Generally hybridizations are carried on overnight for 12 to 16 hr. This is sufficient for most probes and blots. However, with probes of increasing complexity longer hybridization times are required. This is preferable to increasing the probe concentration from experiment to experiment.

Autoradiography requires 1 to 18 hr.

Using Synthetic Oligonucleotides as Probes

The protocols in this unit describe procedures for using mixtures of ^{32}P -labeled oligonucleotides to screen recombinant DNA clones bound to nitrocellulose filters. A partial amino acid sequence of a protein is used to predict the nucleotide sequence of the gene that would encode it. A mixture of oligonucleotides is chosen that includes all possible nucleotide sequences encoding that amino acid sequence. This mixture of oligonucleotides is then used to screen a recombinant DNA library for the corresponding clones. In some cases however, the exact nucleotide sequence of a desired clone is known and it is possible to use a unique oligonucleotide as a probe.

BASIC PROTOCOL

HYBRIDIZATION IN SODIUM CHLORIDE/SODIUM CITRATE (SSC)

This procedure outlines the steps necessary to screen nitrocellulose filters bearing DNA from bacteriophage or plasmids with mixtures of synthetic oligonucleotide probes. Hybridization and washing steps are carried out in solutions containing SSC. The washing temperature that produces the lowest background is determined empirically.

Materials

- Membrane filters bearing plasmid, bacteriophage, or cosmid libraries (UNITS 6.1 & 6.2)
- 3× SSC/0.1% SDS
- Prehybridization solution
- SSC hybridization solution
- 6× SSC/0.05% sodium pyrophosphate, prewarmed to wash temperature
- Filter forceps (e.g., American Scientific Products #2568-1)
- Sealable bags (or equivalent)
- Additional reagents and equipment for autoradiography (APPENDIX 3)

Prehybridize the filters

1. Prepare duplicate nitrocellulose filters of bacterial colonies or bacteriophage plaques. These should be processed and baked as described in UNITS 6.1 and 6.2.

Although some authors recommend wiping the wet filters prior to baking to remove bacterial debris, we do not advise this procedure because the hybridization signal may be reduced.

Filter forceps (i.e., without serrated tips) should be used to handle membrane filters to prevent marring the surface.

2. Wash the filters 3 to 5 times in 3× SSC/0.1% SDS at room temperature; about 50 82-mm filters can be washed in 500 ml. Then wash them once in the same solution at 65°C for at least 1.5 hr or overnight.

This step removes much of the bacterial debris from the filters.

3. Remove filters from 3× SSC/0.1% SDS and prehybridize them 1 hr at 37°C in prehybridization solution.

Herring sperm DNA in the prehybridization solution blocks nonspecific binding of probe to the filters and thus decreases the background level of radioactivity.

Hybridize oligonucleotides to the filters

4. Remove filters from the prehybridization solution and put them into sealable bags containing SSC hybridization solution. Place up to 20 filters and ≥20 ml SSC hybridization solution into each bag. Add 0.125 to 1.0 ng of each ^{32}P -labeled oligonucleotide per ml of hybridization solution to each bag. The mixed oligonucleotide probe is end-labeled with ^{32}P as described in the support protocol. For example, to 20 ml of hybridization solution that will contain a mixture of 128

17-base oligonucleotides, add 320 ng ($0.125 \text{ ng/ml} \times 128 \text{ oligonucleotides} \times 20 \text{ ml}$) of labeled probe. Hybridize filters 14 to 48 hr at the temperature indicated below:

14-base oligonucleotide	room temperature
17-base oligonucleotide	37°C
20-base oligonucleotide	42°C
23-base oligonucleotide	48°C

For bacterial colonies, adding much more than 0.125 ng of each oligonucleotide probe per ml of hybridization solution significantly increases the background on the autoradiogram. For bacteriophage plaques, there is less DNA per plaque than in a bacterial colony; as high backgrounds are not a problem with filters bearing bacteriophage plaques, more probe should be added to the hybridization mixture.

5. Remove filters from the hybridization bag and wash filters for 5 to 15 min, 3 to 5 times, in $6\times \text{SSC}/0.05\%$ pyrophosphate at room temperature.

It is important that the filters are well separated from each other and that the solution is occasionally or continuously gently agitated.

Wash the filters

6. Wash filters for 30 min in prewarmed $6\times \text{SSC}/0.05\%$ sodium pyrophosphate at the temperature indicated below:

14-base oligonucleotide	37°C
17-base oligonucleotide	48°C
20-base oligonucleotide	55°C
23-base oligonucleotide	60°C

Adjust the temperature of $6\times \text{SSC}/0.05\%$ pyrophosphate and filters. Measure the temperature of the filters and surrounding solution by putting the thermometer into the solution, not into the water bath. Make sure the filters are separated and are occasionally or continuously gently agitated.

7. Examine the filters with a Geiger counter; they should not exhibit above-background radioactivity. If the filters still show a significant degree of radioactivity above background, increase the temperature by 2° to 3°C for 15 to 30 min and reexamine the filters with the Geiger counter. Do not exceed the following temperatures:

14-base oligonucleotide	41°C
17-base oligonucleotide	53°C
20-base oligonucleotide	63°C
23-base oligonucleotide	70°C

The background level of bound radioactivity depends upon the amount of bacterial debris left on the filters, the amount of labeled oligonucleotides added to the hybridization mixture, and the guanosine-cytosine (G-C) content of the oligonucleotide mixture.

Perform autoradiography

8. When the filters exhibit a low level of radioactivity or the maximum temperatures referred to in step 7 have been reached, the filters should be removed from the wash solution and mounted wet on a solid support before exposure at -70°C to X-ray film, using an intensifying screen. Cover filters with plastic wrap. Do not allow the filters to dry out. Allow films to expose for 14 to 72 hr.

Autoradiograms made from filters with a high background may still yield interpretable results.

9. Develop the films; if a high background prevents proper interpretation of the films, rewash the filters at a higher temperature.
10. Number and mark the orientation of the films as described in *UNIT 6.3*. Spots that appear in precisely the same place on duplicate filters are “positives” (winners) and should be processed as described in *UNIT 6.5*.

*It is impossible to identify the characteristics of a true positive spot. Only colonies or plaques that produce evidence of hybridization on both filter copies should be processed as described below. Note that the intensity of the spot can vary dramatically between the duplicate filters. If a clear-cut spot appears on one filter and only a darkening of the background appears on the other, this should be considered positive and the plate should be processed as described in *UNIT 6.5*.*

Note that if two different oligonucleotide mixtures representing two different parts of the protein are available, either the positives obtained with one probe can then be hybridized with the other probe or four filter copies of the library can be made and hybridized to the two probes. Of course, depending on how far apart the sequences that hybridize to the two probes are, it is possible that neither will be present on a less than full-length cDNA clone.

BASIC PROTOCOL

HYBRIDIZATION IN TETRAMETHYLAMMONIUM CHLORIDE (TMAC)

This procedure is similar to the SSC protocol except that hybridization and washing are performed in solutions containing TMAC. In TMAC, the melting temperature of an oligonucleotide is a function of length and is independent of base composition; thus, spurious hybridization due to high G-C content of some of the oligonucleotides is reduced. Conditions are described for using 17-base oligonucleotides, but information is provided for determining the conditions when oligonucleotides of various lengths are employed.

Materials

Nitrocellulose or nylon membrane filters bearing plasmid, bacteriophage, or cosmid libraries (*UNITS 6.1* and *6.2*)

150-mm LB agarose plates (*UNIT 1.1*), prewarmed to 37°C

2× SSC/0.5% SDS/50 mM EDTA, pH 8.0, prewarmed to 50°C

TMAC hybridization solution, prewarmed to hybridization temperature

TMAC wash solution

2× SSC/0.1% SDS

15-cm glass crystallizing dishes

Filter forceps (e.g., American Scientific Products #2568-1)

Additional reagents and equipment for autoradiography (*APPENDIX 3*)

Process and prehybridize the filters

1. Process filters bearing bacterial colonies as described in *UNIT 6.2*. Produce filters bearing amplified bacteriophage plaques as follows:
 - a. Plate the bacteriophage from the library on LB agarose plates and transfer to nitrocellulose filters as described in *UNIT 6.1*, steps 1 to 7.

To obtain maximum sensitivity with oligonucleotide probes when the amplification procedure is used, plating density should be reduced to 8,000 to 10,000 plaques per 150-mm plate.

Either nitrocellulose or nylon (Colony/Plaque Screen Filters by New England Nuclear) filters can be used in this procedure. Nitrocellulose filters become fragile when hybridized in TMAC and must be handled very carefully. If this becomes a problem and nylon filters are substituted, the phage plaques must be amplified overnight. The rest of the protocol is unchanged.

- b. Amplify the bacteriophage by transferring the wet filter to a prewarmed (37°C) LB agarose plate so that the surface bearing the bacteriophage is faceup.

Refrigerate the master plates upon which the recombinant phage library were plated to prevent any further plaque expansion.
 - c. Incubate the plates at 37°C until the bacterial lawn re-forms on the surface of the nitrocellulose and plaques are evident. Plaque size will be somewhat larger than those on the original plate. This usually requires a 5- to 12-hr incubation period. Longer periods of growth will produce a dense bacterial lawn without significantly increasing plaque size or affecting hybridization signal.

Bacteriophage that produce small plaques (e.g., EMBL) are usually plated in the evening and allowed to grow overnight. The plaques are transferred to nitrocellulose filters the following morning and the phage are amplified on the filters by incubation for 5 to 7 hr during the day. Phage that produce large plaques (e.g., λgt10) are plated early in the morning, allowed to grow 5 to 7 hr, transferred to nitrocellulose filters (steps 6 and 7 of UNIT 6.1), transferred to fresh plates, and then incubated for amplification overnight.
 - d. Denature and bind the bacteriophage DNA to nitrocellulose filters as described in steps 8 to 11 of UNIT 6.1.
2. Wash filters bearing bacterial colonies as described in step 1 of the SSC protocol. Wet bacteriophage-bearing filters in a prewarmed (50°C) solution of 2× SSC/0.5% SDS/50 mM EDTA (pH 8.0). Float the filters on top of the solution (with the surface containing the dried bacteria and plaques faceup) to allow the nitrocellulose to wet completely. Submerge the filters and, with a gloved hand, gently rub the surface of the filters to remove the dried bacterial debris. Transfer the filters to a container of fresh solution of 2× SSC/0.5% SDS/50 mM EDTA to remove bacterial debris.

Alternatively, the filters can be incubated in this solution at 65°C for one to several hours and then scrubbed. Inadequate scrubbing of the filters results in an increase of nonspecific background hybridization, obscuring positive hybridization signals in the subsequent screening procedure.
 3. Transfer the filters to a 15-cm glass crystallizing dish containing 5 to 10 ml TMAC hybridization solution (per filter), which has been prewarmed to the appropriate hybridization temperature (48°C for 17-mer oligonucleotides; see Fig. 6.4.1 and commentary for other oligonucleotides) and seal the dishes with plastic wrap and rubberbands. Prehybridize 1 to 2 hr at the hybridization temperature, which is 5° to 10°C below the melting temperature.

Prehybridization and hybridization can be performed in glass crystallizing dishes that are slightly larger in diameter than the nitrocellulose filters. Gentle agitation on an orbital platform shaker will allow the solution to pass freely between the stacked filters and prevent the filters from sticking together. Place no more than 25 to 30 filters in each dish.

Alternatively, prehybridization and hybridization can be performed in a sealable bag (see SSC protocol) with <10 filters per bag.

Hybridize oligonucleotides to the filters

NOTE: The following hybridization and wash temperatures have been optimized for the use of oligonucleotide probes of 17 nucleotides in length. If different length oligonucleotide probes are used, these conditions should be adjusted based on the information presented in the commentary.

Figure 6.4.1 Melting temperatures of oligonucleotides of different length in TMAC and SSC hybridization solutions. Dots represent the average melting temperature of several different oligonucleotides of length 14, 16, or 19 bases in TMAC; bars represent the high and low melting temperatures for each length. Triangles represent the high and low melting temperatures for the same oligonucleotides in SSC. The melting temperature of only one oligonucleotide of length 10, 26, or 32 bases was determined. Hybridization temperature should be 5° to 10°C below the melting temperature, and washing temperature also should be 5° to 10°C below the melting temperature (Jacobs et al., 1988).

4. Transfer filters to a hybridization vessel (or bag) containing fresh, prewarmed (48°C) TMAC hybridization solution to remove residual SSC and bacterial debris from step 2 and to restore TMAC concentration to 3 M. Use 5 to 10 ml TMAC hybridization solution per filter.
5. Add 1 to 2×10^6 cpm of ^{32}P -labeled oligonucleotide probe per ml of hybridization solution directly to the solution of step 4 and incubate 40 to 60 hr at 48°C with gentle agitation on an orbital shaker.

^{32}P -label the oligonucleotide(s) with T4 polynucleotide kinase as described in the support protocol.

Wash the filters

6. Discard the hybridization solution containing radioactively labeled probe and rinse the filters with TMAC wash solution at room temperature. Use 5 to 10 ml TMAC wash solution per filter.
7. Transfer the filters individually to fresh TMAC wash solution (200 to 250 ml) and wash 15 min at room temperature with gentle agitation.

Individual transfer of filters reduces background.

