporator.

Do not overdry the pellet or the RNA will not resuspend well.

4. Add the following to the RNA pellet:

12 μl H₂O
4 μl 400 mM Tris·Cl, pH 8.3
4 μl 400 mM KCl.

Heat to 90°C , then cool slowly to 67°C .

This step removes any base-paired regions in the RNA and then allows the RNA and primer to begin to anneal. The best way to heat and cool the sample is to place the microcentrifuge tube in a 400-ml beaker of 90°C water and allow it to cool to 67°C on the benchtop.

5. Microcentrifuge the sample 1 sec to collect the condensate at the bottom of the tube. Incubate 3 hr at 52°C . Microcentrifuge 1 sec to collect condensate.

Perform the centrifugation in this step quickly so the sample does not cool too much. This final annealing temperature can be adjusted according to the base composition of the primer, and increased or decreased depending on the specificity of annealing required (UNIT 6.4).

Synthesize the cDNA

6. Add 29 μl reverse transcriptase buffer and 0.5 μl (16 U) AMV reverse transcriptase. Mix and incubate 1 hr at 42°C .

The temperature can be adjusted from 37° to 55°C if desired. Lower temperatures may be helpful for primers with high A-T base compositions. Higher temperatures may lead to more full-length products by lessening RNA secondary structure.

7. Add 150 μl 10 mM Tris·Cl/10 mM EDTA, pH 7.5, and mix. Add 200 μl buffered phenol and vortex briefly. Microcentrifuge 5 min at high speed, room temperature, and save upper aqueous phase.
8. Add 200 μl of 24:1 chloroform/isoamyl alcohol and vortex briefly. Microcentrifuge 5 min at high speed, room temperature, and save upper aqueous phase.
9. Add 20 μl 3 M sodium acetate, pH 5.5, and 500 μl of 100% ethanol. Mix and precipitate overnight at -20°C or 15 min at -70°C .
10. Microcentrifuge 15 min at high speed, 4°C , and discard supernatant.
11. Dry pellet briefly and resuspend in 40 μl water.

Amplify the cDNA by PCR

12. Mix the following:

- 5 μ l cDNA from step 11
- 5 μ l each amplification primer (~150 μ g/ml or ~20 μ M each)
- 4 μ l 5 mM 4dNTP mix
- 10 μ l 10 \times amplification buffer
- 70.5 μ l H₂O.

Heat 2 min at 94°C. Microcentrifuge 1 sec to collect condensate.

Usually one of the amplification primers is the same as the cDNA primer. If a different amplification primer is used, the cDNA primer should be removed from the cDNA reaction using methods described in UNIT 15.2.

13. Add 0.5 μ l (2.5 U) *Taq* DNA polymerase, mix, and microcentrifuge 1 sec. Overlay with 100 μ l mineral oil.

14. Set up the following automated amplification cycles:

39 cycles:	2 min	55°C
	2 min	72°C
	1 min	94°C
1 cycle:	2 min	55°C
	7 min	72°C.

The number of cycles can be varied depending upon the abundance of the RNA. Forty total cycles is sufficient for rare mRNAs in 2 μ g poly(A)⁺ RNA but more cycles may be necessary if smaller amounts of template are used.

15. Analyze products by electrophoresis in agarose or nondenaturing polyacrylamide gels (UNIT 2.5A & 2.7), choosing a concentration of the gel matrix appropriate for the expected size of the amplification products.

AVOIDING LENGTHY COPRECIPIATION AND ANNEALING STEPS

This Alternate Protocol saves considerable time compared to the Basic Protocol because it eliminates the relatively lengthy coprecipitation and annealing steps. Instead, a quick heating and cooling step is used. Although this reduces the specificity and quantitative efficiency of annealing, the losses incurred are frequently insignificant and should not affect most applications.

Replace steps 1 to 5 of the Basic Protocol with the following:

1. Mix the following:

- 2 μ g poly(A)⁺ RNA
- 25 ng (3 pmol) cDNA primer
- H₂O to 21 μ l.

2. Heat 3 to 15 min at 65°C.

3. Cool on ice and add to reverse transcriptase buffer (see Basic Protocol, step 6).

ALTERNATE PROTOCOL 1

**ALTERNATE
PROTOCOL 2**

INTRODUCING cDNA DIRECTLY INTO THE AMPLIFICATION STEP

This Alternate Protocol saves time by eliminating the extraction and precipitation steps following cDNA synthesis in the Basic Protocol. The products of the cDNA reaction are diluted sufficiently to avoid interference when added to the enzymatic amplification step. This procedure may not be appropriate when the anticipated number of template molecules is small.

Replace steps 7 to 11 of the Basic Protocol with the following:

1. Add 450 μ l of 10 mM Tris·Cl/10 mM EDTA, pH 7.5, to 50 μ l of the reaction mix from step 6 of the Basic Protocol.
2. Add 1 to 5 μ l of the mixture from step 1 of this protocol to the amplification reaction in step 12 of the Basic Protocol.

**SUPPORT
PROTOCOL**

RAPID PREPARATION OF CRUDE RNA

This Support Protocol avoids the need for purifying RNA prior to enzymatic amplification. It is especially useful when many samples are to be analyzed, or when the amount of starting material is small because some of the losses associated with poly(A)⁺ RNA purification are avoided (Higuchi, 1989).

Materials

Phosphate-buffered saline (PBS; *APPENDIX 2*)
Diethylpyrocarbonate (DEPC) solution (see recipe)

CAUTION: DEPC is volatile and toxic and should be handled with precautions. DEPC is also rapidly inactivated in aqueous buffers and in the presence of Tris·Cl, so work quickly.

1. Suspend 10⁶ to 10⁷ cells (or equivalent amount of dispersed tissue) in PBS. Microcentrifuge 5 min and discard supernatant.
2. Resuspend cell pellet in 200 to 400 μ l DEPC solution and vortex briefly.
3. Microcentrifuge nuclei 10 sec and transfer supernatant to a new tube. Incubate 20 min at 37°C, then 10 min at 90°C.
4. Microcentrifuge 5 min to remove precipitate and transfer supernatant to a new tube. Use 5 to 10 μ l directly in step 1 of the Basic Protocol or ethanol precipitate and resuspend (*UNIT 2.1A*). Store frozen.

REAGENTS AND SOLUTIONS

DEPC solution

Dilute diethylpyrocarbonate (DEPC) 1:10 in 100% ethanol. *Immediately* before use, further dilute 1:10 DEPC 1:1000 in lysis buffer (see recipe).

Lysis buffer

140 mM NaCl
10 mM Tris·Cl, pH 8.0 (*APPENDIX 2*)
15 mM MgCl₂
0.5% Nonidet P-40 (NP-40)
Store at room temperature

Reverse transcriptase buffer

Per sample:

2.5 μ l 400 mM Tris·Cl, pH 8.3 (*APPENDIX 2*)

2.5 μ l 400 mM KCl

1 μ l 300 mM MgCl₂

5 μ l 100 mM DTT

5 μ l 5 mM 4dNTP mix

2 μ l 2 mg/ml actinomycin D

11 μ l H₂O

Optional: 10 U RNasin (Promega; reduce volume of H₂O accordingly)

Prepare fresh before each reverse transcription from separate stocks. DTT, dNTP, and actinomycin D stocks should be stored frozen; all other stocks can be stored at room temperature.

COMMENTARY

Background Information

Enzymatic amplification by PCR is well suited for RNA analyses because quantities available for study are frequently limited and often insufficient for more standard methods of analysis. Enzymatic amplification can be used to prepare large amounts of cDNA for subsequent steps, or as an analytical tool to map the structure of RNAs.

RNAs offer additional possibilities relative to DNAs that can readily be exploited: they are relatively small molecules, with discrete 5' and 3' ends, and in many cases the sequence of one or more of the ends is defined. The most obvious example of a defined end is the polyadenylated tail on the 3' end of most (but not all) eukaryotic messenger RNAs. These features can be incorporated in the design of oligonucleotide primers.

Although most commonly used to synthesize quantitative amounts of specific double-stranded cDNAs, amplification of RNA can be utilized as a rapid analytical tool. Both 3' and 5' ends of RNAs can be mapped using internal primers specific for a given transcript, in conjunction with primers specific for 3' ends [oligo(dT)] or 5' ends (common leaders or added primer sites; *UNIT 15.6*; Kapler et al., 1990).

Critical Parameters and Troubleshooting

As discussed in *UNIT 15.1*, several parameters affecting the efficiency and specificity of the amplification process require empirical evaluation. Among these are magnesium concentration, concentration of primers, cyclic annealing temperature, and the number of cycles. Generally, lower primer concentration, fewer cycles, and increased temperature will contribute to

increased specificity.

To confirm amplification of the expected molecules, several methods can be used, such as cleavage with restriction endonucleases or hybridization with an internal oligonucleotide or fragment (*UNIT 15.1*). Hybridization analysis will also increase the sensitivity, allowing detection of amplification products not visualized by ethidium bromide staining.

In planning RNA amplifications, the following points should be considered: (1) method of preparation of the template RNA; (2) design of the specific oligonucleotide primers; (3) synthesis of the first strand of cDNA using the appropriate primer; and (4) enzymatic amplification.

Protocols for many of these steps are discussed in detail in other units as indicated, while parameters specifically relevant to enzymatic amplification of RNA are discussed below.

Source of RNA

Depending upon available quantities, total RNA, cytoplasmic RNA, or poly(A)⁺ RNA can be used. However, because even single molecules can be enzymatically amplified efficiently, dilute crude cellular preparations containing denatured proteins and free RNA can be utilized, as in the Support Protocol.

Design of oligonucleotide primers

Specific oligonucleotide pairs are designed and utilized with many of the same considerations discussed for enzymatic amplification of DNA (*UNIT 15.1*). A point worth emphasizing here is that increased specificity can be gained by using an additional primer internal to that used for cDNA synthesis for PCR. Moreover, reamplification with nested primers can some-

times rescue an RNA amplification that seems to have failed. With RNA, also consider the primers discussed below.

In certain viruses or organisms, many mRNAs contain a common 5' leader sequence. The most extreme example of this is found in trypanosomatid protozoans in which every mRNA contains a common 39-nucleotide leader sequence. These leader sequences can be utilized for priming (Kapler et al., 1990).

Oligo(dT) and enzymatically added primer sites are discussed in *UNIT 15.6*.

Discrimination between RNA and DNA

Given the proclivity of enzymatic amplification to reveal rare molecules, one must consider whether the amplified products arise from RNA or DNA templates. In some cases it is possible to choose primers so that specific amplification products cannot arise from DNA. For example, primers from different exons will yield products of different sizes if DNA or mRNA is used as a template. In other cases, it will not be possible to select such discriminatory primers. Enzymatic treatment of samples with RNase-free DNase, followed by phenol extraction and ethanol precipitation, may be helpful (*UNIT 4.1*).

Anticipated Results

These procedures should allow specific amplification of a defined segment of RNA into double-stranded DNA. The products obtained should be suitable for hybridization analysis, DNA sequencing, or molecular cloning as desired.

Time Considerations

For the Basic Protocol, annealing of the primers requires ~4 hr, cDNA synthesis requires ~3 hr, and enzymatic amplification by

PCR requires ~4 hr. However, the PCR requires little effort from the investigator, because once the reaction mix is assembled, the amplification steps are usually performed by a machine. Alternate Protocol 1 reduces the time required for annealing to 20 min, and the second alternate protocol reduces the time required for cDNA synthesis to 1.5 hr. For all protocols, it is feasible to perform the annealing and extension in a single day, followed by automated amplification overnight.

cDNA Amplification Using One-Sided (Anchored) PCR

Conventional approaches to the characterization and sequencing of mRNA generally rely on the preparation and screening of a cDNA library, and on the subsequent isolation of single cDNA clones from within the library (UNITS 5.5, 5.6 & 5.8A). While this methodology has proven useful overall, success depends critically on the quality of the cDNA library. Frequently, cDNA libraries are vitiated by prematurely terminated cDNA molecules that do not reflect full-length message. In addition, rare messages may frequently be lost altogether in the preparation of cDNA libraries.

The polymerase chain reaction (PCR) offers an opportunity to directly select, amplify, and isolate a message of interest. This protocol presents a modification of PCR, called anchored PCR, that allows amplification of full-length mRNA when only a small amount of sequence information is available. Unlike the amplification of RNA or cDNA by conventional PCR (UNIT 15.4)—which requires prior knowledge of the sequences flanking the region of interest to design the PCR primers—anchored PCR can be employed when only a small region of sequence lying within the mRNA is known in advance.

In theory, only a single specific primer is required to perform anchored PCR. In practice, amplification of a single product requires a second round of PCR amplification, using a second sequence-specific primer. This scheme is depicted in Figures 15.6.1 and 15.6.2. Both the original and reamplifications use an oligo(dT) primer complementary either to the poly(A) tail of the mature mRNA [when amplifying downstream (3') to the known sequence] or to an enzymatically synthesized homopolymer tail added to the cDNA following first strand synthesis [when amplifying upstream (5') to the known sequence]. The two rounds of PCR amplification result in a single product that can be sequenced directly or cloned into an appropriate vector for further analysis.

This unit presents two basic protocols for the amplification of cDNA targets using anchored PCR. The first basic protocol can be used to amplify targets where the downstream (3') sequences are unknown. The second basic protocol permits amplification of target molecules whose upstream (5') sequences are unknown.

AMPLIFICATION OF REGIONS DOWNSTREAM (3') OF KNOWN SEQUENCE

BASIC PROTOCOL

This method can be used to characterize messages of interest from any source of poly(A)⁺ RNA prepared by conventional protocols (UNITS 4.1-4.5). Although the amount of poly(A)⁺ RNA required will depend on the genome complexity of the organism being studied and on the relative abundance of the targeted mRNA, in general 100 to 300 ng of total poly(A)⁺ RNA prepared from vertebrate tissue is sufficient for this procedure. Three PCR primers are required: a 20-mer oligo(dT) primer and two sequence-specific primers, one for the original amplification and the second for the reamplification (see Fig. 15.6.1). The internal sequence-specific primer can be immediately adjacent (3') to or can partially overlap primer 1 at the 3' end.

Materials

- Source of RNA (UNITS 4.1-4.5)
- 5× Moloney murine leukemia virus (MoMLV) reverse transcriptase buffer
- 5 µg/µl bovine serum albumin (BSA)
- 10 mM 4dNTP mix (10 mM each dNTP in TE buffer, pH 7.5, stored at -20°C)
- 500 ng/µl actinomycin D
- 200 U/µl MoMLV reverse transcriptase (Table 3.4.1 & UNIT 3.7)

The Polymerase Chain Reaction

15.6.1

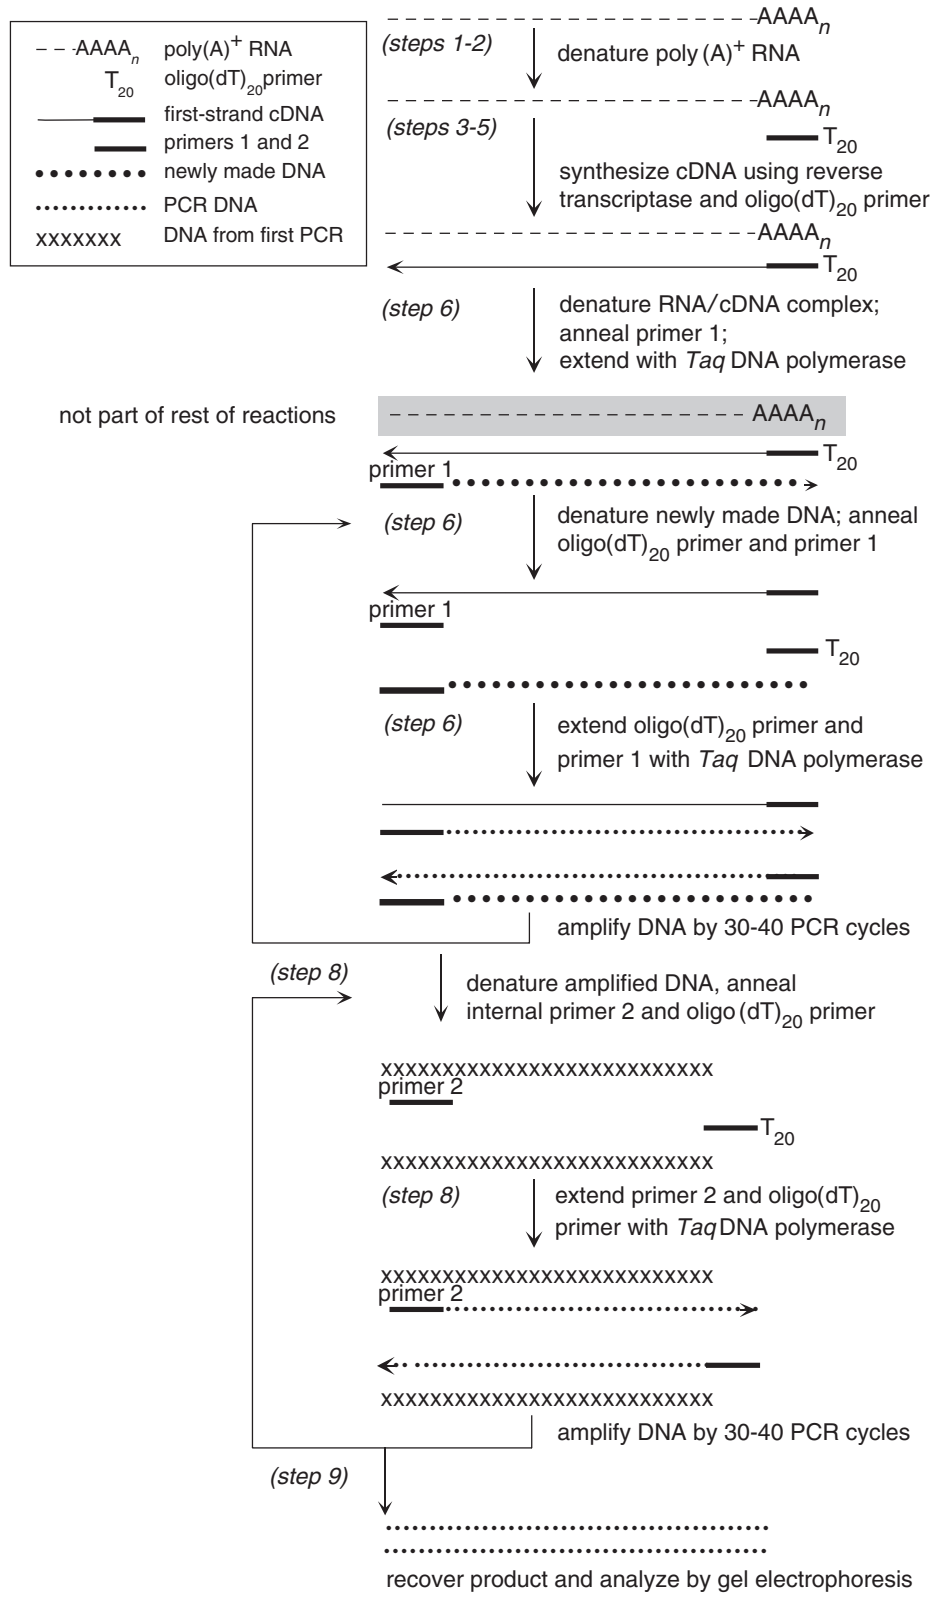

Figure 15.6.1 Flow chart of downstream (3') anchored PCR protocol (see text for details). The steps correspond to those listed in the basic protocol. Note that primer 2 can be immediately adjacent (3') to, or can partially overlap with, primer 1.

cDNA Amplification Using One-Sided (Anchored) PCR

15.6.2

15 pmol/μl (100 ng/μl) oligo(dT)₂₀ primer
100 pmol/μl each of sequence-specific primers 1 and 2 (see Fig. 15.6.1)
TE buffer (APPENDIX 2)
2.5 mM 4dNTP mix (2.5 mM each dNTP in TE buffer, pH 7.5, stored at -20°C)
10× amplification buffer
2.5 U/μl *Taq* DNA polymerase (UNITS 15.1 & 3.5)
Mineral oil

Additional reagents and equipment for preparation of poly(A)⁺ RNA (UNIT 4.1),
PCR amplification (UNIT 15.1), agarose gel electrophoresis (UNIT 2.5), and
Southern blotting and hybridization (UNITS 2.9 & 6.4)

1. Prepare 100 ng poly(A)⁺ RNA at a concentration of ≥100 ng/μl and place in a 1.5-ml microcentrifuge tube.

This high concentration is necessary because the final volume of the reverse transcriptase reaction should be kept as low as possible, preferably ≤10 μl. Larger amounts of poly(A)⁺ RNA (up to 1 μg) can be used if readily available. Amounts below 100 ng may not include the full complement of rare mRNAs.

2. Incubate poly(A)⁺ RNA 2 min at 65°C. Microcentrifuge briefly at room temperature and place immediately on ice.

This incubation melts the secondary structure of the mRNA, removing hairpins and loops that interfere with the synthesis of cDNA.

3. In a clean 1.5-ml microcentrifuge tube, prepare the following reverse transcriptase reaction mix on ice (10 μl total):

2 μl 5× MoMLV reverse transcriptase buffer
1 μl (5 μg) BSA
1 μl poly(A)⁺ RNA (from step 2)
1 μl 10 mM 4dNTP mix
1 μl (500 ng) actinomycin D
1 μl (15 pmol) oligo(dT)₂₀ primer
2 μl sterile H₂O
1 μl MoMLV reverse transcriptase.

4. Mix gently, microcentrifuge briefly at room temperature and incubate 1 hr at 37°C.

This results in synthesis of cDNA.

5. Add 40 μl TE buffer to bring the total reaction volume up to 50 μl.

6. Prepare the following PCR reaction mix on ice (100 μl final):

1 μl cDNA template (from step 5)
10 μl 10× amplification buffer
1 μl (100 pmol) oligo(dT)₂₀ primer
1 μl (100 pmol) sequence-specific primer 1
6 μl 2.5 mM 4dNTP mix
80 μl sterile H₂O
1 μl (2.5 U) *Taq* DNA polymerase.

Overlay reaction mixture with mineral oil. Carry out 30 to 40 cycles of amplification (UNIT 15.1).

Initially, amplifications should be carried out in the presence of 1.5 mM MgCl₂ (final concentration), with annealing temperatures not exceeding 42°C. These conditions can be subsequently modified and optimized for the specific template used (UNIT 15.1). Primer

concentrations can be reduced to 30 pmol of each primer without reducing the efficiency of amplification.

7. Analyze an aliquot by agarose gel electrophoresis.

The result of this first PCR is usually a smear around the expected size range, because specificity is seldom conferred by a single sequence-specific primer. The presence of the desired product can be confirmed by hybridizing a Southern blot (UNITS 2.9 & 6.4) of the gel containing the PCR products to the sequence-specific primer 2 internal to the amplified sequence.

8. Remove a 1- μ l aliquot of the amplification product from step 6 to serve as the template for reamplification. Carry out a second round of PCR as described in step 6, using 40 to 100 pmol each of the oligo(dT)₂₀ primer and the internal sequence-specific primer 2.

Although 100 pmol of each primer are usually added in conventional PCR amplifications, lower concentrations of primer do not appear to reduce amplification efficiency or yield, and may reduce the cost of this procedure.

9. Analyze an aliquot of the second amplification by agarose gel electrophoresis. The amplified product should now appear as a single band on an agarose gel.

10. If desired, characterize the amplification product by cloning into an appropriate vector (UNIT 3.16) or by direct sequencing (UNIT 15.2).

**BASIC
PROTOCOL**

AMPLIFICATION OF REGIONS UPSTREAM (5') OF KNOWN SEQUENCE

In contrast to the first protocol, this procedure uses one of the sequence-specific primers to initiate the synthesis of the cDNA strand. This cDNA is modified by the addition of a poly(A) tail. PCR amplifications—mediated by two sequence-specific primers and a 20-mer oligo(dT) primer complementary to the newly synthesized tail—yield the desired unique product (Fig. 15.6.2).

Materials

- Source of RNA (UNITS 4.1-4.5)
- 100 pmol/ μ l sequence-specific primers 3 and 4 (Fig. 15.6.2)
- 15 pmol/ μ l (~100 ng/ μ l) oligo(dT)₂₀ primer
- 1 M NaCl
- 200 mM Tris·Cl, pH 7.5 (APPENDIX 2)
- 25 mM EDTA
- 100% and 70% ethanol, ice-cold
- 5 \times Moloney murine leukemia virus (MoMLV) reverse transcriptase buffer
- 5 μ g/ μ l bovine serum albumin (BSA)
- 10 mM 4dNTP mix (10 mM each dNTP in TE buffer, pH 7.5, stored at -20°C)
- 500 ng/ μ l actinomycin D
- 200 U/ μ l MoMLV reverse transcriptase (Table 3.4.1 & UNIT 3.7)
- 3 M sodium acetate (APPENDIX 2)
- TE buffer, pH 7.5 (APPENDIX 2)
- 5 \times terminal deoxynucleotidyltransferase (TdT) buffer
- 15 mM CoCl₂
- 1 mM dATP (UNIT 3.4)
- Terminal transferase (Table 3.4.1 & UNIT 3.6)
- 40°C water bath

Additional reagents and equipment for preparation of poly(A)⁺ RNA (UNIT 4.5), phenol extraction (UNIT 2.1), and PCR amplification (UNIT 15.1)

**cDNA
Amplification
Using One-Sided
(Anchored) PCR**

15.6.4

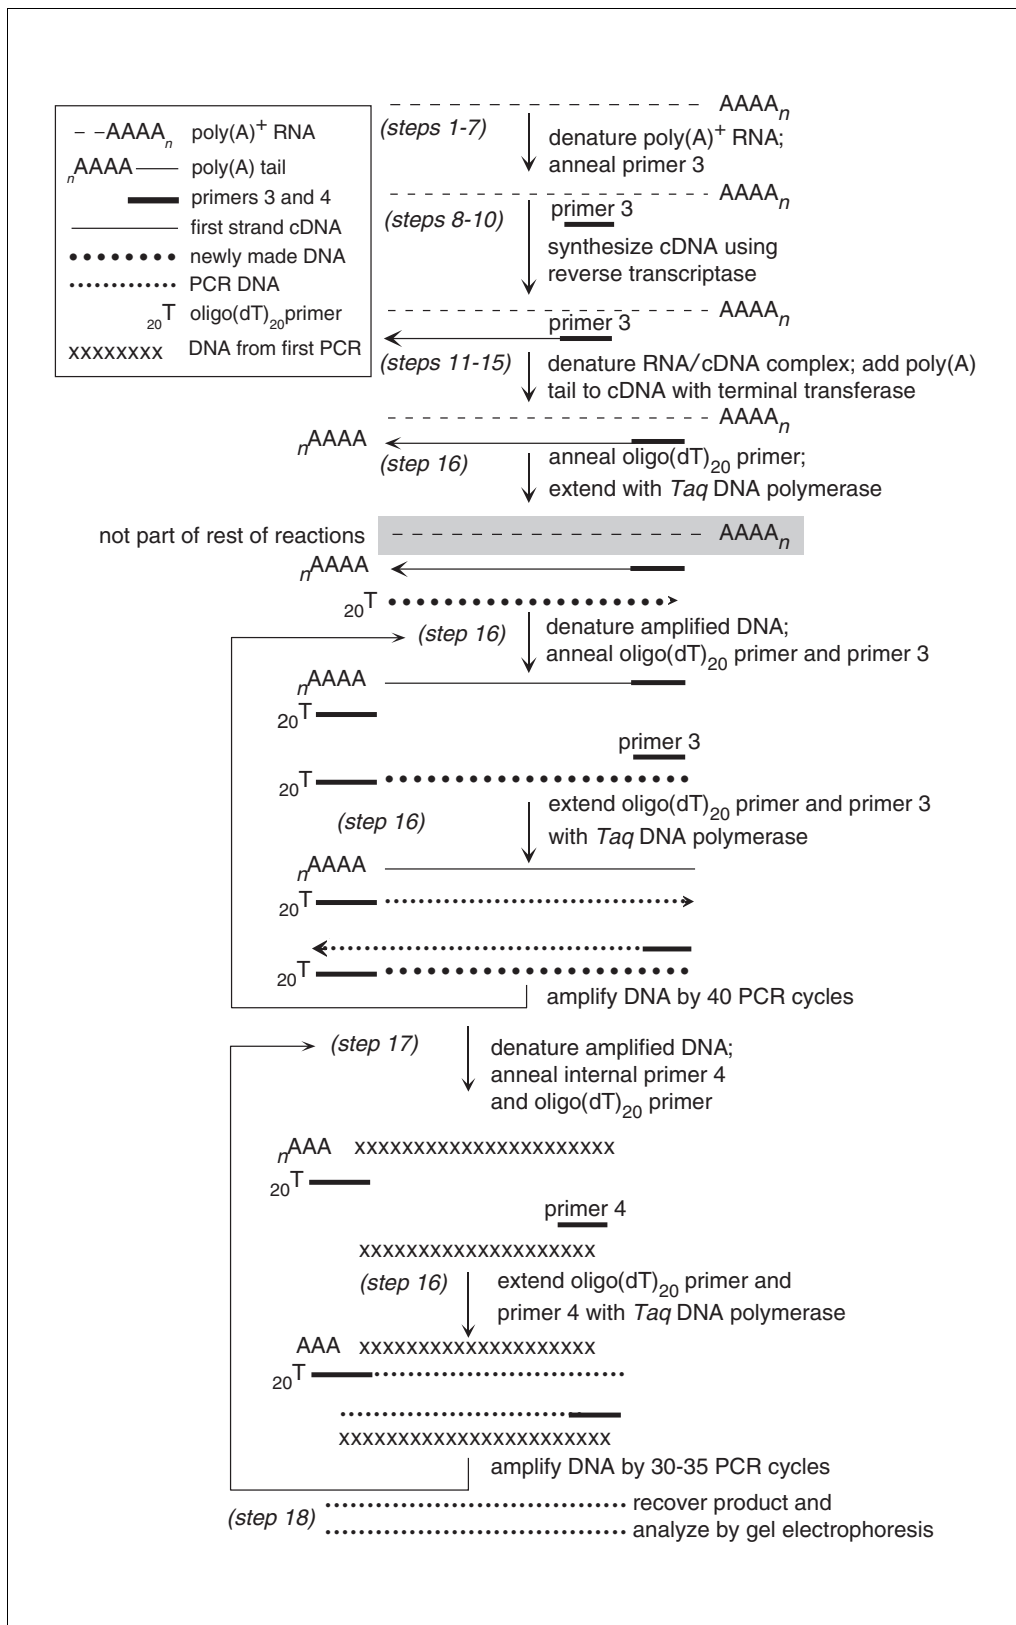

Figure 15.6.2 Flow chart of upstream (5') anchored PCR protocol (see text for details). The steps correspond to those listed in the protocol. Note that primer 4 can be immediately adjacent to, or can partially overlap with, primer 3.

Prepare RNA and anneal sequence-specific primer

1. Prepare 100 ng of poly(A)⁺ RNA at a concentration of 100 ng/μl.
2. Prepare a 5-μl annealing mix containing:
 - 1 μl (1 fmol) sequence-specific primer 3
 - 1 μl 1 M NaCl
 - 1 μl 200 mM Tris·Cl, pH 7.5
 - 1 μl 25 mM EDTA
 - 1 μl (100 ng) poly(A)⁺ RNA (from step 1).

Amount of primer to use for sequence-specific cDNA synthesis depends in part on the abundance of target mRNA. As a rule, a 5- to 10-fold molar excess of oligomer primer relative to target template yields the best results. Note that small amount of primer boosts specificity of targeted cDNA synthesis. Primer 3 should be diluted with water or 0.1× TE buffer, pH 7.5, to reach the desired concentration.

3. Incubate annealing mix 3 min at 65°C, microcentrifuge briefly at room temperature, and place immediately on ice for 2 min.

This incubation melts the secondary structure of the mRNA, removing hairpins and loops that interfere with the synthesis of cDNA. “Snap-cooling” on ice prevents the secondary structure from re-forming.

4. Incubate 3 to 4 hr at 40°C.

The long incubation time and low primer concentration increase the specificity of the primer-template annealing.

5. Add 15 μl ice-cold 100% ethanol, place in dry ice/ethanol bath for 10 min, and microcentrifuge 10 min at high speed, 4°C.
6. Decant supernatant. Add 50 μl ice-cold 70% ethanol and gently invert tube several times to rinse and desalt the pellet (do not vortex). Microcentrifuge 2 min at room temperature, remove supernatant, and dry briefly under vacuum.
7. Resuspend pellet in 10 μl water.

Synthesize first-strand cDNA

8. On ice, prepare reverse transcriptase mix containing (25 μl total):
 - 5 μl 5× MoMLV reverse transcriptase buffer
 - 2.5 μl (12.5 μg) BSA
 - 2.5 μl 10 mM 4dNTP mix
 - 2.5 μl (1.25 μg) actinomycin D
 - 10 μl annealed primer/template (from step 7)
 - 1.5 μl sterile H₂O
 - 1 μl (200 U) MoMLV reverse transcriptase.

Incubate 1 hr at 37°C.

9. Phenol extract the sample. Carefully transfer supernatant to new microcentrifuge tube. Add 2.5 μl of 3 M sodium acetate (0.3 M final) and 75 μl ice-cold 100% ethanol. Place 5 min in dry ice/ethanol bath, then microcentrifuge 20 min at high speed, 4°C. Discard supernatant.

In cases where small amounts of poly(A)⁺ RNA are being used, 1 to 5 μg carrier tRNA (UNIT 4.6) may be added at this step to facilitate the precipitation.

10. Resuspend pellet in 25 μl of TE buffer, pH 7.5. Add 2.5 μl of 3 M sodium acetate (0.3 M final) and repeat the ethanol precipitation as described in step 9, discarding supernatant after spin.

11. Add 100 μ l ice-cold 70% ethanol to pellet and rinse by gently inverting tube several times (do not vortex). Microcentrifuge 5 min at high speed, room temperature; discard supernatant, and dry pellet briefly under vacuum.
12. Resuspend pellet in 5 μ l water and boil 2 min. Microcentrifuge briefly at room temperature and place immediately on ice.

This step denatures the cDNA/RNA hybrid molecules prior to tailing the cDNA molecule with terminal transferase.

Add poly(A) tail to cDNA

13. On ice prepare terminal transferase mix in order listed below (10 μ l final):

2 μ l 5 \times TdT buffer
1 μ l 15 mM CoCl₂ (1.5 mM final)
1 μ l 1 mM dATP (100 μ mol final)
5 μ l cDNA mix (from step 12)
1 μ l (25 U) terminal transferase.

Incubate 30 min at 37°C.

14. Inactivate enzyme by heating 2 min at 65°C.
15. Add 1 μ l of 3 M sodium acetate. Ethanol precipitate, wash and dry pellet as described in step 10.

Amplify by PCR and analyze results

16. Resuspend pellet in 10 μ l water. Carry out 40 amplification cycles as in step 6 of the first basic protocol, using 40 to 100 pmol each of sequence-specific primer 3 and oligo(dT)₂₀.

Although 100 pmol of each primer are usually added in conventional PCR amplifications, lower concentrations of primer do not appear to reduce amplification efficiency or yield, and may reduce the cost of this procedure.

Initially, amplifications should be carried out in the presence of 1.5 mM MgCl₂ (final), with annealing temperatures not exceeding 42°C. These conditions can be subsequently modified and optimized for the specific template used (UNIT 15.1).

The products of this round of PCR will not be visualized by ethidium bromide staining of an agarose gel, but can be seen when a Southern blot of the gel is hybridized to sequence-specific primer 4 internal to the amplified region.

17. Remove a 1- μ l aliquot of the amplification product of step 16 to serve as template for a new round of PCR amplification. Carry out 35 cycles of PCR as in step 6 of the first basic protocol, using 40 to 100 pmol each of primer 4 and the oligo(dT) primer.

Primer 4 can be immediately adjacent to, or partially overlapping with, primer 3. Because the anchored PCR procedures are carried out independently in the 3' and 5' directions, sequence-specific primers 3 and 4 can be the complements of primers 1 and 2 used in the previous protocol (see Fig. 15.6.2).

18. Analyze a 10- μ l aliquot by agarose gel electrophoresis.

The amplified product, stretching from the target site of the sequence-specific primer 4 to the 5' end of the cDNA, should now appear as a single band on an agarose gel.

19. If desired, characterize the PCR product by cloning into an appropriate vector (UNIT 3.16) and/or by direct sequencing (UNIT 15.2).

REAGENTS AND SOLUTIONS

5× MoMLV reverse transcriptase buffer

250 mM Tris·Cl, pH 8.3
375 mM KCl
50 mM DTT
15 mM MgCl₂
Store at −20°C for ≤3 months

10× amplification buffer

500 mM KCl
100 mM Tris·Cl, pH 8.8
15 mM MgCl₂
30 mM DTT
1 mg/ml BSA
Store at −20°C for ≤3 months

5× terminal transferase (TdT) buffer

1 M potassium cacodylate
125 mM Tris·Cl, pH 7.4
1.25 μg/μl BSA
Store at −20°C for ≤6 weeks

COMMENTARY

Background Information

The advent of PCR has spawned a number of procedures that do not require full knowledge of the sequence being amplified (Frohman et al., 1988; Ochman et al., 1988; Loh et al., 1989; Mueller and Wold, 1989; Ohara et al., 1989; Tam et al., 1989), and that assume only a small region of sequence is known. In many of these methods, the PCR amplifications are anchored by a primer derived from the region of known sequence; the second primer is non-specific and is targeted to a general feature of the sequence, such as the poly(A) tail present on most mature mRNAs. Alternatively, the target sequence can be enzymatically modified to provide an annealing site for the second primer. Such modifications include the addition (via terminal transferase) of a homopolymeric tail (UNIT 3.6) or the ligation of a sequence “splint” at the end of the target molecule (UNIT 15.5).

The protocols presented here are specifically designed for the amplification of full-length cDNA when only a fragment of the cDNA sequence is known. The amplification into the unknown downstream (3′) region capitalizes on the poly(A) tail present on most mRNAs. It therefore will not succeed with poly(A)[−] mRNAs, such as those encoding histones. The region of interest is amplified by annealing the oligo(dT) primer to this poly(A) tail and the sequence-specific primer to the

appropriate known region of the cDNA.

Amplification into the unknown upstream (5′) region makes use of an artificial poly(A) tail that is enzymatically added to the 3′ end of an initial, specific cDNA product. In theory, then, upstream and downstream amplifications can succeed with any mRNA for which sufficient sequence to design a single sequence-specific oligonucleotide is known.

In practice, however, a single sequence-specific primer does not always confer sufficient selectivity in the amplification, and the primer may bind to inappropriate or partially complementary sequences, resulting in the amplification of more than one sequence. This problem is further compounded in situations where the only sequence available at the outset comes from the partial sequencing of the protein produced by the mRNA of interest, or from the identification of conserved regions in homologous mRNAs extracted from other organisms. Such cases require the use of degenerate sequence-specific primers, further reducing the specificity of the anchored PCR amplifications. The consequences of using degenerate primers will depend on the template being amplified, the degree of degeneracy, and the amplification conditions. The use of nondegenerate sequence-specific primers is strongly recommended for the protocols described here (Ohara et al., 1989).

Critical Parameters and Troubleshooting

As with any method for the analysis of mRNA, the success of these protocols depends on the quality and integrity of the mRNA being used. Appropriate precautions to ensure high yield of intact mRNA are detailed in Chapter 4 (see introduction to that chapter). Although these protocols can be performed using untreated microcentrifuge tubes and pipet tips, several steps involve single-stranded nucleic acids (mRNA, first-strand cDNA) and the use of silanized microcentrifuge tubes and pipet tips (APPENDIX 3) may be desirable.

It is important to keep in mind that the initial stages of anchored PCR will seldom result in a fully specific amplification, and the amplification products will most often appear as a smear when visualized on an agarose gel. The PCR products produced by this protocol should be monitored by Southern blot hybridization to a target-specific internal oligomer. Such monitoring confirms that the desired product is in fact being amplified in the initial phases of the protocols.

A number of steps may be taken to increase the target specificity of anchored PCR. As described in these protocols, a reamplification carried out using a second internal (nested) sequence-specific primer greatly reduces spurious amplification products. This second primer can lie immediately adjacent to the first specific primer or can partially overlap at the 3' end. Thus, 40 to 50 nucleotides of known sequence are sufficient to fully anchor this two-step procedure.

A second problem that may interfere with the production of a single, distinct PCR product stems from the length of either the naturally occurring or the enzymatically synthesized poly(A) tail. A long poly(A) tail provides a large number of potential pairing sites for the nonspecific oligo(dT) primer. The resultant PCR products may consequently be of variable length.

The difficulties that stem from the variable length of the homopolymeric tails can be partially resolved by synthesizing an oligo(dT) primer with an additional specific sequence at the 5' end, as is done in the race amplification of cDNA ends (RACE) protocol (Frohman et al., 1988). Subsequent reamplifications will then rely on a primer directed to this synthetic sequence. Alternatively, the oligo(dT) primer can be synthesized with a degenerate (A,G,C) 3'-most position, resulting in more precise an-

nealing at the poly(A) tail boundary of the mRNA.

Finally, specificity increases if the first-round amplification products are size-selected by extracting an aliquot of the main PCR band within the smear (or of the "correct" target band, previously determined by Southern hybridization with an internal specific oligomer). The selected products can serve as templates for a second round of PCR amplification. Thus, the first-round products are run out on a low gelling/melting agarose gel (UNIT 2.6), and the desired target is size selected by piercing the appropriate band on the gel with a Pasteur pipet. This small gel core sample can then be placed directly into a new PCR mix and reamplified without further purification.

The products of this second amplification may still appear as a smear when visualized by ethidium bromide staining of an agarose gel (see commentary, UNIT 15.1). This smear results from the multiple positions that the oligo(dT)₂₀ primer can occupy along the length of the poly(A) tail. In such cases, select a small aliquot of product at the upper range of the smear and reamplify with 20 to 25 PCR cycles using the oligo(dT)₂₀ and internal primers (primers 2 or 4).

We have found that certain DNA targets cannot be efficiently amplified using standard PCR conditions. In such cases, low-yield PCR products can be readily cloned into an appropriate vector (Holton and Graham, 1991; Marchuck et al., 1991) and subsequently screened by colony hybridization (UNIT 6.2) to isolate the appropriate clones. Given the relatively high error rate of *Taq* polymerase (UNITS 3.5 & 15.1), sequences obtained from cloned PCR fragments should be confirmed by isolating and sequencing multiple clones.

Time Considerations

With the mRNA already in hand, each of the basic protocols will require 1.5 to 2 days to complete. Upstream and downstream anchored PCR can be carried out synchronously.

**BASIC
PROTOCOL**

This unit presents a protocol that uses the polymerase chain reaction (PCR) to quantitate the numbers of a particular DNA sequence from 1 to 20,000 molecules per sample. In addition, it helps assess the presence of contaminating sequences, the bane of this kind of procedure.

The DNA of interest is prepared and its concentration is determined. A known amount of this DNA is then mixed with two sets of oligonucleotide primers, one set specific for the DNA of interest (e.g., a virus) and the other set specific for an internal control (e.g., a single-copy gene encoded by the host organism). The sequences between the primers are amplified, electrophoresed on a gel, transferred to a filter, and probed with oligonucleotides specific for each amplified product. The amounts of the amplified products from the DNA of interest can then be quantitated by comparison to the internal control. For simplicity, the protocol is written in terms of quantitating viral DNA molecules relative to host cellular sequences; however, it can be adapted readily for other applications.

NOTE: Use molecular biology-grade water solutions (DNase-free, RNase-free, nucleic acid free).

Materials

- Proteinase digestion buffer (see recipe)
- 20 mg/ml proteinase K (store at -20°C)
- Phenol buffered with 50 mM Tris-Cl/10 mM EDTA, pH 7.4 (store at room temperature)
- 24:1 chloroform/isoamyl alcohol (UNIT 2.1A)
- 10 M ammonium acetate (APPENDIX 2)
- Cold 100% ethanol
- 70% ethanol
- TE buffer, pH 7.5 (APPENDIX 2)
- Reaction mix cocktail (see recipe)
- Mineral oil
- 0.8 U/ μl *Taq* DNA polymerase (UNIT 15.1)
- Oligonucleotide primers for hybridization (see recipe)
- Screw-cap microcentrifuge tubes, autoclaved
- Microcapillary pipets *or* positive displacement pipets with disposable tips and plungers *or* micropipettors with barrier tips
- Additional reagents and equipment for PCR (UNIT 15.1), tissue sample preparation (UNIT 2.2), agarose and nondenaturing polyacrylamide gel electrophoresis (UNITS 2.5A & 2.7), ethidium bromide dot quantitation (UNIT 2.6), Southern blotting or electroblotting (UNIT 2.9A), labeling oligonucleotides (UNITS 3.10, 4.6, & 4.8), hybridizing blots with oligonucleotides (UNITS 2.9 & 6.4), UV cross-linking DNA to filters (UNIT 2.9), and autoradiography (APPENDIX 3A)

NOTE: Use sterile, distilled water to prepare all reagents. Do NOT use diethylpyrocarbonate (DEPC) to treat reagents. To avoid contamination with unwanted nucleic acids, prepare reagents and solutions solely for use in this protocol (see Critical Parameters and Troubleshooting). Wear disposable gloves and change them frequently.

Prepare the DNA

1. Place cells or tissue sample in a screw-cap microcentrifuge tube. Add ~ 100 μl proteinase digestion buffer per $\sim 2 \times 10^6$ cells and 20 mg/ml proteinase K to 100 $\mu\text{g}/\text{ml}$. Incubate sample overnight at 50°C .

**The Polymerase
Chain Reaction**

15.7.1

Supplement 56

This is a modification of the protocol in UNIT 2.2. It is best to process samples in the order of increasing likelihood of their containing the sequences of interest. Perform the extractions away from where products of the amplification reactions (PCR products) or large quantities of plasmid DNA are handled. Wear disposable gloves and change them frequently.

Always include several negative control samples that contain no viral sequences. Take care not to contaminate cells or tissue samples with unwanted DNA sequences.

2. Mix sample gently up and down with a 200- μ l microcapillary pipet. Add 100 μ l buffered phenol to digestion mixture, mix gently, add 100 μ l of 24:1 chloroform/isoamyl alcohol, and mix gently.

The initial mixing shears the DNA very slightly, allowing for more efficient extraction. The gentle extraction maintains the DNA as high-molecular-weight molecules. This aids in estimating its concentration but is less important if mere detection is desired.

Screw-cap microcentrifuge tubes and microcapillary pipets minimize aerosol contamination which commonly results from microcentrifuges and automatic pipettors. To prepare microcapillary pipets, autoclave on dry cycle or bake in a 200°C oven overnight. Dedicate a single bulb for each reagent used. Positive displacement pipets with disposable tips and plungers are a more expensive, but easier-to-use alternative to microcapillary pipets.

3. Microcentrifuge 5 min at high speed, room temperature, and transfer aqueous phase (which contains DNA) to a new microcentrifuge tube.

Even with the use of screw-cap microcentrifuge tubes, avoid using a microcentrifuge that has been used for PCR products or large amounts of plasmid DNA.

4. Back-extract organic phase with proteinase digestion buffer (\sim 1/2 original volume).
5. Microcentrifuge 5 min at high speed, room temperature, and add aqueous phase to aqueous phase from step 3.
6. Extract aqueous phase twice with an equal volume of 24:1 chloroform/isoamyl alcohol, centrifuging 5 min at high speed, room temperature, each time to separate the phases.
7. Add 10 M ammonium acetate to 2.5 M (final) in the last aqueous phase and mix gently. Add 2.5 vol cold 100% ethanol and mix gently. Place on crushed dry ice 30 min. Microcentrifuge 15 min at high speed, 4°C, to pellet DNA, and pour off supernatant.

The use of ammonium acetate during ethanol precipitation is critical for subsequent efficient amplification. DNA precipitated from sodium acetate does not amplify as well, but can be improved by reprecipitation with ethanol from 2.5 M ammonium acetate.

8. Wash DNA pellet with 1 ml of 70% ethanol by inverting the tube several times. Microcentrifuge 15 min, pour off supernatant, and dry pellet in a desiccator under vacuum or in a Speedvac evaporator.

Avoid using a desiccator or evaporator that has been used for PCR products or large amounts of plasmid DNA.

9. Resuspend pellet in TE buffer, pH 7.5 (100 μ l for a sample prepared from 2×10^6 cells). Store DNA at 4°C.

The final DNA concentration should be 5 to 100 ng/ μ l. It may take several hours or overnight before the DNA is totally dissolved.

10. Estimate DNA concentration either by running an aliquot on an agarose gel alongside known amounts of standard DNA or more rapidly by ethidium bromide dot quantitation.

This step is important because the subsequent quantitation will be less accurate if $\geq 1 \mu\text{g}$ or $\leq 10 \text{ ng}$ DNA is assayed. Estimating the amount of DNA on a gel has the advantage over ethidium bromide dot quantitation in that it assesses how intact the DNA is. The extra precautions outlined above will diminish yield somewhat.

Amplify the DNA by PCR

11. Prepare one tube containing 110 ng, one tube containing 90 ng, and several tubes each containing 100 ng DNA from uninfected cells or tissue. Use these tubes to make a set of 10-fold serial dilutions of the sequence of interest as follows: Add a known amount (e.g., 20,000 molecules) of DNA containing the sequence of interest to the tube containing 110 ng DNA and mix. Then add one-tenth of this material to a tube containing 100 ng DNA and mix. Add one-tenth of this material to a new tube containing 100 ng of DNA and mix. Repeat several more times until a tube contains ≤ 10 molecules of the sequence of interest. Then add one-tenth of the material from that tube to the tube containing 90 ng of DNA. The final total volume of each tube should be $\leq 71 \mu\text{l}$.

To compare with samples from a mouse infected with a virus, prepare the first tube so there is one copy of viral DNA per mouse cell equivalent in 100 ng of DNA from an uninfected mouse, which is $\sim 20,000$ molecules of viral DNA. Make serial dilutions to yield samples with 0.1, 0.01, 0.001 (etc.) copy per cell equivalent. As a control, prepare a sample containing 100 ng uninfected cell DNA without added viral sequences.

12. For each amplification reaction, prepare a PCR tube containing 24 μl reaction mix cocktail and enough sterile distilled water for a final volume of 100 μl (after addition of DNA and *Taq* DNA polymerase, steps 13 and 15). Mix and overlay each reaction with 2 drops ($\sim 100 \mu\text{l}$) mineral oil, to completely cover the surface of the reaction mixture.

*Overlaying with oil at this step rather than after adding *Taq* DNA polymerase helps minimize contamination because everything is assembled before adding the experimental samples. There is also less chance of contaminating the oil with DNA.*

13. Open only those tubes that will contain equivalent samples (e.g., duplicate samples or samples from animals infected with the same virus inoculum). Add 100 ng sample DNA to each appropriate tube and close the tubes. Microcentrifuge briefly to mix.

Begin with the no-virus control (e.g., 100 ng mouse DNA) followed by other negative controls (include at least two other negative controls). Proceed in order of increasing likelihood that a sample will contain viral sequences of interest, adding serial dilution tubes last. Adding samples in this order lessens the likelihood that aerosols of more concentrated samples will contaminate less concentrated samples.

14. Heat-denature the samples 1 min at 94°C, either in a water bath or in an automated cycler.
15. Open tubes (containing equivalent samples) and add 5 μl of 0.8 U/ μl *Taq* DNA polymerase to each tube. Close tubes and repeat steps 13 to 15 with the next set of equivalent samples.

*Denaturing before adding the *Taq* DNA polymerase puts the polymerase through one less cycle at high temperature.*

16. Microcentrifuge tubes briefly. Cycle tubes one time for 2 min at 55°C (reannealing) and 3 min at 72°C (extension).

The microcentrifuge spin mixes in the polymerase. This step completes the cycle started by the heat denaturation in step 14.

17. Carry out PCR (UNIT 15.1) according to the following program:

29 cycles:	1 min	94°C	(denaturation)
	1 min	55°C	(annealing)
	1 min	72°C	(extension)
1 cycle:	7 min	72°C	(extension)

Store completed reactions at 4°C.

Analyze the PCR products

- Electrophorese product aliquots on an appropriate agarose or polyacrylamide gel (UNIT 2.5A & 2.7). Include lanes with DNA molecular weight markers that will be visible both upon ethidium bromide staining and by autoradiography.

One-tenth of the reaction should be sufficient for detection of the amplified host sequences by ethidium bromide staining and for detection of the amplification products of single molecules following hybridization. Do not use markers that are so radioactive that they will obliterate other lanes during autoradiography.

- Stain and photograph the gel.

The DNA fragment corresponding to the PCR product from the host DNA should be readily visible following ethidium bromide staining and will serve as a measure of the efficiency of each amplification reaction. Don't be surprised to see a number of other bands, especially of higher molecular weights, which are nonspecific PCR products. However, if the reaction has been optimized (UNIT 15.1), the specific PCR product should predominate. Check for specificity by restriction endonuclease digestion (if the product contains a site) or by hybridization with an internal oligonucleotide as described below.

If the PCR reaction is robust and yields a single product, sometimes staining with dyes such as SYBR Gold rather than with ethidium bromide can provide sufficient sensitivity and the bands can be quantitated using fluorimetric equipment. If not, proceed to steps 20 to 22.

- Transfer gel to a nitrocellulose or nylon filter (UNIT 2.9A). If desired, UV cross-link DNA to filter.

Choice of filter and transfer method is an individual preference; however, electroblotting from acrylamide gels to nylon filters followed by UV cross-linking (UNIT 2.9) has proven to be a quantitative method for transferring and retaining small DNA fragments on filters during multiple cycles of hybridization, stripping, and reprobing.

- Prehybridize the filter and hybridize with end-labeled oligonucleotide specific for the sequence of interest. Analyze by autoradiography (APPENDIX 3A) or phosphorimager.

If each reaction is amplified with similar efficiency (which can be assessed from the ethidium bromide-stained gel), the dilution series should give a monotonically decreasing signal of one predominant band with increasing dilution. It should be possible to detect a signal from dilutions containing only one or a few molecules. There should be no signal from the negative controls. A reasonable estimate for the number of molecules of the sequence of interest in each sample can be obtained by comparison with the dilution series, assuming that each reaction amplified with similar efficiency.

- For more quantitative analysis, strip the filter of the previous probe by boiling in water 15 min (if necessary) and hybridize with a probe specific for the host single-copy sequence. Quantitate the signals by densitometric scanning (following the densitometer manufacturer's instructions) and compute a standard curve from the dilution series, normalizing to the host sequence signals. Determine the number of molecules in the experimental samples by interpolation from the standard curve.

The standard curve will ideally give a linear relationship between the log of the autoradiographic signal and the log of the amount of DNA. However, it may not necessarily be completely linear, and it is unlikely to have a slope of 1. At the high end (0.1 to 1 copy per cell equivalent), it may plateau. If this is a problem, it may be necessary to reduce the number of amplification cycles or vary other parameters (see UNIT 15.1).

REAGENTS AND SOLUTIONS

Oligonucleotide primers for amplification

One pair each for each target sequence. Prepare each primer at 50 pmol/ μ l in sterile, distilled water. Store at -20°C .

Oligonucleotide primers for hybridization

One for each target sequence at 50 pmol/ μ l in sterile, distilled water. Store at -20°C .

Proteinase digestion buffer

20 mM Tris·Cl, pH 7.4 (prepared from autoclaved, 1 M stock; *APPENDIX 2*)

20 mM EDTA, pH 8 (prepared from autoclaved, 0.5 M stock; *APPENDIX 2*)

0.5% sodium dodecyl sulfate (SDS)

Store at room temperature

Reaction mix cocktail (per amplification reaction)

10 μ l 10 \times PCR amplification buffer (*UNIT 15.1*)

10 μ l 2 mM 4dNTP mix (*UNIT 15.1*)

1 μ l each oligonucleotide primer for amplification (4 μ l total; see recipe above)

COMMENTARY

Background Information

PCR technology provides the most sensitive methods for detecting nucleic acids. These methods have proven exceedingly useful in the detection of infectious agents in experimental and clinical settings (Kwok et al., 1987) and in analyses of unusual and precious small samples of tissue, such as those from extinct animals (Paabo, 1989). They also have considerable potential for forensic applications (von Beroldingen et al., 1989). Most initial efforts to utilize the sensitivity of PCR were geared to issues of detection. For example, Saiki et al. (1988) showed that they could detect single target sequences (a b-globin gene) in 10^5 to 10^6 cells. Similarly, procedures for amplification of DNA from single cells exist (Li et al., 1988). However, these procedures were not designed to quantitate amounts of target sequence in different samples.

The Basic Protocol presented here to quantitate rare DNAs was developed to measure the amount of herpes simplex virus (HSV) DNA in the ganglia of mice infected with various HSV mutants. Initial efforts used slot-blot hybridization, but failed to detect viral sequences reliably below 0.01 to 0.1 copy of HSV DNA per mouse cell equivalent (Leib et al., 1989). For this reason, a number of parameters in the basic PCR protocol (*UNIT 15.1*) were varied to keep the replication machinery in excess to the number of templates (see Critical Parameters and Troubleshooting). Using this approach, it has been possible to quantitate HSV DNA over a 10^4 -fold range, from a few molecules per 100 ng ganglion DNA from mice infected with mu-

tants with serious growth impairments to tens of thousands of molecules in ganglion DNA from mice infected with wild-type virus (Katz et al., 1990). This approach should be pertinent to numerous other applications where small amounts of nucleic acid need to be detected and quantitated, including diagnostics and forensics. In fact, similar assays have been developed to quantitate nucleic acids encoded by human retroviruses (Arrigo et al., 1989; Pang et al., 1990) and to measure cytokine mRNA and DNA (Gilliland et al., 1990).

Critical Parameters and Troubleshooting

All parameters that are critical in the basic PCR protocol (*UNIT 15.1*) are also critical here. Several additional points particular to this protocol bear emphasis.

Optimization

The PCR must be optimized to the particular set of templates and primers and to the lot of *Taq* DNA polymerase used, following the guidelines in *UNIT 15.1*. Begin optimization with a reconstructed mixture of DNA, such as viral DNA mixed with host DNA at fairly high copy number, where both products can be visualized by ethidium bromide staining (e.g., 1 copy per cell equivalent).

DNA

The amount of added DNA is critical for achieving a quantitative assay. Too much DNA will saturate the replication machinery, not

only in terms of specific products generated, but also nonspecific products. In the protocol presented above, 100 ng of DNA are used per 100 µl reaction. Test a dilution series of the sequence of interest mixed with the endogenous sequences (e.g., various copies of viral DNA per host cell equivalent) at various amounts of total sample DNA to see how much sample DNA will allow a monotonically increasing signal with increasing amounts of the sequence of interest. In addition, impurities in DNA preparations can interfere with PCR; additional organic extractions and/or ethanol precipitations in the presence of ammonium acetate may help.

Internal control

A set of primers to yield an internal control sequence is critical for two major reasons. First, if no signal from the sequence of interest is obtained in a given sample, the internal control will verify whether this is a true or a false negative. It is not uncommon for amplifications to fail, especially since some experimental samples contain contaminants that interfere with PCR. Second, the internal control allows for quantitation, since it normalizes for several factors including variation in the amount of sample DNA, efficiency of amplification, and the amount loaded on the gel. The internal control PCR product should be different enough in size to be resolved easily from the PCR product of interest, but close enough in size so there is no concern about differences in transfer efficiency due to size differences. It should also be clearly distinguished in size from an artifactual “primer-dimer” product (see UNIT 15.1).

In the protocol described here, the internal control product is derived from endogenous cellular sequences. For some applications, this would not be appropriate or practical. An alternative is to spike the samples with a known amount of a foreign sequence and to include primers specific for this DNA in the amplification reaction. This would control for the efficiency of the reaction and certain other factors, but not for variation in the amount of sample DNA.

DNA polymerase

The amount of *Taq* DNA polymerase added per reaction is critical in achieving a quantitative assay. The protocol outlined above uses more polymerase than the Basic Protocol in UNIT 15.1 to insure that the replication machinery is in excess of the number of templates. How-

ever, because *Taq* DNA polymerase is not the cheapest reagent, and because too much of this enzyme is actually inhibitory, vary the amounts of polymerase to determine an amount that permits a quantitative assay without bankrupting the laboratory.

Contamination

It is critical in any procedure that can detect only a few molecules to be absolutely scrupulous in avoiding contamination from exogenous nucleic acids. This protocol explicitly states several precautions one can take to avoid contamination. They are summarized below in order of importance.

Never prepare DNA or PCR reagents or assemble PCRs in the same place that is used to handle large amounts of plasmid DNAs or PCR products. PCR products are the worst possible contaminants because they give rise to more of themselves faster than normal DNA. If possible, perform the two different procedures in different rooms, avoiding even the presence of PCR products in the room where DNA is prepared or PCRs are assembled. In addition, try preparing DNA and PCR reagents and assembling PCRs in a laminar flow hood equipped with a UV light to inactivate contaminating DNA.

If possible, use only sterile disposable plasticware for preparing and storing reagents. If glassware must be used, try to ensure that it has not been contaminated with plasmid or genomic DNAs.

Most pipetting devices can be readily contaminated by the aerosols that they produce. This protocol was originally developed using sterile disposable microcapillary pipets with a separate bulb for each reagent and sample type. This degree of caution may be extreme. A more expensive, but more convenient, alternative may be to use positive displacement pipetting devices with disposable tip and plunger, but even then, be sure not to use the same device for handling PCR products. The least expensive, most convenient approach is to use disposable tips with barriers and a standard micropipettor to minimize aerosol contamination.

Reagents should be sterile whenever possible and stored as small aliquots.

Wear disposable gloves and change them frequently during preparation of DNA and assembly of PCR.

Be careful of static electricity and avoid aerosols from opening tubes. As outlined in the protocol above, keep all tubes closed except those receiving sample DNA. If possible, pre-

pare only equivalent DNA samples at the same time. The use of screw-cap tubes can be helpful. It may also be useful to dedicate a microcentrifuge solely to PCR assembly.

As stated in the protocol, it is critical to include a sufficient number of negative controls (≥ 3) including a zero-copy reconstruction, which can help assess reagent contamination, as well as controls for DNA preparation, such as samples from mock-infected animals.

If contamination by plasmid DNAs or PCR products is suspected, it can be confirmed or ruled out using appropriately chosen sets of primers.

Aside from PCR products and plasmid DNAs, be suspicious of other sources of contamination, including various pieces of lab apparatus that come into contact with large amounts of target sequence. This extends to tools used to extract tissue specimens. In addition, contamination from the investigator should be avoided. Some have found that wearing a mask and hair covering is helpful. Paranoia can be a positive character trait in this situation.

Several investigators have used nucleases or UV light to inactivate contaminants in solutions. These methods can be useful but have their limitations, especially if the contaminating DNA is short and thus represents a small target.

The quantitative protocol described here can be helpful in assessing contamination because unlike nonquantitative assays, it can give an estimate of the level of contamination. Even if negative controls yield positive signals, if they are much lower than those in experimental samples it provides at least tentative assurance that the experimental signals are real.

Transfer and cross-linking

It is very important that PCR products be transferred and retained completely to ensure a quantitative assay. If the products are electrophoresed on acrylamide, the electroblotting and UV-cross-linking protocols in *UNIT 2.9* provide methods that have proven successful in this regard.

An alternative approach to transfer and hybridization is to use PCR primers prelabeled to high-specific activity with polynucleotide kinase. The products can then be quantitated by direct autoradiography of the gel (Arrigo et al., 1989; Pang et al., 1990). Potential disadvantages of this approach are that it adds steps where contamination can be introduced and detects more nonspecific products.

Anticipated Results

Results are obtained at different stages of the protocol. The DNA preparation should yield relatively intact and pure DNA, but due to the precautions described, yields may not be as high as ordinarily obtained.

After the PCR products are electrophoresed on a gel, ethidium bromide staining should reveal an easily visible band corresponding to the internal control product in every product lane. A visible band corresponding to the experimental product of interest should appear in the lane containing the 1-copy-per-cell-equivalent reconstruction and in any lanes that contain similar amounts of the sequence of interest. Because the sequences of interest are relatively nonabundant, a variety of nonspecific products may be seen as well.

After hybridization to the sequence of interest and autoradiography, the expected results are labeled bands of the appropriate size at monotonically decreasing intensities in the reconstructed dilution series, no bands in the negative controls at that size, and bands with varying intensities in the experimental samples. Depending on the probe and the stringency of the hybridization and wash conditions, nonspecific sticking of the probe to the abundant internal control product may be seen. It is also common to see minor specific PCR products of slightly greater or lower mobility than the major specific product, especially at high copy number.

Time Considerations

The time to prepare DNA is mainly occupied by the proteinase K digestion, which usually runs overnight. Therefore, it is usually possible to start the procedure one afternoon and complete the manipulations by noon the next day. It may take somewhat longer for the DNA to dissolve completely.

Assembling the amplification reactions requires only a couple hours or less, depending on the number of samples. Thirty cycles of denaturation, annealing, and extension require ~4 hr in a good automated cycler; slightly less if done by hand with three water baths. With an automated cycler, the gel can be poured during the cycling.

Running the gel only requires a few hours or an overnight run. Staining, destaining, and photographing requires 1 to 2 hr, electroblotting ≥ 3 hr, and prehybridization and hybridization a few hours to overnight. When everything is optimal, the PCR signal from one or a few molecules can be visualized in an overnight

exposure. Thus, from the point of acquiring a sample to autoradiographic signal is usually 4 normal working days.

High-Throughput Real-Time Quantitative Reverse Transcription PCR

This unit describes the use of real-time quantitative PCR (QPCR) for high-throughput analysis of RNA expression. The topics covered include: design and validation of QPCR primers and probes for both SYBR Green- and TaqMan-based assays (see Support Protocol); the standard curve method (see Basic Protocol 1); an efficiency-corrected ΔC_t (cycle time, also called cycle threshold or crossing point) method (see Basic Protocol 2); and the comparative cycle time, or $\Delta\Delta C_t$ method (see Alternate Protocol). While the unit describes the use of the Applied Biosystems 7900HT (high-throughput, 384-well) instrument, the protocols may be utilized for any real-time PCR instrument. The high-throughput design allows analysis of the levels of transcript from a number of genes of interest (GOIs) at one time by using the appropriate primer set for each gene. (Within this unit, the term GOI will refer to the actual gene of interest as well as its RNA product or cDNA copy.)

Because of the simplicity of the mathematical application, the standard curve method (Basic Protocol 1) is the most basic and straightforward QPCR assay described in the unit. In this method, standard curves are constructed for all of the GOIs from which RNA expression is being measured, and linear regression analysis is applied to interpolate arbitrary unknown sample values. The standard curve assay may be performed even if the PCR amplification efficiencies of the primer sets (as determined by the template dilution assay in the Support Protocol) are not equal, since correction for unequal efficiencies is intrinsic to the linear regression formula. One drawback of the standard curve method is that standard curves must be run for each of the primer sets on an assay plate. This results in less space on the plate for the unknown samples, and requires the use of additional reagents. This use of resources is particularly excessive when the PCR amplification efficiencies of the primer sets have been determined to be 100% and relative fold-change is the preferred outcome of the measurements. In such cases, the $\Delta\Delta C_t$ method (see Alternate Protocol) should be employed instead. Another limitation is that unless the levels of all of the GOIs in the cDNAs used to construct the standard curves are known, the relative concentration of one GOI cannot be compared to that of another GOI. If comparison between the levels of different GOIs (without the knowledge of the relative level of the transcripts in the standards) is desired, the efficiency-corrected ΔC_t method (see Basic Protocol 2) should be applied.

The efficiency-corrected ΔC_t method builds upon the standard curve method by incorporating PCR efficiency (E) into the quantity calculations. The standard curve slopes are used to calculate PCR efficiency according to the relationship $E = 10^{(-1/\text{slope})}$. The efficiency has a maximum value of 2 for perfect doubling of the PCR template (see Basic Protocol 2 for an in-depth explanation of E). Note that in this method the standard curve is used only to determine slope and not to interpolate the RNA values of the unknown samples. The efficiency correction is then applied to determine the relative amount of RNA using the measured C_t values for the test samples, and is particularly important when comparing the levels of different RNAs whose standard-curve slopes deviate from each other by greater than ± 0.1 . This application is useful for comparing the expression profiles of many different RNAs, e.g., those belonging to gene families or related biological pathways. The sample-space and reagent-use limitations mentioned for the standard curve method also apply here.

The $\Delta\Delta C_t$ method is the method of choice when the desired output is "fold-change," because standards are not necessary, thus saving both reagents and space on the reaction plate. However, this method requires that the amplification efficiencies of the primer/probe sets be 100%. If the amplification efficiencies are suboptimal, but the primers generate a single product as determined by melting curve analysis (Support Protocol), Basic Protocol 1 should be used to determine fold-changes.

Chapter 4 describes the isolation of RNA from several sources and *UNIT 15.5* details the traditional procedure for reverse transcription of RNA into complementary DNA (cDNA). For QPCR, it is recommended that total RNA be resuspended in diethylpyrocarbonate (DEPC)-treated water or an equivalent nuclease-free buffer that does not contain EDTA. The RNA should be treated with DNase and then reverse transcribed using 0.08 $\mu\text{g}/\mu\text{l}$ (final concentration) random hexamer or nonamer primers. Purified messenger RNA—i.e., poly(A)⁺ RNA (*UNIT 4.5*) or RNA that has been reverse transcribed using oligo(dT) or gene-specific reverse primers—may also be successfully used in the assay. See Commentary for more detailed information.

Following the assay, the resulting raw data are analyzed using second-party software, usually Microsoft Excel or equivalent. The data analyses are dependent on the type of assay performed, and are outlined in detail as part of each protocol.

NOTE: General precautions for working with RNA are described in *UNIT 4.1* and other Chapter 4 units, and general precautions necessary for PCR are described in *UNIT 15.1*. In particular, the use of molecular-biology-grade water, RNase/DNase/nucleic acid-free tubes, aerosol-barrier pipet tips, and dedicated pipettors of all types (i.e., pipettors used only for RNA or PCR applications, which are kept out of areas used for plasmid or genomic DNA work) is strongly recommended for all steps in this unit. If dedicated pipettors are not available, the available pipettors should be thoroughly cleaned to remove nucleases and potential contaminants such as plasmid or genomic DNA. In addition, the use of gloves is required, since even a small amount of any contaminant can greatly impact the results of the assay.

STRATEGIC PLANNING

To begin performing a QPCR assay, design and validation of the appropriate primers and probes must first be completed (refer to Support Protocol). Second, the appropriate assay is selected based on the goal of the experiment and the desired data output (refer to Basic Protocols 1 and 2, and the Alternative Protocol, for guidelines used in making this determination). The chosen assay is then performed and the data are analyzed.

STANDARD CURVE METHOD

The standard curve method is used for determining the level of a gene of interest (GOI) relative to an endogenous reference RNA, and for calculating relative fold-changes of a GOI between experimental samples. The assay is useful for determining an "expression profile" of a single GOI within a group of samples. A dilution series of standard cDNA samples is constructed for the GOI and reference gene, and linear regression analysis is applied. The formulas resulting from the standard curves are used to interpolate the GOI and reference-gene quantities in the unknown samples. An endogenous reference gene, often a housekeeping gene, is used as a control to normalize the amount of input template for each sample (see Commentary for parameters used in choosing the appropriate reference gene). The data are expressed as "normalized RNA level" in arbitrary units. The type of nucleic acid standard chosen depends upon the nature of the unknown samples and is discussed in the Commentary.

BASIC PROTOCOL 1

High-Throughput Real-Time Quantitative Reverse Transcription PCR

15.8.2

The standard curve assay does not require that the amount of the GOI or reference RNA in the standards be known. It depends on the linear regression formula produced by plotting the C_t versus the log nanogram (log ng) of input standard total RNA. It should be noted that cDNA concentrations are not typically determined following reverse transcription of the RNA. Here, quantity refers to total RNA input prior to reverse transcription. The standard curve–plotting function is available in most instrument software. If it is not, graphing software may be used instead. Since the input ng values refer to the input amount of total RNA, and not to a known amount of target molecules, the numbers generated are simply arbitrary and may not be compared with the numbers calculated for a different GOI. If comparison of the relative RNA levels between different RNA targets is desired, refer to the efficiency-corrected ΔC_t method (Basic Protocol 2). The standard curve method should be used instead of the $\Delta\Delta C_t$ method (Alternate Protocol) to find fold-changes between samples when the amplification efficiencies of the primer sets are not 100% as determined by the template dilution assay (Support Protocol).

Materials

- 20 ng/ μ l experimental cDNA samples (concentration based on RNA input for cDNA synthesis; see *UNIT 15.5*)
- Dilution series of standard cDNAs (see recipe)
- No-template control sample (NTC; prepared at the same time as the cDNA samples using molecular-biology-grade water instead of RNA; see Commentary)
- No-reverse-transcriptase control samples (–RT; prepared at the same time as the cDNA samples using molecular-biology-grade water instead of reverse transcriptase; see Commentary)
- 2 \times SYBR Green or TaqMan mix containing ROX (Applied Biosystems, Bio-Rad, Invitrogen, Sigma, *or* see recipe for 2 \times SYBR Green mix)
- Primer mixes, 1.25 μ M each forward and reverse primer (see recipe and Support Protocol), for each reference gene and GOI to be tested
- 5 μ M TaqMan probe (for TaqMan protocol only; see recipe and Support Protocol)
- Molecular-biology-grade water (nucleic acid and nuclease free)
- 8-tube PCR tube strips (optional, but recommended; can be of low quality since they will only be used for mixing reaction components; ISC Bioexpress)
- 96-well PCR tube racks (optional, but recommended; ISC Bioexpress)
- Digital multichannel pipettor, 8- or 12-channel, 5- to 100- μ l capacity (recommended)
- Centrifuge with swinging-bucket rotor and microtiter plate carriers
- 384-well optical reaction plates (Applied Biosystems)
- Optical adhesive covers (Applied Biosystems)
- Real-time thermal cycler: e.g., Applied Biosystems 7900HT
- Microsoft Excel or spreadsheet program with equivalent statistical features

Set up plates

1. Plan the plate arrangement according to the number of samples and primer sets to be assayed (reference gene plus GOIs). For each primer set, include the standards, the NTC, and the –RT control as part of the sample group. See Figure 15.8.1 for an example of a typical plate setup.

All steps may be performed at room temperature if a vendor-supplied SYBR Green or TaqMan mix is used. Most vendor-supplied 2 \times mixes are stable at room temperature for a number of hours.