8. Replace the room-temperature TMAC wash solution with a similar volume of prewarmed TMAC wash solution and incubate the filters 1 hr at the appropriate wash temperature (50°C for 17-mers; see Fig. 6.4.1 and commentary).
9. Replace the TMAC wash solution with a similar volume of $2\times$ SSC/0.1% SDS. Wash the filters 10 min at room temperature.

10. Repeat step 9 twice.

These washes remove residual traces of TMAC from the nitrocellulose filters and prevent crystallization of the TMAC salts upon drying.

Perform autoradiography

11. Autoradiograph the filters as described in steps 8 to 10 of the SSC protocol.

LABELING THE 5' ENDS OF MIXED OLIGONUCLEOTIDES

A mixture of synthetic oligonucleotides is ³²P-labeled using T4 polynucleotide kinase. This protocol is similar to that used to label a single oligonucleotide (*UNIT 3.10*).

Materials

2.5 to 250 pmol mixed oligonucleotides
[γ -³²P]ATP (>7000 Ci/mmol)
25 to 50 U T4 polynucleotide kinase (*UNIT 3.10*) and 10 \times kinase buffer (*UNIT 3.4*)
Ice-cold 10% trichloroacetic acid (TCA)

1. Set up reaction mixture on ice in microcentrifuge tube as follows:

2.5 to 250 pmol mixed oligonucleotides
7.5 μ l 10 \times T4 polynucleotide kinase buffer
66 pmol [γ -³²P]ATP (200 μ Ci)
25 to 50 U T4 polynucleotide kinase
H₂O to 75 μ l

Incubate 30 min at 37°C.

The reaction mixture should have either equimolar amounts of label and oligonucleotide ends, or the label should be in molar excess.

*1 mol deoxyribonucleotide \cong 330 g
1 OD₂₆₀ \cong 40 μ g/ml oligonucleotide
1 μ g 14-base oligonucleotide \cong 0.24 nmol
1 μ g 17-base oligonucleotide \cong 0.18 nmol
1 μ g 20-base oligonucleotide \cong 0.15 nmol*

2. At the end of the reaction, check for incorporation of label by precipitating 1 μ l of a diluted aliquot with ice-cold 10% TCA (acid precipitation, *UNIT 3.4*) and counting the incorporated radioactivity.

Using equimolar amounts of oligonucleotide and label, ~30% to 90% of the counts are incorporated.

*The labeled oligonucleotide can be further purified by a combination of phenol extraction and/or ethanol precipitation (*UNIT 2.1*). To remove unincorporated label, oligonucleotides of 17 bases or longer can be quantitatively precipitated from a solution of 2.5 M ammonium acetate containing 25 μ g carrier DNA plus 9 vol of 100% ethanol. The resulting pellets are washed with 70% ethanol, followed by 95% ethanol, air dried, and resuspended in 100 μ l TE buffer.*

3. Store mixture in appropriate container at -20°C.

REAGENTS AND SOLUTIONS

Prehybridization solution

6 \times SSC (*APPENDIX 2*)
5 \times Denhardtts solution (*APPENDIX 2*)
0.05% sodium pyrophosphate
100 μ g/ml boiled herring sperm DNA *continued*

SUPPORT PROTOCOL

Screening Recombinant DNA Libraries

6.4.6

0.5% sodium dodecyl sulfate (SDS)

SSC hybridization solution

6× SSC (APPENDIX 2)
1× Denhardt's solution (APPENDIX 2)
100 µg/ml yeast tRNA
0.05% sodium pyrophosphate

TMAC hybridization solution

3 M tetramethylammonium chloride (see recipe below for stock solution)
0.1 M NaPO₄, pH 6.8
1 mM EDTA, pH 8.0
5× Denhardt's solution (APPENDIX 2)
0.6% SDS
100 µg/ml denatured salmon sperm DNA

TMAC wash solution

3 M tetramethylammonium chloride (see recipe below for stock solution)
50 mM Tris-Cl, pH 8.0
0.2% SDS

Tetramethylammonium chloride (TMAC), 6 M stock solution

Dissolve 657.6 g TMAC (mol wt = 109.6) in H₂O and bring to 1 liter. Filter the solution through Whatman No. 1 filter paper and determine the precise concentration of the solution by measuring the refractive index (*n*) of a 3-fold diluted solution. The molarity (M) of the diluted solution = $55.6(n - 1.331)$ and the molarity of the stock solution = $3 \times M$. TMAC can be stored at room temperature in brown bottles.

CAUTION: TMAC can irritate eyes, skin, and mucous membranes. It should be used with adequate ventilation in a fume hood. Used TMAC solutions should be collected and discarded as hazardous and/or radioactive waste. Small amounts (<10 ml) can be flushed down the drain with a large quantity of tap water.

COMMENTARY

Background Information and Literature Review

Based on a study of the effect of single-bp mismatches on the hybridization behavior of oligonucleotides to ΦX174 DNA, Wallace et al. (1979) proposed that synthetic oligonucleotide mixtures representing all the possible coding sequences for a particular peptide sequence might be used as specific probes to identify cloned DNA. They demonstrated that duplexes with a single-bp mismatch—formed when 11-, 14-, or 17-base oligonucleotides were hybridized to ΦX174 DNA—were significantly less stable (dissociated at lower temperatures) than their perfectly matched counterparts. This difference in thermal stability made it possible, by the appropriate choice of hybridization conditions, to virtually eliminate the formation of mismatched duplexes without affecting the formation of perfectly matched ones. Mixed-sequence oligonucleotide probes were first used successfully for the isolation of a cloned cDNA encoding human β₂-microglobulin (Suggs et al., 1981). Many different

cDNA clones have been isolated using this approach.

Recombinant DNA libraries can be screened with probes consisting of single oligonucleotides or mixtures of oligonucleotides. Bacteriophage or plasmid clones that encode sequences perfectly complementary to the probe must be distinguished from clones that do not. Most often recombinant DNA libraries are screened with probes consisting of multiple oligonucleotides, chosen to cover all the coding possibilities of a particular amino acid sequence. Since any member of the oligonucleotide pool could match the target sequence, hybridization and wash temperatures are selected that allow the oligonucleotide with the lowest melting temperature (the lowest G-C content) to hybridize efficiently. In solutions containing SSC, oligonucleotides of high G-C content can potentially form stable duplexes with sequences to which they are not perfectly complementary.

Mixed probes can produce a high number of false positives using the SSC hybridization

conditions. This problem can be minimized by replacing SSC with TMAC in the hybridization and wash solutions. The melting temperature of long, native DNA in 3 M TMAC is independent of base composition (Melchior and von Hippel, 1973) and rate of renaturation is approximately the rate of renaturation in SSC (Wetmur, 1976). In solutions containing 3 M TMAC, the thermal stability of oligonucleotides 16 bases or longer is sequence-independent (Wood et al., 1985; Jacobs et al., 1988), and non-Watson-Crick base pairs decrease the thermal stability of oligonucleotide duplexes 1° to 1.5°C per percent mismatch (Jacobs et al., 1988). Thus, when the hybridization and wash are performed in 3 M TMAC the appropriate temperature is defined by the length of the oligonucleotide probes. All of the oligonucleotides in the pool will hybridize with equal efficiency to their complementary sequences and with reduced efficiency to sequences to which they are not perfectly complementary. The gene encoding erythropoietin was isolated using TMAC (Jacobs et al., 1985).

The support protocol describes a procedure for ³²P-labeling synthetic oligonucleotides and is adapted from Richardson (1971).

Critical Parameters

In choosing the stretch of amino acids to be used as the blueprint for the mixture of oligonucleotides, one finds a stretch of amino acids that is encoded by a minimum number of possible codons. Unfortunately, most amino acids are encoded by two or four codons. Only methionine and tryptophan—among the rarest of amino acids—are encoded by a single codon. In addition, three of the commonest amino acids have a total of six different codons each (see codon chart, APPENDIX 1). Computer programs are available to determine the optimal structure of oligonucleotide probes from amino acid sequences (Yang et al., 1984).

As the number of different sequences present in an oligonucleotide mixture increases, several possible problems arise. First, unfavorable signal-to-noise ratios may be a problem. However, mixtures of 17-bp oligonucleotides containing 300 to 600 different sequences have been used. Second, as the number of different sequences increases, the probability of completely matching an unrelated and undesired mRNA sequence increases. Third, the distinct possibility remains that the sequence of interest may not be present, and/or incorrect oligonucleotides may be present in the mixture.

Another strategy is to use a single, long,

synthetic oligonucleotide probe selected from codon usage frequencies (reviewed by Lathe, 1985). The uncertainty at each codon is ignored and increased probe length is used to confer probe specificity. The choice of the codon for each amino acid is based on codon utilization data, intercodon dinucleotide frequencies, and other rules. Knowledge of dinucleotide frequencies is important because of the decreased frequency of the dinucleotide pair, CpG. A list of codons recommended by Lathe (1985) is given in Table 6.4.1.

Determining the temperatures for hybridizing and washing is important to reduce the number of false positive plaques or colonies. Although there are examples of isolating clones that have a one-base mismatch with the oligonucleotide probe (<23 nucleotides), this usually is the result of a wrong sequence being

Table 6.4.1 Optimum Codon Choice When Deducing a Probe Sequence from Human Amino Acid Sequence Data

Amino acid	Optimum codon ^a when subsequent codon begins with	
	A or C or T	G
Methionine	ATG	nc ^b
Tryptophan	TGG	nc
Tyrosine	TAC	TAT
Cysteine	TGC	TGT
Glutamine	CAG	nc
Phenylalanine	TTC	TTT
Aspartic acid	GAC	GAT
Asparagine	AAC	AAT
Histidine	CAC ^c	CAT
Glutamic acid	GAG	nc
Lysine	AAG	nc
Alanine	GCC	GCT
Isoleucine	ATC	ATT
Threonine	ACC	ACA ^f
Valine	GTG ^d	nc
Proline	CCC ^e	CCT
Glycine	GGC	nc
Leucine	CTG	nc
Arginine	CGG	nc
Serine	TCC	TCT

^aThe optimum codon is the most frequent codon in all cases except Arg and Ser, where the indicated triplets generate a higher overall homology to all possible codons. Reprinted with permission from *Journal of Molecular Biology*.

^bNo change.

^cCAT when followed by C.

^dGTC when followed by T.

^eCCA when followed by T.

^fThese cases do not follow the “replace C by T” rule applied when the subsequent codon is headed by G.

present in the oligonucleotide mixture. Furthermore, one occasionally synthesizes a mixture of oligonucleotides that is missing the single correct sequence. This possibility should be remembered if no positive results are obtained after screening a library.

Using two copies of each filter to compare the signal obtained with both is an important method for eliminating false positive clones. Because of the variation in the appearance of positive signals and the frequently high backgrounds, it is virtually impossible to tell if a signal from one filter represents true oligonucleotide hybridization. Libraries can be screened in duplicate with one oligonucleotide pool or can be screened with two different oligonucleotides derived from amino acid sequences for the same protein.

The SSC hybridization procedure is similar to that presented by Woods et al. (1982). Other procedures use Tris buffers instead of sodium citrate buffers in the hybridization solution and employ a shorter period of time for the final stringent wash (Connor et al., 1983).

In the SSC protocol, a low temperature for hybridizing the oligonucleotide to the filters is critical to allow maximal binding of the perfectly complementary oligonucleotides. A high temperature in the stringent wash is essential to remove mismatch hybrids. The method for optimizing the signal-to-noise ratio is to wash the hybridized filters at an empirically determined temperature. Initial hybridization and stringent washing conditions can be determined by formulas (see Lathe, 1985) and improved upon by trial-and-error adjustments. Generally, probes ≥ 50 bp long that have $\geq 80\%$ homology will be specific and will hybridize to the sequence of interest. The probability of constructing an appropriate oligonucleotide probe is high but there is a possibility that a nonhybridizing probe will be made (Parker et al., 1986).

In the SSC protocol, background level of radioactivity can vary between none (unusual) to dark gray (usually not a problem). If the background is high, positive spots can often be identified by comparing duplicate filters. Filters can be re washed at a higher temperature and reexposed to film if the background is too dark. If this does not remove the high background, too little hybridization solution was used or the oligonucleotide probe is no good and should be remade. Another possibility is that the probe is hybridizing to *E. coli* DNA.

The TMAC protocol describes hybridization times and temperatures appropriate for screening libraries with 17-mers. In practice we

find that using both hybridization and wash temperatures in the range of 5° to 10°C below the melting temperature (T_m) for an oligonucleotide of particular length gives optimal results. With increasing degeneracy of the oligonucleotide, it is advisable to use the lower range of hybridization and wash temperatures (10°C below T_m) because of the reduced signal. For other applications or when using oligonucleotides of different lengths and complexity, the appropriate conditions can be determined using the information in Figure 6.4.1. A plot of T_m versus oligonucleotide length in TMAC and SSC is shown in Figure 6.4.1. Clearly, there is a broader melting range in SSC than in TMAC. By referring to this figure, the T_m for an oligonucleotide from 16 to 32 bases can be determined. Alternatively, the following equation can be used:

$$T_m = -682(L^{-1}) + 97$$

where L is the number of bases in the oligonucleotide and T_m is $^\circ\text{C}$.

With TMAC, background level due to radioactivity occurs sometimes with particular oligonucleotides but has not obscured duplicate positives. If oligos shorter than 17 bases are used, the general background will be higher, presumably because of the lower temperature used. If the background is too high, the filters can be washed at 5°C below the T_m , but only in preequilibrated buffer and for no more than 10 to 15 min (steps 7 to 10 of TMAC protocol).

When bacteriophage plaques were amplified and probes hybridized in TMAC, 17-mers that were 600-fold degenerate were used to isolate clones from a λ gt10 cDNA library; hybridization was performed for 3 days and exposure times of 24 hr were sufficient. Genomic libraries have been screened with 17-mers that were 512-fold degenerate, requiring hybridization times of 2 to 3 days and exposure times of 1 to 2 days. These times were not rigorously determined. For longer oligonucleotides or with less complex pools, shorter hybridization times may be used. Exposure times are usually determined by developing a few films and making a judgement based on the background and number of positives. When the bacteriophage plaques are amplified, stripping and screening the filters a second time is not recommended.

Anticipated Results

Any recombinant DNA library screened with oligonucleotides will yield "positives" because statistically there will be sequences that are

partially complementary to the probe and hybridization is not an all-or-nothing event. The number of positives will depend upon the completeness of the recombinant DNA library and, in the case of a cDNA library, the level of expression of the gene of interest. In fact, if no "positives" are obtained, there is a high probability that there was procedural error.

Using the TMAC hybridization protocol facilitates the process of identifying the clones of interest because true positives are darker than false positives and thus readily distinguished. If the correct clone is not identified after several attempts, consider remaking the oligonucleotides or making different oligonucleotides. There remain, of course, the unpleasant possibilities that there is an intron spanning the probe or the target sequence is underrepresented in the library.

Time Considerations

For the SSC protocol, 14 to 60 hr is recommended for hybridization and at least 3 hr for washing filters. The TMAC protocol requires 40 to 60 hr hybridization and 1 to 2 hr for washing filters.

PURIFICATION OF BACTERIOPHAGE, COSMID, AND PLASMID CLONES

After the screening procedure has identified potentially desirable clones they must be purified. The following protocols (which are similar to those in *UNITS 1.3* and *1.11*) minimize the number of steps because of the large number of clones on a plate and because of the difficulties associated with retesting these clones.

Purification of Bacteriophage Clones

UNIT 6.5

BASIC
PROTOCOL

Phage plates are correctly oriented to the autoradiograph film, and a region that should contain the clone of interest is sampled by toothpicking each phage plaque onto secondary plates containing a lawn of host cells. Alternatively, a plug of agarose can be taken from the primary plate, placed in SM, and this solution used to plate a small secondary library. Plaques on the secondary plates are transferred to nitrocellulose filters, hybridized to ³²P-labeled probe, and an isolated positive plaque is picked, diluted in SM, and regrown. This process is repeated until the desired plaque is purified.

Materials

- 0.7% top agarose (*UNIT 1.1*)
- Host bacteria (OD₆₀₀ 1.5 to 2 in 10 mM MgSO₄)
- LB plates (*UNIT 1.1*)
- Suspension medium (SM; *UNIT 1.11*)
- Chloroform
- Sterile round toothpicks (*UNIT 1.1*) or Pasteur pipet
- Nitrocellulose membrane filters
- Additional reagents and equipment for autoradiography (*APPENDIX 3*) and phage titering (*UNIT 1.11*)

Growth of secondary plaques

1. Plate 3 ml of 0.7% top agarose containing 200 µl host bacteria on 82-mm LB plates (one plate per clone) and allow to set 10 min.

Top agar cannot be used because it tends to lift off with the nitrocellulose filter.

2. Orient the autoradiograph to the primary library filters by radioactive tags that have been placed on the material used to support the filters. Then mark the autoradiograph at the points where the filters contain needle holes. Place plates containing the library on top of the autoradiograph on an X-ray view box and orient according to the needle marks.

To reduce the number of irrelevant clones, it is often helpful to produce two different exposures of the primary filters. One can then eliminate from consideration spots that do not appear on both autoradiographs.

- 3a. Insert toothpicks first into the primary plate in the area over the hybridization spot on the autoradiograph and then into the top agarose of one of the secondary plates prepared in step 1 above (see *UNIT 1.11*). A grid is helpful to guide spacing of the stabs 5 to 8 mm apart on the secondary plate. Initially attempt to pick individual plaques from the primary plate, then insert the toothpicks at random to ensure that an entire circular area with a 1-cm diameter has been well sampled. This usually requires 30 to 40 stabs per potential clone. It is advisable to make a duplicate secondary plate at the time of picking by simply sticking each toothpick into a second secondary plate in roughly the same pattern as the first.

- 3b. An alternate screening procedure to the above is as follows. Insert the large end of a Pasteur pipet into the top agarose of the primary plate to cut a circular plug corresponding to the region of the autoradiogram demonstrating radioactivity. Remove this plug with the Pasteur pipet or with a spatula and place into 1 ml SM with one drop of chloroform. Allow to sit 1 to 2 hr and then titer. As soon as the titer is known, make 3 to 6 plates with a density of <500 phage per plate. These secondary plaques are handled as in step 4 below.

Screening secondary plaques by hybridization

4. Grow secondary plates at 37°C overnight. Transfer plaques to nitrocellulose filters, process, hybridize, wash, and expose as outlined in *UNITS 6.1 to 6.4*. Mark filter orientation points on the autoradiograph and identify positive plaques on the secondary plates. Insert toothpick into the most strongly hybridizing plaque for each clone and placed into 1 ml SM for 5 min. Plate 1 µl of this phage stock and 1 and 10 µl of a 1:100 dilution onto tertiary LB plates.
5. Screen tertiary plates as above. Insert toothpick into an isolated hybridizing plaque and transfer to SM. This phage stock may be pure, but it is plated and evaluated by hybridization of these plates. If all plaques are positive, make a final SM stock from one of the plaques on these plates. Repeat these steps until the phage is pure. A high-titer stock solution can then be made, as outlined in *UNIT 1.12*.

COMMENTARY

Background Information

Careful purification of the clone of interest away from contaminating phage is required before growth and characterization of the clone can proceed. It is common for a “purified” clone to be contaminated by a second phage, leading to confusing results and wasted time. Several rounds of purification should be performed even if the phage appears pure as early as the secondary screening stage. This approach is similar to that presented by Kaiser and Murray (1984).

Critical Parameters

Plaque purification depends on the ability to go from a hybridization signal on the autoradiograph back to the correct plaque on the LB plate. Thus, attention to orientation of the filter to plate, filter to X-ray film, and film to plate is important.

If more than one potential clone is being plaque purified, it is important to prevent cross-contamination (e.g., via SM or agarose) between clones. Because only a single plaque is sampled at each step of purification, contamination could result in the loss of clones.

Troubleshooting

Occasionally, a clone will be lost during the purification process. When this happens it is usually best to go back as far as possible, i.e., to the secondary plates or to the SM stock.

Potential clones lost with the toothpick technique (step 3a) can sometimes be recovered by the plug procedure (step 3b). It is rarely worthwhile to attempt to purify a clone more than twice, since two unsuccessful attempts usually indicate a false primary clone.

Anticipated Results

This technique normally recovers >90% of clones confirmed by duplicate filters.

Time Considerations

A few hours are required every day for 5 to 8 days. Days picking and plating positive phage can alternate with days setting up filters and hybridization. Maintaining this schedule requires washing filters and obtaining an autoradiograph in 1 day.

Purification of Cosmid and Plasmid Clones

UNIT 6.6

Cosmid- or plasmid-bearing colonies that are identified by hybridization are purified by spreading the cosmids or plasmids on an agar plate and repeating the colony hybridization.

**BASIC
PROTOCOL**

Materials

Cold LB medium containing antibiotic (UNIT 1.1)

LB plates containing antibiotic (UNIT 1.1)

Round toothpicks (UNIT 1.1)

Nitrocellulose membrane filters

Spreader (UNIT 1.3)

Additional reagents and equipment for plating bacteria (UNIT 1.3), plating and transferring plasmid/cosmid libraries (UNIT 6.2), plasmid minipreps (UNIT 1.6), and autoradiography (APPENDIX 3)

NOTE: All materials coming into contact with *E. coli* must be sterile.

1. Pick the positive clones, as detected by the in situ hybridization of nitrocellulose replica filters (UNITS 6.3 & 6.4), with a sterile toothpick.

If plate is dense with colonies, be sure to pick from a 3- to 5-mm circle to ensure selecting the correct clone.

2. Rinse the tip of the toothpick off into a microcentrifuge tube containing 1 ml cold LB medium with the appropriate antibiotic. Store these tubes at 4°C to inhibit any continued growth.

The vector must encode a gene conferring resistance to the appropriate antibiotic.

3. Plate out, using a sterile spreader, from 1 to 25 µl of the bacterial suspension onto an LB plate with the appropriate antibiotic. The correct number of clones to screen is from 25 to 250 per 100-mm plate. Allow the colonies to grow overnight at 37°C.
4. Make a replica copy of the bacterial lawn onto a nitrocellulose filter (UNIT 6.2). Denature, renature, bake, and hybridize as described in UNIT 6.2.
5. From the autoradiograph of the secondary plate, select the most isolated, positive colony. Grow the colony and isolate the DNA (UNIT 1.3).

COMMENTARY

Critical Parameters

If the colonies are too dense, purification of a single colony following a second round of hybridization is difficult. If the colonies are too sparse, many plates must be screened to identify a single hybridizing plaque. The number of clones required depends upon the original number of colonies picked in the original toothpicking. The purpose of rinsing the tip of the toothpick in cold LB medium and keeping the suspension cold is to stop the overgrowth of a single colony and to be able to reliably predict the titer of the suspension.

from 25 to 250 colonies per 100-mm plate—will allow the isolation of a single positive clone.

Time Considerations

Starting from a positive colony identification, this procedure requires one night for the colonies to grow, 10 min per plate for colony transfer to nitrocellulose, and one night for the second hybridization. If a probe with a high specific activity is used, an autoradiograph can be produced from the washed filters in a few hours.

Anticipated Results

Plating cosmid- or plasmid-bearing bacteria on an agar surface at the appropriate density—

**Screening
Recombinant
DNA Libraries**

6.6.1

Supplement 17

Antibodies that recognize a specific protein can be used to identify the desired clones in a recombinant DNA library. In this system the DNA inserts are cloned in an expression vector where the insert sequence should be expressed as part of a fusion protein, or the insert is used to select mRNA that can be translated *in vitro*. Both fusion proteins and *in vitro* translated mRNA can be detected with antibodies, as described in the two units of this section.

The basic requirement of the approaches described here is an antibody that is able to recognize the fusion form of the desired protein. Most investigators assume that the fusion form resembles its denatured form and thus use antibodies that are able to recognize the desired protein in a western blot (UNIT 10.8). A major problem with this technique is that false positive plaques are identified. A simple second test, independent of this technique (e.g., chromosomal assignment or tissue specificity), is extremely useful in establishing the validity of a positive clone.

UNIT 6.7

Immunoscreening of Fusion Proteins Produced in Lambda Plaques

Screening large numbers of plaques containing particular proteins is accomplished by techniques that are analogous to those described for screening with radioactive DNA probes. However, in the basic protocol described here the plaques are screened with antibodies specific to the desired proteins. The alternate protocol provides a method for increasing the amount of recombinant protein in each plaque by inducing expression from the *lac* promoter that directs its expression.

One requirement of the antibody screening procedure is that the recombinant sequences must be carried by expression vectors. A problem often encountered with this technique is that the cDNA library is not made in an expression vector.

BASIC PROTOCOL

SCREENING A λ gt11 EXPRESSION LIBRARY WITH ANTIBODIES

A particular cDNA clone in a bacteriophage λ gt11 library is identified by the protein that is produced after infection of *E. coli*. Bacteriophage from a λ gt11 library are plated. The proteins produced during phage growth and cell lysis are transferred to nitrocellulose filters. The filters are blocked with protein (nonfat milk) to prevent nonspecific interactions with antibody, incubated with antibody, washed, reacted with radiolabeled second antibody, washed again, and autoradiographed. The clones that are identified by autoradiography are isolated by plaque purification.

Materials

- λ gt11 cDNA expression library
- 150-mm LB plates (UNIT 1.1)
- E. coli* LE392 (Table 1.4.5)
- 1% LB top agar (UNIT 1.1)
- 0.05% (v/v) NaN_3 in India ink (optional)
- Immunoscreening buffer
- First-stage antibody
- ^{125}I -labeled second-stage reagent reactive with first-stage antibody

Immunoscreening of Fusion Proteins Produced in Lambda Plaques

132-mm nitrocellulose membrane filters

Additional reagents and equipment for titrating and plating bacteriophage (UNITS 1.11 & 6.1) and autoradiography (APPENDIX 3)

NOTE: All materials coming into contact with *E. coli* must be sterile.

1. Titer and plate a λ gt11 cDNA library with *E. coli* LE392 on 150-mm LB plates, using 7 ml of 1% LB top agar per plate (see UNIT 6.1).

We have not found it necessary to use lysogenic inducing, protease-deficient (lon) strains, or late lytic inductions of the lacZ-cDNA fusion genes in order to detect antigenic material on a solid support. Normally E. coli LE392 is used for λ gt11.

2. Incubate plates 8 hr at 37°C.
3. Lay a numbered 132-mm nitrocellulose filter on the plate (UNIT 6.1, step 6).
4. Incubate the plates and filters overnight at 37°C.

Continued plaque growth in close contact with nitrocellulose strongly enhances the autoradiographic signal over that achieved by short-term contact at any time during plaque growth. This may be due to enhanced binding of fusion protein during lysis of infected bacteria that grow in the membrane rather than in the top agar.