If the instrument is equipped with a plate-loading robotic arm, several plates may be prepared at once and stacked into the robotic arm queue. Alternatively, plates may be made several days in advance and stored at 4°C until ready to run, without a decline in the performance of the PCR enzyme. Advance preparation of plates is not recommended if SYBR Green or TaqMan mixes are prepared in the laboratory, since the home-made

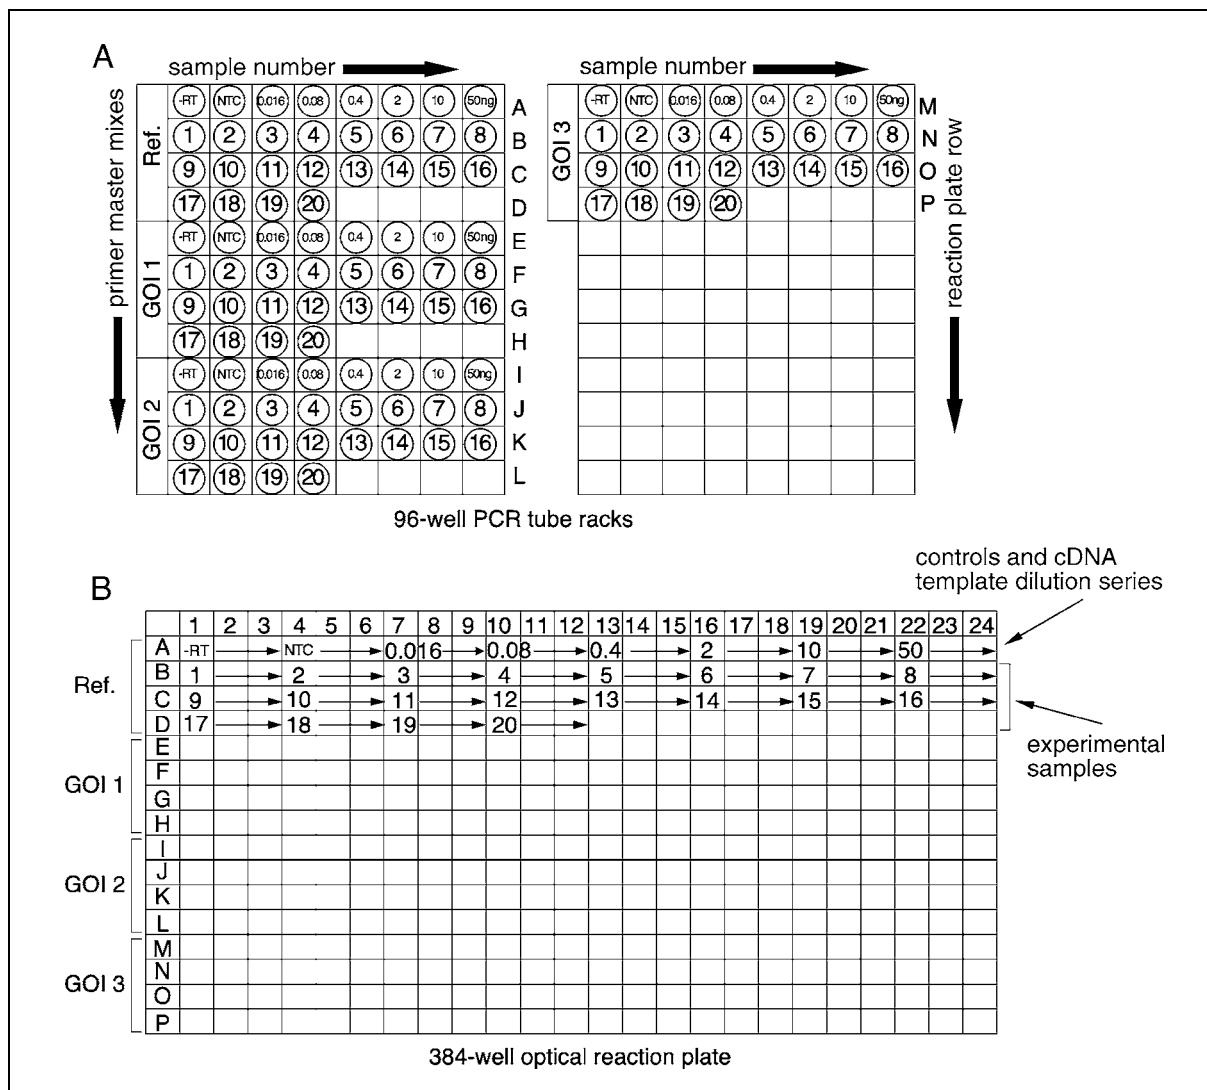

Figure 15.8.1 Typical plate setup for the standard curve and efficiency-corrected ΔC_t assays. **(A)** Organization of PCR tube strips on a 96-well PCR rack when preparing for any QPCR assay. It is advisable to premix the cDNA templates with the primer master mixes in tube strips before putting them into the reaction plate. This practice decreases the variability between replicate wells. A typical cDNA/primer mix setup is shown in relation to the final 384-well reaction plate **(B)**. The plate arrangement shown represents an experiment in which 20 samples taken from experimental animals will be assayed for levels of one endogenous control RNA and three GOIs. The samples are plated in triplicate for each of the RNAs assayed, and a standard curve is required for each of the RNAs to be measured (the row before the unknown samples contains the standard samples, whose amounts are shown in ng total RNA). Abbreviations: GOI, gene of interest; NTC, no-template control; Ref, endogenous control gene; -RT, no-reverse-transcriptase control.

mixes lack additives present in the commercial mixes that confer stability to the reaction components.

2. Prepare primer master mixes according to Table 15.8.1, but without template cDNA.

This can be done in advance, and the tubes may be put on ice or stored at 4°C for a few hours before preparing the reaction plate.

The authors always use the same mixes because this greatly increases the high-throughput nature of the assay. Keeping the mixes constant allows not only universal mix conditions but universal cycling conditions. If the initial primer set does not perform well, new primers are designed (also see Support Protocol).

Table 15.8.1 Master Mixes for the Standard Curve and Efficiency-Corrected Δ Ct Assays

Components	Final concentration	Volume per well	Volume for each cDNA/primer mix (per sample in triplicate + 1 extra)	Master mix (no. of samples + 8 standards ^a + 1 extra)
<i>SYBR Green assay</i>				
2× SYBR Green mix	1×	5 μ l	20 μ l	
1:1 primer mix (1.25 μ M each)	150 nM each primer	1.2 μ l	4.8 μ l	
Template cDNA	10-25 ng ^b	1.25 μ l	5 μ l	—
H ₂ O	N/A	to 10 μ l	to 40 μ l	
Total volume		10 μ l	40 μ l	Aliquot 35 μ l into each tube containing cDNA
<i>TaqMan assay</i>				
2× TaqMan mix	1×	5 μ l	20 μ l	
1:1 primer mix (1.25 μ M each)	300 nM each primer	2.4 μ l	9.6 μ l	
5 μ M TaqMan probe	250 nM	0.5 μ l	2.0 μ l	
Template cDNA	10-25 ng ^b	1.25 μ l	5 μ l	—
H ₂ O	N/A	to 10 μ l	to 40 μ l	
Total volume		10 μ l	40 μ l	Aliquot 35 μ l into each tube containing cDNA

^aFor this assay, the no-template control (NTC) and no-reverse-transcriptase (–RT) control are included as part of the standard sample set.

^bRecommended amount of template for detection of both high and low levels of GOIs. If necessary, significantly less template may be used (picograms). Note that the cDNA template quantity is based upon the amount of total RNA input into the reverse transcription reaction.

- Place the appropriate number of 8-tube PCR strips into a 96-well PCR tube rack (see Fig. 15.8.1A). For convenience, use a different color tube strip for each different primer master mix that has been prepared. Label the side of each strip with the letter of the row of the reaction plate into which the samples will be placed.

Alternatively, cDNA/primer mixes may be made in 0.65-ml microcentrifuge tubes or 0.2- or 0.5-ml PCR tubes.

The cDNA may be put directly into the optical reaction plates followed by the primer master mix. However, this is not recommended because it introduces a potential source of experimental error, since the assay replicates are not premixed, but pipetted individually. The end result may be lower assay precision.

- Using a multichannel pipettor, put 5 μ l of cDNA (experimental samples, standards, and controls) into the bottom of the appropriate tubes in the strips.
- Being careful not to touch the cDNA inside the tubes, use a multichannel pipettor to place a 35- μ l aliquot of the appropriate primer master mix into each tube.
- Cover the entire rack of tube strips with Parafilm and gently vortex to mix. Gently tap or briefly centrifuge the PCR tube racks (2 to 3 min at 1700 \times g, 4°C or room temperature, in a swinging-bucket rotor with microtiter plate carriers) to get contents to the bottoms of the tubes.

- Using a multichannel pipettor, dispense 10 μ l of each cDNA/primer mix into the appropriate three wells of the optical reaction plate to generate each sample in triplicate (as planned in step 1; see Fig. 15.8.1B).

If the multichannel pipettor has 8- or 12-channel dispensing capability, the triplicates can be dispensed at the same time for different rows. Note that due to the spacing between rows of a 384-well reaction plate, every other row can be added at once (i.e., A, C, E, G, I, K, M, O, and then B, D, F, H, J, L, N, P), thus greatly minimizing the pipetting time.

- Cover the plate with the optical adhesive cover and then briefly centrifuge the plate as above to get contents to the bottoms of the wells.

Perform real-time PCR

- For real-time PCR:* Transfer the plate to the real-time thermal cycler and run real-time PCR using the following program (consult the instrument manual for specific instructions):

1 cycle:	10 min	95°C (activates the hot-start <i>Taq</i> DNA polymerase)
40 cycles:	15 sec	95°C (collect data throughout)
	1 min	60°C (collect data throughout).

- For melting (dissociation) curve analysis (for use with SYBR Green only):* Add these steps following the 40 cycles of the thermal cycling program.

15 sec	95°C
15 sec	60°C (collect data)
Increase from 60° to 95°C at a 2% temperature ramping rate (collect data)	
15 sec	95°C (collect data).

See Support Protocol for a description of the use of melting curve analyses.

Analyze data

- Analyze and export raw data (see instrument manual for detailed instructions about document setup, baseline, and threshold settings).

Some instrument software applications contain a standard curve plotting feature. If this function is not available, use Excel or another graphing program to plot C_t versus the log nanograms (ng) of input total RNA for each standard, and apply a best-fit line to generate the linear regression formula $y = mx + b$, where y is C_t of the unknown sample, m is the slope, x is the quantity of the unknown sample (in log ng), and b is the y intercept for both the reference gene and each GOI. Interpolate the unknown sample quantities using the resulting formulas.

The transformation of the fluorescence signal into C_t data, as well as methods for baseline and threshold settings, vary by instrument. The specific instrument manual should be consulted.

In analyzing the raw data, it is important to adjust the cycle threshold (C_t) of the amplification plot to within the geometric phase of amplification. This is critical for proper analysis because the geometric phase represents the point of the reaction at which C_t is quantitatively related to the amount of initial PCR template. Note that a C_t decrease of 1 unit represents a two-fold increase in initial PCR template.

It is also important that the coefficient of determination, or R^2 -value, for the linear regression formula be 0.99. If the R^2 value is less than 0.99, this suggests that one or more points of the standard curve are deviating significantly from the best-fit line. In this case, the accuracy of the data obtained from the linear regression formula of this standard curve may be compromised. The R^2 value will never be above 0.99.

- Import data into Microsoft Excel or equivalent spreadsheet program with statistical features.

12. For each of the three replicates of a sample, calculate the average quantity (avg) of target cDNA interpolated from the standard curve, the standard deviation of the average (stdev), and the coefficient of variation (CV) according to the formula $CV = \text{stdev}/\text{avg}$.
13. Remove any outlier points (>17% CV). After removing the outlier point, recalculate avg, stdev, and CV.

Only one point per replicate may be removed.

A 17% CV correlates with the maximum allowable standard deviation that can distinguish a two-fold change with 99% confidence when samples are assayed in triplicate wells for both the endogenous reference and the GOI. If a 95% confidence interval is acceptable, a 21.8% CV may be used as the threshold for removing outliers. On the other hand, the Q-test (a test for rejection of discordant data) may be used to determine outlier points. Refer to Shoemaker et al. (1974) for a more in-depth description of this test.

14. For each sample, normalize the GOI quantity to that of the reference gene for the sample according to Equation 15.8.1. Use the recalculated values if outlier points were removed in step 13.

$$\text{normalized value} = \frac{\text{avg GOI quantity}}{\text{avg reference quantity}}$$

Equation 15.8.1

15. Calculate the standard deviation of the normalized value (SD) according to Equation 15.8.2.

$$SD = (\text{normalized value}) \times \sqrt{(\text{CV of reference})^2 + (\text{CV of GOI})^2}$$

Equation 15.8.2

16. Plot the resulting values as a bar graph of normalized value versus sample name or experimental treatment group, with the error bars equal to the SD.
17. If desired, calculate fold-changes between samples by choosing a calibrator sample (usually vehicle-treated or wild-type control) and dividing all of the normalized values from step 14 and the SD calculated in step 15 by the normalized value of this calibrator.

The resulting values are then expressed as fold-changes relative to the calibrator sample, which should now be equal to 1.

EFFICIENCY-CORRECTED ΔC_t METHOD

The efficiency-corrected ΔC_t method is used for determining the relative amounts of different GOIs that are normalized to an endogenous reference RNA. It may also be used to determine fold-changes of a specific RNA between samples, but may be excessive if the desired output is only fold-change (see Basic Protocol 1 or Alternate Protocol). Data obtained from the efficiency-corrected ΔC_t method are expressed as "normalized RNA level" in arbitrary units, and the calculated levels may be compared to those of other GOIs when the same threshold setting and assay chemistry are used (i.e., SYBR Green or TaqMan chemistry). It should be noted that an assumption is made that the reverse transcription efficiency is equal for all RNA transcripts in a single sample and for the same transcript between samples. In some cases, this may not be true (see Pfaffl, 2004, for further discussion); therefore, it is recommended that the RNA extraction method

**BASIC
PROTOCOL 2**

**The Polymerase
Chain Reaction**

15.8.7

remain the same for all samples, and that all samples under study be reverse transcribed at the same time with the same reaction buffer.

The basis of quantitative PCR lies in the principle that for every additional thermocycle, a two-fold increase of template-specific product occurs. Several factors affect whether a change in one cycle truly represents a two-fold growth in product, in other words, whether the reaction is 100% efficient. To assess the reaction's efficiency, linear regression analysis is applied to a standard cDNA dilution series, just as in Basic Protocol 1. The slope of the resulting standard curve is used as a measure of PCR efficiency (E) according to the equation $E = 10^{(-1/\text{slope})}$. Note that different GOIs may produce different E values.

A slope of -3.3 produces an E value of 2, indicating that a perfect doubling of the template has occurred. Calculated E values of less than 2 imply that the template has not been perfectly doubled. Template, primer, and probe quality and quantity, in addition to pipet calibration and buffer conditions like MgCl_2 , salt, additives, and deoxynucleotide concentrations, all contribute to this efficiency (Pfaffl, 2004; see *UNITS 15.1 & 15.5* for further details on these parameters). Given optimal buffer conditions and adequate primer, probe, and sample qualities, slight fluctuations in efficiency may still be observed between primer sets run on the same plate or between assay plates, even if they have been assembled and run on the same day by the same user. Efficiency correction is a means to account for inter- or intra-assay variability that is attributable to the aforementioned parameters.

The materials and setup of the assay are the same as in the standard curve method (see Basic Protocol 1), except that the linear regression formula produced by plotting the Ct versus the log ng of input standard total RNA is used only to determine PCR efficiency. This computed efficiency is then used to calculate the RNA levels (in arbitrary units) of the GOI and the endogenous control genes. The GOI RNA level in each sample is then expressed as a ratio relative to the endogenous control RNA level in that sample. Because the data are dependent upon Ct values and not an arbitrary standard curve, the resulting values may be compared to those of another RNA.

1. Set up and run assay as described in Basic Protocol 1 (steps 1 to 9). Refer to Figure 15.8.1 for an example of a typical plate setup and to Table 15.8.1 for master mix components.
2. Analyze and export raw data (see Basic Protocol 1, step 10), and then import into Microsoft Excel or equivalent spreadsheet program.

The threshold values for all RNAs measured (including the endogenous reference) must be the same. It is important to determine a suitable threshold within the geometric phase of the amplification plots for all RNA transcripts to be compared.

3. Calculate PCR efficiency, $E = 10^{(-1/\text{slope})}$, for the endogenous control RNA and each GOI from the slopes of their corresponding standard curves.
4. Calculate the quantity of the endogenous control RNA and each GOI from their Ct values according to the formula quantity = $E^{-\text{Ct}}$.

When the efficiency is 100% (i.e., slope = -3.3 and $E = 2$), the equation becomes quantity = $2^{-\text{Ct}}$. This serves as the basis for the calculation performed in $\Delta\Delta\text{Ct}$ method (Alternate Protocol).

5. For each of the three replicates of a sample, calculate the average quantity (avg), the standard deviation of the average (stdev), and the coefficient of variation (CV), where $\text{CV} = \text{stdev}/\text{avg}$.
6. Remove outliers, normalize the GOI, calculate the SD, and plot the results (see Basic Protocol 1, steps 13 to 17).

COMPARATIVE OR $\Delta\Delta$ Ct METHOD

The comparative Ct or $\Delta\Delta$ Ct method is used for measuring the fold-changes in expression of a particular RNA transcript between experimental samples. Typically, this assay is used when investigating gene-expression differences between wild-type and knockout or transgenic animals, or between vehicle-control and drug-treated samples. The results are then expressed as "fold-changes" relative to a calibrator, such as an untreated or wild-type sample. The $\Delta\Delta$ Ct method is only applicable when the primer sets for both the GOI and the endogenous reference gene have been shown to give perfect standard curve slopes (slopes = -3.3 ± 0.1 with $R^2 = 0.99$) as assayed in the Support Protocol.

1. Set up assay as described in Basic Protocol 1 (steps 1 to 9), except refer to Figure 15.8.2 for an example of a typical plate setup and to Table 15.8.2 for master mix components.

Standard cDNA samples are not needed in this method.

2. Analyze and export raw data (see Basic Protocol 1, step 10) and then import into Microsoft Excel or equivalent spreadsheet program.
3. For each of the three replicates of a sample, calculate the average (avg) cycle time (Ct) and then calculate the standard deviation (stdev).
4. Remove any outlier wells from the averaged Ct values (>0.3 stdev).

Only one point per replicate may be removed.

%CV may not be used, due to the logarithmic nature of both the Ct avg and Ct stdev. Instead, stdev must be used, where a stdev of 0.3 correlates with the maximum allowable standard deviation that can distinguish a two-fold change with 99% confidence; 0.4 stdev may be used for a 95% confidence interval.

Figure 15.8.2 Typical plate setup for the $\Delta\Delta$ Ct method. The plate arrangement shown represents an experiment in which 20 samples taken from experimental animals will be assayed for one endogenous control gene and four GOIs. The samples are plated in triplicate for each of the RNAs assayed. Abbreviations: GOI, gene of interest; NTC, no-template control; Ref, endogenous control gene.

Table 15.8.2 Master Mixes for the $\Delta\Delta\text{Ct}$ Assay

Components	Final concentration	Volume per well	Volume for each cDNA/primer mix (per sample in triplicate + 1 extra)	Master mix (no. of samples + 1 NTC + 1 extra)
<i>SYBR Green assay</i>				
2× SYBR Green mix	1×	5 μl	20 μl	
1:1 primer mix (1.25 μM each)	150 nM each primer	1.2 μl	4.8 μl	
Template cDNA	10-25 ng ^a	1.25 μl	5 μl	—
H ₂ O	N/A	to 10 μl	to 40 μl	
Total volume		10 μl	40 μl	Aliquot 35 μl into each tube containing cDNA
<i>TaqMan assay</i>				
2× TaqMan mix	1×	5 μl	20 μl	
1:1 primer mix (1.25 μM each)	300 nM each primer	2.4 μl	9.6 μl	
5 μM TaqMan probe	250 nM	0.5 μl	2.0 μl	
Template cDNA	10-25 ng ^a	1.25 μl	5 μl	—
H ₂ O	N/A	to 10 μl	to 40 μl	
Total volume		10 μl	40 μl	Aliquot 35 μl into each tube containing cDNA

^aRecommended amount of template for detection of both high and low levels of GOIs. If necessary, significantly less template may be used (picograms). Note that the cDNA template quantity is based upon the amount of total RNA input into the reverse transcription reaction.

5. For each sample, normalize the GOI Ct values to those of the reference gene for the same sample according to the equation:

$$\Delta\text{Ct} = \text{avgCt}_{\text{GOI}} - \text{avgCt}_{\text{ref}}$$

Equation 15.8.3

Calculate the standard deviation of ΔCt ($\text{stdev}_{\Delta\text{Ct}}$) as:

$$\text{stdev}_{\Delta\text{Ct}} = \sqrt{(\text{stdev of reference})^2 + (\text{stdev of GOI})^2}$$

Equation 15.8.4

6. Choose a calibrator.

This will be the sample, tissue, gene, or control group to which the others will be compared.

7. Find the $\Delta\Delta\text{Ct}$, or calibrated value, for each sample, according to the equation:

$$\Delta\Delta\text{Ct} = \Delta\text{Ct}_{\text{sample}} - \Delta\text{Ct}_{\text{calibrator}}$$

Equation 15.8.5

The $\text{stdev}_{\Delta\Delta\text{Ct}}$ will be the same as $\text{stdev}_{\Delta\text{Ct}}$, since the calibrator is arbitrarily set to be a constant.

8. Find the fold-change for each sample relative to the calibrator according to the equation:

$$\text{fold-change} = 2^{(-\Delta\Delta Ct)}$$

Equation 15.8.6

For the sample that is chosen as the calibrator, the $\Delta\Delta Ct = 0$ and therefore the fold-change = $2^{(-\Delta\Delta Ct)} = 1$.

9. Plot the resulting fold-changes on a bar graph of fold-change versus sample name or experimental treatment group. Determine the measure of experimental error as:

$$SD_{\text{fold-change}} = (\ln 2)(\text{stdev}_{\Delta\Delta Ct})(2^{(-\Delta\Delta Ct)})$$

Equation 15.8.7

DESIGN AND VALIDATION OF SYBR GREEN AND TaqMan PRIMER/PROBE SETS

SUPPORT PROTOCOL

Considering that QPCR relies on the quality and the fidelity of the primers and probes that are used, very strict parameters for their design and subsequent validation are required. A common misconception in performing QPCR assays is that if the primer works for traditional end-point PCR, it is suitable for QPCR. In some cases this is true. However, the primer set must be tested in a QPCR validation assay before it can be used for RNA expression analysis. In keeping with the high-throughput capacity of QPCR, the thermocycling conditions are kept constant for all assays: 10 min at 95°C activates the hot-start *Taq* polymerase, followed by 40 cycles of the two-step 95°C melting and 60°C annealing. An extension step in the thermocycler program is not required, since all of the PCR products are 50 to 150 bp, thus making the run last only 1.5 to 2 hr. The concentrations of PCR reagents such as *Taq* DNA polymerase, MgCl₂, other salts, and dNTPs remain constant within the same chemistry (i.e., SYBR Green or TaqMan), and these so-called universal cycling conditions make primer and probe sequences the only point of flexibility in performing the assays.

The design of primer/probe sets requires the availability of reliable sequence information that may be obtained from databases like NCBI's GenBank or Ensembl, or from data produced by direct sequencing. The assay does not tolerate base mismatches between primer and template, especially in the probe sequence, a feature that allows for the detection of single-nucleotide polymorphisms (SNPs). Several primer/probe design software packages are available either for purchase or online. Otherwise, the user may design the primer sets by directly examining the sequence and choosing primers with the correct characteristics, as outlined in this protocol. The probe is labeled at the 5' end with a fluorescent reporter such as 6-FAM or VIC, and at the 3' end with a fluorescent or nonfluorescent quencher. The user should consult with the vendor that will synthesize the probe for the availability of each type of label.

The assay consists of a standard cDNA dilution series from which linear regression curves may be plotted. The slope of the resulting curve gives a measure of PCR efficiency, where -3.3 ± 0.1 with a coefficient of determination (R^2) of 0.99 indicates a reaction efficiency of 100%. Part of the initial SYBR Green validation also includes a melting (or dissociation) curve analysis. At the end of the repetitive cycles of the PCR, an additional melt-anneal-melt cycle is performed. The final melt occurs very slowly and

The Polymerase Chain Reaction

15.8.11

the changes in both temperature and fluorescent signal are monitored over time. This decrease in fluorescence correlates with the dissociation of the double-stranded PCR product releasing the bound SYBR Green I fluorophores. The instrument software uses an algorithm to transform and display the melting curve as the negative first derivative of the normalized fluorescence versus temperature (Applied Biosystems, 2001a). The presence of a single peak in the melting curve is indicative of a single PCR product, and occurs at the melting temperature of the product. Multiple peaks in this plot indicate that nonspecific products or primer dimers have been formed. Formation of a single product can be confirmed by running the PCR products on a 2% agarose gel following the QPCR run. Occasionally, when two products are observed, the second product may have been formed during the plateau phase, which would not affect quantitation. To confirm whether this has occurred, the QPCR run could be repeated and stopped during the exponential phase, and the reaction products run on an agarose gel. However, this is not feasible in practice because of the high-throughput nature of the assay. The best course of action when multiple products are observed in the dissociation curve is to redesign and validate a new primer set. Only primer sets that give a single peak in this curve should be used for experimental assays. Once a SYBR Green-based primer set has passed validation testing, the corresponding TaqMan probe is ordered and validated for PCR efficiency only. In rare cases, the SYBR Green assay conditions (e.g., primer concentration, Mg^{2+} concentration) will not be appropriate for TaqMan assays. This is observed as a decline in PCR efficiency. In this case, new primers may be designed to flank the probe sequence.

Additional Materials (also see *Basic Protocol 1*)

Primer/probe design software (Primer Express, Applied Biosystems)

Design primers

1. Retrieve the RNA sequence information from the appropriate source (e.g., Genbank or Ensembl).
2. Determine the locations of exon boundaries by aligning the mRNA sequence with its gene or by using NCBI's Entrez Gene Evidence Viewer (<http://www.ncbi.nlm.nih.gov>) or Ensembl's Genome Browser (<http://www.ensembl.org>).

Some genes do not have introns, so this step may not be applicable.

3. Copy the sequence into the design software.

Several design programs are available both commercially as stand-alone applications and as Web-based applications. Alternatively, primers and probes may be designed "by hand." Omit this step if designing by hand.

4. If using software other than Primer Express, use the following parameters:
 - a. *QPCR primers*: Should have 40% to 60% GC content and melting temperatures around 60°C. Should not contain runs of the same nucleotide, repetitive sequences, or more than two G's and/or C's on the 3' end (also called GC clamp).
 - b. *PCR product (amplicon)*: Should be 50 to 150 bases in length with an approximate melting temperature between 85° and 95°C.
 - c. *TaqMan probe (anneals to sequence between primers)*: Should have the same properties as the primers, except that the melting temperature should be around 70°C, and the sequence should not contain G's within a few bases of the 5' end because of increased reporter quenching. In addition, the sequence must have more C's than G's, which can be accomplished by using the complementary strand sequence for the probe (Applied Biosystems, 2002b).

Primer Express contains templates into which these parameters have been preloaded.

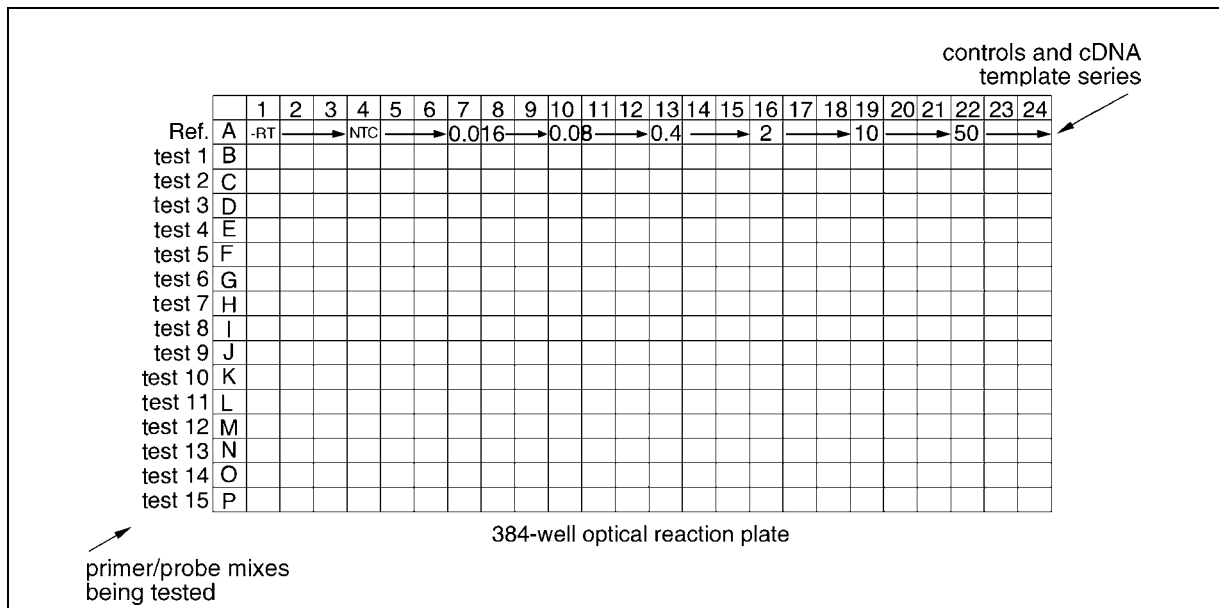

Figure 15.8.3 Typical plate setup for primer and probe validation assays. The plate arrangement shows a standard cDNA template dilution series that is being used to test 15 primer sets along with an endogenous control primer set that has already been validated. The same format is used when testing new probe sets. If different standard cDNAs are used to test primers/probes on the same plate (i.e., standards derived from different tissues), the validated endogenous reference primers/probes must also be run for that standard.

- Choose a primer/probe set for which the primers anneal in different exons, or which have less than 5-bp overhangs into the adjacent exon on the 3' end of the primer.

This step is necessary to avoid amplification of contaminating genomic DNA. Although the RNA is DNase-treated prior to reverse transcription, complete removal of genomic DNA is never achieved.

For intron-less transcripts or other primer sets that bind sequence within a single intron, the -RT controls are essential for each sample, to ensure that genomic DNA is not being amplified.

- Perform a BLAST (or equivalent) search of both primers of the set together to verify that they will fully anneal to the correct sequence and only that sequence.
- If the TaqMan probe will be used, run BLAST (*UNIT 19.3*) on the probe sequence to assess whether it binds to the correct sequence with 100% identity.
- Order a small-scale synthesis of the primers from a suitable vendor. Standard desalting of the primers is sufficient, and no additional purification (e.g., HPLC) is required.

Once a primer set has been validated, large-scale synthesis may be more cost effective, especially for frequently used primers like the reference genes.

- Validate the primer set according to the remaining steps of this protocol. If performing TaqMan-based assays, validate the primer set before ordering the probe. Once the primer set is validated, order the dual-labeled probe from an appropriate vendor, and validate according to the following steps.

Validate primer set

- Set up assay as described in Basic Protocol 1 (steps 1 to 9), except refer to Figure 15.8.3 for an example of a typical plate setup and to Table 15.8.3 for master mix components.
- Test the new primer set using SYBR Green chemistry. If valid, test the TaqMan-based chemistry.

Table 15.8.3 Master Mixes for Primer/Probe Validation Assays

Components	Final concentration	Volume per well	Volume for each cDNA/primer mix (per sample in triplicate + 1 extra)	Master mix (for 8 standards ^b + 1 extra)
<i>SYBR Green assay</i>				
2× SYBR Green mix	1×	5 μl	20 μl	180 μl
1:1 primer mix (1.25 μM each)	150 nM each primer	1.2 μl	4.8 μl	43.2 μl
Template cDNA	0.016-50 ng ^a	1.25 μl	5 μl	—
H ₂ O	N/A	to 10 μl	to 40 μl	91.8 μl
Total volume		10 μl	40 μl	Aliquot 35 μl into each tube containing cDNA
<i>TaqMan assay</i>				
2× TaqMan mix	1×	5 μl	20 μl	180 μl
1:1 primer mix (1.25 μM each)	300 nM each primer	2.4 μl	9.6 μl	86.4 μl
5 μM TaqMan probe	250 nM	0.5 μl	2.0 μl	18 μl
Template cDNA	0.016-50 ng ^a	1.25 μl	5 μl	—
H ₂ O	N/A	to 10 μl	to 40 μl	30.6 μl
Total volume		10 μl	40 μl	Aliquot 35 μl into each tube containing cDNA

^aRecommended template dilution series. The user may modify the range of cDNA concentrations based on the experimental system. Note that the cDNA template quantity is based upon the amount of total RNA input into the reverse transcription reaction.

^bFor this assay, the NTC and –RT controls are included as part of the standard sample set.

12. Following the instrument run, first check the dissociation curve. If more than one peak is present, the primer set is invalid and no other parameters are checked.
13. If a single peak is found in the dissociation curve, assess the PCR efficiency by calculating the slope of the linear regression curve as follows.
 - a. Plot Ct (or crossing point, CP) versus log ng of the standard cDNA input for each concentration of standard as an *xy* scatter plot.

This may be performed directly in the instrument software on the Applied Biosystems instrument, or can be done in Excel (or equivalent).

- b. Apply a best-fit curve and display the corresponding linear regression formula.

If the slope of the curve is -3.3 ± 0.1 with $R^2 = 0.99$, the primer set amplifies at 100% efficiency, and the set is considered valid.

Efficiency is dependent upon several factors including pipet calibration, primer quality and dilution, and even variability in the instrument run. The slope, therefore, may not be exactly -3.3 ± 0.1 . In this case, the slope of the test primer set must match that of a previously validated endogenous reference gene run for the same standard cDNA within ± 0.1 . For example, if the test primer gives a slope of -3.6 and the endogenous reference for the standard cDNA used to test the set gives a slope of -3.5 , then the test set is valid. However, if the endogenous reference primer set gives a slope of -3.3 and the test primer has a slope of -3.6 , the test set is invalid.

14. Repeat the linear regression analysis for the TaqMan probe/primer set to assess PCR efficiency.

Melting curve analysis cannot be performed for TaqMan-based assays, since cleavage of the probe releases the reporter that continuously fluoresces.

REAGENTS AND SOLUTIONS

Use molecular-biology-grade (nucleic acid- and nuclease-free) or sterile-filtered double-deionized water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Primer mixes, 1.25 μ M each forward and reverse primer

Mix small aliquots of 2.5 μ M forward and reverse primer stocks (see recipe) in equal volumes (1:1). Store up to 1 to 2 months at 4°C in screw-capped tubes to prevent evaporation. Do not freeze, as repeated freeze-thaw cycles will degrade the primers.

Primer stocks, 100 and 2.5 μ M

Purchase lyophilized oligonucleotides from any commercial source (synthesized at a 25-nM scale; standard desalting is sufficient, no additional purification is needed). Briefly centrifuge the tubes of powdered oligonucleotide to get contents to the bottom. Resuspend in molecular-biology-grade water to 100 μ M. Before preparing primer mixes, dilute each stock (forward and reverse) to 2.5 μ M. Store at -20°C. When stored properly and subjected to minimal freeze-thaw cycles, primer stocks can last >2 years.

Primer pairs produced at a 25-nM scale will yield enough reagent to test ~4000 samples using SYBR Green, or ~2000 samples using TaqMan assays.

Sterile-filtered double-deionized water may be used instead of purchased molecular-grade water. Do not use DEPC-treated water, because the slightly acidic pH may promote primer degradation. Tris buffer may be used instead of water, but should not contain EDTA, which acts as a Mg²⁺-chelating agent and can inhibit the PCR.

Standard cDNAs, dilution series

DNase-treat (UNIT 3.12) and reverse transcribe (UNIT 3.7) a suitable RNA using 0.08 μ g/ μ l random hexamer primers such that the final concentration of the standard is 40 ng/ μ l (based on RNA quantity; see UNIT 15.5). Include both a no-template control (NTC) for which water is used instead of RNA, and a no-reverse-transcriptase control (-RT). Following the reverse transcription, make a 5-fold dilution series of the 40 ng/ μ l standard to obtain working concentration standards of 40, 8, 1.6, 0.32, 0.064, and 0.0128 ng/ μ l. Store up to 1 month at 4°C or >2 years at -20°C (with minimal freeze-thaw cycles).

By using 1.25 μ l/well of each of the standards in the final reaction plate, the resulting amount of starting template will be 50, 10, 2, 0.4, 0.08, and 0.016 ng. See Commentary for more information and suggestions about control and standard RNA samples.

SYBR Green mix, 2 \times

Combine the following components as indicated in Table 15.8.4:

25 mM MgCl₂, molecular biology grade (store at -20°C)

10 \times Gold PCR buffer (supplied with PCR enzyme; Applied Biosystems; store at -20°C)

10 \times dNTP mix: equal volumes of 2 mM dATP, dTTP, dCTP, and dGTP (store at -20°C)

Dimethylsulfoxide (DMSO), molecular biology grade (store at room temperature)

continued

Table 15.8.4 Preparation of 2× SYBR Green Mix

Component	Volume (μl)				
25 mM MgCl ₂	48	288	600	720	1200
10× Gold PCR buffer	40	240	500	600	1000
10× dNTP mix	40	240	500	600	1000
DMSO	40	240	500	600	1000
1:1000 SYBR Green I	20	120	250	300	500
50× ROX	8	48	100	120	200
AmpliTaq Gold polymerase (5 U/μl)	2	12	25	30	50
H ₂ O	2	12	25	30	50
Total volume in 2× buffer	200	1200	2500	3000	5000

SYBR Green I dye (Molecular Probes; store at −20°C), diluted 1:1000 in water

50× ROX passive reference dye (Invitrogen; store at −20°C)

AmpliTaq Gold polymerase (5 U/μl; Applied Biosystems; store at −20°C)

Water, molecular biology grade

Prepare fresh and keep on ice prior to use in primer master mixes. Protect dyes and all prepared mixes from prolonged exposure to light by wrapping tubes in foil.

To maintain the high-throughput nature of the assay, all buffer conditions, including the concentrations of Mg²⁺, dNTPs, and other additives, are kept constant. It is strongly recommended that a preformulated buffer be purchased from a reliable vendor, since these are stable at room temperature and have been quality-control tested to ensure optimal performance. The authors have obtained comparable results using mixes from Applied Biosystems, Bio-Rad, Invitrogen, and Sigma.

TaqMan probe, 100 and 5 μM

Depending on the vendor, the probe may be supplied in a lyophilized form. In this case, resuspend to 100 μM in Tris·Cl, pH 8.0 (APPENDIX 2), prepared with molecular-biology-grade water and reagents. Before use, dilute a small amount of 100 μM stock to 5 μM with more Tris·Cl, pH 8.0. Store either concentration at −20°C. Avoid repetitive freeze-thaw cycles, and thaw on ice prior to use to preserve the integrity of the probe. Protect the probe from excessive exposure to light (e.g., using amber-colored screw-cap tubes) to prevent photobleaching of the fluorescent dyes and evaporation. See Support Protocol and Commentary for additional considerations regarding the TaqMan probe.

COMMENTARY

Background Information

Quantitative PCR is a rapid, robust, and highly sensitive polymerase chain reaction method used to quantify specific nucleic acid targets. Real-time quantitative PCR is different from end-point, or in-gel, analysis (see UNIT 15.7) in several ways. For real-time analysis, the increase in fluorescent signal resulting from PCR product synthesis is recorded during the course of the thermocycle. This allows the user to specify the point in the assay at which to "read" the data. Measurements are obtained from the geometric phase of the amplification

reaction. This is the phase during which all of the components required for the PCR (e.g., dNTPs, primers, polymerase) are in excess, and therefore the deficit of an essential reaction component will not quench the efficiency of product synthesis. Following geometric amplification, the fluorescence curve reaches a plateau (i.e., the saturation point) as the reaction components begin to become limited and the kinetics of the reaction become unpredictable. At this stage, an increase of one thermocycle no longer correlates with a two-fold change in product (Applied Biosystems,

2002a). In contrast, in end-point PCR, quantitation is often obtained by in-gel densitometry measurements at the end (or the saturation point) of the reaction. The unpredictable nature of the PCR at this stage makes this method semiquantitative at best.

Real-time PCR depends both on a set of universal thermocycling and buffer conditions and on primer efficiency testing and correction where necessary. As a result, the accuracy and precision of the resolution (smallest detectable fold-change) is less than 2-fold, whereas resolution for end-point in-gel measurement is limited to about 10-fold (Applied Biosystems, 2002a). Semiquantitative PCR assays (in which samples are removed at measured cycle times and electrophoresed and possibly hybridized) have better resolving power than end-point analysis. However, both in-gel methods suffer from the lengthy processing steps, compared to real-time PCR.

The two most widely used fluorescent detection methods, or chemistries, for QPCR are SYBR Green, a DNA-intercalating dye, and the fluorogenic probe. Several types of fluorogenic probes are currently available: the popular, dual-labeled hydrolysis probe (TaqMan probe) and the hybridization probes known as molecular beacons and scorpions. Both types of probes bind the sequence intervening the forward and reverse primer binding sites, and both rely on fluorescence resonance energy transfer (FRET) to silence the signal from the reporter dye while it is in proximity to the quencher dye. A hydrolysis probe is cleaved by the 5' nuclease activity of the polymerase during the primer-extension phase of the reaction, and the reporter is released and becomes free to fluoresce continuously. Hybridization probes rely on a stem-loop structure to keep the reporter and quencher in proximity. Upon hybridization to the specific sequence, the distance between the reporter and quencher becomes too large to silence the reporter, and signal is detected (Tyagi and Kramer, 1996; Whitcombe et al., 1999).

There are advantages and disadvantages to each type of chemistry (SYBR Green versus TaqMan) in terms of sensitivity and specificity. SYBR Green I binds any double-stranded DNA and does not depend on a probe-cleavage event. Therefore, SYBR Green produces earlier Ct values, resulting in an apparent enhanced sensitivity (Whittwer et al., 1997; Morrison et al., 1998). TaqMan probes, on the other hand, supply another layer of sequence specificity in addition to the forward and reverse primers.

There are two methods of quantitation that may be performed using real-time PCR: absolute and relative. Absolute quantitation allows for the assessment of the copy number of a specific nucleic acid target in a sample, while relative quantitation results in the ratio of a specific target relative to an endogenous reference gene. The absolute method requires the availability of a standard sample in which the copy number of the particular target has been carefully and accurately measured. From this standard sample, a dilution series is made and assayed for the target at the same time as the unknown samples. From the values obtained from linear regression analysis of the standard dilution series, the GOI copy number values may be interpolated. This will allow the user to assess the sensitivity (i.e., the lowest detectable copy number) of the GOI primer set. As an example, this type of analysis is used in both clinical and food science for the assessment of pathogen load and gene copy number (Pfaffl, 2004).

Relative quantitation, which is covered in detail in protocols in this unit, does not rely on the knowledge of a given transcript copy number in a standard sample. Instead, the changes in gene expression or the levels of a specified transcript may be measured and described as an arbitrary unit relative to some control sample ($\Delta\Delta\text{Ct}$ or standard curve method), or to the level of some other control transcript in the same sample (standard curve or efficiency-corrected ΔCt method). For example, relative quantitation allows for the measurement of the fold-change in expression for gene A in a treated sample versus an untreated sample, or for the assessment of the level of gene A in a sample relative to some housekeeping gene in the same sample.

Critical Parameters and Troubleshooting

Primer/probe design and validation

For RNA analysis, it is important to differentiate message from genomic DNA. In this respect, the use of amplicons that span an exon junction allows this requirement to be met. This is achieved by designing primer sets with the forward and reverse primers sitting in different exons. However, when the intervening intron is small, genomic DNA may still be amplified. This can be avoided by allowing a few base pairs on the 3' end of either primer to overhang onto the neighboring exon.

To distinguish knockout or mutant samples using QPCR, primers/probes should be

designed in the knocked-out or mutated region of the transcript. In this way, no amplification of the transcript will occur for the knockout, since the region recognized by the primers has been deleted or altered. Primers for transcripts that are rapidly degraded should be placed near the 5' end of the RNA sequence, as degradation by ribonucleases generally occurs 3' to 5' (Brown, 2002). However, RNA transcripts that have undergone linear RNA amplification (for instance, RNA isolated from laser capture microdissected cells) are around 200 to 1000 bases in length and represent the 3' ends of the transcripts. In this case, primers must be designed in a region near the poly(A)⁺ tail.

It is absolutely mandatory to validate both primers and probes on the same instrument used to perform the experimental assay, i.e., when the instrument used to validate the primer sets is a different brand than the one that will be used for the experimental assays (e.g., Roche iCycler versus ABI 7900HT). Published primer/probe sets for which the PCR product is ≤ 150 base pairs and the annealing temperature is around 60°C, which have been validated properly, should be transferable to any system, but this must be empirically determined to ensure the reliability of the data.

In rare cases, the PCR efficiency of a validated primer set changes when switched from SYBR Green to TaqMan-based chemistry. This is due to the difference in primer concentration and/or MgCl₂ concentrations between the two buffers, and may often be overcome by redesigning the primers to recognize a sequence around the already synthesized probe.

Choice of chemistry

The selection between SYBR Green I and TaqMan-based assays depends upon the RNA sequence. If the RNA of interest has no polymorphisms or other variations in the region to which the primers bind, and the primers have been correctly designed and validated, then SYBR Green-based assays are adequate for gene-expression analyses. It is up to the user to decide if the addition of the often-costly TaqMan probe is worth the additional specificity it confers. In the case of polymorphisms or variants, differentiation between different RNA species may require the specificity of the probe, which can discriminate a single base difference.

Template quality

The quality of the cDNA template depends upon the integrity of the RNA. QPCR will tol-

erate some degradation of the RNA when random hexamers (or other -mers) are used to prime the reverse transcription reaction. However, it is not good laboratory practice to use degraded RNA, and the cause of the degradation should be addressed. Transcripts decay at different rates and have variable stability, so partial degradation of a sample at any point could lead to complete absence of detection of the desired target RNA in a subsequent QPCR assay, with little to no change in the house-keeping gene used as a control.

Total RNA is used for QPCR to reduce the number of steps and potential sources of degradation during sample preparation. Purified messenger, or poly(A)⁺, RNA can also be used. However, this subtractive purification could lead to the loss of transcripts that do not have a poly(A)⁺ tail, or to the preferential enrichment of RNAs that have internal A tracts. The added processing reduces the recovery of material for subsequent use, and can cause degradation. If poly(A)⁺ RNA is used, 50- to 100-fold less (~100 pg) sample template is required in the reaction mixture because mRNA represents 3% of total cellular RNA (Alberts et al., 1994).

Reverse transcription primers

Reverse transcription (RT) of RNA into complementary DNA (cDNA; refer to *UNIT 15.5*) may be performed using several different types of oligonucleotide primers. For QPCR, the preferred primer is a random hexamer, nonamer, or dodecamer oligo with 6, 9, or 12-base stretches of random sequences, respectively. Random primers have a much higher probability of efficiently amplifying all RNA transcripts, due to their indiscriminate nature (ABI, pers. comm.). This property also enables RNA secondary structure to be overcome, since the priming occurs in random places along the length of the transcript. mRNA-specific priming by oligo(dT)s at the poly(A)⁺ tail and any internal poly(A) tract is another method of RT priming. This method will allow only polyadenylated RNAs to be converted to cDNA, thus limiting amplification of some GOIs or partially degraded samples. A mixture of a random oligo with an oligo(dT) primer may enhance detection of rare messages while still allowing for the detection of transcripts that lack polyadenylation. However, the use of this procedure may skew the measurement of relative RNA abundance towards intact, full-length mRNA over incomplete or rapidly degraded messages. Users should decide and test these parameters

in their particular experimental systems. The third method of reverse transcription priming is the gene-specific reverse primer. The reverse PCR primer is used to specifically target the GOI for conversion to cDNA. This is often performed in the same QPCR plate as the PCR by adding RT enzyme to the PCR mix and adding an incubation step prior to the first step in the PCR cycling program (known as one-step RT-PCR). While this may enhance detection of a specific RNA target, RNA secondary structure may not be overcome, depending on the priming site, and RT efficiency must be considered in addition to PCR efficiency.

An important assumption that is made when performing RT-QPCR is that RT efficiency is similar for the GOI between samples and for different GOIs. However, different tissues/sample types may contain variable levels of RT-inhibiting or -enhancing factors (Pfaffl, 2004). To control for these variables, it is recommended that all samples to be compared be prepared under the same conditions and at the same time (i.e., with regard to RNA extraction method and RT reaction).

Endogenous reference gene

Normalization of sample loading is essential in any quantitative comparative analysis to ensure that the measured differences between samples is not attributable to disproportionate amounts of starting material. For gene-expression assays, the normalizer must be an endogenous gene that is expressed at equal levels in all tissue or cell types and treatment conditions under study. Traditionally, one of the so-called housekeeping genes (e.g., GAPDH, cyclophilin, β -actin, HPRT, U36B4, 18S rRNA) is selected to serve this function. The choice is a point of controversy, since there are examples of fluctuations for most of the abovementioned genes under various treatment or physiological conditions (Schmittgen and Zakrajsek, 2000; Suzuki et al., 2000; Guo et al., 2001; Vandesompele et al., 2002; Dheda et al., 2004). The user should run a small pilot experiment to determine which endogenous reference is appropriate for the particular studies. A good method for doing this is to perform a $\Delta\Delta C_t$ assay using several potential normalizer RNAs and a GOI that is not expected to show any fold-changes within a small set of samples. The GOI is then normalized to each of the reference RNAs individually for all of the samples. Finally, the housekeeping gene for which there is no detectable fold-change of the GOI between the test samples is chosen for use in experimental assays (Applied

Biosystems, 2001b; Guo et al., 2001; Roche Applied Science, 2002).

Controls and standards

Controls for the assay that are made alongside the cDNA standards and unknowns include a no-template control (NTC), made by substituting water for RNA, and a no-reverse-transcriptase (-RT) control, made by omitting the reverse transcriptase. For primers that span an exon junction, a -RT control is not needed for every sample if, during the validation process, this control shows no amplification product. If the system under study is the result of introduction of an expression construct into cells, or if the GOI does not have introns or has a known processed pseudogene, then -RT controls should be made and assayed for every sample. An NTC should be run for every primer set of an assay to facilitate the detection of contaminants that contribute to fluorescent signal.

If amplification of the NTC occurs, primer-dimer or other nonspecific PCR products may have been formed, or contamination of a reagent or degradation of the primer mix may have taken place. If amplification occurs in the -RT control, this indicates the presence of genomic DNA if the primer/probe set does not span an exon junction, or the presence of primer-dimer or nonspecific PCR products, a contaminant, or degradation of the primer mix. Although all amplification products (including those that are nonspecific) contribute to the fluorescence signal, this fluorescence contribution can be considered negligible if the C_t values of the NTC and -RT are ≥ 7 cycles different from the experimental samples (Applied Biosystems, pers. comm.).

If the unknowns are RNA samples, the standard of choice is an RNA that is reverse transcribed in the same manner as the unknowns. A suitable standard RNA is one in which the expression of the GOI is at a moderate to high level and that has a similar composition to the unknown samples. The use of a plasmid or linear DNA standard is not advised for measurement of an endogenous tissue transcript, because these types of nucleic acids have different background compositions than RNA, are extracted differently, and are not reverse transcribed, and therefore may not have the same RT or PCR amplification efficiency as the experimental samples (Applied Biosystems, 2003; Pfaffl, 2004). Several vendors (e.g., Ambion, Clontech, Stratagene) supply total RNA preparations of many cell and tissue types collected from many different

species. Both Stratagene and Clontech make total RNA pools termed "universal reference RNA," composed of mixtures of either various cell lines or whole tissues, respectively. These RNA pools represent $\geq 90\%$ gene coverage on microarrays (Novoradovskaya et al., 2000; Clontech, 2002), and are very useful as standards both for validation of primer/probe sets and for large-scale multigene studies.

Anticipated Results

The setup of the $\Delta\Delta C_t$ assay allows 64 samples (one of which should be the NTC) to be assayed for an endogenous reference gene and one gene of interest in triplicate; the standard curve and efficiency-corrected ΔC_t assays will accommodate an endogenous reference gene and one gene of interest in triplicate for 56 unknowns, six standards, and two control samples. Assays performed on the ABI 7900HT are completed in 1.5 and 2 hr for TaqMan and SYBR Green-based assays, respectively. The results yield data that are highly reproducible and correlate well with traditional northern blotting and RNase-protection assays.

Time Considerations

In preparation for performing a QPCR assay, RNA and subsequent cDNA preparation may be carried out in advance. Prior to an actual experimental assay, primers and probes must be designed and validated. In most cases, design and validation may take several days to a few weeks. This includes the time to design, order, and synthesize the primers (~ 2 days, depending on the vendor), test the primers (a few hours), and, if desired, synthesize (~ 7 to 14 days, depending on the vendor) and test (a few hours) the corresponding probes.

Once the required primer/probe sets are validated, the experimental assays are performed. A single-plate assay may take 0.5 to 2 hr to prepare and 2 hr to run. The preliminary raw-data analyses on the instrument software may take less than half an hour. The time required for the following final analyses will depend upon the user's familiarity with both the mathematical and software applications. The typical workflow for an experimental assay is as follows:

Day 1: Prepare total RNA and determine concentration by UV or fluorescence spectroscopy (1 to 4 hr, depending on number of samples and method of preparation).

DNase-treat and reverse transcribe RNA to cDNA (~ 3 hr for setup and incubations).

Day 2: Prepare master mixes for the assay (~ 30 min to 1 hr).

Prepare QPCR plate(s) (~ 30 min to 1 hr per plate).

Run plate on instrument (1.5 to 2 hr).

Collect and analyze data (1 to 3 hr).

CHAPTER 16

Protein Expression

INTRODUCTION

Protein expression, as used in this chapter, refers to the directed synthesis of large amounts of desired proteins. In early applications, molecular biologists interested in obtaining great quantities of prokaryotic regulatory proteins arranged their synthesis in large amounts, a process that came to be called overproduction, expression, or overexpression. These early techniques used genetic manipulations to select *in vivo* recombination events that inserted the desired gene into bacteriophages. Later, as it was developed, recombinant DNA technology was used to create phages and plasmids *in vitro*, which directed the synthesis of large amounts of the products of cloned genes.

This chapter describes methods to express proteins. In all these methods, a gene whose product is to be expressed is introduced into a plasmid or other vector, and that vector is introduced into living cells. Typical expression vectors contain promoters that direct the synthesis of large amounts of mRNA corresponding to the gene. They may also include, for example, sequences that allow their autonomous replication within the host organism, sequences that encode genetic traits allowing cells containing the vectors to be selected, and sequences that increase the efficiency with which the mRNA is translated.

There are three basic strategies used to express proteins, each of which has advantages. *E. coli* expression techniques are probably the most popular: the organism is already used by most investigators, the techniques necessary to express usable amounts of protein are relatively simple, the amount of time necessary to generate an overexpressing strain is very short, and a familiarity with standard recombinant DNA techniques is all that is necessary to begin pilot expression experiments. *E. coli* has other advantages that have made it widely used for expression of commercially important proteins: it is cheap to grow, and the vast body of knowledge about it has made it possible to tinker intelligently with its genetics and physiology, so that strains producing 30% of their total protein as the expressed gene product can often be obtained. However, expression in *E. coli* does have disadvantages. First, eukaryotic proteins expressed in *E. coli* are not properly modified. Second, proteins expressed in large amounts in *E. coli* often precipitate into insoluble aggregates called “inclusion bodies,” from which they can only be recovered in an active form by solubilization in denaturing agents followed by careful renaturation. Third, it is relatively difficult to arrange the secretion of large amounts of expressed proteins from *E. coli*, although it has often been possible to secrete small amounts into the periplasmic space and to recover them by osmotic shock.

The baculoviral expression system has a number of advantages that have contributed to its recent popularity: proteins are almost always expressed at high levels; expressed proteins are usually expressed in the proper cellular compartment (that is, membrane proteins are usually localized to the membrane, nuclear proteins to the nucleus, and secreted proteins secreted into the medium); and the expressed protein is often properly modified. Expression using baculoviral vectors also has some drawbacks: the techniques to grow and work with the virus are more sophisticated than those used with *E. coli*, and thus the system is more prone to “crashing” due to cell growth difficulties; the expressed proteins

are not always properly modified; and generation of a recombinant baculovirus to express a given protein takes several steps.

Compared with the above systems, all mammalian expression techniques have certain advantages, particularly for the expression of higher eukaryotic proteins: expressed proteins are usually properly modified, and they almost always accumulate in the correct cellular compartment. Generally speaking, mammalian expression techniques are more difficult, time-consuming, and expensive than those used to express proteins in *E. coli*, and they are much more difficult to perform on a large scale; however, they are quite practical for small- and medium-scale work by investigators already familiar with mammalian cell culture techniques. The several procedures described here for mammalian expression can produce transient expression, stable expression, or inducible expression. Each technique has specific advantages, and considerable care should be taken in deciding which technique to pursue (see below) because of the amount of time required to establish these techniques.

GENERAL OVERVIEW

Section I (UNITS 16.1-16.8) describes techniques for expressing proteins in *E. coli*. UNIT 16.1 contains an introduction to *E. coli* expression. UNIT 16.2 describes the use of T7 vectors, in which synthesis of large amounts of foreign gene products is directed by the phage T7 gene 10 promoter, which uses T7 RNA polymerase. This polymerase transcribes the gene 10 promoter so efficiently that it uses up most of the ribonucleotide triphosphates in the cell and drastically inhibits transcription of genes by the host polymerase. UNIT 16.3 describes the use of p_L -derived vectors and their appropriate host strains. These vectors carry the powerful bacteriophage p_L promoter and take advantage of a number of other useful aspects of phage lambda biology. The next units contain techniques for expression of fusion proteins in which the expressed protein carries an additional stretch of amino acids at its N terminus to aid its expression and purification. UNIT 16.4 introduces the concept of fusions and provides methods for cleavage of fusion proteins. UNITS 16.5, 16.6, 16.7 & 16.8 describe techniques for expressing *lacZ* protein (β -galactosidase), *trpE* protein, maltose-binding protein, glutathione-S-transferase (GST), and thioredoxin fusions.

Section II (UNITS 16.9-16.11) describes the use of the baculovirus system. In this system, genes for proteins to be expressed are inserted into an insect virus in lieu of a highly expressed dispensable gene. The foreign protein is produced by growing the recombinant virus in cultured insect cells. UNIT 16.9 introduces the system. UNIT 16.10 describes how to grow the cultured insect cells and viral stocks and how to isolate recombinant baculoviruses and use them to produce the desired protein. Finally, UNIT 16.11 describes the optimization of protein expression, first on a small scale, then maximized for large-scale production, and then provides instructions for purifying the recombinant proteins using GST- and His-tag systems.

Section III (UNITS 16.12-16.24) describe techniques for expressing proteins in mammalian cells. UNIT 16.12 describes expression using COS cell vectors. In this approach, vectors containing the gene to be expressed are transiently transfected into COS cells, which constitutively produce SV40 large T antigen. COS cell vectors contain an SV40 replication origin; when they are transfected into COS cells, they replicate, and protein is expressed from mRNA synthesized by hundreds of copies of the vectors. UNITS 16.13 & 16.14 describe expression from stably transfected cell lines. UNIT 16.13 describes the fusion of a protein of interest to an epitope tag, and the production of a stable cell line that expresses the tagged protein. Cell lines of this type are widely used to purify either individual proteins, or more frequently intact complexes that contain as one component the tagged protein. This strategy does not always work, as in certain cases even slight misexpression of a

protein can impair cell growth. To get around this problem, inducible systems are used; one widely used system uses the bacterial Tet repressor protein to engineer an expression system that responds to tetracycline concentration in the medium (UNIT 16.14).

Expression of proteins using viral vectors is presented in UNITS 16.15-16.22 and UNIT 16.24. UNITS 16.15-16.19 outline how to construct recombinant vaccinia viruses and characterize their products. UNIT 16.20 describes how to carry out expression using Semliki Forest Virus (SFV) vectors. Both vaccinia systems and SFV systems are able to produce large amount of protein following infection of cells with the appropriate virus. In both cases, the normal viral machinery is used to produce a single protein at very high levels, and thus these systems are useful for overexpression of protein in mammalian cells, but not useful if it is desirable to isolate the protein of interest in complex with a group of cellular proteins, as the expressed protein will be made at much higher levels than any endogenous protein.

An important goal that cannot be achieved by any of the above methods is the stable expression of protein in nondividing cells. In both therapeutic and basic science settings it can be important to express a protein in a post-mitotic cell, a need that has led to the development of vectors based on HIV and other related lentiviruses. Use of these systems is described in UNITS 16.21 & 16.22.

Another approach is to use vectors based on Adenovirus. Earlier generations of this strategy, based on replication-competent viruses, raised some concerns related to safety and duration of protein expression. Both issues have been addressed, at least in part, by a newer generation of helper-dependent (sometimes called “gutless”) adenoviral vectors (HDAds). The only Adenoviral *cis* elements present in these vectors are those required for vector genome replication and packaging into the capsid. Preparation of these defective viruses is dependent on a helper virus that provides the various necessary factors but lacks the packaging sequences and is not incorporated into viral particles. Advantages of these vectors include the large insert size of approximately 30 kb and the ability to transduce a variety of cell types, both in vitro and in vivo.

UNIT 16.23 addresses a somewhat different problem than is addressed in the previous units. While it is relatively easy to produce milligram amounts of any protein using viral expression systems, it is considerably more challenging to make stable cell lines that will continue to produce milligram quantities of a given protein over extended periods of time. Specially constructed CHO cell lines are used to solve this problem. These lines contain integrated constructions to direct the synthesis of the mammalian protein; the constructions carry either the dihydrofolate reductase or the glutamine synthetase gene, whose products confer drug resistance. Lines that carry increased numbers of the constructs are obtained by selecting cell lines that grow in increasing drug concentrations of methotrexate. Once selected, these lines are permanent reagents, which can be stored frozen and used to produce the protein whenever desired.

STRATEGIC CONSIDERATIONS WHEN USING MAMMALIAN EXPRESSION SYSTEMS

The importance of the initial planning stage cannot be overemphasized when discussing strategies for mammalian overexpression. With the exception of COS cell transfection, each of the strategies described in Section III requires a significant amount of set-up time. While a lot of this time is not hands-on time, as it consists of waiting for cells to grow, the total time between conception and completion of a specific experimental approach might easily be several months. Thus, it is more important than usual to devise an appropriate strategy, as strategic errors might not become apparent for several months.

The first consideration in choosing a strategy is to consider the goals of the expression work. If expression is desired to demonstrate that a clone has some functional activity or to perform an initial characterization of this activity, then transfection of COS cells might prove sufficient. If large amounts of an individual protein are required, then viral systems, such as vaccinia or SFV, or stable cell lines, such as CHO, will be the method of choice. If expression of an ectopic protein at the level of endogenous proteins is the goal, then creation of stable cell lines using retroviral (*UNIT 16.13*, see also *UNITS 9.9-9.14*) or lentiviral vectors should work.

The decision can come down to choosing between a viral system or the creation of stable cell lines. Creating stable cell lines offers the advantage that the engineered cells can be frozen and then thawed for use whenever the expressing line is needed. In addition, selection techniques can be used to isolate a clonal line that has desired expression levels of the protein. This clonal line should express similar amounts of protein in every cell, an important consideration if the goal is to purify a complex of proteins, or if the function of a given protein in an entire cell population is under study.

Creating stable cell lines requires both the choice of a suitable host cell and a suitable means of introducing the gene to be expressed. Obviously, the appropriate cell type (e.g., a lymphoid cell or neuronal cell) must be used if a specific cellular process is under study. Other considerations can be important later in the process. If eventually it will be important to grow large amounts of cells, then a cell line that can be adapted easily to growth in spinner culture is needed. If cells must be infected at a later stage in the experimental plan, then a cell line that is easily infected is important. Thus, planning several steps ahead when creating stable cell lines can help create a cell line that is maximally useful. Since it can take several months to isolate a clonal cell line in reasonable amounts, this planning takes on added importance.

Stable cell lines can be made using either transfection procedures or infection procedures. Transfection can be used to introduce several genes at once; however, the integrated genes might not prove to be completely stable. Retroviral vectors can be used, and can lead to more stable expression, but are considerably more cumbersome if more than one protein is to be introduced.

If overproduction of a single protein is the goal, frequently viral systems are the best choice. It usually takes less time to create an overexpressing virus than it does to make a high production stable cell line. Viral overproduction can also offer flexibility in that coinfection can be used to express two, three, or even more proteins in the same cell at the same time. This approach is not useful when it is important to purify the expressed protein with interacting proteins within the cell (e.g., as described in *UNIT 16.13*). The overexpressed protein will be expressed at such high levels that there will be insufficient endogenous protein to copurify in anywhere near stoichiometric amounts.

This necessarily brief discussion of mammalian expression systems points out just a few of the numerous specific issues that might be important in choosing an effective strategy. A thorough plan, with all future goals for the experimental system explicitly taken into account, will lead to the most efficient strategy for creating a maximally useful mammalian expression system.

Bob Kingston and Roger Brent

EXPRESSION OF PROTEINS IN *ESCHERICHIA COLI*

Overview of Protein Expression in *E. coli*

The study of *Escherichia coli* during the 1960s and 1970s made it the best understood organism in nature (Chapter 1). Today's recombinant DNA technology is a direct extension of the genetic and biochemical analyses carried out at that time. Even before the advent of molecular cloning, genetically altered *E. coli* strains were used to produce quantities of proteins of scientific interest. When cloning techniques became available, most cloning vectors utilized *E. coli* as their host organism. Thus, it is not surprising that the first attempts to express large quantities of proteins encoded by cloned genes were carried out in *E. coli*.

E. coli has two characteristics that make it ideally suited as an expression system for many kinds of proteins: it is easy to manipulate and it grows quickly in inexpensive media. These characteristics, coupled with more than 10 years' experience with expression of foreign genes, have established *E. coli* as the leading host organism for most scientific applications of protein expression.

Despite a growing literature describing successful protein expression from cloned genes, each new gene still presents its own unique expression problems. No one, and certainly no laboratory manual, can provide a set of methods that will guarantee successful production of every protein in a useful form. Nevertheless, the vast body of accumulated knowledge has led to a general approach that often helps to solve specific expression problems. This unit introduces general considerations and strategies, while subsequent units (16.2-16.7) describe procedures that can be applied to specific expression problems.

GENERAL STRATEGY FOR GENE EXPRESSION IN *E. COLI*

The basic approach used to express all foreign genes in *E. coli* begins with insertion of the gene into an expression vector, usually a plasmid. This vector generally contains several elements: (1) sequences encoding a selectable marker that assure maintenance of the vector in the cell; (2) a controllable transcriptional promoter (e.g., *lac*, *trp*, or *tac*) which, upon induction, can produce large amounts of mRNA from

the cloned gene; (3) translational control sequences, such as an appropriately positioned ribosome-binding site and initiator ATG; and (4) a polylinker to simplify the insertion of the gene in the correct orientation within the vector. Once constructed, the expression vector containing the gene to be expressed is introduced into an appropriate *E. coli* strain by transformation (UNIT 1.8).

SPECIFIC EXPRESSION SCENARIOS

Although this general approach—insertion of the gene of interest into an expression vector followed by transformation in *E. coli*—is common to all expression systems, specific procedures differ greatly. When choosing a procedure, it is helpful to consider the final application of the expressed protein, as this often dictates which expression strategy to use (UNIT 16.4A).

Antigen Production

If the goal is to use the expressed protein as an antigen to make antibodies, several approaches are available to make protein reliably and to allow for rapid purification of the antigen. The two best approaches are synthesis of fusion proteins with specific "tag" sequences that can be retrieved by affinity chromatography (UNITS 16.5, 16.6, 16.7 & 16.8; see also UNIT 10.11B) and synthesis of the native protein, or a fragment of it, under conditions that cause it to precipitate into insoluble inclusion bodies (UNITS 16.4A & 16.6). These inclusion bodies can be purified sufficiently by differential centrifugation so preparative denaturing polyacrylamide gel electrophoresis (UNIT 10.2) will yield an isolated band that can be cut out and crushed, or electroeluted, to provide antigenic material for injection into an animal.

Biochemical or Cell Biology Studies

If the goal is to use the expressed protein as a reagent in a series of biochemical or cell biology experiments, other considerations are relevant. In this case, the authenticity of the protein's function (e.g., high-specific-activity enzyme, binding protein, or growth factor) is

Contributed by Paul F. Schendel

Current Protocols in Molecular Biology (1998) 16.1.1-16.1.3
Copyright © 1998 by John Wiley & Sons, Inc.

very important, while the ease of preparing the protein matters less. For this application, it is possible to express the protein as a fusion protein containing a specific protease-sensitive cleavage site so the N-terminal peptide tail can be removed easily, leaving only the native amino acid sequence (UNITS 16.4, 16.6, 16.7 & 16.8). Alternatively, direct expression vectors of the type described in UNITS 16.2 & 16.3 may be used to produce the authentic primary sequence. When expressed, the protein may be soluble and active, as is the case with many intracellular enzymes. If it is insoluble, as is the case for many secreted growth factors when they are made cytoplasmically in *E. coli*, it may be necessary to isolate inclusion bodies, solubilize the protein using denaturing agents, and refold the protein. Refolding is usually not too difficult when the protein is of moderate size (Marston and Hartley, 1990). Whether the protein is expressed in a soluble form or whether it requires refolding, its integrity can usually be checked by specific enzyme assays or by bioassays.

Structural Studies

If the goal is to do structural studies of the expressed protein, the greatest constraints are imposed on the expression system. Because it is nearly impossible to show that a protein of unknown structure has been precisely refolded after denaturing, the protein must generally be made in a soluble form so its purification does not require a denaturation/renaturation step. Usually, the soluble form of the protein—either intracellular or secreted—must be made in strains and by induction protocols that minimize proteolytic degradation.

Soluble expression of most eukaryotic proteins is best achieved with systems that allow induction of synthesis without changing the temperature; for example, by inducing transcription from the *trp* (Edman et al., 1981; de Boer et al., 1983) or *tac* (de Boer et al., 1983) promoters. Maximum accumulation of soluble product is best achieved by testing expression in several strains and at several temperatures, and picking the combination that works best. This is an active area of research at present (Schein, 1989); the rules are not yet understood, so little more than trial and error can be recommended.

TROUBLESHOOTING GENE EXPRESSION

Once an expression strategy has been chosen and the gene is introduced into an appropriate

expression vector, several strains of *E. coli* should be transformed with the vector and protein production should be monitored. Ideally, the protein of interest will be produced in an active form and in sufficient amounts to allow its isolation. Often, however, the protein will be made either in very small amounts or in an insoluble form, or both. If this happens, there are various approaches that may correct the problem.

If not enough protein is produced:

1. Reconstruct the 5'-end of the gene, maximizing its A+T content while preserving the protein sequence it encodes. This may reduce secondary structure within the mRNA (DeLamar et al., 1985), or it may alter an as yet undefined parameter of the reaction. Regardless of the underlying cause, this procedure usually increases translation efficiency.

2. Determine if a transcriptional terminator is present. If the vector does not have a transcriptional terminator downstream from the site at which the gene is inserted, put one in. This often aids expression, probably by increasing mRNA stability and by decreasing nucleotide drain on the cell.

3. Examine the sequence of the cloned gene for codons used infrequently in *E. coli* genes. These so-called rare codons are usually not a rate-limiting problem, but if four or more happen to occur contiguously, they can reduce expression significantly (Robinson et al., 1984), perhaps by causing ribosomes to pause. Ribosomal pausing can uncouple transcription from translation, leading to premature termination of the message. Even if transcription proceeds normally, the mRNA 3' to the stalled ribosomes can be exposed to degradation by host ribonucleases, reducing its stability. Thus, if stretches of rare codons are found, they should be altered to codons more favorable to high expression in *E. coli*.

If enough protein is produced, but it is insoluble when the application requires it to be active and soluble:

1. Vary the growth temperature. As mentioned above, many proteins are more soluble at lower than at higher temperatures (Schein and Noteborn, 1988). On the other hand, some enzymes have a higher specific activity when made at temperatures >37°C (J. McCoy and P. Schendel, unpub. observ.). *E. coli* can synthesize proteins at temperatures ranging from 10° to 43°C, so trying expression at different temperatures is often worthwhile.

2. Change fermentation conditions. Many proteins contain metals as structural and catalytic cofactors. If the protein is being made faster than metals can be transported into the cell, the apoprotein without its metal cofactor will accumulate. This apoprotein will not fold correctly and will likely be insoluble. At the very least, the average specific activity of the expressed protein will be lower than expected. Different media and metal supplements can be tested and the best combination used. Clearly, if there is information about the metal content of the protein, these supplements can be designed more rationally. If no information is available, a more random approach must be tried.

3. Alter the rate of expression by using low-copy-number plasmids. This can be done by using the pACYC family (Chang and Cohen, 1978) or using single-copy chromosomal inserts of the cloned gene into a suitable target gene (Hamilton et al., 1989). Such reductions in gene dosage often reduce the final yield of protein, but the slower kinetics of synthesis they afford can sometimes result in production of soluble proteins.

To restate the obvious, protein expression is an inexact science at present. However, most proteins can be made in *E. coli* in a form that is useful for a variety of functions. The procedures employed are relatively quick and uncomplicated, and the rewards for success are great.

Expression Using the T7 RNA Polymerase/Promoter System

This unit describes the expression of genes by placing them under the control of the bacteriophage T7 RNA polymerase. This approach has a number of advantages compared to approaches that rely on *E. coli* RNA polymerase. First, T7 RNA polymerase is a very active enzyme: it synthesizes RNA at a rate several times that of *E. coli* RNA polymerase and it terminates transcription less frequently; in fact, its transcription can circumnavigate a plasmid, resulting in RNA several times the plasmid length in size. Second, T7 RNA polymerase is highly selective for initiation at its own promoter sequences and it does not initiate transcription from any sequences on *E. coli* DNA. Finally, T7 RNA polymerase is resistant to antibiotics such as rifampicin that inhibit *E. coli* RNA polymerase, and consequently, the addition of rifampicin to cells that are producing T7 RNA polymerase results in the exclusive expression of genes under the control of a T7 RNA polymerase promoter (hereafter referred to as p_{T7}).

To use the two-plasmid p_{T7} system, it is necessary to clone the gene to be expressed into a plasmid containing a promoter recognized by the T7 RNA polymerase. The gene is then expressed by induction of T7 RNA polymerase. The gene for T7 RNA polymerase is present on a second DNA construction. This second construction can either permanently reside within the *E. coli* cell (basic protocol), or can be introduced into the cell at the time of induction by infection with a specialized phage, such as an M13 vector (mGP1-2; Tabor and Richardson, 1987) or a λ vector (CE6; Studier et al., 1990) containing the T7 RNA polymerase gene (second alternate protocol).