5. Mark each filter asymmetrically with needle holes, as done for DNA plaque filter hybridization (UNIT 6.1, step 7).

It is helpful to add sodium azide to 0.05% to India ink to prevent contamination of the plaque plates.

6. Remove the nitrocellulose filters and block the protein binding sites by washing the filter in immunoscreening buffer at room temperature for 30 min. Repeat this wash 2 to 4 times to remove the bulk of the bacteria from the filter.
7. Incubate the filters with the first-stage antibody at a concentration of 0.5 to 10 μ g/ml diluted in immunoscreening buffer in a heat-sealed bag for 2 to 24 hr at 4°C on a horizontal shaker platform. Multiple filters may be placed in a single bag as long as there is sufficient liquid so that mixing between the filters occurs.

*In order to stabilize immune complexes, all reactions and washings should be done at 4°C with cold buffer. The dissociation rate of a high-affinity antibody is probably low enough that the antibody reaction could be performed at room temperature. Low-affinity sera, and especially monoclonal antibodies, may be more of a problem. Crude polyclonal rabbit serum, affinity-purified, or ammonium sulfate-precipitated sera have all been used with positive results. Monoclonal antibodies in a variety of forms including ascites fluid and tissue culture supernatants have also been used successfully. It is not generally necessary to remove immune reactivity to bacterial proteins prior to screening filters. However, if reaction to all of the plaques is observed, first-stage antibody can be absorbed with *E. coli* extracts. *E. coli* extracts are commercially available for the absorption of antibodies reactive to *E. coli* proteins. Another method for removing antibody specific for bacterial or bacteriophage proteins is to reuse first-stage antibody.*

8. Wash the filters 4 to 5 times in immunoscreening buffer at 4°C for 5 to 10 min per wash.

It is necessary to consider the dilution factor during washing to be sure that the concentration of residual first-stage antibody in the detection-stage probing is insignificant.

9. Incubate the filters with ^{125}I -labeled second-stage antibody, at a concentration of 0.5×10^6 cpm/ml diluted in immunoscreening buffer in heat-sealed bags for 2 to 6 hr at 4°C .

The second-stage antibody should react very specifically with the first-stage antibody. The use of protein A to detect those antibodies able to bind it is recommended. The use of anti-immunoglobulin as a second-stage reagent may result in the detection of cDNA clones by the anti-immunoglobulin alone. Several manufacturers produce enzyme-linked chromagenic detection kits for use in phage plaque immunological screening procedures. It has been this author's experience that the signals obtained with these kits do not match the absolute signal-to-noise ratio offered by ^{125}I -labeled second-stage reagent. Should the use of such kits be desirable, it is recommended that the researcher carefully follow the manufacturer's directions.

10. Wash 4 to 5 times in immunoscreening buffer at 4°C .

Be aware of local isotope disposal recommendations and treat waste accordingly.

11. Blot dry, wrap in plastic wrap, and expose to X-ray film with an intensifying screen at -70°C .

12. Purify λ cDNA fusion-protein clones by repeated dilutions until pure, and grow for DNA preparation (UNIT 6.5).

The techniques used for picking plaques are similar to those used in DNA hybridization screening.

SHORT PROTOCOL

SCREENING A λ gt11 EXPRESSION LIBRARY WITH ANTIBODIES

1. Titer and plate a λ gt11 cDNA library with *E. coli* LE392 on LB plates with 7 ml of 1% LB top agar/plate. Incubate 8 hr at 37°C .
2. Lay a numbered nitrocellulose filter on plate and incubate overnight at 37°C .
3. Mark each filter with needle holes and India ink, remove, and wash 3 to 5 times in immunoscreening buffer, 30 min per wash at room temperature.
4. Incubate filters with first-stage antibody (0.5 to 10 $\mu\text{g}/\text{ml}$ in immunoscreening buffer) in a heat-sealed bag, 2 to 24 hr at 4°C on a horizontal shaker platform.
5. Wash filters 4 to 5 times in cold immunoscreening buffer, 5 to 10 min per wash at 4°C . Incubate with ^{125}I -labeled second stage antibody (0.5×10^6 cpm/ml in immunoscreening buffer) 2 to 6 hr at 4°C .
6. Wash filters 4 to 5 times as described in step 5. Blot dry, wrap in plastic wrap, and expose to X-ray film at -70°C with intensifying screen.
7. Purify λ cDNA fusion-protein clones by repeated dilutions until pure, and grow for DNA preparation (UNIT 6.5).

INDUCTION OF FUSION PROTEIN EXPRESSION WITH IPTG PRIOR TO SCREENING WITH ANTIBODIES

ALTERNATE
PROTOCOL

The probability of success in screening a λ gt11 cDNA library with an antibody can sometimes be increased by preventing the expression of the fusion protein until the plaques are well established. The expression of the potential β -galactosidase-cDNA fusion proteins can be induced after 3 to 4 hr of plaque growth by placing a nitrocellulose filter containing the inducer IPTG onto the plate and continuing growth at 37°C. The nitrocellulose filters are then screened with antibodies as in the basic protocol.

Additional Materials

E. coli Y1090 (Table 1.4.5)
10 mM IPTG (Table 1.4.2)
42°C room or incubator

1. Absorb 10^4 to 5×10^4 cDNA-fusion λ phage (UNIT 1.11) with 0.5 to 1.0 ml *E. coli* Y1090. These cells should be from a fresh overnight culture grown at 37°C.

E. coli Y1090 cells express high levels of the lac repressor, ensuring that no fusion gene expression occurs until plaque growth is well established and the strain bears a mutation in a bacterial protease gene (*lon*), thus reducing degradation of the recombinant protein.

2. Plate on 150-mm LB plate with 7 ml LB top agar.

These plates should be reasonably fresh, poured 2 to 3 days before use. Plates that are too wet will have a tendency to lose the top agar layer to the first or second piece of nitrocellulose placed on the plate. Using 1% agar (instead of 0.7%) for the top layer will reduce this tendency.

3. Incubate the plates 3.5 hr at 42°C.

This higher temperature incubation should make any fusion protein produced as unstable as possible, as well as ensure that the temperature-sensitive λ cI857 repressor is completely denatured.

4. While the plates are incubating, soak a 132-mm nitrocellulose filter in 10 mM IPTG. Dry the filter.

5. Lay the filters on the plates bearing the bacteriophage library. Incubate 3.5 hr at 37°C. Mark each filter and remove from plate. Block the remaining protein-binding capacity and probe the filters as described in basic protocol (steps 6 to 12).

The IPTG in the filter induces expression of the phage lacZ-cDNA fusion gene. A second filter may be applied to the plate after removal of the first filter. In this case, incubate the plate at 37°C for an additional 3 hr before marking and probing the second filter.

REAGENTS AND SOLUTIONS

Immunoscreening buffer

Prepare in phosphate-buffered saline (PBS):
5% nonfat dry milk
0.1% Nonidet P-40 (NP-40)
0.05% sodium azide (made from 5% stock solution)

Screening
Recombinant
DNA Libraries

6.7.4

COMMENTARY

Background Information

The use of *in situ* immunoassays to isolate bacteriophage or plasmid recombinants expressing fusion proteins is straightforward in both concept and execution. Normally, production of a cDNA library of sufficient quality is more difficult than screening the library. The various techniques used to date are the generally standard immunoassays. The immunological screening of bacterially synthesized fusion proteins produced by either plasmids or phage involves two basic technical procedures: the synthesis and immobilization of antigenic material to a solid support followed by a sensitive detection procedure.

Demonstration that a cDNA encodes an antigenic determinant does not prove that it encodes the protein of interest. It is essential to note that the isolation of DNA sequences encoding an antigenic determinant (e.g., with a monoclonal antibody or an antisera directed, as most may be, against only a single epitope within any given cDNA sequence) carries the risk that the detected determinant is not encoded by the desired sequence, but by a sequence related only at the level of protein product structure. Additionally, it is important to determine early in the experiment that the autoradiographic signal of a positive clone is dependent upon the first antibody stage.

Antibody reactive sequences should be tested for the presence of at least one other distinguishing property that the desired sequence may reasonably be expected to have. These distinguishing properties may be unusual mRNA or encoded protein sizes, regulated expression in appropriate cell types, expression of the expected gene product or an appropriate genetic function by transfected genomic DNA or cDNA expression vector clones, or the expression of a second, different antigenic determinant in common with the known protein within the same clone. In general, clones isolated by monoclonal antibodies directed to different epitopes of the same protein would either cross-hybridize or be contained within the same full-length clone if the identified sequences were correct.

Literature Review

The development of *in situ* immunoassays for the detection of cloned gene products expressed on either plasmids or bacteriophage λ began no later than the report by Skalka and

Shapiro (1976) on immunological techniques for the detection of β -galactosidase protein in phage plaques and bacterial colonies. These techniques depended on the production of an immunoprecipitate within the plaque or colony and were superseded by more sensitive techniques based on the detection of immobilized antigen with ^{125}I -labeled detection stages. The immobilization techniques used in these procedures were either direct or required the binding of antigen to antibody followed by detection with a second antibody (Erlich et al., 1978; Kemp and Cowman, 1981; Helfman et al., 1983; Young and Davis, 1983).

Critical Parameters

It is important to ensure that the density of the plated phage is not too high. Most of the protein during phage growth is produced relatively late in the infection at the edge of the plaque when the largest number of cells have been infected. As a result, if such a large number of phage are present that plaques begin to touch one another, fewer cells will be infected in the area of contact, less protein will be produced, and a lower signal will result. The same consideration applies to DNA plaque filter hybridizations.

The antibody used as a probe must be as pure in immunological activity as possible. These techniques are exquisitely sensitive to immunological impurities and already suffer from the problems of cross-reactivity with other antigens produced as fusion proteins. The ideal probe would be a collection of monoclonal antibodies directed to different epitopes on the same protein. Used separately, these probes would each have their own special patterns of cross-reactivity with related protein structures. An immunologically very pure antisera may have activity directed to multiple epitopes on the same protein, but all potential cross-reactivities are present at once. It is possible that a sera may give a higher signal than a monoclonal antibody, but this does not seem to be routinely supported by experience. Signal strengths vary considerably. The higher the specific titer, the more likely it is that a positive signal will be detected. There is no obvious correlation as yet with the type of probe, monoclonal versus sera, or the isotype of the monoclonal. Be aware that occasional bacterial contaminants may give "signals."

It is the preference of this author to use ¹²⁵I-labeled reagent for reasons of increased sensitivity and for the ability to make multiple autoradiograms of each experiment.

Time Considerations

These procedures are well suited for 1- to 3-day cycle times. Generally, the phages are plated in the morning of the first day and the filters placed on the plates at the appropriate time. In the basic protocol, the filters are left on the plates overnight. The antibody probing may be completed the second day, or if the first-stage probing is also done overnight, the detection stage probing may be done on the third day. After probing with the first antibody, it is probably a good idea to finish the probing as quickly as possible to avoid any problem of dissociation of the primary antibody from the filter-bound antigen. In the alternate protocol, the filters may be either stored wet overnight or incubated in the first-stage antibody and the probing continued the following day.

Immunoscreening after Hybrid Selection and Translation

BASIC PROTOCOL

In this procedure plasmid cDNA clones are screened for their ability to select a particular mRNA. Plasmid DNA is bound to nitrocellulose filters, hybridized to mRNA, washed, and the selected mRNA is eluted from the filter. Eluted mRNA is characterized by translation into ³⁵S-labeled protein, which is identified by immunoprecipitation and denaturing (SDS) polyacrylamide gel electrophoresis. The desired clone is that which is able to select an mRNA that translates into the desired protein. This procedure can be modified to characterize cosmids and bacteriophage DNA.

Materials

Brain-heart-infusion (BHI) medium (37.5 g/liter, autoclaved) containing appropriate antibiotics
 Chloramphenicol (Table 1.4.1)
 TE buffer, pH 7.6 (APPENDIX 2)
 1 M NaOH
 Neutralization solution
 6× SSC (APPENDIX 2)
 Hybridization solution IV
 Poly(A)⁺ mRNA (UNIT 4.5)
 65°C TES buffer in 0.5% SDS
 65°C TES buffer
 10 mg/ml yeast tRNA
 Buffered phenol (UNIT 2.1)
 50:1 chloroform/isoamyl alcohol
 3 M sodium acetate, pH 5.2
 Ethanol
 Translation mixture
 [³⁵S]methionine (800 Ci/mmol)
 Immunoprecipitation buffer
 Nonimmune serum
 Protein A–Sepharose suspension
 Polyclonal or monoclonal antibodies (Chapter 11)
 High-salt immunoprecipitation buffer
 2× SDS/sample buffer (UNIT 10.2)
 96-well microtitration dish
 Beckman JS-4.2 rotor or equivalent
 Sterile 15-ml capped glass culture tubes
 0.45-μm nitrocellulose filters (2.5-cm diameter)
 Multifilter washing apparatus
 80°C vacuum oven
 Sterile 1.8-ml round-bottom plastic tubes (Nunc)
 Sterile silanized 1.5-ml microcentrifuge tubes (APPENDIX 3)
 Sterile needles
 Additional reagents and equipment for preparation of plasmid DNA (UNIT 1.6) and denaturing (SDS) polyacrylamide gel electrophoresis (UNIT 10.2)

Isolate plasmid DNA

1. Pick individual cDNA clones into wells of a microtiter dish containing 0.25 ml BHI medium plus the appropriate selective antibiotics. Grow overnight at 37°C.
2. Inoculate 50 ml BHI/antibiotic medium in a 250-ml flask, with 0.1 ml from each of 10 individual overnight clone cultures. Grow at 37°C in thermo-regulated shaker

until A_{590} is 0.7. Add chloramphenicol to a final concentration of 100 $\mu\text{g/ml}$ and grow overnight at 37°C. Harvest cells by centrifugation 10 min at 3000 rpm (2000 \times g), 4°C.