In the basic protocol, two plasmids are maintained within the same *E. coli* cell. One (the expression vector) contains p_{T7} upstream of the gene to be expressed. The second contains the T7 RNA polymerase gene under the control of a heat-inducible *E. coli* promoter. Upon heat induction, the T7 RNA polymerase is produced and initiates transcription on the expression vector, resulting in turn in the expression of the gene(s) under the control of p_{T7} . If desired, the gene products can be uniquely labeled by carrying out the procedure in minimal medium, adding rifampicin to inhibit the *E. coli* RNA polymerase, and then labeling the proteins with [³⁵S]methionine (first alternate protocol).

EXPRESSION USING THE TWO-PLASMID SYSTEM

The gene to be induced is subcloned into an expression vector containing p_{T7} . Two series of vectors have been developed for this purpose—the pT7 series (Fig. 16.2.1) and the pET series (Studier et al., 1990); see commentary for discussion of choice of vector. The plasmid containing the introduced gene is then used to transform an *E. coli* strain already containing the plasmid pGP1-2 (Fig. 16.2.2). pGP1-2 contains the gene for T7 RNA polymerase under the control of the λp_L promoter that is repressed by a temperature-sensitive repressor (*cI857*). pGP1-2 contains a p15A origin of replication that is compatible with the ColE1 origin of replication on the expression vector. The two plasmids are maintained in the same cell by selection with kanamycin (pGP1-2) and ampicillin (the expression vector).

Cells containing the two plasmids are grown for several hours at 30°C and then the gene for T7 RNA polymerase is induced by raising the temperature to 42°C. The production of T7 RNA polymerase in turn induces expression of the genes under the control of p_{T7} . (Rifampicin can be subsequently added to inhibit transcription by *E. coli* RNA polymerase, although this is usually not necessary since T7 RNA polymerase becomes responsible for most of the transcription even in the absence of rifampicin.) Figure 16.2.1 pT7-5, pT7-6, and pT7-7. pT7-5, pT7-6, and pT7-7 are cloning vectors that contain a T7 promoter and are used to express genes using T7 RNA polymerase. All three vectors contain a T7 RNA polymerase promoter, the gene encoding resistance to the antibiotic ampicillin and the ColE1 origin of replication. pT7-7 has a strong ribosome-binding site (rbs) and start codon (ATG) upstream of the polylinker sequence; the sequence of this region is shown below the map of pT7-7. pT7-5 and pT7-6 lack any ribosome-binding site upstream of the polylinker sequence and consequently are only useful when expressing genes that already contain the proper control sequences. pT7-5, pT7-6, and pT7-7 were constructed by S. Tabor and are derivatives of pT7-1 described in Tabor and Richardson (1985).

of the genes at 37°C, the cells are harvested and the induced proteins are analyzed. An alternative approach is to induce T7 RNA polymerase with IPTG rather than by heat induction. In this method, the expression plasmid containing p_{T7} can be placed into *E. coli* BL21 (DE3), which contains the gene for T7 RNA polymerase on the *E. coli* chromosome under the control of the *lac* promoter (Studier and Moffatt, 1986; Studier et al., 1990).

Materials

pT7-5, pT7-6, or pT7-7 vectors (available from author)
E. coli JM105, DH1, or equivalent (Table 1.4.5)
 LB plates and medium containing 60 µg/ml ampicillin (UNIT 1.1)
E. coli K38 or equivalent (Table 1.4.5)
 pGP1-2 (available from author)
 LB plates and medium containing 60 µg/ml kanamycin (UNIT 1.1)
 LB plates and medium containing 60 µg/ml ampicillin plus 60 µg/ml kanamycin (UNIT 1.1)

Cracking buffer
 Sorvall SS-34 or GS-3 rotor or equivalent

Additional reagents and equipment for subcloning DNA fragments (UNITS 1.4 & 3.16), transformation of competent *E. coli* cells (UNIT 1.8), minipreps of plasmid DNA (UNIT 1.6), restriction mapping (UNITS 3.1-3.3), and SDS-PAGE (UNIT 10.2).

1. Subclone the fragment containing the gene to be expressed into pT7-5, pT7-6, or pT7-7. Transform a standard *E. coli* strain (e.g., JM105 or DH1); this strain should *not* carry a plasmid that directs synthesis of T7 RNA polymerase (i.e., pGP1-2). Plate the transformants on LB/ampicillin plates and grow overnight at 37°C.

Figure 16.2.2 pGP1-2. pGP1-2 enables T7 RNA polymerase to be produced by heat induction in any *E. coli* host. pGP1-2 contains the gene for T7 RNA polymerase under the control of the λ p_L promoter. It also contains the gene for the λ repressor (*c1857*) that is expressed under the control of *E. coli* p_{lac} promoter. This repressor inhibits transcription from the λ p_L promoter at low temperature (30°C); however, at high temperature (42°C) it is inactivated, resulting in induction of the p_L promoter, that in turn results in induction of the T7 RNA polymerase. pGP1-2 also contains the gene encoding resistance to the antibiotic kanamycin, and the p15A origin of replication. pGP1-2 is described in Tabor and Richardson (1985).

It is important to first transform the plasmid into a strain that contains no T7 RNA polymerase, in case small amounts of the gene product are toxic to the cell (see critical parameters for discussion on toxic genes).

2. Grow individual transformants in LB/ampicillin medium at 37°C and obtain plasmid DNA by a miniprep procedure. Confirm that the gene has been correctly inserted by restriction mapping.
3. Transform *E. coli* K38 with pGP1-2, plate on LB/kanamycin plates, and grow overnight at 30°C. Grow an individual *E. coli* K38/pGP1-2 transformant in LB/kanamycin medium at 30°C.

*Colonies take ~24 hr to appear on plates at 30°C. *E. coli* K38/pGP1-2 can be stored in the absence of the plasmid containing p_{T7} as a glycerol stock at -80°C (see commentary).*

4. Transform the vector containing the gene to be expressed under the control of p_{T7} into *E. coli* K38/pGP1-2 grown in LB/kanamycin medium. Plate the transformants (containing both plasmids) on LB/ampicillin/kanamycin plates and grow overnight at 30°C.

Cells may be heat-shocked during transformation; the T7 RNA polymerase gene, under the control of a heat-inducible promoter, is not induced by this brief heating step.

*As a control, transform *E. coli* K38/pGP1-2 with the parent p_{T7} vector (without an insert). If the transformation efficiency of the vector containing the insert is significantly lower (by more than a factor of 50) than that of the parent vector, the gene product may be toxic to *E. coli* cells. This toxicity arises from background expression of the gene product by basal levels of T7 RNA polymerase. In this situation, the transformants that do arise invariably contain deletions or other mutations in one of the two plasmids, and the desired gene product will not be produced. If the expression of the inserted gene is toxic, it is necessary to use an alternative strategy for the repression and induction of the T7 RNA polymerase gene (see discussion on toxic genes in critical parameters).*

5. Pick a single *E. coli* colony that contains the two plasmids with a sterile toothpick or pipet. Inoculate it into 5 ml LB/ampicillin/kanamycin medium and grow overnight at 30°C.
6. Dilute the overnight culture of cells 1:40 into fresh LB/ampicillin/kanamycin medium and grow several hours at 30°C to an $OD_{590} \cong 0.4$.

The size of the culture will depend on the amount of cells needed. For an analytical preparation, use ~1 ml of cells.

7. Induce the gene for T7 RNA polymerase by raising the temperature to 42°C for 30 min, which in turn induces the genes under the control of p_{T7} .

To obtain consistent results, raise the temperature relatively quickly. If small cultures (~1 ml) are being induced, place the cultures into a 42°C water bath. For larger cultures (~500 ml), place the flask under hot tap water until the temperature of the media reaches 42°C (measured by inserting a thermometer wiped with ethanol into the flask). Once the cells reach 42°C, continue incubating at 42°C for 30 min.

*The *E. coli* RNA polymerase can be inhibited by adding rifampicin to a final concentration of 200 µg/ml; when used, it should be added after T7 RNA polymerase has been induced at 42°C for 30 min. Although rifampicin reduces the background of host proteins being expressed, in general it does not significantly increase the final accumulation of gene products, and in some cases it decreases the final yield. Thus, as a general rule, rifampicin is only added to cells when the plasmid-encoded proteins are being uniquely labeled with [³⁵S]methionine (see first alternate protocol).*

8. Reduce temperature to 37°C and grow the cells an additional 90 min with shaking.
9. Harvest the cells by centrifuging and discarding the supernatant. For 1-ml cultures, microcentrifuge 20 sec at 10,000 rpm (14,000 × *g*), room temperature. For 2-ml to 100-ml cultures, centrifuge 5 min in a Sorvall SS-34 rotor at 5000 rpm (3000 × *g*), 4°C. For >100-ml cultures, centrifuge 10 min in a Sorvall GS-3 rotor at 5000 rpm (4000 × *g*), 4°C.
10. To analyze the induced proteins by SDS-PAGE, resuspend the equivalent of 1.0 ml of cells in 0.1 ml cracking buffer. Heat at 100°C for 5 min immediately prior to loading a 20- μ l aliquot of each sample onto an SDS-polyacrylamide gel (UNIT 10.2). To analyze the cells for an induced enzymatic activity, prepare an appropriate cell extract from ~10 ml of cells.

One example of the preparation of an extract for the purification of T7 RNA polymerase is described in Tabor and Richardson (1985).

SELECTIVE LABELING OF PLASMID-ENCODED PROTEINS

**ALTERNATE
PROTOCOL**

Plasmid-encoded proteins under the control of a p_{T7} (see basic protocol) can be exclusively labeled by inducing the T7 RNA polymerase in cells growing in minimal medium, inhibiting the host *E. coli* RNA polymerase with rifampicin, and labeling the newly synthesized proteins with [³⁵S]methionine. This procedure provides an attractive alternative to maxicells or minicells for labeling of plasmid-encoded proteins (Dougan and Sherratt, 1977; Sancar et al., 1981).

Additional Materials

- M9 medium (UNIT 1.1) without and with 5% (v/v) of 18 amino acid mixture
- 20 mg/ml rifampicin in methanol (e.g., Sigma #R-3501; store in dark at 4°C for 2 weeks; Table 1.4.1)
- 10 mCi/ml [³⁵S]methionine (>800 Ci/mmol) diluted 1:10 in M9 medium
- Fluorographic enhancing agent (e.g., Enlightning from Du Pont NEN or Amplify from Amersham)

1. Repeat steps 3 to 6 of the basic protocol (using the T7-promoter expression plasmid obtained from steps 1 and 2 of the basic protocol).

*An alternative to the use of LB/ampicillin/kanamycin medium for growing cells is M9 medium containing 25 μ g/ml ampicillin and 25 μ g/ml kanamycin, and any required nutrients. The addition of one part in twenty of the 18 amino acid mixture (0.1% stock, 0.005% final concentration) stimulates the growth of cells in M9 medium without interfering with the subsequent labeling of the proteins with [³⁵S]methionine. Note that to grow in this medium, the *E. coli* strain must be Cys⁺ and Met⁺.*

2. When OD₅₉₀ \cong 0.4, remove 1 ml of cells, microcentrifuge 10 sec, and discard supernatant.
3. Wash cell pellet with 1 ml M9 medium, microcentrifuge 10 sec at room temperature, and discard supernatant.

Washing the cells after growth in LB medium is very important in order to remove the unlabeled methionine present in LB medium that otherwise dilutes the [³⁵S]methionine during labeling.

4. Resuspend cell pellet in 1 ml M9 medium containing 18 amino acid mixture. Grow cells 60 min at 30°C with shaking.

A time of 30 to 180 min is adequate for adapting cells to M9 medium. Although the OD₅₉₀ may not increase significantly during this step, induction of T7 RNA polymerase and

**Protein
Expression**

16.2.5

efficient labeling of the plasmid-encoded proteins will occur even in the absence of apparent cell growth.

5. Induce the gene for T7 RNA polymerase by placing the cells in a 42°C water bath for 20 min.
6. Add 20 mg/ml rifampicin to 200 µg/ml final. Keep cells at 42°C for an additional 10 min after adding rifampicin.

It is important to incubate the cells at 42°C for an additional 10 min after adding rifampicin, since rifampicin is more effective at inhibiting expression of host proteins at 42°C, possibly because the cells are more permeable to it at this temperature. The temperature of the cells is subsequently reduced for the labeling since in general the labeling is less efficient at 42°C than at 30° or 37°C.

7. Shift cells to a 30°C water bath for an additional 20 min. Remove 0.5 ml of cells for labeling with [³⁵S]methionine.

The other 0.5 ml can be used to label the cells at a later time point (e.g., after an additional 30 min) in order to follow the duration of protein synthesis.

8. Label newly synthesized proteins by adding 10 µl (10 µCi) diluted [³⁵S]methionine to 0.5 ml of cells and incubating for 5 min at 30°C.
9. Microcentrifuge cells 10 sec and discard supernatant. (**CAUTION:** the supernatant is radioactive; discard properly.) Resuspend cell pellet in 100 µl cracking buffer.
10. Heat samples to 100°C for 5 min. Load a 20-µl aliquot onto an SDS-polyacrylamide gel and electrophorese (*UNIT 10.2*).
11. Treat the gel with a fluorographic-enhancing agent by soaking it in the fluor for 30 min. Dry the gel under vacuum 2 hr at 65°C and autoradiograph (*APPENDIX 3*).

A 1-hr exposure should be adequate to visualize most proteins induced with this system.

*To determine whether the plasmid-encoded proteins are susceptible to proteases in the *E. coli* cell, prepare and induce the cells as described above; however, reduce the duration of the labeling step to 1 min (step 8), and follow this with a chase of nonradioactive methionine at 0.5% final concentration. Remove an aliquot for analysis both immediately prior to the chase, and after a chase reaction of 5, 15, and 60 min. After removing each aliquot, immediately pellet the cells by centrifugation, resuspend in cracking buffer, and heat the aliquot to 100°C for 5 min to inactivate the proteases. Analyze as in step 10.*

ALTERNATE PROTOCOL

EXPRESSION BY INFECTION WITH M13 PHAGE mGP1-2

Whenever the gene for T7 RNA polymerase is present in *E. coli* cells, low levels of T7 RNA polymerase are constitutively produced. This can be a problem when the gene products under the control of p_{T7} are toxic. One strategy to avoid this is to keep the gene for T7 RNA polymerase out of the cell until the time of induction. In the protocol presented here, T7 RNA polymerase is introduced into the cell by infection with the M13 phage mGP1-2. This phage contains the gene for T7 RNA polymerase under the control of the *lac* promoter (Fig. 16.2.3). Host cells for this phage must carry the F factor so that they are susceptible to M13 infection (e.g., JM101 or K38). The cells are transformed with the single plasmid that contains the gene to be expressed under the control of p_{T7} . The cells are grown at 37°C, and induction occurs by infection with a high multiplicity of mGP1-2 in the presence of IPTG. A λ vector, CE6, that contains the gene for T7 RNA polymerase has also been used to express toxic genes (Studier and Moffatt, 1986; Studier et al., 1990).

Additional Materials

M13 phage mGP1-2 (available from author)

PEG solution (UNIT 1.7)

100 mM IPTG (Table 1.4.2)

Additional reagents and equipment for preparing M13 phage (UNIT 1.15) and titering phage (UNIT 1.11)

1. Prepare a stock of M13 phage mGP1-2 and concentrate the phage by precipitation with PEG solution. (DO NOT proceed to add TE buffer or phenol.) Resuspend phage in M9 medium and titer.

If the cell proteins are to be labeled, it is important that the phage used to infect the cells are free of unlabeled methionine. In this case, precipitate the phage with PEG twice, each time resuspending the pellet in M9 medium. For long-term storage of the M13 phage mGP1-2, it is best to purify the phage through a CsCl gradient (Nakai and Richardson, 1986).

2. Transform *E. coli* cells susceptible to M13 infection (e.g., JM101 or K38) with the T7-promoter expression plasmid obtained from steps 1 and 2 of the basic protocol. Plate the transformants on LB/ampicillin plates and grow overnight at 37°C.
3. Pick a single colony and grow in LB/ampicillin medium overnight at 37°C.
4. Dilute the overnight culture of cells 1:100 in LB/ampicillin medium and grow several hours at 37°C with gentle shaking to $OD_{590} \cong 0.5$.

*It is very important that only gentle shaking is used when growing cells for M13 infection. Vigorous agitation results in shearing of the pili on the surface of the *E. coli* cells, resulting in inefficient infection.*

5. Infect cells with M13 phage mGP1-2 (from step 1) at a ratio of ~10 phage for each *E. coli* cell. Add 100 mM IPTG to 1 mM final (a 1:100 dilution) to induce production

Figure 16.2.3 mGP1-2. M13 phage mGP1-2 contains the gene for T7 RNA polymerase under the control of the *E. coli* p_{lac} promoter. It is especially useful for the production of gene products that are toxic to the *E. coli* cell. When *E. coli* cells are infected with this phage, and IPTG is added to induce the p_{lac} promoter, T7 RNA polymerase is produced. As a result, any genes within the cell under the control of p_{T7} will be induced. mGP1-2 is described in Tabor and Richardson (1987).

of T7 RNA polymerase. Incubate the cells 2 hr at 37°C.

*At $OD_{590} \cong 0.5$, the density of *E. coli* cells will be $\sim 2 \times 10^8$ cells/ml. Thus, it is necessary to add M13 mGP1-2 phage at a final concentration of 2×10^9 phage/ml to obtain a multiplicity of infection of 10. Small cultures (~ 50 ml) can be incubated in a water bath without shaking. Larger cultures should be incubated at 37°C with gentle shaking.*

6. Harvest cells and analyze induced proteins as in steps 9 and 10 of the basic protocol.

REAGENTS AND SOLUTIONS

18 amino acid mixture

Prepare a solution containing 0.1% (v/v) of each amino acid except cysteine (minus cysteine) and methionine (minus methionine). Filter sterilize through a 0.2- μ m filter. Store at -20°C for several years.

Cracking buffer

60 mM Tris-Cl, pH 6.8
1% 2-mercaptoethanol
1% sodium dodecyl sulfate (SDS)
10% glycerol
0.01% bromphenol blue

COMMENTARY

Background Information

Bacteriophage T7 and T7-related phage (e.g., SP6, T3) encode their own RNA polymerase (see *UNIT 3.8*). Compared to other known RNA polymerases, this RNA polymerase is both relatively simple and highly efficient. T7 RNA polymerase is a single polypeptide of 96,000 kDa. It initiates transcription specifically at a 23-nucleotide promoter sequence, a sequence not present on the *E. coli* genome. Transcription is very processive, producing transcripts that are many thousands of nucleotides in length. Transcription is relatively rapid—five times the rate of *E. coli* RNA polymerase. All of these properties make T7 RNA polymerase and its promoter an attractive system for controlling the expression of foreign genes in *E. coli* and in other organisms. Expression systems in *E. coli* based on the controlled induction of T7 RNA polymerase have been developed by Tabor and Richardson (1985) and Studier and his colleagues (Studier and Moffatt, 1986; Rosenberg et al., 1987; Studier et al., 1990). The vectors described here are those developed by Tabor and Richardson. T7 RNA polymerase/promoter expression systems have also been successfully applied in yeast (Chen et al., 1987) and mammalian cells (Dunn et al., 1988; Fuerst et al., 1986).

Critical Parameters

Choice of vector

Questions that determine what vector to use to express a gene using T7 RNA polymerase include: Is there a ribosome-binding site upstream of the gene? What are the restriction sites available on each end of the gene? Is the gene product toxic to the *E. coli* cell? Examples of three standard vectors (pT7-5, pT7-6, and pT7-7) are shown in Figure 16.2.1. These vectors are derivatives of pBR322. The β -lactamase gene encoding amp^r is in the opposite orientation of p_{T7} ; consequently the only plasmid-encoded genes expressed by T7 RNA polymerase are those cloned into the polylinker region. pT7-5 and pT7-6 contain the polylinker region located immediately downstream of pT7 in opposite orientations. There is no ribosome-binding sequence in these two plasmids; they should thus be used either for the production of transcripts without expectation of good translation of the protein, or for the expression of genes that already have strong ribosome-binding sequences. pT7-7 differs from pT7-5 and pT7-6 in that it contains a strong ribosome-binding sequence between p_{T7} and the polylinker region; it is recommended for the expression of genes that lack a strong ribosome binding sequence or for the production of fusion proteins.

An extensive series of additional vectors containing p_{T7} , the pET series, have been described by Studier et al. (1990). These vectors are particularly useful for applications that require a greater selection of restriction endonuclease sites to insert the gene into, or that involve the expression of a gene that is toxic to the cell (see below). Some of these vectors contain other transcriptional regulatory elements (i.e., terminators, operators, RNase III cleavage sites) that could be of use for specific applications.

A large number of commercially available vectors contain a T7 RNA promoter (e.g., pIBI vectors, available from IBI; pSP6/T7-19, available from GIBCO/BRL; pBluescript II vectors, available from Stratagene; and pTZ18R and pTZ19R, available from U.S. Biochemical). These are intended to be used for producing specific transcripts in vitro using T7 RNA polymerase. In principle, they should be useful for the expression of genes using T7 RNA polymerase in vivo as well. In practice, however, the use of some of these vectors can result in some unexpected problems. (1) Most commercial vectors have extremely high copy numbers within the cell; this can accentuate the problems encountered with toxic genes. (2) In most vectors, the β -lactamase gene is oriented in the same direction as p_{T7} , complicating the analysis of radiolabeled proteins. (3) Some commercial vectors have p_{T7} oriented in a potentially deleterious direction. Derivatives of pBR322 that contain p_{T7} oriented clockwise with respect to the standard map are inviable in some *E. coli* strains that contain the gene for T7 RNA polymerase. This is due to the fact that high levels of transcription through the origin region of these plasmids in this orientation interferes with the replication of the plasmids. (4) Most commercial vectors have a *lac* operator sequence within them. This can titrate out the *lac* repressor (UNIT 1.4) and cause problems when the p_{lac} is used to control the T7 RNA polymerase gene.

Toxic genes

In some cases the gene to be expressed is toxic to the cells, even when it is not induced. This is due to a low level of constitutive expression present even under uninduced conditions. Although most genes are not toxic when expressed using the two-plasmid p_{T7} system, it is important to recognize the symptoms of toxicity to avoid selecting for mutations and to allow alternate systems for induction to be tried. The degree of toxicity varies greatly with each gene.

The symptoms encountered with toxic genes are discussed below, in order of increasing toxicity.

Some genes are mildly toxic to the cells when expressed using the two-plasmid p_{T7} system. In such cases, the cells can be stably transformed with the two plasmids and the gene product is produced at a high level. However, after the cells are several days old, they no longer induce the expected gene product even though they remain resistant to ampicillin and kanamycin. To avoid this problem, it is recommended that the *E. coli* K38/pGP1-2 be stored in the absence of the plasmid containing p_{T7} as a glycerol stock at -80°C (UNIT 1.3). The plasmid containing p_{T7} and the gene to be expressed should be stored as DNA at -20°C or -70°C (UNIT 1.6). To prepare the strain for induction, streak K38/pGP1-2 on an LB/kanamycin plate at 30°C , grow up a single colony, transform with the plasmid containing p_{T7} and the gene to be expressed, and plate the transformants on LB/ampicillin/kanamycin plates at 30°C . A single colony should then be grown at 30°C and induced as described above. This procedure is not necessary for genes that are not toxic. Strains that do not induce toxic genes can be stored in glycerol at -80°C for many months (UNIT 1.3).

A more toxic class of genes consists of those that can be successfully cloned into a plasmid under the control of p_{T7} , but that render the resulting plasmid unable to stably transform a cell that contains the gene for T7 RNA polymerase. Genes that are toxic to the cells only in the presence of pGP1-2 (which expresses the T7 RNA polymerase) are relatively common, occurring on the average ~5% of the time (S. Tabor, unpublished observation). Note that such plasmids will give transformants in *E. coli* cells containing pGP1-2, but that the frequency of transformation will be greatly reduced (>50-fold) compared to the frequency of transformation by the parent vector alone. The cells that do grow in the presence of ampicillin and kanamycin will invariably contain deletions or other mutations in one of the two plasmids, and the desired gene product will not be produced.

When genes are toxic at this level, it is necessary to use an alternative strategy that reduces the expression of the gene under uninduced conditions. One strategy is to remove the gene for T7 RNA polymerase from the cell until induction is desired, and then introduce it by a phage infection. Such an alternate protocol is described using an M13 phage harboring the gene for T7 polymerase, mGP1-2. A lambda

vector, CE6, that contains the gene for T7 RNA polymerase has also been used for this purpose (Studier and Moffatt, 1986; Studier et al., 1990). Another strategy is to retain the gene for T7 RNA polymerase in the cell but reduce the level of transcription by T7 RNA polymerase under uninduced conditions. For example, a system has been developed that expresses an inhibitor of T7 RNA polymerase—the T7 lysozyme—to reduce the activity of T7 RNA polymerase until it is induced (Studier et al., 1990). Another recent modification is the placement of p_{T7} under the control of the *lac* repressor, reducing the activity of T7 RNA polymerase until IPTG has been added (Studier et al., 1990).

Finally, some genes are difficult to clone in multicopy plasmids even in the absence of a known *E. coli* promoter. The difficulty in cloning these genes arises from the fact that their products are extremely toxic and that the residual low level of transcription by *E. coli* RNA polymerase in most plasmids is sufficient to direct the synthesis of small amounts of these proteins. One strategy that can be used to clone such toxic genes is to insert the gene near a strong *E. coli* promoter that is oriented so that transcription by the *E. coli* RNA polymerase results in the accumulation of RNA that is antisense to the toxic gene, reducing the level of its gene product. It is important to remember that the amount of a gene product synthesized is a function not only of the level of transcription but also of the efficiency at which translation is initiated. This is determined primarily by the ribosome-binding sequence located upstream of the start codon. Thus, some toxic genes with relatively weak ribosome-binding sequences can be cloned into multicopy plasmids, but not into a multicopy plasmid that also introduces a strong ribosome-binding sequence (S. Tabor, unpublished observations).

In summary, the first step in using the T7 RNA polymerase/promoter system is to clone the gene into an appropriate vector containing a p_{T7} and be certain it has an efficient ribosome-binding sequence. Once this is accomplished, the next step is determining whether the plasmid can stably transform an *E. coli* cell containing pGP1-2 at an efficiency comparable to that of the parent vector alone. If this is successful, the system is ready to be induced. If unsuccessful, it is necessary to induce the gene either by infection with M13 phage mGP1-2

(see second alternate protocol), or to use one of the more specialized vectors that further reduce the expression of T7 RNA polymerase in the cell under uninduced conditions (Studier et al., 1990).

Troubleshooting

For gene expression, one of the major advantages of the T7 RNA polymerase/promoter system over an *E. coli* RNA polymerase system is the ability to exclusively label the gene products under the control of p_{T7} . If the level of induction of the gene is estimated by inspection of a standard SDS-polyacrylamide gel, and it is difficult to see the expected induced product, then it is recommended that the induced proteins be labeled using [³⁵S]methionine as described in the first alternate protocol. This is a much more sensitive and specific assay for the specific protein production. Be sure that there is at least one methionine codon in the gene other than the one at the start of the protein (which is often removed in *E. coli*; Kirel et al., 1989); if not, then it is necessary to label with a cysteine or some other amino acid.

If it is not possible to detect the expected labeled product, there may be a problem with one of the two plasmids in the cell. One possibility is that the expressed protein is toxic to the cell, and as a result, a mutation has been selected for such that the toxic product is not synthesized. For more information on determining whether a gene is toxic, see the discussion on toxic genes in critical parameters. To determine if the cells and T7 RNA polymerase gene (e.g., pGP1-2) are inducing T7 RNA polymerase, attempt to induce a control protein that has been shown to work well in this system (e.g., the β -lactamase gene in pT7-1; Tabor and Richardson, 1985).

If the expressed protein does not accumulate significantly after induction, determine its stability in *E. coli* cells by pulse labeling with [³⁵S]methionine and chasing for various time periods with unlabeled methionine. If it is rapidly degraded, try to induce the gene in a protease-deficient strain. It should be noted that there are no known mutations that inactivate several very active *E. coli* proteases, and thus there is a strong probability that the mutant strains available (e.g., *lon*⁻) will have no effect on the stability of the gene product. In addition, such mutant strains generally grow poorly, and as a consequence the gene products are poorly produced upon induction of T7 RNA polymerase.

The most common reason for poor induc-

tion of a gene is that the translation does not initiate efficiently. Therefore, it is very important that there be an efficient ribosome-binding sequence the proper distance upstream of the gene. If a gene product does not induce well, and the problem is not the stability of the product, try a different ribosome-binding sequence—one that is known to work efficiently. The sequence and spacing between the ribosome-binding sequence and the start codon is critical. Because of this, it is recommended that the gene be inserted into a vector such as pT7-7, without altering any of the sequences between the ribosome-binding sequence and the start codon.

Anticipated Results

Under optimal conditions, the gene product expressed by the T7 RNA polymerase/promoter system can accumulate to >25% of the total cellular protein. However, in most instances the amount of gene product that accumulates is significantly less than this. There are numerous reasons for poor yields of gene product, as discussed in troubleshooting (see above).

Time Considerations

It should take ~1 week to insert the gene of interest into the pT7 vector, prepare minipreps of the DNA, and characterize the recombinants for the correct size and orientation of the insert. It should then take 3 days to transform the recombinant plasmid into the *E. coli* strain containing pGP1-2, induce the cells, and test the extracts for the production of the expected gene product.

Expression Using Vectors with Phage λ Regulatory Sequences

Many expression systems have been developed that utilize pBR322-based plasmids into which transcriptional and translational regulatory signals have been inserted. In the system described here, however, plasmids (pSKF) utilize regulatory signals—such as the powerful promoter p_L —from the bacteriophage λ . Transcription from p_L can be fully repressed and plasmids containing it are thus stabilized by the λ repressor, cI . The repressor is supplied by an *E. coli* host which contains an integrated copy of a portion of the λ genome. This so-called defective lysogen supplies the λ regulatory proteins cI and N but does not provide the lytic components that would normally lead to cell lysis. Thus, cells carrying these plasmids can be grown initially to high density without expression of the cloned gene and subsequently induced to synthesize the product upon inactivation of the repressor.

This system also ensures that p_L -directed transcription efficiently traverses any gene insert, which is accomplished by providing the phage λ antitermination function, N , to the cell and by including on the p_L transcription unit a site necessary for N utilization (Nut site). The N protein interacts with and modifies the RNA polymerase at the Nut site so as to block transcription termination at distal sites in the transcription unit.

In order to express the coding sequence, efficient ribosome-recognition and translation-initiation sites have been engineered into the p_L transcription unit. Expression occurs after temperature or chemical induction inactivates the repressor (see first and second basic protocols). Restriction endonuclease sites for insertion of the desired gene have been introduced both upstream and downstream from an ATG initiation codon. Thus, the system allows either direct expression or indirect expression (via protein fusion) of any coding sequence, thereby potentially allowing expression of any gene insert. Direct expression generates “authentic” gene products (first support protocol), while expression of heterologous genes fused to highly expressed gene partners generates chimeric proteins that differ from the native form. In the latter case, the fusion partner can be removed to obtain an unfused version of the gene product (second support protocol).

BASIC PROTOCOL

TEMPERATURE INDUCTION OF GENE EXPRESSION

Expression from p_L -containing vectors can be induced by raising the temperature. The *E. coli* lysogens used with these vectors are typically defective for phage replication and carry a temperature-sensitive mutation in the phage λ cI gene ($cI857$). After transformation and growth, induction is accomplished by raising the temperature of the culture from 32° to 42°C.

Materials

- Expression vector (e.g., pSKF series; see support protocols)
- E. coli* AR58 or equivalent (Table 1.4.5)
- LB plates containing the appropriate antibiotic (UNIT 1.1)
- LB medium containing appropriate antibiotic (room temperature and prewarmed to 65°C; UNIT 1.1)
- SDS/sample buffer (UNIT 10.2)
- Gyrotory air or water shaker, 32° and 42°C
- Additional reagents and equipment for transformation (UNIT 1.8)

1. Transform the expression vector into an *E. coli* λ lysogen (such as AR58) carrying a temperature-sensitive mutation in its repressor gene (λ $cI857$). Plate on LB/antibiotic plates and incubate transformants at 32°C.

Expression Using Vectors with Phage λ Regulatory Sequences

16.3.1

Current Protocols in Molecular Biology (1994) 16.3.1-16.3.11

Copyright © 2000 by John Wiley & Sons, Inc.

Heat-shock at 37° or 42°C for ≤90 sec during transformation is not a problem.

2. Grow the transformed cells overnight at 32°C in LB/antibiotic medium.
3. Dilute the overnight culture ≥1:20 into fresh LB/antibiotic medium. Grow the culture at 32°C in a gyrotory shaker at 250 to 300 rpm until OD₆₅₀ = 0.6 to 0.8.
4. Add 1/3 vol of 65°C LB/antibiotic medium with swirling in order to elevate the culture temperature rapidly to 42°C.

In our experience, a rapid increase in temperature favors production. Small shake-flask cultures (≤25 ml) are more easily induced by transfer to a 42°C gyrotory water bath without addition of prewarmed media. This generally raises the culture temperature to 42°C within 3 to 5 min.

5. Continue growing the culture 2 to 3 hr at 42°C.
6. Remove a 1-ml aliquot for analysis and harvest the remainder of cells by centrifuging 15 min in a low-speed rotor at 3000 × g, 4°C. Discard the supernatant.

Freeze cell pellet at -70°C until ready to isolate the gene product.

7. Spin the 1-ml aliquot 1 min at top speed in a microcentrifuge, then resuspend the pellet in 50 μl SDS/sample buffer. Boil 5 to 10 min and analyze gene product by SDS–polyacrylamide gel electrophoresis.

CHEMICAL INDUCTION OF GENE EXPRESSION

Expression using the pSKF system can also be induced chemically in lysogens that carry a wild-type (*ind*⁺) repressor gene (*cI857* cannot be used as it is *ind*⁻). This is accomplished by treating the bacterial host with an agent such as nalidixic acid. Nalidixic acid inhibits DNA gyrase and leads to DNA damage, which induces the SOS response. During the SOS response, wild-type repressor protein is cleaved. In this case, the wild-type repressor protein is cleaved by the RecA protease, which is induced by the SOS response. In contrast to induction by heat (product accumulates in 45 to 90 min) nalidixic acid–mediated induction of protein expression is comparatively slow (product accumulates in 5 to 6 hr).

Materials

Expression vector (e.g., pSKF series; see support protocols)

E. coli AR120 or equivalent (Table 1.4.5)

LB plates containing appropriate antibiotic (UNIT 1.1)

LB medium containing appropriate antibiotic (UNIT 1.1)

60 mg/ml nalidixic acid in 1 N NaOH (not necessary to filter sterilize; Table 1.4.1)

Additional reagents and equipment for transformation (UNIT 1.8)

1. Transform the expression vector into a replication-defective, *E. coli* *cI*⁺ lysogen (e.g., AR120). Plate on LB/antibiotic plates and incubate the transformants at 37°C.
2. Grow the transformed cells overnight at 37°C in LB/antibiotic medium.
3. Dilute the overnight culture ≥1:20 into fresh LB/antibiotic medium. Grow the culture at 37°C in a gyrotory shaker at 250 to 300 rpm until OD₆₅₀ = 0.4.
4. Add 1/1000 vol of 60 mg/ml nalidixic acid solution to give 60 μg/ml final concentration.
5. Continue growing the culture 5 to 6 hr at 37°C.
6. Harvest cells and analyze gene product (steps 6 and 7 of first basic protocol).

BASIC PROTOCOL

Protein Expression

16.3.2

AUTHENTIC GENE CLONING USING pSKF VECTORS

It is often most desirable to express a gene product in a form as similar to the native protein as possible. Such an “authentic” gene product will have the greatest chance of having a structure and activity identical to that of the native protein. Efficient translation of a coding sequence for an authentic gene product is typically accomplished by placing the inserted information immediately adjacent to a ribosome-binding site (a translational regulatory signal that interacts with the 16S rRNA of *E. coli* and contains an ATG initiation codon; Gold et al., 1981).

Strategic Planning

The translation-initiation signal utilized here is that of the phage λ *cII* gene. In order to make the translational information generally useful, the coding region of the gene has been removed from the vectors, leaving only their initiator *fMet* codon and upstream translational regulatory sequences. Additionally, these vectors have been engineered to provide restriction endonuclease sites on either side of the ATG, such that the initiation codon can be supplied by either the plasmid or the gene being inserted. Finally, restriction sites have also been engineered upstream of the translational regulatory region to permit insertion of other ribosome-binding sites. Those genes that contain restriction sites compatible with the sites on the vector may be inserted directly into the vector. As most genes do not contain appropriately positioned restriction sites, it is often necessary to adapt existing restriction cloning sites within the gene to fuse it to the translation-initiation signals provided by the vectors.

For example, pSKF101 (Fig. 16.3.1) and pSKF102 both have a *Bam*HI site adjacent to the initiation codon (ATGgatcc), while pSKF201 has an *Nco*I site (ccATGg) and pSKF301 (Fig. 16.3.2) has an *Nde*I site (catATG). The protocol presented below summarizes the steps to obtain an authentic gene clone using pSKF101 as an example.

Sample Protocol**Materials**

Appropriate restriction endonucleases and buffers (UNIT 3.1)

pSKF101 vector (available from A. Shatzman; Fig. 16.3.1)

Competent *E. coli* AS1 (Table 1.4.5; also known as MM294cI⁺)

Additional reagents and equipment for restriction digestion, (UNIT 3.1), oligonucleotide synthesis and purification (UNITS 2.11 & 2.12), nondenaturing PAGE (UNIT 2.7), isolation, recovery, and quantitation of DNA (UNIT 2.6 & APPENDIX 3), subcloning DNA fragments (UNIT 3.16), transforming, plating, and growing *E. coli* (UNITS 1.8, 1.1, & 1.3), and DNA miniprep (UNIT 1.6)

1. Identify a unique restriction endonuclease site close to the 5' end of the coding sequence of the gene to be expressed, as well as another unique site 3' to this gene's termination codon.
2. Synthesize two single-stranded DNA oligonucleotides, recreating the coding sequence immediately preceding the unique restriction endonuclease site near the 5' end of the gene to be expressed. Purify and quantitate the DNA, then anneal in order to obtain double-stranded DNA.

This synthetic DNA sequence is used to link the gene to be expressed to the initiating ATG of the pSKF expression vector. The double-stranded oligonucleotide should be designed to have ends that are complimentary to the restriction sites identified at the 5' end of the gene to be expressed as well as the chosen restriction site in the expression vector.

Figure 16.3.1 pSKF101. pSKF101 is a vector used for authentic gene cloning which allows direct expression of the inserted gene. It is a derivative of pBR322 (UNIT 1.5) containing sequences inserted between *Hind*III and *Bam*HI sites of pBR322. The inserted λ sequences contain the p_L promoter and *cII* ribosome-binding site (rbs); these are the transcriptional and translational regulatory sequences necessary to express heterologous genes in *E. coli*. Within this region are several unique restriction sites that permit insertion of the gene. The regions derived from pBR322 and λ are indicated. This plasmid can be maintained stably in a λ -lysogenized *E. coli* strain. The selectable marker is ampicillin, encoded by β -lactamase.

An alternate name for pSKF101 is pAS1 (Rosenberg et al., 1983). Alternative names of related vectors are as follows: pSKF102 is pOTSV (Shatzman and Rosenberg, 1987); pSKF201 is pOTS-Nco (Shatzman and Rosenberg, 1987); and pSKF301 is pMG1.

3. Digest 25 to 50 μ g plasmid DNA containing the gene to be expressed with the restriction endonucleases identified in step 1.

To ensure complete digestion, determine that the restriction endonuclease buffer is appropriate for each enzyme to be used. If the endonucleases require different buffers, then each restriction digestion must be done separately.

4. Electrophorese the doubly digested plasmid DNA on a polyacrylamide gel.

If the DNA fragment to be isolated is between 150 and 1100 bp, a 6% gel can be used. Either a borate- or acetate-buffer system can be used. If digestion was done in a large volume, ethanol precipitate the DNA (UNIT 2.1) and resuspend in 40 to 100 μ l TE buffer. Mix with loading dye and load.

5. Locate the fragment of interest by staining with an agent such as ethidium bromide and cut the DNA fragment out of the gel.

6. Recover the DNA by electroelution and quantitate the amount of DNA.

Confirm that the correct fragment has been isolated by running a small aliquot on an agarose gel. Be sure to run appropriate size markers in an adjacent lane.

7. Digest 10 μ g pSKF101 with *Bam*HI and a restriction endonuclease that generates ends compatible with the 3' end of the coding sequence (to accommodate the 3' end of the gene to be expressed).

Confirm that complete digestion of the vector has occurred by analysis of digested DNA

Figure 16.3.2 pSKF301. pSKF301 is a vector that can be used for both indirect and direct expression. It is similar to pSKF101 in that it contains the same transcriptional and translational regulatory sequences as well as selectable markers; it differs in that it contains a shorter segment of λ DNA than pSKF101. pSKF301 also contains the coding sequence of the first 81 amino acids of the influenza protein, NS1, shown as NS1-81. This region is adjacent to the *dl* ribosome-binding site (fbs) and contains restriction sites at the 3' end of NS1-81 that allow construction of translational fusions in any of the three reading frames. Removal of NS1-81 permits direct expression of the cloned gene. (This vector is also known as pmG1.)

on an agarose gel. Compare undigested pSKF101 with digested to make sure that pSKF101 has been completely linearized.

8. Prepare a ligation reaction (using the conditions described in UNIT 3.16) by combining the following ingredients:

- 1 ng digested pSKF101 vector DNA
- 10 ng of the gene fragment to be expressed (from step 6)
- 20 ng synthetic oligonucleotide (from step 2)
- T4 DNA ligase.

Ligate 10 to 12 hr at 4°C.

There is no need to dephosphorylate pSKF101 as long as there is at least a 5-fold molar excess of vector DNA to isolated DNA fragment and synthetic DNA.

9. Remove one-third of the ligation reaction and transform 50 to 100 μ l competent *E. coli* AS1. Plate on LB/ampicillin plates and incubate overnight at 37°C.
10. Pick 12 to 24 colonies and transfer with a sterile toothpick to 3 ml LB/ampicillin medium. Grow cells 5 to 18 hr and isolate DNA by a miniprep method.

Cells may be harvested once the broth appears turbid. For best results, allow 8 to 12 hr of growth.

11. Perform appropriate restriction endonuclease digests to determine which clones contain the desired construction of the gene to be expressed.
12. Transform an *E. coli* strain with the DNA and express the gene as in the basic protocols.

CONSTRUCTION AND DISASSEMBLY OF FUSED GENES IN pSKF301

By fusing the gene to be expressed to a coding region of another gene (the fusion partner), a chimeric gene can be constructed in an appropriate vector. Numerous vectors are available for this purpose but most share the common feature of a fusion partner that is a highly expressed gene. When expression of the chimeric gene is induced, the resulting proteins carry additional peptide information at the N terminus. Although the fusion product may have physical and/or functional properties that differ from the “authentic” protein, advantages of the approach include highly efficient expression (up to 30% of total cell protein) without complicated alterations on the gene, and the presence of a “handle” on the expressed protein which can help to identify and purify it. Such proteins are often used to develop antisera to specific proteins that have diagnostic potential, and have been used successfully to identify and define a variety of gene products (Casadaban et al., 1983; Rose and Botstein, 1983; Guarente, 1983).

Strategic Planning

Plasmid pSKF301 has been constructed to permit initial expression of a gene as a fusion product, followed by removal of the DNA encoding the fusion portion by restriction digestion. Finally, the unfused version of the gene is expressed as an authentic protein.

pSKF301 contains an *NdeI* restriction site adjacent to the ATG following the *cII* ribosome-binding site (Fig. 16.3.3). This ATG also serves as the translational start (Gold et al., 1981) of the *NS1* gene derived from the influenza nonstructural gene. This gene has been truncated to express only its first 81 amino acids. Just beyond the coding sequence for the 81st amino acid is a second *NdeI* site followed by three unique blunt-ended restriction sites, *HpaI*, *EcoRV*, and *StuI*, which allow for the insertion of genes into any of three reading frames. Immediately following the *StuI* site are sequences coding for translational stops in any of the three reading frames.

Figure 16.3.3 Sequence and restriction endonuclease sites (in the region used for cloning) of pSKF301 (**A**). Restriction endonuclease digestion shows the strategy utilized to obtain pSKF301 as a vehicle for expression in all three reading frames (**B**).

The expression of a gene of interest as a fusion protein may be achieved by utilizing any of the following restriction sites in pSKF301: *Nco*I, *Hpa*I, *Eco*RV, or *Stu*I. Choice of restriction site depends upon the reading frame necessary for the translation of a specific protein sequence. First, a unique restriction site close to the 5' end of the gene (or portion of the gene) to be expressed must be identified. Second, the appropriate restriction endonuclease is selected for digesting pSKF301 such that the gene will be expressed.

If the chosen restriction site is a blunt-end cutter, no further manipulation of that end is required. In the event the restriction site identified leaves either a 5' or 3' protruding end, further manipulation is required. "Filling in" using the Klenow fragment of *E. coli* DNA polymerase for 5' protrusions, or T4 DNA polymerase, S1, or mung bean nuclease for 3' protrusions, are methods of choice (see UNIT 3.16).

Sample Protocol

Materials

- Appropriate restriction endonucleases and buffers (UNIT 3.1)
- Klenow fragment of *E. coli* DNA polymerase I (UNIT 3.5)
- pSKF301 vector (available from A. Shatzman; Figs. 16.3.1 & 16.3.2)
- T4 DNA ligase (UNIT 3.14)
- Competent *E. coli* AS1 (Table 1.4.5; also known as MM294cI⁺)
- Additional reagents and equipment for large-scale plasmid prep (UNIT 1.7), agarose gel electrophoresis (UNIT 2.5), extraction and precipitation of DNA (UNIT 2.1), transformation of competent cells (UNIT 1.8), and restriction digestion and mapping (UNITS 3.1-3.3)

Construct a gene fusion in pSKF301

1. Assume the restriction site identified in the gene is a *Bam*HI site. Digest with *Bam*HI to obtain:

GATCC	XXX	XXX	XXX	XXX
G	YYY	YYY	YYY	YYY

2. Treat with Klenow fragment to fill in the unpaired bases to obtain:

GATCC	XXX	XXX	XXX	XXX
CTAGG	YYY	YYY	YYY	YYY

As noted above, Klenow fragment is used to fill in for 5' protrusions. For 3' protrusions, use T4 DNA polymerase (UNIT 3.5) or S1 or mung bean nuclease (UNIT 3.12).

3. Determine the proper reading frame of the gene. In this example assume XXX XXX XXX XXX is the proper reading frame; therefore, the coding sequence of the filled-in fragment should read:

GA	TCC	XXX	XXX	XXX
----	-----	-----	-----	-----

4. Determine which restriction endonuclease should be used to digest pSKF301 to allow expression of the fusion protein. For this example, *Stu*I is required to yield:

ccatg	gat	cat	atg	tta	aca	gat	atc	aag	gGA	TCC	XXX	XXX	XXX	XXX
pSKF301									fusion gene					

5. Prepare the vector and the fragment of the gene to be expressed as in the first support protocol, steps 3 to 12 (*except* no synthetic DNA is required).

Generate an authentic version of the gene

Once a gene has been expressed as a fusion protein, it may be desirable to obtain an unfused version of the gene product. If this is useful, follow steps 6 to 12.

To convert a fusion protein to an unfused protein when using pSKF301, be certain that the gene of interest does not contain an *NdeI* site. The following theoretical fusion construct will be used as an example in these steps:

6. Set up a large-scale plasmid preparation of the fusion construct to yield ~100 µg plasmid DNA.
7. Digest 10 µg of the construct with *NdeI*. Verify that all of the vector DNA has been completely digested by taking a small aliquot of the digested material and running it on an agarose gel next to lanes containing uncut plasmid and appropriate size markers. A 280-bp fragment should be observed; this contains the NS1-81 gene sequence being liberated from the construct.

Confirmation of complete digestion is extremely important.

8. Purify the digested construct by phenol/chloroform/isoamyl alcohol extraction followed by ethanol precipitation.
9. Add T4 DNA ligase to 1 µg of the *NdeI*-digested construct and incubate overnight at 4°C.
10. Transform ligated DNA into competent *E. coli* AS1 cells (or any other suitable *cI*⁺ lysogen).
11. Determine that the construct no longer contains the NS1-81 gene sequence by restriction analysis.

*Consult the restriction map of pSKF301 and the gene to be expressed to determine which endonucleases are diagnostic for identifying the construct devoid of the NS1-81 gene. If the *NdeI* digestion was complete upon ligation, reclosure is highly efficient. Expect 95% to 100% of the resulting transformants to contain the unfused construct.*

12. Transform the DNA and express the gene by temperature or chemical induction as in the basic protocols.

COMMENTARY

Background Information

Expression of a heterologous gene or gene fragment in *E. coli* requires that the coding sequence be placed under the transcriptional and translational control of regulatory elements recognized by the bacterial cell. The pSKF vectors were designed specifically to direct gene expression by providing regulatory signals from bacteriophage λ. Phage regulatory signals were chosen because of their high efficiency and ability to be tightly regulated. This system uses a promoter that can be tightly controlled, eliminating problems with “leaky”

basal expression sometimes found in other expression systems (see below). This system uses an antitermination mechanism to help assure efficient transcription across any gene insert. The different vectors used with this system offer several choices of antibiotic selection markers, contain elements that optimize plasmid stability, and carry a variety of restriction sites that permit relatively easy insertion of the gene of interest adjacent to the efficient translation regulatory information.

The pSKF system offers some advantages that differentiate it from many other expression

systems. Perhaps most important is the “tightness” of regulation of the p_L promoter. Several other strong regulatable promoters— p_{tac} (de Boer et al., 1982), p_{trp} (Edman et al., 1981), and p_{T7} (promoter of T7 gene 10; Studier and Moffatt, 1986)—are also used routinely for optimizing heterologous gene expression in *E. coli*. These promoters, along with p_L , are all of comparable strength and are sufficient to achieve very high levels of mRNA production (UNIT 16.1). In fact, these promoters are so powerful that further enhancement of promoter strength would not be expected to result in an increase of protein production; indeed, these promoters are so strong that it is very difficult to keep them fully turned off even in the “repressed” state. Because of this basal transcription under repressed conditions, use of the p_{tac} , p_{trp} , or p_{T7} (coupled with the p_{tac} -T7 polymerase) systems often leads to some expression of the cloned gene even under nonpermissive conditions. This may lead to plasmid loss or rearrangement, or possibly cell death, if small amounts of the gene product are lethal to *E. coli*. In contrast, one does not typically see expression of the cloned gene in the p_L system until cultures have been induced.

A second advantage of the p_L system over other promoter systems is the flexibility gained from having completely different induction systems (thermal and chemical). In contrast, the p_{tac} and p_{T7} systems mentioned above permit induction only by a chemical route. Different routes of induction lead to completely different cellular states (e.g., different physiology, morphology, and growth patterns) and these variations can lead to significant differences in gene product accumulation and stability (unpub. observ.). It should be pointed out that p_{trp} also permits dual modes of induction (by β -indolyl acetic acid or Trp starvation) and that a different version of the p_{T7} system has been developed (UNIT 16.2; Tabor and Richardson, 1985) in which the T7 RNA polymerase is thermally regulated via the p_L -cI857 system (however, this system is not chemically inducible as well).

The third major advantage of the pSKF system is the availability of a single vector that permits expression of either an authentic or a fusion gene product; furthermore, this vector allows the fusion gene to be converted to an authentic gene by a simple restriction digest followed by self ligation. Thus, a gene may be rapidly expressed at high levels as a protein fusion to give an initial reagent for use in activity studies and antisera preparation. Time

may then be taken to optimize the expression of the authentic (nonfusion) gene product, which will be better suited for functional and structural studies. Most other expression systems do not provide this flexibility.

Critical Parameters

Gene expression is not solely a function of message levels. The efficiency of the ribosome-binding region—including the sequences both upstream and downstream of the ATG initiation codon—also play a role in determining the extent to which a protein is made. Alterations in these sequences may affect the secondary structure of a message and the conformational presentation of the initiation signals which, as a result, can alter translational efficiency (Gold et al., 1981).

From our experience, the host strain plays a major role in determining the ultimate levels of gene expression. The reasons for the rather dramatic differences seen in product yield from different host strains are poorly understood. Product stability is, however, one determining factor that has been somewhat characterized. Host strains have been developed that are defective in certain proteases (UNIT 16.6). These specialized host strains can have a significant impact on the expression of certain gene products. However, proteases are not the only factor involved in strain-to-strain variations observed in protein expression. Other uncharacterized factors can have equally dramatic effects. It is therefore recommended that expression be tried in a number of different *E. coli* strains.

Following the induction of cultures carrying the desired expression vector, cells may be analyzed in a variety of ways to detect the presence of the cloned gene product. Most typically, the presence of the novel gene product is determined directly by observing in SDS-polyacrylamide gels a new, inducible protein band not present in lanes from control cultures.

The expression of any gene insert can also be identified and/or confirmed in several ways related to the activity or function of the protein including: (1) direct detection of a novel function or activity imparted to the living bacterial host; (2) genetic complementation of the appropriate mutant host; (3) assay of whole-cell extracts for the activity of the cloned gene product; and (4) assay after partial or complete purification of the cloned gene product.

Immunochemical methods such as immunoprecipitation (UNIT 10.16) or western blotting (UNIT 10.8) are some of the most sensitive meth-

ods available to detect expression of a gene product. These methods, of course, require that an antiserum be available which is specific for the protein to be expressed. These methods, however, are primarily quantitative and do not necessarily indicate anything about the level of expression, homogeneity, or activity of the gene product.

If a good antiserum to the protein of interest is not available, purification of sufficient amounts of a gene product allows generation of high-titer, antigen-specific mono- or polyclonal antisera (UNITS 11.3-11.13). One approach to generate an antiserum is to produce the desired heterologous gene product in bacteria as a native protein, as a fusion, or as a protein fragment. The protein may then be purified and used to produce high-titer mono- or polyclonal antisera. Such antisera have been used to (1) map natural expression of the gene product with respect to cell type, subcellular distribution, and temporal regulation; (2) determine relative levels of expression in various cell types; (3) study protein processing and stability; (4) map immuno-dominant domains; (5) purify by immunoaffinity both the native and modified forms of the protein; and (6) provide in vivo diagnostic reagents for examining tissue distribution and expression of the gene product by immunofluorescent methods.

Troubleshooting

There is never a guarantee that a gene will be expressed at high levels, but poor expression upon initial trials does not signify defeat. As mentioned earlier, transcription is rarely limiting and is, therefore, not the first parameter to be addressed in attempting to improve expression. Instead, the easiest parameter to change is the host strain being used for production. Typically, five or six different strains (which might or might not be closely related to each other) may have to be tested in pilot experiments to see which gives optimal production.

The next parameter to examine in the event of poor expression is translation. Expression may be increased by altering ribosome-binding sites to improve complementarity to the 16S rRNA, or by increasing the A-T richness of the 5'-end of the gene's coding region.

After steps have been taken to optimize translation, it is often helpful to alter the promoter and repressor system in order to change the induction system and the physiology of the cells during the production phase. For example, inducing the *cI857*-containing p_L system via a temperature shift generates a cellular heat-

shock response and protein synthesis at 42°C. Induction of this system with nalidixic acid leads to a cellular SOS response (see glossary, Chapter 1 introduction) and protein production at 37°C. Induction of the *trp* system by tryptophan starvation turns on the host stringent response (a generalized response of *E. coli* to amino acid starvation). Thus, in each case, a different host response leads to induction of a different set of host proteins as well as to greatly different physiological effects (such as changes in respiration, filamentation, and growth rate).

Finally, it may be possible to improve expression by optimizing the temperature at which the protein is made, as this parameter has often been shown to affect the proteins' solubility, stability, and activity.

Anticipated Results

Expression of most gene products as fusions with the first 81 amino acids of the NS1 protein (using pSKF301) can be achieved at levels between 5% and 30% of total cellular protein. Expression levels of nonfusion proteins (authentic) are less predictable and may vary from <1% to 30% of total cell protein. By systematically optimizing each of the parameters described in the troubleshooting section, it may be possible to increase the level of expression of a nonfusion gene product from the low end of this range to the high end. In shake flask cultures this is equivalent to hundreds of milligrams per liter and in fermenters (where greater cell densities are achieved) to grams per liter of the desired product. The expressed product can usually be visualized by running a small aliquot of cell extract on an SDS-polyacrylamide gel and staining with Coomassie Brilliant Blue. The majority of the protein produced will be insoluble, but can often be solubilized and renatured to an active state (UNIT 16.5).

Time Considerations

Cell growth, induction, and harvesting require 6 to 8 hr depending on the strain of *E. coli* and the mode of induction used. Following harvest, the cell pellets may be frozen at -70°C for long periods with no obvious loss of gene product. It is often convenient to analyze a small aliquot of the induced culture (removed prior to harvesting the remainder of the culture) by SDS-PAGE the next day, as this step will require several hours including gel preparation, gel running, staining, and destaining. Once it is clear that sufficient levels of protein have been produced to merit purification efforts, cells may be lysed and product extracted (if insoluble) by

use of detergents and/or chaotropes. This will take 1 to 2 days depending on the number of extraction steps required and the length of dialysis steps chosen between extractions.

Introduction to Expression by Fusion Protein Vectors

UNIT 16.4A

Expression—the directed synthesis of a foreign gene—is often the logical next step for researchers who have isolated a gene and want to study the protein it encodes. During the early days of recombinant DNA technology, it was thought that a strong promoter and a start codon at the beginning of the gene would be sufficient for good expression in *Escherichia coli*. Since then it has been learned that the requirements for efficient translation are a good deal more complicated. In addition to a promoter and a start codon, good expression requires that the mRNA encoding the protein to be expressed contain a ribosome-binding site that is not blocked by mRNA secondary structure. The level of expression is also affected by codon preferences, especially in the second codon of the gene (Stormo et al., 1982), and may be affected by the coding sequence in other ways that are not yet well understood (UNIT 16.1). In virtually all cases, these problems can be solved by altering the sequence preceding the start codon, and/or by making changes in the 5' end of the coding sequence that do not change the protein sequence, taking advantage of the degeneracy of the genetic code.

However, it is often quicker to solve these problems by making fusions between genes. In this approach the cloned gene is introduced into an expression vector 3' to a sequence (carrier sequence) coding for the amino terminus of a highly expressed protein (carrier protein). The carrier sequence is often from an *E. coli* gene, but it can be from any gene that is strongly expressed in *E. coli*. The carrier sequence provides the necessary signals for good expression, and the expressed fusion protein contains an N-terminal region encoded by the carrier. In such vectors, the portion of the fusion protein encoded by the carrier can be as small as one amino acid (UNIT 16.3; Amann and Brosius, 1985), although expression from such vectors can still be subject to problems caused by the coding sequence of the expressed protein. Perhaps more typical examples of short carrier sequences are those contained in the *trpE* vectors (UNIT 16.5) or the λ cII vectors (Nagai and Thøgersen, 1987).

The carrier sequence can also code for an entire functional moiety or even for an entire protein. For example, the following four units

(UNITS 16.5-16.8) describe the use of vectors that express β -galactosidase and *trpE* fusions, maltose-binding protein (MBP) fusions, glutathione-S-transferase (GST) fusions, and thioredoxin (Trx) fusions. These carrier regions often can be exploited in purifying the protein, either with antibodies or with an affinity purification specific for that carrier protein. Alternatively, unique physical properties of the carrier protein (e.g., heat stability) can be exploited to allow selective purification of the fusion protein. In addition, some carrier proteins such as MBP and Trx can be selectively released from intact cells by osmotic shock or freeze/thaw procedures, even though they reside in different cellular compartments. Often, proteins fused to these carriers can be separated from the bulk of intracellular contaminants by taking advantage of this attribute.

There are three problems often encountered when expressing fusion proteins: solubility of the expressed protein, stability of the expressed protein, and presence of the carrier protein. The first two problems are often encountered with both fusion and nonfusion expression systems (UNIT 16.1), while the third is unique to fusion systems.

SOLUBILITY OF THE EXPRESSED PROTEIN

The high-level expression of many proteins can lead to the formation of *inclusion bodies*, very dense aggregates of insoluble protein and RNA that contain most of the expressed protein (Schein, 1989). Precipitation of a protein into inclusion bodies sometimes can work to one's advantage, because inclusion bodies are insoluble and dense, and can be purified relatively easily by centrifugation (UNIT 16.5). In addition, some proteins that are degraded when expressed in the soluble fraction are quite stable as inclusion bodies. Once purified, protein in inclusion bodies can be solubilized by denaturation with guanidine·HCl or urea, and then can often be refolded by dialyzing away the denaturant. A problem, however, with denaturation/renaturation is that the yield of properly refolded protein is variable and sometimes quite low; some proteins, especially large ones, cannot be properly refolded at all (see UNIT 16.5).

If expression of a particular fusion protein produces insoluble aggregates and a soluble protein is required, there are several things to try. One important variable is temperature; for reasons not well understood, higher temperatures (37° and 42°C) promote inclusion-body formation and lower temperatures (30°C) inhibit it (Bishai et al., 1987; Schein, 1989). Another variable is the level of expression; sometimes lowering the expression level can increase the proportion of protein that is soluble. A third variable is the strain background of the cells bearing the expression vector; large differences in the proportion of a particular expressed protein that is soluble are seen among different strains (M. Southworth, S. Levitt, and F. Perler, unpub. observ.; it is not known which of the genetic differences between the strains is responsible for the differences in solubility). Finally, it is worth noting that changes in the carrier protein can affect the solubility of an expressed fusion protein (La Vallie et al., 1993).

STABILITY OF THE EXPRESSED PROTEIN

Stability problems are often encountered when foreign proteins, especially eukaryotic proteins, are expressed in *E. coli*. The carrier protein can sometimes stabilize an expression fusion protein (Lee et al., 1984). Sometimes, however, the expressed protein is degraded but the carrier protein is not. Moreover, fusion proteins are sometimes cleaved in vivo at the fusion joint between the carrier and expressed portions of the fusion, which obviously creates problems if the carrier protein is to be used as an aid in purification. These facts about fusion proteins are consistent with a model in which the carrier and the rest of the protein form independent domains. In this view, it can be imagined that there are cases where the carrier domain folds correctly and the expressed protein does not (and is degraded). There are also cases where both domains fold correctly but the joint region between them is sensitive to one or more *E. coli* proteases.

Approaches that have been used to stabilize fusion proteins are generally the same as those used to stabilize nonfusion proteins. One method is to arrange for the fusion protein to be expressed as insoluble aggregates. Another method is to use *E. coli* strains deficient in known proteases. For example, a *lon htpR* double-mutant strain—which is deficient in several cytoplasmic proteases—shows reduced degra-

ation of unstable proteins (Baker et al., 1984; I. Hall and P. Riggs, unpub. observ.). Similarly, the *degP* mutant has been shown to stabilize fusion proteins in the periplasm (Strauch and Beckwith, 1988) and *ompT* mutants have proven useful in preventing cleavage between exposed basic residues (e.g., Arg-Arg) in several nonfusion proteins during preparation of crude extracts (Grodberg and Dunn, 1988; Sugimura and Higashi, 1988). Finally, the stability of a particular fusion can vary even among different “wild-type” lab strains, perhaps due to uncharacterized differences in protease levels among the strains (I. Hall, P. Riggs, M. Southworth, S. Levitt, and F. Perler, unpub. observ.).

CLEAVAGE OF FUSION PROTEINS TO REMOVE THE CARRIER

The use of fusion proteins is growing rapidly for the many reasons described above. The various systems described in the following units have been used to produce many different kinds of proteins ranging from enzymes and growth factors to transmembrane receptors and DNA binding proteins. Often it is advantageous to remove the carrier protein moiety from the protein of interest to facilitate biochemical and functional analyses. Several methods for site-specific cleavage of fusion proteins have been developed (UNIT 16.4B). The choice of method is usually determined by the composition, sequence, and physical characteristics of the particular protein. Chemical cleavage of fusion proteins can be accomplished with reagents such as cyanogen bromide (Met↓, Itakura et al., 1977), 2-(2-nitrophenylsulphenyl)-3-methyl-3'-bromoindolenine (BNPS-skatole, Trp↓, Dykes et al., 1988), hydroxylamine (Asn↓Gly, Bornstein and Balian, 1977), or low pH (Asp↓Pro, Szoka et al., 1986). Chemical cleavage procedures tend to be inexpensive and efficient, and often can be accomplished under denaturing conditions to cleave otherwise insoluble fusion proteins (Szoka et al., 1986). However, their use is hampered by the likely occurrence of cleavage sites in the protein of interest, along with the propensity for side reactions that result in unwanted modifications to the protein. As an alternative to chemical methods, enzymatic cleavage procedures are desirable for their relatively mild reaction conditions and, most importantly, for the high degree of specificity exhibited by some proteases commonly used for this purpose. Among the useful enzymes are factor Xa (Nagai and

Thøgersen, 1984, 1987; Gardella et al., 1990), thrombin (Smith and Johnson, 1988; Gearing et al., 1989), enterokinase (Dykes et al., 1988; LaVallie et al., 1993), renin (Haffey et al., 1987), and collagenase (Germino and Bastia, 1984). All of these enzymes have extended substrate recognition sequences (up to 7 amino acids in the case of renin), which greatly reduces the likelihood of unwanted cleavages elsewhere in the protein. Of the above-mentioned proteases, factor Xa and enterokinase are most useful in this application because they cleave on the carboxy-terminal side of their respective recognition sequences, allowing the release of fusion partners containing their authentic amino-termini.

UNITS 16.5, 16.6, 16.7 & 16.8 describe five different fusion protein vector systems; of these, only three include recognition sites for interdomain cleavage. The MBP fusion system (UNIT 16.6) provides a factor Xa cleavage site. The GST fusion system (UNIT 16.7) includes vectors that contain either a thrombin cleavage site, a factor Xa cleavage site, or an Asp-Pro acid cleavage site. The Trx fusion system (UNIT 16.8) uses an enterokinase cleavage site. UNIT 16.4B describes fusion protein cleavages in detail, including specific protocols for cleaving fusion proteins produced with each of the aforementioned vector systems, along with methodologies for the site-specific cleavage of proteins using various chemical reagents.

Enzymatic and Chemical Cleavage of Fusion Proteins

The use of gene fusion expression systems has become an increasingly popular method of producing foreign proteins in *Escherichia coli*. This popularity is due in large part to the development of fusion systems that are capable of producing large amounts of fusion protein in a soluble form. The maltose-binding protein (MBP, UNIT 16.6), glutathione-S-transferase (GST, UNIT 16.7), and thioredoxin (Trx, UNIT 16.8) fusion systems have proven singularly successful in producing properly folded and biologically active proteins. Each of these systems also provides convenient methods for specific purification of the fusion protein from cellular contaminants. As a result, proteins produced using these systems are readily amenable to the study of their biological activities and/or interactions. As a consequence of the popularity of fusion protein expression strategies, the ability to cleave the N-terminal fusion “carrier” protein from the C-terminal protein of interest has become increasingly important.

This unit provides protocols for some commonly used methods of site-specific cleavage of fusion proteins. The first three protocols describe enzymatic cleavage of proteins using proteases that display highly restricted specificities, which greatly decrease the likelihood that unwanted secondary cuts will occur. The first basic protocol describes the use of factor Xa, a mammalian serine protease that cleaves following the sequence Ile-Glu(or Asp)-Gly-Arg↓. This protocol can be applied to fusion proteins produced with either the MBP (UNIT 16.6) or the GST system (pGEX3X vector; UNIT 16.7); both systems utilize expression vectors that encode a factor Xa cleavage site. A support protocol describes conditions for denaturing proteins for factor Xa cleavage if necessary. The next two protocols (first and second alternate protocols) describe cleavage with thrombin, a site-specific protease that recognizes the sequence Leu-Val-Pro-Arg↓Gly-Ser in one of the GST expression vectors (pGEX2T) described in UNIT 16.7. The third enzymatic cleavage protocol (third alternate protocol) uses enterokinase (enteropeptidase), a mammalian intestinal protease that cleaves following the sequence Asp-Asp-Asp-Asp-Lys↓. The Trx fusion vectors pTRXFUS and hpTRXFUS (UNIT 16.8) encode an enterokinase cleavage site immediately prior to their fusion junctions.

Three additional protocols describe cleavage of fusion proteins with chemical reagents as an alternative to enzymatic cleavage. These have some advantages. Though these methods may require modification of the fusion protein so a scissile or labile bond resides at the desired point of cleavage, they may be useful for cleaving fusion proteins with solubility problems or those that are otherwise refractory to enzymatic cleavage. Chemical cleavage methods have the disadvantage of being less specific, and it is necessary to ensure that a susceptible peptide bond does not exist in the protein of interest. The first of the chemical cleavage protocols (second basic protocol) uses cyanogen bromide to cleave after methionine residues. The second method (fourth alternate protocol) uses hydroxylamine to specifically cleave between asparagine and glycine residues. The final chemical cleavage protocol (fifth alternate protocol) cleaves fusion proteins by exploiting the lability of the Asp-Pro bond at low pH.

ENZYMATIC CLEAVAGE OF FUSION PROTEINS WITH FACTOR Xa

Fusion proteins that have been produced with the MBP fusion vectors pMAL-c2, pMAL-p2, or the GST fusion vector pGEX3X contain a recognition sequence for coagulation factor Xa encoded in the DNA immediately preceding the polylinker cloning site. Fusion proteins produced in other systems must be adapted to encode this recognition sequence. It is important to note that factor Xa will not cleave if a proline residue follows the arginine of the recognition sequence. Purification of the fusion protein prior to cleavage is recommended to minimize degradation of the product by nonspecific cellular proteases during incubation with factor Xa protease. Prior purification of the fusion protein also allows subsequent isolation of the cleaved product by simply repeating whatever affinity purification step was performed to purify the fusion protein. This step now removes the fusion partner.

Factor Xa is typically added to the fusion protein substrate at a ratio of 1% to 2% (w/w). However, cleavage efficiency varies depending upon the individual fusion, and ratios ranging from 0.1% to 5% may be effective. Incubation times can be from 1 hr to several days at either room temperature or 4°C. A support protocol describes denaturing and renaturing soluble fusion proteins that do not cleave well under the standard native cleavage conditions. This procedure should be considered a last resort because of the uncertainty of regaining properly folded protein and the inevitable decrease in overall yield.

Materials

For recipes, see Reagents and Solutions in this unit (or cross-referenced unit); for common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

- 1 mg/ml fusion protein
- 200 µg/ml factor Xa (New England Biolabs) in reaction buffer (see step 1)
- 2× SDS sample buffer (UNIT 10.2)
- Boiling water bath
- Additional reagents and equipment for SDS-PAGE (UNIT 10.2)

1. Prepare two small-scale trial reactions to determine optimum incubation time as follows:

Reaction 1: 20 µl of 1 mg/ml fusion protein with 1 µl of 200 µg/ml factor Xa.

Reaction 2: 5 µl of 1 mg/ml fusion protein and no factor Xa (mock digestion).

Incubate at room temperature.

Fusion protein in column buffer from amylose-resin purification (UNIT 16.6; with 1 mM CaCl₂) or in PBS from glutathione-agarose purification (UNIT 16.7) is suitable for factor Xa digestion; otherwise the protein should be prepared in 20 mM Tris·Cl (pH 8.0)/1 mM CaCl₂/100 mM NaCl.

Although most fusion proteins could be kept at 4°C, any remaining fusion protein solution can be stored at -70°C, in 10% glycerol, until used in step 6.

2. At 2, 4, 8, and 24 hr, remove 5-µl aliquots of the factor Xa reaction, add 5 µl of 2× SDS sample buffer, and freeze at -20°C.
3. At 24 hr mix 5 µl mock digestion with 5 µl of 2× SDS sample buffer.
4. Mix 5 µl of original fusion protein solution with 5 µl of 2× SDS sample buffer (uncut control).

5. Heat all samples 10 min in a boiling water bath and load onto an SDS-polyacrylamide gel. Evaluate extent of cleavage to determine correct incubation time.

Gel composition and running conditions will be determined by the size of the fusion protein.

If only partial cleavage is evident, increase amount of enzyme and/or incubation time. If no cleavage is apparent, proceed to the next support protocol.

6. Once satisfactory cleavage conditions have been determined, scale up the trial reaction for the remainder of the fusion protein sample, saving a small amount of uncleaved fusion protein for comparison purposes. Monitor the extent of cleavage by SDS-PAGE.

The cleavage products can be separated using any of the support protocols in UNIT 16.6.

DENATURING A FUSION PROTEIN FOR FACTOR Xa CLEAVAGE

It has been observed that some fusion proteins are resistant to cleavage with factor Xa. This problem can sometimes be alleviated by denaturing the fusion protein, renaturing it, and then incubating it with protease. The following protocol has been adapted from New England Biolabs' recommendations for MBP fusion proteins, and should be applicable to any fusion protein that contains an inaccessible factor Xa cleavage site. Denaturation is accomplished by incubating the fusion protein in 6 M guanidine-HCl followed by dialysis against the reaction buffer.

Additional Materials

*For recipes, see **Reagents and Solutions** in this unit (or cross-referenced unit); for common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.*

20 mM Tris·Cl (pH 7.4)/6 M guanidine-HCl

20 mM Tris·Cl (pH 8.0)/1 mM CaCl₂

1. Dialyze fusion protein for ≤4 hr against ≥10 vol of 20 mM Tris·Cl (pH 7.4)/6 M guanidine-HCl, or add guanidine-HCl to the fusion protein to give a final concentration of 6 M.
2. Dialyze the sample for 4 hr against 100 vol of 20 mM Tris·Cl (pH 8.0)/1 mM CaCl₂.
3. Repeat the second dialysis for an additional 4 hr against 100 vol fresh buffer.

This denaturation procedure is intended to allow better accessibility of the cleavage site to factor Xa before the protein can completely reassume its former protease-resistant conformation. Therefore, it is best to proceed with the cleavage reaction immediately following dialysis. However, rapid removal of denaturant sometimes results in precipitation of the protein; in these cases, gradual removal of denaturant by stepwise dialysis against 2-fold dilutions of the guanidine-HCl solution may keep the protein from precipitating. Alternatively, the fusion protein remaining in solution after rapid dialysis precipitation can be recovered and cleaved, and the insoluble material discarded.

4. Proceed with step 1 of the first basic protocol for factor Xa cleavage.

SUPPORT PROTOCOL

ENZYMATIC CLEAVAGE OF FUSION PROTEINS WITH THROMBIN

Thrombin is a mammalian serine protease that cleaves in a trypsin-like manner; that is, it cleaves after arginine and lysine residues. However, thrombin displays distinct subsite preferences, with optimum cleavage occurring at sites containing P4-P3-Pro-Arg↓P1'-P2' (where P4 and P3 are hydrophobic amino acids and P1' and P2' are nonacidic amino acids). The GST fusion system (UNIT 16.7) utilizes a vector that encodes a cleavage site with this restricted specificity (Leu-Val-Pro-Arg↓Gly-Ser). GST fusion proteins expressed with the pGEX2T vector (Fig. 16.7.1) can be cleaved with thrombin either after affinity purification on glutathione-agarose, or alternatively, while still bound to the affinity matrix. The following alternate protocols describe both methods for cleaving the fusion protein: first, cleavage of fusion proteins with thrombin in solution, an approach that is applicable to any fusion protein containing a thrombin recognition sequence; and second, thrombin cleavage of GST fusion proteins bound to glutathione-agarose. The latter technique is preferred for GST fusion proteins because it is faster and usually requires less work. However, the approach may not always work: some proteins may become insoluble when separated from the GST carrier, thus complicating their physical separation from the affinity matrix. In this case, the first alternate protocol should be used.

Additional Materials

For recipes, see **Reagents and Solutions** in this unit (or cross-referenced unit); for common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.

Thrombin cleavage buffer (see recipe)
Heparin, sodium salt (with ≥ 140 U/mg activity, Sigma; optional)
Thrombin (human, with ~ 3000 U/mg activity; Sigma or Boehringer Mannheim)

1. Prepare two pilot cleavage reactions to determine optimal reaction conditions as follows:

Reaction 1: 20 μ l of 1 mg/ml fusion protein solution (in appropriate buffer) and 0.2 μ g thrombin.

Reaction 2: 5 μ l of 1 mg/ml fusion protein solution only (mock digestion).

Incubate at 25°C.

GST fusion protein that has been eluted from glutathione-agarose in 50 mM Tris·Cl (pH 7.5)/5 mM reduced glutathione can be used after addition of NaCl to 150 mM and CaCl₂ to 2.5 mM and adjustment of the protein concentration to 1 mg/ml. Other fusion proteins can be resuspended or dialyzed in thrombin cleavage buffer (without glutathione) for subsequent cleavage.

Addition of 10 μ M heparin to the cleavage reaction is optional. It has been reported (Chang, 1985) that this increases the rate of some cleavages by 10% to 50%, apparently due to a direct interaction with the enzyme.

2. At 30 min, 1, 2, and 4 hr, remove 5 μ l from the thrombin reaction and mix with 5 μ l of 2 \times SDS sample buffer. Freeze at -20°C .
3. At the 4 hr time point, add 5 μ l of 2 \times SDS sample buffer to the mock digestion.
4. Mix 5 μ l of original fusion protein solution with 5 μ l of 2 \times SDS sample buffer (untreated control).
5. Boil all samples 10 min and load on an SDS-polyacrylamide gel to analyze sample stability and efficiency of cleavage.
6. Use those conditions determined empirically to be best for cleaving the fusion protein to scale up the cleavage reaction for the desired quantity of protein.

In addition to varying the time of incubation, the amount of thrombin and the temperature of incubation (up to 37°C) may also be varied to determine the optimum conditions for cleavage of a particular fusion protein.

ENZYMATIC CLEAVAGE OF MATRIX-BOUND GST FUSION PROTEINS

ALTERNATE PROTOCOL 2

In this alternate protocol, GST fusion proteins that contain a thrombin cleavage site are bound to glutathione-agarose as described in *UNIT 16.7*. Prior to elution from the matrix, thrombin is added and the protein of interest is cleaved from the GST carrier. The cleaved protein is collected in the wash buffer and the GST carrier remains bound to the beads, permitting easy and efficient physical separation of the reaction products.

Additional Materials

*For recipes, see **Reagents and Solutions** in this unit (or cross-referenced unit); for common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.*

GST fusion protein bound to glutathione-agarose beads (*UNIT 16.7*)
1% (v/v) Triton X-100 in phosphate-buffered saline (PBS; *APPENDIX 2*)
GST wash buffer: 50 mM Tris·Cl (pH 7.5)/150 mM NaCl
GST elution buffer: 50 mM Tris·Cl (pH 8.0)/5 mM reduced glutathione
20- or 50- ml screw-cap tube

1. Wash GST fusion protein bound to glutathione-agarose beads with 20 vol of 1% Triton X-100 in PBS, using a 20- or 50-ml screw-cap tube. Centrifuge 10 sec in a tabletop centrifuge at $500 \times g$, room temperature, to pellet the beads. Carefully remove and discard the supernatant. Resuspend the beads in 20 vol Triton X-100 buffer and repeat wash.
2. After the second centrifugation, carefully remove and discard the supernatant. Resuspend the beads in 20 vol GST wash buffer.
3. Pellet the beads and discard the supernatant. Resuspend the beads in 20 vol thrombin cleavage buffer. Repeat the centrifugation and resuspend the beads in ≤ 1 ml thrombin cleavage buffer.

Although it is easier to wash the beads in large volumes, the amount of thrombin cleavage buffer to use in the cleavage reaction is best kept to a minimum.

4. Remove a small aliquot of resuspended beads and add an equal volume of $2\times$ SDS sample buffer. Store at -20°C until analyzed by SDS-PAGE (step 7).

This sample is used to estimate the amount of fusion protein bound to the beads.

5. Add thrombin to the remaining bead slurry at a ratio of 1% (w/w) thrombin to the estimated amount of bound fusion protein. Incubate 1 hr at 25°C .

As in solution cleavage, the amount of thrombin, time, and temperature of incubation can be adjusted to optimize the cleavage efficiency.

6. Elute the cleaved and released protein by washing the beads with 1 bed volume of GST wash buffer. Centrifuge as in step 1 to pellet beads and collect supernatant. Repeat five times, but keep each wash fraction separate. Remove 20- μl aliquots from each wash fraction for SDS-PAGE.
7. Elute bound GST by repeating step 6 with GST elution buffer instead of GST wash buffer. Remove 20- μl aliquots from each fraction and analyze by SDS-PAGE to determine extent of cleavage. Include the aliquot of beads from step 4 on this gel.

If cleavage is incomplete, the time of incubation and/or the amount of enzyme can be increased.

Protein Expression

16.4.9

Because this is an analytical-scale experiment, it is easiest to discard these beads after one use. Upon scaling up the procedure, the beads can be regenerated, as described in *Reagents and Solutions*, UNIT 16.7.

ALTERNATE PROTOCOL 3

ENZYMATIC CLEAVAGE OF FUSION PROTEINS WITH ENTEROKINASE

Enterokinase (also called enteropeptidase) is a mammalian trypsin-like serine protease that displays a high degree of specificity for the sequence (Asp)₄-Lys, cleaving on the carboxy-terminal side of the lysine residue of the recognition sequence. Although in mammals the enzyme has evolved to recognize and cleave this sequence from the amino-termini of trypsinogens, it has been shown that enterokinase is also capable of cleaving fusion proteins that are expressed in bacteria and that contain this recognition sequence inserted between the carrier protein and the carboxy-terminal fusion partner. Enterokinase is capable of cleaving fusion proteins under a wide range of reaction conditions, with pH ranging from 4.5 to 9.5 and temperatures ranging from 4° to 45°C. Enterokinase is also extremely tolerant of the nature of the amino acid residue in the P1' position (except that the peptide bond between Lys-Pro at this position is totally refractory to cleavage; E. LaVallie and L. Racie, unpub. observ.). At sufficiently low ionic strength, enterokinase can cleave fusion proteins at a weight ratio of 1:500 to 1:2000. At these ratios, typical cleavage reactions are carried out for 16 to 24 hr at 37°C, but these parameters (time, temperature, and enzyme/substrate ratio) can be adjusted as needed.

The thioredoxin fusion vector pTRXFUS (UNIT 16.8) encodes an enterokinase cleavage site immediately preceding the polylinker cloning region. Proteins produced as Trx fusions using this system can be subsequently released by incubation with enterokinase, leaving their authentic amino-terminal sequence. The protocol below describes the use of bovine enterokinase in this application.

Additional Materials

For recipes, see *Reagents and Solutions* in this unit (or cross-referenced unit); for common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

- 1 mg/ml thioredoxin fusion protein (UNIT 16.8) in 50 mM Tris·Cl (pH 8.0)/1 mM CaCl₂
- 10 µg/ml bovine enterokinase (Biozyme EK-3 grade) in 50 mM Tris·Cl (pH 8.0)/1 mM CaCl₂

NOTE: Many commercial preparations of enterokinase (bovine or porcine), with the exception of the source listed, are extremely impure and tend to be contaminated with, among other things, trypsin and chymotrypsin which can extensively degrade the fusion protein. It is recommended that only commercial enterokinase of the highest quality be used.

1. Perform a pilot experiment to monitor the efficiency of cleavage with various ratios of enterokinase to fusion protein. Prepare five reactions:

Reactions 1 to 4: 20 µl of 1 mg/ml fusion protein, 1 µl, 2 µl, 5 µl, and 10 µl of 10 µg/ml bovine enterokinase, and 50 mM Tris·Cl (pH 8.0)/1 mM CaCl₂, to a total of 30 µl.

Reaction 5: 20 µl of 1 mg/ml fusion protein and 10 µl of 50 mM Tris·Cl (pH 8.0)/1 mM CaCl₂ (mock digestion).

Incubate samples ≥ 16 hr at 37°C.

The fusion protein must be (at least) partially purified prior to digestion with enterokinase because the enzyme is inactive in crude bacterial lysates.

2. Stop the reaction by adding 30 μ l of 2 \times SDS sample buffer to each reaction. Boil 10 min.

For larger-scale applications, the reaction can be stopped by adding p-aminobenzamidinium (PABA) to 5 mM. PABA is a competitive inhibitor of most intestinal serine proteases. It should provide protection from nonspecific proteolysis of the reaction products by contaminants in the enzyme preparation before the protein of interest is purified further.

3. Load 10 μ l of each sample onto an SDS-polyacrylamide gel to analyze the extent of cleavage. Adjust enterokinase concentration and length of incubation accordingly to accomplish complete digestion.
4. Scale up the reaction components linearly to digest a larger amount of fusion protein.

Calcium ions marginally increase the efficiency of cleavage, but their presence sometimes promotes fusion protein degradation by stimulating contaminating proteolytic activities. If degradation of the cleaved fusion protein occurs, omit calcium and add 5 mM EDTA to the cleavage reaction to try to eliminate the problem.

CHEMICAL CLEAVAGE OF FUSION PROTEINS USING CYANOGEN BROMIDE

**BASIC
PROTOCOL 2**

Cyanogen bromide (CNBr) has been used to cleave proteins at methionine residues for many years. CNBr has been used industrially for the production of both somatostatin (Itakura et al., 1977) and insulin (Chance et al., 1981). The reaction is typically carried out at low pH in 70% formic acid, and cleavage occurs at the C-terminal side of methionine residues. The protein concentration is relatively unimportant, as the CNBr is in vast excess for hydrolysis. The technique is useful only if the protein of interest lacks methionine residues. Cleavage with CNBr is usually efficient, but side chain modifications and nonspecific cleavages are common upon prolonged incubation at low pH. These problems, along with the potential for reduction of intramolecular disulfide bonds during treatment with 70% formic acid, can be minimized by replacing the formic acid with 6 M guanidine·HCl/0.2 M HCl.

CAUTION: Cyanogen bromide is extremely toxic. It should only be used in a properly ventilated fume hood. Exercise appropriate caution in its use and disposal.

Materials

*For recipes, see **Reagents and Solutions** in this unit (or cross-referenced unit); for common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.*

- 1 mg/ml fusion protein
- 50 mg/ml cyanogen bromide (CNBr)/70% (v/v) formic acid
- 70% (v/v) formic acid
- 1 \times SDS sample buffer (*UNIT 10.2*)

Additional reagents and equipment for SDS-PAGE (*UNIT 10.2*)

1. Perform a pilot experiment to determine minimum incubation time. Lyophilize two 50- μ l aliquots of fusion protein solution. Resuspend one aliquot in 50 μ l of 50 mg/ml CNBr/70% formic acid. Resuspend the other in 50 μ l of 70% formic acid *without* CNBr. Incubate at room temperature.
2. At 0, 8, 24, and 48 hr, remove a 5- μ l aliquot and lyophilize.

**Protein
Expression**

16.4.11

3. Resuspend all aliquots in 20 μ l of 1 \times SDS sample buffer, boil 10 min, and load onto an SDS-polyacrylamide gel.
4. Based on analysis of the gel, determine the minimum incubation time necessary to completely cleave the protein.

The protocol can be easily scaled up to accommodate larger amounts of fusion protein. Some proteins are resistant to cleavage with cyanogen bromide. In such cases, or when the fusion protein to be cleaved is insoluble, guanidine-HCl can be added to the reaction at a final concentration of 6 M.

ALTERNATE PROTOCOL 4

CHEMICAL CLEAVAGE OF FUSION PROTEINS USING HYDROXYLAMINE

Hydroxylamine cleaves proteins at Asn-Gly bonds and can be used as a reagent for chemical cleavage of fusion proteins. This cleavage site is less common than that for cyanogen bromide, and therefore the presence of a susceptible bond in the protein of interest is less likely. One disadvantage is that the released carboxy-terminal fusion partner will retain a glycine residue at its amino terminus, which is unacceptable in some applications. Also, the reaction requires incubation of the fusion protein at alkaline pH, which may cause modification of some amino acid side chains. Finally, protein digestions by this technique are usually incomplete due to the nature of the cleavage mechanism (E.L., unpub. observ.), reducing yield and possibly complicating post-cleavage purification of the desired protein product. However, the technique does have advantages: speed, economy, and the ability to perform digestions under denaturing conditions (e.g., 6 M guanidine-HCl) for otherwise insoluble fusion proteins.

CAUTION: Hydroxylamine is potentially explosive if mishandled. Be sure to follow all precautions indicated by the manufacturer.

Additional Materials

*For recipes, see **Reagents and Solutions** in this unit (or cross-referenced unit); for common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.*

- 1 mg/ml fusion protein in 10 mM Tris-Cl (pH 8.0)/150 mM NaCl
- 2 \times hydroxylamine cleavage solution (see recipe)
- Guanidine-HCl (optional)
- 2 \times SDS sample buffer (*UNIT 10.2*)
- Boiling water bath

1. Perform a pilot experiment to determine minimum incubation time. Mix 50 μ l of 1 mg/ml fusion protein in 10 mM Tris-Cl (pH 8.0)/150 mM NaCl with 50 μ l of 2 \times hydroxylamine cleavage solution in a 1.5-ml microcentrifuge tube. Incubate at 45°C.

If the fusion protein is insoluble, guanidine-HCl can be added to the cleavage reaction at a final concentration of 6 M. This may also help in cases where a particular Asn-Gly bond appears to be resistant to cleavage.

2. At 0, 2, 4, 8, 16, and 24 hr, remove 10- μ l aliquots from the cleavage reaction and mix with 10 μ l of 2 \times SDS sample buffer. Freeze each tube on dry ice until all time points have been collected.
4. Heat samples 10 min in a boiling water bath. Load all samples onto an SDS-polyacrylamide gel to analyze the extent of cleavage.
5. Determine the minimum incubation time necessary for maximum cleavage.

If cleavage after 24 hr is still poor, add guanidine-HCl to 6 M final, increase hydroxylamine concentration to 3 M final, or both.

CHEMICAL CLEAVAGE OF FUSION PROTEINS BY HYDROLYSIS AT LOW pH

This method exploits the fact that the Asp-Pro bond is labile at low pH. Hydrolysis of this peptide bond occurs at elevated temperatures (37° to 40°C) under acidic conditions (pH 2.5). Nonspecific cleavages can occur upon prolonged incubation under these conditions, and it is necessary to determine empirically the minimum length of time necessary for cleavage. Like the other chemical cleavage methods described in this unit, the reaction conditions are somewhat harsh and may result in denaturation or modification of the protein. On the other hand, this treatment allows insoluble fusion proteins to be cleaved by acid hydrolysis of Asp-Pro bonds in the presence of 6 M guanidine-HCl. To use this procedure the amino acid sequence of the carboxy-terminal fusion partner should first be examined carefully to verify the absence of other Asp-Pro bonds. The released protein will retain a proline residue at its amino-terminus.

This method will potentially cleave any protein containing an Asp-Pro bond. The GST fusion vector pGEX1 (UNIT 16.7, and Fig. 16.7.1 therein) contains an Asp-Pro cleavage site encoded by the *Bam*HI site of the polylinker cloning region, so fusions at this site will result in fusion proteins that can be released from GST using this protocol.

Additional Materials

For recipes, see **Reagents and Solutions** in this unit (or cross-referenced unit); for common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.

Fusion protein containing an Asp-Pro bond between the component domains
70% (v/v) formic acid
13% (v/v) acetic acid
0.1 M Tris base
Guanidine-HCl

1. Perform a pilot experiment to determine optimal hydrolysis conditions. Prepare four reaction mixtures:

Reaction 1: ~20 µg fusion protein in 70% formic acid

Reaction 2: ~20 µg fusion protein in 70% formic acid/6 M guanidine-HCl

Reaction 3: ~20 µg fusion protein in 13% acetic acid

Reaction 4: ~20 µg fusion protein in 13% acetic acid/6 M guanidine-HCl.

Incubate all samples at 37°C.

2. At 0, 24, 48, and 72 hr, remove a 5-µg aliquot of each reaction mixture and lyophilize to dryness.

The 0 time point can serve as the negative control.

3. Resuspend the hydrolyzed protein in 20 µl of 1× SDS sample buffer and neutralize by gradual addition of 0.1 M Tris base until the sample turns from yellow to blue. Analyze samples on a tricine SDS-polyacrylamide gel for extent of digestion.
4. Choose the mildest condition and shortest incubation time that give the desired extent of cleavage. Scale up to larger amounts of fusion protein accordingly.

There is a great deal of variation in the susceptibility of Asp-Pro bonds to cleavage. Some Asp-Pro bonds cleave readily under mild conditions, whereas others are resistant to cleavage and require incubation in stronger acid conditions and/or strong denaturants to attain hydrolysis. Even under strong conditions, some Asp-Pro bonds remain uncleaved and others may not be cleaved to completion, i.e., they may be cleaved in only a fraction of the proteins. However, to avoid unwanted denaturation or modification of the protein of interest, it is important to determine the mildest conditions that give the desired degree of cleavage.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Hydroxylamine cleavage solution, 2×

4 M hydroxylamine
0.4 M CHES buffer
Adjust pH to 9.5 with NaOH
Prepare fresh

Thrombin cleavage buffer

50 mM Tris-Cl, pH 7.5
150 mM NaCl
2.5 mM CaCl₂
Store indefinitely at -20°C

COMMENTARY

Background Information

The use of fusion proteins in *Escherichia coli* for production of proteins from other organisms is becoming increasingly popular. The principal advantages of fusion proteins include high expression levels, ease of purification, and ease of detection with biochemical or immunological reagents. However, early protein fusion methods fused the target protein to the carboxy-terminus of *E. coli* β -galactosidase; such proteins are usually insoluble, have restricted usefulness (except as antigens for antibody production), and require refolding of the protein in an attempt to retain biological activity. The development of improved fusion protein expression systems that are often capable of producing properly folded and biologically active proteins in *E. coli*, such as the MBP system (UNIT 16.6), the GST system (UNIT 16.7), and the Trx system (UNIT 16.8), has increased the need for suitable methods of separating the protein of interest from the so-called carrier protein. Such separation is desirable only after the carrier domain has been exploited for its particular attributes—e.g., to facilitate specific purification or detection, or to enhance stability or solubility. Subsequent site-specific cleavage of the carrier domain from the correctly folded protein of interest then allows evaluation of the biological activity of the protein without potential interference from a covalently-attached fusion partner.

Over the years, many different enzymatic and chemical methods for site-specific cleavage of polypeptides have been developed (Gross, 1967; Spande et al., 1970; Maroux et al., 1971; Landon, 1977; Nagai and Thøgersen, 1984; Chang, 1985; Szoka et al., 1986; Smith and Johnson, 1988; Gearing, et al., 1989; Ham-

mond et al., 1991). The choice of cleavage reagents for those expression vectors obtained from molecular biology suppliers that are used “off the shelf” will usually be dictated by the recognition sequences that lie at their respective fusion junctions. For example, MBP vectors (UNIT 16.6; Maina et al., 1988) are designed for factor Xa cleavage, GST vectors (UNIT 16.7) offer a choice of factor Xa, thrombin, or acid cleavage, and the Trx vector (UNIT 16.8; LaVallie et al., 1993a) utilizes enterokinase for cleavage. However, it is important to remember that these vectors, or any other fusion protein expression vector, can be manipulated by the user to include junction amino acids that will allow enzymatic or chemical hydrolysis with other cleavage reagents.

Critical Parameters and Troubleshooting

The cleavage methods described in this unit have been chosen based upon their specificity, efficiency, and reagent availability. Ultimately, the choice of cleavage reagent will depend upon many factors. First of all, the primary sequence of the protein of interest must be scrutinized to identify sequences that will be susceptible to the cleavage reagents in question. Because of the highly restricted specificity in the case of the proteases described in the preceding protocols, the occurrence of such additional sites is unlikely. However, the use of chemical cleavage methods or less specific proteases such as trypsin (Lys↓ or Arg↓) requires careful consideration of the composition of the protein of interest to avoid unwanted fragmentation of the product. Secondly, the physical characteristics of the fusion protein are an important consideration in choosing an

appropriate cleavage method. Fusion proteins that are insoluble generally require a chemical cleavage method that allows incubation in the presence of protein denaturants such as guanidine-HCl or urea followed by proper refolding. Conversely, soluble fusion proteins should be cleaved under conditions where denaturation is minimized to preserve their structure and/or biological activity. In addition, some cleavage methods require incubation at pH extremes, which may result in modifications to some of the side chains or aggregation and precipitation of the protein and may ultimately be deleterious to the usefulness of the cleaved product.

When the fusion protein is produced in a soluble fashion, enzymatic cleavage protocols are preferred for many reasons. These reactions are carried out under mild conditions of neutral pH, low ionic strength, and moderate temperature (25° to 37°C). Such conditions approximate physiological environments and typically should be least harmful to the integrity of the protein. The high degree of specificity exhibited by these proteases ensures a low probability of unwanted cleavage elsewhere in the protein of interest. Finally, the extent of enzymatic cleavage typically can be altered by modulating parameters such as amount of enzyme, substrate concentration, and length of incubation.

The use of proteases sometimes causes problems, however. The most common problem is unwanted secondary proteolysis or degradation of the fusion protein by contaminating proteolytic activities in the cleavage reaction. Degradation may be caused by *E. coli* proteases that have not been purified away from the fusion protein prior to cleavage. Such contaminants can often be alleviated by additional purification prior to enzymatic digestion. Alternatively, the unwanted proteolytic activity may result from a contaminant in the enzyme preparation itself. These enzymes are serine proteases that have been purified from natural sources, so it is probable that they are contaminated with other proteases that copurify in trace amounts. For example, even highly purified enterokinase from bovine intestine contains trace amounts of tryptic and chymotryptic activity that can cause minor secondary proteolysis of thioredoxin fusion proteins (LaVallie et al., 1993a). This degradation can be reduced by omitting Ca⁺⁺ ions from the digestion and using EDTA to chelate residual Ca⁺⁺. The best solution to this problem, however, is to use a recombinant source of enzyme produced in cell cul-

ture; such enzymes are free of contaminating proteases found in intestinal preparations (LaVallie et al., 1993b and unpub. observ.).

Another potential problem that has been observed with some enzymatic cleavages is cleavage at sites other than the anticipated peptide bonds. This has been reported for factor Xa (Nagai and Thøgersen, 1987; Lauritzen et al., 1991) and thrombin (Chang, 1985); enterokinase has been observed to cleave at subsites that resemble the (Asp)₄-Lys recognition sequence when the substrate is denatured or otherwise improperly folded (Light et al., 1980, E. LaVallie and L. Racie, unpub. observ.). Almost always, this relaxed site specificity can be minimized by decreasing the enzyme/substrate ratio and/or the time of incubation. There are also more exotic strategies; for example, reversible acylation of the fusion protein has been used to eliminate nonspecific cleavage by factor Xa (Wearne, 1990).

Although it is less desirable than enzymatic digestion in most circumstances, chemical cleavage of fusion proteins is sometimes necessary and may be advantageous in certain applications. This is in spite of the significant disadvantages. First, chemical cleavage procedures almost universally employ harsh conditions, such as pH extremes or high temperatures, that can denature the fusion protein and/or modify amino acid side chains (e.g., deamidation of Asn residues and oxidation of Met residues). Second, cleavage specificity tends to be limited to single amino acids or, at most, dipeptide sequences, greatly decreasing the utility of chemical reagents in site-specific cleavage of large polypeptide substrates. Even this low degree of specificity is not absolute, and low levels of side reactions at alternate sites have been noted for hydroxylamine (Bornstein and Balian, 1970; Steinman et al., 1974) and cyanogen bromide (Langley and Smith, 1971). Even acidic cleavage of Asp-Pro bonds is sometimes accompanied by nonspecific peptide bond hydrolysis when incubation is prolonged (Landon, 1977). Third, using chemical cleavage reagents involves the danger of working with hazardous compounds such as cyanogen bromide and hydroxylamine. Extreme care must be used in the storage, use, and disposal of these reagents. Material Safety Data Sheets (MSDSs) should be obtained from the manufacturer for any of these compounds and should be read carefully.

In spite of these shortcomings, however, specific chemical hydrolysis of junction peptide bonds in fusion proteins is preferred for

some applications. For instance, fusion proteins that are produced in an insoluble form cannot be cleaved enzymatically unless they have been solubilized and refolded, but site-specific cleavage of the protein domains often can be accomplished using chemical hydrolysis in the presence of strong chaotropic agents such as guanidine-HCl (Landon, 1977; Szoka et al., 1986; Villa et al., 1989). Chemical cleavages are also useful when a soluble fusion protein is refractory to cleavage under nondenaturing conditions using either enzymatic or chemical cleavage methods. Other advantages of chemical cleavage reagents are economy, purity, and wide availability.

Anticipated Results

Enzymatic digestion of fusion proteins is sensitive to many different parameters such as temperature, pH, ionic strength, buffer composition, substrate concentration, enzyme concentration, and length of incubation. Optimum parameters must be determined empirically for each fusion protein. However, if the fusion protein is of adequate purity and the cleavage site is accessible, in most cases the standard conditions described in the protocols will give satisfactory cleavage.

Chemical cleavages are much more forgiving of small variations in reaction conditions, and cleavage should be attainable using the reaction conditions given. However, the extent of protein modifications caused by these general reaction conditions may often be significant to the ultimate usefulness of the cleaved protein. Reaction parameters may be adjusted as described to minimize any modifications or secondary cleavages that may occur.

With any of these methods, complete digestion of the fusion protein is often difficult to attain, and cleavage efficiencies of 70% to 80% should be considered satisfactory.

Time Considerations

Fusion protein cleavage can be accomplished in hours or days, depending upon the reagents used and the reaction conditions. For factor Xa, thrombin, and enterokinase, the enzyme-to-substrate ratio and substrate concentration are often chosen so the digestions are usually complete in 8 to 24 hr. By contrast, chemical cleavages are often highly variable in the amount of time necessary for total cleavage. Overnight digestion under standard conditions is common for cyanogen bromide and acid cleavages, whereas hydroxylamine cleavages are often complete in 2 to 4 hr.

Expression and Purification of *lacZ* and *trpE* Fusion Proteins

BASIC PROTOCOL

Fusion proteins are commonly used as a source of antigen for producing antibodies and in many cases can be useful for biochemical analyses. This unit describes how to express fusion proteins and prepare extracts for both applications.

Two widely used expression systems for producing large amounts of proteins in *E. coli* are presented. One system expresses *lacZ* fusions using the pUR series of vectors (UNIT 1.5; Rütther and Müller-Hill, 1983) and the other expresses *trpE* fusions using the pATH vectors (Koerner et al., 1990). The gene of interest is first subcloned into either a pUR or pATH vector in the correct reading frame. The correct transformant is selected, grown, and then induced with either IPTG or IAA. The method for preparing extracts—i.e., sonication of cells in the presence of protease inhibitors—is suitable for both types of fusion proteins, as well as for other types of proteins overexpressed in *E. coli*. The extracts are checked for the presence of fusion protein on an SDS-polyacrylamide gel.

Materials

- pUR (UNIT 1.5) or pATH (GenBank file name M32985) vectors
- E. coli* C600, HB101, RR1 or equivalent (Table 1.4.5)
- LB plates and medium containing 50 µg/ml ampicillin (UNIT 1.1)
- 100 mM IPTG (store at –20°C)
- M9 plates and medium containing 50 µg/ml ampicillin, 0.5% Casamino acids, 10 µg/ml thiamine, and with/without 20 µg/ml tryptophan (supplemented M9; UNIT 1.1)
- 2.5 mg/ml indoleacrylic acid (IAA) in 95% ethanol (store at –20°C)
- Phosphate-buffered saline (PBS; APPENDIX 2), ice-cold
- HEMGN buffer, ice-cold
- 50 mg/ml lysozyme in 0.25 M Tris·Cl, pH 8.0 (store at –20°C)
- HEMGN buffer/8 M guanidine·HCl (prepare 100 ml and store at 4°C)
- HEMGN buffer/1 M guanidine·HCl (prepare 500 ml and store at 4°C)
- Sorvall RC-5B centrifuge with GSA rotor (or equivalent) and 200-ml bottles
- Sorvall Omnispin clinical centrifuge (or equivalent) and 15-ml conical tubes
- Sonicator with a microtip
- Sorvall SS-34 rotor (or equivalent) and 50-ml tubes
- Ultracentrifuge with Beckman 60Ti rotor (or equivalent) and tubes
- Dialysis tubing, MWCO 12,000 to 14,000 (APPENDIX 3)
- Additional reagents and equipment for subcloning of DNA fragments (UNITS 1.4 & 3.16), transformation of competent *E. coli* cells (UNIT 1.8), quantitation of proteins by the Bradford method (UNIT 10.1), and SDS-PAGE (UNIT 10.2)

Subclone, grow, and induce cells

To express *lacZ* fusion proteins using pUR vectors:

- 1a. Subclone gene of interest into a pUR vector in the correct reading frame, transform competent *E. coli* cells, and select transformants on LB/ampicillin plates.

E. coli C600, HB101, and RR1 (Bolivar et al., 1977) have been used successfully as hosts for pUR expression vectors.

- 2a. Inoculate 2 to 5 ml LB/ampicillin medium with a single colony containing the expression vector. Grow overnight at 37°C with shaking.
- 3a. Add 1 ml of the overnight culture to 400 ml LB/ampicillin medium in a 2-liter flask.

Grow at 37°C with vigorous shaking until OD₆₀₀ reaches 0.5.

- 4a. Add 1.6 ml of 100 mM IPTG (0.4 mM final). Grow cells an additional 2 hr.

IPTG is a nonmetabolizable analog of lactose, the natural inducer of the lac promoter.

To express trpE fusion proteins using pATH vectors:

- 1b. Subclone gene of interest into a pATH vector in the correct reading frame, transform competent *E. coli* cells, and select transformants on supplemented M9/tryptophan plates.

- 2b. Inoculate 2 to 5 ml supplemented M9/tryptophan medium with a single colony containing the expression vector. Grow overnight at 37°C with shaking.

E. coli RR1 (Bolivar et al., 1977) has been used successfully for expressing trpE fusions; C600 and HB101 have also been used.

Inclusion of tryptophan in the medium represses expression of the trp operon. If fusion protein production is toxic for the host cell, repression of expression will promote maintenance of the plasmid in cells prior to induction.

- 3b. Add 1 ml of the overnight culture to 400 ml supplemented M9 medium *without* tryptophan. Grow at 37°C with vigorous shaking until OD₆₀₀ reaches 0.5.

- 4b. Add 1.6 ml of 2.5 mg/ml IAA (10 µg/ml final). Grow an additional 2 hr.

Growth of cells in medium without tryptophan induces expression of the trp operon. The addition of IAA to the medium further induces expression (Morse et al., 1969). IAA is an analog of the co-repressor tryptophan and competes with tryptophan for binding to trp repressor protein. The IAA-repressor complex is unable to bind to the trp operator and repress transcription, thereby allowing high levels of expression (Joachimiak et al., 1983).

Prepare protein extracts

Perform all steps on ice or at 4°C.

5. Split the cell culture into two 200-ml centrifuge bottles. Harvest cells by centrifugation for 10 min in a Sorvall RC-5B using a GSA rotor at 5000 rpm (4000 × g) and discard supernatant.
6. Resuspend each pellet in 5 ml PBS by pipetting up and down. Transfer each to a 15-ml conical centrifuge tube.
7. Centrifuge 10 min in a Sorvall Omnispin clinical centrifuge at 3500 rpm (3000 × g) and discard supernatant.
8. Resuspend cells in 2 ml HEMGN buffer with protease inhibitors. Add 20 µl of 50 mg/ml lysozyme (0.5 mg/ml final). Incubate 15 to 30 min on ice.
9. Disrupt the cells by sonicating two times for 15 sec each using a microtip, placing the sample on ice between rounds of sonication. Pool the lysate into one 50-ml centrifuge tube.

Hold the tube containing the sample so the tip of the sonicator probe is at the surface of the solution. Adjust the output level of the sonicator to the minimum setting required to achieve vigorous churning of the solution without creating foam.

Alternatively, a cup sonicator may be used. The advantage is that it is easier to keep the extract cold during sonication by filling the cup with ice water. The major disadvantage is that DNA is not as completely sheared, resulting in a lysate that is more viscous, thereby making it more difficult to get good separation between the soluble and insoluble fractions

during subsequent centrifugation. Sonicate two times for 30 sec each if using a cup sonicator.

10. Centrifuge cell lysate 15 min in a Sorvall SS-34 rotor at 15,000 rpm ($27,000 \times g$).
11. Pour off the supernatant and save (check for the presence of the fusion protein and its biological activity in step 17). Save the pellet, which usually contains almost all of the induced protein in an insoluble form. To prepare soluble protein, proceed to the next step.

The insoluble material from this step can be used for purification of the fusion protein by gel electrophoresis.

Solubilize the fusion protein

12. Resuspend the pellet in 2 ml HEMGN buffer with protease inhibitors.

The pellet is usually very viscous and can be difficult to resuspend. Scrape the pellet off the side of the tube using a pipettor and pipet up and down a few times. Resuspension of the pellet can be aided by further sonication.

13. Add 2 ml HEMGN buffer/8 M guanidine-HCl (4 M final guanidine). Incubate with gentle shaking 30 min at 4°C.
14. Centrifuge 30 min in a precooled ultracentrifuge using a Beckman 60Ti rotor at 35,000 rpm ($87,000 \times g$).
15. Transfer the supernatant to dialysis tubing and dialyze in three steps, each ≥ 3 hr to overnight: first, against 500 ml HEMGN buffer/1 M guanidine-HCl, and then twice against 1 liter HEMGN buffer excluding guanidine.

Only the protease inhibitors PMSF and sodium meta-bisulfite are necessary in the dialysis buffer (see reagents and solutions); the others are relatively expensive and have been safely omitted at this step. During dialysis about half of the protein in the extract will come out of solution as the guanidine is removed, resulting in the formation of a large amount of white precipitate.

16. Transfer all material in the dialysis bag to a centrifuge tube and centrifuge 5 min in an SS-34 rotor at 10,000 rpm ($12,000 \times g$) to remove insoluble material. Save the supernatant (~4 ml), which should be a clear, colorless solution with a protein concentration of ~1 mg/ml. (The fusion protein typically constitutes between 1% and 10% of the total protein.) Save the insoluble pellet, which usually contains most of the fusion protein and can be used for gel purifying the protein.

This pellet fraction usually contains a higher percentage of the fusion protein than the first insoluble fraction of the lysate (from step 11).

17. Determine the protein concentration of the supernatant and pellet from the cell lysate (steps 11 and 12) and of the final supernatant and pellet after guanidine extraction (step 16) by the Bradford method. Check the results of the induction by SDS-PAGE, loading 5 to 10 μg of protein per lane.

*For analysis of fusion protein production, it is useful to compare extracts containing the fusion protein with control extracts prepared from uninduced cells or from cells containing the expression vector with no insert. The molecular weight of the β -gal protein is 116 kDa, and the *trpE* protein is 37 kDa. The molecular weight of the fusion protein can be predicted from the length of the open reading frame ligated to the vector sequences.*

REAGENTS AND SOLUTIONS

HEMGN buffer

100 mM KCl
25 mM HEPES, pH 7.6
0.1 mM EDTA, pH 8.0
12.5 mM MgCl₂
10% glycerol
0.1% Nonidet P-40

Prepare 2 liters of the above solution. For resuspending the cells (step 8) and resuspending the pellet (step 12), take 10 ml and add 10 μ l of each of the following just before using (save the remainder of the 2 liters for dialysis):

1 M dithiothreitol (DTT; 1 mM final)
2 mg/ml aprotinin (2 μ g/ml final)
1 mg/ml leupeptin (1 μ g/ml final)
1 mg/ml pepstatin in methanol (1 μ g/ml final)
100 mM phenylmethylsulfonyl fluoride (PMSF) in ethanol (0.1 mM final)
100 mM sodium *meta*-bisulfite (0.1 mM final)

The last five ingredients are protease inhibitors. Solutions of DTT, aprotinin, leupeptin, and pepstatin should be stored at -20°C. PMSF solution should be stored at 4°C. Sodium meta-bisulfite should be made fresh and stored on ice during use.

For dialysis, only PMSF and sodium meta-bisulfite are necessary for protease inhibition (see annotation to step 15). DTT should be included in all the dialysis buffers.

COMMENTARY

Background Information

The production of fusion proteins in *E. coli* has become a widely used technique among molecular biologists. The principle advantages of this strategy for overproducing proteins are the relative ease of constructing the appropriate expression vector and the large amounts of protein that can be produced. A potential disadvantage of fusion proteins is that they are usually predominantly present in the insoluble fraction of the cell lysate. However, the insolubility of fusion proteins is actually beneficial for their most common application, producing protein for use as an antigen for generating antibodies, because the insolubility of the protein can be used as a significant purification step prior to final purification by preparative-scale SDS-PAGE (UNIT 10.8; Rio et al., 1986; Spindler et al., 1984). In addition, insolubility of fusion proteins may protect them from degradation by host cells.

In many cases, fusion proteins have also been used to study the biochemical properties of the induced protein. For example, *lacZ* fusions have been used to study the DNA binding activities of several proteins (Johnson and Herskowitz, 1985; Desplan et al., 1985; Kadonaga et al., 1987), and *trpE* fusions have been used

to characterize the properties of reverse transcriptase (Tanese et al., 1985) and a protein-tyrosine kinase (Sadowski et al., 1986).

An advantage of using fusion proteins for biochemical studies is that the β -gal or *trpE* moiety can be used as a means of identifying the protein. Antibodies directed against the β -gal or *trpE* protein can be used for affinity purification of the protein or to follow the protein during chromatographic fractionation (Rüther and Müller-Hill, 1983; Johnson and Herskowitz, 1985). Of course, a potential problem in using fusion proteins for biochemical analyses is that the properties of the native protein may be significantly altered because of inclusion of the foreign residues encoded by *trpE* or *lacZ*. Therefore, if the major goal is to purify the protein to study its enzymatic or other biochemical activities, a different type of expression vector containing little or no coding sequence downstream of the translation start site might be more suitable (UNITS 16.2 & 16.3).

Critical Parameters and Troubleshooting

Typically, fusion proteins are expressed at a very high level in the induced cell using the

methods described in this protocol. However, if expression of the expected product is low, it can sometimes be attributed to extreme toxicity caused by the induced protein or by protein instability (or both). One approach that is usually successful in overcoming the toxicity problem is to keep the cell density low prior to induction. If a small amount of fusion protein production kills the cells, the cells that are making protein productively before induction will be lost during growth of an overnight culture, and the culture will be overtaken by cells that have lost the plasmid or by cells containing mutations that prevent expression of the protein. To circumvent this problem, the amount of ampicillin in the medium can be increased (up to 200 $\mu\text{g/ml}$), and an overnight culture should not be used to inoculate the 400-ml culture. Instead, start a 2-ml culture from a fresh plate and let it grow 2 to 3 hr until it reaches mid-log phase. Pour the small culture into 400 ml fresh medium and grow to an OD_{600} of 0.5 (this usually takes 4 to 5 hr).

Proteolysis sometimes occurs in fusion proteins at or near the junction of the β -gal or *trpE* sequences and the heterologous sequences. Most commonly, proteolysis occurs within the cell after induction. This can be tested by checking the amounts of full-length protein and breakdown products at various times after induction. Whole cells can be lysed by boiling in 1 \times SDS sample buffer and then loaded onto an SDS-polyacrylamide gel (a sample prepared in this way is very viscous and difficult to load on a gel; the viscosity can be reduced by sonication). Shorter induction times may increase the ratio of full-length protein to breakdown products, although the total amount of protein will be lower.

Alternatively, proteolysis can occur during preparation of the extract. To check this, compare the relative amounts of full-length protein and truncated versions from various stages in making the extract with the state of the protein immediately after harvesting the cells. If a significant amount of proteolysis occurs during preparation of the extract, try more or different kinds of protease inhibitors (see the Boehringer Mannheim catalog for the different types of protease inhibitors). The use of protease-deficient mutants of *E. coli* might also be useful (Buell et al., 1985).

Other potential problems are complete insolubility of the fusion protein even after guanidine treatment or loss of biochemical ac-

tivity due to the guanidine denaturation. The guanidine denaturation/renaturation method described here works quite well for most proteins. However, each protein has some unique characteristics and this method cannot be expected to be optimal in every case. For both problems, one thing to try is to use urea as a denaturant rather than guanidine. Although guanidine and urea denature proteins by a similar mechanism (forming hydrogen bonds with amino acid residues, leading to disruption of the secondary and tertiary structure of the protein), some proteins may respond differently to the two denaturants. The insoluble fraction of the lysate can be resuspended in urea at concentrations up to 8 M, then dialyzed in steps to gradually reduce the urea concentration. In some cases, overexpressed proteins can be solubilized without any denaturant by extraction with high salt (Johnson and Herskowitz, 1985; Gross et al., 1976). If the protein cannot be solubilized or recovered with any activity, try expressing the protein in a different type of construct. Smaller proteins might be more stable or more soluble expressed from other constructs while retaining the domains required for biological activity (Tanese et al., 1985; Desplan et al., 1985). Other approaches that may result in improved solubility are to shorten the time of induction or to perform the induction at a lower temperature. In some cases the solubility of the expressed protein has been increased by inducing for 30 min at 30°C.

Anticipated Results

A 400-ml culture of *E. coli* will yield 15 mg to 20 mg of total protein. About two-thirds of the total protein will be in the soluble fraction of the lysate, and one-third in the insoluble fraction (step 11). The induced protein usually represents ~1% of the soluble protein and 10% to 20% of the insoluble protein. Therefore, a typical yield from a 400-ml culture is between 0.5 mg and 1 mg of induced protein. The guanidine denaturation/renaturation procedure usually solubilizes half of the protein in the pellet, and, on average, the fusion protein is ~5% to 10% of the total in the guanidine-extracted supernatant. The material that precipitates during removal of guanidine by dialysis is ~25% to 50% induced protein.

Time Considerations

It takes 2 to 3 hr to grow a 400-ml culture to an OD_{600} of 0.5 starting with an overnight

culture. The cells are usually grown an additional 2 hr after induction. Preparation of the protein extract requires ~3 hr to reach the first dialysis step which can then go 3 hr to overnight. Analysis of the protein extract takes 1 to 2 days.

Expression and Purification of Maltose-Binding Protein Fusions

The maltose-binding protein (MBP) vectors allow the expression and purification of a protein encoded by a cloned gene by fusing it to MBP, which is encoded by the *malE* gene of *Escherichia coli* (Fig. 16.6.1). This method uses the strong, inducible *tac* promoter and the *malE* translation initiation signals to give high-level expression of the cloned gene, and isolation of the fusion protein is facilitated by an affinity purification for MBP (Kellerman and Ferenci; Fig. 16.6.2).

The gene or open reading frame of interest is subcloned into one of the MBP vectors—pMAL-c2 or pMAL-p2—so the coding sequence of interest is fused in-frame to the 3' end of the *malE* gene. The vector pMAL-c2 has an exact deletion of the *malE* signal sequence which leads to cytoplasmic expression of the fusion protein. Fusion plasmids made with this vector usually give a higher yield of fusion protein than those made with pMAL-p2. The vector pMAL-p2 contains the normal signal sequence of the *malE* gene, which potentially directs the fusion protein through the cytoplasmic membrane to the periplasm. This promotes proper folding and disulfide bond formation for some proteins and allows purification from the periplasm (Hsiung et al., 1986; Lauritzen et al., 1991).

Figure 16.6.1 pMAL vectors. The vectors contain the inducible p_{tac} promoter positioned to transcribe a *malE-lacZ* gene fusion. The *lacI* gene encodes the *lac* repressor, which turns off transcription from p_{tac} until IPTG is added. The polylinker provides several restriction endonuclease sites for inserting the gene of interest so it is fused to the *malE* gene. The *rrnB* terminators prevent transcription from p_{tac} from interfering with plasmid replication or maintenance functions. pMAL-c2 (6646 base pairs) has an exact deletion of the *malE* signal sequence. pMAL-p2 (6721 base pairs) includes the *malE* signal sequence. Arrows indicate the direction of transcription. Restriction sites indicated are unique.

The MBP vectors also include a sequence that encodes the four-amino-acid recognition site for the specific protease factor Xa. The site is placed so it can be used to separate the protein of interest from MBP after affinity purification. Factor Xa cuts after arginine in the sequence Ile-Glu(or Asp)-Gly-Arg. Depending on which restriction endonuclease site is used to insert the gene of interest, this means that few or no amino acids encoded by the vector are present on the protein of interest after cleavage by factor Xa (see UNIT 16.4B).

The basic protocol of this unit outlines subcloning the sequence encoding the protein of interest into an MBP vector, and expressing and purifying the protein from the cytoplasm. The first support protocol provides a pilot experiment for analyzing the solubility, affinity for the amylose resin, and export of a particular fusion protein. The alternate protocol gives instructions for purifying a fusion protein from the periplasm for fusions that are

Figure 16.6.2 Schematic representation of expression and purification of a protein using the MBP vectors. “fx” denotes the sequence coding for the recognition site of factor Xa. The gene of interest is cloned 3’ to the *malE* gene and expressed, cells are lysed, and the extract is poured over a column of amylose resin. The MBP fusion protein binds to the column and the remaining proteins in the cell extract are washed through the column (Kellerman and Ferenci, 1982). The fusion protein is eluted with free maltose and then cleaved with factor Xa to separate MBP from the protein of interest. Modified from Maina et al., 1988 with permission of Elsevier Science Publishing.

made in the signal sequence vector and are exported. Methods for cleaving the purified fusion protein with factor Xa and for preparing a fusion protein for factor Xa cleavage when the cleavage site is initially blocked are provided in *UNIT 16.4B*. The second and third support protocols detail two different chromatographic methods for separating the protein of interest from MBP after factor Xa cleavage.

CONSTRUCTION, EXPRESSION, AND PURIFICATION OF MBP FUSION PROTEINS

The sequence encoding the protein of interest is subcloned into an MBP vector. Cells bearing the fusion plasmid are grown, the tac promoter is induced with isopropyl-1-thio- β -D-galactoside (IPTG), and the cells are harvested. A crude cell extract is prepared and passed over a column containing an agarose resin derivatized with amylose (a polysaccharide consisting of maltose subunits). The fusion protein binds to the column because of MBP's affinity for amylose, is eluted with free maltose, and is analyzed by SDS-PAGE (Fig. 16.6.2).

Materials

For recipes, see **Reagents and Solutions** in this unit (or cross-referenced unit); for common stock solutions, see **APPENDIX2**; for suppliers, see **APPENDIX4**.

- pMAL-c2 and/or pMAL-p2 (New England Biolabs; see Fig. 16.6.1)
- Escherichia coli* TB1 (New England Biolabs) or any transformable strain of *E. coli* (see Table 1.4.5)
- LB plates and medium containing 0.2% glucose and 100 μ g/ml ampicillin (*UNIT 1.1*)
- LB plates containing 100 μ g/ml ampicillin, 0.3 mM isopropyl-1-thio- β -D-galactoside (IPTG), and 80 μ g/ml Xgal (*UNIT 1.1*)
- 1 \times and 2 \times SDS sample buffer (*UNIT 10.2*)
- 0.1 M IPTG
- Column buffer, without and with 10 mM maltose
- Coomassie brilliant blue solution (*UNIT 10.1*)
- Amylose resin (New England Biolabs)
- Beckman JS-4.2 and JA-17 rotors (or equivalents)
- Sonicator
- 2.5 \times 10-cm column
- Centricon or Centriprep concentrator *or* stirred-cell concentrator (Amicon), or equivalent
- Boiling water bath
- Additional reagents and equipment for replica plating (*UNIT 1.3*), subcloning of DNA fragments (*UNITS 1.4 & 3.16*), preparing miniprep plasmid DNA (*UNIT 1.6*), restriction mapping (*UNIT 3.2*), quantitation of protein by the Bradford method (*UNIT 10.1*), and SDS-PAGE (*UNIT 10.2*)

NOTE: A kit containing the pMAL vectors, TB1, amylose resin, factor Xa, anti-MBP serum, MBP as a gel marker, and an MBP fusion as a factor Xa control is available from New England Biolabs.

Obtain and grow the fusion plasmid

1. Subclone target gene or open reading frame into pMAL-c2 and/or pMAL-p2 so it is in the same translational reading frame as the *malE* gene of the vector (see Fig. 16.6.1). The insert should have a stop codon at the end of the coding sequence, and if the *XmnI* site is used, the first three bases of the insert should not code for a proline residue.

If an appropriate restriction site is not available at the 5' end of the gene, one must be introduced, e.g., by oligonucleotide-directed mutagenesis (UNIT 8.1), by cloning with synthetic oligonucleotides (UNIT 3.16), by PCR (UNIT 15.1), or by generating half restriction sites (UNIT 15.7).

If a stop codon is not present at the end of the open reading frame, a linker containing a stop codon can be inserted into one of the downstream polylinker sites after step 2. A proline codon immediately following the arginine codon of the factor Xa site will preclude separation of MBP from the protein of interest, as factor Xa cannot cleave the Arg-Pro bond (Nagai and Thøgersen, 1984, 1987).

2. Transform *E. coli* TB1 with the ligated vector + insert and plate on LB/glucose/ampicillin. Incubate overnight at 37°C.
3. Replica plate transformants onto an LB/glucose/ampicillin master plate and an LB/ampicillin/IPTG/Xgal indicator plate. Incubate 8 to 16 hr at 37°C. Identify transformants on the indicator plate (positive transformants are white, those with vector alone are blue). Recover clones with inserts from the corresponding spot on the master plate.

*The vectors are lethal to *E. coli* when *p_{tac}* is induced, so screening for inserts cannot be done with IPTG and Xgal in the transformation plates. For directional cloning (UNIT 3.16), the ligation efficiency is usually so high that the screen is unnecessary.*

4. Prepare miniprep DNA from candidate transformants and confirm the presence and orientation of the insert by restriction mapping.
5. Inoculate 10 ml LB/glucose/ampicillin medium with a single colony containing the fusion plasmid. Grow overnight at 37°C with shaking.
6. Inoculate 1 liter LB/glucose/ampicillin medium with 10 ml overnight culture (a 1:100 dilution). Grow at 37°C, shaking, to 2×10^8 cells/ml ($OD_{600} = 0.4$ to 0.6).
7. Remove a 1-ml sample, microcentrifuge 2 min, and discard supernatant. Resuspend cells in 50 μ l of 1 \times SDS sample buffer and set aside on ice for analysis in steps 20 and 21 (uninduced cells).

Induce the promoter and harvest the cells

8. Add 3 ml of 0.1 M IPTG (0.3 mM final) to remainder of culture. Incubate 2 hr at 37°C with good aeration.
9. Remove another 1-ml sample, microcentrifuge 2 min, and discard supernatant. Resuspend cells in 100 μ l of 1 \times SDS sample buffer, and set aside on ice for analysis in steps 20 and 21 (induced cells).
10. Centrifuge remaining cells 20 min at $4000 \times g$ (4200 rpm in a JS-4.2 rotor), 4°C, and discard supernatant.
11. Resuspend cells in 50 ml column buffer. Freeze sample at -70°C (or overnight at -20°C). Thaw in cold water.

Freezing weakens the cells so that lysis occurs more readily. Slow freezing overnight at -20°C is more effective than quick freezing at -70°C . This step can be omitted, but doing so necessitates more sonication in step 12.

12. Put cell suspension in a plastic or metal tube and place in an ice-water bath. Sonicate using short bursts to avoid heating the extract (if sonicator has a “pulse” mode, use a 50% duty cycle). Monitor release of protein by adding 10 μ l sonicate to 1.5 ml Coomassie brilliant blue to obtain a Bradford reaction. Check protein concentration

every 30 sec of sonication time. Continue sonication until released protein reaches a maximum (usually ~1 to 3 min of sonication time).

13. Centrifuge the sonicated cells 20 min at $14,000 \times g$ (10,000 rpm in a JA-17 rotor), 4°C . Discard pellet.
14. Remove a 5- μl sample of the supernatant (crude extract), add 5 μl of 2 \times SDS sample buffer, and set aside on ice for analysis in steps 20 and 21. Save the rest of the supernatant for passage over the amylose resin column in step 16.

Purify and analyze the fusion protein

15. Pour amylose resin in a 2.5×10 -cm column. Wash with 8 column volumes of column buffer.

The amount of resin needed depends on the amount of fusion protein produced. The resin binds about 3 mg/ml bed volume; a column of ~15 ml should be sufficient for a yield of ≤ 45 mg fusion protein/liter culture. A 50-ml syringe plugged with silanized glass wool can be substituted for the column, but the glass wool should cover the bottom of the syringe (not just fill the tip) to achieve an acceptable flow rate.

16. Dilute crude extract 1:5 with column buffer. Load at a flow rate of ~1 ml/min [$10 \times$ (diameter of column in cm)² ml/hr].
17. Wash with 12 column volumes of column buffer.
18. Elute fusion protein with column buffer/10 mM maltose, collecting ten to twenty 3-ml fractions. Assay fractions for protein by the Bradford method or by measuring the A_{280} .

The fractions containing the MBP fusion should have easily detectable protein. The fusion protein starts to elute after ~5 ml. Proteins that contain tyrosine and/or tryptophan residues absorb at 280 nm, so A_{280} measurements can often be used instead of the Bradford method to detect protein.

19. Pool the protein-containing fractions. If necessary, concentrate to ~1 mg/ml in a Centricon or Centriprep concentrator or stirred-cell concentrator.
20. Remove 3 μg eluted protein and mix with an equal volume of 2 \times SDS sample buffer. Heat uninduced cells, induced cells, crude extract, and eluted protein 5 min in a boiling water bath.
21. Electrophorese on an SDS-polyacrylamide gel. Load 20 μl uninduced and induced cell samples, all 10 μl crude extract sample, and ~3 μg eluted protein.

If the fusion protein is present in the crude extract, but absent from the maltose-eluted fraction, use the following pilot experiment (first support protocol) to determine if the fusion protein is soluble and has affinity for the amylose resin.

SUPPORT PROTOCOL 1

PILOT EXPERIMENT TO CHARACTERIZE THE BEHAVIOR OF AN MBP FUSION PROTEIN

This is a small-scale experiment to determine the behavior of a particular MBP fusion protein. It can be used either as a pilot experiment or to troubleshoot the basic protocol. The protocol results in five (pMAL-c2) or seven (pMAL-p2) samples: uninduced and induced cells, a crude extract of the soluble proteins, a suspension of the insoluble material, a sample of protein that binds to the amylose resin, and (if the fusion was made with pMAL-p2) a periplasmic fraction prepared by the cold osmotic shock procedure and the cells that remain after osmotic shock.

Additional Materials

For recipes, see **Reagents and Solutions** in this unit (or cross-referenced unit); for common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.

Cells containing fusion plasmid (basic protocol)
30 mM Tris·Cl/20% sucrose, pH 8.0
0.5 M EDTA, pH 8.0 (**APPENDIX 2**)
5 mM MgSO₄, ice-cold

Grow, induce, and harvest the cells

1. Inoculate 80 ml LB/glucose/ampicillin medium with cells containing the fusion plasmid (e.g., a 1:100 dilution from an overnight culture from step 3, basic protocol).
2. Grow at 37°C with good aeration to 2×10^8 cells/ml ($OD_{600} = 0.4$ to 0.6).
3. Remove a 1-ml sample, microcentrifuge 2 min, and discard supernatant. Resuspend cells in 50 μ l of 1 \times SDS sample buffer and place on ice for analysis in step 12 (uninduced cells).
4. Add 0.24 ml of 0.1 mM IPTG (0.3 mM final) to remaining culture. Continue incubation 2 hr at 37°C.
5. Remove a 1-ml sample, microcentrifuge 2 min, and discard supernatant. Resuspend cells in 100 μ l of 1 \times SDS sample buffer and place on ice for analysis in step 12 (induced cells).

Take samples at 1 and 3 hr to help determine optimum expression time.

6. Divide culture into two aliquots (samples A and B). Centrifuge 10 min at $7000 \times g$ (7000 rpm in a JA-17 rotor), 4°C, and discard supernatant.
7. Resuspend one pellet (sample A) in 5 ml column buffer. Resuspend the other pellet (sample B) in 10 ml of 30 mM Tris·Cl/20% sucrose, pH 8.0 (8 ml for each 0.1 g cells, wet weight).

Prepare samples A and B

For sample A (*pMAL-c2* and *pMAL-p2*):

- 8a. Freeze sample in a dry ice/ethanol bath or at -20°C and thaw in cold water. Put cell suspension in a plastic or metal tube, place in an ice-water bath, and sonicate using short bursts as in step 12 of the basic protocol.
- 9a. Centrifuge the cells 20 min at $14,000 \times g$ (10,000 rpm in a JA-17 rotor), 4°C. Decant supernatant (crude extract) and save on ice for analysis in steps 11a and 12. Resuspend pellet (insoluble matter) in 5 ml column buffer and save on ice for analysis in step 12.
- 10a. Place 200 μ l amylose resin in a 1.5-ml tube and microcentrifuge briefly. Remove supernatant by aspiration and discard. Resuspend resin in 1.5 ml column buffer, then microcentrifuge briefly and discard supernatant. Repeat this wash and resuspend the resin in 200 μ l column buffer.
- 11a. Mix 100 μ l crude extract with 50 μ l amylose resin slurry. Incubate 15 min on ice. Microcentrifuge the sample 1 min, then remove supernatant and discard. Wash pellet with 1 ml column buffer, microcentrifuge 1 min, and resuspend the resin (bound protein) in 50 μ l of 1 \times SDS sample buffer. Save for analysis in step 12.

For sample B (pMAL-p2 only):

- 8b. Add 20 μ l of 0.5 M EDTA, pH 8.0 (1 mM final) and incubate 5 to 10 min at room temperature with shaking or stirring.
- 9b. Centrifuge the cells 10 min at $7000 \times g$ (7000 rpm in a JA-17 rotor), 4°C. Remove and discard all the supernatant.
- 10b. Resuspend pellet in 10 ml ice-cold 5 mM $MgSO_4$. Shake or stir 10 min in an ice bath.
- 11b. Centrifuge the cells 10 min at $14,000 \times g$ (10,000 rpm in a JA-17 rotor), 4°C. Save the supernatant (cold osmotic shock fluid). Resuspend pellet (shocked cells) in 5 ml column buffer.

Analyze samples by SDS-PAGE

12. Add 5 μ l of 2 \times SDS sample buffer to 5 μ l crude extract, insoluble matter, and (for pMAL-p2) shocked cells. Add 10 μ l of 2 \times SDS sample buffer to 10 μ l cold osmotic shock fluid. Heat these samples, along with the uninduced and induced cell samples and the amylose resin sample, 5 min in a boiling water bath. Microcentrifuge 2 min.
13. Load the samples on a 10% SDS-polyacrylamide gel as follows: 20 μ l uninduced cells, 20 μ l induced cells, 10 μ l crude extract, 10 μ l insoluble matter, 20 μ l bound protein, and (for pMAL-p2 fusions only) 20 μ l osmotic shock fluid and 10 μ l shocked cells. Electrophorese.

If fusion protein is present in cold osmotic shock fluid, use the purification procedure in the following alternate protocol.

If desired, prepare an immunoblot (UNIT 10.8) and develop with anti-MBP serum (New England Biolabs) and, if available, serum directed against the protein of interest.

ALTERNATE PROTOCOL

PURIFICATION OF FUSION PROTEINS FROM THE PERIPLASM

This protocol is useful if the protein of interest is exported and must be purified from the periplasm. The method includes preparation of a periplasmic fraction by cold osmotic shock followed by affinity purification as in the Basic Protocol.

Additional Materials

*For recipes, see **Reagents and Solutions** in this unit (or cross-referenced unit); for common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.*

Cells containing fusion plasmid (basic protocol)
30 mM Tris·Cl/20% (w/v) sucrose, pH 8.0
0.5 M EDTA, pH 8.0 (*APPENDIX 2*)
5 mM $MgSO_4$
1 M Tris·Cl, pH 7.4 (*APPENDIX 2*)
Beckman JA-14 rotor (or equivalent)

1. Inoculate 1 liter LB/glucose/ampicillin medium with cells containing the fusion plasmid (e.g., a 1:100 dilution from an overnight culture from step 3, basic protocol).
2. Grow to 2×10^8 cells/ml ($OD_{600} = 0.4$ to 0.6).
3. Add 3 ml of 0.1 M IPTG (0.3 mM final). Incubate cells 2 hr at 37°C with good aeration.
4. Centrifuge the cells 10 min at $7000 \times g$ (7000 rpm in a JA-14 rotor), 4°C, and discard supernatant.

5. Resuspend cells in 400 ml of 30 mM Tris·Cl/20% sucrose, pH 8.0 (80 ml for each gram of cells, wet weight). Add 0.8 ml of 0.5 M EDTA, pH 8.0 (1 mM final) and incubate 5 to 10 min at room temperature with shaking or stirring.
6. Centrifuge the cells 10 min at $10,000 \times g$ (8000 rpm in a JA-14 rotor), 4°C. Remove all supernatant and resuspend pellet in 400 ml ice-cold 5 mM MgSO₄. Shake or stir 10 min in an ice bath.
7. Centrifuge again as in step 6. Save the supernatant (cold osmotic shock fluid) and add to it 8 ml of 1 M Tris·Cl, pH 7.4.
8. Prepare amylose resin column as in step 15 of the basic protocol. Load cold osmotic shock fluid on column at a flow rate of ~1 ml/min [$10 \times (\text{diameter of column in cm})^2$ ml/hr].
9. Recover and analyze protein fractions as in steps 17 to 21 of the basic protocol.

PURIFYING THE CLEAVED PROTEIN BY ION EXCHANGE CHROMATOGRAPHY

**SUPPORT
PROTOCOL 2**

After factor Xa cleavage (UNIT 16.4B), the protein of interest can be separated from MBP, factor Xa, and trace contaminants by Sepharose ion-exchange chromatography. Cleaved fusion protein amounts of ≤ 25 mg can be purified by this procedure, which can also be scaled up for larger amounts.

Additional Materials

For recipes, see **Reagents and Solutions** in this unit (or cross-referenced unit); for common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.

Fusion protein cleaved with factor Xa (UNIT 16.4B)

20 mM Tris·Cl/25 mM NaCl, pH 8.0

DEAE-Sepharose or Q-Sepharose resin

20 mM Tris·Cl/500 mM NaCl, pH 8.0

1 \times 10–cm column

Additional reagents and equipment for purification of proteins by conventional chromatography (UNIT 10.10)

1. Dialyze fusion protein cleaved with factor Xa two or three times against ≥ 100 vol of 20 mM Tris·Cl/25 mM NaCl, pH 8.0.
2. Wash ~6 ml Sepharose resin twice in 20 ml of 20 mM Tris·Cl/25 mM NaCl, letting resin settle and pouring off supernatant between washes.
3. Pour resin into a 1 \times 10–cm column to give a bed volume of 5 ml with a 6 to 7-cm bed height. Wash with 15 ml of 20 mM Tris·Cl/25 mM NaCl.
4. Load dialyzed fusion protein onto column. Collect 2.5-ml fractions of the column flow-through.
5. Wash column with 3 to 5 column volumes of 20 mM Tris·Cl/25 mM NaCl. Continue collecting 2.5-ml fractions.
6. Start a gradient of 20 mM Tris·Cl/25 mM NaCl to 20 mM Tris·Cl/500 mM NaCl, pH 8.0. Collect 1-ml fractions.
7. Identify protein-containing fractions by the Bradford method or by measuring A_{280} .
MBP elutes as a sharp peak at 100 to 150 mM NaCl. Factor Xa elutes at ~400 mM NaCl. The target protein may flow through the column, or it may elute during the gradient.

**Protein
Expression**

16.6.8

- Analyze relevant fractions by SDS-PAGE. Pool fractions containing the target protein free of MBP and concentrate as needed.

**SUPPORT
PROTOCOL 3**

**PURIFYING THE CLEAVED PROTEIN BY AFFINITY
CHROMATOGRAPHY**

In this method, all the protein from the factor Xa cleavage reaction (*UNIT 16.4B*) is bound to hydroxylapatite and the maltose is washed away from the bound protein. This step is a substitute for dialysis, which is impractical for removing all traces of maltose from the MBP binding site (Silhavy et al., 1975). The protein mixture is then passed over a fresh amylose column and the MBP binds to the column, allowing the protein of interest to be collected in the flow-through. Although this protocol requires two steps, no dialysis is needed and both columns are step-eluted, so the procedure is fairly simple. It should be carried out at room temperature to avoid precipitation of the 0.5 M sodium phosphate buffer. This method does not remove factor Xa or any trace contaminants, and any MBP that has been denatured or otherwise damaged will not bind to the amylose column. The procedure is written for ≥ 25 mg, and can be scaled up for larger amounts.

Additional Materials

For recipes, see Reagents and Solutions in this unit (or cross-referenced unit); for common stock solutions, see APPENDIX2; for suppliers, see APPENDIX4.

Hydroxylapatite resin
Fusion protein cleaved with factor Xa (*UNIT 16.4B*)
0.5 M sodium phosphate, pH 7.2
1 or 1.5×10 -cm column

Additional reagents and equipment for hydroxylapatite chromatography (*UNIT 2.10*)

1. Swell 1 g hydroxylapatite in column buffer for 15 min. Wash resin three times in column buffer by swirling it, then letting it settle 1 min. Pour off milky supernatant.

This washes the resin and removes the "fines" that can cause the column to flow slowly.

2. Pour hydroxylapatite into a 1 or 1.5×10 -cm column.

The larger-diameter column will give a faster flow rate.

3. Load fusion-protein cleaved with factor Xa onto the column. Wash column with 80 ml column buffer.

This step removes the maltose.

4. Elute protein with 20 ml of 0.5 M sodium phosphate, pH 7.2. Collect 2-ml fractions. Assay for protein by the Bradford method or by measuring the A_{280} .

Most of the protein usually elutes in the first 8 ml.

5. Prepare 15-ml amylose column as in step 15 of the basic protocol.

6. Load hydroxylapatite-eluted protein onto the amylose column. Reapply flow-through two times. Collect final flow-through as 5-ml fractions. Wash column with 50 ml column buffer, continuing to collect 5-ml fractions. Assay for protein by the Bradford method or by measuring the A_{280} . Concentrate the protein as needed.

Most of the protein flows through in the first 35 ml. Protein should be free of MBP and consist of target protein and factor Xa.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX2; for suppliers, see APPENDIX4.

Column buffer

Per liter:

20 ml 1.0 M Tris·Cl, pH 7.4 (20 mM final)

11.7 g NaCl (0.2 M final)

2.0 ml 0.5 M EDTA (1 mM final)

0.7 ml 2-ME (optional; 10 mM final)

1 ml 1 M NaN₃ (optional; 1 mM final)

Store ~1 month at room temperature

Isopropyl-1-thio-β-D-galactoside, 0.1 M

1.41 g isopropyl-β-D-thiogalactoside (IPTG)

H₂O to 50 ml

Filter sterilize and store ~1 year at 4°C

0.5 M sodium phosphate buffer, pH 7.2

A: 69.0 g NaH₂PO₄·H₂O, to 1 liter with H₂O

B: 134.0 g Na₂HPO₄·7H₂O, to 1 liter with H₂O

Mix 117 ml A with 383 ml B

Store indefinitely at room temperature

COMMENTARY

Background Information

The maltose binding protein (MBP) vectors (Fig. 16.6.1) were constructed as a way of expressing and purifying a cloned protein or peptide by fusing it to maltose-binding protein, coded for by the *malE* gene of *Escherichia coli* (Guan et al., 1988; Bedouelle and Duplay, 1988; Maina et al., 1988). The vectors have the strong, inducible *tac* promoter (Amann and Brosius, 1985) expressing the *malE* gene (with or without its signal sequence), fused to the *lacZα* gene. When present, the signal peptide on pre-MBP directs fusion proteins to the periplasm. Restriction endonuclease sites between *malE* and *lacZα* are available for insertion of the coding sequence of interest in a way that interrupts the *malE-lacZα* fusion.

The *p_{tac}* region of these plasmids is from pTP201 (T. Poteet, unpub. observ.; the same construction as pKK207-1, Amann & Brosius, 1985), with a fragment carrying *lacI^q* (*EcoRI-BanI* partial-digest product, filled in with Klenow fragment) adjacent upstream from *p_{tac}*. The *lacI^q* gene codes for the *lac* repressor, which keeps expression from *p_{tac}* low in the absence of isopropyl-1-thio-β-D-galactoside (IPTG) induction. The *malE* region is the *HinFI* (filled in) fragment of *malE* (Duplay et al., 1984). The vector backbone is from *AvaI* (filled in) to *EcoRI* (filled in) of pKK233-2 (Amann

& Brosius, 1985). This gives the vectors a pBR322-like copy number. The vectors also include the origin of DNA replication of bacteriophage M13 from the plasmid pZ150 (Zagursky and Berman, 1984), to facilitate the production of single-stranded DNA for sequencing or mutagenesis (UNIT 1.15).

Insertion of the target sequences downstream of *malE* interrupts the *malE-lacZα* fusion. This allows use of the blue-to-white screen for inserts when transforming into an α-complementing *E. coli* host, such as TB1 or JM107, and plating on Xgal plates (Yanisch-Perron et al., 1985; UNIT 1.4). Because the vectors are lethal to *E. coli* when *p_{tac}* is induced, screening for inserts cannot be done with IPTG in the transformation plates. The screen can be accomplished by picking colonies with a sterile toothpick or by replica plating onto an LB/ampicillin master plate and an LB/ampicillin/IPTG/Xgal indicator plate.

Choice of MBP vector

If little is known about the protein of interest, the best strategy is to construct fusions in both vectors and empirically determine which is best. However, some information about the protein, if available, may help guide the choice of vector. The vector lacking the signal sequence, pMAL-c2, produces a cytoplasmic fu-

sion protein and has several advantages. Most importantly, it generally gives at least a four-fold higher yield than pMAL-p2. In addition, unstable proteins are often more stable when expressed from pMAL-c2 than when expressed from pMAL-p2, suggesting that there is more protease activity in the periplasm. Moreover, cytoplasmic expression can sometimes circumvent the instability and folding problems caused by the attempt to export cytoplasmic proteins (Bedouelle and Duplay, 1988; Gentz et al., 1988).

However, there are cases where use of the signal sequence vector, pMAL-p2, may prove advantageous. Some foreign proteins cannot fold correctly when expressed in the *E. coli* cytoplasm, and are produced in an inactive or unstable form. Secretion into the periplasm has been used to promote proper folding of such proteins (Hsiung et al., 1986; Lauritzen et al., 1991). In particular, the *E. coli* cytoplasm is a reducing environment, so disulfide bonds do not usually form until the cells are lysed to make a crude extract. This may allow abnormal disulfide bonds to form (e.g., interchain rather than intrachain). *E. coli* proteins do, however, form disulfide bonds in the periplasm, and in fact an accessory protein that catalyzes this process in *E. coli* has been described (Bardwell et al., 1991). Thus, for some foreign proteins, secretion into the periplasm can provide a protein-folding pathway that more closely mimics the native environment of the protein of interest. For these reasons, pMAL-p2 may be the vector of choice for proteins that are secreted in their native host or have disulfide bonds. In addition, in spite of the lower yield of fusion protein when expressed from pMAL-p2 relative to pMAL-c2, the number of different *E. coli* proteins in the periplasm is much lower than in the cytoplasm. This makes export to the periplasm a purification step, and the number of different proteins present in trace amounts in the affinity-purified protein is probably lower for fusion proteins purified from the periplasm.

Separation of the protein from MBP

After purification of the fusion protein, the MBP domain can be separated from the protein of interest by cleavage with factor Xa protease (UNIT 16.4B; Nagai and Thøgersen, 1984, 1987). About 50% of the time, the cleavage reaction works on the native fusion protein as it is eluted from the column. The remaining 50% of the cases break down into two categories: fusion proteins that do not cut with factor Xa and

fusion proteins that are cleaved at secondary sites within the protein of interest (see Troubleshooting). Many fusion proteins that do not cut with factor Xa after elution from the amylose column can be cleaved after denaturation and removal of the denaturant (UNIT 16.4B).

Once the fusion protein has been cleaved with factor Xa, the two domains can be separated chromatographically. Sepharose chromatography has an advantage over the affinity method, because it provides for the removal of factor Xa and any other trace contaminants. For Sepharose and most other chromatography resins, there is an equivalent HPLC method that increases the resolution of this step (UNIT 10.13).

Troubleshooting

One problem that is often encountered when expressing foreign proteins in *E. coli* (including MBP fusion proteins) is that the expressed protein is unstable. In these cases, conditions for expression and crude extract preparation can be optimized in a number of ways. The time allowed for expression can be shortened to 1 hr, which usually decreases the yield by half but can lead to a higher proportion of full-length fusion protein. In addition, the stability of a particular fusion protein can show large differences among different strain backgrounds. Apparently, different laboratory strains of *E. coli* differ a good deal in the levels and types of proteases that are produced.