The number of clones in a pool that would allow the detection of an individual clone depends on the abundance of the specific mRNA and on the sensitivity of the immunodetection assay. If none of these parameters is known, 10 clones per pool are recommended. Manipulation of 10 to 20 different pools in parallel throughout the entire process is reasonable to handle.

3. Prepare plasmid DNA as described in UNIT 1.6.

Bind plasmid DNA to nitrocellulose filters

4. Dilute ~50 μg crude plasmid DNA in 1.5 ml TE buffer, transfer the solution into 15-ml sterile, capped glass culture tubes, incubate 10 min in a boiling water bath, immediately add 1.5 ml of 1 M NaOH, and leave at room temperature for 10 min. Add 9 ml neutralization solution, mix well, and place on ice while checking the pH.

pH after neutralization should be 6.5 to 7.5; otherwise, correct with NaOH or HCl. Do this as quickly as possible, as renaturation of DNA before binding to the filter should be prevented.

5. Place a 0.45- μm nitrocellulose filter (2.5-cm diameter) on porous support attached to a vacuum line. Pour denatured DNA solution (~50 μg plasmid DNA) over the filter at a flow rate of 1 ml/min. After all the DNA solution passes through the filter, continue suction for 3 min, increasing the vacuum to maximum. Wash each filter with 50 ml of 6 \times SSC. Fix the DNA to the filter by baking at 80°C in vacuum for 2 hr.

Binding of the DNA to the filter can be done on any of the commercially available filter washing devices. An apparatus allowing the manipulation of 10 filters simultaneously is preferable.

Once the filters have been baked at 80°C, be careful to handle and store in a sterile manner.

6. Punch out disks of 0.5 cm diameter from the filter using a sterile one-hole paper punch. Mark the filter disks with a ballpoint pen.

Select desired mRNA by hybridizing to plasmid DNA

7. Place 0.3 ml hybridization solution in a sterile, capped plastic tube (1.8-ml round bottom Nunc tubes are the most suitable for this purpose). Add 10 to 50 μg poly(A)⁺ mRNA, preheat 10 min at 70°C, then put up to ten filter disks in the tube and incubate 2 hr at 50°C.
8. Transfer filter disks to a 50-ml test tube (up to 20 filters per tube), wash with 25 ml TES/0.5% SDS buffer prewarmed to 65°C, hand vortex 0.5 min, and remove supernatant using a sterile Pasteur pipet connected to a vacuum line. Repeat nine more times and then wash twice with 25 ml prewarmed (65°C) TES buffer.
9. Transfer individual filters to sterile silanized 1.5-ml microcentrifuge tubes. Add to each tube 0.3 ml sterile water and 2 μl of 10 mg/ml yeast tRNA. Boil 60 sec then quick-freeze in a dry ice/ethanol bath and thaw at room temperature.

Commercial preparations of tRNA should be phenol extracted several times prior to use.

10. Remove filters with a sterilized needle, add to each eluted RNA solution 0.15 ml buffered phenol and 0.15 ml chloroform/isoamyl alcohol and extract once. Add 30 μl of 3 M sodium acetate to the aqueous solution and then precipitate the RNA with

2 vol ethanol. Pellet the RNA by a 15-min spin in a microcentrifuge. Wash the pellets with 0.5 ml ethanol, dry by lyophilization, and resuspend in 10 μ l water.

The RNA solutions should be stored at -70°C , or preferably used immediately in the translation reaction.

Translate selected mRNA and characterize by immunoprecipitation

11. To 5 μ l hybrid-selected RNA add 10 μ l translation mixture containing ^{35}S -labeled methionine. (Use amount of label recommended by the manufacturer of the translation mixture.) Incubate 60 min at 30°C .

At this stage the procedure can be discontinued by freezing the translation mixture at -70°C . The efficiency of the translation reaction can be monitored by determining ^{35}S -labeled methionine incorporation. To do so, apply 1 μ l translation mixture to 3-mm filter paper, place the filter in boiling 10% TCA for 10 min, rinse filter twice with ethanol, dry, and count incorporated label in a liquid scintillation counter.

12. To 15 μ l translation mixture add 15 μ l immunoprecipitation buffer and 1 μ l nonimmune serum (serum from a nonimmunized animal, or normal ascites fluid if monoclonal antibodies will be used for immunoprecipitation). Incubate 10 min at room temperature, then add 40 μ l protein A–Sepharose suspension and leave at room temperature for 30 min. Spin down Sepharose 2 min in microcentrifuge, carefully transfer the supernatant to another microcentrifuge tube, and discard the Sepharose pellet.

This step removes polypeptides from the translation mixture that bind nonspecifically to Sepharose or to antibodies.

13. Add 1 μ l polyclonal or monoclonal antibodies directed against the relevant gene product to the supernatant and incubate 10 min at room temperature. Add 40 μ l protein A–Sepharose suspension and incubate at room temperature for another 30 min. Spin down Sepharose and discard the supernatant.
14. Wash the Sepharose beads three times with 1 ml immunoprecipitation buffer, once with 1 ml high-salt immunoprecipitation buffer, and once with 1 ml water.
15. Resuspend pellet in 20 μ l $2\times$ SDS/sample buffer, boil 10 min to elute bound polypeptides from Sepharose protein-A beads. Spin down the Sepharose and put 15 to 20 μ l into slots of polyacrylamide gel.

Fractionate immunoprecipitated protein on denaturing gel

16. Run a denaturing SDS/polyacrylamide gel at the conditions optimal for separation of the polypeptide. Dry the gel and expose it to autoradiography.

Remember to run in parallel an appropriate control containing the polypeptide encoded by the gene for which selection is being made.

17. If one of the lanes contains the required polypeptide band, subject the individual clones of the positive pool to the same procedure.

REAGENTS AND SOLUTIONS

High-salt immunoprecipitation buffer

Same recipe as immunoprecipitation buffer, except NaCl is 0.5 M

Hybridization solution IV

65% deionized formamide
0.4 M NaCl
0.2% sodium dodecyl sulfate
30 mM PIPES, pH 6.5
50 µg yeast tRNA
50 to 500 µg poly(A)⁺ mRNA (see critical parameters)

Hybridization solution should be made fresh prior to use.

Immunoprecipitation buffer

10 mM Tris-Cl, pH 7.4
2 mM EDTA
0.15 M NaCl
10% (v/v) Nonidet P-40

Neutralization solution

200 ml 20× SSC (APPENDIX 2)
100 ml 1 N HCl
100 ml 1 M Tris-Cl, pH 8

Protein A–Sepharose suspension

1.5 g of Sepharose Protein-A (Pharmacia) is resuspended in:

10 mM Tris-Cl, pH 7.5
0.15 M NaCl
0.4% Triton X-100 (v/v)
0.5% Aprotinin (v/v) (Sigma)

Shake for 5 min. Spin down beads, wash 3 times with same buffer, then resuspend in 11 ml of the buffer.

TES buffer

0.15 M NaCl
10 mM Tris-Cl, pH 7.6
1 mM EDTA

Translation mixture

Any reticulocyte or wheat germ translation mixture system can be used; prepare as recommended by manufacturer.

COMMENTARY

Background Information

In hybrid selection screening, the various immobilized cDNA clones select homologous mRNA molecules from an mRNA pool. Individual mRNA species can then be eluted and used to direct the synthesis of the corresponding polypeptide in an *in vitro* translation system. This will yield a battery of polypeptides encoded by the various genes represented in a given cDNA library. The actual screening step in the procedure involves the specific identifi-

cation of the polypeptide molecule.

In the protocol described here, precipitation by homologous antibodies is suggested for the recognition of the desired polypeptide. The immunodiagnostic steps can be replaced by monitoring the specific biological activity of the polypeptide, providing the test of this activity is sensitive enough and the activity does not require interaction with multiple polypeptides (March et al., 1985).

The hybrid selection method can also be

used as a backup for other screening procedures. Subtractive hybridization screening procedures or hybridization with mixed oligonucleotides (see *UNITS 6.3* and *6.4*, respectively) are often ambiguous and result in the isolation of other clones in addition to the ones that are required. Here the hybrid selection system can be easily applied to distinguish between the various isolates and identify the correct one (Lemke and Axel, 1985).

This protocol is designed for screening a large number of cDNA clones and for isolating cDNAs corresponding to rare mRNAs.

Literature Review

Hybridization of mRNA to filter-immobilized DNA followed by translation of the eluted mRNA as a means for identification of specific DNA sequence was first suggested by Harpold et al. (1978) and Ricciardi et al. (1979). This approach was adapted for the screening of cDNA libraries by Parnes et al. (1981), upon which the protocol given here is based. Hybrid selection screening has been used for the identification of numerous genes during the past several years. Among the more recent examples are the Interleukin I gene (March et al., 1985) and structural protein of myelin cells (Lemke and Axel, 1985).

Critical Parameters

The number of cDNA clones that can be applied on one filter, the amount of mRNA that should be used for hybridization, and the temperature and duration of the hybridization can vary significantly from one clone to the other. These parameters depend on the abundance of the specific mRNA species in the mRNA pool, on the sensitivity of the assay used for polypeptide identification, and on the G:C content of the nucleic acids involved. The protocol given here is as "universal" as possible, but one should experiment with the above-mentioned parameters to obtain optimal results.

Degradation of the mRNA during hybridization or elution from filters is among the common problems of this method. RNA degradation can be easily monitored by incorporating into the assay a labeled SP6-derived mRNA transcript and its corresponding cDNA as an internal control. Such a control also allows a quantitative evaluation of each of the steps of the procedure.

Anticipated Results

A cDNA clone is considered positive if a filter carrying the cDNA binds an mRNA spe-

cies that can be translated into a polypeptide recognized by the specific antibody. The sequence of all positive clones should be determined for final verification. False positive clones may be detected by this method due to cross-reactivity of the antibodies or presence of additional specificities in the antiserum preparation.

Time Considerations

When planning hybrid selection screening it is advisable to separate the preparation of filters carrying the cloned DNA from the hybridization and translation steps. Filters can be prepared in advance and stored under sterile conditions for a couple of weeks. Preparation of 10 to 30 filters per day is very reasonable so that within a week, as many as 500 to 1500 individual clones can be transferred onto nitrocellulose. Hybridization to mRNA can be done in batches of 10 filters; 20 to 50 filters can be processed in one experiment and translated the same day. The procedure can be interrupted either after the translation by freezing the translation mixture or after immunoprecipitation by freezing the eluates recovered from the Sepharose beads.

YEAST ARTIFICIAL CHROMOSOME LIBRARIES

Overview of Strategies for Screening YAC Libraries and Analyzing YAC Clones

Emphasis on identification of disease genes by positional cloning has underscored the need to clone fragments of genomic DNA >100 kb into a vector. The size of genomic inserts that can be carried in traditional cloning vectors has been limited to 20 to 25 kb for λ vectors and 40 to 45 kb for cosmid vectors. These vectors are of limited utility for analyzing very large genes or for “walking” to disease genes from DNA markers that may be 1 to 2 Mb away. Considerable progress has been made in cloning large DNA fragments in *Saccharomyces cerevisiae* using yeast artificial chromosome (YAC) vectors (see Fig. 13.4.6). YACs containing inserts that are >1 Mb have been produced and these are routinely propagated with apparent stability, suggesting that the major limitation to the size of YAC inserts is the quality of the starting genomic DNA. Large “core” laboratories that generate human YAC libraries—such as the Center for Genetics in Medicine, Washington University School of Medicine, St. Louis; the Centre d’Etude du Polymorphisme Humain (CEPH), Paris; and the Genome Analysis Laboratory, Imperial Cancer Research Fund, London—prepare human YACs with average insert sizes ranging from 0.3 to 1.2 Mb. Additional high-quality YAC libraries have been constructed using inserts from *Drosophila melanogaster*, *Caenorhabditis elegans*, *Schizosaccharomyces pombe*, and mouse (Burke et al., 1991; Rossi et al., 1992).

Anecdotal reports indicate YAC libraries may support the propagation of certain insert sequences that are poorly represented in *Escherichia coli*-based libraries. The YAC cloning system also offers the advantage that large genomic YAC inserts can be easily manipulated in yeast by homologous recombination. Thus, it is relatively simple to truncate a YAC insert or to introduce specific deletions, insertions, or point mutations with high efficiency using methods such as those described in UNIT 13.10.

This unit provides an introduction to the use of yeast artificial chromosome-bearing yeast clones (hereafter referred to as YAC clones) in genome analysis. It describes criteria for de-

signing a polymerase chain reaction (PCR) assay to be used in screening a YAC core library and discusses the rationale for verification and characterization of YAC clones obtained from these core laboratories. Protocols for maintaining YAC clones, analyzing YAC insert structure, preparing YAC DNA, and subcloning YAC inserts into other vectors are presented in UNIT 6.10. These protocols are outlined in the flow chart in Figure 6.9.1.