If the fusion protein is being expressed cytoplasmically (in pMAL-c2), the use of *E. coli* protease mutants such as *lon* and *htrP* can reduce the degree of degradation (Baker et al., 1984; I. Hall and P. Riggs, unpub. observ.). In addition, some cytoplasmically expressed proteins are stabilized by using a host deficient in the chaperonin *DnaJ* (Straus et al., 1988; Reidhaar-Olson et al., 1990). It is possible that fusions that are exported to the periplasm might be stabilized by using a *degP* mutant (Strauch and Beckwith, 1988) or a *tsp* mutant (Silber et al., 1992). These mutations also could lead to stabilization of a cytoplasmically expressed fusion protein because such proteins are exposed to periplasmic proteases upon cell lysis. Similarly, fusion proteins being prepared from either the cytoplasm or the periplasm might be stabilized by using an *ompT* mutant, which lacks an outer membrane protease that has been shown to cleave prokaryotic and eukaryotic proteins during the preparation of crude extracts (Grodberg and Dunn, 1988; Sugimura and Higashi, 1988). Often, most of the degradation of MBP fusion proteins takes place in

vivo or during harvesting the cells and preparing the crude extract; once the crude extract is made, most proteins are fairly stable. However, if a fusion protein is unstable in the crude extract, the addition of protease inhibitors could help. One reason for the EDTA in the column buffer is to chelate calcium and inhibit the activity of calcium-dependent proteases once the cells are lysed.

A second problem sometimes seen when expressing MBP fusion proteins is that high levels of fusion protein can lead to the formation of insoluble aggregates. If a fusion protein is insoluble, lowering the temperature of expression and/or the level of induction of p_{tac} sometimes yields soluble fusion protein (e.g., induction with 10 to 100 μ M IPTG at $\leq 30^\circ\text{C}$; Tagaki et al., 1988; Schein, 1989). Similarly, switching to a different host strain can result in large differences in the proportion of a particular fusion protein that is soluble (M. Southworth, S. Levitt, and F. Perler, unpub. observ.). However, there are cases when no conditions can be found that result in soluble fusion protein expression. In these cases, the fusion protein can usually be solubilized by dissolving it in 6 M guanidine-HCl or 8 M urea, and then dialyzing away the denaturant. The fusion protein can then be applied to the amylose column for affinity purification. Alternatively, the denatured protein can be purified by conventional means (Nagai and Thøgersen, 1987). One advantage to the latter approach is that insoluble protein is usually very stable and can be purified away from proteases before it is refolded.

A third problem seen with MBP fusion proteins is failure to cleave with factor Xa. There are two possible explanations for this failure. The first involves the primary sequence of the cleavage site. Although factor Xa has a low degree of discrimination for the residue that follows the arginine in its recognition site, it will not cleave if that residue is a proline. The second explanation involves the three-dimensional conformation of the fusion protein. For some fusions, the factor Xa site can be blocked by the protein of interest. In this case, cleavage can often be obtained by denaturing the fusion protein to render the site accessible. However, some proteins remain resistant to cleavage, presumably because the protein quickly refolds into a factor Xa-resistant conformation upon removal of the denaturant. Cleavage can sometimes be facilitated by inserting a spacer between the factor Xa site and the protein of interest, but this results in extra residues (en-

coded by the spacer) attached to the amino-terminus of the protein of interest.

Another problem that sometimes arises during factor Xa cleavage is proteolysis at secondary sites within the protein of interest. This problem often (but not always) coincides with instability in *E. coli* during expression of the fusion protein (P. Riggs and I. Hall, unpub. observ.). Cleavage at arginines that are not in the factor Xa site has been observed (Nagai and Thøgersen, 1987; Lauritzen et al., 1991). Because there are arginine residues in other positions that are not cleaved, it is thought that the three-dimensional structure of the protein is important in determining these secondary cleavage sites. Cleavage at lysine residues has also been observed, and can be blocked by reversible acylation of lysine residues at the ϵ -amino group (Wearne, 1990).

Anticipated Results

Fusion protein expressed from pMAL-c2 usually constitutes 20% to 40% of the total cellular protein. Fusion protein expressed from pMAL-p2 usually constitutes 5% to 10% of the total cellular protein. In both cases, a band corresponding to the fusion protein can often be seen by running small samples of uninduced and induced cells on an SDS-polyacrylamide gel (e.g., 400 μ l of cells at $\text{OD}_{600} = 0.5$; first support protocol). The yield of fusion protein from the affinity purification ranges from ≤ 1 mg to 100 mg/liter culture at $\text{OD}_{600} = 1.0$; the remaining fusion protein is present in the column flow-through. The yield varies greatly depending upon the sequences fused to *malE*. In cases where the yield has been compared directly, pMAL-c2 (no signal sequence) gives from 4- to 15-fold more protein in the affinity purification than pMAL-p2.

Approximately 70% of the time, a fusion protein is reasonably stable and will yield ≥ 1 mg/liter culture in the affinity purification. When the fusion protein is insoluble or unstable, changing the conditions of expression has helped $\sim 5\%$ of the time. The rest of the time, affinity purification yields little or no fusion protein. In most of these cases, the fusion protein does not bind well to the column, perhaps because the target protein either blocks or distorts the binding site of MBP. In this situation, it is probably best to purify large amounts of fusion protein by conventional means (*UNITS 10.9-10.16*) or to try a different expression system.

Time Considerations

Growth of the cells, expression of the fusion protein, and harvest of the cells takes 6 to 7 hr. After harvest, the cells resuspended in column buffer can be stored at -20°C for ≥ 1 month. The thawed cell suspension should be stored for as short a time as possible, but once the crude extract is made and diluted 1:5 with column buffer, the fusion protein is usually reasonably stable at 4°C . After sonication and centrifugation of the cell debris, the crude extract (or the diluted crude extract) can again be frozen at -20°C for ≥ 1 month. Affinity chromatography takes ~ 9 hr and should be done in one day, if at all possible; if the fusion protein is left on the column too long, it starts to lose affinity for the amylose matrix. This may be due to maltose that is released from the column by trace amounts of amylase that are purified from *E. coli* along with the fusion protein. The purified protein can be stored for short periods of time (1 day) at 4°C , or at -20°C for long-term storage. Many proteins denature after freezing and thawing, so freezing in small aliquots or with the addition of 50% glycerol is recommended.

Expression and Purification of Glutathione-S-Transferase Fusion Proteins

UNIT 16.7

**BASIC
PROTOCOL**

This unit describes how pGEX vectors can be used in bacterial systems to express foreign polypeptides as fusions with glutathione-S-transferase (GST). In general, such fusion proteins are soluble and are easily purified from lysed cells under nondenaturing conditions by absorption with glutathione-agarose beads, followed by elution in the presence of free glutathione. Potential applications of the pGEX vectors include the expression and purification of individual polypeptides (including short peptides) for use as immunogens and as biochemical and biological reagents, and in the construction of cDNA expression libraries.

The screening procedure given here has the advantage (over restriction analysis of plasmid DNA, for example) of rapidly identifying transformants that express fusion proteins, and also revealing whether such fusion proteins are readily purified by the affinity absorption step. If true transformants are likely to be rare because of a high background with the vector alone, screening is better conducted by DNA hybridization to lysed colonies (UNITS 6.3 & 6.4) or by immunological screening (UNITS 6.7 & 6.8).

This protocol describes production and screening of pGEX transformants and purification of milligram quantities of fusion proteins from 1-liter cultures. UNIT 16.4B describes removal of the GST portion of a fusion protein by cleavage with site-specific proteases. Because the vagaries of heterologous protein expression in *Escherichia coli* are such that the basic protocol for purifying fusion proteins may not always suffice, Critical Parameters and Troubleshooting describe several modifications to the expression and purification protocol that may be useful in cases where fusion proteins are insoluble or unstable.

Each pGEX vector contains an open reading frame encoding GST, followed by unique restriction endonuclease sites for *Bam*HI, *Sma*I, and *Eco*RI, followed in turn by termination codons in all three frames (Fig. 16.7.1). The cloning sites are present in a different reading frame in each of the three vectors, so the vector in which the foreign polypeptide will be expressed in-frame with GST must be chosen first. pGEX2T or pGEX3X should be used if the GST carrier is eventually to be removed by site-specific proteolysis (UNIT 16.4B). Fusion proteins produced using pGEX1 can be cleaved by chemical hydrolysis at low pH (UNIT 16.4B).

Materials

For recipes, see **Reagents and Solutions** in this unit (or cross-referenced unit); for common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.

- pGEX vector (pGEX1 from Amrad or pGEX2T and pGEX3X from Pharmacia Biotech)
- Transformation-competent *Escherichia coli* (UNIT 1.8)
- LB plates containing 50 µg/ml ampicillin (UNIT 1.1)
- LB medium containing 10 µg/ml ampicillin (UNIT 1.1)
- 100 mM isopropyl-1-thio-β-D-galactoside (IPTG), filter sterilized
- Phosphate-buffered saline (PBS; APPENDIX 2), ice-cold
- Glutathione-agarose bead slurry (see recipe)
- 2× SDS sample buffer (UNIT 10.2)
- 10% (v/v) Triton X-100
- 50 mM Tris·Cl (pH 8.0)/5 mM reduced glutathione (freshly prepared; pH 7.5, final)
- Glycerol
- 37°C shaking incubator
- Beckman JA-10 and JA-20 rotors (or equivalents)

**Protein
Expression**

16.7.1

Figure 16.7.1 pGEX1. pGEX1 is a fusion-protein expression vector that expresses a cloned gene as a fusion protein to GST. The *lac* repressor (product of the *lacI* gene) binds to the p_{tac} promoter, repressing the expression of GST fusion protein. Upon induction with IPTG, derepression occurs and GST fusion protein is expressed. The gene of interest can be inserted into the polylinker located at the end of the GST gene. The polylinker sequences are shown below the map of pGEX1, where the restriction endonuclease cloning sites are bracketed. The polylinker of pGEX2T and pGEX3X contains protease cleavage sites so the cloned protein can be released from the GST moiety (or “carrier”). The recognition sequences for thrombin and factor Xa are bracketed above the polylinker sequences, with the actual cleavage site between Arg and Gly. The nucleotide sequence of pGEX1 is available under Genbank accession number M21676.

Probe sonicator (with 2- and 5-mm-diameter probes)

Additional reagents and equipment for subcloning DNA fragments (UNITS 1.4 & 3.16), SDS-PAGE (UNIT 10.2), and Coomassie blue staining (UNIT 10.6)

Produce and analyze transformants

1. Subclone the chosen DNA fragment into the appropriate pGEX vector in the correct reading frame, transform competent *E. coli* cells, and select transformants on LB/ampicillin plates. Incubate plates 12 to 15 hr at 37°C.

*Include a control of vector ligated to itself in the absence of insert DNA. Unless the insert DNA is being cloned with ends generated by digestion with two different restriction endonucleases, treat the vector with phosphatase after digestion to minimize screening. Any standard *E. coli* strain should be suitable for this transformation because the *lacI^q* repressor allele that controls expression of the fusion protein via the *tac* promoter (a *trp/lac* promoter fusion) is present on each pGEX vector.*

- Pick transformant colonies into 2 ml LB/ampicillin medium and streak out onto a master LB/ampicillin plate. Inoculate a control tube with bacteria transformed with the parental pGEX vector. Incubate the master plate 12 to 15 hr at 37°C. Grow liquid cultures with vigorous agitation in a 37°C shaking incubator until visibly turbid (3 to 5 hr).

The number of transformants to be screened can be judged from the number over background obtained with the self-ligated vector alone.

- Induce fusion protein expression by adding 100 mM IPTG to 0.1 mM. Continue incubation another 1 to 2 hr.
- Transfer liquid cultures to labeled microcentrifuge tubes, microcentrifuge 5 sec at maximum speed, room temperature, and discard supernatants. Resuspend pellets in 300 μ l ice-cold PBS. Remove 10 μ l to labeled tubes (for use in step 7).

Except where noted, keep all samples and tubes on ice.

- Lyse cells using a probe sonicator with a 2-mm-diameter probe. Microcentrifuge 5 min at maximum speed, 4°C, to remove insoluble material. Transfer supernatants to fresh tubes.

Lysis is complete when the cloudy cell suspension becomes translucent. The frequency and intensity of sonication should be adjusted so no frothing occurs and so lysis is complete in 10 sec. For a Tekmar Sonic Disruptor with a microtip probe, the output frequency should be set to the microtip limit noted on the dial. An alternative to sonication that may be useful when large numbers of samples have to be processed is lysis by repeated cycles of freezing in dry ice followed by thawing at 20°C. However, fusion proteins are more likely to suffer degradation with the freeze-thaw method.

- Add 50 μ l of 50% slurry of glutathione-agarose beads to each supernatant and mix gently \geq 2 min at room temperature. Add 1 ml PBS, vortex briefly, microcentrifuge 5 sec at maximum speed, room temperature to collect beads, and discard supernatants. Repeat the PBS wash twice.
- Add an equal volume of 1 \times SDS sample buffer to the washed beads, and 30 μ l to the 10- μ l samples of resuspended whole cells (from step 4). Heat 3 min at 100°C, vortex briefly, and load onto a 10% SDS-polyacrylamide gel. Run the gel for the appropriate time and stain with Coomassie blue solution to visualize the parental GST (made in control cells carrying a pGEX vector) and the fusion protein (Fig. 16.7.2).

Ideally, transformants expressing the desired fusion protein will be identified by the absence from total cellular proteins of the 27.5-kDa molecule specified by parental pGEX vectors, and by the presence of a novel, larger species. Where two orientations of the insert DNA are possible, the relative mobilities of the new species should distinguish between them; otherwise, conventional restriction endonuclease analysis will be required (UNIT 3.1). If the fusion protein has absorbed to the glutathione-agarose beads, proceed to large-scale purification as in steps 8 to 15. If, on the other hand, the fusion protein is absent from the purified material, it may be insoluble; see Critical Parameters and Troubleshooting for a discussion of this problem and for instances where neither the 27.5-kDa protein nor a larger fusion protein is visible (perhaps indicating toxicity or instability of the fusion protein). Interpretation is sometimes complicated when unstable fusion proteins break down and release the 27.5-kDa GST moiety. Such cases are usually recognized by the reduced level of the 27.5-kDa species, and by the series of larger, partial proteolytic fragments above it.

Figure 16.7.2 Stained protein gel showing expression of GST. The total cell lysate of a pGEX1 transformant is shown before IPTG induction (lane 1) and after IPTG induction (lane 2). The GST protein after elution from glutathione-agarose beads is shown at the position indicated by the arrow (lane 3). The lane marked M contains molecular-weight markers for sizes indicated.

Purify fusion proteins on a large scale

8. Inoculate a colony of the pGEX transformant into 100 ml LB/ampicillin medium and grow 12 to 15 hr at 37°C in a shaking incubator.
9. Dilute this culture 1:10 into 1 liter fresh LB/ampicillin medium, split between two 2-liter flasks, and grow 1 hr at 37°C.
10. Add 100 mM IPTG to 0.1 mM (final) and continue incubation an additional 3 to 7 hr.

By optimizing growth conditions, the yield of fusion protein may be greatly improved. Investigate the effects of delaying the addition of IPTG and altering the induction period. For example, if the fusion protein is not detrimental to the growth of the bacteria, and the protein is stable, the yield may be improved by increasing the duration of the induction period. However, if the protein is detrimental to the cells, the yield may be improved by delaying the addition of IPTG until the culture is more dense (i.e., when more cells are present) and also by decreasing the duration of induction, to decrease cell loss during this period.

11. Centrifuge 10 min at 5000 × g (~5500 rpm in a Beckman JA-10 rotor), room temperature, to collect cells. Discard supernatant and resuspend pellet in 10 to 20 ml ice-cold PBS.
12. Immerse the tube in ice and lyse cells using a probe sonicator with a 5-mm-diameter probe.

Lysis can be detected as a change in color from a rich straw brown (intact cells) to a dull gray-brown (lysed cells). Adjust the frequency and intensity of sonication so lysis occurs in ~30 sec, without frothing. Excessive sonication can result in contamination of purified fusion protein with other proteins. Lysis by freeze-thaw is a slower alternative.

13. Add 10% Triton X-100 to 1% (final) and mix. Centrifuge 5 min at 10,000 × g (~9500 rpm in a Beckman JA-20 rotor), 4°C, to remove insoluble material and intact cells. Alternatively, it may be convenient to microcentrifuge 1.5-ml aliquots for 5 min at top speed, 4°C. Collect supernatants (carefully avoiding the pellets) and pool them.

Triton X-100 is added to the lysed cells to minimize association of fusion protein with

bacterial proteins, and thus to prevent appearance of these contaminants in the final preparation.

14. Add supernatant to 1 ml of 50% slurry of glutathione-agarose beads and mix gently ≥ 2 min at room temperature. Wash by adding 50 ml ice-cold PBS, mixing, and centrifuging 10 sec in a tabletop centrifuge at $500 \times g$, room temperature. Repeat the wash two more times. Resuspend the beads in a small volume (1 to 2 ml) of ice-cold PBS and transfer to a 1.5-ml microcentrifuge tube.

The capacity of glutathione-agarose is ≥ 8 mg protein/ml swollen beads.

To remove the GST carrier by protease cleavage, see UNIT 16.4B.

15. Centrifuge 10 sec at $500 \times g$, room temperature, to collect beads; discard supernatant. Elute fusion protein by adding 1 ml of 50 mM Tris-Cl (pH 8.0)/5 mM reduced glutathione. Mix gently 2 min, centrifuge 10 sec at $500 \times g$, and collect supernatant. Repeat elution two to three times and analyze each fraction by SDS-PAGE. Store eluted protein in aliquots containing 10% glycerol at -70°C .

The majority of fusion protein should appear in the first two elutions. If a concentrated solution of the fusion protein is required, elution can be carried out while the beads are immobilized in a small column. See Critical Parameters and Troubleshooting regarding problems with contamination, instability, or yield. The concentration of glutathione in the elution buffer may be increased to 10 or 15 mM if the fusion protein is not quantitatively eluted using the lower concentration. Determine the yield of fusion protein by measuring the absorbance at 280 nm. For the GST carrier, $A_{280} = 1$ corresponds to a protein concentration of 0.5 mg/ml.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Glutathione-agarose bead slurry

Preswell S-linkage glutathione-agarose beads (Sigma or Pharmacia Biotech) 1 hr in 10 vol phosphate-buffered saline (PBS, APPENDIX 2). Wash twice with PBS and store as a 50% (v/v) slurry ≤ 1 month at 4°C .

The beads can be recycled by boiling 5 min in PBS containing 1% SDS (Frangioni and Neel, 1993), but should then only be used to purify the same fusion protein to prevent cross-contamination.

COMMENTARY

Background Information

The pGEX vectors are designed so that foreign polypeptides can be expressed in *Escherichia coli* in a form that allows them to be purified rapidly under nondenaturing conditions (Smith and Johnson, 1988). Foreign polypeptides are expressed as fusions to the C terminus of glutathione-S-transferase (GST), a common 26-kDa cytoplasmic protein of eukaryotes. The GST gene used to generate the pGEX vectors was originally cloned from the parasitic helminth, *Schistosoma japonicum* (Smith et al., 1986).

The fusion proteins typically remain soluble within the bacteria and can be purified from lysed cells because of the affinity of the GST

moiety for glutathione immobilized on agarose beads. Recovery of the fusion proteins is by elution with free reduced glutathione at neutral pH.

The main advantage of this system for expressing and recovering foreign proteins from *E. coli* is that most fusion proteins remain soluble; native proteins expressed in *E. coli* often denature and precipitate. Furthermore, denaturing conditions are not required at any stage during purification, and consequently, foreign polypeptides may retain their functional activities and antigenicity. Additional features are the efficiency and rapidity of purification, the high level of inducible expression achieved with the strong tac promoter, and the

broad range of suitable bacterial hosts (because the pGEX vectors carry the *lacI^q* repressor allele). Furthermore, the GST carrier is small compared to other carriers (e.g., β -galactosidase), and lacks the immunological complications of fusion proteins containing fragments of protein A. (Peptides containing protein A are likely to interact and/or combine with a wide variety of antibodies, but the GST moiety will not interfere with specific antibody-antigen interactions.)

The main determinant for successful purification of foreign polypeptides using the pGEX system is solubility of the fusion protein. To some extent, this can only be discovered empirically. More difficulties are encountered as the size of the desired fusion protein increases (particularly when >50 kDa), or when the protein contains regions that are strongly hydrophobic or highly charged (D.B.S. and L.M.C., unpub. observ.). Insoluble fusion proteins can sometimes be coaxed into solution (see Critical Parameters and Troubleshooting) or can otherwise be purified after solubilization in denaturing reagents.

If necessary, the GST moiety can be removed from fusion proteins by cleavage with site-specific proteases (UNIT 16.4B). Note however, that often the GST carrier does not compromise the antigenicity or functional activity of the foreign polypeptide. Modified versions of the original pGEX vectors have been produced that simplify cloning, cleavage or detection of fusion proteins (for review, see Smith, 1993).

Critical Parameters and Troubleshooting

Contamination of fusion proteins by host cell proteins is usually a sign that sonication has been too severe, perhaps because denaturation exposes regions on proteins that are more likely to cause aggregation. Some contaminating species may represent degraded fragments of the fusion protein that bind to glutathione. Such fragments are not easy to eliminate, except by increasing the stability of the fusion protein. The addition of protease inhibitors [e.g., 1% (w/v) aprotinin and 1 mM phenylmethylsulfonyl fluoride (PMSF)] may help in this regard, and inclusion of 50 to 100 mM EDTA in the lysis buffer has also been beneficial. The *E. coli* host strain can have a major and unpredictable effect on stability, and it is worth testing several different strains, including the protease-deficient *lon*⁻ strains (D.B.S. and L.M.C., unpub. observ.; UNIT 1.4). Alterna-

tively, degradation of fusion proteins can be minimized by adding isopropyl-1-thio- β -D-galactoside (IPTG) later in the course of the culture and keeping the induction period to a minimum. The overall yield of fusion protein can sometimes be improved by increasing the quantity of glutathione-agarose beads, minimizing the volume of liquid during absorption, and extending the period of absorption to 1 hr.

Insolubility of fusion proteins can be addressed by several means. In some cases, growth of cells at 30°C is sufficient to alter solubility (D.B.S., unpub. observ.), but in other cases it may be necessary to investigate the effect of mild detergent treatment after cell lysis. Examples of conditions under which binding of GST to glutathione-agarose is unaffected are 1% Triton X-100, 1% Tween-20, 1% CTAB, 10 mM DTT, and 0.03% SDS. Alternatively, fusion proteins can be solubilized in 1% to 2% Sarkosyl prior to sonication; they can be solubilized in 2% to 4% Triton X-100 prior to binding to glutathione agarose (Frangioni and Neel, 1993). Even if a fusion protein is largely insoluble, it may be possible to purify the small proportion that is still soluble, with a yield of perhaps 50 μ g/liter. Otherwise, a fusion protein that is abundant, but stubbornly insoluble, can be purified by gel filtration after solubilization under denaturing conditions or by electroelution from a gel after SDS-PAGE.

A different approach is to express the polypeptide as smaller fragments, particularly if it is possible to express parts of the protein that do not contain severely hydrophobic or highly charged regions. If the fusion protein is not of the expected size, it may be worth sequencing across the cloning site to ensure that the reading frame of the vector and the insert are matched. There is a hairpin in GST sequences near the cloning sites, so a sequencing primer complementary to either the extreme 3' end of the GST gene or to sequences within the DNA insert should be used.

Anticipated Results

Yields of fusion protein vary from more typical yields of 1 to 3 mg/liter up to 10 mg/liter, and can be as low as 50 μ g/liter if most of the fusion protein is insoluble. The single affinity chromatography step can generate fusion protein preparations that are >90% pure.

Time Considerations

A full day is required to screen colonies of transformants for expression of fusion proteins,

although continuous attention is not required. Large-scale purification and cleavage of fusion proteins require another day of intermittent work. Cells can be stored as pellets at -70°C before lysis, although with fusion proteins that are unstable, this may be undesirable. Purification is best completed in one session.

Expression and Purification of Thioredoxin Fusion Proteins

This unit describes a gene fusion expression system that uses thioredoxin, the product of the *Escherichia coli trxA* gene, as the fusion partner. The system is particularly useful for high-level production of soluble fusion proteins in the *E. coli* cytoplasm; in many cases heterologous proteins produced as thioredoxin fusion proteins are correctly folded and display full biological activity. Although the thioredoxin gene fusion system is routinely used for protein production, high-level production of peptides—i.e., for use as antigens—is also possible because the prominent thioredoxin active-site loop is a very permissive site for the introduction of short amino acid sequences (10 to 30 residues in length). The inherent thermal stability of thioredoxin and its susceptibility to quantitative release from the *E. coli* cytoplasm by osmotic shock can also be exploited as useful tools for thioredoxin fusion protein purification. In addition, a more generic method for purification of any soluble thioredoxin fusion employs a modified form of thioredoxin (called “His-patch Trx”), which has been designed to bind to metal chelate resins. Protein fusions to His-patch Trx can usually be purified in a single step from cell lysates (see Strategic Planning).

The basic protocol outlines the construction of a fusion of *trxA* to any desired gene and expression of the fusion protein in an appropriate host strain at 37°C. Additional protocols describe *E. coli* cell lysis using a French pressure cell and fractionation (first support protocol), osmotic release of thioredoxin fusion proteins from the *E. coli* cytoplasm (second support protocol), and heat treatment to purify some thioredoxin fusion proteins (third support protocol).

STRATEGIC PLANNING

The thioredoxin gene fusion expression vectors pTRXFUS and hpTRXFUS, both of which carry the *E. coli trxA* gene (Fig. 16.8.1), are used for high-level production of C-terminal fusions to thioredoxin. The vector hpTRXFUS differs from pTRXFUS in that it contains a modified *E. coli trxA* gene which produces a mutant protein (“His-patch” thioredoxin) that can specifically bind to metal chelate matrices charged with nickel or cobalt, otherwise known as native metal-chelate affinity chromatography (MCAC; UNIT 10.11B). The *trxA* translation termination codon has been replaced in both vectors by DNA encoding a ten-residue peptide linker sequence that includes an enterokinase (enteropeptidase; LaVallie et al., 1993a) cleavage site. This highly specific site can be cleaved with enterokinase following purification of the fusion protein to release the protein of interest from its thioredoxin fusion partner (cleavage of the fusion protein is covered in UNIT 16.4B). Immediately downstream of the DNA encoding the enterokinase site in pTRXFUS and hpTRXFUS lies a DNA polylinker sequence containing a number of unique restriction endonuclease sites that can be used for forming in-frame translational fusions of any desired gene to *trxA*. Downstream of the DNA polylinker lies the *E. coli aspA* transcription terminator. Replication of these vectors is controlled by a modified colE1 replication origin similar to that found in pUC vectors (Norrander et al., 1983). Plasmid selection and maintenance is ensured by the presence of the β -lactamase gene on the vector. The vector pALtrxA-781 (Fig. 16.8.1) is very similar to pTRXFUS. However in this plasmid the *trxA* gene is followed by a translation termination codon, and the sequences encoding the enterokinase-site peptide linker are absent. A unique *RsrII* site, present in both pALtrxA-781 and pTRXFUS, allows for the easy insertion of short peptide-encoding DNA sequences into *trxA* within the region that encodes the active-site loop.

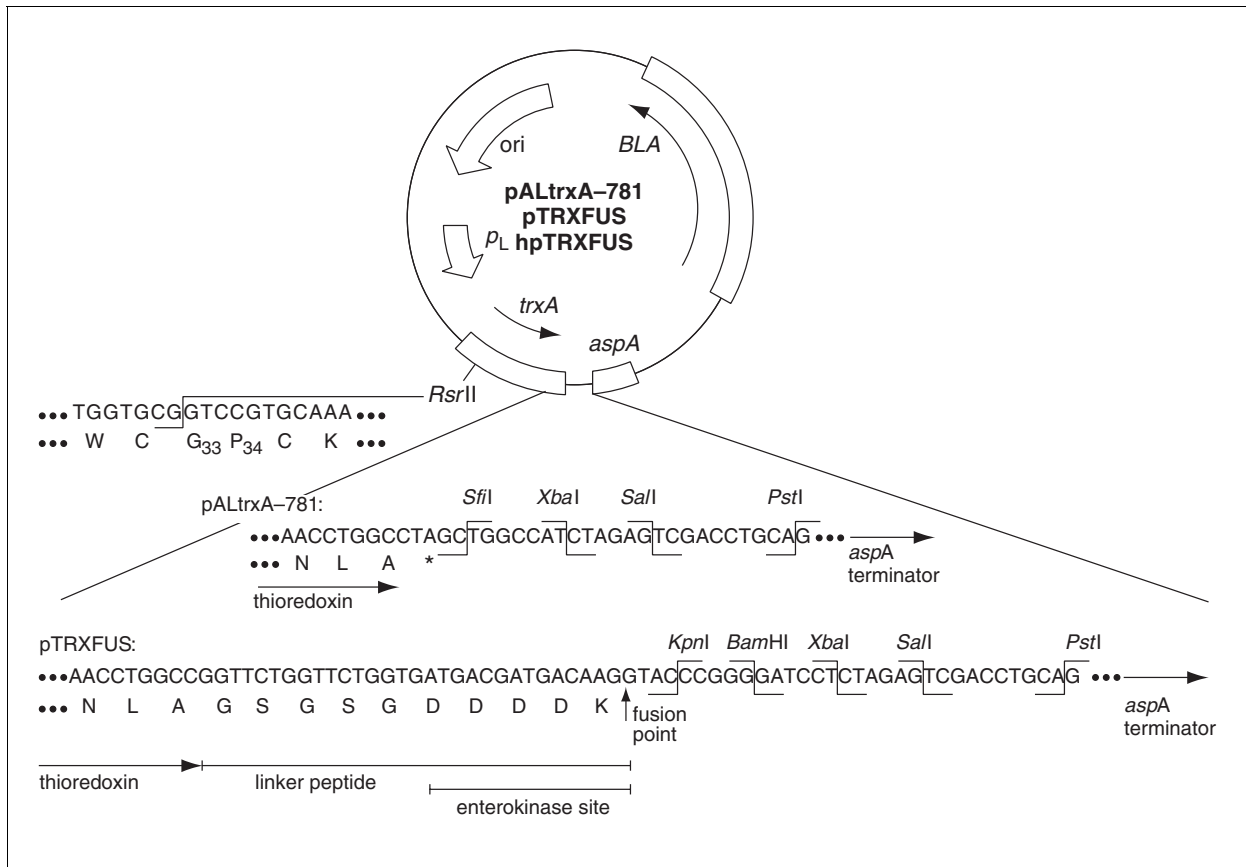

Figure 16.8.1 Thioredoxin gene fusion expression vectors pTRXFUS, hpTRXFUS, and pALtrxA-781. pALtrxA-781 contains a polylinker sequence at the 3' end of the *trxA* gene. pTRXFUS and hpTRXFUS contain a linker region encoding a peptide that includes the enterokinase cleavage site between the *trxA* gene and the polylinker. The sequence surrounding the active site loop of thioredoxin has a single *RsrII* site that can be used to insert peptide coding sequence. The asterisk indicates a translational stop codon. Abbreviations: *trxA*, *E. coli* thioredoxin gene; *BLA*, β -lactamase gene; *ori*, *colE1* replication origin; *pL*, bacteriophage λ major leftward promoter; *aspA* terminator, *E. coli* aspartate amino-transferase transcription terminator.

pTRXFUS, hpTRXFUS, and pALtrxA-781 carry the strong bacteriophage λ promoter *pL* (Shimatake and Rosenberg, 1981) positioned upstream of the *trxA* gene. Transcription initiation at the *pL* promoter is controlled by the intracellular concentration of λ repressor protein (*cI*). *UNIT 16.3* describes λ strains that carry either a temperature-sensitive form of *cI* (*cI*⁸⁵⁷) or a wild-type *cI* repressor protein. *cI*⁸⁵⁷-containing strains can be used for heat inductions of *pL* at 42°C; alternatively, in the strains carrying the wild-type repressor, *pL* can be induced by a prior induction of the *E. coli* SOS stress response. However, it is often desirable to express heterologous genes in *E. coli* at temperatures considerably lower than 42°C, or under conditions where cells are not undergoing a physiological stress. Strains GI698, GI724 and GI723 were designed to allow the growth and induction of *pL* expression vectors, including pTRXFUS, hpTRXFUS, and pALtrxA-781, under mild conditions over a wide range of temperatures (see Table 16.8.1; Mieschendahl et al., 1986). Each of these strains carries a wild-type allele of *cI* stably integrated into the *E. coli* chromosome at the nonessential *ampC* locus. A synthetic *trp* promoter integrated into *ampC* upstream of the *cI* gene in each strain directs the synthesis of *cI* repressor only when intracellular tryptophan levels are low. When tryptophan levels are high, synthesis of *cI* is switched off; therefore, the presence of tryptophan in the growth medium of GI698, GI723, or GI724 will block expression of λ repressor and thus will turn on *pL*. Because

Table 16.8.1 *E. coli* Strains for Production of Thioredoxin Fusion Proteins at Varying Temperatures

Strain	Desired production temperature (°C)	Pre-induction growth temperature (°C)	Induction period (hr)
GI698	15	25	20
GI698	20	25	18
GI698	25	25	10
GI724	30	30	6
GI724	37	30	4
GI723	37	37	5

the three strains carry ribosome-binding sequences of different strengths at the 5'-end of their respective *cI* genes, they maintain intracellular concentrations of λ repressor that increase in the order GI698 < GI724 < GI723. The choice of which strain to use for a particular application is dependent on the desired culture conditions as described below.

Although some thioredoxin fusion proteins produced at 37°C are insoluble, expression at lower temperatures can often result in the fusion protein being produced in a soluble form. Each of the three pL host strains GI698, GI723, and GI724 is suitable for the production of thioredoxin fusion proteins over a particular temperature range. Table 16.8.1 indicates the correct strain for expression of thioredoxin fusion proteins at any temperature between 15°C and 37°C. The induction protocol at any of these temperatures is the same as that described in the basic protocol for induction of GI724 at 37°C, except the preinduction growth temperature and the length of the induction period vary according to the strain used and the temperature chosen. Cultures should be grown at the indicated preinduction growth temperature until they reach a density of 0.4 to 0.6 OD₅₅₀/ml. They should then be moved to the desired induction temperature and induced by the addition of 100 µg/ml tryptophan.

Low-temperature inductions are best performed in strain GI698. However, this strain makes only enough *cI* repressor protein to maintain the vectors in an uninduced state at temperatures below 25°C. GI698 should therefore never be grown above 25°C when it carries a pL plasmid. A nonrefrigerated water bath can be maintained below room temperature by placing it in a 4°C room and setting the thermostat to the desired temperature.

It is often a good idea to collect timepoints during the course of a long induction period and to fractionate cells from these timepoints using the procedure in the first support protocol (steps 9 to 13). Although a particular fusion protein may be soluble during the early part of an induction, during the later phases of induction, it may become unstable or its concentration inside the cell may exceed a critical threshold above which it will precipitate and appear in the insoluble fraction.

**CONSTRUCTION AND EXPRESSION OF A THIOREDOXIN
FUSION PROTEIN**

This protocol describes construction and subsequent expression of a gene fusion between *trxA* (encoding thioredoxin) and a gene encoding a particular protein or peptide. After a clone carrying the correct fusion sequence is constructed, analyzed, and isolated, cultures are grown and expression is induced. The protocol is described in terms of the *E. coli* host strain GI724 with expression at 30°C; it may also be applied to strains GI698 and GI723 (also available from Genetics Institute) for expression at other temperatures by using the parameters specified in Table 16.8.1 (see Strategic Planning).

Materials

For recipes, see Reagents and Solutions in this unit (or cross-referenced unit); for common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

- DNA fragment encoding desired sequence
- Thioredoxin expression vectors (Fig. 16.8.1): pTRXFUS or pALtrxA-781 (Genetics Institute or Invitrogen) or hpTRXFUS (Genetics Institute)
- E. coli* strain GI724 (Genetics Institute or Invitrogen), grown in LB medium and made competent (UNIT 1.8)
- LB medium (UNIT 1.1)
- IMC plates containing 100 µg/ml ampicillin (see recipe)
- CAA/glycerol/ampicillin 100 medium (see recipe)
- IMC medium containing 100 µg/ml ampicillin (see recipe)
- 10 mg/ml tryptophan (see recipe)
- SDS-PAGE sample buffer (see recipe)
- 30°C convection incubator
- 18 × 50–mm culture tubes
- Roller drum (New Brunswick Scientific)
- 250-ml culture flask
- 70°C water bath
- Microcentrifuge, 4°C
- Additional reagents and equipment for subcloning of DNA fragments (UNIT 3.16), transforming competent *E. coli* cells (UNIT 1.8), preparing miniprep DNA (UNIT 1.6), restriction mapping (UNIT 3.2), direct sequencing of plasmid DNA (UNITS 7.3 & 7.4), SDS-PAGE (UNIT 10.2), and Coomassie brilliant blue staining (UNIT 10.6)

Construct the *trxA* gene fusion

1. Use DNA fragment encoding the desired sequence to construct either an in-frame fusion to the 3'-end of the *trxA* gene in pTRXFUS or hpTRXFUS, or a short peptide insertion into the unique *RsrII* site of pALtrxA-781.

A precise fusion of the desired gene to the enterokinase linker sequence in pTRXFUS or hpTRXFUS can be made by using the unique KpnI site trimmed to a blunt end with the Klenow fragment of E. coli DNA polymerase. The desired gene can usually be adapted to this blunt-end construct by using a synthetic oligonucleotide duplex ligated between it and any convenient downstream restriction site close to the 5' end of the gene. When designing the fusion junction, note that enterokinase is able to cleave —DDDDK↓X—, where X is any amino acid residue except proline. Synthetic oligonucleotides encoding short peptides for insertion into the thioredoxin active-site loop at the RsrII site will insert only in the desired orientation, because the RsrII sticky end consists of three bases.

2. Transform the ligation mixture containing the new thioredoxin fusion plasmid into competent GI724 cells. Plate transformed cells onto IMC plates containing 100 µg/ml

ampicillin to select transformants. Incubate plates in a 30°C convection incubator until colonies appear.

Strains GI698, GI723, and GI724 are all healthy prototrophs that can grow under a wide variety of growth conditions, including rich and minimal media and a broad range of growth temperatures (see Table 16.8.1). These strains can be prepared for transformation with pL-containing vectors by growing them in LB medium at 37°C. LB medium may also be used for these strains during the short period of outgrowth immediately following transformation. This growth period of 30 min to 1 hr is often used to express drug resistance phenotypes before plating out plasmid transformations onto solid medium. Subsequently, however, these strains should be grown only on minimal or tryptophan-free rich media, such as IMC medium containing 100 µg/ml ampicillin (for expression of the fusion protein) or CAA/glycerol/ampicillin 100 medium (for plasmid DNA preparations). Except during transformation, LB medium should never be used with these three strains when they carry pL plasmids because LB contains tryptophan. The pL promoter is extremely strong and should be maintained in an uninduced state until needed so that expression of the protein will not lead to selection of mutant or variant cells with lower expression due to undesirable genetic selections or rearrangements in the expression strain.

3. Grow candidate colonies in 5 ml CAA/glycerol/ampicillin 100 medium overnight at 30°C. Prepare minipreps of plasmid DNA and check for correct gene insertion into pTRXFUS by restriction mapping.
4. Sequence plasmid DNA of candidate clones to verify the junction region between thioredoxin and the gene or sequence of interest.

Induce expression

5. Streak out frozen stock culture of GI724 containing thioredoxin expression plasmid to single colonies on IMC plates containing 100 µg/ml ampicillin. Grow 20 hr at 30°C.

Occasionally there is induction of pL plasmids grown in GI698 and GI724 at 37°C, even in medium containing no tryptophan. Such induction appears to be a temperature-dependent phenomenon. If growth at 37°C prior to pL induction is essential, then GI723 should be used as the host strain because GI723 produces higher levels of cI repressor than both GI698 and to GI724. Otherwise, plasmid-containing GI698 should be grown at 25°C and plasmid-containing GI724 should be grown at 30°C prior to induction (see Table 16.8.1).

6. Pick a single fresh, well-isolated, colony from the plate and use it to inoculate 5 ml IMC medium containing 100 mg/ml ampicillin in an 18 × 150–mm culture tube. Incubate overnight at 30°C on a roller drum.
7. Add 0.5 ml overnight culture to 50 ml fresh IMC medium containing 100 µg/ml ampicillin in a 250-ml culture flask (1:100 dilution). Grow at 30°C with vigorous aeration until absorbance at 550 nm reaches 0.4 to 0.6 OD/ml (~3.5 hr).
8. Remove a 1-ml aliquot of the culture (uninduced cells). Measure the absorbance at 550 nm and harvest the cells by microcentrifuging 1 min at maximum speed, room temperature. Carefully remove all the spent medium with a pipet and store the cell pellet at –80°C.
9. Induce pL by adding 0.5 ml of 10 mg/ml tryptophan (100 µg/ml final) to remaining cells immediately.
10. Incubate 4 hr at 37°C. At hourly intervals during this incubation, remove 1-ml aliquots of the culture and harvest cells as in step 8.

11. Harvest the remaining cells from the culture 4 hr post-induction by centrifuging 10 min at 3000 rpm (e.g., in a Beckman J6 rotor), 4°C. Store the cell pellet at –80°C.

Procedures for further analysis of these cells are outlined in the support protocols.

Verify induction

12. Resuspend the pellets from the induction intervals (steps 8 and 10) in 200 µl of SDS-PAGE sample buffer/OD₅₅₀ cells. Heat 5 min at 70°C to completely lyse the cells and denature the proteins. Run the equivalent of 0.15 OD₅₅₀ cells per lane (30 µl) on an SDS-polyacrylamide gel.
13. Stain the gel 1 hr with Coomassie brilliant blue. Destain the gel and check for expression.

Most thioredoxin fusion proteins are produced at levels that vary from 5% to 20% of the total cell protein. The desired fusion protein should exhibit the following characteristics: it should run on the gel at the mobility expected for its molecular weight; it should be absent prior to induction; and it should gradually accumulate during induction, with maximum accumulation usually occurring 3 hr post-induction at 37°C.

SUPPORT PROTOCOL 1

E. COLI LYSIS USING A FRENCH PRESSURE CELL

A small 3.5-ml French pressure cell can be used as a convenient way to lyse *E. coli* cells. The whole-cell lysate can be fractionated into soluble and insoluble fractions by microcentrifugation. Other lysis procedures may be used—for example, sonication (UNITS 4.4 & 16.6) or treatment with lysozyme-EDTA (UNIT 4.4).

Additional Materials

*For recipes, see **Reagents and Solutions** in this unit (or cross-referenced unit); for common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.*

Cell pellet from 4-hr post-induction culture (basic protocol)

20 mM Tris·Cl, pH 8.0 (APPENDIX 2), 4°C

Lysis buffer: 20 mM Tris·Cl (pH 8.0) with protease inhibitors (optional)—0.5 mM phenylmethylsulfonyl fluoride (PMSF), 1 mM *p*-aminobenzamidine (PABA), and 5 mM EDTA

French press and 3.5-ml mini-cell (Fig. 16.8.2; SLM Instruments), 4°C

Lyse the cells

1. Resuspend cell pellet from 4-hr post-induction culture in 20 mM Tris·Cl, pH 8.0, to a concentration of 5 OD₅₅₀/ml.

Protease inhibitors can be included in the resuspension if desired. Cells can also be resuspended at densities of 100 OD₅₅₀/ml or greater; however, at high densities cell lysis may be less efficient.

2. Place 1.5 ml resuspended cell pellet in the French pressure cell. Hold the cell upside down with the base removed, the piston fully extended downwards, and the outlet valve handle that holds the nylon ball seal in the open position (loose).

Before filling the pressure cell, check that the nylon ball, which seals the outlet port and sits on the end of the outlet valve handle, is not deformed. If it is, replace it with a new one. Both the condition of the nylon ball and its seat in the pressure cell body are critical for the success of the procedure.

3. Bring the liquid in the pressure cell to the level of the outlet port by raising the piston slowly to expel excess air from the cell. With the outlet valve open and at the same time maintaining the piston in position, install the pressure cell base. Gently close the outlet valve.

Figure 16.8.2 French pressure cell, equipped with 3.5-ml mini-cell.

CAUTION: Do not over-tighten the valve as this will deform the nylon ball and may irreparably damage its seat on the pressure cell body.

4. Turn the sealed cell right side up and place it in the hydraulic press.
5. Turn the pressure regulator on the press fully counter-clockwise to reset it to zero pressure. Set the ratio selector to medium. Turn on the press.

CAUTION: The larger (50-ml) pressure cell is usually used with the selector set on high. The small (3.5-ml) cell is only used on medium ratio.

6. Slowly turn the pressure regulator clockwise until the press just begins to move. Allow the press to compress the piston. It will stop moving after a few seconds.
7. Position a collection tube under the pressure cell outlet. Slowly increase the pressure in the cell by turning the pressure regulator clockwise. Monitor the reading on the gauge and increase the pressure to 1000 on the dial, corresponding to an internal cell pressure of 20,000 lb/in².
8. While continuously monitoring the gauge, very slowly open the outlet valve until lysate begins to trickle from the outlet.

The lysate should flow slowly and smoothly, and the cell pressure should not drop more than 100 divisions on the dial.

At 20,000 lb/in² and 5 OD₅₅₀/ml, cell lysis will be complete after one passage through the press. Lower pressures and/or higher cell densities may require a second passage.

Fractionate the lysate

9. Remove a 100- μ l aliquot of the lysate and freeze at -80°C (whole-cell lysate).
10. Fractionate the remainder of the lysate by microcentrifuging 10 min at maximum speed, 4°C .
11. Remove a 100- μ l aliquot of the supernatant and freeze at -80°C (soluble fraction). Discard the remainder of the supernatant.

Because this is a pilot experiment, it would not produce enough material to warrant saving any remaining supernatant.

12. Resuspend the pellet in an equivalent volume of lysis buffer. Remove a 100- μ l aliquot and freeze at -80°C (insoluble fraction).
13. Lyophilize the 100- μ l aliquots to dryness in a Speedvac evaporator. Solubilize in 100 μ l SDS-PAGE sample buffer. Analyze 30- μ l samples by SDS-PAGE.

This crude fractionation provides a fairly reliable indication of whether a protein has folded correctly. Usually proteins in the soluble fraction have adopted a correct conformation and proteins in the insoluble fraction have not. However, occasionally proteins found in the soluble fraction are not truly soluble; instead they form aggregates that do not pellet in the microcentrifuge. Conversely, sometimes a protein found in the insoluble fraction may be there because it has an affinity for cell wall components and cell membranes, and it may not be intrinsically insoluble. Occasionally proteins can be recovered from these insoluble fractions by extracting with agents such as mild detergents.

SUPPORT PROTOCOL 2

OSMOTIC RELEASE OF THIOREDOXIN FUSION PROTEINS

Thioredoxin and some thioredoxin fusion proteins can be released with good yield from the *E. coli* cytoplasm by a simple osmotic shock procedure.

Additional Materials

*For recipes, see **Reagents and Solutions** in this unit (or cross-referenced unit); for common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.*

Cell pellet from 4-hr post-induction cultures (basic protocol)
20 mM Tris·Cl (pH 8.0)/2.5 mM EDTA/20% (w/v) sucrose, ice-cold
20 mM Tris·Cl (pH 8.0)/2.5 mM EDTA, ice-cold

1. Resuspend cell pellet from 4-hr post-induction cultures at a concentration of 5 $\text{OD}_{550}/\text{ml}$ in ice-cold 20 mM Tris·Cl (pH 8.0)/2.5 mM EDTA/20% sucrose. Incubate 10 min on ice.
2. Microcentrifuge 30 sec at maximum speed, 4°C , to pellet the cells.
3. Discard the supernatant and gently resuspend the cells in an equivalent volume of ice-cold 20 mM Tris·Cl (pH 8.0)/2.5 mM EDTA. Incubate 10 min on ice and mix occasionally by inverting the tube.

Osmotic release from the cytoplasm occurs at this stage.

4. Microcentrifuge 30 sec at maximum speed, 4°C . Save the supernatant (osmotic shockate). Resuspend the cell pellet in an equivalent volume 20 mM Tris·Cl (pH 8.0)/2.5 mM EDTA (retentate).
5. Lyophilize 100- μ l aliquots of osmotic shockate and retentate to dryness in a Speedvac evaporator.
6. Solubilize each in 100 μ l SDS-PAGE sample buffer. Analyze 30- μ l aliquots by SDS-PAGE.

*The osmotic shock procedure provides a substantial purification step for some thioredoxin fusion proteins. This procedure will remove most of the contaminating cytoplasmic proteins as well as almost all of the nucleic acids. However the shockate will contain as contaminants about half of the cellular elongation factor-Tu (EFTu) and most of the *E. coli* periplasmic proteins.*

PURIFICATION OF THIOREDOXIN FUSION PROTEINS BY HEAT TREATMENT

Wild-type thioredoxin is resistant to prolonged incubations at 80°C. A subset of thioredoxin fusion proteins also exhibit corresponding thermal stability, and heat treatment at 80°C can sometimes be used as an initial purification step. Under these conditions the majority of contaminating *E. coli* proteins are denatured and precipitated.

Additional Materials

For recipes, see Reagents and Solutions in this unit (or cross-referenced unit); for common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Cell pellet from 4-hr post-induction cultures (basic protocol)

20 mM Tris·Cl (pH 8.0)/2.5 mM EDTA

80°C water bath

10-ml glass-walled tube

1. Resuspend cell pellet from 4-hr post-induction cultures at a concentration of 100 OD₅₅₀/ml in 20 mM Tris·Cl (pH 8.0)/2.5 mM EDTA.

It is important to start off with a high protein concentration in the lysate to ensure efficient precipitation of denatured proteins.

2. Lyse the cells at 20,000 lb/in² in a French pressure cell as described in steps 2 to 8 of the first support protocol. Collect whole-cell lysate in a 10-ml glass-walled tube.
3. Incubate whole-cell lysate 10 min at 80°C. Remove 100-μl aliquots after 30 sec, 1 min, 2 min and 5 min and plunge immediately into ice. At 10 min plunge the remaining heated lysate into ice.

A glass-walled tube (not plastic) provides good thermal conductivity to provide a rapid rise in temperature to 80°C and then a rapid drop in temperature to 4°C. A suitable volume to use in a 10-ml glass tube is 1.5 ml lysate. For large-scale work, a glass-walled vessel should be used and the lysate should be mixed well during both heat treatment and cooling.

4. Microcentrifuge the aliquots 10 min at maximum speed, 4°C to pellet heat-denatured, precipitated proteins.
5. Remove 2-μl aliquots of the supernatants and add 28 μl SDS-PAGE sample buffer. Analyze the samples by SDS-PAGE to determine the heat stability of the fusion protein and the minimum time of heat treatment required to obtain a good purification.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see *APPENDIX 2*; for suppliers, see *APPENDIX 4*.

Casamino Acids (CAA), 2% (w/v)

20 g Casamino Acids (Difco certified)
H₂O to 1 liter
Autoclave or filter sterilize through a 0.45- μ m filter
Store \leq 2 months at room temperature

Do not use technical-grade Casamino Acids because it has a higher NaCl content.

CAA/glycerol/ampicillin 100 medium

800 ml 2% (w/v) Casamino Acids (see recipe; 1.6% final)
100 ml 10 \times M9 salts (see recipe; 1 \times final)
100 ml 10% (v/v) glycerol (sterile; 1% final)
1 ml 1 M MgSO₄ (sterile; 1 mM final)
0.1 ml 1 M CaCl₂ (sterile; 0.1 mM final)
1 ml 2% (w/v) vitamin B1 (sterile; 0.002% final)
10 ml 10 mg/ml ampicillin (sterile; 100 μ g/ml final)
Prepare fresh

IMC medium

200 ml 2% (w/v) Casamino Acids (see recipe; 0.4% final)
100 ml 10 \times M9 salts (see recipe; 1 \times final)
40 ml 20% (w/v) glucose (sterile; 0.5% final)
1 ml 1 M MgSO₄ (sterile; 1 mM final)
0.1 ml 1 M CaCl₂ (sterile; 0.1 mM final)
1 ml 2% (w/v) vitamin B1 (sterile; 0.002% final)
658 ml glass-distilled H₂O (sterile)
10 ml 10 mg/ml ampicillin (sterile; optional; 100 μ g/ml final)
Use fresh

IMC plates

15 g agar [Difco; 1.5% (w/v)]
4 g casamino acids [Difco-certified; 0.4% (w/v)]
858 ml glass-distilled H₂O (sterile)
Autoclave 30 min
Cool in a 50°C water bath
100 ml 10 \times M9 salts (see recipe; 1 \times final)
40 ml 20% (w/v) glucose (sterile; 0.5% final)
1 ml 1 M MgSO₄ (sterile; 1 mM final)
0.1 ml 1 M CaCl₂ (sterile; 0.1 mM final)
1 ml 2% (w/v) vitamin B1 (sterile; 0.002% final)
10 ml 10 mg/ml ampicillin (sterile; optional; 100 μ g/ml final)
Mix well and pour into Petri plates
Store \leq 1 month at 4°C

M9 salts, 10 \times

60 g Na₂HPO₄ (0.42 M)
30 g KH₂PO₄ (0.24 M)
5 g NaCl (0.09 M)
10 g NH₄Cl (0.19 M)
H₂O to 1 liter

continued

Adjust pH to 7.4 with NaOH
Autoclave or filter sterilize through a 0.45- μ m filter
Store \leq 6 months at room temperature

SDS-PAGE sample buffer

15% (v/v) glycerol
0.125 M Tris-Cl, pH 6.8 (APPENDIX 2)
5 mM Na₂EDTA
2% (w/v) SDS
0.1% (w/v) bromphenol blue
1% (v/v) 2-mercaptoethanol (2-ME; add immediately before use)
Store indefinitely at room temperature

Tryptophan, 10 mg/ml

Heat 500 ml glass-distilled H₂O to 80°C. Stir in 5 g L-tryptophan until dissolved. Filter sterilize the solution through a 0.45 μ m filter and store \leq 6 months in the dark at 4°C.

COMMENTARY

Background Information

Two significant problems plague researchers who hope to express heterologous proteins in *Escherichia coli*: inefficient initiation of translation of many eukaryotic mRNA sequences on bacterial ribosomes (Stormo et al., 1982), and proteins that often form insoluble aggregates, called inclusion bodies, that are composed of misfolded or denatured proteins (Mitraki and King, 1989). Although successful protocols for refolding eukaryotic proteins from inclusion bodies can be developed, the process is always uncertain and usually time-consuming; in most instances it is preferable to prevent inclusion-body formation in the first place. The use of *trxA* fusions provides a solution to both problems.

Inefficient initiation of translation of eukaryotic messages in *E. coli* can often be improved by modifying sequences at the 5' end of the gene. A more reliable technique that avoids the problem entirely is to use a gene fusion strategy in which the gene of interest is linked in-frame to the 3' end of a highly translated partner gene. In this case protein synthesis always initiates on the same efficiently translated fusion partner mRNA, thus high-level expression is assured. Some earlier gene fusion expression systems, for example the *trpE* and *lacZ* systems described in UNIT 16.5, offer very reliable ways of producing large quantities of any desired eukaryotic protein. However, these gene fusion systems still suffer from the pervasive inclusion-body problem. They are thus mainly useful for the production of antigens, rather than correctly folded, biologically active

proteins. More recently the maltose binding protein (MBP) and glutathione-S-transferase (GST) gene fusion expression systems (see UNITS 16.6 & 16.7) have proven more successful in producing soluble fusion proteins; these systems retain the translation advantage of the earlier fusion systems. Apart from the obvious advantages in making a correctly folded product, the synthesis of soluble fusion proteins also allows for the development of generic purification schemes based on some unique property of the fusion partner.

Why would any particular eukaryotic protein produced in the *E. coli* cytoplasm be more soluble when it is linked to a fusion partner than it would be by itself? It is likely that physical properties of the fusion partner protein are important, with efficient self-folding and high solubility being useful in this role. It is possible that some good fusion partners (proteins that fold efficiently and are highly soluble), by virtue of their desirable physical qualities, are able to keep folding intermediates of linked heterologous proteins in solution long enough for them to adopt their correct final conformations. In this respect the fusion partner may serve as a covalently joined chaperon protein, in many ways fulfilling the role of authentic chaperon proteins (McCoy, 1992), analogous to the covalent chaperon role proposed for the N-terminal pro regions of a number of protein precursors (Silen et al., 1989; Shinde et al., 1993).

Many of the known properties of *E. coli* thioredoxin (Holmgren, 1985) suggested that it would make a particularly effective fusion partner in an expression system. First, thiore-

doxin, when overproduced from plasmid vectors, can accumulate to 40% of the total cellular protein, yet even at these expression levels all of the protein remains soluble. Second, the molecule is small (11,675 M_r) and would contribute a relatively modest amount to the total mass of any fusion protein, in contrast to other systems such as the *lacZ* system. Third, the tertiary structure of thioredoxin (Katti et al., 1990) reveals that both the N- and C-termini of the molecule are accessible on the surface and in good position to link to other proteins. The structure also shows that the molecule has a very tight fold, with >90% of its primary sequence involved in strong elements of secondary structure. This provides an explanation for thioredoxin's observed high thermal stability (T_m 85°C), and suggests that the molecule might possess the robust folding characteristics that could make it a good fusion partner protein. In support of this view, complete thioredoxin domains are found in a number of naturally occurring multidomain proteins, including *E. coli* DsbA (Bardwell et al., 1991), the mammalian endoplasmic reticulum proteins ERp72 (Mazzarella et al., 1990), and protein disulfide isomerase (PDI; Edman et al., 1985). These proteins can all be considered as natural precedents for thioredoxin fusion proteins.

The synthesis of small peptides in *E. coli* is often difficult, with the products frequently being extensively degraded or insoluble. The thioredoxin tertiary structure revealed that the characteristic active site, —CGPC—, protrudes from the body of the protein as a surface loop, with few interactions with the rest of the molecule. The loop does not seem to contribute to the overall stability of thioredoxin, so the production of peptides as insertions at this site was an attractive possibility. In this location they would be protected from host-cell amino- and carboxypeptidases, and thioredoxin's high solubility should help keep them in solution. In addition, the conformation of peptides inserted at this position would be constrained, which could be an advantage for applications in which it is desirable for the peptide to adopt a particular form.

Thioredoxin has indeed proven to be an excellent partner for the production of soluble fusion proteins in the *E. coli* cytoplasm (LaVallie et al., 1993b). Figure 16.8.3 demonstrates the production of soluble fusion proteins between thioredoxin and eleven human and murine cytokines and growth factors using the *trxA* vectors. All of these mammalian proteins had been previously produced in *E. coli* only as

insoluble inclusion bodies. As thioredoxin fusions, the growth factors are not only made in a soluble form, but in most cases they are also biologically active in *in vitro* assays.

Experience gained while working with these and a number of other *trxA* fusion proteins shows that two further characteristics of thioredoxin can be exploited as purification tools. The first is the inherent thermal stability of the molecule, a property that is retained by some thioredoxin fusion proteins. This enables heat treatment to be used as an effective purification step. The second additional property relates to thioredoxin's cellular location. Although *E. coli* thioredoxin is a cytoplasmic protein, it has been shown to occupy a special position within the cell—it is primarily located on the cytoplasmic face of the adhesion zones that exist between the inner and outer membranes of the *E. coli* cell envelope (Lunn and Pigiet, 1982). From this location thioredoxin is quantitatively released to the exterior of the cell by simple osmotic shock or freeze/thaw treatments, a remarkable property that is retained by some thioredoxin fusion proteins, thus providing a simple purification step.

A more generic method for purification of any soluble thioredoxin fusion employs a modified form of thioredoxin (called “His-patch Trx”), which has been designed to bind to metal chelate resins (E.A. DiBlasio, J.M. McCoy, and E.R. LaVallie, manuscript in preparation).

Critical Parameters

Lack of protein solubility leading to inclusion-body formation in *E. coli* is a complex phenomenon with many contributing factors: simple insolubility as a result of high-level expression, insolubility of protein-folding intermediates, lack of appropriate bacterial chaperon proteins, and lack of glycosylation mechanisms in the bacterial cytoplasm. Fusion of heterologous proteins to thioredoxin or to other fusion partners can help address most of these solubility issues. However, another important factor contributing to inclusion body formation is the inability to form essential disulfide bonds in the reducing environment of the bacterial cytoplasm, which leads to incorrect folding. Thermal lability of even correctly folded heterologous proteins in the absence of these stabilizing disulfide cross-links is a significant problem, so the expression of fusion genes should be attempted over a wide range of temperatures, even as low as 15°C (the limit for *E. coli* growth is ~8°C). Thermal denaturation is

Figure 16.8.3 Expression of thioredoxin gene fusions. The gel shows proteins found in the soluble fractions derived from *E. coli* cells expressing eleven different thioredoxin gene fusions. Lane 1, host *E. coli* strain GI724 (negative control, 37°C); lane 2, murine interleukin-2 (IL-2; 15°C); lane 3, human IL-3 (15°C); lane 4, murine IL-4 (15°C); lane 5, murine IL-5 (15°C); lane 6, human IL-6 (25°C); lane 7, human MIP-1a (37°C); lane 8, human IL-11 (37°C); lane 9, human macrophage colony-stimulating factor (M-CSF; 37°C); lane 10, murine leukemia inhibitory factor (LIF; 25°C); lane 11, murine steel factor (SF; 37°C); and lane 12, human bone morphogenetic protein-2 (BMP-2; 25°C). Temperatures in parentheses are the production temperature chosen for expressing each fusion. This is a 10% SDS-polyacrylamide gel, stained with Coomassie brilliant blue.

a time-dependent process, so it is also prudent to monitor the solubility of the expressed fusion protein over the time course of induction.

A great many proteins contain distinct structural domains. For example, hormone receptor proteins usually have an extracellular ligand-binding domain, a transmembrane region, and an intracellular effector domain. Sometimes expressing these domains individually as fusion proteins can yield better results than expressing the entire protein. The exact positions chosen for boundaries of the domains to be expressed in the fusion protein are important and can be determined from a knowledge of the tertiary structure of the protein of interest, by homology comparisons with similar proteins, by limited proteolysis or other domain-mapping experiments, or empirically by generating multiple fusions that test different boundary positions.

It is important to be consistent in treating samples for loading on gels. For example, using different heating conditions from one experi-

ment to the next can result in a mobility shift for the protein of interest.

Anticipated Results

Thioredoxin fusion protein yields are usually in the range of 5% to 20% of total cell protein. At these expression levels a 1-liter induction culture in a shaker flask will yield ~3 g (wet weight) of cells, 300 mg total protein, and 15 to 60 mg of thioredoxin fusion protein. The final recovered yield will depend on factors such as solubility of the fusion protein and the efficiency of downstream purification procedures.

Time Considerations

From a single colony on a plate, the basic induction protocol requires an overnight growth to prepare a liquid inoculum and a 3.5-hr preinduction growth at 30°C the next day, followed by a 4-hr 37°C induction period. These times are significantly longer if lower induction temperatures are required (see Table

16.8.1). Lysis of a sample in the French pressure cell should require ≤ 5 min, and both the heat-treatment and osmotic-shock procedures require <1 hr each. SDS-PAGE takes 2.5 hr.

EXPRESSION OF PROTEINS IN INSECT CELLS USING BACULOVIRUS VECTORS

Overview of the Baculovirus Expression System

Baculoviruses have emerged as a popular system for overproducing recombinant proteins in eukaryotic cells (Miller et al., 1986; Luckow and Summers, 1988; Miller, 1988; Luckow, 1991). Several factors have contributed to this popularity. First, unlike bacterial expression systems, the baculovirus-based system is a eukaryotic expression system and thus uses many of the protein modification, processing, and transport systems present in higher eukaryotic cells. In addition, the baculovirus expression system uses a helper-independent virus that can be propagated to high titers in insect cells adapted for growth in suspension cultures, making it possible to obtain large amounts of recombinant protein with relative ease. The majority of this overproduced protein remains soluble in insect cells, in contrast to the insoluble proteins often obtained from bacteria. Furthermore, the viral genome is large (~130 kbp) and thus can accommodate large segments of foreign DNA. Finally, baculoviruses are non-infectious to vertebrates, and their promoters have been shown to be inactive in most mammalian cells (Carbonell et al., 1985), which gives them a possible advantage over other systems when expressing oncogenes or potentially toxic proteins.

This unit gives an overview of the baculovirus expression system. A comprehensive guide describing further details can be found in O'Reilly et al. (1992).

BACULOVIRUS LIFE CYCLE

Currently, the most widely used baculovirus expression system utilizes a lytic virus known as *Autographa californica* nuclear polyhedrosis virus (AcMNPV; hereafter called baculovirus). This virus is the prototype of the family *Baculoviridae*. It is a large, enveloped, double-stranded DNA virus that infects arthropods. The baculovirus expression system takes advantage of some unique features of the viral life cycle (Fig. 16.9.1). See Doerfler and Bohm (1986) for a comprehensive review.

As with mammalian DNA viruses, the bacu-

lovirus life cycle is divided temporally into immediate early, early, late, and very late phases. Viruses enter the cell by adsorptive endocytosis and move to the nucleus, where their DNA is released. DNA replication begins ~6 hr after infection and is followed by viral assembly in the nucleus of the infected cell. Two types of viral progeny are produced during the life cycle of the virus: extracellular virus particles (nonoccluded viruses) during the late phase and polyhedra-derived virus particles (occluded viruses) during the very late phase of infection. Extracellular virus is released from the cell by budding, beginning at ~12 hr postinfection, and is produced at a logarithmic rate until 20 hr postinfection, after which production drops off. Polyhedra-derived virus, on the other hand, appears in the nucleus at ~18 hr postinfection and continues to accumulate as late as 72 hr postinfection, or until the cells lyse. Occluded viral particles are embedded in proteinaceous viral occlusions called polyhedra within the nucleus of infected cells. The polyhedrin protein (29 kDa) is the major protein component of the occlusion bodies.

The polyhedrin protein serves an important function for the survival and propagation of the virus in nature. Because baculoviruses are lytic, they quickly kill their insect host after infection. The polyhedrin protein serves to sequester, and thereby protect, hundreds of virus particles from proteolytic inactivation by the decomposing host tissue. The virus is transmitted when occlusion bodies are ingested by a new host as it feeds on a contaminated food source. The polyhedrin protein dissolves in the alkaline environment of the new host's gut and the occluded virus is released. This virus infects the gut epithelial cells and virus replication takes place. Nonoccluded virus is then produced and budded from the infected gut cells. At this point, the virus spreads throughout the tissues of its new host. Although the polyhedrin protein is essential for survival of the virus in nature, it is dispensable for virus survival and propagation in tissue culture cells.

Figure 16.9.1 Baculovirus life cycle. Viruses enter cells by adsorptive endocytosis and move to the nucleus where their DNA is released. Both DNA replication and viral assembly take place in the nuclei of infected cells to generate two types of viral progeny. These include extracellular (nonoccluded) virus particles and polyhedra-derived (occluded) virus particles. Extracellular virus is released from the cell by budding, starting at ~12 hr postinfection and ending ~36 hr postinfection. Polyhedra-derived virus, on the other hand, appears later (~18 hr postinfection) and accumulates in the nuclei of infected cells ≤ 72 hr postinfection or until cellular lysis. Polyhedra-derived virus is embedded in proteinaceous viral occlusions, the major protein component of which is the viral polyhedrin protein. Secondary infection of cells and tissues occurs by two pathways. In the first, the extracellular virus, once budded from the site of primary infection, is free to infect neighboring cells by the pathway just described. Alternatively, polyhedra-derived virus is released from occlusion bodies after an infected food source is ingested by a new host. Reproduced from Summers and Smith (1987) with permission from the Texas Agricultural Experiment Station.

BACULOVIRUS EXPRESSION SYSTEM

The baculovirus expression system takes advantage of several facts about polyhedrin protein: (1) that it is expressed at very high levels in infected cells, constituting more than half of the total cellular protein late in the infectious cycle; (2) that it is nonessential for infection and replication of the virus, meaning that the recombinant virus does not require any helper function; and (3) that viruses lacking the polyhedrin gene have a plaque morphology that is distinct from that of viruses containing the gene. Recombinant baculoviruses are generated by replacing the polyhedrin gene with a foreign gene through homologous recombina-

tion. In this system, the distinctive plaque morphology provides a simple visual screen for identifying the recombinants.

To produce a recombinant virus that expresses the gene of interest, the gene is first cloned into a transfer vector (see discussion below under Choosing a Baculovirus Transfer Vector). Most baculovirus transfer vectors contain the polyhedrin promoter followed by one or more restriction enzyme recognition sites for foreign gene insertion. Once cloned into the transfer vector, the gene is flanked both 5' and 3' by viral-specific sequences. Next, the recombinant vector is transfected along with wild-type viral DNA into insect cells. In a homologous recombination event, the foreign gene is

inserted into the viral genome and the polyhedrin gene is replaced. Thus recombinant viruses lack the polyhedrin gene and in its place contain the inserted gene, whose expression is under the control of the polyhedrin promoter.

Homologous recombination between circular wild-type DNA and the recombinant plasmid DNA occurs at a low frequency (typically 0.1% to 0.5%). This limitation was recently overcome by the development of viruses having *Bsu*36I restriction sites positioned within an essential gene—*Open Reading Frame (ORF) 1629*—which is downstream of the AcMNPV polyhedrin gene—and also in the upstream *ORF 603*—in such a way that digestion releases a fragment containing a sequence necessary for virus growth (Kitts and Possee, 1993). When insect cells are cotransfected with an appropriate recombinant transfer plasmid and linearized *ORF 1629*-deleted baculovirus DNA, the necessary *ORF 1629* is provided by the transfer plasmid through homologous recombination. The vast majority of the progeny viruses, in many cases >99.9%, that are derived from these cotransfections contain the repaired virus with the target gene, thus minimizing the need to screen and plaque-purify recombinants. Several companies (Pharmingen, Invitrogen, Clontech, and Novagen; see APPENDIX 4) market linearized *ORF 1629*-deleted AcMNPV DNA. To further facilitate the identification of recombinants, several of these commercially available baculovirus DNAs contain the bacterial *lacZ* gene, which codes for β -galactosidase in lieu of the AcMNPV polyhedrin gene, thereby allowing *lacZ*-negative recombinants to be distinguished visually from any residual nonrecombinant viruses via a plaque assay. Nonrecombinant viruses form blue plaques on Xgal plates because they contain a functional *lacZ* gene, whereas recombinants form colorless, opaque plaques. Recombinant viruses can also be identified by DNA hybridization and polymerase chain reaction (PCR) amplification.

Another rapid and efficient method for generating recombinant baculoviruses uses site-specific transposition to insert foreign genes by homologous recombination into a bacmid propagated in *E. coli* rather than in insect cells. In this case, recombinant viral DNA is isolated from individual bacterial colonies and is free of any wild-type viral DNA. Upon transfection of insect cells, recombinant virus is generated free of parental nonrecombinant virus, thereby eliminating the need for multiple rounds of plaque purification. This is the basis of the Bac-to-Bac

baculovirus expression system, which is available commercially from Invitrogen.

POSTTRANSLATIONAL MODIFICATION OF PROTEINS IN INSECT CELLS

Because baculoviruses infect invertebrate cells, it is possible that the processing of proteins produced by them is different from the processing of proteins produced by vertebrate cells. Although this seems to be the case for some posttranslational modifications, it is not the case for others. For example, two of the three posttranslational modifications of the tyrosine protein kinase, pp60^{c-src}, that occur in higher eukaryotic cells (myristylation and phosphorylation of serine 17) also take place in insect cells. However, another modification of pp60^{c-src} observed in vertebrate cells, phosphorylation of tyrosine 527, is almost undetectable in insect cells (Piwnicka-Worms et al., 1990).

In addition to myristylation, palmitylation has been shown to take place in insect cells. However, it has not been determined whether all or merely a subfraction of the total recombinant protein contains these modifications. Cleavage of signal sequences, removal of hormonal prosequences, and polyprotein cleavages have also been reported, although cleavage varies in its efficiency. Internal proteolytic cleavages at arginine- or lysine-rich sequences have been reported to be highly inefficient, and alpha-amidation, although it does not occur in cell culture, has been reported in larvae and pupae (Hellers et al., 1991). In most of these cases a cell- or species-specific protease may be necessary for cleavage. Protein targeting seems conserved between insect and vertebrate cells. Thus, proteins can be secreted and localized faithfully to either the nucleus, cytoplasm, or plasma membrane. Although much remains to be learned about the nature of protein glycosylation in insect cells, proteins that are glycosylated in vertebrate cells will also generally be glycosylated in insect cells. However, with few exceptions the N-linked oligosaccharides in insect cell-derived glycoproteins are only high-mannose type and are not processed to complex-type oligosaccharides containing fucose, galactose, and sialic acid. O-linked glycosylations have been even less well characterized in *Sf9* cells, but have been shown to occur. For further information on posttranslational modifications of proteins and protein processing in insect cells, see Davidson et al. (1990), O'Reilly et al. (1992), Jarvis and Sum-

mers (1992), Grabenhorst et al. (1993), James et al. (1995), Jarvis and Finn (1995), Davis and Wood (1995), and Ogonah et al. (1996).

STEPS FOR OVERPRODUCING PROTEINS USING THE BACULOVIRUS SYSTEM

The use of the baculovirus expression system is presented in detail in *UNITS 16.10 & 16.11*. The following steps comprise a brief overview (also see Fig. 16.9.2).

1. Clone the gene of interest into the appropriate baculovirus expression vector and cotransfect with linearized baculoviral DNA (available from various vendors) or use transposition to create recombinant bacmid DNA in *E. coli* (BAC-TO-BAC system; Invitrogen). Alternatively, purify circular wild-type baculovirus DNA (*UNIT 16.10*, Alternate Protocol 1).

2. Cotransfect baculovirus DNA with the recombinant baculovirus plasmid or transfect purified bacmid DNA into *Sf9* insect cells (*UNIT 16.10*, Basic Protocol 2).

3. Collect the medium, which contains the baculoviral particles (*UNIT 16.10*, Basic Protocol 2), and plaque the virus on *Sf9* cells to separate recombinant from nonrecombinant virus (*UNIT 16.10*, Basic Protocol 4). This and subsequent rounds of plaque purification are optional when linearized virus that contains a lethal deletion is used (e.g., BaculoGold from Pharmingen), as in that case >99.9% of all amplified virus particles will be recombinant because of selection pressure. Similarly, when bacmid DNA is used, no purification is required.

4. Amplify the virus stock by infecting fresh insect cells (*UNIT 16.10*, Basic Protocol 3) and determine titer of the amplified virus stock (*UNIT 16.10*, Basic Protocol 4).

5. Express the protein of interest by infecting a new batch of insect cells with the high-titer baculovirus stock (*UNIT 16.11*, Basic Protocol 1). Determine the expression level of the recombinant protein of interest and analyze its biological activity (*UNIT 16.11*, Support Protocols 1 and 2).

CHOOSING A BACULOVIRUS TRANSFER VECTOR

The majority of available baculovirus vectors are pUC-based and confer ampicillin resistance. Most contain the polyhedrin gene promoter and insertion site(s) for cloning a foreign gene of interest, flanked by viral sequences that lie 5' to the promoter and 3' to the foreign gene insert. These flanking sequences facilitate ho-

mologous recombination between the vector and baculovirus DNA. Other baculovirus vectors contain the p10 promoter, another strong, very late promoter, or the basic protein promoter expressed late in the infection process. Some vectors are designed to express more than one heterologous gene or to express genes as fusions to N-terminal signal sequences or leader peptides, which facilitate secretion and purification of the recombinant protein. For more information on these vectors, see Table 16.9.1, O'Reilly et al. (1992), and relevant catalogs from Pharmingen, Clontech, Invitrogen, Novagen, and Stratagene.

A major consideration when choosing the appropriate baculovirus expression vector is whether to express the recombinant protein as a fusion or nonfusion protein in insect cells. Fusion proteins containing a specific tag have the advantage of easy purification and detection. For nonfusion proteins, there are several vectors available—notably pVL1392 and pVL1393 (Pharmingen and Invitrogen)—each of which contains a polylinker in the opposite orientation from the other. These vectors are derived from pAcYM1 (Matsuura et al., 1987) and pAcCL29 (Livingston and Jones, 1989) and differ only in the order of the cloning sites. Other nonfusion vectors include pBacPAK8 and pBacPAK9 (Clontech), pBac-1 (Novagen), pFAST Bac 1 (Invitrogen), and pAcSG2 (Pharmingen). To express the protein as a polyhistidine fusion protein, there are several available vectors: pAcHLT-A, -B, and -C (Pharmingen), pBlueBacHis-A, -B, and -C and pFAST BacHT -A, -B, and -C (Invitrogen), and pBac-2cp (Novagen). These vectors allow easy purification of the recombinant protein using a nickel-chelating resin (*UNIT 10.11B*). To express the protein as a glutathione-S-transferase (GST) fusion protein, the pAcGHLT-A, -B, and -C vectors are commercially available (Pharmingen). These produce an N-terminal GST fusion protein. As with all fusion protein vectors, the gene of interest has to be cloned in the proper reading frame with respect to the tag. Several other affinity tags, such as FLAG, HA, and myc, have also been used successfully for purification using commercially available affinity resins. These tags can be fused to coding sequences using PCR.

Secretion of recombinant proteins into insect cell medium simplifies purification and characterization of expressed recombinant proteins. The ease of purification is further enhanced by the use of serum-free medium. There are several vectors that contain signal se-

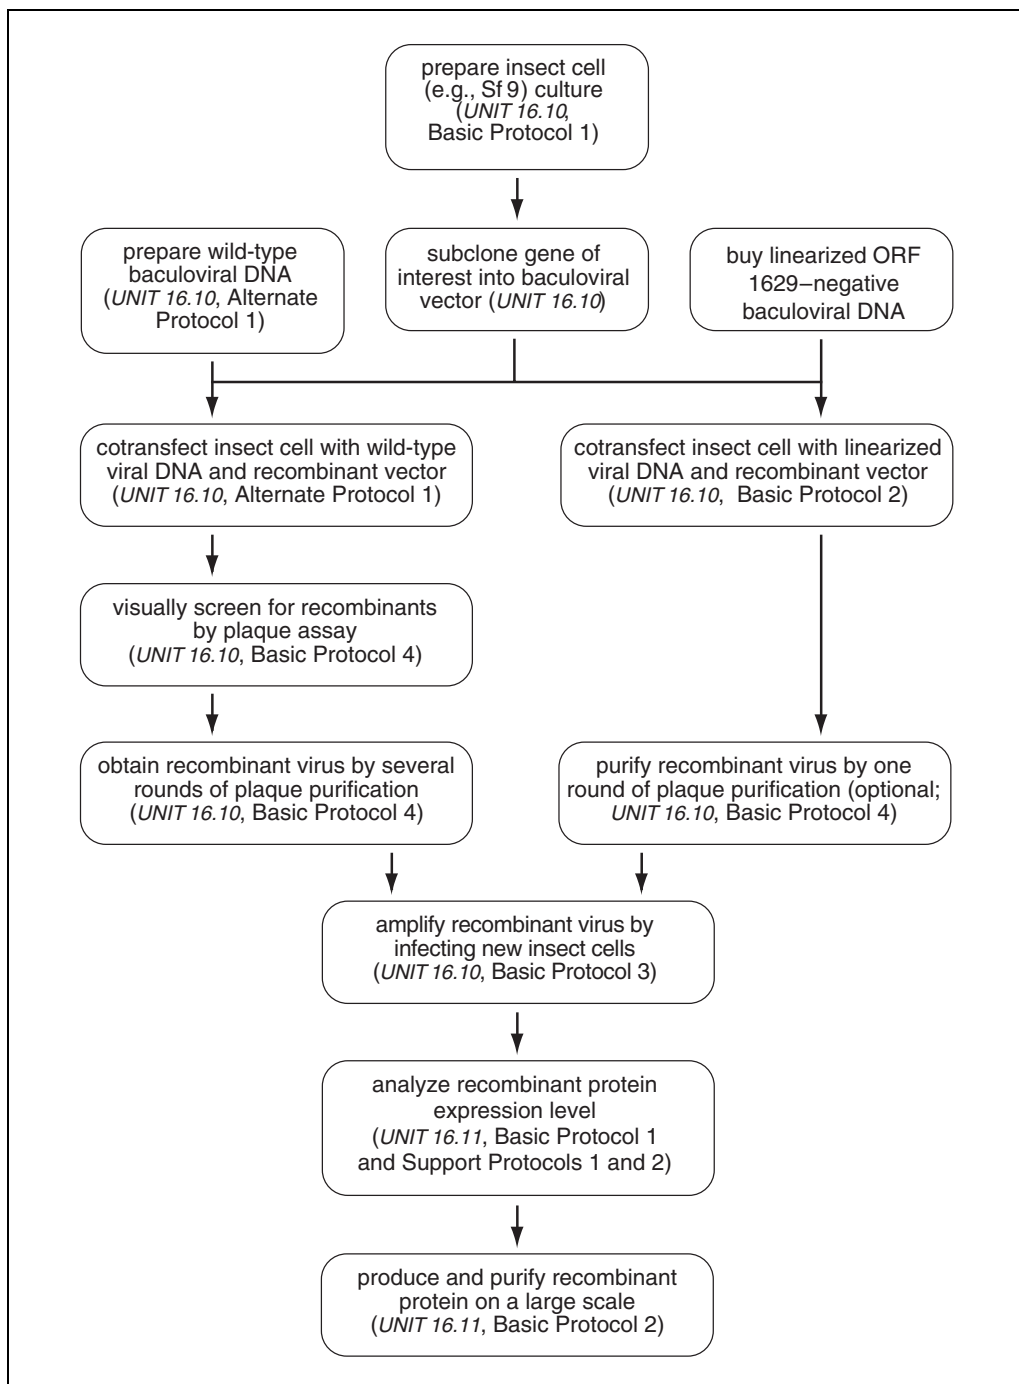

Figure 16.9.2 Flow chart for the expression of proteins in insect cells using the baculovirus system. The flow chart describes the production of recombinants using circular wild-type baculovirus DNA and the more recently developed linearized *ORF 1629*-negative variants. The use of linearized baculovirus DNA, now widely accepted, simplifies the whole protocol and produces viral-infection stocks with little or no background of nonrecombinants, which may be used directly without plaque purification.

quences under strong polyhedrin-promoter control that direct the nascent polypeptide chain toward the secretory pathway of the cell. The sequences to be expressed are inserted downstream with respect to the signal sequences to generate a fusion gene that is transcribed under strong polyhedrin-promoter control. The secretion of biologically active protein from insect cells is the final step in a complex pathway of posttranslational modifications performed in the endoplasmic reticulum (ER) and the Golgi complex (GC). Proteins destined for secretion are first cotranslationally translo-

cated into the lumen of the ER, where initial steps of carbohydrate processing occur. Later, the protein is transported to the GC, where further modifications take place. During translocation, the amino-terminal leader peptide sequence is, in most cases, proteolytically removed. The major determinants for the final form of posttranslational modification of a protein are its primary structure and the conformation presented to successive processive steps. Each secreted protein will present its own characteristics and potential problems for efficient secretion in a biologically active form. In gen-

**Protein
Expression**

16.9.7

eral, the protein produced by baculovirus-infected insect cells carries modifications that are very similar to those of the native protein. With no need for cell lysis, purification of the secreted recombinant proteins is extremely easy. For an example of a recombinant protein expressed and purified in this way, see Murphy et al. (1993). Several vectors have been developed that utilize the gp67 secretory sequence of the baculovirus envelope protein: pAcGP67-A, -B, or -C (Pharmingen) and pBac surf-1 (Novagen). Two additional vectors, pMbac and pPbac (Stratagene), have insertions, respectively, of the melittin and human placental alkaline phosphatase secretory signal sequences. Additionally, these two vectors contain a p10-promoter-driven *lacZ* gene, allowing color selection of recombinants on Xgal plates.

To improve screening of recombinant baculoviruses when using wild-type AcMNPV DNA, pBlueBacIII (Invitrogen), derived from pJVNheI (Vialard et al., 1990), was developed. pBlueBacIII has a multiple cloning site and contains two promoters—the polyhedrin promoter and the early-to-late (ETL) promoter—downstream with respect to which the *lacZ* gene has been inserted. As with the other baculovirus vectors, the gene of interest is cloned downstream of the polyhedrin promoter, which then controls synthesis of the recombinant protein. The recombinant virus is plaqued using agarose overlays containing 150 µg/ml Xgal; the plaques are visualized as described in Basic Protocol 4 of *UNIT 16.10*. Recombinant viruses generate plaques that are blue and lack occlusion bodies.

CHOOSING A BACULOVIRUS DNA

There are several methods for generating recombinant baculovirus. Initially it was required that researchers cotransfect the recombinant transfer vector with wild-type baculovirus DNA, generate a supernatant containing recombinant baculovirus, and screen out the nonrecombinant wild-type virus background through several rounds of plaque purification. This was a time-consuming process requiring technical expertise developed over a long period of time. The development of modified linearized baculovirus DNA allowed the generation of an initial viral stock containing little or no nonrecombinant virus, thus abolishing the need for plaque purification. The principle of this technique lies in the construction of a modified type of baculovirus DNA which, after linearization, contains a lethal deletion and no longer codes for any viable virus.

Cotransfection of the linearized baculoviral DNA with a complementing plasmid construct rescues the lethal deletion of the essential gene—*ORF 1629*—that lies downstream of the AcMNPV polyhedrin gene of the baculovirus DNA (see Fig. 16.9.3). Therefore, the baculovirus transfer vector must be polyhedrin-locus based to rescue this deficiency. This means that the flanking sequences of its promoter region must be derived from the polyhedrin locus of the AcMNPV wild-type virus, otherwise it will not recombine with the polyhedrin locus of linearized *ORF 1629*-deleted baculoviral DNA. Protocols for both methods are covered in *UNIT 16.10*, which also discusses a new baculovirus variant allowing the gene of interest to be cloned directly into the baculovirus genome, thus obviating the need for transfer vectors.

Another method for avoiding the time-consuming purification by plaque assay is the Bacto-Bac system (Invitrogen). The gene of interest is cloned into a donor plasmid, pFastBac1, and transformed into competent *E. coli* cells containing a helper plasmid and a baculovirus shuttle vector (bacmid). pFastBac1 contains Tn7 sites, and is transposed into the bacmid using functions supplied by the helper plasmid in *trans*. The recombinant bacmid is isolated from the competent bacteria by miniprep and transfected into insect cells using a cationic lipid reagent (Cellfectin). Screening for recombinants is done in *E. coli* and can therefore be done much more quickly than via multiple rounds of plaque purification, as is done in generation of recombinant baculovirus using wild-type virus.

REAGENTS, SOLUTIONS, AND EQUIPMENT FOR THE BACULOVIRUS SYSTEM

Reagents and solutions commonly used for expression of proteins using baculovirus vectors are summarized below. See *APPENDIX 4* for supplier contact information.

1. *Suitable insect cell lines.* Sf9 cells are derived from the ovaries of the fall armyworm (*Spodoptera frugiperda*) and are available from American Type Culture Collection, Pharmingen, or Invitrogen. A similar cell line, Sf21, is available from the same vendors. As an alternative to *S. frugiperda* cell lines, the *Trichoplusia ni* High Five line, derived from *T. ni* egg-cell homogenates, is available from Invitrogen. Several proteins have been reported to have significantly higher expression using this *T. ni* cell line. Additionally, High Five cells have a

Figure 16.9.3 Generation and purification of recombinant baculovirus.

rapid doubling time as adherent cultures and adapt quickly to serum-free media.

2. *Fully prepared TNM-FH insect medium.* This will contain trace metals, lactalbumin hydrolysate, yeastolate, 10% fetal bovine serum (FBS), and gentamicin. The medium can be purchased from Pharmingen and several other vendors. It can also be prepared from Grace's insect-cell culture medium (available at 1× and 2× concentration in powdered or liquid form from Invitrogen). For instructions on preparing media from individual components, see O'Reilly et al. (1992). FBS is available from many vendors. Obtain and test different lots of serum from a number of suppliers. The lot that promotes the best growth rate and cell viability should be purchased in bulk. See APPENDIX 3F for additional discussion of FBS. Alternatively, a serum-free insect cell culture medium can be purchased from several vendors (BaculoGold medium from Pharmingen, Sf-900 II from Invitrogen, HYQ-CCM3 and SFX-Insect from Hyclone, or ExCell 401 from JRH Biosciences). These synthetic, low-protein media are recommended for secreted proteins and facilitate subsequent purification.

3. *Incubator at 27°C ± 1°C.* CO₂ is not required and humidification is optional. The Biological Oxygen Demand (B.O.D.) low-temperature incubator (VWR Scientific) or the larger Isotemp (Fisher) are good examples.

4. *Magnetic spinner flasks.* These are available in a variety of sizes from Techne or Bellco.

5. *Stir plate for multiple spinners.* This is available from Techne or Bellco.

6. *SeaKem ME agarose.* (FMC Bioproducts).

7. *60-mm, 100-mm, and 150-mm tissue culture plates.* (Falcon or Corning).

8. *Antibiotics (optional).* Gentamicin (available from numerous vendors) and amphotericin B (Fungizone from Flow Laboratories) are used.

9. *Microscope.* Either an inverted light microscope or a dissecting microscope is required.

10. *Appropriate cloning vectors.* These are available from many vendors (see Table 16.9.1). Several additional vectors, a manual of methods, and wild-type baculovirus DNA are also available upon request from Dr. Max D. Summers, Department of Entomology, Texas Agricultural Experiment Station, Texas A & M University, College Station, Texas 77843 (Phone: 409-845-9730). It is necessary to sign a licensing agreement before the material will be sent. Commercial kits are available from Pharmingen, Invitrogen, Clontech, Novagen and Stratagene.

11. *Linearized ready-to-use baculovirus DNA.* This can be purchased from many of the same vendors.

12. *Shaking incubators (90 to 150 rpm)* can also be used to culture Sf9 cells. In this case, disposable polycarbonate Erlenmeyer flasks (Corning) or Fernbach flasks with screw caps

(Bellco) should be used instead of magnetic spinner flasks.

Maintenance of Insect Cell Cultures and Generation of Recombinant Baculoviruses

UNIT 16.10

This unit describes the maintenance and care of insect cell cultures as well as the generation, purification, and storage of recombinant baculoviruses. Procedures are included for maintenance and subculturing of insect cells (see Basic Protocol 1) and cotransfection of insect cells with linearized baculovirus DNA and recombinant transfer plasmid containing the gene of interest (see Basic Protocol 2). Bacmid DNA may be prepared for this procedure (see Alternate Protocol 1). In the event that the linearized virus is not available, wild-type baculovirus (AcMNPV) DNA may be used to produce recombinant baculoviruses (see Alternate Protocol 2). A procedure is also included for the generation of recombinant baculoviruses using a novel method, direct cloning (see Alternate Protocol 3), which eliminates the need to first clone the gene of interest into a baculoviral transfer vector. Preparation of baculovirus infection stocks from both monolayer and suspension cultures is also described (see Basic Protocol 3). Finally, a protocol is given for a plaque assay to be used for determining the titer of baculoviral stocks as well as for selection of recombinants and plaque purification (see Basic Protocol 4).

NOTE: All reagents and equipment coming into contact with live cells must be sterile and proper sterile technique should be used accordingly.

MAINTENANCE AND CULTURE OF INSECT CELLS

This protocol describes how to maintain and subculture *Spodoptera frugiperda* (*Sf9*) cells in both monolayer and suspension (spinner) cultures, in either serum-containing or serum-free medium. A culture of insect cells is begun using frozen *Sf9* cells. Cultures are maintained by subculturing and their viability is checked periodically. Aliquots of these cultures can be frozen in a liquid nitrogen freezer for long-term storage.

Materials

- TNM-FH insect medium (see recipe) containing 10% fetal bovine serum (FBS), with and without 20% (v/v) DMSO
- Spodoptera frugiperda* (*Sf9*) cells (ATCC #CRL 1711) derived from fall armyworm ovaries (also see UNIT 16.9)
- 70% ethanol
- 0.4% trypan blue stain (Life Technologies)
- Serum-free insect cell culture medium (BaculoGold Protein-Free Insect Medium from Pharmingen; *Sf*-900 II from Life Technologies; HyQ-CCM3 and HyQSFX-Insect from Hyclone; or ExCell 401 from JRH Biosciences)
- 60-mm tissue culture plates or 25-cm² flasks
- 27°C incubator (humidification optional)
- Spinner culture flasks (for suspension cultures) and stir plate for multiple spinner flasks (all available from Techne or Bellco) *or* disposable (plastic) shaker flasks (Corning) and shaking incubator set to 27°C, 90 to 150 rpm
- Beckman GPR centrifuge with GH-3.7 horizontal rotor (or equivalent)
- Screw-top cryostat freezing vials
- Liquid nitrogen freezer
- Additional reagents and equipment for counting cells with a hemacytometer (APPENDIX 3F)

16.10.1

Supplement 65

Begin culture of Sf9 cells

1. Place 3 ml TNM-FH medium containing 10% FBS in a 60-mm tissue culture plate or 25-cm² flask.
2. Thaw a frozen ampule of *Sf9* cells rapidly in a 37°C water bath by moving it back and forth by hand. When ampule contents are almost completely thawed, immerse ampule in 70% ethanol to sterilize the outside.
3. Break the neck of the ampule and transfer contents to 60-mm tissue culture plate or 25-cm² flask from step 1. Rock plate gently by hand to distribute the cells evenly and incubate 2 to 3 hr at 27°C until cells have attached.
4. Remove old medium and replace with 3 ml fresh TNM-FH/10% FBS. Continue incubation, feeding culture every 3 days (by removing old medium and replacing with fresh) until cells reach confluency (form a packed monolayer).

It is important to hold the plates at an angle and remove and add medium at one corner so as not to dislodge the cells from the monolayer.

Maintain and subculture monolayer cultures

5. Remove the old medium from a confluent plate or flask of *Sf9* cells and resuspend cells by gently spritzing them with medium from a pipet.
6. Count the cells using a hemacytometer designed for tissue culture cells (*APPENDIX 3F*).
Each cell in a small square of the hemacytometer is equivalent to 10⁴ cells/ml.
7. Seed 1–2 × 10⁶ cells from step 5 in new 60-mm plates or 25-cm² flasks and rock to evenly distribute the cells (or use a larger plate or flask with more medium if preparing a larger culture of cells). Add fresh TNM-FH/10% FBS to bring the volume to 3 ml.
8. Incubate at 27°C, feeding the culture every 3 days with TNM-FH/10% FBS, until the cells reach confluency.

Maintain and subculture suspension cultures

9. Remove medium and resuspend cells from confluent monolayer culture as described in step 5. Count the cells using a hemacytometer (*APPENDIX 3F*).
- 10a. Seed cells in a spinner culture flask at ~4–5 × 10⁵ cells/ml. Incubate at 27°C with constant stirring on a stir plate set at 60 to 80 rpm. Leave the side-arm caps slightly loosened to ensure adequate aeration.
- 10b. Alternatively, seed cells in a shaker flask and incubate at 27°C in a shaking incubator. When initially adapting cells, shake at 80 to 90 rpm. Increase by 10 rpm each time cells are split until cultures are shaking at 150 rpm.

The volume of cell suspension in the shaker flasks should not exceed 40% of the total capacity.

11. Count cells every 2 to 3 days using a hemacytometer (*APPENDIX 3F*). Subculture when cells reach a concentration of 2–2.5 × 10⁶ cells/ml by transferring the appropriate number of cells to a new flask containing fresh TNM-FH/10% FBS to achieve a final density of 4–5 × 10⁵ cells/ml.

Alternatively, pour out the appropriate volume of cell suspension and replace it with fresh medium.

12. Determine cell viability by adding 0.1 ml of 0.4% trypan blue to 1 ml log-phase cells and examining the cells under a microscope at low power. Count the number of cells that take up trypan blue (dead cells) and count the total number of cells, then calculate the percentages of dead cells and viable cells.

A healthy culture of cells should be >97% viable. To maintain a sufficient transfer of oxygen to the cells in suspension, a minimum ratio of surface area to volume of culture must be maintained (Maiorella et al., 1988). If this value decreases, the cells will not grow exponentially and will stop growing at a lower cell density. This ratio is adequate for a 100-ml culture grown in a 100-ml spinner flask, but decreases when larger spinner flasks are used at maximum volume. Thus, to maintain sufficient oxygen transfer, smaller volumes should be used in the larger flasks unless an outside source of air is introduced into the flask (UNIT 16.11).

Adapt cells to serum-free medium

13. Subculture monolayer cells (from step 5) or suspension cells (from step 11) into medium composed of one part complete TNM-FH/10% FBS and one part serum-free medium (BaculoGold, Sf-900 II, or ExCell 401). Allow cells to grow to confluency (monolayer cultures) or to a density of $2\text{--}3 \times 10^6$ cells/ml (suspension cultures).

Other commercially available serum- or protein-free media besides BaculoGold, Sf-900 II, and ExCell 401 may be used. The final choice of serum-free medium should be based on a comparison of cell growth curves and production of recombinant protein in different media.

14. Repeat the subculture and growth procedure as in step 13 using a medium composed of one part FBS-containing complete medium and three parts serum-free medium.
15. Repeat the subculture and growth procedure as in step 13 using a medium composed of one part FBS-containing complete medium and between 7 and 9 parts serum-free medium.
16. Subculture the cells into serum-free medium.

Cells may adapt slowly to serum-free medium and may require several passages before growth rates and viability return to normal.

Freeze cells

17. Count cells to be frozen from an exponentially growing culture using a hemacytometer (APPENDIX 3F).
18. Centrifuge cells 10 min at $1000 \times g$ (2000 rpm in a GH-3.7 rotor), room temperature, and discard supernatant.
19. Resuspend cell pellet at $1\text{--}2 \times 10^7$ cells/ml in TNM-FH/10% FBS. Add an equal volume of TNM-FH/10% FBS containing 20% DMSO and place cells on ice. Dispense 1-ml aliquots of this cell suspension into screw-top cryostat freezing vials and incubate 1 hr at -20°C , then overnight at -70°C .

Alternatively, cells can be frozen using serum-free medium (with and without DMSO) if the cells have been adapted to serum-free medium as described in steps 13 to 16.

20. Transfer frozen cells to a liquid nitrogen freezer for long-term storage.

COTRANSFECTION OF INSECT CELLS USING LINEARIZED BACULOVIRAL DNA

There are several protocols available for preparing baculoviral supernatant, including transfection with bacmid DNA, transfection with linearized baculoviral DNA, and cotransfection with wild-type baculoviral DNA. Reagents and protocols for these methods are available commercially, and are summarized below. In general, the authors have found that preparation of bacmid DNA is the simplest means of generating baculovirus (Bac-to-Bac system, Invitrogen; see Alternate Protocol 1); however, cotransfection with linearized baculoviral DNA is still also used widely.

**BASIC
PROTOCOL 2**

**Protein
Expression**

16.10.3

One of the most commonly used methods of introducing baculovirus and transfer-plasmid DNA into susceptible insect cells is to coprecipitate the DNA with calcium phosphate and present the mixture to insect cells. For cotransfection, prepare $\geq 10 \mu\text{g}$ of purified plasmid DNA. Care must be taken that the plasmid be as clean as possible. With impure plasmids, cells may lyse shortly after transfection, resulting in a lower viral titer. At ~ 24 hr post-transfection, *Sf9* cell viability should be greater than 97%.

It should be noted that this protocol is optimized for use with Pharmingen linear DNA. Clontech and Invitrogen (see APPENDIX 4) have their own protocols for use with the linear DNA that they offer.

Materials

Spodoptera frugiperda (*Sf9*) cells growing in tissue culture at 50% to 70% confluence *or* growing in suspension culture at $1\text{--}1.5 \times 10^6$ cells/ml (see Basic Protocol 1)

TNM-FH insect medium (see recipe) containing 10% fetal bovine serum (FBS)

Linearized ORF 1629–deleted AcMNPV DNA (e.g., BaculoGold from Pharmingen; see Fig. 16.9.3)

Recombinant baculovirus transfer vector containing gene of interest (UNIT 16.9)

Transfection buffer B (see recipe)

Control transfer vector: pVL1392-Xyle (Pharmingen)

Transfection buffer A (see recipe)

500 mM catechol/50 mM sodium bisulfate

60-mm tissue culture plates

27°C incubator (humidification optional)

Inverted microscope

15-ml conical centrifuge tubes

Beckman GPR centrifuge with GH-3.7 horizontal rotor (or equivalent), 4°C

Additional reagents and equipment for amplification of viral supernatants to produce baculoviral stocks (see Basic Protocol 3) and plaque assay of baculovirus (see Basic Protocol 4)

Prepare cells and DNA

1. In each of three 60-mm tissue culture plates seed 2×10^6 *Sf9* cells in TNM-FH medium containing 10% FBS. Incubate in a 27°C incubator until cells attach.

Cell attachment should be done on a flat and even surface, allowing the cells to attach firmly, which usually takes ~ 5 min. If cells do not attach after that time, either they are not healthy or the wrong plates (e.g., petri dishes that have not been tissue culture treated) have been used.

The quality of the insect cells is very important and only rapidly dividing cells should be used.

2. While cells are attaching, combine in a microcentrifuge tube 0.5 μg linearized ORF 1629–deleted AcMNPV DNA and 2 to 5 μg recombinant baculovirus transfer vector containing the gene of interest. Mix well by gently vortexing or flicking the tube. Let mixture sit 5 min, then add 1 ml transfection buffer B.
3. Prepare positive control by combining, in a microcentrifuge tube, 0.5 μg linearized ORF 1629–deleted AcMNPV DNA and 2 μg pVL1392-Xyle control transfer vector DNA. Mix well by gently vortexing or flicking the tube. Let mixture sit 5 min, then add 1 ml transfection buffer B.

4. Label the first plate (from step 1) as the cotransfection plate. Aspirate old medium and replace with 1 ml transfection buffer A, making sure that the entire surface of the plate is covered to prevent the cells from drying out.
5. Label the second plate (from step 1) as the positive control. Aspirate old medium and replace with 1 ml of transfection buffer A, as in step 4.
6. Label the third plate (from step 1) as negative control. Aspirate old medium and replace with 3 ml fresh TNM-FH/10% FBS, without adding any DNA.

Transfect cells

7. Add 1 ml of the solution prepared in step 2 (containing the vector with the gene of interest) drop-by-drop to the cotransfection plate. After every three to five drops, gently rock the plate back and forth to mix the drops with the medium.

During this procedure, a fine calcium phosphate/DNA precipitate should form. The quality of the precipitate that is optimal for transfection can be assessed visually. It should be of a fine white milky appearance.

8. Add 1 ml of the solution prepared in step 3 (containing the positive control vector) drop-by-drop to the positive control plate, repeating the procedure in step 7.
9. Incubate all three plates 4 hr in a 27°C incubator.

The time of exposure to the calcium precipitate is critical for optimal transfection results. If the incubation time is too long, cell viability will be dramatically reduced. For different cell lines, the optimal incubation time varies. For Sf9 cells, the optimal time is 4 hr.

10. After 4 hr, remove the medium from the cotransfection plate and the positive control plate (but not the negative control plate). Add 3 ml fresh TNM-FH/10% FBS to each plate, rock the plate back and forth several times, then remove all the medium again. Add 3 ml of fresh TNM-FH/10% FBS to each plate and incubate all three plates 4 to 5 days at 27°C.

It is not necessary to change the medium of the negative control plate.

Check for successful transfection

11. After 4 days, check the three plates for signs of infection using an inverted microscope. Compare the negative and positive controls to the cotransfection plate.

Infected cells are much larger than uninfected cells and have enlarged nuclei. Because they stop dividing early in infection, their cell density will be much lower as compared to the uninfected population. Furthermore, infected cells do not attach well to the plate and a high percentage of them will float in the medium. Many of these infection signs may not be visible at this time because the virus titer during the cotransfection is usually low. A further amplification step (see below) may be needed to visualize these changes.

12. After 5 days, collect the supernatants of the cotransfection and positive control plates. Determine viral titer by plaque screening (see Basic Protocol 4).

Alternatively, cotransfection efficiency may be assessed by endpoint dilution assay (see Basic Protocol 4, step 7 annotation).

13. Check the expression of the protein of interest by lysing the transfected cells (for recombinant proteins that are not secreted) or using an aliquot of the supernatant (for recombinant proteins that are secreted), and performing an appropriate assay.

Unless a sensitive assay is available for the protein of interest, expression of the recombinant protein may not be detectable at this stage.

14. Assay for cells expressing the XylE protein in the positive control plate by adding 100 μ l of 500 mM catechol/50 mM sodium bisulfate.

Infected cells expressing XylE protein will turn bright yellow in ~5 min.

15. Transfer the transfection supernatants from each plate to sterile conical 15-ml centrifuge tubes and centrifuge 10 min at $1000 \times g$ (2000 rpm in GH-3.7 rotor), 4°C. Transfer viral supernatant to new sterile tubes and store at 4°C in the dark.

16. Amplify viral supernatant to produce a high-titer virus stock for production of the recombinant protein by infection of insect cells (see Basic Protocol 3).

Alternatively, a single recombinant virus, obtained by plaque purification (see Basic Protocol 4), may be used for virus amplification.

ALTERNATE PROTOCOL 1

GENERATION OF RECOMBINANT BACULOVIRUS BY PREPARATION AND TRANSFECTION OF BACMID DNA USING THE BAC-TO-BAC SYSTEM

The Bac-to-Bac manual from Invitrogen provides detailed protocols for preparation and transfection of bacmid DNA. The following is a brief overview of the protocol starting from the cDNA being cloned into a pFastBac vector. All protocols and reagents are available from Invitrogen (<http://www.invitrogen.com>).

Materials

cDNA of interest (e.g., UNIT 5.5)

Bac-to-Bac Baculovirus Expression System (Invitrogen) including:

pFastBac plasmid vector and control plasmid

DH10Bac competent *E. coli* cells

Bac-to-Bac manual (available online at http://invitrogen.com/content/sfs/manuals/bactobac_man.pdf)

Cellfectin lipid transfection reagent

Selection plates for transposition (see recipe)

Bacmid selection medium (see recipe)

Sf9 cells in serum-free medium

Serum-free medium

27°C incubator

6-well tissue culture plates

Additional reagents and equipment for cloning DNA into plasmids (UNIT 3.16), introduction of plasmid DNA into *E. coli* cells (UNIT 1.8), growing *E. coli* on solid (UNIT 1.3) and in liquid (UNIT 1.2) medium, alkaline lysis miniprep (UNIT 1.6), and preparation of insect cells for transfection (see Basic Protocol 2, steps 1 to 6, in this unit), and amplification of recombinant baculovirus to produce stocks (see Basic Protocol 3 in this unit)

1. Transpose cDNA into bacmid to create recombinant bacmid as follows (also see Bac-to-Bac manual).
 - a. Clone the cDNA of interest into the pFastBac plasmid vector (also see UNIT 3.16).
 - b. Transform plasmid DNA into DH10Bac competent cells (also see UNIT 1.8).

The DH10Bac competent cells carry the bacmid DNA and helper plasmid (encoding proteins required for transposition).
 - c. Incubate 4 hr at 37°C to allow transposition of the gene of interest into the bacmid.

2. Grow colonies (also see *UNIT 1.2*) for 24 hr on selection plates for transposition. Identify recombinant bacmid-containing clones by blue-white selection.

Transposition disrupts the bacmid lacZ α gene, enabling selection via Bluo-Gal, which is included in the selection plates. Also see UNIT 1.4.

3. Pick colonies and culture 24 hr in bacmid selection medium.
4. Prepare bacmid DNA by alkaline lysis miniprep (*UNIT 1.6*).
5. Prepare Sf9 cells (see Basic Protocol 2, steps 1 to 6, in this unit). Use Cellfectin lipid transfection reagent to transfect cells with the bacmid DNA (see Bac-to-Bac manual), then incubate for 3 days at 27°C.
6. Collect transfection supernatant (containing recombinant baculovirus) and amplify to produce baculovirus stock (see Basic Protocol 3).

GENERATION OF RECOMBINANT BACULOVIRUS USING WILD-TYPE BACULOVIRAL DNA

**ALTERNATE
PROTOCOL 2**

As an alternative to linearized ORF 1629–deleted baculoviral DNA, circular wild-type AcMNPV DNA can be used for cotransfection of insect cells with baculoviral transfer plasmids (also see Basic Protocol 2). However, recombination efficiency is dramatically lower (usually around 0.1% to 0.2%) as compared to that obtained with linearized DNA. The technique described here thus requires the identification and purification of recombinants by multiple rounds of plaque assay.

The following protocol describes how to isolate and purify AcMNPV wild-type baculoviral DNA, which can then be used to cotransfect susceptible insect cells (e.g., Sf9) with an appropriate plasmid vector to generate recombinant baculoviruses. The cotransfection of wild-type baculovirus DNA and recombinant transfer plasmid should be performed as described in Basic Protocol 2 (using wild-type baculoviral DNA instead of linearized ORF 1629–negative AcMNPV DNA). To facilitate screening between wild-type and recombinant viral plaques, pBlueBacIII (Invitrogen) or pVL1393-XylE (Pharmingen) can be used as a positive control, making it possible to visualize differences between nonrecombinant wild-type viral plaques and recombinant viral plaques.

Wild-type baculovirus available upon request from Dr. Max D. Summers, Department of Entomology, Texas Agricultural Experiment Station, Texas A & M University, College Station, Texas 77843 (Phone: 409-845-9730).

Additional Materials (also see *Basic Protocol 2*)

- Wild-type baculovirus (Dr. Max D. Summers, see above, or Pharmingen)
- Sucrose cushion solution (see recipe)
- 0.1 \times and 1 \times TE buffer, pH 7.4 (*APPENDIX 2*)
- 25% and 56% (w/v) sucrose (ultrapure) in 0.1 \times TE buffer (filter sterilize and store up to 1 month at 4°C)
- Extraction buffer (see recipe)
- 10 mg/ml proteinase K (prepare fresh)
- 10% *N*-lauroylsarcosine (sodium salt; filter sterilize and store up to 1 year at 4°C)
- 25:24:1 phenol/chloroform/isoamyl alcohol (*UNIT 2.1*)
- 100% (ice-cold) and 70% (room temperature) ethanol
- 3 M sodium acetate, pH 5.2 (*APPENDIX 2*)

**Protein
Expression**

16.10.7

150-mm tissue culture dishes
50-ml conical centrifuge tubes
Beckman GPR centrifuge with GH-3.7 horizontal rotor (or equivalent), 4°C
Beckman ultracentrifuge with SW-27 or SW-28 rotor *and* SW-41 rotor (or other ultracentrifuge with equivalent rotors), 4°C, and appropriate tubes
Sucrose gradient maker
15-ml polypropylene centrifuge tubes
50°C water bath
5- or 10-ml wide-mouth pipets

Additional reagents and equipment for phenol/chloroform extraction and ethanol precipitation of DNA (*UNIT 2.1*) and quantitating DNA by absorbance spectrometry (*APPENDIX 3D*)

Prepare viral supernatant and collect virus

1. Seed at least ten 150-mm plates with 2.0×10^7 Sf9 cells/plate in 30 ml TNM-FH medium containing 10% FBS. Incubate 1 hr at 27°C to allow the cells to attach firmly, then infect them with AcMNPV wild-type virus at a multiplicity of infection (MOI) of 0.1. Incubate 3 to 5 days at 27°C, examining plates periodically with an inverted microscope for the presence of occlusion bodies.

Dr. Max D. Summers provides a manual with his materials that includes details for these procedures. Pharmingen provides similar documentation with its wild-type baculovirus. Also see O'Reilly et al. (1992).

MOI is equal to plaque-forming units (pfu; see Basic Protocol 4) divided by the number of cells (pfu/cell). If the supplier of the virus does not provide adequate information regarding pfu, this can be determined by plaque assay (see Basic Protocol 4).

Occlusion bodies are highly refractile, giving them a yellowish-green crystalline appearance that is readily detected under a light microscope.

2. When occlusion bodies are observed in most cells, pool the viral supernatant (~30 ml per plate) in six 50-ml conical tubes. Centrifuge 10 min at $1000 \times g$ (2000 rpm in GH-3.7), 4°C, then pour viral supernatant into six new tubes. Repeat centrifugation to completely remove any remaining cells.

Sterile technique is not required in this step nor for any of the remaining steps of this protocol.

3. Place 6 to 35 ml of viral supernatant in each of an appropriate number of ultracentrifuge tubes for the SW-27 or SW-28 rotor and balance the tubes. Underlay with 3 ml sucrose cushion solution. Precool the ultracentrifuge and rotor to 4°C.

The amount of sucrose cushion may have to be increased for larger volumes of viral supernatant.

4. Centrifuge 60 min at $100,000 \times g$ (24,000 rpm in an SW-27 or -28 rotor), 4°C, to pellet the virus. Pour off supernatants and invert tubes on a Kimwipe to drain as much liquid as possible.

Separate virus from cellular contaminants (if necessary)

5. Examine the viral pellets carefully. If the viral pellet is pure (i.e., has a light bluish appearance), proceed to DNA isolation (step 11). If the pellet appears yellowish, separate the virus from cellular contaminants by steps 6a to 10a or 6b to 10b.

To purify viral pellet by sucrose-gradient fractionation

- 6a. Add 2 ml of $0.1 \times$ TE buffer to one of the viral pellets and repeatedly pipet up and down with a Pasteur pipet to resuspend. Transfer the buffer with the resuspended virus to a second tube containing a pellet and repeat the resuspension, then repeat in turn for each pellet until all pellets are pooled in the same 2 ml.

If pellet is difficult to resuspend, incubate preparation overnight at 4°C.

- 7a. Place 25% and 56% sucrose solutions in $0.1 \times$ TE buffer in the reservoirs of a gradient maker and prepare two linear 25% to 56% sucrose gradients in SW-41 ultracentrifuge tubes.

If a gradient maker is unavailable, simply layer the 25% sucrose carefully atop the 56% sucrose to form a step gradient. Some investigators report that a step gradient gives a sharper band.

- 8a. Carefully layer 1 ml of the pooled viral suspension on top of each sucrose gradient. Centrifuge 90 min at $100,000 \times g$ (28,000 rpm in an SW-41 rotor), 4°C.

After centrifugation, virus should be visible as a broad bluish-white band inside the gradient.

- 9a. Using a Pasteur pipet, transfer the viral bands to a new SW-41 ultracentrifuge tube. Add enough $0.1 \times$ TE buffer to fill the tube (~35 ml), then centrifuge 30 min at $100,000 \times g$ (28,000 rpm in an SW-41 rotor), 4°C, to pellet the virus. Decant supernatant and invert tube on a Kimwipe to drain as much liquid as possible.

- 10a. Resuspend the virus pellet in 9 ml extraction buffer and transfer 4.5-ml aliquots to two 15-ml polypropylene centrifuge tubes. Proceed to step 11.

To purify viral pellet by microcentrifugation

- 6b. Add 3 ml extraction buffer to one of the viral pellets and repeatedly pipet up and down with a Pasteur pipet to resuspend. Transfer the buffer with the resuspended virus to a second tube containing a pellet and repeat the suspension, then repeat in turn for each pellet until all pellets are pooled in the same 3 ml.

If pellet is difficult to resuspend, incubate preparation overnight at 4°C.

- 7b. Transfer 1.5 ml viral suspension into each of two 1.5-ml microcentrifuge tubes. Microcentrifuge 5 min at maximum speed and pool supernatants in one 15-ml polypropylene centrifuge tube.

- 8b. Resuspend each pellet in 1 ml extraction buffer.

- 9b. Microcentrifuge the pellets 5 min at maximum speed and combine the two supernatants with the pooled supernatants in the 15-ml tube.

- 10b. Bring volume in the 15-ml tube to 9 ml with extraction buffer and transfer 4.5-ml aliquots to two new 15-ml polypropylene centrifuge tubes. Proceed to step 11.

Isolate DNA from purified virions

11. Add 200 μ l of 10 mg/ml proteinase K to each tube and incubate 1 to 2 hr at 50°C.
12. Add 0.5 ml of 10% N-lauroylsarcosine to each tube and incubate 2 hr or overnight at 50°C.
13. Extract DNA twice with an equal volume of 25:24:1 phenol/chloroform/isoamyl alcohol (see UNIT 2.1 for additional details on extraction of DNA).

Extreme care should be taken to be as gentle as possible to avoid shearing the DNA at this point. Use a wide-bore Pasteur pipet and mix DNA solutions by inverting the tubes rather than by vortexing.

14. Transfer the aqueous phase containing the DNA to another 15-ml tube using a wide-mouth 5- to 10-ml pipet. Add 10 ml of ice-cold 100% ethanol to each tube and mix gently by inverting the tubes several times. Incubate 10 min at -80°C (see *UNIT 2.1* for additional details on ethanol precipitation of DNA).
15. Centrifuge 20 min at $1500 \times g$ (2500 rpm in GH-3.7 rotor), 4°C , and discard supernatant. Rinse the DNA pellet with 70% ethanol and air dry pellet for 30 to 60 min. Resuspend pellet in 800 μl of $1\times$ TE buffer.
16. Transfer 400 μl of the resuspended DNA to each of two microcentrifuge tubes and reprecipitate the DNA by adding 40 μl of 3 M sodium acetate and 2 vol of ice-cold 100% ethanol to each tube. Incubate 10 min at -80°C .
17. Microcentrifuge 10 min and discard supernatant. Rinse DNA pellet with 70% ethanol and air dry pellet. Resuspend DNA in 0.3 to 1.0 ml of $1\times$ TE buffer.
18. Quantitate DNA by measuring A_{260} (*APPENDIX 3D*) and calculate yield. Store the circular wild-type baculoviral DNA at 4°C (stable for several months).

This method should yield 50 to 100 μg viral DNA per ten 150-mm dishes. If difficulty is encountered resuspending the DNA, heat mixture for ~ 15 min at 65°C .

19. Cotransfect Sf9 cells with the circular wild-type baculoviral DNA and a baculoviral transfer plasmid containing a gene of interest as in Basic Protocol 2, substituting the wild-type DNA for the linearized ORF 1629–deleted DNA in step 2 of that protocol.

Recombination efficiency is dramatically lower with wild-type DNA as compared to that obtained with linearized DNA. The technique described here thus requires the identification and purification of recombinants by multiple rounds of plaque assay (see Basic Protocol 4).

ALTERNATE PROTOCOL 3

GENERATION OF RECOMBINANT BACULOVIRUSES BY DIRECT CLONING

This protocol describes the generation of recombinant virus by direct cloning methods (see Fig. 16.10.1), which may be applicable to the production of high-diversity expression libraries in baculovirus. Two modified AcMNPV baculoviruses—vEHuni and vECuni—have been constructed that have two *Bsu36I* sites downstream, respectively, of the *hsp70* promoter and the synthetic promoter *PcapminXIV* (Lu and Miller, 1996). Cleavage of the *Bsu36I* sites produces overhanging TTA ends, which are filled in by incubation with the Klenow fragment of DNA polymerase I in presence of dTTP, thus leaving a TT overhang. Ready-to-use vEHuni and vECuni baculoviral DNA can be purchased from Pharmingen. The gene to be cloned must be flanked by *EcoRI* sites and the *EcoRI* ends produced by cleavage at these sites have to be partially filled in with Klenow fragment in the presence of dATP to leave AA overhangs. The gene can then be cloned directly into the vEHuni or vECuni genome.

Additional Materials (also see Basic Protocol 2)

- Purified vector containing gene of interest, flanked by *EcoRI* sites
- Klenow fragment of DNA polymerase I (*UNIT 3.5*)
- Reaction buffer for Klenow fragment (see recipe)
- 25:24:1 phenol/chloroform/isoamyl alcohol (*UNIT 2.1*)
- $1\times$ TE buffer (*APPENDIX 2*)
- vEHuni or vECuni (Pharmingen), linearized, partially filled in by Klenow fragment treatment, and containing TTA ends
- T4 DNA ligase (*UNIT 3.14*)
- 15°C water bath

Additional reagents and equipment for agarose gel electrophoresis (*UNIT 2.5A*) and phenol/chloroform extraction and ethanol precipitation of DNA (*UNIT 2.1*)

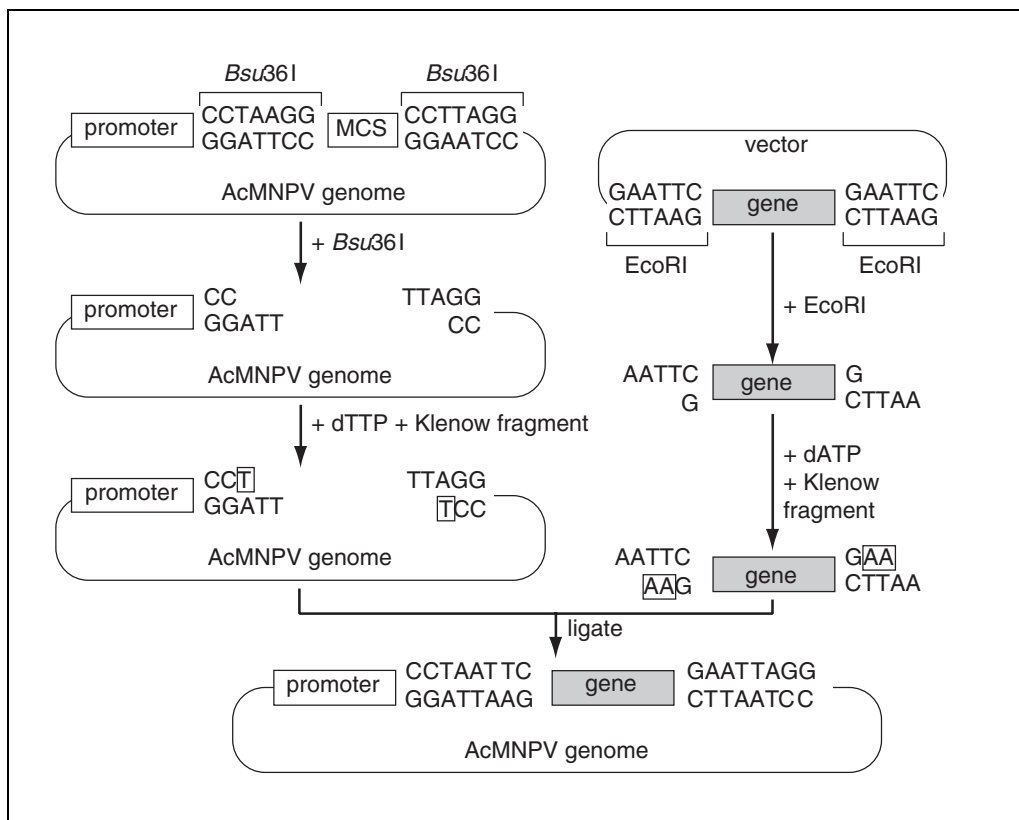

Figure 16.10.1 Direct cloning of a gene of interest into baculovirus DNA. At the left is a diagram representing an AcMNPV recombinant containing two different *Bsu361* sites. Digestion of this viral DNA with *Bsu361* followed by a partial fill-in reaction with dTTP and Klenow fragment of DNA polymerase I generates a linear viral DNA with TT overhanging ends. At the right, a foreign gene with flanking *EcoRI* sites is digested with *EcoRI* to generate overhanging ends, which are then partially filled in using dATP. The resulting AA overhanging ends are then compatible with the TT overhanging ends of the viral DNA. The viral DNA and foreign gene DNAs are then combined, ligated, and transfected into insect cells.

1. Digest vector containing gene of interest with *EcoRI* in a total volume of 50 μ l for 16 hr at 37°C and isolate gene of interest that contains flanking *EcoRI* sites by agarose gel electrophoresis (UNIT 2.5A).

If gene of interest does not contain flanking EcoRI sites, a polymerase chain reaction with specific primers containing EcoRI sites can be used to insert flanking EcoRI sites. Alternatively, EcoRI linkers can be ligated to the purified gene.

2. In a total volume of 50 μ l, incubate up to 5 μ g of *EcoRI*-digested and purified gene of interest with 5 U Klenow fragment in reaction buffer for Klenow fragment for 20 min at 37°C.
3. Extract reaction mix with 1 vol of 25:24:1 phenol/chloroform/isoamyl alcohol, then ethanol precipitate DNA and resuspend in 10 μ l of 1 \times TE buffer (UNIT 2.1).
4. In a total volume of 50 μ l, mix 0.5 μ g vEHuni or vECuni DNA with 0.1 to 1 μ g of the treated gene fragment from step 3 (to obtain an ~1:60 molar ratio of baculoviral DNA to gene fragment), and add 2 U T4 DNA ligase. Incubate overnight at 15°C.

The ligated AcNPV DNA is now ready to be transfected into susceptible insect cells.

5. Transfect the entire ligation mixture from step 4 into 2×10^6 *Sf9* cells as described in Basic Protocol 2.

The ligation mixture from this protocol replaces the reaction mixture composed of ORF 1629–deleted AcMNPV DNA and recombinant baculovirus transfer vector used in step 2 of Basic Protocol 2. As in Basic Protocol 2, use pVLI392-XylE as a control.

To purify recombinant plaques obtained by direct cloning, see Basic Protocol 4.

PREPARATION OF BACULOVIRUS STOCKS

This protocol describes how to prepare a large-scale stock of wild-type or recombinant AcMNPV virus from either monolayer or suspension culture. Growing insect cells (*Sf9*) are infected with virus at a low MOI (<1.0). A viral stock is obtained by harvesting the culture supernatant when the majority of cells show cytopathic effects (~4 to 5 days postinfection). Viral stocks can be stored at 4°C, but must be shielded from light to maintain the viral titer. Liquid nitrogen freezing is recommended for long-term storage. Plaque assay should be used to determine the titer of viral stocks.

Materials

Sf9 cells in monolayer culture (see Basic Protocol 1, step 5) or suspension culture (see Basic Protocol 1, step 11)

TNM-FH insect medium (see recipe) containing 10% fetal bovine serum (FBS)

Baculoviral inoculum, wild-type (*UNIT 16.9*) or recombinant (e.g., supernatant from cotransfected *Sf9* cells; see Basic Protocol 2), pfu determined by plaque assay (see Basic Protocol 4)

150-mm tissue culture dishes

27°C incubator (humidification optional)

Inverted microscope

Beckman GPR centrifuge with GH-3.7 horizontal rotor (or equivalent), 4°C

Screw-top cryostat freezing vials

Liquid nitrogen freezer

Spinner culture flasks (for suspension cultures) and stir plate for multiple spinner flasks (all available from Techne or Bellco) *or* disposable (plastic) shaker flasks (Corning) and shaking incubator set to 27°C, 90 to 150 rpm

To amplify virus from monolayer cultures

- 1a. Seed two 150-mm plates with 1.8×10^7 *Sf9* cells/dish maintained in TNM-FH medium containing 10% FBS. Incubate 1 hr in a 27°C incubator to allow cells to attach.
- 2a. While cells are attaching, add the viral inoculum to 30 ml of fresh TNM-FH/10% FBS in sufficient quantity to achieve an MOI of 0.1 to 1. When cells have attached, remove the medium from the plates and add 15 ml of this virus-containing medium to each plate.

MOI is defined as pfu/cell. The volume of viral inoculum needed to infect a given number of cells equals $MOI \times (\text{number of cells/titer of viral stock in pfu/ml})$.

- 3a. Incubate cells with virus-containing medium for several days at 27°C. Examine the cells daily under an inverted microscope for signs of infection—i.e., cytopathic effects (if occlusion body–negative recombinant viruses are used) or occlusion bodies (if wild-type baculovirus or occlusion body–positive recombinant viruses are used).

Occlusion bodies are highly refractile, giving them a yellowish-green crystalline appearance that is readily detected under a light microscope.

- 4a. When the majority of cells show cytopathic effects or occlusion bodies (usually 4 to 5 days postinfection) transfer the cells to sterile tubes, centrifuge 10 min at $1000 \times g$ (2000 rpm in a GH-3.7 rotor), 4°C , and transfer supernatant to new, sterile tubes. Dispense several 1-ml aliquots into screw-top cryostat freezing vials and freeze them in a liquid nitrogen freezer for long-term storage. Keep the remaining stock at 4°C in the dark for short-term storage.

This protocol should result in ~40 ml of a virus stock at 1×10^8 to 3×10^8 pfu/ml.

If the virus to be amplified is a single plaque isolate (see Basic Protocol 4), place the agarose plug in a microcentrifuge tube containing 0.5 ml TNM-FH/10%FBS and rotate the tube overnight at 4°C . Infect fresh Sf9 cells as in step 1a using 2×10^6 cells in a 100-mm flask and incubate 1 hr at 27°C . Add 8 ml of TNM-FH/10% FBS medium and incubate them for 4 days at 27°C . Harvest the virus as in step 4a. Determine the viral titer by plaque assay (see Basic Protocol 4) and amplify the virus by repeating steps 1a to 3a to obtain a high-titer stock. Virus stocks can also be prepared in serum-free insect cell culture medium if the cells have been adapted to serum-free medium (see Basic Protocol 1). Follow steps 1a to 4a but use serum-free culture medium instead of TNM-FH/10% FBS medium.

To amplify virus from suspension cultures

- 1b. Grow Sf9 cells in a 500-ml spinner culture bottle or a 250-ml shaker flask with 50 ml TNM-FH/10% FBS to a density of $\sim 1 \times 10^6$ cells/ml (see Basic Protocol 1).

Sf21 cells (see UNIT 16.9) may be used instead of Sf9 cells. They are grown in the same way as Sf9 cells.

- 2b. Centrifuge cells 10 min at $1000 \times g$, room temperature, and discard supernatant. Resuspend cell pellet in 10 to 20 ml fresh TNM-FH/10% FBS. Add viral inoculum at an MOI of 0.1 to 0.5.

See annotation to step 2a regarding how to calculate the volume of viral inoculum needed.

- 3b. Add cells back to spinner flask and bring volume to 100 ml with TNM-FH/10% FBS. Incubate 3 to 4 days at 27°C with constant stirring on a stir plate set at 60 to 80 rpm. Leave the side-arm caps slightly loosened to ensure adequate aeration. Periodically remove aliquots of the suspension and examine microscopically for cytopathic effects and occlusion bodies.

- 4b. When the majority of cells show cytopathic effects or occlusion bodies (usually 4 to 5 days postinfection) transfer the cells to sterile tubes, centrifuge 10 min at $1000 \times g$, 4°C , and transfer supernatant to new sterile tubes. Dispense several 1-ml aliquots into screw-top cryostat freezing vials and freeze them in a liquid nitrogen freezer for long-term storage. Keep the remaining stock at 4°C in the dark for short-term storage.

Virus stocks can also be prepared in suspension by growing insect cells (Sf9, Sf21, and High Five) in serum-free or protein-free insect cell culture medium in either a 100-ml spinner flask or a 500-ml spinner flask filled only to 250 ml until the cell density is $1\text{--}2 \times 10^6$ cells/ml. Virus should be added at an MOI of 0.1 to 0.5 directly to the suspension culture, the cells incubated 4 to 5 days, and the virus harvested as in step 4b.

TITERING BACULOVIRUS STOCKS USING PLAQUE ASSAY

This protocol describes how to titer viral stocks using the plaque-assay procedure. When preparing new viral stocks or when carrying out infections for protein production and protein analyses, it is important to know the titer of a viral stock, which is expressed in plaque-forming units per milliliter (pfu/ml). In this procedure, serial dilutions of viral stock are used to infect exponentially growing Sf9 cells. After removing the viral supernatant, the cells are covered with an agarose overlay and incubated 6 to 10 days. Plaques are counted visually to determine the viral titer. To become familiar with the morphological differences between plaques produced by wild-type virus versus those

BASIC PROTOCOL 4

Protein Expression

16.10.13

produced by recombinant virus, it is helpful to first practice plaquing β -Gal recombinant virus alongside wild-type virus (in a manner analogous to that used with plaque purification of bacteriophage; *UNIT 1.11*). This greatly facilitates screening of recombinant viruses encoding the gene of interest. It is possible to distinguish a wild-type plaque from a recombinant plaque by holding the plate overhead and looking at the bottom of the plate directly. Regions surrounding wild-type plaques will look grayish-white, whereas recombinant plaques will not. After identifying putative recombinant viral plaques by one of these methods, pick several plaques and place the agarose plugs in 1-ml serum-free medium. Vortex and store up to several months at 4°C until needed.

As a simple and rapid alternative to plaque assays, commercially available titer kits that use antibodies to viral proteins can be used (e.g., BacPAK viral titer kit, BD Biosciences).

Materials

Exponentially growing *Sf9* cells (see Basic Protocol 1) in monolayer culture
TNM-FH insect cell medium (see recipe) with and without 10% fetal bovine serum (FBS)

Baculoviral stock

Agarose overlay (prepare 30 min before use in step 5; see recipe)

Trypan blue overlay (optional; see recipe)

60-mm tissue culture plates

27°C incubator (humidification optional)

1.5-ml screw-top cryostat tube

1. Dilute a culture of exponentially growing *Sf9* cells to $\sim 5 \times 10^5$ cells/ml in TNM-FH medium containing 10% FBS. Seed cells onto 60-mm tissue culture plates at two different densities— 2×10^6 and 1.5×10^6 cells/plate—several hours before plaquing. Set up duplicate plates for each dilution of viral stock. Incubate in 27°C incubator.

Duplicates of each dilution are required because of the variability encountered using plaque assays. Thus, there will be four plates for each dilution: two with 2×10^6 cells and two with 1.5×10^6 cells. Generally, a total of three viral dilutions are plaqued, necessitating a total of twelve dishes for each stock being titered (six with 2×10^6 cells and six with 1.5×10^6 cells).

The density of the cell monolayer is critical to the success of the plaque assay. If the plaques are too small after 5 days, the initial cell density was too high. If the plaques are large and diffuse, the initial cell density was too low. Use a series of cell densities to find the optimal plaquing cell density for the particular cell line being used.

2. When ready to plaque, make 5-ml serial dilutions of the baculoviral stocks in TNM-FH medium/10% FBS as follows, depending on the nature of the viral stock:

high-titer viral stock— 10^{-6} , 10^{-7} , and 10^{-8} dilutions

transfection supernatant from circular AcMNPV DNA— 10^{-4} , 10^{-5} , and 10^{-6} dilutions

transfection supernatant from linear AcMNPV DNA— 10^{-1} and 10^{-2} dilutions

single plaque pick-ups— 10^{-1} , 10^{-2} , and 10^{-3} dilutions.

Making serial dilutions is analogous to titering phage stocks (see UNIT 1.11).

3. Remove medium from cells (from step 1) with a sterile pipet. Add 1 ml of each viral dilution to duplicate plates and incubate 1 hr at 27°C. Rock the plates when adding the virus inoculum to ensure even infection of the cells.

It is important to hold the plates at an angle and remove and add medium at one corner so not to dislodge the cells from the monolayer.

4. After 1 hr incubation, prepare the agarose overlay.

The agarose overlay keeps the virus released from the infected cells from diffusing far from the site where the initial infection took place. Thus, only cells immediately neighboring the cell of primary infection are subsequently infected by progeny virus. When enough cells in the immediate vicinity of the primary infection are lysed, a plaque (or hole in the cell monolayer) results.

5. Remove the viral supernatant from the cells with a sterile pipet and add 4 ml agarose overlay. Allow the agarose to harden on the plates for 10 to 20 min at room temperature (to allow condensation to escape). Wrap the plates individually with Parafilm (to avoid desiccation) and incubate 6 to 8 days at 27°C.

If the recombinant virus contains a lacZ gene—e.g., as in recombinants derived from pBlueBacIII (Invitrogen) or pAC360 β-Gal (available from Dr. Max Summers; see Alternate Protocol 2)—150 μg/ml of Xgal (from 20 mg/ml stock prepared in sterile dimethylformamide; stable for several months at –20°C) should be added to the agarose before it hardens. Recombinant plaques will then develop a bright blue color and will be easily distinguished from nonrecombinants.

If a humidified 27°C incubator is used, it is not necessary to wrap the plates with Parafilm.

If plaques are not clearly visible after 1 week, the plates can be incubated longer, because plaques continue to form for up to 2 weeks. If no plaques are visible after 2 weeks, the cells were probably plated at too high a density and should be replated at a lower density (between 1×10^6 and 1.3×10^6 cells/plate).

6. On plates containing plaques that are well formed and easily visualized, count the number of plaques at each dilution within a set. Calculate the viral titer (pfu/ml).

Ten plaques at a 10^{-7} dilution or one plaque at a 10^{-8} dilution gives a titer of 10^8 pfu/ml.

7. If difficulties are encountered visualizing plaques, stain with trypan blue as follows. Prepare the trypan blue overlay and dispense 1 ml on plates that have been incubated for 6 to 8 days so that plaques are well formed. Incubate the plates overnight at 27°C to allow the dye to diffuse into the dead cells. Count the number of blue plaques and determine the viral titer.

The dead cells within a plaque will take up the trypan blue dye but the surrounding live cells will exclude the dye.

Another procedure for determining virus titer is by endpoint dilution (O'Reilly et al., 1992). In this method, a series of viral dilutions are made and used to infect cells in microtiter wells. Each well is then scored for the presence or absence of viral infection and a 50% endpoint is determined. However, results from this method are often more difficult to interpret than plaque assays when titrating recombinant virus stocks. Wild-type virus is very easy to score because of the accumulation of occlusion bodies, but recombinant-virus infection can sometimes be difficult to score because of the lack of occlusion bodies.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Agarose overlay

- 40 ml 2× Grace's insect medium, supplemented (Life Technologies)
- 10 ml fetal bovine serum (FBS), heat-inactivated 30 min at 56°C
- 0.25 ml 10 mg/ml gentamicin (Life Technologies; optional)
- 50 ml 1% (w/v) agarose stock (sterile; see recipe)

continued

**Protein
Expression**

16.10.15

Mix the first three ingredients together, filter sterilize, and equilibrate to 42°C. Microwave the 1% agarose ~2 min until liquid and equilibrate to 42°C. Mix the two solutions just prior to the end of the 1-hr viral incubation (see Basic Protocol 4, step 3). Use immediately (this solution cannot be stored).

This is enough for 24 60-mm tissue culture dishes, using 4 ml/plate. The optimal temperature for equilibration is 42°C. If the overlay is too hot, the cells will lyse; if it is too cool the agarose will solidify into clumps, making visual screening difficult.

Agarose stock, 1% (w/v)

Place 0.5 g SeaKem agarose (FMC Bioproducts) into each of ten 100-ml Wheaton bottles. Add 50 ml distilled water to each bottle, close loosely, and autoclave 20 min. When the solutions have cooled, tighten lids. Store indefinitely at room temperature.

SeaKem agarose is recommended over SeaPlaque agarose for plaque assays because it can be used at a lower concentration. High concentrations of agarose tend to obscure the plaques or even kill the underlying insect cells.

Bacmid selection medium

LB medium (UNIT 1.1) containing:

50 µg/ml kanamycin

7 µg/ml gentamicin

5 µg/ml tetracycline

Extraction buffer

100 mM Tris·Cl, pH 7.5 (APPENDIX 2)

90 mM EDTA

200 mM KCl

Filter sterilize and store up to 1 year at 4°C

Reaction buffer for Klenow fragment

10 mM Tris·Cl, pH 7.5 (APPENDIX 2)

10 mM MgCl₂

10 mM dATP

Store up to 2 years at -20 °C

Selection plates for transposition

LB plates (UNIT 1.1) containing:

50 µg/ml kanamycin

7 µg/ml gentamicin

10 µg/ml tetracycline

100 µg/ml Bluo-Gal (Invitrogen)

40 µg/ml IPTG

Sucrose cushion solution

25% (w/v) sucrose

5 mM NaCl

10 mM EDTA

Store up to 1 month at 4°C

TNM-FH medium

To 500 ml 1× Grace's insect medium supplemented with yeastolate and lactalbumin hydrolysate (Life Technologies), add 5 ml 10 mg/ml gentamicin (optional), and 50 ml heat-inactivated fetal bovine serum (FBS; 10% final; see below). Filter sterilize. Incubate a 5-ml sample 2 days at 37°C to check sterility; store remainder at 4°C until manufacturer's expiration date.

continued

For medium with 20% DMSO, add sterilized (autoclaved) DMSO to 20% (v/v).

TNM-FH medium with and without FBS is needed for the protocols throughout this unit. TNM-FH medium including FBS and antibiotics can be obtained from several vendors (e.g., Pharmingen).

To heat-inactivate FBS, incubate 30 min at 56°C and store in 50-ml aliquots at -20°C (stable ≥1 year).

Transfection buffer A

To unsupplemented 1× Grace's insect medium (Life Technologies) add fetal bovine serum (FBS) to 10% and filter sterilize. Prepare fresh for each transfection and store in 10-ml aliquots.

Transfection buffer A is also sold by Pharmingen.

Transfection buffer B

25 mM HEPES, pH 7.1

125 mM CaCl₂

140 mM NaCl

Filter sterilize and store in 10-ml aliquots up to 6 months at 4°C

Transfection buffer B is also sold by Pharmingen.

Trypan blue overlay

Prepare a 1% (w/v) trypan blue solution in distilled water and filter sterilize. Microwave 1% agarose (see recipe) 2 min until liquid and equilibrate solution to 42°C. In parallel, equilibrate the 1% trypan blue solution to 42°C. Add 4 ml of the trypan blue solution to 50 ml of 1% agarose and mix well. Use immediately (this solution cannot be stored).

COMMENTARY

Background Information

Although recent research has provided more knowledge of the molecular biology of protein expression in insect cells using the baculovirus system, the ability of a given recombinant virus to produce large quantities of foreign proteins must still be determined empirically. Levels of expression have been reported to vary from 1 to 500 mg of recombinant protein/liter (assuming that 1 liter contains 2×10^9 cells). In general, recombinant proteins comprise 1% to 5% of total cell protein.

There are, however, several factors that may influence gene expression in the baculovirus system that should be taken into account when selecting a transfer plasmid and constructing the recombinant gene. Plasmids derived from the vector pVL941 (e.g., pVL1393 and pBlue-BacIII) contain an ATT in place of the original polyhedrin translation initiation codon ATG. Beames et al. (1991) have reported that translation can initiate at the ATT in these vectors. This results in the fusion of polyhedrin amino-terminal sequences to some of the heterologous proteins produced by these vectors if the foreign gene is cloned into the same reading frame

as the ATT. The lengths of the 5' and 3' untranslated regions of foreign genes expressed using this system have varied greatly. The significance of these sequences for transcriptional and translational efficiencies is unknown, and the standard practice is to keep their length to a minimum. One advantage of this expression system, however, is that it is unnecessary to precisely engineer sequences 5' to the initiation codon for efficient expression, as often must be done for bacterial expression systems, although the presence of an A at -3 (relative to AUG at +1, +2, and +3) may be important (O'Reilly et al., 1992). In addition, the inserted gene does not have to carry its own polyadenylation signal because the polyhedrin-gene polyadenylation signal is present in most expression vectors.

Because no intron-containing genes have been identified for baculovirus, it is recommended that inserted genes be derived either from cDNAs or genomic clones lacking introns. Reports in the literature, however, indicate that proper splicing may occur in some cases. For example, Jeang et al. (1987) reported preferential and proper processing of the small T antigen splicing signals when the SV40 virus

early region was cloned into the baculovirus expression vector.

Finally, if the recombinant protein contains a signal peptide, it may be expressed more efficiently in insect cells if it is fused to a heterologous signal peptide in place of the homologous one. The human immunodeficiency virus envelope protein gp120 is expressed and secreted at a much higher level when fused to signal peptides derived from baculovirus proteins (Murphy et al., 1993). Some transfer vectors that contain signal peptide coding regions are available commercially (see Table 16.9.1). However, this approach does not necessarily result in higher levels of protein production for every recombinant protein (Jarvis et al., 1993).

Critical Parameters and Troubleshooting

Sf9 cells have a doubling time of 18 to 24 hr in TNM-FH medium/10% FBS and should be subcultured two to three times per week. *Sf9* cells should be grown at 27°C. As carbon dioxide is not essential, the cells can actually be grown on the benchtop as long as room temperature remains within the range of 25° to 30°C. Medium should be equilibrated to room temperature before use. Gentamicin is optional and can be added to the medium if contamination is a problem.

Sf9 cells are adapted for growth in monolayer or suspension cultures. Trypsin is not required to detach them from monolayer cultures. *Sf9* cells may be repeatedly transferred between monolayer and suspension cultures without noticeable changes in viability or growth rate. It is easiest to carry cells and maintain their viability when they are carried in suspension rather than in monolayer cultures. A 50-ml culture of cells in a 100-ml spinner flask is routinely carried and used to subculture and seed monolayer cultures when needed.

For preparing viral stocks, low MOIs (e.g., 0.1) should be used. When this is the case the virus goes through multiple rounds of replication and infection and there is less chance for mutant viruses or defective interfering particles to form. When infecting for high levels of protein production, a high MOI (between 5 and 10) is recommended in monolayer cultures. For large suspension cultures (>100 ml), an MOI of 1 or 2 is sufficient. The virus is stable for 6 months at 4°C but must be shielded from light to maintain the titer (Jarvis and Garcia, 1994). Placement of 1 ml of each stock in liquid

nitrogen is recommended for long-term storage.

It is highly recommended that linear wild-type DNA be used for cotransfection or that bacmid DNA be prepared in *E. coli* and used for transfection. This greatly simplifies the screening procedure and saves time in obtaining a pure recombinant viral stock. If circular wild-type DNA is used, it is important to purify the recombinant viral DNA through several rounds of plaque assay.

Degradation by mechanical shearing and by nuclease contamination are the major problems encountered when trying to purify viral DNA from intact virions. Use of wide-mouth 5- or 10-ml pipets or Pasteur pipets with the necks broken off to handle the viral DNA helps to avoid shearing. In addition, tubes containing viral DNA should be mixed by inversion rather than by vortexing when performing phenol extractions and ethanol precipitations, and the purified DNA should be stored at 4°C rather than frozen and thawed.

It is very useful to practice visualizing recombinant plaques using the β -Gal recombinant virus as described in Basic Protocol 4. As mentioned, screening for recombinants is the most time-consuming and variable part of the entire expression system. The cell density at the time of plaquing seems to be the most critical parameter for achieving good plaques in the shortest period of time. Thus, it is helpful to seed duplicate plates at a couple of different cell densities. A perfect plaque assay will yield easily visualized plaques within 6 to 8 days.

Anticipated Results

Maintenance and culture of insect cells

When grown at 27°C, healthy insect cells should double every 18 to 24 hr. Healthy, logarithmically growing cells will be maintained in suspension cultures most readily when they are cultured at densities between 5×10^5 and 2×10^6 cells/ml. Cell viability should be ~97%.

Cotransfection

After 5 days, 20% to 100% of the cells should be showing signs of infection. Infected cells are of increased size with enlarged nuclei. They stop dividing and do not attach well to the plate. Many of the signs of infection may not be obvious if the transfection efficiency results in a low viral titer. In this case, it is necessary to amplify the virus in order to verify the success of the cotransfection. When generating recombinant baculovirus using wild-type bacu-

loviral DNA (see Alternate Protocol 2), the recombination frequency will be 0.1% to 0.2%. This method requires selection based upon identification of viral occlusion bodies. The direct cloning method (see Alternate Protocol 3) results in ~99% recombinant virus with ~50% containing the foreign gene in the correct orientation.

Plaques can generally be identified within 5 to 10 days post-infection and counted to determine viral titers. When individual plaques are picked to isolate recombinant virus, the resulting viral titer is generally low (5×10^5 pfu/ml) and will need to be amplified several times to produce a high-titer stock.

Time Considerations

Purification of wild-type viral DNA takes ~7 days to complete. Subcloning and large-scale production of recombinant DNA should take 1 to 2 weeks. The transfection procedure takes 1 day, and the transfection supernatant is harvested after 4 to 5 days. Plaquing takes 1 day, and it generally takes 1 week before the plaques are sufficiently formed to begin screening. Screening takes an additional day. It takes 4 to 5 days from the time of infecting Sf9 cells with a plaque to the time of harvesting the culture supernatant for an expanded virus stock. Purifying recombinants takes from <1 week to 3 weeks, depending on whether linear DNA was used in the transfection and whether several rounds of plaquing are required to purify recombinant virus from wild-type virus.

Using the Bac-to-Bac system (Invitrogen) to generate and transfect bacmid DNA, virus can be generated from a cloned cDNA in 7 days.

Expression and Purification of Recombinant Proteins Using the Baculovirus System

UNIT 16.11

This unit describes how to analyze protein expression in cells infected with recombinant baculovirus on a small scale for optimizing protein production (see Basic Protocol 1 and Support Protocols 1 and 2), how to maximize and scale up recombinant protein production (see Basic Protocol 2), and how to purify recombinant proteins (see Basic Protocol 3; see Alternate Protocol). Before proceeding with large-scale expression, it is recommended that the putative recombinants obtained be assayed for their ability to produce the protein of interest. This will exclude the possibility of using a recombinant virus that does not produce the protein of interest, and will, in the long run, save time. Basic Protocol 1 details the expression of protein on a small scale for further analysis. In order to optimize protein expression, it is very important to determine the time course of maximum protein expression (see Support Protocol 1). If the recombinant protein is expressed in small quantities and cannot be visualized without radiolabeling, a metabolic labeling of infected insect cells is advised (see Support Protocol 2). After the recombinant protein expression has been characterized on a small scale, Basic Protocol 2 describes how to scale up protein expression. Methods are also described for co-infection with multiple baculoviruses for purification of recombinant protein complexes (see Alternate Protocol 1). If purification of the recombinant protein is needed and it is expressed as a fusion protein with either a polyhistidine (6×His), glutathione-*S*-transferase (GST), or FLAG tag, it can be purified in a single step according to Basic Protocol 3, or Alternate Protocols 2 or 3.

SMALL-SCALE EXPRESSION FOR INITIAL ANALYSIS

In this procedure, *Sf9* cells (UNITS 16.9 & 16.10) are infected with an expanded recombinant virus stock and can be analyzed 2 to 3 days later. The assays employed depend on the nature of the protein being produced. This protocol gives some suggested approaches but is certainly not comprehensive. Screening should be individually tailored to the properties of the protein being overproduced and the availability of detection reagents.