GENERATING YAC LIBRARIES

Although YAC cloning is the method of choice when insert sizes >100 kb are required, a number of features of the system have interfered with its rapid assimilation for routine cloning. Because the *S. cerevisiae* genome is at least an order of magnitude more complex than the *E. coli* genome and existing YACs are carried as only a single copy within yeast cells, the signal-to-noise ratio is less favorable for identifying a cognate clone in a YAC library than in a λ or cosmid library. Moreover, efforts to develop high-density screening methods for YACs have enjoyed only limited success. Most laboratories that maintain YAC libraries organize them as collections of individual clones in 96-well microtiter plates, which can be replicated faithfully and kept frozen for storage; in this form, a standard library representing 5 to 8 genome-equivalents comprises more than 500 microtiter plates. As a result, the effort and resources required to construct YAC libraries and prepare them for screening are enormous. Consequently, it is generally most practical for investigators wishing to obtain YACs carrying a specific DNA sequence to arrange for screening of a preexisting library maintained by a core laboratory.

Initially, YAC libraries were constructed with total genomic DNA (Burke et al., 1987). More recently, there has been interest in generating libraries from targeted DNA using somatic cell hybrids carrying a specific chromosome or portion of a chromosome. The feasibility of this approach has been demonstrated with the construction of a library carrying a portion of the human X chromosome (Abidi et

al., 1990). Additional targeted libraries are in the late stages of development and should reduce the cost and effort of screening for loci whose chromosomal location has been established.

YAC LIBRARY SCREENING BY A CORE LABORATORY

Methods used by YAC core laboratories for library screening evolve rapidly. It is possible to screen a library by hybridizing a single-copy probe to nylon filters stamped with a replica of one or more microtiter arrays. However, because of the low signal-to-noise ratio for hybridization and the substantial cost required to produce all of the nylon filter replicas, most laboratories perform library screening using PCR (Green and Olson, 1990).

At the time of this writing, most core facilities first extract DNA from pools of clones, usually representing 1 to 4 microtiter plates (96 to 384 YACs) per pool, and then combine this pooled DNA into more superpools of 1500 to 2000 YACs. The pools and superpools are screened by PCR to identify candidate microtiter plates containing at least one amplifying YAC clone. Final identification of the clone is most commonly performed either by colony hybridization using the PCR product as the probe or by screening pools of rows and col-

umns from the same microtiter plate using PCR. The time required for a YAC core laboratory to verify the specificity and parameters of the PCR assay and screen complex clone pools and subpools is usually 3 to 8 weeks.

As an example, the screening strategy used by one major core laboratory is described in the accompanying box. It should be noted that this procedure may change as technology advances; for instance, the recent advent of techniques providing reliable DNA extraction from small quantities of thousands of individual clones has made it feasible to screen individual wells on a plate and eliminate the laborious filter-hybridization step.

DESIGNING A LOCUS-SPECIFIC PCR ASSAY FOR SCREENING

An investigator arranging with a core laboratory for library screening is required to design a strategy for detecting the inserted genomic DNA and to provide the appropriate probe(s). It is worth investing considerable effort to create a convenient and reliable assay because the assay's success depends on its ability to detect the target sequence with high sensitivity while being insensitive to the presence of large excesses of yeast and plasmid sequences. Because a core laboratory must adopt PCR assays that have been imported

EXAMPLE: SCREENING OF HUMAN-GENOME YAC LIBRARY AT THE WASHINGTON UNIVERSITY SCHOOL OF MEDICINE

At this core facility, screening of the human-genome YAC library proceeds in three stages: (1) initial evaluation of the PCR assay; (2) screening of pools of YACs; and (3) identification of individual YACs from subpools to the single well by filter hybridization.

To permit pretesting of assays before they are sent to a screening core, new PCR assays are evaluated using four control DNA samples as templates: (1) CGM-1 human genomic DNA (33 ng/ μ l) from a lymphoblastoid cell line established from the donor whose DNA was used in preparing the YAC library; (2) YY212 DNA from a yeast strain carrying a YAC whose insert is yeast chromosomal DNA; (3) "single-membrane-pool" DNA (33 ng/ μ l) prepared from a pool of 396 YAC isolates; and "spiked-pool" DNA, which is single-membrane-pool DNA augmented with 5 ng/ μ l of CGM-1 DNA.

CGM-1 DNA serves as a positive control to demonstrate that the sensitivity of the PCR assay is adequate. YY212 DNA serves as a negative control, demonstrating that no product is amplified from either yeast host genomic DNA or the YAC vector. DNA from the single-membrane pool and the spiked pool provide additional negative/positive controls that more closely mimic library screening conditions. A negative signal from single-membrane-pool DNA demonstrates lack of cross-reactivity of the probe with the YAC vector, yeast genomic DNA, or common human repetitive sequences. A positive signal obtained from the spiked-pool DNA (containing only 5 ng/ μ l of CGM-1 DNA) is a strong indication that the assay possesses sufficient sensitivity against a yeast DNA background for successful library screening.

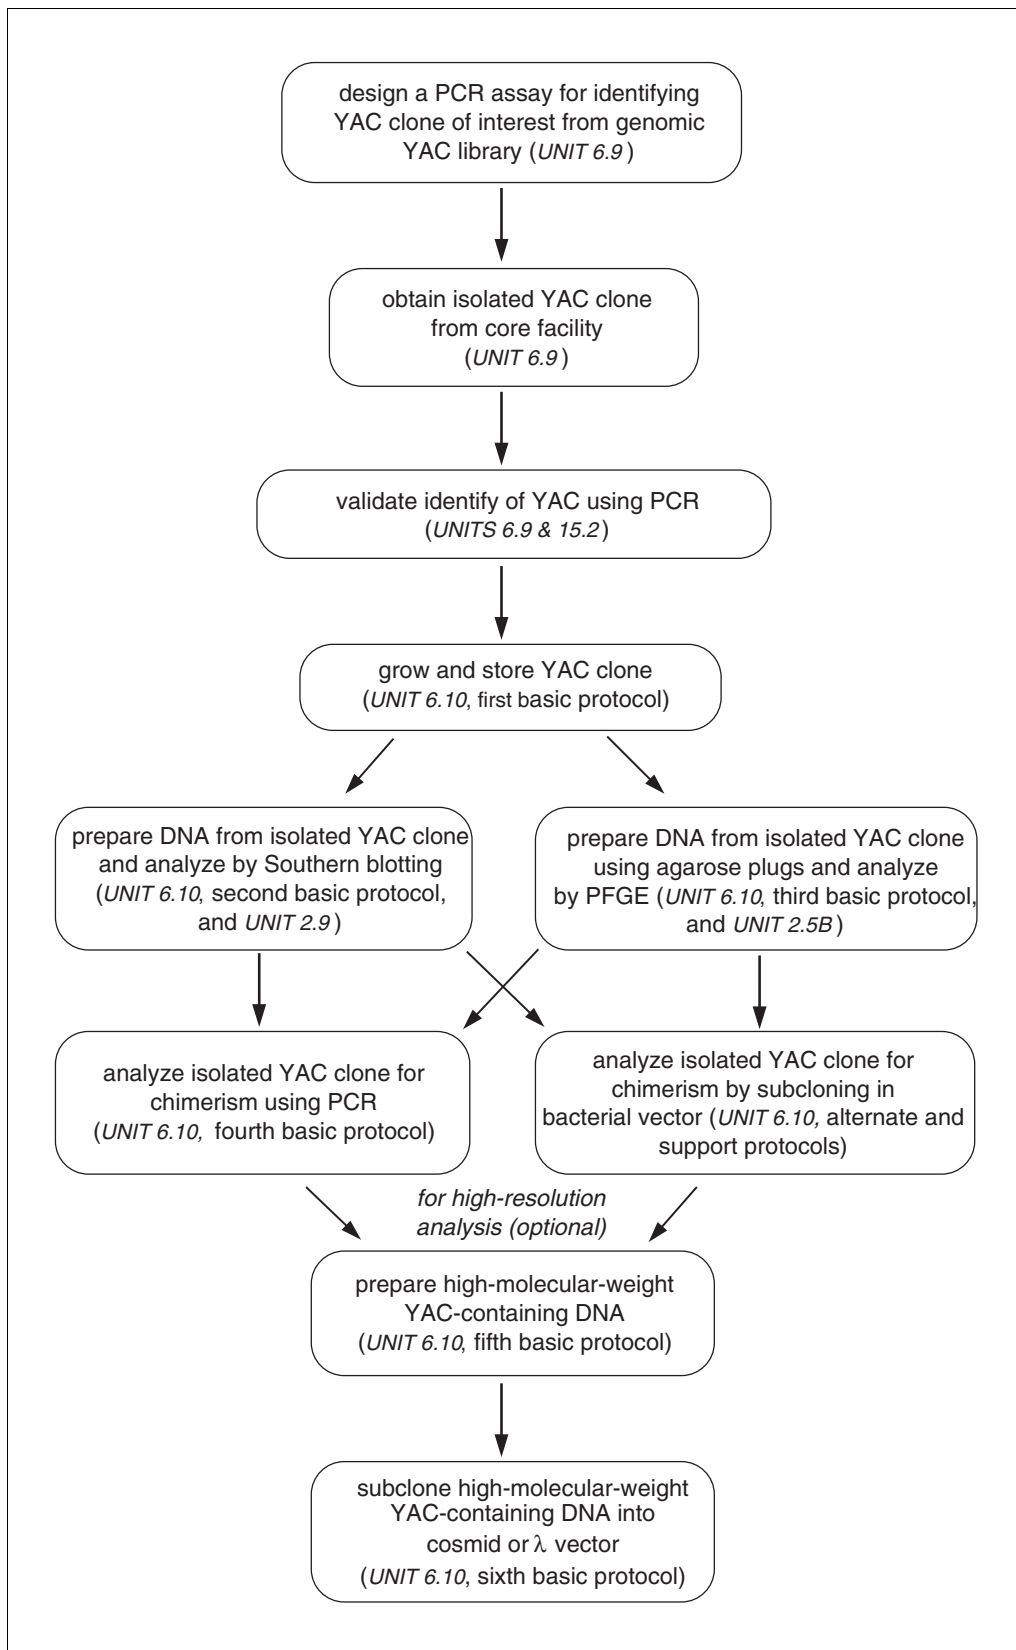

Figure 6.9.1 Flow chart showing protocols used to obtain and analyze YAC clones.

from outside laboratories, it is a good idea to inquire in advance about the protocols preferred by the specific core facility that will be performing the screening.

In general, any highly specific, sensitive, and robust PCR assay is suitable for screening a YAC library (see Chapter 15). Typically, two 18- to 30-mer oligonucleotide primers for use in amplifying a single-copy 75- to 750-bp product are satisfactory. Such primers define a landmark for genome mapping called an STS (sequence-tagged site; see introduction to Chapter 7 and Olson et al., 1989). When designing a PCR assay from scratch, it is useful to consider the following:

Fragment size

The STS should be 75 to 750 bp in length. Fragments in this range are most efficiently amplified by PCR and are easily detected by either polyacrylamide (UNIT 2.7) or standard agarose (UNIT 2.5A) gel electrophoresis.

Primer length

Each primer should ideally be 18 to 30 nucleotides long, be composed of 50% to 55% G + C, and be contained within a single-copy human-genomic-DNA segment. This ensures efficient priming and decreases the probability of false priming, enhancing the sensitivity and specificity of the assay. This also permits the amplified fragment to be used as a hybridization probe in the final hybridization-dependent steps of library screening (see below). If it is not possible to amplify a single-copy fragment, then some other single-copy probe (e.g., a synthetic oligonucleotide 30 nucleotides long) should also be prepared. Oligonucleotide design strategies are discussed further in UNITS 2.11 & 15.1.

Primer affinity

Primers should show little affinity for self-annealing or for annealing with each other. This prevents the production of small, template-independent PCR products that compete for primers in the reaction. A number of academic and commercial DOS-based and Macintosh software programs permit rapid selection of non-self-annealing primers from within a known DNA sequence (e.g., Oligo 4.0, National Biosciences; Primer, S. Lincoln and M. Daly, Whitehead Institute for Biomedical Research, Cambridge, Mass., and OSP, Hillier and Green, 1991; see UNIT 7.7). Although the use of these programs cannot remove all the uncertainty associated with designing a new PCR

assay, it does help eliminate some of the most trivial causes of assay failure.

ANALYZING INDIVIDUAL YAC CLONES

Once library screening has been successfully completed and the isolated YAC clone has been furnished to the investigator, attention should be directed to analyzing its structure. Initial studies should focus on determining whether the genomic insert is chimeric, checking for evidence of rearrangement within the insert, and verifying that the YAC is propagated in stable fashion in the yeast cell (see below). Simply analyzing several isolates of the same YAC in parallel may provide a means of recognizing instability, as each isolate serves as a control for the others. The following sections give an overview of strategies for analyzing YAC clones; specific protocols are given in UNIT 6.10.

Chimerism of the YAC Insert

A consistent problem in YAC cloning is chimerism of the YAC insert—i.e., the insert is composed of two or more separate genomic fragments joined in a single YAC. The mechanism(s) giving rise to chimeric YAC clones are currently not fully understood (Green et al., 1991). In most existing total genomic YAC libraries, chimeric clones represent from 5% to 50% of the total clones. Preliminary data suggest that targeted, chromosome-specific libraries may contain only 5% to 15% chimeric clones. Although future generations of YAC libraries are likely to contain lower frequencies of chimeric clones, chimerism will probably remain a significant problem requiring assessment for every new YAC clone being analyzed.