Materials

- Spodoptera frugiperda* (*Sf9*) cells (UNIT 16.10)
- TNM-FH insect medium (see recipe in UNIT 16.10) with or without 10% fetal bovine serum (FBS)
- High-titer recombinant baculovirus stocks (UNIT 16.10)
- Phosphate-buffered saline (PBS; APPENDIX 2)
- 1× SDS sample buffer (UNIT 10.2)
- 60-mm tissue culture plates
- 27°C incubator (humidification optional)
- 15-ml polypropylene centrifuge tubes
- Beckman GPR centrifuge with GH-3.7 rotor (or equivalent), 4°C
- Boiling water bath or 100°C heating block
- Sonicator
- Additional reagents for quantitating protein using the Bradford method (UNIT 10.1) and preparing insect cell cultures and viral stocks (UNIT 16.10)

Prepare and process cultures

1. Seed 2.5×10^6 *Sf9* cells into 60-mm tissue culture plates containing 3 ml TNM-FH insect medium with or without 10% FBS. Incubate 1 hr at 27°C to allow cells to attach.

Prepare one plate for each viral stock to be tested and one plate as an uninfected control.

BASIC
PROTOCOL 1

Protein
Expression

16.11.1

Contributed by Cheryl Isaac Murphy, Helen Piwnica-Worms, Stefan Grünwald, William G. Romanow, Nicole Francis, and Hua-Ying Fan

Current Protocols in Molecular Biology (2004) 16.11.1-16.11.14

Supplement 65

2. Replace the medium with fresh TNM-FH/10% FBS medium and add 0.1 ml high-titer baculovirus stock to the appropriate plates at an MOI of 1 to 10. Incubate 3 days at 27°C.
3. Harvest cells by gently dislodging them from the plates, and transfer cells and culture medium to 15-ml polypropylene centrifuge tubes.
4. Centrifuge 10 min at 1000 × *g* (2000 rpm in a GH-3.7 rotor), 4°C.

For secreted proteins

- 5a. Transfer the culture supernatants to new tubes.
- 6a. Determine the protein concentrations in the supernatants using the Bradford method (UNIT 10.1). Proceed to analysis (step 7).

Supernatants may be frozen up to several months at –80°C.

For intracellular proteins

- 5b. Discard the supernatants. Rinse cells by resuspending the cell pellets gently in PBS, centrifuging again as in step 4, then discarding the supernatants.
- 6b. Add 500 µl of 1× SDS sample buffer to each pellet and boil 5 to 10 min by placing the tube in a boiling water bath or 100°C heating block. Sonicate samples if they are too viscous because of the presence of DNA. Continue to sonicate until viscosity clears, then determine the protein concentration in each sample using the Bradford method. Proceed to analysis (step 7).

Sonication times will vary with individual sonicators. DNA can also be disrupted by passing the lysate through an 18- or 20-G needle approximately ten times.

Alternatively, lyse cell pellets in 0.5 ml of an appropriate lysis buffer, which may differ according to cell type (e.g., insect cell lysis buffer; see Reagents and Solutions) supplemented with protease inhibitors. Lysis buffers containing EDTA must not be used with 6×His fusion products. Microcentrifuge 10 min at 4°C to clarify the lysates and transfer supernatants to new tubes. Add 100 µl of each lysate to 100 µl of 2× SDS sample buffer and boil 3 min in a boiling water bath. Freeze remaining lysate up to several months at –80°C.

Analyze proteins

7. Analyze the proteins in each sample by one of the following methods.
 - a. *Immunoblotting* (UNIT 10.8): Load 20 to 40 µg total cell protein per lane on a one-dimensional SDS-polyacrylamide gel. Remember to include the uninfected control.
 - b. *Coomassie brilliant blue staining* (UNIT 10.6): Load 20 to 40 µg total cell protein per lane on a one-dimensional SDS-polyacrylamide gel. If the recombinant virus is not pure, recombinant protein will be detected only if it is produced at very high levels in the infected cells.
 - c. *Functional assays*: Use any assay that is typically used to monitor the protein of interest—e.g., mobility-shift DNA-binding assays (for a DNA-binding protein; UNIT 12.2), in vitro kinase assays (for a protein kinase), nucleotide-binding assays (for a protein that binds nucleotides), or thymidine-incorporation assays (for a protein that is a growth factor).
 - d. *Metabolic labeling of recombinant proteins*: Perform as described (see Support Protocol 2).

If there are no easy assays for monitoring the recombinant protein produced by the baculovirus, then the putative recombinants should be monitored for the presence or

absence of the foreign gene. A simple dot hybridization technique is given in Summers and Smith (1987); alternatively PCR amplification can be used (Chapter 15 of this manual and O'Reilly et al., 1992). Several companies (e.g., Invitrogen and Clontech) sell PCR primers that will work for most baculovirus vectors.

8. Interpret results to identify which of the putative recombinant stocks is an actual recombinant that produces the desired protein. Plaque-purify recombinants so they are free from any contaminating wild-type virus (if they were not produced with linearized baculoviral or bacmid DNA; see *UNIT 16.10*). Prepare a large viral stock and titer the recombinant virus (*UNIT 16.10*).

DETERMINING TIME COURSE OF MAXIMUM PROTEIN PRODUCTION

Because expression of the recombinant protein is regulated by the polyhedrin promoter, which is activated very late in the lytic cycle of the virus, the recombinant protein will be expressed late as well. Recombinant proteins are usually detected between 15 and 24 hr postinfection and accumulate until ~40 hr postinfection, at which time their accumulation levels off. Because individual proteins display differences in their stability within insect cells, it is recommended that the time course of protein accumulation be charted for each protein expressed using this system. The following protocol describes how to determine when an intracellular recombinant protein is maximally produced by harvesting and analyzing cells at various times after infection.

Additional Materials (also see Basic Protocol 1)

Wild-type baculovirus (available from Dr. Max D. Summers; see *UNIT 16.10* for instructions on generating recombinant baculoviruses using wild-type baculoviral DNA)

1. Seed 3×10^6 Sf9 cells/plate into fifteen 60-mm tissue culture plates, each containing 3 ml TNM-FH medium with or without 10% FBS. Incubate 1 hr at 27°C to allow cells to attach, then infect seven plates with wild-type baculovirus and seven plates with recombinant virus, each at an MOI of 10. Leave one plate as an uninfected control.

Alternatively, Sf9 cells can be cultured in suspension in three 100-ml spinner or shaker flasks. When cells reach a density of 1.5×10^6 cells/ml, infect one flask with recombinant virus and one with wild-type virus, leaving one as an uninfected culture. Use an MOI of 1 to 2.

2. Harvest cells at various times (from ~15 to 72 hr) postinfection by transferring cells and culture supernatants to centrifuge tubes and centrifuging 10 min at $1000 \times g$ (2000 rpm in a GH-3.7 rotor), 4°C. Harvest the uninfected cells at 15 hr postinfection.

If cells are growing in suspension, remove 2-ml aliquots at each time point and process the cells and supernatants in the same way as for the monolayer cultures discussed here.

3. Process and analyze the cells (if the recombinant protein is not secreted) or supernatants (if the recombinant protein is secreted) as described (see Basic Protocol 1).

When staining with Coomassie brilliant blue (see Basic Protocol 1, step 7), look for a protein that appears as a function of time postinfection with the recombinant virus but not with the wild-type virus. The protein must be reasonably abundant for this method to be successful.

SUPPORT PROTOCOL 1

Protein Expression

16.11.3

METABOLIC LABELING OF RECOMBINANT PROTEINS

Metabolic labeling *in vivo* is a sensitive way to detect recombinant proteins, because at the time the recombinant protein is expressed, host protein synthesis is essentially terminated. Thus, all label is incorporated into late-viral-specific proteins, including the protein of interest. The most commonly used procedure for radiolabeling proteins is the incorporation of [³⁵S]methionine and [³⁵S]cysteine, both of which are essential amino acids. For better results, the intracellular pool of these two amino acids should be depleted prior to radiolabeling. This can be achieved by preincubating the cells in methionine/cysteine-free medium for 30 min. The efficiency of incorporation depends on the number of methionines and cysteines in the particular protein of interest. After labeling, the cells are lysed. The proteins are resolved by SDS-PAGE and visualized by autoradiography.

Additional Materials (also see Basic Protocol 1)

Wild-type baculovirus (available from Dr. Max D. Summers; see *UNIT 16.10* for instructions on generating recombinant baculoviruses using wild-type baculoviral DNA)

Methionine-free or methionine-free/cysteine-free Grace's insect cell culture medium (Invitrogen)

EXPRE³⁵S³⁵S, containing [³⁵S]methionine and [³⁵S]cysteine (>1000 Ci/mmol; Du Pont NEN)

Additional reagents and equipment for one-dimensional SDS-PAGE (*UNIT 10.2*) and autoradiography (*APPENDIX 3A*)

1. Seed 2.5×10^6 cells into 60-mm tissue culture plates containing 3 ml TNM-FH medium with 10% FBS. Prepare one plate to be infected with each putative recombinant virus and one control plate to be infected with wild-type baculovirus.
2. Incubate 1 hr at 27°C to allow cells to attach. Aspirate medium, then add 1 ml recombinant virus or 1 ml medium containing wild-type virus at an MOI of 5 to 10. Incubate 1 hr at room temperature.
3. Remove the medium from each plate by aspiration. Add 3 ml TNM-FH/10% FBS medium to the cells and incubate 24 to 48 hr at 27°C.
4. Carefully remove medium from each plate, then rinse cells once with methionine-free or methionine-free/cysteine-free medium. Add 1 ml methionine-free or cysteine-free medium to each plate. Incubate cells 30 min at 27°C, then add 0.25 to 0.5 μ Ci EXPE³⁵S³⁵S per plate and incubate 3 to 4 hr at 27°C.

It is important to hold the plates at an angle and remove and add medium at one corner so as not to dislodge the cells from the monolayer.

5. Transfer cells and culture supernatant from each plate to a separate 15-ml polypropylene centrifuge tube and centrifuge 10 min at $1000 \times g$ (2000 rpm in a GH-3.7 rotor), 4°C.
6. Process and analyze the cells (if the recombinant protein is not secreted) or the supernatant (if the recombinant protein is secreted) according to the appropriate procedures in Basic Protocol 1 (see Basic Protocol 1, steps 5a or 5b, 6a or 6b, and 7).

*If an antibody is available, it is recommended that the labeled lysates be immunoprecipitated (*UNIT 10.16*) prior to boiling in SDS sample buffer and resolution by SDS-PAGE. Immunoprecipitation will help detect the recombinant protein if it comigrates with a labeled host or late-viral-specific protein.*

*Polyhedra (*UNIT 16.9*) are solubilized only under very alkaline conditions (0.1 M final NaOH concentration). Without prior disruption under alkaline conditions, <10% of polyhedra will be solubilized in SDS sample buffer.*

7. Visualize proteins by autoradiography (APPENDIX 3A). Inspect the autoradiogram for protein of the expected molecular weight that appears in cells infected with recombinant baculovirus but not with wild-type baculovirus.

LARGE-SCALE PRODUCTION OF RECOMBINANT PROTEINS

This protocol describes how to maximize and scale up recombinant protein production in *Sf9* cells. The cells are grown in suspension in serum-free medium in 1- to 10-liter spinner flasks (Techne or Bellco) or in shaker flasks (Bellco). They are then infected with recombinant virus and harvested and analyzed at the time of optimum protein accumulation (see Support Protocol 1).

Materials

Spodoptera frugiperda (*Sf9*) cells (UNIT 16.10)

Serum-free insect cell culture medium (e.g., BaculoGold medium from Pharmingen, *Sf*-900 II from Invitrogen, or ExCell 401 from JRH Biosciences)

High-titer recombinant baculovirus (UNIT 16.10)

1- to 10-liter spinner (Techne or Bellco) or shaker (Bellco) flasks

Two-port cap assemblies for spinner flasks (Techne or Bellco; optional)

Silicone tubing (Cole-Palmer) with $\frac{3}{16}$ -in. (0.48-cm) inner diameter (i.d.), $\frac{5}{16}$ -in. (0.8-cm) outer diameter (o.d.), and $\frac{1}{16}$ -in. (0.16-cm) wall

0.2- μ m filter units (Millipore)

4-in. (10.16-cm) cable ties (Cole-Palmer)

Tension tool (Cole-Palmer)

Stir plate for multiple spinner flasks (Techne or Bellco; optional)

27°C incubator

Air-supply pump (Bellco)

Additional reagents and equipment for preparing insect cell cultures and viral stocks (UNIT 16.10)

- 1a. Grow *Sf9* cells in suspension culture and adapt to serum-free medium (see UNIT 16.10, Basic Protocol 1). Perform steps 2 through 4.
- 1b. Alternatively, incubate cells in a 27°C orbital shaker set at 150 rpm for 500-ml flasks or 100 rpm for 2.8-liter Fernbach flasks. Proceed to step 5.
2. Prepare spinner flasks to be used for scale-up of *Sf9* cells by attaching the appropriately sized two-port cap to one side arm and a plain cap to the other sidearm. Put a short (~6-in. or 15-cm) piece of tubing on the air-vent port and attach a filter to the end. Secure the tubing to the port and filter with cable ties using a tension tool.

Refer to Figure 16.11.1 for these procedures.

3. Put a longer piece of tubing (1 to 2 feet or 30 to 60 cm) on the air-supply port and attach a 0.2- μ m filter unit to the end. Secure with cable ties. Attach another piece of tubing to the other end of the filter with a cable tie. Cover the end of the tubing with aluminum foil.

The length of the silicone tubing attached to the air-supply port will depend on the distance between the sidearm and the air-supply pump in the incubator.

Several sizes of two-port cap assemblies are available for Bellco spinner flasks. The smallest size fits the 1-liter flask and the next larger size fits the 3-liter flask. The largest size fits the 6-, 8-, and 15-liter flasks.

4. Loosen the cap on the side arm opposite to the two-port assembly a quarter turn and autoclave flask 1 hr.

Figure 16.11.1 Bellco spinner flask with two-port cap assembly.

- 5a. *For spinner flasks:* Seed the autoclaved flask with *Sf9* cells adapted to serum-free medium (from step 1). Fill the flask to between half full and full (e.g., 1.5 to 3 liters in a 3-liter flask), adding enough serum-free medium to make a final cell density of $5\text{--}6 \times 10^5$ cells/ml.

If enough cells are available, flasks can be seeded at densities up to 1.5×10^6 cells/ml.

- 5b. *For shaker flasks:* Adapt cells to larger flasks for 1 to 2 days prior to infection. Once the culture is established, proceed to step 8.

A 2.8-liter shaker flask will hold 1 liter of culture.

6. Place the flask on a stir plate for spinner flasks in a 27°C incubator. Set the stir speed at 80 rpm. Remove the aluminum foil from the air-intake tube and attach the end of the tube to the air-supply pump. Turn on the pump and set to the lowest setting.

A flow rate of 500 to 700 ml/min works well with these flasks; the larger flasks require a higher flow rate than the smaller ones. It is recommended that the pump flow rate be measured empirically before hooking it up to the flask or that a flow meter be attached between the pump and the flask.

7. Grow the cells to a density of $\sim 1.5 \times 10^6$ cells/ml. Working in a laminar-flow hood, add virus at a multiplicity of infection (MOI) of 1 to 2 directly to the flask through the side arm.

8. Place the flask on the magnetic stir plate at 27°C and connect the air supply. For shaker cultures, place flask in the shaker with a loosened cap. Incubate the culture for the optimal amount of time as determined in Support Protocol 1.

9. Process the supernatant for secreted proteins or the cells for intracellular proteins.

There are many protein purification methods available and the choice of which ones to use depends on the nature of the recombinant protein expressed. For additional information see Chapter 10 or Coligan et al. (1997).

CO-INFECTION WITH MULTIPLE BACULOVIRUSES FOR PURIFICATION OF RECOMBINANT PROTEIN COMPLEXES

ALTERNATE
PROTOCOL 1

In this procedure, *Sf9* cells are co-infected with multiple baculoviruses that express subunits of multiprotein complexes. Complexes can then be purified using an affinity tag on a single subunit. This protocol is essentially identical to the one described above (see Basic Protocol 2), except that multiple viruses are used to infect each culture. The two parameters that need to be optimized are the ratio of viruses encoding different subunits of the complex and the timing of infection. Two examples of successful expression and purification of recombinant complexes are Phelan et al. (1999) and Zhang et al. (1999).

Additional Materials (see *Basic Protocol 2*)

Recombinant baculoviruses for complex subunits with one subunit carrying an affinity tag for purification
Shaker or spinner flask cultures (see *Basic Protocol 2*)

1. Grow *Sf9* cells in suspension culture in serum-free medium (*UNIT 16.10*). Prepare flasks for infection as described (see *Basic Protocol 2*, steps 2 to 6).

*Infect cells with multiple viruses at an $MOI \geq 2$ to 10 for each virus. *Sf9* cells will be multiply infected so that all subunits can be expressed in each cell. Ratios of various viruses can be adjusted to maximize stoichiometric complex formation. In general, more virus should be used for larger subunits and less for smaller subunits. For example, for a four-protein complex with two 170-kDa and two ~50-kDa proteins, the authors use a 3:1 ratio of virus (large:small protein). Epitope tagging the subunit (*UNIT 16.13*) expressed at the lowest levels should mainly result in purification of complex rather than free subunit. Some experimentation may be required to determine optimal ratios for complex production. This will require production of enough protein to purify at least a small amount of complex to assess subunit stoichiometry. If obtaining reproducible stoichiometries proves to be difficult, changing which subunit is epitope-tagged or adding a second type of epitope tag to a different subunit (and using a two-step affinity purification; *UNIT 10.15*) may help.*

Certain proteins do not co-express well; mixing extracts expressing the two proteins prior to purification sometimes yields successful complex formation (e.g., Phelan et al., 1999).

2. Incubate culture for an optimal amount of time (see *Support Protocol 1*).

In general, larger proteins tend to be more unstable and timing determined for single large proteins frequently work best for multiprotein complexes. The time of maximal expression is not always optimal for maximal intact protein—shorter infection times that may yield less protein tend to give more intact and active complex.

3. Harvest cells and process for intracellular proteins.

*To maintain complex integrity, it may be necessary to adjust lysis conditions or use subcellular fractionation (e.g., nuclear extracts for nuclear proteins, *UNIT 12.1*).*

PURIFICATION OF RECOMBINANT PROTEINS CONTAINING A POLYHISTIDINE (6×HIS) TAG

BASIC
PROTOCOL 3

The pAcHLT-A, -B, and -C transfer vectors (Pharming) and the pBlueBacHis A, B, and C vectors (Invitrogen) contain DNA that encodes an N-terminal tag of six histidine residues, followed by an extended multiple cloning site (MCS). The MCS is in a different reading frame in each of the vectors to simplify cloning. The expressed recombinant protein will be a 6×His fusion protein suitable for affinity purification on Ni-NTA agarose. Approximately 1 to 2 mg of 6×His recombinant fusion protein is routinely obtained per liter insect cell culture.

Protein
Expression

16.11.7

Materials

Insect cell lysis buffer (see recipe) containing 1× protease inhibitors (see recipe for 50×)

Ni-NTA agarose (Qiagen)

6×His wash buffer (see recipe)

6×His elution buffer (see recipe) containing imidazole as either a step or linear gradient

Beckman GPR centrifuge with GH-3.7 horizontal rotor (or equivalent), 4°C

Sorvall centrifuge and SS-34 rotor (or equivalent) or 0.2-μm filter

Suitable chromatography column

Additional reagents and equipment for preparing insect cell cultures and viral stocks (UNIT 16.10) and quantitation of protein by absorbance spectrometry (APPENDIX 3D)

Harvest and lyse cells

1. Infect the desired amount of cells (e.g., 5×10^6 cells per 100-mm plate) with the amplified recombinant virus at an MOI of 5 to 10. Cultivate 3 to 5 days and examine for typical signs of infection (UNIT 16.10).
2. Harvest the cells and supernatant from infected plate(s) by gently spritzing the cells with a sterile pipet to resuspend. Transfer to a centrifuge tube. Centrifuge 10 min at $1000 \times g$ (2000 rpm in a GH-3.7 rotor), 4°C.
- 3a. *For secreted proteins:* Transfer the supernatant to a new tube and proceed to purification (step 6).
- 3b. *For intracellular proteins:* Discard the supernatant, then rinse the cells by resuspending the cell pellet gently in PBS, repeating the centrifugation, and discarding the supernatant.
4. Lyse the cells by adding 1 ml insect cell lysis buffer containing 1× protease inhibitors for every 1×10^7 cells and incubating 45 min on ice.

Choice of lysis buffer may vary with cell type, but EDTA-containing lysis buffers must not be used with 6×His fusion proteins.
5. Clarify the lysate by centrifuging 30 min at $40,000 \times g$ (18,000 rpm in an SS-34 rotor), 4°C to pellet the cellular debris or filter the lysate through a 0.2-μm filter.
6. Gently resuspend the Ni-NTA agarose and pour into a suitable chromatography column. Allow the beads to settle and the column to drain, then wash twice with 3 to 5 column volumes of 6×His wash buffer to remove the ethanol preservative. Allow the column to drain.

One milliliter of Ni-NTA agarose will bind ~5 to 10 mg of 6×His fusion protein.
7. Apply clarified lysate to column. Adjust the column flow rate to a maximum of 5 column volumes per hour.

Keep the flowthrough fraction to run on SDS-PAGE (UNIT 10.2) in case the binding capacity of the Ni-NTA agarose was exceeded.
8. Wash the column with 10 bed volumes of 6×His wash buffer and allow the column to drain while periodically monitoring the A_{280} . Repeat washing (~4 times) until the A_{280} of the column effluent is <0.01 . Discard the washes.
9. Add 3 bed volumes of the 6×His elution buffer (including imidazole either as a step or a linear gradient) to the column. Adjust the column flow rate to a maximum of 1 ml/min per milliliter of resin beads. Allow the column to drain completely while collecting the eluted fractions.

The optimal amount of imidazole (0.1 M to 0.5 M) needed for elution will vary on the basis of the properties of the bound protein, and should be empirically determined by the researcher.

Pharmingen has also introduced the BioColors-His baculovirus transfer vector set, which allows the production of a fusion protein consisting of the desired gene product along with one of several derivatives of the *Aquorea victoria* green fluorescent protein (GFP; see UNIT 9.7C) and a histidine affinity tag. Under UV light, such a recombinant fusion protein can be visualized during the entire purification process, which facilitates the establishment of an optimized purification procedure.

PURIFICATION OF RECOMBINANT PROTEINS CONTAINING A GST TAG

ALTERNATE PROTOCOL 2

Several baculovirus vectors are commercially available that allow the expression of glutathione-S-transferase (GST)-tagged fusion proteins, which greatly facilitate the purification of recombinant proteins. Pharmingen's pAcGHLT-A-, -B, and -C transfer vectors, for example, encode N-terminal 6×His and GST tags followed by an extended MCS. The MCS is in a different reading frame in each of the vectors to simplify cloning. Because the GST vectors also contain a 6×His sequence, the expressed recombinant protein will be a 6×His-containing GST fusion protein. This feature allows affinity purification using either glutathione agarose beads or Ni-NTA agarose. A thrombin cleavage site following the affinity tags allows for the proteolytic cleavage of the GST-6×His fusion partner from the protein of interest.

The GST purification method is based on the remarkable selectivity and affinity of recombinant proteins equipped with a GST affinity tag toward glutathione immobilized on a resin. The expressed GST fusion proteins are authentically processed, and may be purified without the use of detergents under completely nondenaturing conditions. Purifications to >90% homogeneity are easily achieved in a single step by affinity chromatography using glutathione agarose beads. The affinity of GST for glutathione is so strong that it allows a highly efficient separation of GST fusion proteins from contaminating polypeptides even under nondenaturing conditions.

Although addition of a 6×His or GST tag to a recombinant protein may greatly simplify purification, these methods do not work for all proteins and should be tried on a small scale first.

Additional Materials (also see Basic Protocol 3)

- Glutathione agarose beads (Pharmingen or Sigma)
- PBS wash buffer (Pharmingen)
- GST elution buffer (see recipe)
- 50 mM Tris·Cl, pH 8.0 (APPENDIX 2)
- Thrombin, bovine (e.g., Sigma or Boehringer Mannheim)
- Additional reagents and equipment for dialysis (APPENDIX 3C)

Purify GST fusion protein

1. Prepare clarified solution of recombinant protein (see Basic Protocol 3, steps 1 to 5).
2. Gently resuspend the glutathione agarose beads and pour slurry into a suitable chromatography column. Allow the beads to settle and the column to drain. Wash twice with 3 to 5 bed volumes of PBS wash buffer to remove the ethanol preservative, then allow the column to drain.
3. Apply the clarified solution of recombinant proteins to the column. Adjust column flow rate to a maximum of 5 ml/min per milliliter of beads.

Keep the flowthrough fraction to run on SDS-PAGE (UNIT 10.2) in case the binding capacity of the glutathione beads was exceeded.

Protein Expression

16.11.9

4. Wash the column twice with 5 bed volumes PBS wash buffer. Allow the column to drain and discard the washes.
5. Add 3 bed volumes GST elution buffer to the column. Adjust the column flow rate to a maximum of 1 ml/min per milliliter beads. Allow the column to drain completely while collecting the eluted fraction.

The addition of 150 mM NaCl, 5 mM CaCl₂ (or for some proteins 5 mM MgCl₂), and 0.1% 2-mercaptoethanol is optional but may be required for the solubility of some proteins.

6. Remove the free glutathione by dialysis (*APPENDIX 3C*) for ≥4 hr against 100 vol of 50 mM Tris-Cl (pH 8.0), 4°C. Change dialysis buffer after 2 hr.

Perform thrombin cleavage

7. Add 200 μg (10 thrombin units) of bovine thrombin per milligram purified GST or 6×His fusion protein containing a thrombin cleavage site.
8. Mix, then incubate at room temperature up to 12 hr.

In many cases a 20- to 60-min incubation will be sufficient.

9. Add 2 vol of a 50% (v/v) slurry of glutathione agarose beads at the end of the cleavage reaction.

This directly removes GST and uncleaved GST fusion protein. Similarly, 6×His and uncleaved 6×His fusion protein may be removed by directly adding Ni-NTA agarose at the end of the cleavage reaction.

10. Incubate 30 min at 4°C, then centrifuge 10 min at 5000 × g (2250 rpm in an SS-34 rotor), 4°C. Retain the supernatant and freeze at –80°C.

The supernatant will contain the purified protein as well as thrombin and can be stored frozen at –80°C. Some proteins may require the addition of BSA or glycerol (50% final concentration) for stability.

Thrombin cleaves in 50 mM Tris-Cl buffer and does not require specific metal ions for its activity (Haun and Moss, 1993; Wu et al., 1992). However, Guan and Dixon (1991) have recommended using a buffer containing 50 mM Tris-Cl (pH 8.0), 150 mM NaCl, 2.5 mM CaCl₂, and 0.1% 2-mercaptoethanol for efficient cleavage.

*An efficient thrombin cleavage primarily depends on the sequence of the thrombin consensus site and the three-dimensional structure surrounding that site. The thrombin cleavage consensus site is *XXP(K/R)*BB*, where *X* stands for hydrophobic apolar amino acids, *P* stands for proline, (*K/R*) symbolizes that both lysine and arginine work in this position, and *B* stands for nonacidic amino acids. The (*) symbolizes the cleavage position, which is at the carboxy-terminal side of the arginine or the lysine residue. The thrombin site used in the pAcGHLT and pAcHLT vectors is LVPR*GS. A BamHI site codes for the amino acids GS within the cloning site and allows the insertion of the desired gene within the thrombin coding sequence. This cloning strategy allows release of nearly authentic proteins after thrombin cleavage.*

ALTERNATE PROTOCOL 3

PURIFICATION OF RECOMBINANT PROTEINS CONTAINING A FLAG TAG

Baculovirus vectors allowing the expression of FLAG-tagged fusion proteins, which generally retain the biochemical activities of untagged proteins, are not commercially available; however, the FLAG epitope can be conveniently added to either the N- or C-terminus of proteins of interest by PCR. FLAG-tagged proteins can be affinity purified using anti-FLAG M2 affinity beads (Sigma) and eluted with FLAG peptide (Sigma). The resulting proteins are often pure enough for many biochemical assays.

Additional Materials (see also *Basic Protocol 3*)

Anti-FLAG M2 affinity beads (Sigma)

BC buffers (*UNIT 16.13*)

FLAG peptide (Sigma)

Additional reagents and equipment for lysing cells (*UNIT 16.7*) and SDS-PAGE (*UNIT 10.2A*)

Purify FLAG-tagged protein

1. Prepare the clarified solution of recombinant protein as described (see *Basic Protocol 3*, steps 1 to 5). Alternatively, if detergent inhibits subsequent assays, prepare the cell lysate by repeated cycles of freezing in dry ice and thawing at 37°C, followed by sonication (*UNIT 16.7*).

Additionally, a subcellular fraction containing recombinant protein may be used as starting material (e.g., nuclear extract, S100 fraction, nuclear pellet prepared according to UNIT 12.1).

2. Equilibrate anti-FLAG M2 affinity beads with 10 bead volumes of the buffer used in step 1. Collect beads by centrifuging 5 min at 1000 × g, 4°C.
3. Mix recombinant protein-containing solution with beads and incubate for 3 hr at 4°C.
4. Centrifuge M2-beads 5 min at 1000 × g, 4°C. Save a portion of supernatant to assess binding and discard the remainder.
5. Resuspend M2-beads with BC300 and pour into a suitable chromatography column (e.g., Bio-Rad Econo-Column). Allow beads to settle and column to drain.
6. Sequentially wash column with 10 bead volumes buffer containing increasing salt concentrations up to 2 M KCl (e.g., BC600, BC1200, and BC2000).
7. Sequentially wash column with 10 bead volumes buffer containing decreasing salt until desired concentration is obtained (e.g., BC100).
8. Allow column to drain completely. Add 0.5 bead volumes of 0.5 to 2 mg/ml FLAG peptide in elution buffer (e.g., BC100). Collect flow-through as pre-elution.
9. Add 0.25 bead volumes elution buffer and let sit over column surface for 1 hr at 4°C.
10. Collect elution in fractions of 1/3 to 1/2 of the bead volume for a total of 3 to 5 bead volumes.

Beads can be incubated with peptide for a second hour and a second elution collected; this can be repeated a third time. FLAG peptide may be omitted for the final elution.

11. Analyze unbound and eluted fractions by SDS-PAGE (*UNIT 10.2A*)

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

GST elution buffer

Dissolve 42 mg reduced dry glutathione in 40 ml of 50 mM Tris·Cl, pH 8.0 (*APPENDIX 2*). Divide into small aliquots and store up to 6 months at –20°C.

6×His elution buffer

50 mM sodium phosphate, pH 8.0 (APPENDIX 2)
300 mM NaCl
10% (v/v) glycerol
Imidazole to make either a step or linear gradient for elution
Prepare using distilled water and filter sterilize
Store up to 6 months at 4°C.

A maximum concentration of 0.5 M imidazole is recommended for the final elution. The concentration of imidazole should be determined empirically by the researcher.

6×His wash buffer

50 mM sodium phosphate, pH 8.0 (APPENDIX 2)
300 mM NaCl
10% (v/v) glycerol
Prepare using distilled water and filter sterilize
Store up to 6 months at 4°C.

For a more stringent wash, the pH may be adjusted to 6.0 and 0.8 to 40 mM imidazole may be added. The concentration of imidazole should be determined empirically by the researcher.

Insect cell lysis buffer, 1×

10 mM Tris-Cl, pH 7.5 (APPENDIX 2)
130 mM NaCl
1% (v/v) Triton X-100
10 mM NaF
10 mM sodium phosphate, pH 7.5 (APPENDIX 2)
10 mM sodium pyrophosphate
Prepare using distilled water and filter sterilize
Store up to 6 months at 4°C.
Add 50× protease inhibitor cocktail (see recipe) to 1× before use

Protease inhibitor cocktail, 50×

Prepare in 100% ethanol
800 µg/ml benzamidine
500 µg/ml phenanthroline
500 µg/ml aprotinin
500 µg/ml leupeptin
500 µg/ml pepstatin A
50 mM PMSF
Vortex to resuspend insoluble constituents before use
Store up to 6 months at -20°C

COMMENTARY

Background Information

There are many protein purification methods available, and the choice of which to use depends on the nature of the recombinant protein expressed (for additional information see Chapter 10). Suspension (spinner or shaker) cultures are often more convenient to use for protein expression than monolayer cultures and densities of up to 10^7 cells/ml with >97% viability can be achieved. Suspension cultures are also preferred when growing large quantities of cells (e.g., to prepare large viral stocks or large

quantities of recombinant protein), because the entire process can be carried out in one flask. For small-scale procedures, by contrast, monolayer cultures are preferred because they seem less susceptible to contamination and can more easily be assessed to monitor the progress of viral infections. Monolayer cultures are absolutely required for transfections as well as for plaquing viral supernatants, and they are also preferred for preparing viral stocks or producing recombinant protein.

Most cell lines are readily adaptable to serum-free medium when in suspension. The use of serum-free medium has several advantages. First, cells can be grown to higher cell densities in serum-free medium. Second, serum-free medium is more consistent and less expensive than serum-supplemented medium. In addition, serum-free medium has a low protein content, which aids in the purification of secreted recombinant proteins. It should be determined empirically which cell line and medium formulation is most productive for the particular recombinant protein of interest. *Spodoptera frugiperda* (*Sf9*, *Sf21*) cells grown in serum-free medium are more sensitive to centrifugation, stick more tightly to plasticware, undergo a growth lag when seeded at too low a density, and cannot be passaged more than ~50 times.

In regard to purification, secreted recombinant proteins are much easier to purify than nonsecreted proteins, because the ratio between recombinant protein and host proteins in the medium is much higher than in lysates, especially when protein-free medium has been used. The general strategy for purifying protein from the medium depends on the nature of the recombinant protein. If an antibody against the desired protein is available in large quantities, it can be used for affinity purification. Otherwise, conventional ion-exchange chromatography may perform equally well.

Critical Parameters

The efficiency of heterologous gene expression in the baculovirus system can differ 1000-fold as a result of the intrinsic nature of the gene and the encoded protein. Modifying the heterologous gene will generally influence gene expression by only 2- to 5-fold. Researchers should not feel compelled to modify their gene excessively. For some general rules regarding the improvement of gene expression, see O'Reilly et al. (1992). When expressing protein, a time-course experiment should be conducted to determine peak protein production.

To optimize for protein production, it is recommended that log-phase *Sf9* cells be infected at high multiplicity of infections (MOIs)—e.g., 5 to 10 for monolayer culture and 1 to 2 for suspension culture. Cells to be infected should be >97% viable. Use of high-quality media and FBS also seems to contribute to high protein yields.

The most common method for radiolabeling protein involves incorporating [³⁵S]methionine or [³⁵S]cysteine. To improve results, the intra-

cellular pool of these essential amino acids should be depleted prior to radiolabeling by incubating the cells in methionine/cysteine-free medium. If an antibody is available, the labeled lysate should be immunoprecipitated to help detect the recombinant protein if it comigrates with a labeled host protein.

To maximize large-scale production of recombinant proteins, *Sf9* cells should be grown in suspension in serum-free medium. Flasks should remain <50% full or be vented to ensure proper oxygenation. Cells should be grown to a density of 1.5×10^6 cells/ml before infecting at an MOI of 1 to 2.

Purification of recombinant proteins can be simplified by expressing them with either a GST or 6×His tag. When purifying these proteins via affinity chromatography, the flow-through fractions should be retained for analysis by SDS-PAGE. Analysis of these fractions may help in troubleshooting poor affinity binding. Other affinity tags such as FLAG, myc, or HA—for which high-quality affinity resins are commercially available, and for which gentle elutions with peptide can be used—work well for insect cell expression. For purification of complexes, only a single subunit should be tagged. In general, epitope tagging the protein expressed at the lowest levels results in optimal stoichiometries of purified complexes.

The addition of a 6×His or GST tag to a recombinant protein may greatly simplify purification; however, these methods do not work for all recombinant proteins and should be tried on a small scale first.

Anticipated Results

When expressing proteins in the baculovirus system, one can typically expect to produce up to 1 to 5 mg protein per liter insect-cell culture. However, it is extremely important to note that gene expression can vary 1000-fold as a result of the intrinsic nature of the protein. Recombinant protein levels can vary from 1% to 50% of the total insect-cell protein. When using an MOI >1, it is expected that most cells in the culture will become infected at the same time and thus produce protein within the same time frame. A time course can be run to test for peak protein production. Cells infected during log-phase growth with a high surface-to-volume ratio to allow for proper gas exchange will produce protein optimally.

Approximately 1 to 2 mg of 6×His and GST fusion protein are routinely obtained per liter of insect-cell culture. Affinity purifications to

>90% homogeneity are easily achieved using single-step affinity purification with Ni-NTA, glutathione agarose, or other epitope tags.

Time Considerations

It takes 1.5 to 2 weeks to obtain a spinner culture from a frozen vial of *Sf9* cells. A viral stock can be obtained in ~4 days and plaqued in 1 day. It takes ~1 week before the plaques are formed and ready to be counted.

It takes an additional 2 days to infect *Sf9* cells to obtain cells or medium for protein analysis. Analyzing for the recombinant protein after harvesting should take 1 to 3 days. Finally, it will take ~4 days to complete the time course and another 2 to 3 days to harvest and analyze the infected cell pellets or culture supernatants.

EXPRESSION OF PROTEINS IN MAMMALIAN CELLS

SECTION III

Transient Expression of Proteins Using COS Cells

UNIT 16.12

This unit describes the use of COS cells to efficiently produce a desired protein in a short period of time. These cells express high levels of the SV40 large tumor (T) antigen, which is necessary to initiate viral DNA replication at the SV40 origin. Three factors contribute to make COS cell expression systems appropriate for the high-level, short-term expression of proteins: (1) the high copy number achieved by SV40 origin-containing plasmids in COS cells 48 hr post-transfection, (2) the availability of good COS cell expression/shuttle vectors, and (3) the availability of simple methods for the efficient transfection of COS cells. Each COS cell transfected with DNA encoding a cell-surface antigen (in the appropriate vector) or cytoplasmic protein will express several thousand to several hundred thousand copies of the protein 72 hr post-transfection. If the transfected DNA encodes a secreted protein, up to 10 μg of protein can be recovered from the supernatant of the transfected COS cells 1 week post-transfection. COS cell transient expression systems have also been used to screen cDNA libraries, to isolate cDNAs encoding cell-surface proteins, secreted proteins, and DNA binding proteins, and to test protein expression vectors rapidly prior to the preparation of stable cell lines (UNIT 9.5).

BASIC
PROTOCOL

This transfection protocol is a modification of that presented in UNIT 9.2 and gives conditions for optimal transfection of COS cells. The main difference between this procedure and that in UNIT 9.2 is the composition of the DEAE-dextran/chloroquine solution, which is prepared here in PBS, not TBS, and contains chloroquine to prevent the acidification of endosomes presumed to carry the DEAE-dextran/DNA into the cell. (This acidification results in acid hydrolysis of the DNA, giving rise to mutations and destruction of the DNA.) With this protocol, 40% to 70% of the cells can be routinely transfected.

Materials

- Appropriate vector (see Background Information)
- COS-7 cells to be transfected (see Critical Parameters), adapted to growth in 2% serum (see annotation to step 2)
- Dulbecco's minimum essential medium (DMEM) with 2% calf serum (DMEM-2 CS)
- DMEM with 2% NuSerum (Collaborative Research) (DMEM-2 NS), 37°C
- Phosphate-buffered saline (PBS; APPENDIX 2)
- DEAE-dextran/chloroquine solution: PBS containing 10 mg/ml DEAE-dextran (Sigma) + 2.5 mM chloroquine (Sigma)
- 10% dimethyl sulfoxide (DMSO; Sigma) in PBS (see APPENDIX 2 for PBS)
- 0.5 mM EDTA in PBS
- 100-mm tissue culture dishes
- Humidified 37°C, 6% CO₂ incubator
- Phase-contrast microscope
- Sorvall RT-6000B rotor (or equivalent)

Supplement 60

Additional reagents and equipment for subcloning of DNA (UNIT 3.16), preparation of miniprep DNA (UNIT 1.6), purification of DNA by CsCl/ethidium bromide equilibrium centrifugation (UNIT 1.7), and flow cytometric analysis (Otten et al., 1995)

NOTE: All cell culture incubations should be carried out in a humidified 37°C, 6% CO₂ incubator unless otherwise stated.

1. Subclone the gene of interest into the appropriate vector to obtain the desired recombinant DNA (UNIT 3.16). Purify the recombinant DNA by a miniprep procedure (5-ml culture UNIT 1.6), or by CsCl/ethidium bromide centrifugation (UNIT 1.7).
2. Seed COS-7 cells in DMEM-2 CS at ~20% confluence per 100-mm dish the day prior to transfection (so they will be ~50% confluent the next day). Grow cells overnight to ~50% confluence.

The COS-7 cells should be adapted to 2% serum (from the usual 10% serum) by passaging them through decreasing concentrations of serum, in 2% increments, over ~1 month. The procedure can be carried out in 10% serum, but at much greater expense.

A confluent dish of COS-7 cells (~10⁶ cells) is usually split 1:5 on the day prior to transfection to give 2 × 10⁵ cells/100-mm dish in 10 ml of DMEM-2 CS. In some cases cells may benefit from an extra day of growth prior to transfection (see step 6 annotation).

3. Just before use (for each 100-mm dish of COS cells to be transfected), thoroughly mix 5 ml of 37°C DMEM-2 NS with 0.2 ml of DEAE-dextran/chloroquine solution. Add 5 to 10 µg recombinant DNA and mix.

It is important that the DEAE-dextran be well mixed with the medium before the DNA is added—otherwise, the DNA, a negatively charged polymer, will form large precipitates with DEAE-dextran, a positively charged polymer. These large precipitates cannot be taken up by the cell, resulting in a reduced transfection efficiency. When larger dishes are used, the amount of medium/DEAE/DNA should be sufficient to easily cover the cells and should include 400 µg/ml DEAE-dextran, 100 µM chloroquine, and 1 to 2 µg/ml DNA in DMEM-2 NS.

Either CsCl-purified (UNIT 1.7) or miniprep (UNIT 1.6) plasmid DNA can be used for the transfections. If miniprep DNA is used, use one-fifth of the miniprep per transfection.

4. Aspirate medium from COS cells and add the DMEM-2 NS/DEAE-dextran/DNA prepared in step 3. Incubate cells 3 to 4 hr. Observe the cells using a phase-contrast microscope.

The DEAE-dextran will cause cells to retract and become vacuolated. Efficiency of transfection increases with longer incubation periods; on the other hand, so does cell death. The 3- to 4-hr incubation suggested here is a good starting point. However, several time points should be tried to optimize transfection of the particular population of cells used.

5. Aspirate DMEM/DEAE-dextran/DNA and add 5 ml of 10% DMSO (prepared in PBS). Incubate cells 2 min at room temperature.

The DMSO shock results in increased transfection efficiencies. Without this step, transfection efficiencies might be lower by a factor of two or more.

6. Aspirate DMSO and add 10 ml DMEM-2 CS. Grow cells overnight (12 to 20 hr).

If a significant number of the cells have lifted from the plate after overnight growth, the procedure will need to be repeated, but cells should be allowed to grow an extra day at step 2.

7. Passage (split and replat) each 100-mm dish of transfected COS cells into two new 100-mm dishes.

After transfection, the COS cells will look unhealthy. Passaging them the day after transfection facilitates recovery, resulting in better levels of protein expression. In addition,

DEAE-dextran treatment makes the cells sticky, and passaging the cells the morning after transfection restores their adhesion characteristics so that they may be once again lifted by a gentle treatment with PBS and EDTA (see step 8b).

- 8a. *When expressing secreted proteins:* 96 hr (4 days) after completing step 7, add 5 ml DMEM-2 CS and incubate 4 days. Harvest the medium, remove dead cells and debris by centrifuging 10 min in a Sorvall RT-6000B rotor at ~2000 rpm (~1000 × g), room temperature, and save the supernatant (see Anticipated Results). Detect secreted proteins by bioassay (UNIT 9.5) or by metabolic labeling and immunoprecipitation (UNITS 10.18 & 10.16), immunoaffinity chromatography (UNIT 10.11), radioimmunoassay (UNIT 11.17), or western blotting (UNIT 10.8).

Do not aspirate the old medium prior to addition of 5 ml DMEM-2 CS because this medium contains the secreted protein. Addition of extra medium 96 hr post-transfection results in better yield of expressed protein; however, it also increases the level of total protein (since the medium contains 2% serum), which could complicate protein purification. To eliminate this problem, COS cells can be placed in serum-free medium 10 to 12 hr after they have been replated, although (in our hands) this results in a 10-fold lower yield of expressed protein than in the presence of serum. Thus, unless it is absolutely necessary to remove additional contaminating protein, serum should be present in the medium even at reduced levels (1%).

- 8b. *When expressing cell-surface or intracellular proteins:* Aspirate medium from cells 72 hr (3 days) after transfection in step 6. Add 5 ml PBS, swirl, and aspirate PBS. Add 5 ml of 0.5 mM EDTA in PBS and incubate 15 min. Lift cells from the dish by gently dislodging them with a Pasteur pipet. Stain cell-surface proteins with the appropriate fluorescent antibody and detect by microscopy or flow cytometry (Otten et al., 1995).

Transfected COS cells will tend to clump when lifted from the dish. Pipetting the cells up and down will tend to disrupt these clumps. More effective dispersion of the clumps can be obtained by forcing the cells through a 100- μ M nylon mesh.

COMMENTARY

Background Information

COS cells

COS cells are African green monkey kidney cells (CV-1) that have been transformed with an origin-defective SV40 virus, which has integrated into COS cell chromosomal DNA. Therefore, COS cells produce wild-type SV40 large T antigen but no viral particles. Since SV40 large T antigen is the only viral protein required *in trans* for viral replication (i.e., its coding sequence need not be located on the DNA molecule on which it acts), SV40 origin-containing plasmids replicate in these cells to a high copy number (10,000 to 100,000 copies/cell) 48 hr post-transfection. If the plasmid carries a cDNA or genomic insert encoding a desired protein (under the control of the appropriate promoter), COS cells will express the protein at relatively high levels over a short period of time. Transfected COS cells produce protein in a burst that starts ~24 hr post-trans-

fection and can last for up to a week. However, due to the excessive burden placed on the transfected cell by the replicating plasmid and the high levels of protein production, the transfected cells typically either die or lose the plasmid a week after transfection.

COS cells were developed by Yakov Gluzman (1981) as a host for the propagation of SV40 virus early-region mutants. The first SV40 origin-containing plasmids to be used in conjunction with COS cells were made by Lusky and Botchan (1981). Short-term expression systems using both COS cells and SV40 origin-containing plasmids were initially used to identify DNA sequences required for transcription of the human α 1-globin gene (Mellon et al., 1981).

COS cells were first used to produce cell-surface and secreted proteins by Rose and Bergmann (1982), who looked at the expression of wild-type and mutant vesicular stomatitis virus glycoprotein in transfected cells. This

technique was subsequently used to study the expression of insulin (Laub and Rutter, 1983), somatostatin (Warren and Shields, 1984), and acetylcholine receptors (Mishina et al., 1984). These experiments demonstrated that COS cells could be used to express biologically active cell-surface and secreted proteins. Furthermore, these proteins were correctly processed although they are normally not produced by COS cells.

COS cell expression was initially used to screen a cDNA library to isolate a cDNA encoding human granulocyte/macrophage colony-stimulating factor (Wong et al., 1985). This was subsequently extended to isolation of cDNAs encoding cell-surface proteins (Aruffo and Seed, 1987a; Seed and Aruffo, 1987) and DNA-binding proteins (Tsai et al., 1989).

The expressed protein produced in COS cells is in most cases biologically active. However, although COS cells are able to carry out some post-translational modifications, they may not modify the expressed protein in exactly the same way as the cell that would normally produce it. For example, COS cells do not express the α -(1,3)fucosyltransferase, which is capable of transferring fucose to either sialyl or asialyl precursors (Goelz et al., 1990). In addition, insufficient post-translational modification occurs in the case of lymphocyte cell-surface proteins, which tend to be underglycosylated in COS cells (Aruffo and Seed, 1987b). This might be due to an overburdening of the COS cell glycosylation machinery by the high levels of protein expression and/or by the lack of enzymes required to carry out the full post-translational modifications.

An alternative to COS cells is provided by WOP cells (Dailey and Basilico, 1985), which are mouse 3T3 cells transformed by an origin-defective polyoma virus. Like COS cells, they produce no viral particles. However, they produce polyoma large T antigen and are therefore capable of replicating a plasmid containing a polyoma origin of replication to a copy number that is typically ten times lower than that obtained in COS cells. WOP cells are also more delicate than COS cells, making them harder to transfect. For these two reasons, COS cells should be used whenever possible. However, WOP cells should be used in those cases where a monoclonal antibody that is used to identify and/or purify the protein being expressed cross-reacts with COS cell proteins. This situation has arisen when transient expression in COS cells was carried out in order to clone a human

protein with a mouse anti-human monoclonal antibody that also recognizes the equivalent monkey protein (Seed and Aruffo, 1987). In this situation, the mouse cell line presented a useful alternative to COS cells by avoiding monoclonal antibody cross-reactivity.

Vectors

The main requirements of any COS cell expression/shuttle vector are: (1) an SV40-derived origin of replication, (2) appropriate eukaryotic transcription regulatory elements (i.e., enhancer, promoter, and polyadenylation signal sequences), (3) a prokaryotic origin of replication, and (4) a prokaryotic genetic marker for selection in *Escherichia coli*. A particularly useful example of such a vector is CDM8 (Fig. 16.12.1; Seed, 1987). The eukaryotic transcription element of CDM8 is composed of the cytomegalovirus (CMV) enhancer-promoter, with an SV40 virus-derived intron and polyadenylation signal; the CMV promoter is a *cis* element (i.e., one that must be located adjacent to the DNA it acts on) that directs transcription of the DNA subcloned downstream from it. The prokaryotic genetic marker in CDM8 is provided by the *supF* (amber suppressor) gene. CDM8 is propagated in host bacterial cells containing helper plasmid P3, which contains amber mutations in the genes responsible for tetracycline and ampicillin resistance. (P3 has been introduced into many *E. coli* strains.) When CDM8 is transformed into an *E. coli* strain containing P3, the amber mutations are suppressed, rendering the host resistant to tetracycline and ampicillin. In addition to these elements, the CDM8 expression/shuttle vector contains an M13 origin of replication so that it can be used for the production of single-stranded DNA, a T7 RNA polymerase promoter for preparation of mRNA *in vitro*, and a polyoma virus-derived origin of replication which permits plasmid replication in WOP cells.

Other vectors commonly used for COS cell transient expression include pXM (Yang et al., 1986) and pDC201 (Sims et al., 1988). These two plasmids contain the adenovirus-2 major late promoter and tripartite mRNA leader. This element acts in conjunction with the adenovirus VA RNA (also produced by the vectors) to increase the translatability of the mRNA encoding the desired protein. It is thought that adenovirus VA RNAs increase translation efficiency of mRNAs containing the major late promoter tripartite leader by facilitating the

Figure 16.12.1 CDM8. CDM8 (Seed, 1987) is a COS cell expression/shuttle vector that contains an SV40-derived origin of replication (SV40 ori), eukaryotic transcription regulatory elements [splice and poly(A)⁺], a prokaryotic origin of replication (π vX; derived from the pBR322 ori), and a prokaryotic genetic marker (*supF*). In addition, CDM8 contains an M13 origin of replication (M13 ori), a T7 RNA polymerase promoter ($p_{CMV/T7}$), and a polyoma-derived origin of replication (Py ori). Any restriction endonuclease sites shown can be used for cloning, but the inserted fragment must have its 5' end nearest the enhancer $p_{CMV/T7}$. The stuffer sequence is used to detect a size difference after restriction digestion.

interaction between mRNA and a 43S ribosomal protein translation preinitiation complex (Kaufman, 1985).

Critical Parameters

Efficiency of transfection depends critically on the length of time that the cells (COS or other cells) are incubated in the presence of DEAE-dextran/DNA. Longer periods of time result in higher transfection efficiencies. However, the DEAE-dextran/chloroquine solution is quite toxic to cells and in general, cells should not be in its presence for >4 hr. In the past, DEAE-dextran transfections were carried out in the absence of serum, because a precipitate of unknown composition that seemed to be very toxic formed in DEAE-dextran/calf serum mixtures. Medium containing NuSerum, on the other hand, does not form this precipitate and tends to enhance the ability of the cells to tolerate DEAE-dextran; thus NuSerum should always be included in transfection medium.

Efficiency of transfection can also be affected by the quality of the DNA and the age of the DEAE-dextran/chloroquine solution. It is preferable to use CsCl-purified or other highly purified DNA whenever possible (*UNIT*

1.7). However, miniprep DNA (*UNIT* 1.6) or DNA purified using a pZ523 column (5'→3') or by other methods can also be used. The DEAE-dextran chloroquine solution can be kept at 4°C for several months but it is wise to prepare it fresh about every 3 months.

COS cells can be obtained from the American Type Culture Collection; several sublines exist, including COS-1 and COS-7. The COS-7 subline is recommended because it produces a higher plasmid copy number. These cells grow as a monolayer in DMEM-2 CS in a humidified 37°C, 5% CO₂ incubator; however, the ATCC grows its COS cells in DMEM-10 fetal bovine serum (FBS). Since serum is expensive, changing the growth medium is worthwhile. The change from FBS to CS should be done slowly over 1 to 2 weeks; the concentration of CS should then be reduced to 2% in 2% increments over ~1 month.

Because the growth characteristics, transfectability, and protein expression properties of COS cells change with time and with repeated subculturing, and because these changes tend not to favor the production of high levels of proteins, it is prudent to freeze aliquots of the original COS cell stock in DMEM-10 CS/10%

DMSO for later use in a -70°C freezer for 24 hr and then transfer them to a -150°C (liquid nitrogen) freezer. COS cells grow rapidly requiring passage every 4 to 5 days; typically, a confluent plate of cells is split 1 to 10.

To obtain good levels of transient protein production from transfected COS cells, it is very important to replat the transfected cells onto new dishes with fresh medium the morning after transfection. In addition to enhancing protein production, replating the transfected cells allows lifting of the cells from the dish using only PBS/EDTA (without trypsin). This is very important when transient expression by COS cells is used to produce cell-surface proteins.

Anticipated Results

The Basic Protocol should yield transfection efficiencies of 40% to 70%. When COS cells are being used to produce cell-surface or intracellular proteins, it can be expected that each transfected cell will express several thousand copies of this protein (10,000 to 100,000 copies/cell) 72 hr post-transfection. If COS cells are used to produce secreted proteins, up to 1 $\mu\text{g}/\text{ml}$ of protein can be recovered from the supernatant of a 100-mm dish of transfected cells 1 week post-transfection. However, the amount of protein produced by COS cells can vary dramatically depending on the protein being produced. This was the case when COS cells were used to produce soluble immunoglobulin fusion forms of cell-surface proteins (Aruffo et al., 1990). In this case, one of the fusion proteins, CD8 immunoglobulin, was secreted from COS cells at high levels (1 $\mu\text{g}/\text{ml}$) while the other, CD44 immunoglobulin, was secreted very poorly if at all. It was found that the CD44 fusion protein was sequestered inside the cell. To obtain efficient secretion of the CD44 fusion protein, it was necessary to change the amino-terminal signal sequence of the CD44 fusion protein. Interestingly, the native cell-surface forms of both CD8 and CD44 are expressed equally efficiently on the surface of transfected COS cells. For some of these immunoglobulin fusion proteins, 0.5 ml of medium contained plenty of protein (~500 ng) after concentration using a protein A affinity matrix. In some cases, it is possible to use such COS cell supernatants directly without further purification (Aruffo et al., 1990).

Time Considerations

It is important not to transfect the cells too soon after replating; >8 to 12 hr should pass

between the time the cells are seeded on the plate and the time of transfection. Once the transfection has started, the DEAE-dextran/DNA mixture should be left on the cells for a minimum of 2 hr and a maximum of 4 hr; because the mixture increases transfection efficiency it should remain in contact with the cells as long as they appear viable. After transfection, the cells look quite unhealthy, and 12 to 24 hr post-transfection they should be replated in new dishes with fresh medium.

The peak of plasmid replication in transfected COS cells occurs 48 to 72 hr post-transfection. Protein production starts 24 hr post-transfection but peaks 72 to 96 hr post-transfection. Thus, when expressing cell-surface or cytoplasmic proteins, the cells should be harvested 72 to 96 hr post-transfection. However, transfected cells continue to produce protein for up to a week post-transfection and when expressing secreted proteins, the supernatants should be harvested a week post-transfection.

Expression and Purification of Epitope-Tagged Multisubunit Protein Complexes from Mammalian Cells

Biochemical characterization and functional studies of mammalian proteins are often hampered by the availability of the purified protein, in particular, when the functional entity is present as a multisubunit protein complex in the cell. To overcome the difficulties in the purification of multisubunit protein complexes from mammalian cells, one may create stable cell lines containing epitope-tagged protein. In general, a stable cell line that expresses an epitope-tagged subunit of a protein complex is first established either by retrovirus-mediated gene transfer (for constitutive expression) or by a tetracycline-regulated system (for inducible expression). Immunoaffinity purification using epitope-specific monoclonal antibody-conjugated beads is then performed to pull down the epitope-tagged multisubunit protein complex, which is finally recovered by peptide elution under neutral pH or physiological conditions and is readily available for functional assays.

Several commonly used epitopes are listed in Table 10.15.1 (UNIT 10.15). For simplicity, only protocols using the FLAG epitope (Asp-Tyr-Lys-Asp-Asp-Asp-Asp-Lys, or DYKDDDDK) are described here. The authors normally use human HeLa cells, which can grow in monolayer as well as in suspension, as parental cells for establishing stable cell lines, although other cells, such as human 293, can also be used for the experiments. By and large, HeLa-derived cell lines expressing an epitope-tagged protein are initially isolated in monolayer culture and then adapted to suspension culture for the purpose of collecting large quantities of cells for protein purification. The first protocol in this unit (see Basic Protocol 1) describes the procedures involved in the establishment of a stable cell line constitutively expressing the FLAG-tagged protein by retrovirus-mediated gene transfer and immunoaffinity purification of the epitope-tagged multisubunit protein complex. The next protocol (see Basic Protocol 2) outlines the steps involved in the establishment of an inducible cell line conditionally expressing the FLAG-tagged protein by a tetracycline-regulated system, and the one-step immunoaffinity purification of the multisubunit protein complex.

Since an epitope-tagged protein may exist as different complexes in the cell, it is also important to isolate various forms of multisubunit protein complexes. This can sometimes be achieved simply by careful selection of the starting material (e.g., using nuclear extract, cytoplasmic S100 fraction, or the chromosomal fraction) for immunoaffinity purification or by manipulating the wash conditions with different concentrations of salt, detergent, and chaotropic agents during immunoaffinity purification. The Alternate Protocol provides an excellent example for the purification of different forms of human RNA polymerase II complexes, achieved simply by choosing the appropriate starting material and by varying wash conditions. Frequently, multiple forms of the epitope-tagged protein complexes coexist in the same starting material. In that case, a simple chromatographic column, such as the P11 ion-exchange resin, can be used to separate multiple forms of protein complexes into different fractions prior to immunoaffinity purification. The isolation of various human TATA-binding protein (TBP)-containing complexes, described in the Support Protocol, is a good example of combining the P11 column and immunoaffinity purification. These protocols, collectively, illustrate a powerful methodology in applying epitope tagging and stable cell line approaches for the purification of multisubunit protein complexes from mammalian cells.

PURIFICATION OF MULTISUBUNIT PROTEIN COMPLEXES FROM CLONAL CELL LINES CONSTITUTIVELY EXPRESSING A FLAG-TAGGED PROTEIN

To purify a multisubunit protein complex, the authors usually begin with a constitutive expression system using retrovirus-mediated gene transfer for the establishment of clonal cell lines expressing the FLAG-tagged subunit of a protein complex. Retrovirus-mediated gene transfer (*UNITS 9.9-9.14*) provides a gene delivery system with few copies of the viral integrant to ensure the expressed FLAG-tagged protein can be efficiently assembled into a large protein complex, in a stoichiometric ratio, with endogenous cellular proteins. A retroviral vector containing a drug-selection marker and the FLAG sequence introduced either at the N-terminus or at the C-terminus of the protein-coding region is first created and delivered into a packaging cell line that provides all the viral proteins essential for virion assembly. Viral particles are then collected from the cell culture medium and used to infect HeLa or other chosen cells. Cellular clones potentially expressing the tagged protein are initially selected by drug resistance and further identified by immunoblotting from individually expanded colonies. Clonal cell lines expressing the FLAG-tagged protein are then adapted to suspension culture and used for immunoaffinity purification of the epitope-tagged protein complexes.

*NOTE:*All culture incubations should be performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

Materials

FLAG-tagged protein-coding sequence
Retroviral vector (e.g., pBabe neo, Morgenstern and Land, 1990; also see *UNITS 9.9-9.14*)
2× HEPES-buffered saline (HBS), pH 7.12 (*UNIT 16.14*)
0.25 M CaCl₂
Retrovirus-packaging cells (e.g., Ψ_{CRIP} , Danos and Mulligan, 1988)
Dulbecco's modified Eagle's medium (DMEM) with and without 10% calf serum
15% (v/v) glycerol/DMEM
DMEM with 10% fetal bovine serum (FBS; *APPENDIX 3F*)
2.5 mg/ml polybrene stock solution
50% confluent HeLa cells
Drug-containing selection medium (e.g., 1 mg/ml of G418 (total weight), 0.2 mg/ml of hygromycin, or 0.5 $\mu\text{g/ml}$ of puromycin; see *UNIT 9.5*)
Trypsin-EDTA (*APPENDIX 3F*)
1× PBS (*APPENDIX 2*)
1× SDS-PAGE protein sample buffer (*UNIT 10.2A*)
Anti-FLAG M2 monoclonal antibody (and/or anti-protein antibodies; Sigma)
Joklik's medium (Sigma) with 10% calf serum and 5% calf serum
Anti-FLAG M2 monoclonal antibody-conjugated beads (Sigma)
BC100 (see recipe)
BC300 (see recipe)/0.1% Nonidet P-40
FLAG peptide (100 mg/ml in water)
Liquid nitrogen
5-ml round-bottom Falcon tube
60-mm and 100-mm tissue culture plates
15-ml sterile tube
0.45- μm cellulose acetate syringe filter
24-well tissue culture plate
1.5-ml and 0.5-ml microcentrifuge tubes

250-ml, 500-ml, 1-liter, 3-liter, and 12-liter spinner flasks
End-over-end tube rotator
Rotor (e.g., Sorvall H-6000A or equivalent)
Microcentrifuge spin column

Additional reagents and equipment for use of retroviral vectors (*UNITS 9.9-9.14*),
preparation of nuclear extracts (*UNIT 12.1*), and immunoblotting (*UNIT 10.8*)

Establish stable cell lines by retrovirus-mediated gene transfer

1. Clone the FLAG-tagged protein-coding sequence into a retroviral vector containing a drug-selection marker (e.g., neomycin).

UNITS 9.9-9.14 describe the use of retroviral vectors.

2. Transfer 20 μg plasmid DNA into a 5-ml round-bottom Falcon tube and mix with 0.5 ml of 2 \times HBS, pH 7.12.

The following transfection procedure works well for Ψ_{CRIP} and many other packaging cell lines.

3. Add 0.5 ml of 0.25 M CaCl_2 dropwise while vortexing. Leave for 20 to 30 min at room temperature.
4. Vortex the calcium phosphate–DNA coprecipitates vigorously and then add the solution to 50% confluent Ψ_{CRIP} cells, which are maintained in DMEM plus 10% calf serum in a 100-mm tissue culture plate. Leave cells for 3 to 4 hr in a 37°C, 5% CO_2 incubator.
5. Remove medium and add 3 ml of 15% (v/v) glycerol/DMEM for 3 min at room temperature.
6. Add 8 ml DMEM to quickly dilute glycerol, mix well, and remove solution.
7. Repeat washes three additional times with 3 ml DMEM for each wash.
8. Add 10 ml DMEM with 10% calf serum to transfected cells and leave plates for 18 hr in a 37°C, 5% CO_2 incubator.
9. Collect viral particles in a 15-ml sterile tube after filtering cell culture supernatant (18-hr post glycerol shock) through a 0.45- μm cellulose acetate syringe filter to remove floating cells and large cellular debris.
10. Mix 1 ml of filtered viral stock with 1 ml of DMEM plus 10% FBS and polybrene (final concentration 8 $\mu\text{g}/\text{ml}$), and incubate mixture with 50% confluent HeLa cells, which are grown in DMEM with 10% FBS in 100-mm cell culture plates and have been prewashed with medium two times, for 2.5 hr at 37°C with intermittent mixing.
11. Add an additional 8 ml of DMEM with 10% FBS, without removing the original infection medium, and leave cells for 1 to 1.5 days in a 37°C, 5% CO_2 incubator.
12. Split cells 1:5 in drug-containing medium and change the selection medium every 3 to 4 days.

The drug concentrations normally used for HeLa cells, depending on individual drug-selection markers, are: 1 mg/ml of G418 (total weight), 0.2 mg/ml of hygromycin, or 0.5 $\mu\text{g}/\text{ml}$ of puromycin. See UNIT 9.5 for additional details.

Drug-resistant colonies are usually visible after 2 to 3 weeks.

Identify clonal cell lines expressing FLAG-tagged protein

13. Prepare a 24-well plate and add 2 drops (~100 μ l) of trypsin-EDTA to each well at alternate positions to avoid cross contamination between neighboring wells.
14. Circle the drug-resistant colonies (~2- to 3-mm diameter), to be picked up, on the bottom of the plate with a black (or blue) marker pen, remove medium, wash cells once with 1 \times PBS, and then remove solution.
15. Take ~50 μ l of trypsin-EDTA from the first well using a 200- μ l pipet tip and transfer a circled colony back to the first well after pipetting up and down several times.
16. Repeat the transfer process for a total of 12 colonies.
17. Add 1 to 2 ml of selection medium to each well and put the 24-well cell culture plate back to a 37°C, 5% CO₂ incubator for cells to attach and grow.

Depending on the number of viable cells transferred, it may take 3 to 14 days for cells to become confluent in the wells.

18. Transfer cells to a 60-mm cell culture plate when they become confluent in the 24-well plate and continue the expansion for individual cellular clones.
19. When cells are nearly confluent on the 60-mm cell culture plate, split cells again to one 60-mm cell culture plate and two 100-mm cell culture plates.

The cells grown on the 100-mm plates will be frozen down as individual cloned cell lines.

20. Prepare whole-cell lysates from 80% to 90% confluent cells still in log phase grown on the 60-mm cell culture plate by adding 300 μ l of 1 \times SDS-PAGE protein sample buffer to plate, after washing cells two times with 1 \times PBS. Pipet lysate up and down many times until the sample is no longer viscous, and then transfer the lysate to a 1.5-ml microcentrifuge tube.
21. Perform immunoblotting (*UNIT 10.8*) on individually collected whole-cell lysates with anti-FLAG M2 monoclonal antibody and/or anti-protein antibodies to identify the cellular clones that express FLAG-tagged protein.

Purify FLAG-tagged protein complexes from established cell lines

22. Select a positive clone expressing FLAG-tagged protein for further expansion by adapting it to suspension culture. Combine cells from twelve 100-mm cell culture plates into a 250-ml spinner flask and adjust the cell density to 0.5×10^6 cells/ml using Joklik's medium with 10% FBS. Maintain cells at the same density using Joklik's medium with 10% FBS for ≥ 3 days. If cells are healthy and nearly grow exponentially, start to feed cells using Joklik's medium with 10% calf serum. Continue feeding cells using Joklik's medium with 10% calf serum for at least three days. If cells still look healthy and grow well, begin to feed cells using Joklik's medium with 7.5% (or 5%) calf serum.

During the expansion and serum-switching/reducing process, if cells look unhealthy or cell density drops, centrifuge cells for 5 min at $300 \times g$ and resuspend cells in fresh Joklik's medium with the same concentration of calf serum, this helps to remove cell debris. Readjust the cell density to 0.5×10^6 cells/ml. Once cells are healthy and continue to grow, begin to lower the concentration of serum as previously described. Repeat the process until cells are maintained in Joklik's medium with 5% calf serum.

23. Grow and expand the cells growing in Joklik's medium with 5% calf serum continually to 20 liters or any other desired volume.

24. Prepare nuclear extract, cytoplasmic S100, and nuclear pellet (or chromosomal fraction) according to *UNIT 12.1* (Dignam et al., 1983).
25. Perform immunoblotting (*UNIT 10.8*) to identify the cellular fractions containing FLAG-tagged protein.
26. Add 0.4 ml of anti-FLAG M2 monoclonal antibody-conjugated beads, which have been prewashed several times with BC100, to a 15-ml tube containing 10 to 14 ml of nuclear extract (or S100, or solubilized nuclear pellet). Incubate the sample for 6 to 12 hr at 4°C on an end-over-end tube rotator.
27. Centrifuge for 2 min at $300 \times g$ (Sorvall H-6000A rotor 1000 rpm), 4°C, to separate supernatant from beads.
28. Remove the supernatant and wash protein-bound beads five times with BC300/0.1% Nonidet P-40.
Inclusion of Nonidet P-40 prevents protein/bead aggregation and also helps the immunoaffinity beads rotate better during the elution step.
29. Transfer the M2-conjugated beads with bound proteins to a microcentrifuge spin column.
30. Microcentrifuge for 10 sec at maximum speed (10,000 rpm) to remove the residual liquid.
31. Add 0.5 ml of BC300/0.1% Nonidet P-40 plus 0.2 mg/ml of FLAG peptide to the dried beads. Mix well and incubate for 20 to 60 min at 4°C with continuous rotation.
32. Collect the eluate (i.e., the first elution) by centrifuging for 10 sec at 4°C.
33. Repeat the elutions (steps 31 and 32) for a total of four times to recover the majority of FLAG-tagged protein complexes.
34. Dispense samples into small aliquots (e.g., 20 μ l) in 0.5-ml microcentrifuge tubes and freeze in liquid nitrogen. Store aliquots of the purified complexes at -80°C until use.

PURIFICATION OF MULTISUBUNIT PROTEIN COMPLEXES FROM CLONAL CELL LINES CONDITIONALLY EXPRESSING THE FLAG-TAGGED PROTEIN

Sometimes, the introduced FLAG-tagged protein-coding sequence is not expressed in the established clonal cell lines following retrovirus-mediated gene transfer and drug selection. This is likely due to cytotoxicity resulting from unregulated or constitutive expression of the ectopic gene product. To overcome this problem, an inducible mammalian expression system can be used to turn “on” or “off” expression of the FLAG-tagged protein based on the use of tetracycline. In the process of establishing FLAG-tagged protein-expressing cell lines, tetracycline is continuously added to silence ectopic gene expression. The inducibility of individual cellular clones is then screened by immunoblotting using whole-cell lysates collected in the presence and absence of tetracycline. Once identified, the inducible cell line is adapted to suspension culture and used for immunoaffinity purification of FLAG-tagged multisubunit protein complexes after removing tetracycline.

**BASIC
PROTOCOL 2**

**Protein
Expression**

16.13.5

Materials

Protein-coding sequence
Tetracycline-regulated expression plasmid (e.g., pTetCMV-F^o(S), Wu and Chiang, 1996; UNIT 16.14)
Sheared calf thymus DNA
SacI-linearized plasmid containing a drug-selection marker (e.g., pREP4, Invitrogen)
Cell line expressing a tetracycline-controlled transactivator (e.g., HtTA-1, Gossen and Bujard, 1992)
DMEM with 10% FBS (APPENDIX 3F)
G418 sulfate
Trypsin-EDTA (APPENDIX 3F)
1 M BES buffer, pH 7.2 (see recipe)
Hygromycin B
Tetracycline
1× SDS-PAGE protein sample buffer (UNIT 10.2A)
1× PBS (APPENDIX 2)
Anti-FLAG M2 monoclonal antibody and/or anti-protein antibodies
Joklik's medium (Sigma) with 10% calf serum
Joklik's medium with 5% calf serum
HeLa cells
Anti-FLAG M2-conjugated beads
BC100 and BC300 (see recipe)
10% Nonidet P-40
FLAG peptide
Liquid nitrogen

0.4-cm cuvettes for electroporation
24-well, 60-mm, and 100-mm tissue culture plates
15-ml and 50-ml Falcon tubes
Rotor (e.g., Sorvall H-6000A or equivalent)
Electroporator (e.g., Bio-Rad Gene Pulser II)
Disposable glass pipet
1.5-ml and 0.5-ml microcentrifuge tubes
250-ml, 500-ml, 1-liter, 3-liter, and 12-liter spinner flasks
250-ml sterile conical centrifuge tubes
Microcentrifuge spin column

Additional reagents and equipment for tissue culture (APPENDIX 3F) and immunoblotting (UNIT 10.8)

Establish tetracycline-regulated cell lines by electroporation

1. Clone the protein-coding sequence into a tetracycline-regulated expression plasmid containing the FLAG epitope sequence, such as pTetCMV-F^o(S).
2. Mix 10 μg of linearized tetracycline-regulated FLAG-tagged protein-expressing plasmid (e.g., *PvuI* used to linearize most pTetCMV-F^o(S)-derived constructs), 50 μg of sheared calf thymus DNA, and 0.5 μg of *SacI*-linearized pREP4, which contains a hygromycin-selection marker, into an electroporation cuvette.
3. Combine HtTA-1 cells (or other cells expressing a tetracycline-controlled transactivator), which are grown in DMEM with 10% FBS containing 0.6 mg/ml of G418, from several 100-mm cell culture plates into a 50-ml Falcon tube after trypsin-EDTA treatment, centrifuge for 5 min at 300 × *g* (Sorvall H-6000A rotor 1000 rpm), and

resuspend cell pellets in DMEM with 10% FBS and 5 mM BES buffer, pH 7.2, at a density of 2×10^7 cells/ml.