The most reliable way to determine if a YAC insert is chimeric is to isolate a small fragment from each end of the insert and determine its chromosome of origin and whether it shares sequences with overlapping YACs derived from the same chromosomal region. Many approaches have been suggested for isolating such YAC genomic insert end fragments, all of them relying upon the fact that end fragments are marked by their adjacent YAC vector sequences. Thus, it is possible to determine whether a YAC insert is chimeric by preparing probes from the two YAC vector arms and using these to demonstrate that both ends of the YAC map to the same general chromosomal region. This is generally done using hybridization or PCR analysis of a somatic hybrid cell line containing the appropriate human chromo-

some (or preferably a fragment thereof) as its sole human DNA. The appropriate end-fragment probes may be produced in several ways, two of which are presented in *UNIT 6.10*.

The most rapid and versatile approaches to producing end-fragment probes use PCR amplification (Riley et al., 1990; Green, 1992). The template is a restriction fragment produced by cutting the YAC DNA at sites near the two ends of the genomic insert. The YAC DNA is digested with a frequently cutting restriction endonuclease to produce a collection of small restriction fragments. One of the fragments contains the distal portion of the YAC insert still associated with a portion of the left vector arm, while another contains the other end of the insert associated with a portion of the right vector arm (the arm of the YAC vector containing the yeast centromere is arbitrarily designated the left vector arm and the arm containing the *ura3* selection marker is arbitrarily designated the right vector arm). These fragments are prepared for PCR amplification by ligation of a synthetic double-stranded DNA tag to both ends. This tag contains a 29-nucleotide “bubble” of noncomplementary sequence flanked by two 12-nucleotide complementary sequences (Fig. 6.10.2). The two YAC-insert end fragments can then be selectively amplified using one PCR primer derived from the YAC vector and one primer with the sequence of the noncomplementary portion of the bubble.

These methods are generally favored because of their speed, but they depend on the fortuitous placement of restriction sites close enough to the ends of the genomic insert that a fragment suitably sized for PCR amplification can be generated. Moreover, if highly repetitive sequences are present at the distal portions of the insert, the PCR method may fail to generate useful information.

A reliable but more time-consuming method of generating probes for end-fragment analysis is conventional subcloning of larger YAC-derived restriction fragments into plasmid or λ vectors (Bronson et al., 1991). Subcloning an end fragment several kilobases in size is time-consuming, but reliably assures identification of nonrepeated sequences for use as probes. The subcloning protocol given in *UNIT 6.10* involves double-digesting the YAC DNA to enrich for end fragments in the course of subcloning the insert into a pUC19-based vector. One of two specific enzymes that cut rarely in yeast and human genomic DNA, *ClaI* or *SalI*, is included in the double digestion mixture. A *ClaI* recognition sequence lies in the left arm

of the YAC vector, while a *SalI* recognition site lies in the right arm (Fig. 6.10.1). When one of these rarely cutting restriction enzymes is used together with a frequently cutting enzyme, doubly-digested fragments constitute only a small fraction of the total digested product. Ligation to a doubly-digested plasmid vector eliminates all of the single-digested fragments, resulting in a substantial enrichment for the YAC end fragment.

Internal Rearrangement or Instability of the YAC Insert

Internal rearrangement of a YAC insert is more difficult to identify than chimerism, and may become apparent only after high-resolution analysis of the clone. Existing reports of internal rearrangement of YAC inserts are anecdotal, infrequent, and usually identify only rather large-scale changes. It is likely, however, that subtle rearrangements will be recognized as more clones are analyzed. Nevertheless, the data suggest that important rearrangements will remain relatively infrequent and will not impede most YAC cloning efforts.

Although YACs are usually stable in culture, deletion or other rearrangements of the insert may occur months after the initial isolation of a clone. Thus, it is wise to verify the size of a YAC following prolonged passage in culture or after it has been thawed from a frozen stock. Several different colonies of the same YAC strain should be analyzed in parallel, using the protocols in *UNIT 6.10*, to confirm that the artificial chromosome is the same size in each of the isolates.

Because cytosine methylation, which is quite frequent in the DNA of higher eukaryotic species, does not occur in yeast (Proffitt et al., 1984), it is not possible to perform direct structural comparisons of the YAC inserts and the corresponding genomic DNA isolated from higher eukaryotic cells using infrequently cutting restriction enzymes to create large-scale restriction maps. Consequently, direct structural comparisons must be carried out using methylation-insensitive restriction enzymes and frequently spaced probes.

Evidence of internal rearrangement within a YAC clone can be obtained by preparing chromosomes from the clone (*UNIT 6.10*) and analyzing them by pulsed-field gel electrophoresis (PFGE; *UNIT 2.5B*). The CHEF gel system (Vollrath and Davis, 1987) is particularly useful in that it permits excellent resolution in the size range most common for individual YAC clones. Following electrophoresis, the artificial chro-

mosome can be visualized using ethidium bromide staining as an extra chromosome not present in the host yeast strain. Occasionally, the YAC is not immediately recognizable because it comigrates with one of the endogenous yeast chromosomes. As described in the third basic protocol in *UNIT 6.10*, the PFGE gel should be Southern blotted and analyzed by successive hybridization with probes specific for the locus used in the library screening and for one or both of the YAC vector arms [e.g., for pYAC4, the 351-bp *Clal/BamHI* fragment of pBR322 (left YAC arm) and the 276-bp *BamHI/SalI* fragment of pBR322 (right YAC arm)]. These blots should show hybridization to a single chromosome of the same size in all isolates from the same YAC strain as well as no hybridization to the AB1380 host strain.

CONSTRUCTION AND ANALYSIS OF A YAC-INSERT SUBLIBRARY

Although the large genomic DNA fragments provided by the YAC cloning system are easy to manipulate, it is often convenient to reduce a YAC to smaller fragments by subcloning it into a cosmid or λ vector. In particular, such smaller fragments are more amenable to high-resolution analysis; this is important because information concerning the specific content of the YAC insert is typically limited, and often the only internal probe that is available is the one used for YAC library screening. Protocols for preparing YAC insert DNA and constructing a cosmid sublibrary are provided in *UNIT 6.10*.

Two general strategies are available for preparing YAC insert DNA in order to create a saturating collection of subclones. The more elegant strategy is to purify the artificial chromosome itself by preparative CHEF gel electrophoresis (*UNIT 2.5B*). This permits isolation and analysis of the resulting recombinant clones without further selection, assuming that only a small amount of contaminating yeast DNA is present in the purified YAC, and that essentially all subclones isolated are derived from the human YAC insert. In practice, however, it is difficult to recover sufficient quantities of purified YAC DNA to permit construction of a cosmid or λ library. An alternate approach is to prepare a library from the total DNA of the YAC-carrying yeast strain. YAC-specific subclones must then be selected by hybridization. An initial round of screening is usually performed with total human genomic DNA (rich in repetitive sequences) as the probe.

This detects subclones that contain human repetitive elements and eliminates subclones consisting of yeast DNA. Additional analysis is performed to identify overlapping sequences and thereby establish an approximate map of the original YAC insert. Ultimately, one or more rounds of chromosome walking may be required to fill in gaps between contiguous groups of subclones.

Analysis of Isolated YAC Clones

The preceding unit gives an overview of methods involved in screening a YAC library to isolate a particular clone of interest (UNIT 6.9), with the sequence of methods illustrated in a flow chart (Fig. 6.9.1). This unit provides a series of protocols describing the analysis and manipulation of an isolated YAC clone. The procedures are based upon the use of the YAC vector pYAC4.

Once an isolated YAC clone has been obtained from a core laboratory (UNIT 6.9), the clone can be analyzed as described herein. As depicted in Figure 6.9.1, methods for analysis involve growing and storing YAC-containing yeast strains and purifying YAC DNA in a form suitable for assessing the size of the artificial chromosome and for conventional Southern blotting. Preparation of yeast chromosomes in agarose plugs for subsequent analysis by pulsed-field gel electrophoresis is also described. Additional protocols are provided for recovering DNA fragments from the ends of a YAC genomic insert to be used as probes for detecting chimerism and for chromosome walking. Finally, preparation of high-molecular-weight YAC DNA is described and a general method for subcloning YAC inserts into cosmid or λ vectors for higher-resolution analysis is provided.

NOTE: All solutions, media, glassware, and plasticware coming into contact with yeast or bacterial cells must be sterile, and sterile techniques should be followed throughout.

BASIC PROTOCOL

PROPAGATION AND STORAGE OF YAC-CONTAINING YEAST STRAINS

YACs prepared using the pYAC4 vector (Figs. 6.10.1 and 13.4.6; pYAC4 contains an *EcoRI* site within the *SUP4* gene in addition to the *SnaBI* site found in pYAC3, but is otherwise identical to pYAC3, carrying selectable markers *TRP1* and *URA3*) and the *S. cerevisiae* host strain AB1380 (*trp1⁻*, *ura3⁻*, *ade2-1*) are grown on AHC plates. They can be stored short-term on AHC plates or stored long-term (after growth in YPD medium) in YPD containing glycerol at -80°C .

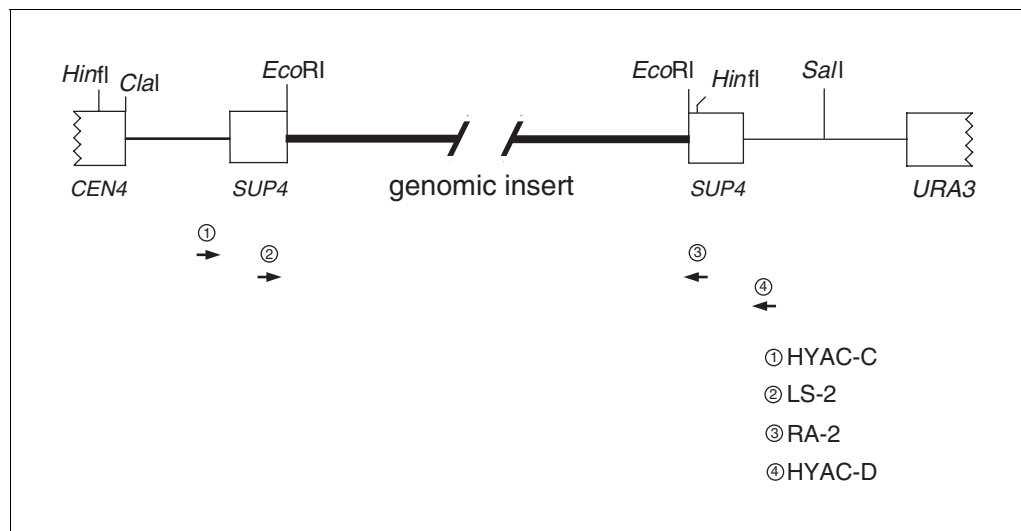

Figure 6.10.1 Structure of a representative pYAC4 clone at the vector/insert junction. Open boxes represent portions of the pYAC4 vector derived from yeast sequences (*CEN4*, the two halves of the *SUP4* element, and *URA3*). Thin lines represent sequences derived from pBR322 and the bold line represents the YAC genomic insert fragment. Sites of annealing of the HYAC-C, LS-2, RA-2 and HYAC-D oligonucleotides are indicated by arrows 1, 2, 3, and 4, respectively. The *EcoRI* cloning site, the *ClaI* and *SalI* sites (used for the end-fragment subcloning alternate protocol), and the *HinfI* sites that are utilized in the bubble linker end-fragment isolation protocol are indicated.

Materials

S. cerevisiae strain AB1380 containing pYAC4 with insert (from core facility; UNIT 6.9)

AHC plates (*ura*⁻, *trp*⁻)

YPD medium (UNIT 13.1)

80% (v/v) glycerol in YPD medium

30°C orbital shaking incubator (e.g., New Brunswick Scientific #G-24)

Cryovials

Additional reagents for preparation of yeast media (UNIT 13.1) and growth and manipulation of yeast (UNIT 13.2)

1. Streak strain AB1380 containing pYAC4 with insert onto AHC plates.

AHC medium selects for the presence of both arms of the YAC vector and thereby favors high stability of the YAC through successive passages.

2. Invert plate and incubate at 30°C until colonies are 1 to 3 mm in size.

*The AB1380 strain carries the *ade2-1* ochre mutation, a block in the purine biosynthetic pathway that leads to accumulation of red-hued intermediates. Because a genomic insert in the YAC interrupts the *SUP4* (ochre) gene in the YAC vector, colonies will have a red pigmentation.*

- 3a. *For short-term storage:* Seal plates with Parafilm and store at 4°C for 4 to 6 weeks.

- 3b. *For long-term storage:* Inoculate an individual colony into 3.2 ml YPD medium and shake overnight at 30°C. Add 1 ml of 80% glycerol in YPD medium, mix thoroughly, and transfer in 0.2- to 1.0-ml aliquots to cryovials. Store at -80°C.

YPD is a nonselective medium used to favor rapid growth and high cell viability.

Strains stored in this fashion are stable for ≥5 years. Before strains are used in an experiment, they should first be grown on selective medium (e.g., AHC plates) to avoid recovery of a contaminant clone or one that has lost its YAC.

PREPARATION OF YAC-CONTAINING DNA FROM YEAST CLONES FOR ANALYSIS BY SOUTHERN BLOTTING

Procedures used by core laboratories for isolating an individual clone from a YAC library ensure that the purified YAC supports amplification of an appropriately sized PCR product using the screening primer pair. However, it is best to confirm the identity of the clone by hybridization analysis. Various methods can be used to prepare DNA suitable for Southern blot analysis using frequently cutting restriction enzymes. This protocol yields substantial quantities of DNA in the size range of 50 to 200 kb; it involves growing and lysing a single red colony containing pYAC4 with the insert DNA, then obtaining the DNA from the supernatant after centrifugation and analyzing by Southern blotting. Yeast chromosomes prepared in agarose plugs or very-high-molecular-weight DNA prepared in solution (third and fifth basic protocols) may also be used.