4. Add 250 μ l of resuspended cells, using a 200- μ l pipet tip to transfer 125 μ l of cells two times, to the electroporation cuvette containing plasmids and carrier DNA (see step 2). Mix well by pipetting up and down several times.
5. Electroporate DNAs into cells using the Bio-Rad Gene Pulser II with setting at 960 μ F and 200 V. Leave cuvette for 10 min at room temperature and then transfer cells, using a disposable glass pipet, to a 15-ml centrifuge tube containing 10 ml DMEM with 10% FBS.
6. Centrifuge for 5 min at $300 \times g$. Aspirate and discard the supernatant, which contains untransfected DNAs and cell debris generated by electroporation.
7. Resuspend cells in 5 ml DMEM with 10% FBS and distribute cells onto five 100-mm cell culture plates, each containing 9 ml DMEM with 10% FBS, and leave for 2 days in a 37°C , 5% CO_2 incubator.
8. Initiate drug selection by changing medium to DMEM with 10% FBS containing 400 $\mu\text{g/ml}$ of G418, 200 $\mu\text{g/ml}$ of hygromycin B, and 2 $\mu\text{g/ml}$ of tetracycline.
9. Change medium every 3 or 4 days and continue drug selection for ~ 3 weeks until drug-resistant colonies are clearly visible.

Identify clonal cell lines conditionally expressing FLAG-tagged protein

10. Pick up 12 to 24 drug-resistant colonies and expand them into cell lines following the procedures described in Basic Protocol 1, steps 13 to 18.
11. When cells are nearly confluent on the 60-mm cell culture plate during expansion, split cells to one 100-mm cell culture plate and two 60-mm cell culture plates.

The cells grown on the 100-mm cell culture plate will be frozen down as individual cloned cell lines. The cells grown on the two 60-mm cell culture plates are plated in selection medium, one with and the other without tetracycline, for 48 to 72 hr.

12. Prepare whole-cell lysates from cells grown on the two 60-mm cell culture plates by adding 300 μ l of $1\times$ SDS-PAGE protein sample buffer to each plate, after washing the cells two times with $1\times$ PBS. Pipet the lysate up and down many times until the sample is no longer viscous and then transfer lysate to a 1.5-ml microcentrifuge tube.
13. Perform immunoblotting (UNIT 10.8) on an aliquot of the individually collected whole cell lysates with anti-FLAG M2 monoclonal antibody and/or anti-protein antibodies to identify the cellular clones that express FLAG-tagged protein only in the absence of tetracycline.

Purify FLAG-tagged protein complexes from established cell lines

14. Select a positive clone expressing FLAG-tagged protein for further expansion by adapting it to suspension culture. Combine cells from twelve 100-mm cell culture plates into a 250-ml spinner flask (at a density of 0.5×10^6 cells/ml) and gradually replace medium from DMEM with 10% FBS to Joklik's medium with 10% calf serum, and eventually to Joklik's medium with 5% calf serum, but include 1 $\mu\text{g/ml}$ of tetracycline and 0.6 mg/ml of G418 to the medium throughout the expansion process until culture volume reaches 250 ml.
15. Continue to expand cells in tetracycline-containing medium, but omit G418 after 250 ml culture.

16. After expansion of cell culture to 12 liters, remove tetracycline by centrifuging cells for 5 min at $300 \times g$ (Sorvall H-6000A rotor 1000 rpm) using 250-ml sterile conical tubes. Repeat the process until all of the cells are consolidated into two 250-ml conical tubes.
17. Wash cell pellets with 250 ml of $1 \times$ PBS in each tube. Centrifuge for 5 min at $300 \times g$ (Sorvall H-6000A rotor 1000 rpm). Repeat washes for a total of 4 to 6 times.
18. Resuspend cell pellets in ~ 120 ml of Joklik's medium with 5% calf serum without tetracycline, and dispense cells into six 12-liter flasks, each containing 1.5 liters of Joklik's medium with 5% calf serum.
19. Four days after protein induction with medium doubling every day, prepare nuclear extract, cytoplasmic S100, and nuclear pellet (or chromosomal fraction) according to *UNIT 12.1*.

Protein induction in suspension culture usually takes longer than induction in monolayer culture. From the time course study, protein induction after 4 days maximizes the quantity of the induced FLAG-tagged protein, in part due to a reduced doubling time in a larger volume of suspension culture using less expensive and lower concentrations of calf serum. Induction also appears to work better under a slightly dilute condition with medium doubling every day.

20. Perform immunoblotting (*UNIT 10.8*) to identify the cellular fractions containing FLAG-tagged protein.
21. For immunoaffinity purification of FLAG-tagged protein complexes, follow the same procedures as described in Basic Protocol 1, steps 26 to 34.

**ALTERNATE
PROTOCOL**

PURIFICATION OF MULTIPLE FORMS OF EPITOPE-TAGGED PROTEIN COMPLEXES BY VARYING THE STARTING MATERIAL AND WASH CONDITIONS

Using human RNA polymerase II (pol II) as an example, this protocol describes the purification of epitope-tagged protein complexes. RNA pol II is a multisubunit protein complex containing 12 polypeptides (RPB1-12). The largest subunit (RPB1) of pol II has a unique C-terminal domain (CTD) containing heptapeptide sequence, Tyr-Ser-Pro-Thr-Ser-Pro-Ser (YSPTSPS), which occurs 26 times in yeast and 52 times in humans. This CTD can be phosphorylated by many protein kinases, resulting in three forms of pol II commonly found in eukaryotes. The IIO form of pol II contains a highly or hyper-phosphorylated CTD, whereas the IIA form of pol II has a non- or hypo-phosphorylated CTD. The IIB form of pol II does not have the CTD, likely generated due to protease cleavage. In addition, pol II can form an extremely large protein complex, so-called pol II holoenzyme, by association with a subset of general transcription factors and other cellular proteins involved in chromatin remodeling, mRNA processing, and DNA repair. This Alternate Protocol exemplifies an application of the epitope-tagging and stable cell line approaches for the simultaneous purification of the IIO, IIA, and IIB forms of pol II as well as pol II holoenzyme, which contains only the nonphosphorylated form of RPB1. This is achieved simply by careful selection of the starting material and by modifying the composition of protein buffer used for immunoaffinity purification (see Fig. 16.13.1). Please note that the conditions outlined herein will vary with other tagged protein systems.

Additional Materials (also see Basic Protocols 1 and 2)

- 10 M urea
- BC850 (see recipe)
- Buffer B (see recipe)

**Purification of
Epitope-Tagged
Multisubunit
Protein
Complexes**

16.13.8

Buffer D (see recipe)
 FLAG peptide elution buffer (see recipe)
 Ammonium sulfate
 Sonicator
 Rotor (e.g., Bechman 45-Ti or equivalent)

Purify FLAG-tagged human pol II holoenzyme

- 1a. Establish a tetracycline-regulated HeLa-derived cell line conditionally expressing a FLAG-tagged subunit of human pol II, and prepare nuclear extract, cytoplasmic S100, and nuclear pellet according to the procedures described in Basic Protocol 2, steps 1 to 20.
- 2a. For immunoaffinity purification of FLAG-tagged human pol II holoenzyme from nuclear extract or S100, follow Basic Protocol 1, steps 26 to 34, except use BC100/0.1% Nonidet P-40 as wash and elution buffer.

Purify IIA form of FLAG-tagged human pol II

- 1b. For immunoaffinity purification of FLAG-tagged human pol II from nuclear extract or S100, follow Basic Protocol 1, steps 26 to 34, except wash the protein-bound beads sequentially five times each with BC850/0.1% Nonidet P-40 containing 1.0 M urea,

Figure 16.13.1 Purification of human RNA polymerase II complexes. The hRPB9-3 cells (Wu and Chiang, 1998), derived from human HeLa cells that conditionally express the FLAG-tagged RPB9 subunit of human RNA polymerase II, are first separated into cytoplasmic S100, nuclear extract, and nuclear pellet. Immunoaffinity purification is then performed with S100 or nuclear extract under either low salt (100 mM KCl-containing buffer) or high salt (850 mM KCl and 1.0 M urea-containing buffer) wash conditions, which results in the purification of human RNA polymerase II (pol II) holoenzyme and pol II, respectively. The pol II holoenzyme complex purified from S100 or nuclear extract contains pol II, a subset of general transcription factors (TFIIB, TFIIH, TFIIF, and TFIIIE), SRBs, histone acetyltransferase GCN5, and chromatin remodeling factor SWI/SNF (Wu and Chiang, 1998; Wu et al., 1999). Additional forms of pol II complexes with different phosphorylation status on the largest subunit (RPB1) of pol II can also be purified from the nuclear pellet under the high salt wash condition. The IIO form of pol II contains the highly phosphorylated carboxy-terminal domain (CTD), indicated by a tail, in RPB1, whereas the IIA and IIB forms of pol II have non-phosphorylated or truncated CTD in RPB1, respectively.

and BC100, then finally elute the bound proteins with BC100 containing 0.2 mg/ml of FLAG peptide (FLAG peptide elution buffer).

Inclusion of high salt and urea during the washes disrupts the interactions between pol II and other weakly associated polypeptides found in the pol II holoenzyme, thereby allowing the recovery of only the IIA form of the core pol II, which forms a tight complex resistant to high salt and urea washes.

Purify FLAG-tagged human pol II containing a mixture of IIA, IIB, and IIO forms

1c. Slowly agitate 35 ml of nuclear pellet isolated from hRPB9-3, which is a HeLa-derived cell line conditionally expressing the FLAG-tagged RPB9 subunit of human pol II, with 70 ml of buffer B at 4°C (or on ice) and then with 11 ml of 3 M (NH₄)₂SO₄ to adjust the ammonium sulfate concentration to 0.3 M. Stir for an additional 30 min.

The use of buffer B together with ammonium sulfate provides both a magnesium ion and high salt concentration to help dissociate pol II complexes from the chromosomal fraction and at the same time preserve pol II activity.

2c. Sonicate five times, for 1 min each, on an ice water slurry with 20-sec intervals between bursts.

3c. Centrifuge the mixture for 90 min at 185,000 × g (Beckman 45-Ti rotor 40,000 rpm), 4°C, and then pour the supernatant into a 500-ml beaker.

4c. Add 2 volumes of buffer B dropwise with a syringe to gradually adjust the ammonium sulfate concentration to 0.1 M.

5c. Remove precipitated material by centrifuging for 60 min at 185,000 × g (Beckman 45-Ti rotor 40,000 rpm) and pour supernatant to another 500-ml beaker.

6c. Precipitate pol II by slowly adding solid ammonium sulfate to 65% saturation (i.e., 0.42 g/ml of suspension) and stir for an additional 30 min.

7c. Centrifuge for 60 min at 142,000 × g (Beckman 45-Ti rotor 35,000 rpm) and resuspend the pellet in 40 ml of buffer D.

8c. Dialyze the sample against 4 liters of BC100 for 6 hr with at least one change of buffer.

The final recovered sample is ~46 ml.

9c. For immunoaffinity purification of FLAG-tagged human pol II complexes containing a mixture of IIA, IIB, and IIO forms, follow Basic Protocol 1, steps 26 to 34, except sequentially wash the protein-bound beads with five times each of BC850/0.1% Nonidet P-40 with 1.0 M urea, and BC100, before final elutions with BC100 containing 0.2 mg/ml of FLAG peptide (FLAG peptide elution buffer).

The inclusion of high salt and urea during the initial washes disrupts the interactions between pol II and other weakly associated polypeptides found in the pol II holoenzyme, thereby allowing the recovery of core pol II complexes with different phosphorylation states. Equilibration of the immobilized complexes to BC100 is necessary before final elutions with FLAG peptide BC100 elution buffer.

PURIFICATION OF MULTIPLE FORMS OF EPITOPE-TAGGED PROTEIN COMPLEXES FOLLOWING A P11 ION-EXCHANGE CHROMATOGRAPHIC COLUMN

Human TATA-binding protein (TBP) can associate with different classes of cellular proteins to form distinct protein complexes, such as SL1, TFIID, and TFIIB, which are required for transcription by RNA polymerase I, II, and III, respectively. These distinct protein complexes are all found in nuclear extract. A simple chromatographic step, such as a P11 ion-exchange column, is then used to separate various TBP-containing complexes into different fractions prior to immunoaffinity purification (see Fig. 16.13.2). This Support Protocol illustrates an application of conventional chromatography together with immunoaffinity purification for the isolation of multiple protein complexes containing a common subunit.

Additional Materials (also see Basic Protocol 1)

- P11 ion-exchange resin
- Various BC buffers (BC100, BC300, BC500, BC850, and BC1200; see recipe)
- Chromatographic column (~100 ml capacity)
- Flow adapter
- Chart recorder
- Fraction collector
- Dialysis tubing (MWCO 12,000; Sigma)
- Additional reagents and equipment for dialysis (APPENDIX 3C)

Purify TFIID and TFIIB from a cell line expressing FLAG-tagged human TBP

1. Establish a HeLa-derived cell line expressing FLAG-tagged human TBP by retrovirus-mediated gene transfer (UNITS 9.9.9.14) and prepare nuclear extract, S100, and nuclear pellet from the established cell line using the procedures described in Basic Protocol 1, steps 1 to 24.
2. Pack a P11 ion-exchange column containing ~60 ml of resin in a chromatographic column.
3. Connect the column to a flow adapter, a chart recorder, and a fraction collector, and equilibrate the whole system with BC100 overnight. Set the flow rate at ~1 column volume (CV) per hr (i.e., 1 ml/min).

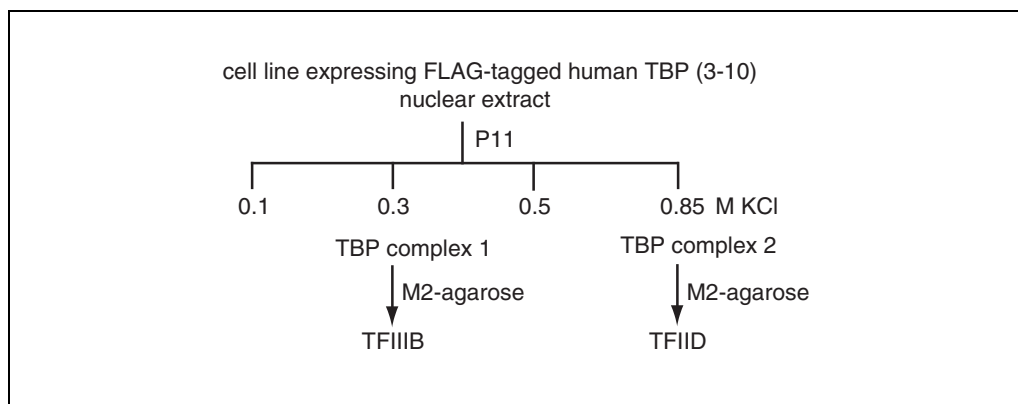

Figure 16.13.2 Purification of different FLAG-tagged TBP complexes. Nuclear extract prepared from 3-10 (Chiang et al., 1993), which is a HeLa-derived cell line constitutively expressing FLAG-tagged TBP, is loaded onto a P11 ion-exchange column. Proteins bound to the P11 resin are sequentially eluted off the column by step elutions with 0.1, 0.3, 0.5, and 0.85 M KCl-containing buffer. The FLAG-tagged TBP complexes are mainly detected at the 0.3 and 0.85 M KCl fractions, which are then used for immunoaffinity purification by anti-FLAG M2 monoclonal antibody-conjugated beads to isolate TFIIB and TFIID complexes, respectively.

4. Thaw ~100 ml of nuclear extract in an ice bucket overnight at 4°C.
5. Centrifuge nuclear extract for 20 min at 105,000 × g (Beckman 45-Ti rotor 30,000 rpm), 4°C.
6. Pour supernatant into 50-ml tubes and load the sample onto an equilibrated P11 column at a flow rate of 1 CV/hr. Collect the eluate, ~12 ml/tube, with a fraction collector.

Remember to save a small aliquot (~100 μl) for immunoblotting analysis.

7. Wash the column with ~2 CV of BC100 or until the absorption profile, monitored at 280 nm, almost reaches the baseline.
8. Step elute the bound proteins by sequentially switching to BC300, BC500, BC850, and BC1200, when the protein curve of each elution buffer nearly reaches the baseline.
9. Combine the fractions representing each of the BC100, BC300, BC500, and BC850 protein peaks.

The BC1200 fractions, containing a minor amount of SL1, are not collected for further purification.

10. Dialyze BC500 and BC850 samples against 4 liters of BC100 for 5 hr at 4°C.
11. Centrifuge samples for 15 min at 46,000 × g (Beckman 45-Ti rotor 20,000 rpm), 4°C.
12. Aliquot the supernatant of BC500 and BC850, as well as the BC100 and BC300 fractions, individually, into several 15-ml tubes (for immunoaffinity purification) and 1.5-ml microcentrifuge tubes (for immunoblotting and protein analysis).
13. Freeze the aliquots in liquid nitrogen and store samples at –80°C until use.
14. Perform immunoblotting (*UNIT 10.8*) to locate the P11 fractions containing FLAG-tagged TBP.
15. Purify TFIIB from the P11 0.3 M KCl fraction and TFIID from the P11 0.85 M KCl fraction according to the procedures described in Basic Protocol 1, steps 26 to 34.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

BES buffer, 1 M (pH 7.2)

21.32 g of BES (*N, N*-bis[2-hydroxyethyl]-2-aminoethanesulfonic acid) (Sigma)
 60 ml H₂O
 Adjust pH to 7.12 with 1 M NaOH and bring up total volume to 100 ml
 Autoclave and store up to 6 months at room temperature

BC100

20 mM Tris·Cl, pH 7.9 at 4°C (*APPENDIX 2*)
 20% glycerol
 0.2 mM EDTA, pH 8.0 (*APPENDIX 2*)
 100 mM KCl
 1 mM DTT (added prior to use)
 0.5 mM PMSF (added prior to use)
 Store up to 6 months at 4°C

BC300, BC500, BC850, and BC1200

Prepare as for BC100 (see recipe) except the KCl concentration is adjusted to 300, 500, 850, and 1200 mM, respectively.

Buffer B

50 mM Tris·Cl, pH 7.9 at 4°C (*APPENDIX 2*)
25% glycerol
5 mM MgCl₂
5 mM EDTA, pH 8.0 (*APPENDIX 2*)
5 mM EGTA, pH 8.0
5 mM DTT (added prior to use)
0.5 mM PMSF (added prior to use)
Store up to 6 months at 4°C

Buffer D

50 mM Tris·Cl, pH 7.9 at 4°C (*APPENDIX 2*)
25% glycerol
5 mM EDTA, pH 8.0 (*APPENDIX 2*)
5 mM EGTA, pH 8.0
2 mM DTT (added prior to use)
0.5 mM PMSF (added prior to use)
Store up to 6 months at 4°C

FLAG peptide elution buffer

Diluting FLAG peptide from 100 mg/ml of FLAG peptide (in water) in BC100 or BC300 (see recipe) prior to use.

COMMENTARY

Background Information

The FLAG epitope consists of 8 amino acids that are mostly charged residues (Hopp et al., 1988). The popularity of this epitope lies in the following facts.

1. It is synthetic, so that very few, if any, cross-reacting species are detected in bacterial, yeast, insect, or mammalian cells.

2. It is very hydrophilic and tends to help proteins stay soluble in aqueous solution.

3. It is small and highly antigenic. The introduction of the FLAG sequence rarely changes protein conformation and has a tendency to stimulate the immune response when injected into animals for antibody production (Chiang and Roeder, 1995).

4. A heart muscle kinase site linked to the FLAG sequence offers a unique way to label proteins with ³²P after purification (Blonar and Rutter, 1992). The labeled proteins can be used for interaction studies, expression library screening and protein tracking (Chiang and Roeder, 1995).

5. A peptide elution method has been developed to elute the FLAG-tagged protein (Chiang and Roeder, 1993) or protein complexes (Chiang et al., 1993) off the anti-FLAG M2

monoclonal antibody-conjugated beads under neutral pH or physiological conditions, thereby allowing the recovery of fully active proteins ready for functional assays.

6. The fold purification achieved by M2-agarose beads, which are commercially available, is exceedingly high, making it possible to purify FLAG-tagged multisubunit protein complexes to near homogeneity via one-step immunoaffinity purification (Chiang et al., 1993; Fondell et al., 1996; Kershner et al., 1998; Ogryzko et al., 1998; Sif et al., 1998; Wu et al., 1998; Gu et al., 1999; Ikura et al., 2000).

Although purification of recombinant FLAG-tagged protein can be easily achieved by using bacterial and baculovirus expression systems (Chiang and Roeder, 1993; Wu et al., 1999), the reconstitution of a fully functional protein complex from individually purified subunits or from insect cells coinfecting with several recombinant baculoviruses expressing different subunits remains challenging (Bell et al., 1995; Chen and Tjian, 1996; Guermah et al., 1998; Phelan et al., 1999). Therefore, we and others have applied retrovirus-mediated gene transfer to deliver an epitope-tagged subunit of a large protein complex into human

HeLa cells for the natural assembly of multisubunit protein complexes in a mammalian cell. Isolation of the *in vivo*-assembled large protein complexes is then facilitated by immunoaffinity purification using epitope-specific monoclonal antibody-conjugated beads and peptide elution (Zhou et al., 1992; Chiang et al., 1993). This methodology, combining epitope-tagging and stable cell line approaches, has made it possible to purify many multisubunit protein complexes, as long as a clonal cell line expressing the tagged subunit of a protein complex is available.

Sometimes, cytotoxicity caused by constitutive expression of the tagged protein prevents the establishment of a stable cell line by retrovirus-mediated gene transfer. The application of an inducible mammalian expression system, in combination with FLAG epitope-tagging and peptide elution methods, has further expanded our ability to establish stable cell lines expressing essentially any epitope-tagged protein (Wu and Chiang, 1996). The purification of human pol II and TFIIF from tetracycline-regulated clonal cell lines conditionally expressing FLAG-tagged RPB9 and the FLAG-tagged p62 subunit of human TFIIF, respectively, was the first documentation detailing the procedures for biochemical purification of multisubunit protein complexes from an inducible mammalian expression system (Kershnar et al., 1998). The protocols described here not only greatly simplify the purification steps, but also dramatically reduce the cost of preparation.

Critical Parameters and Troubleshooting

Location of the epitope tag. In general, the FLAG epitope sequence is introduced at either the N-terminus or the C-terminus of the protein-coding region. A critical parameter is to keep the tag away from essential regions of the protein. In many cases, however, it is hard to predict where the best location is in a protein and which subunit may be exposed on the surface of a protein complex. The suggestion is to tag different subunits in parallel to enhance the successful rate.

Isolation of drug-resistant colonies. The cellular colonies are ready to be picked up when their diameter is between 2-3 mm. However, some slow-growing colonies should not be ignored, as expression of potentially toxic proteins may reduce the growth rate of the cells. The suggestion is to pick up colonies of various

sizes, especially if there are clear differences in the diameter of the colonies.

Identification of positive clones. It is very important to use anti-FLAG M2, not M1, monoclonal antibody for immunoblotting, as anti-FLAG M2 monoclonal antibody can recognize the FLAG sequence at any location on the protein, whereas the M1 monoclonal antibody only recognizes the FLAG sequence at the very N-terminal region of the protein. In addition, a negative result with the M2 monoclonal antibody does not necessarily indicate a failure in establishing clonal cell lines. The FLAG epitope may sometimes be masked by the fusion partner, thereby preventing its detection by anti-epitope antibodies. In this case, it is essential to further confirm the results by anti-protein antibodies.

Induction in suspension culture. It often happens that the tagged protein is not successfully induced after continued expansion in suspension culture. This is probably caused by residual tetracycline, which prevents tetracycline-dependent transactivator (tTA) from binding to the regulated gene, or by a reduced expression of tTA in the clonal cell line. To overcome these problems and to ensure a high level of protein induction, we usually follow these four guidelines. First, preselect cells with antibiotic (G418) in a small culture (~100 ml) in the presence of tetracycline for at least three days before further expansion in the absence of antibiotic (G418). Presumably, this will boost the expression of tTA in the cell, thereby enhancing the level of transactivation from the tetracycline-regulated promoter. Second, wash cells at least 4 to 6 times with 1×PBS to remove tetracycline prior to induction. Third, use 250-ml conical centrifuge tubes instead of 1-liter flat bottom bottles to spin down cells when washing with 1×PBS. Conical centrifuge tubes allow for better cell adhesion; thus medium and PBS washes can be completely removed after each successive centrifugation without losing cell volume. The 1-liter flat bottom centrifuge bottles, although convenient to use, do not permit complete removal of the original medium without disturbing the cell pellet; a minor residual tetracycline contaminant is sufficient to prohibit the induction. Fourth, use tetracycline-free serum as a growth supplement when protein induction is desired. The authors have discovered that some batches of calf serum contain endogenous tetracycline, likely resulting from the use of tetracycline in cattle feed to protect animals from bacterial infection.

Removal of FLAG peptide. The presence of the free FLAG peptide in the purified protein complexes, following elution from the M2-conjugated beads, is unlikely to cause problems in functional assays. In fact, the free peptide can enhance the stability of the purified protein complexes, which are often present in dilute concentrations after the final step of purification. However, if the presence of FLAG peptide presents a problem, e.g., by masking the surfaces of protein complexes or by competing for resin binding to an ion-exchange chromatographic column, a dialysis step can be included to remove the free peptide. Thus, depending on the purpose, FLAG peptide may or may not be removed after immunoaffinity purification.

Specificity of purified protein complexes. Normally, a control purification with extract prepared from the parental cells is conducted in parallel to identify polypeptides binding non-specifically to the M2-conjugated beads. This is critical, especially for the characterization of the protein composition in a purified protein complex. It is also a good idea to perform a small-scale purification, e.g., by using 200 μ l of protein sample and 10 μ l of M2-conjugated beads in each tube (Chiang et al., 1993), in order to compare different washing conditions. Once the condition is optimized, a large-scale purification is then conducted. In this way, the specificity of the protein complexes is enhanced, while the nonspecific background is minimized.

Consideration of elution buffer. The elution conditions also play an important role in immunoaffinity purification. Ideally, proteins are stored in low salt-containing buffers which allow for better manipulation of the salt conditions in later functional assays. But when comparing the elution conditions, we find that some proteins, such as the FLAG-tagged human papillomavirus E2 protein, elute better in 300 mM KCl-containing buffer (Hou et al., 2000), while the majority of other proteins elute well in 100 mM KCl-containing buffer. Inclusion of a minor amount (0.1% to 0.01%) of detergents, such as Nonidet P-40 or Triton X-100, in the elution buffer prevents protein/bead aggregation, allowing the immunoaffinity beads to rotate better during the elution step. A caveat in using detergent, however, is that the activity of some proteins (or complexes) may be sensitive to different concentrations of detergent. Luckily, protein complexes purified with these procedures, including human TFIID, TFIIF,

RNA polymerase II, and RNA polymerase II holoenzyme, are fully functional in both basal and activated transcription (Chiang et al., 1993; Chiang and Roeder, 1995; Kershnar et al., 1998; Wu and Chiang, 1998; Wu et al., 1998, 1999).

Combination of immunoaffinity purification and conventional column chromatography. Additional steps of conventional column chromatography, such as ion-exchange and gel filtration, can be included prior to or following immunoaffinity purification to further enhance the purity of the target protein complex.

Anticipated Results

The percentage of drug-resistant colonies expressing FLAG-tagged protein via retrovirus-mediated gene transfer is theoretically 100%. However, integration of the coding cassette into a transcriptionally silenced region of the cellular chromosomes may prevent the expression of FLAG-tagged protein, thereby reducing the number of positive clones. Even so, there are usually several clonal cell lines expressing FLAG-tagged protein from a dozen cellular isolates. In contrast, only 5 to 10% of clonal cell lines expressing FLAG-tagged protein were identified when the tetracycline-regulated expression system was used to establish stable cell lines. This is in part due to random integration of the tetracycline-regulated expression plasmid into cellular chromosomes. Thus, more drug-resistant colonies (>12) should be expanded when using the inducible expression system.

The level of induced FLAG-tagged protein, which can vary over three orders of magnitude, is modulated by the amount of tetracycline included in the growth medium (Wu and Chiang, 1996). A maximal induction is usually achieved by complete removal of tetracycline. Normally the concentration of tetracycline is kept at either zero or 1 μ g/ml to turn "on" or "off" the expression of the tagged protein throughout the entire experiment.

The purified protein complexes are finally analyzed, in comparison with a control sample purified in parallel, by silver staining and immunoblotting. A purification table listing variables, including protein amount of the starting material, units, specific activity, fold purification, and yield, is typically generated. This is helpful for estimating the efficiency of immunoaffinity purification and other chromatographic steps (Kershnar et al., 1998).

Time Considerations

It usually takes three to four weeks to see drug-resistant colonies and an additional three weeks to identify clonal cell lines expressing FLAG-tagged protein by either retrovirus-mediated gene transfer or the tetracycline-regulated expression system. Expansion of a clonal cell line in suspension culture ready for extract preparation may take another 3 to 4 weeks. Once cells are ready for harvesting, it takes only one day to prepare nuclear extract, S100, and nuclear pellet, and another two days for immunoaffinity purification. If a chromatography step is involved, only one additional day is needed. Taken together, it may take 2 to 3 months to purify a multisubunit protein complex when beginning with an expression plasmid containing the FLAG-tagged protein-coding sequence.

Inducible Gene Expression Using an Autoregulatory, Tetracycline-Controlled System

Tetracycline-regulated gene expression systems have been developed to overcome some of the obstacles encountered using other strategies for inducible gene expression in mammalian cells. These difficulties include pleiotropic, nonspecific effects or toxicity of inducing agents or treatments, and high uninduced background levels of expression. This unit describes protocols for using a modified tetracycline-regulated system in which a transcriptional transactivator drives expression of itself and a target gene in cultured cells and, to some extent, in transgenic mice. This transactivator (tTA) is a fusion protein consisting of the tetracycline-repressor of *E. coli* and the transcriptional activation domain of the VP16 protein of herpes simplex virus. In the absence of tetracycline, tTA binds to and activates genes preceded by a heptamerized version of the tetracycline-resistance operator of Tn10 plus a minimal CMV promoter (here collectively referred to as Tet P). Binding of tTA to Tet P and subsequent gene activation are blocked in the presence of tetracycline. The plasmid pTet-Splice (Fig. 16.14.1A) contains Tet P upstream, and SV40 splice and polyadenylation signals downstream, of a multiple cloning site into which sequences encoding the open reading frame (ORF) of a target gene of choice is easily inserted. Autoregulatory tTA expression is driven from the plasmid pTet-tTAK (Fig. 16.14.1B), in which the tTA ORF (including an optimal sequence for initiation of translation according to Kozak) has been inserted into pTet-Splice.

The protocols in this unit describe the transfection of adherent cells and the testing of resultant clones for inducible transactivator or target gene protein expression. Stably transfected fibroblast cell lines expressing transactivator and target gene(s) can be derived by first cotransfecting pTet-tTAK and a plasmid encoding a selectable marker and obtaining stable lines with inducible transactivator expression (see Basic Protocol). These lines are subsequently stably cotransfected with plasmids encoding the target gene(s) and a second selectable marker. The procedure may also be used to cotransfect pTet-tTAK with the target gene–encoding plasmid(s) and a single selectable marker plasmid. The choice of method depends upon the feasibility of screening for the protein products of the target genes. While the consecutive method is more systematic, cotransfection may be faster given a relatively straightforward screening method for expression of the target gene (see Critical Parameters).

A Support Protocol also describes methods to test stably transfected cell lines for inducible gene expression, for transient transfection and induction of tet-regulated plasmids, and for detection of the tTAK gene in cells (or transgenic mice).

CALCIUM PHOSPHATE-MEDIATED STABLE TRANSFECTION OF NIH3T3 CELLS WITH pTet-tTAK AND TETRACYCLINE-REGULATED TARGET PLASMIDS

This protocol describes the stable transfection of adherent cells with pTet-tTAK for the derivation of cell lines expressing inducible tTA. In the first round of transfection stable cell lines expressing inducible tTA alone are produced. The single transfection procedure may also be used for stable cotransfection of pTet-tTAK and plasmids expressing the target gene(s). In the second round of transfection tTA expressing lines are transfected with plasmids expressing the target gene(s).

PROTOCOL**

**Protein
Expression**

16.14.1

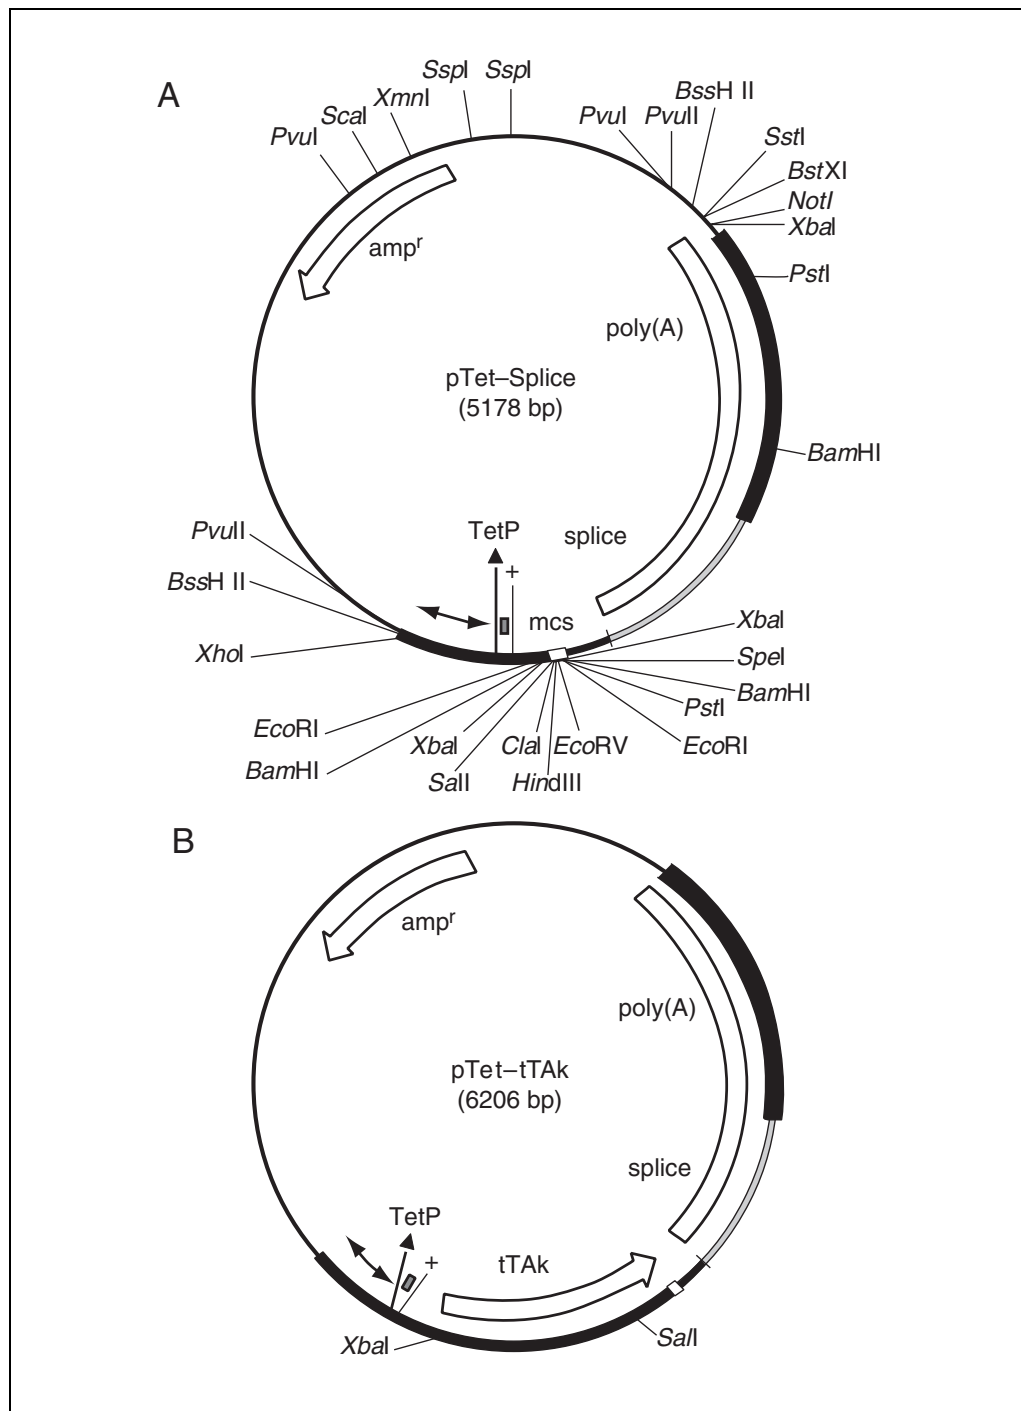

Figure 16.14.1 (A) The plasmid pTet-Splice (Shockett et al., 1995) is designed to drive tetracycline-regulated expression of a target gene inserted into the multiple cloning site (mcs). The tetracycline-regulated promoter (TetP) consists of a heptamerized tetracycline operator (double-ended arrow) upstream of a minimal human CMV promoter that includes bases -53 (triangle) to +75. The transcriptional start site (+) and TATAA box (small rectangle) are also indicated. This TetP fragment is an *XhoI-Sall* fragment derived from pUHC13-3 (Gossen and Bujard, 1992). SV40-derived sequences downstream of the MCS drive mRNA splicing and polyadenylation. The backbone of the plasmid is from Bluescript II KS+ (Stratagene) and carries the ampicillin resistance gene (*amp^r*). (B) pTet-tTak (Shockett et al., 1995) consists of the tTak open reading frame inserted into the *HindIII-EcoRV* sites of pTet-Splice.

Materials

NIH3T3 cells
Complete DMEM-10 medium (see recipe)
Complete DMEM/tet: complete DMEM-10 medium (see recipe) containing 0.5 µg/ml tetracycline hydrochloride (Sigma; dilute 10 mg/ml stock in 70% ethanol and store protected from light at -20°C)
Selection medium (see recipe) containing 125 µM, 250 µM, or 500 µM L-histidinol
Plasmids for first-round or cotransfection procedure: pTet-tTAk (Life Technologies) and plasmids containing target gene ORF(s) cloned into pTet-Splice (Life Technologies), pSV2-His, or another selectable marker plasmid; purified by CsCl banding (UNIT 1.7) or anion-exchange chromatography (UNIT 2.1B)
Plasmids for second round transfection procedure: plasmids containing target gene ORF(s) cloned into pTet-Splice, pPGKpuro, or another selectable marker plasmid; purified by CsCl banding (UNIT 1.7) or anion-exchange chromatography (UNIT 2.1B)
2 M CaCl₂
HEPES-buffered saline (HeBS; see recipe)
10 mg/ml chloroquine (19 mM; optional; Sigma); dilute in water and store at -20°C
85% HeBS/15% glycerol, prewarmed to 37°C
3 mg/ml puromycin (Sigma) diluted in PBS (APPENDIX 2)
Phosphate-buffered saline (PBS; APPENDIX 2)
1× trypsin/EDTA (Life Technologies)
10-cm and 6-cm tissue culture plates
4-ml polystyrene tubes (Falcon)
24-well and 6-well tissue culture plates

NOTE: All tissue culture incubations are performed in a humidified 37°C, 5% CO₂ incubator.

Grow the cells

1. *First round only:* Grow cells in complete DMEM-10 medium. The day before transfection split cells into 10-cm tissue culture plates in complete DMEM/tet to achieve one-third confluence on the day of the transfection.

From this point on cells are kept in the presence of 0.5 µg/ml tet.

One plate per transfection is needed at this stage. A typical experiment might include one plate for tTA only, one for tTA plus target gene, and one to serve as the untransfected control plate.

Second round only: Grow stable cell lines that inducibly express autoregulatory tTA in selection medium/500 µM L-histidinol. The day before transfection split into 10-cm plates in this same medium to achieve one-third confluence on the day of transfection.

Transfect the cells

2. Linearize plasmids prior to transfection and adjust concentration to ≥0.5 mg/ml.

See Damke et al. (1995) for discussion of other selectable markers. All plasmids should be purified by CsCl banding (UNIT 1.7) or on a Qiagen column (UNIT 2.1B).

3. *First round only:* Mix 10 to 20 µg of pTet-tTAk (in the presence or absence of an equimolar amount of target gene plasmids) plus 1 to 2 µg pSV2-His (a molar ratio

of ~10:1 of each tet plasmid to selectable marker plasmid) with 500 μ l HeBS in a clear 4-ml polystyrene tube.

A control mock transfection should be performed with no DNA added to the transfection. All of these cells should die in the selection medium/125 μ M L-histidinol introduced in step 14.

Second round only: Mix 10 to 20 μ g each of target gene plasmid(s) plus 1 to 2 μ g pPGKPuro (a molar ratio of ~10:1 of each tet plasmid to selectable marker plasmid) with 500 μ l HeBS in a clear 4-ml polystyrene tube.

A control mock transfection should be performed with no DNA added to the transfection. All of these cells should die in the presence of the puromycin introduced in step 14. The optimal killing concentration for puromycin (lowest dose between 0.1 μ g/ml to 10 μ g/ml that kills all untransfected cells within a few days) should be determined empirically prior to the transfection and varies with the cell type.

4. Add 32.5 μ l of 2 M CaCl₂ to plasmid DNA and mix immediately by gentle vortexing. With occasional gentle mixing, allow precipitate to form for 15 to 30 min at room temperature or until solution is visibly cloudy when compared to a tube containing water.
5. Aspirate all of the medium from cells, doing one plate at a time. Mix precipitate a few times by pipetting with a Pasteur pipet, and apply dropwise and evenly over cells.
6. Incubate 30 min, gently rocking the plate after 15 min to ensure even coverage over entire plate.
7. *First round only:* Add 10 ml complete DMEM/tet, with or without 25 μ M chloroquine (final), to each plate.

Although the use of chloroquine may further reduce cell integrity during the glycerol shock (step 9), it can improve transfection efficiency.

Second round only: Add 10 ml selection medium/500 μ M L-histidinol, with or without 25 μ M chloroquine (final), to each plate.

8. Incubate 4 to 5 hr.

The optimal length of incubation may vary for different cell types.

9. Gently aspirate medium from cells with minimal disruption of the precipitate that has settled onto the cells. Shock cells by adding dropwise 2.5 ml of prewarmed 85% HeBS/15% glycerol.

It is normal for the cells to look somewhat ragged before and especially after glycerol shock. Two to four plates may be shocked at one time, depending on the speed of the researcher.

10. Aspirate HeBS/glycerol after exactly 2.5 min. Work quickly, as glycerol can be very toxic to the cells.

The length of time cells are exposed to glycerol solution can be varied and increased up to 4 to 5 min to optimize transfection efficiency for different cell types. Cells should be shocked the maximal length of time which results in the least cell death.

11. *First round only:* Immediately, gently, and quickly wash cells twice by adding 10 ml complete DMEM/tet and immediately aspirating.

Because cells tend to come loose from the plate after glycerol addition, add all medium to a single spot on the plate.

Second round only: Immediately, gently, and quickly wash cells twice by adding 10 ml selection medium/500 μ M L-histidinol and immediately aspirating.

Again, add medium to a single spot on the plate to avoid loosening the cells.

12. *First round only:* Add 10 ml complete DMEM/tet. Incubate cells overnight.
- Second round only:* Add 10 ml selection medium/500 μM L-histidinol. Incubate cells overnight.
13. *First round only:* The morning after the transfection, aspirate the medium and replace with 10 ml complete DMEM/tet. Continue incubation.
- Second round only:* The morning after the transfection, aspirate the medium and replace with 10 ml selection medium/500 μM L-histidinol. Continue incubation.

Select and clone transfected cells

14. *First round only:* At 48 hr posttransfection, split cells into selection medium/125 μM L-histidinol at several dilutions ranging from 3×10^4 to 1×10^6 cells per 10-cm plate. Make more than one plate in the mid-range that corresponds to an approximate split from one confluent plate of 1:16 to 1:32.

Second round only: At 48 hr posttransfection, split cells as above, using selection medium/500 μM L-histidinol containing 3 $\mu\text{g/ml}$ puromycin (final).

The optimal killing concentration for puromycin (lowest dose between 0.1 $\mu\text{g/ml}$ to 10 $\mu\text{g/ml}$ that kills all untransfected cells within a few days) should be determined empirically prior to the transfection and varies with the cell type. The concentration of 3 $\mu\text{g/ml}$ puromycin is sufficient for selection of transfected NIH3T3 cells.

15. *First round only:* Refeed cells 4 days later with selection medium/125 μM L-histidinol. When colonies have formed, increase the concentration of L-histidinol in the selection medium to 250 μM .

L-histidinol is normally toxic to cells. The concentration of L-histidinol in the selection medium is therefore kept low initially and is raised as the number of cells expressing pSV₂-His at high levels reaches a critical mass.

Second round only: Refeed cells 4 days later with selection medium/500 μM L-histidinol/puromycin.

16. When colonies are well established (at about day 12 to 14 of selection), circle their borders with a marker. Aspirate medium from plate and place a plastic cloning ring (autoclaved upright in vacuum grease) on the plate to surround an individual clone. Wash clones quickly with ~ 100 μl PBS and add 2 drops of trypsin (~ 100 μl) for 30 sec to 1 min.

Pick cells from plates on which individual colonies are moderately spaced and can easily be distinguished.

17. *First round only:* Loosen cells by pipetting up and down with a Pasteur pipet and transfer colonies to wells of a 24-well plate into 1 ml selection medium/250 μM L-histidinol.

Second round only: Loosen cells as for first round, transferring them into 1 ml selection medium/500 μM L-histidinol/puromycin.

18. *First round only:* When cells are heavy in wells, split into 6-cm dishes in selection medium/500 μM L-histidinol.

Second-round only: When cells are heavy in wells, split into 6-cm dishes in selection medium/500 μM L-histidinol/puromycin.

All trypsinization is performed by standard methods (APPENDIX 3F), involving a quick PBS wash, a 1 to 3 min trypsin/EDTA incubation (2 ml per confluent 10-cm plate), and using 3rd selection medium/500 μM L-histidinol (\pm puromycin) and containing 10% calf serum to dilute and stop the trypsin.

19. *First round only:* Expand cells for testing in selection medium/500 μM L-histidinol. Freeze aliquots of cells for storage in liquid nitrogen and grow in selection medium/500 μM L-histidinol from this point on. Test for tTA or target gene expression (if applicable; see Support Protocol for methods that may be used). Or, if applicable, repeat transfection procedure with target gene plasmid(s), following steps 1 to 18 and using the options listed for second-round transfection.

Second round only: Test for target gene expression by northern or immunoblotting after induction (see Support Protocol). Freeze aliquots for storage in liquid nitrogen and grow in selection medium/500 μM L-histidinol/puromycin from this point on.

ANALYSIS OF TARGET GENE PROTEIN EXPRESSION

This protocol outlines methods for the analysis of target gene expression and inducibility. Instructions for inducing stable cell lines, for examining transient target gene expression with and without induction, and for PCR amplification of the tTA gene are included, with references to detection procedures such as Southern, northern, and immunoblotting techniques.

Induction of Stable Cell Lines

Stable cell lines can be tested for tTA or target gene expression by comparing induced to uninduced cells for tTA mRNA or target gene mRNA (see Detection of tTA Transgene in Cellular or Tail DNA by Southern Blotting), or protein expression or protein activity. Multiple lines may be screened at a time.

The night before induction, the cells are plated in selection medium/500 μM L-histidinol (see recipe) containing 3 $\mu\text{g/ml}$ puromycin at an appropriate density such that cells will be subconfluent to confluent at the time of harvest. Cells are washed three times with PBS (*APPENDIX 2*), with gentle swirling. Immediately, the medium is replaced with selection medium *without* 0.5 $\mu\text{g/ml}$ tetracycline hydrochloride (tet). (For tet⁺ controls, simply aspirate medium and replace with fresh selection medium containing tet.) Cells are incubated 6 to 48 hr in a humidified 37°C, 5% CO₂ incubator, then trypsinized (*APPENDIX 3F*) and harvested at 4°C, and an aliquot of 0.15–0.4 $\times 10^6$ cells is analyzed by immunoblotting (see *UNIT 10.8*).

Alternatively, cells may be grown in selection medium in the presence of tet, transferred to tubes [with a quick wash with cold PBS followed by trypsinization (*APPENDIX 3F*) and stopping of the trypsin by addition of selection medium containing tet], washed three times with PBS (or just pelleted, for tet⁺ controls), and replated into selection medium with and without tet at an appropriate density such that the cells will be subconfluent to confluent at the time of harvest.

Induction of Gene Expression in Transiently Transfected Cells

Transient transfection of tet-regulated plasmids is useful in several situations, including the initial testing of the autoregulatory system in a given cell line, screening stable tTA expressors for inducible expression, and biological applications where transient expression is specifically desired.

The night before the transfection, cells are split into medium containing 0.5 $\mu\text{g/ml}$ tetracycline hydrochloride; the following day they are then transfected by methods appropriate for the cells being used (*UNITS 9.1-9.4*). Cells are induced by washing them three times in medium without tet. For CaPO₄ transfection, washes are incorporated into those normally performed after glycerol shock (see Basic Protocol, step 11). Uninduced cell

controls are washed with medium containing tet. Medium with and without tet is added to the appropriate plates, then the cells are incubated for 12 to 48 hr in a humidified 37°C, 5% CO₂ incubator. The cells are harvested at 4°C and, if trypsinized (*APPENDIX 3F*), cold medium containing 10% FBS (with and without tet, as appropriate) is used to stop the action of the trypsin. Cells are pelleted for freezing or lysis, and tTA or target gene (experimental or reporter) expression can be analyzed by northern blotting (*UNIT 4.9*), immunoblotting (*UNIT 10.8*), or by an appropriate activity assay (see Commentary).

Detection of tTA Transgene in Cellular or Tail DNA by PCR

PCR is routinely used to detect the Tet-tTA transgene in candidate transgenic mouse tail DNA. The forward primer derives from the minimal human CMV promoter, CMV-F1:

5'-TGACCTCCATAGAAGACACC-3'

The reverse primer, TTA-REV1, is specific for the tTA ORF:

5'-ATCTCAATGGCTAAGGCGTC-3'

Hot-start PCR (*UNIT 15.1*) is performed on 150 ng of each tail DNA to be analyzed in a reaction mix containing 1.5 mM MgCl₂, 0.5 μM each primer, and 0.2 mM each dNTP. PCR cycling conditions are as follows:

1 cycle:	3 min	94°C	
		80°C	(pause) add <i>Taq</i> polymerase
30 cycles:	45 sec	94°C	(denaturation)
	45 sec	58°C	(annealing)
	90 sec	72°C	(extension)
1 cycle	10 min	72°C	(extension)
		8°C	(end).

Products are analyzed on a 1% to 1.3% agarose gel; the main product of interest is visible as a 290-bp band after ethidium bromide staining.

Detection of tTA Transgene in Cellular or Tail DNA by Southern Blotting

The tTA transgene may also be detected by Southern blot analysis (*UNIT 2.9*). Tail DNA is digested with *EcoRI* and blots are probed with a 761-bp *XbaI-SalI* tTA insert from pTet-tTA. This fragment detects a 1094-bp tTA fragment of the transgene. This probe may also be used to detect tTA mRNA by northern blotting (*UNIT 4.9*).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see *APPENDIX 2*; for suppliers, see *APPENDIX 4*.

Complete DMEM-10

Dulbecco's minimal essential medium containing:

10% donor bovine calf serum (JRH Biosciences)

100 U/ml penicillin/100 μg/ml streptomycin (Life Technologies)

2 mM glutamine (Life Technologies)

All DMEM complete medium used in this unit (with or without selection reagents or 0.5 μg/ml tetracycline hydrochloride) may be stored protected from light ~1 month at 4°C.

Fetal bovine serum (FBS) may also be used in place of donor bovine calf serum, but the latter is less expensive.

HEPES-buffered saline (HBS)

6 mM dextrose
137 mM NaCl
5 mM KCl
0.7 mM Na₂HPO₄·7H₂O
21 mM HEPES (free acid)
Adjust final pH to 7.05 with NaOH
Filter sterilize and store in aliquots at –20°C

Selection medium

Complete histidine-free DMEM (Irvine Scientific, purchased without glutamine), containing:

10% donor bovine calf serum (JRH Biosciences)
100 U/ml penicillin/100 µg/ml streptomycin (Life Technologies)
2 mM glutamine (Life Technologies)
0.5 µg/ml tetracycline-HCl (Sigma; dilute 10 mg/ml stock in 70% ethanol and store protected from light at –20°C)
125 µM, 250 µM, or 500 µM L-histidinol (Sigma, dilute in water as a 125 mM stock and store at –20°C)

COMMENTARY

Background Information

Inducible, tetracycline-regulated gene expression systems were initially developed to allow the controlled expression in eukaryotic cells of foreign genes not tolerated constitutively in cultured cells or during the development of transgenic animals. The general features of tetracycline-regulated gene expression strategies and their improvements over previous inducible expression systems have been addressed in current review articles (Gossen et al., 1993; Barinaga, 1994; Damke et al., 1995; Shockett and Schatz, 1996). The autoregulatory tTA system used in this protocol derives directly from a constitutive tTA system described by Gossen and Bujard (1992). Although tight regulatory control and high inducibility was achieved with the original system in HeLa cells, the inability to detect clones expressing moderate to high levels of tTA by immunoblotting suggested that the tTA was toxic when expressed constitutively. The autoregulatory tTA system was designed to overcome possible toxic effects of constitutive tTA expression by making tTA expression itself tetracycline regulated. Autoregulated tTA expression theoretically allows for the selection of clones expressing higher levels of tTA via an autoregulatory feed-forward mechanism that is activated only in the absence of tetracycline. In the presence of tetracycline, low-level tTA and target gene expression are driven from the minimal human CMV promoter. However, any tTA produced is

unable to bind to tet operators upstream of the tTA or target gene. Conversely, when tetracycline is removed from the system, the small amounts of tTA protein expressed from the minimal promoter can bind the *tet* operators upstream of the tTA gene, driving higher levels of tTA (for controlled periods of time) and, subsequently, target gene expression.

The theoretical benefits of the autoregulatory tTA system have been confirmed by experiments in stably transfected NIH3T3 cell lines (Shockett et al., 1995). In these experiments, expression of the recombination activating genes *RAG-1* and *RAG-2*, and subsequent DNA recombination activated by these proteins, was higher and more frequently detected among stable transfectants expressing autoregulatory tTA than in constitutive tTA expressors. In transgenic mice expressing a luciferase reporter target transgene, the levels of expression appear to be 1 to 2 orders of magnitude greater with the autoregulatory system, although the uninduced levels also appear to be higher.

Since the description of the early tTA systems, several laboratories have created modified vectors, including streamlined versions containing both tTA and the target gene, viral vectors, and vectors in which expression of two different target genes may be differentially or co-regulated. Some of these systems and their applications have recently been reviewed (Shockett and Schatz, 1996).

Critical Parameters and Troubleshooting

Cell lines stably expressing both autoregulatory tTA and target genes have been derived at fairly high efficiencies by simultaneous transfection of all plasmids. This method may be faster, but it may require the screening of more clones than if stable lines with low basal and high induced levels of tTA are first derived and subsequently transfected with plasmids encoding the target genes. For the derivation of these clones, any selectable marker combination should theoretically work for consecutive cotransfection. Additionally, although the Basic Protocol describes calcium phosphate-mediated transfection of adherent fibroblast cell lines, the procedure can be adapted for other cell types using their optimal methods of transfection and selection. The protocol can also be scaled down to require fewer cells by using smaller dishes or wells and reducing all components proportionately.

Using the autoregulatory tTA system, tTA mRNA induction appears to be a good indicator of induced tTA expression (see Support Protocol). Alternatively, the vector pUHC13-3 (Life Technologies) encoding luciferase under tet control may be transiently transfected into putative stable tTA expressors as previously described (see Support Protocol and Damke et al., 1995). Cells are then cultured for 12 to 48 hr in the presence and absence of tetracycline. Luciferase activity is easily measured in cell lysates using a kit (Luciferase Assay System and Dual-Luciferase Reporter Assay System; Promega) in which luciferase activity in cell lysates is normalized either to total protein determined using a Bradford protein assay (*UNIT 10.1*), or to a transfection control, respectively. Although basal expression of target plasmids tends to be higher when transiently transfected and luciferase detection is extremely sensitive, this method can be useful for the initial testing of the system in a given cell type (Damke et al., 1995).

It is imperative after stable transfection with pTet-tTA that cells be maintained in medium containing 0.5 µg/ml tetracycline to prevent any toxic effects of tTA expression and subsequent selection against clones expressing high levels of tTA.

Anticipated Results

In the authors' experience with stably transfected NIH3T3 cells, expression of induced

tTA and target gene has been observed by 6 hr and peaks at ~12 hr after induction. In cells that stably express tTA, transient target gene expression has been observed by 12 hr. In cells transiently expressing tTA and a tet-sensitive luciferase reporter (pUHC13-3), luciferase activity induced by 2 orders of magnitude has been observed by 20 hr.

Time Considerations

Starting with the plasmid vectors and following the transfection protocols above, stable clones expressing tTA (or tTA + target gene(s) if cotransfecting) are obtained in ~12 to 14 days. Approximately 2 additional weeks are required for expansion and testing of candidate clones. Subsequent transfection of a stable inducible tTA clone with vectors expressing target genes will require the same amount of time. Transient transfection and inducible gene expression may be achieved within 48 hr.

Overview of the Vaccinia Virus Expression System

Vaccinia virus was introduced in 1982 as a vector for transient expression of genes in mammalian cells (Mackett et al., 1982; Panicali and Paoletti, 1982). This expression system differs from others in that transcription occurs in the cytoplasm of the cell rather than in the nucleus. As a vector, vaccinia virus has a number of useful characteristics, including a capacity that permits cloning large fragments of foreign DNA (>20 kbp) with retention of infectivity, a wide host range, a relatively high level of protein synthesis, and “appropriate” transport, secretion, processing, and posttranslational modifications as dictated by the primary structure of the expressed protein and the cell type used. For example, *N*- and *O*-glycosylation, phosphorylation, myristylation, and cleavage, as well as assembly of expressed proteins, occur in an apparently faithful manner.

Laboratory applications of vaccinia virus vectors include production of biologically active proteins in tissue culture, analysis of mutant forms of proteins, and determination of transport and processing signals. In addition, recombinant vaccinia viruses have been important for immunological studies (Benink and Yewdell, 1990). Infected cells can serve as targets to analyze the antigenic specificity of cytotoxic T cells. Recombinant viruses can be used to infect animals in order to determine cell-mediated and humoral responses to specific proteins, and are being evaluated as candidate vaccines for human and veterinary uses.

Several variations of the vaccinia vector system have been developed and either standard or more attenuated, host-restricted strains may be used. After obtaining the virus stock (UNIT 16.16), the gene of interest is placed under control of a vaccinia virus promoter and integrated into the genome of vaccinia so as to retain infectivity (UNIT 16.17). Alternatively, expression can be achieved by transfecting a plasmid containing the vaccinia promoter-controlled gene into a cell that has been infected with vaccinia virus. These recombinant viruses are then characterized using various methods (UNIT 16.18). In still another variation, the bacteriophage T7 RNA polymerase gene can be integrated into the genome

of vaccinia so that a gene controlled by a T7 promoter, either in a transfected plasmid or a recombinant vaccinia virus, will be expressed.

VACCINIA REPLICATION CYCLE

Vaccinia is the prototypic member of the *Orthopoxvirus* genus of the *Poxviridae* family. Poxviruses differ from other eukaryotic DNA viruses in that they replicate in the cytoplasm rather than in the nucleus. Vaccinia virus has a linear, double-stranded DNA genome of nearly 200,000 bp that encodes most of the proteins needed for replication and transcription in the cytoplasm.

The replication cycle of poxviruses is represented in Figure 16.15.1. The virus particle or virion consists of a complex core structure surrounded by a lipoprotein envelope. Remarkably, all proteins necessary for transcription of the early class of genes are packaged with the genome in the core. These include the following virus-encoded proteins: a multisubunit, DNA-dependent RNA polymerase, an early transcription factor, capping and methylating enzymes, and a poly(A) polymerase. The transcription system is activated upon infection, and early mRNAs and proteins can be detected within the first hour. The early mRNAs closely resemble their eukaryotic counterparts—they are capped, methylated, polyadenylated, and of discrete size. Termination of transcription occurs ~50 bases after the sequence TTTTNT (where N can be any nucleotide; the termination signal is actually recognized in the nascent RNA as UUUUUNU). There is no evidence for splicing or other kinds of processing involving RNA cleavage.

DNA replication begins within a few hours postinfection and leads successively to the intermediate and late phases of gene expression. The promoters associated with intermediate and late genes differ in sequence from early promoters and have different transcription factor requirements. The intermediate factors are synthesized early in order to facilitate transcription of newly replicated viral DNA. Some of the late factors are products of intermediate genes and hence are made and used after viral DNA replication.

Figure 16.15.1 Replication cycle of vaccinia virus. After entry of vaccinia virus into the cells, early genes are expressed, leading to secretion of several proteins (including a growth factor), uncoating of the virus core, and the synthesis of DNA polymerase (and other replication proteins), RNA polymerase subunits, and transcriptional transactivators of the intermediate class of genes. After DNA replication, intermediate mRNAs are made, some of which encode late transcriptional transactivators. This in turn leads to expression of late genes, which encode structural proteins, enzymes, and early transcription factors that are packaged in the assembling virus particles. Some of the mature virions are wrapped in Golgi-derived membranes and are released from the cell. The bold arrows indicate products that exit the cell. Reprinted with permission from Raven Press (Moss, 1996a).

The mRNAs transcribed from intermediate and late genes differ from typical early mRNAs as follows. First, the termination signal UUUUUNU is not recognized; consequently the mRNAs are long and heterogeneous in length, making procedures like northern blotting virtually useless. Second, the 5' ends of intermediate and late mRNAs contain a capped poly(A) leader of ~35 nucleotides that is probably the result of an RNA polymerase slippage mechanism within the conserved AAA at the initiation site.

Many early proteins are not synthesized beyond ~6 hr postinfection (unless an inhibitor of DNA replication such as cytosine arabinoside is added) because of the cessation of early gene transcription and the relatively short half-life of all mRNAs at late times. Some genes, however, have tandem early and late promoters so that they are expressed throughout the growth cycle. Intermediate

genes are expressed for a relatively short period after DNA replication. Either because of intrinsic promoter strength, DNA copy number, or prolonged expression (>20 hr), much more protein is made from the strongest late promoters than from early or intermediate promoters.

EFFECTS OF VACCINIA INFECTION

Standard vaccinia virus strains can productively infect most mammalian and avian cell lines, with a few exceptions such as Chinese hamster ovary (CHO) cells, but may not complete the replication cycle in primary lymphocytes or macrophages. The host-restricted modified vaccinia virus Ankara (MVA) strain has been shown to replicate efficiently only in chick embryo fibroblasts and BHK-21 cells, but viral and recombinant protein expression occurs in all cell lines infectable by standard strains. Vaccinia infection generally results in

rapid inhibition of host nucleic acid and protein synthesis. Inhibition of host protein synthesis is dramatic and probably results from several factors whose identities are uncertain; the relative contribution of each factor may depend on the virus multiplicity, cell type, and time of analysis. At the time of maximal late gene expression, host protein synthesis has been largely suppressed, facilitating the identification of viral or recombinant proteins by pulse-labeling with radioactive amino acids (*UNIT 10.18*).

In fibroblasts, the initial cytopathic effect is cell rounding, and is obvious by several hours postinfection. Nevertheless, the majority of cells remain intact for ≥ 48 hr. Some virus strains may cause less cytopathic effects than others, but mutants that efficiently express recombinant proteins but do not inhibit host gene expression have not been identified. Approximately 100 to 200 plaque-forming units (pfu), equivalent to ~ 2500 to 5000 particles, are made per cell within a 20- to 40-hr period. With the commonly used vaccinia virus Western Reserve (WR) strain, $>95\%$ of the infectious virus remains cell-associated. With some other vaccinia virus strains, notably IHD-J, larger amounts of extracellular virus are produced.

VACCINIA VECTOR EXPRESSION SYSTEM

Genes or cDNAs containing open reading frames derived from prokaryotic, eukaryotic, or viral sources have been expressed using vaccinia virus vectors. The gene of interest is usually placed next to a vaccinia promoter and this expression cassette is then inserted into the virus genome by homologous recombination or direct ligation (*UNIT 16.17*). Use of poxvirus promoters is essential because cellular and other viral promoters are not recognized by the vaccinia transcriptional apparatus. Strong late promoters are preferable when high levels of expression are desired. An early promoter, however, may be of use if it is desirable to express proteins prior to the occurrence of major cytopathic effects, or when the purpose is to make cells that express antigens in association with major histocompatibility class I molecules so they form cytotoxic T cell targets or prime animals for a cytotoxic T cell response. (The ability of vaccinia viral vectors to direct this type of antigen presentation seems to diminish late in infection.) The most versatile and widely used promoters contain early and late promoter elements. Transcripts originating early will terminate after the sequence

TTTTTNT; thus, any cryptic TTTTTNT termination motifs within the coding sequence of the gene should be altered by mutagenesis if an early poxvirus promoter is used (Earl et al., 1990). To mimic vaccinia virus mRNAs, untranslated leader and 3'-terminal sequences are usually kept short.

A number of plasmids have been designed with restriction endonuclease sites for insertion of foreign genes downstream of vaccinia promoters (*UNIT 16.17*). The expression cassette is flanked by vaccinia DNA to permit homologous recombination when the plasmid is transfected into cells that have previously been infected with a vaccinia virus. The flanking vaccinia virus DNA is chosen so that recombination will not interrupt an essential viral gene.

Without selection, the ratio of recombinant to parental vaccinia virus is usually $\sim 1:1000$. Although this frequency is high enough to permit the use of plaque hybridization (*UNITS 6.3 & 6.4*) or immunoscreening (*UNIT 6.7*) to pick recombinant viruses, a variety of methods have been employed to facilitate identification of recombinant viruses. Some widely used selection or screening techniques are described in *UNIT 16.17*. Commonly, the expression cassette is flanked by segments of the vaccinia thymidine kinase (TK) gene so that recombination results in inactivation of TK. Virus with a TK⁻ phenotype can then be distinguished from those with a TK⁺ phenotype by infecting a TK⁻ cell line in the presence of 5-bromodeoxyuridine (BrdU), which must be phosphorylated by TK to be lethally incorporated into the virus genome. Alternatively, recombinant viruses can be selected by the co-expression of a bacterial antibiotic resistance gene such as guanine phosphoribosyltransferase (*gpt*). Co-expression of the *Escherichia coli lacZ* gene or other color markers allows rapid screening of recombinant virus plaques. Complementation of host-range and plaque-forming defects are also useful for isolation of recombinant viruses (*UNIT 16.17*).

STEPS FOR EXPRESSION OF GENES USING VACCINIA VECTORS

The expression of genes using the vaccinia expression system is presented in detail in *UNITS 16.16-16.18* and is outlined in the flowchart in Figure 16.15.2. A brief overview is presented below.

1. Prepare a stock of standard, host-range-restricted, or bacteriophage T7 RNA polym-

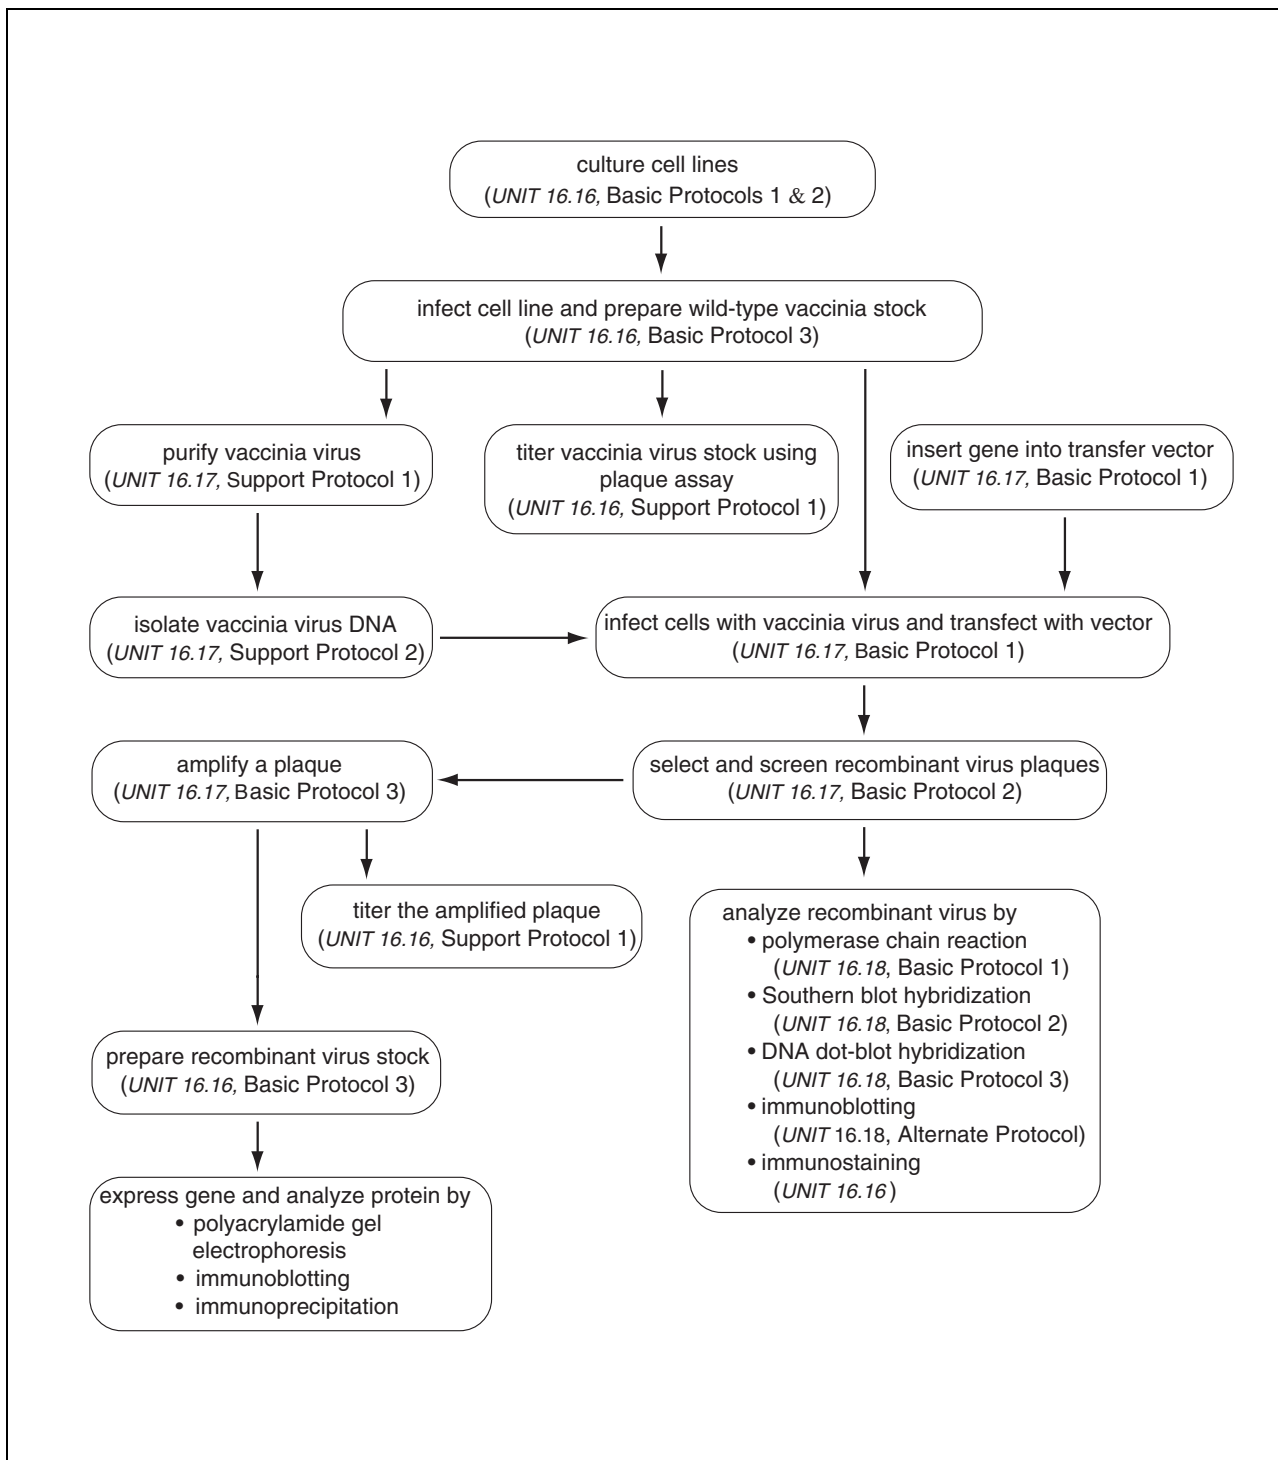

Figure 16.15.2 Flowchart showing protocols for gene expression using the recombinant vaccinia virus system.

erase-expressing vaccinia virus. At the same time, subclone the gene of interest into a plasmid transfer vector (UNITS 16.16 & 16.17).

2. Infect cells with vaccinia virus and transfect with the recombinant plasmid (UNIT 16.17).

3. Lyse the cells and plaque the virus under suitable selection or screening conditions (UNIT 16.17).

4. Pick plaques and confirm the presence and/or expression of the foreign gene (UNIT 16.18).

5. Amplify the plaque and prepare recombinant virus stock (UNIT 16.17).

6. Infect cells and analyze proteins synthesized (UNIT 16.18).

SAFETY PRECAUTIONS FOR USING VACCINIA

Vaccinia virus is not to be confused either with variola virus, another member of the *Orthopoxvirus* genus that caused smallpox prior to its eradication, or with varicella virus, a herpes virus that causes chicken pox. Until 1972, vaccinia virus was routinely used in the United States as a live vaccine to prevent smallpox, and a residual scar, commonly on the upper arm, is evidence of that vaccination.

To prevent laboratory infections, the Centers for Disease Control (CDC) and the National Institutes of Health (NIH) recommend that individuals who come into contact with vaccinia virus receive vaccinations at 10-year intervals (Richmond and McKinney, 1993). The CDC has supplied vaccine for such purposes when requested by qualified health workers. Eczema or an immunodeficiency disorder in the laboratory worker or a close contact, however, may be a contraindication to vaccination, which should only be given under medical supervision. The benefits of routine vaccination for healthy investigators have also been questioned (Baxby, 1989; Wenzel and Nettelmann, 1989). Vaccinia virus is very stable and parenteral inoculation, ingestion, and droplet or aerosol exposure of mucous membranes are the primary hazards to laboratory or animal care personnel. Standard biosafety level 2 (BL-2) practices and class I or II biological safety cabinets should be employed (Richmond and McKinney, 1993). The NIH intramural program has lowered the safety requirements for highly attenuated vaccinia virus strains such as modified vaccinia virus Ankara (MVA; UNIT 16.6) and NYVAC (Tartaglia et al., 1992). However, local institutional biosafety offices should be contacted to determine current policy regarding vaccination and physical containment.

Additional precautions may be necessary for expression of certain genes such as toxins or large segments of other viral genomes, and guidelines for recombinant DNA work should be consulted. Approval of local biosafety committees may be necessary.