Materials

Single colony of *S. cerevisiae* AB1380 containing pYAC4 with insert (first basic protocol)

AHC medium (*ura*⁻, *trp*⁻)

SCE buffer

SCEM buffer

50 mM Tris·Cl (pH 7.6)/20 mM EDTA (Tris/EDTA lysis buffer)

BASIC PROTOCOL

Screening of Recombinant DNA Libraries

6.10.2

10% (w/v) sodium dodecyl sulfate (SDS)
5 M potassium acetate, pH 4.8, ice-cold (*UNIT 1.6*)
95% ethanol, room temperature
TE buffer, pH 8.0 (*APPENDIX 2*)
1 mg/ml DNase-free RNase A (*UNIT 3.13*)
Isopropanol, room temperature
5 M NaCl
Total genomic DNA of the species or individual from which the library was made (e.g., *UNITS 2.2, 2.3 & 5.3*)
Appropriate single-copy probe designed to hybridize with the YAC insert (see *UNITS 2.9 & 6.9*)

Orbital shaker (e.g., New Brunswick Scientific #G-24)
50-ml conical plastic centrifuge tubes
Beckman JS-4.2 rotor or equivalent

Additional reagents and equipment for digestion of DNA with restriction endonucleases (*UNIT 3.1*), Southern blotting and hybridization (*UNIT 2.9*), and pulsed-field gel electrophoresis (*UNIT 2.5B*)

Culture and lyse cells from YAC clone

1. Inoculate a single red colony of a YAC-containing clone into 20 ml AHC medium in a 250-ml Erlenmeyer flask. Shake 24 hr at 250 rpm, 30°C, on an orbital shaker.

The culture should begin to turn pink. If not, continue incubation an additional 24 hr. If culture is still not pink, discard and start over with a new red colony.

Orbital shakers are preferred because they give much better aeration.

2. Inoculate 1 ml of culture from step 1 into 100 ml AHC medium in a 1-liter Erlenmeyer flask. Shake 24 hr at 250 rpm, 30°C.
3. Transfer culture to 50-ml plastic conical centrifuge tubes. Centrifuge 5 min at 2000 × g (2800 rpm in Beckman JS-4.2 rotor), 4°C.
4. Discard supernatants and resuspend cell pellets in a total of 5 ml SCE buffer. Pool into a single tube.
5. Add 1 ml SCEM buffer. Mix gently 1 to 2 hr at 100 rpm, 37°C, on an orbital shaker.
SCEM buffer contains lyticase, which will digest the cell wall.
6. Centrifuge 5 min at 2000 × g, 4°C. Discard supernatant and resuspend cell pellet in 5 ml Tris/EDTA lysis buffer.
7. Add 0.5 ml of 10% SDS and invert several times to mix. Incubate 20 min at 65°C.

Isolate nucleic acids

8. Add 2 ml of ice-cold 5 M potassium acetate, pH 4.8, and invert to mix. Keep 60 min on ice.
9. Centrifuge 10 min at 2000 × g, room temperature. Carefully pour nucleic acid-containing supernatant into a new tube. Add 2 vol room-temperature 95% ethanol and invert to mix.
10. Centrifuge 5 min at 2000 × g, room temperature. Discard supernatant and air-dry nucleic acid pellet 10 to 15 min. Add 3 ml TE buffer, pH 8.0, and dissolve overnight at 37°C.

Recover and analyze DNA

11. Add 0.1 ml of 1 mg/ml DNase-free RNase A and incubate 1 hr at 37°C.
12. Add 6 ml room-temperature isopropanol with swirling, then invert to mix.
13. Spool DNA using a capillary pipet and dissolve in 0.5 ml TE buffer, pH 8.0. Add 50 μ l of 5 M NaCl and 2 ml of room-temperature 95% ethanol. Mix by inverting.
14. Spool DNA again and dissolve in 0.5 ml TE buffer. Store at 4°C.

A yield of 1 to 1.5 μ g DNA/ 10^8 yeast cells can be expected.

15. Analyze 2- μ g aliquots of YAC DNA and 15- μ g aliquots of total genomic DNA from the species or individual from which the YAC library was made by digesting with several frequently cutting restriction enzymes. Proceed with Southern blotting and hybridization using a single-copy probe.

The product amplified by PCR screening (see UNIT 6.9) may be used as probe. Because the YAC donor may exhibit a restriction-fragment-length polymorphism for this probe, two restriction fragments may be observed in the donor DNA. One of these fragments should be identified in the isolated YAC DNA.

16. Once the YAC clone has been verified by Southern blotting, determine its size and obtain a preliminary assessment of its stability by preparing chromosomes in agarose plugs (third basic protocol) and analyzing by pulsed-field gel electrophoresis.

PREPARATION OF YEAST CHROMOSOMES IN AGAROSE PLUGS FOR PULSED-FIELD GEL ELECTROPHORESIS

BASIC PROTOCOL

In order to assess size, stability, and possible rearrangements within YACs, and to identify overlapping YACs, it is useful to isolate the YACs by embedding them in agarose plugs for subsequent analysis by pulsed-field gel electrophoresis (PFGE). Most methods of pulsed-field gel electrophoresis can be used (UNIT 2.5B); the CHEF (contour-clamped homogeneous electric-field electrophoresis) gel system is particularly suitable in that it reliably permits excellent resolution in the size range most common for YACs.

Materials

AHC medium (*ura*⁻, *trp*⁻)

Single colony of *S. cerevisiae* containing pYAC4 with insert (first basic protocol)

0.05 M EDTA, pH 8.0 (APPENDIX 2)

SEM buffer

10 mg/ml Lyticase (Sigma #L-8137 or ICN Biomedicals #190123)

2% InCert or SeaPlaque agarose (FMC Bioproducts), dissolved in SEM buffer and equilibrated to 37°C

SEMT buffer

Lithium lysis solution

20% (v/v) NDS solution

0.5 \times TBE (APPENDIX 2) or GTBE buffer (UNIT 2.5B)

30°C rotary platform shaking incubator

Beckman JS-4.2 rotor or equivalent

Gel sample molds (e.g., CHEF gel molds, Bio-Rad #1703622)

60-mm tissue culture plate

Additional reagents and equipment for pulsed-field gel electrophoresis (UNIT 2.5B)

Screening of Recombinant DNA Libraries

6.10.4

Prepare and lyse YAC clone

1. Inoculate 25 ml AHC medium with a single red colony of a YAC-containing clone. Shake 48 to 60 hr at 250 rpm, 30°C.

The culture should be pink. If it is not, discard and start over with a new red colony.

To assess the stability of an individual YAC and to facilitate distinguishing of the artificial chromosome from the native yeast chromosomes, it is useful to analyze 4 or 5 individual colonies from the same YAC strain as well as a colony of the untransformed yeast host.

2. Centrifuge 10 min at $2000 \times g$ (2800 rpm in a Beckman JS-4.2 rotor), 4°C. Discard supernatant and resuspend cell pellet in 10 ml of 0.05 M EDTA, pH 8.0.
3. Centrifuge 10 min at $2000 \times g$, 4°C. Remove all liquid from pellet and resuspend in 150 μ l SEM buffer.

Prepare agarose molds

4. Warm YAC sample to 37°C and add 25 μ l Lyticase. Add 250 μ l of 2% InCert or SeaPlaque agarose that has been melted in SEM buffer and equilibrated to 37°C.
5. Mix quickly and pour into CHEF gel sample molds. Chill 10 min at 4°C. Transfer solidified plugs to a 60-mm tissue culture plate.
6. Cover each plug with 4 ml SEMT buffer. Incubate 2 hr with gentle shaking at 37°C.
7. With a pipet, remove SEMT buffer and replace with 4 ml lithium lysis solution. Incubate 1 hr with gentle shaking at 37°C.
8. Remove and replace lithium lysis solution two or three times, shaking ≥ 1 hr each time. Shake the last change overnight.
9. Remove lithium lysis solution, replace with 4 ml of 20% NDS solution, and shake 2 hr at room temperature. Repeat once.

Electrophorese samples in individual agarose plugs

10. Cut into plugs of suitable size to fit into wells of a pulsed-field gel.

Store plugs individually in 20% NDS solution at 4°C. Plugs prepared and stored in this manner are usually stable for 4 to 8 weeks.

11. Soak each plug 30 min in 1 ml of 0.5 \times TBE or GTBE buffer. Change three times.
12. Analyze by pulsed-field gel electrophoresis.

Following electrophoresis, the artificial chromosome can be visualized in an ethidium bromide-stained gel as an extra chromosome not present in the host yeast strain. If desired, Southern blot hybridization (UNIT 2.9) with appropriate probes can be carried out.

END-FRAGMENT ANALYSIS USING PCR AMPLIFICATION

BASIC PROTOCOL

This protocol provides a means for recovering end fragments from the YAC insert using PCR amplification of end fragments. Digestion of YAC-containing DNA with a frequently cutting restriction enzyme produces a collection of small fragments: among these, one contains the distal portion of the YAC insert associated with part of the left vector arm, and another contains the other end of the insert associated with part of the right vector arm. Fragments encoding these vector sequences are prepared for PCR amplification by ligation of a double-stranded DNA tag containing a “bubble” of noncomplementary sequence flanked by short complementary sequences (Fig. 6.10.2). Selective amplification of these two end-fragment sequences is achieved using one PCR primer derived from the YAC vector (HYAC-C or LS-2 for the left arm or HYAC-D or RY-2 for the right arm) and one primer containing the sequence of the noncomplementary portion of the bubble (the 224 primer template, created by extension from the YAC-vector-specific primer; Fig. 6.10.3). Occasionally, nonspecific DNA fragments are amplified from the bubble PCR reaction. If this occurs, specificity may be restored using a hemi-nesting strategy. A small aliquot of the product of the initial PCR reaction (containing a mixture of the specific and nonspecific amplified fragments) is reamplified in a second round of PCR using an internal sequence from the vector arm as one of the primers. Because this sequence is not present in the nonspecific fragments, only the specific fragment will be amplified.

Materials

“Bubble-top” and “bubble-bottom” oligonucleotide primers (Fig. 6.10.2)

YAC-containing DNA (second basic protocol)

*Rsa*I and *Hinf*I restriction endonucleases and appropriate buffers (UNIT 3.1)

10× T4 DNA ligase buffer and 1 U/μl T4 DNA ligase (UNITS 3.4 & 3.14)

PCR reaction mix

PCR amplification primers HYAC-C, HYAC-D, 224, and RA-2, 4 μM each (Fig. 6.10.2)

Thermal cycling apparatus

65° and 68°C water baths

Additional reagents and equipment for phosphorylating synthetic oligonucleotides (UNIT 3.10), restriction endonuclease digestion (UNIT 3.1), PCR (UNIT 15.1), nondenaturing PAGE (UNIT 2.7), preparing radiolabeled oligonucleotide probes (UNITS 3.10, 4.6 & 15.2), and blunt-end ligation (UNIT 3.16)

Prepare bubble oligonucleotide tags

1. Phosphorylate the bubble-top oligonucleotide.

This step can usually be eliminated, but may modestly increase efficiency.

2. Adjust bubble-top and bubble-bottom oligonucleotide concentrations to 4 nmol/ml with water. Mix together 1 nmol of each, then anneal by heating 15 min at 68°C in a water bath, followed by slow cooling to room temperature over 30 to 60 min.

Digest YAC DNA and ligate to bubble oligonucleotides

3. Digest 2.5-μg aliquots of purified YAC-containing DNA to completion with *Rsa*I or *Hinf*I in 20 μl final volume, 37°C.

*Digestion of separate samples with *Rsa*I and *Hinf*I increases the chance of obtaining an end fragment of a size suitable for PCR amplification (<1.5 kb) and containing a substantial portion of insert sequence (>75 bp).*

4. Heat samples 15 min at 65°C to inactivate the restriction enzymes.

Figure 6.10.2 Oligonucleotides for amplification and sequencing of YAC insert end-fragments. **(A)** Annealing of the 53-mer universal “bubble-bottom” oligonucleotide to the 53-mer *RsaI* bubble oligonucleotide yields a blunt-ended DNA duplex in which 12-bp complementary sequences flank a 29-nucleotide “bubble” of noncomplementary sequence. This bubble linker can be ligated to any blunt-ended fragment (e.g., one generated by digestion with *RsaI*). The 224 primer does not anneal to either strand of the bubble, but is fully complementary to any DNA strand that is generated during PCR using the universal bubble-bottom strand as a template (see Fig. 6.10.3). **(B)** Annealing of the 53-mer universal bubble-bottom oligonucleotide to the 56-mer *HinfI* bubble-top oligonucleotide yields a DNA duplex with one blunt end and one cohesive end with the degenerate *HinfI* site. A mixture of all four nucleotides at a specific position is indicated by (N). **(C)** The HYAC-C, HYAC-D, RA-2, and LS-2 primers anneal to sequences in the pYAC4 vector (see Fig. 6.10.1). The bubble sequencing primer anneals to the *RsaI* and *HinfI* bubble-top sequences near their 5′ ends, permitting DNA sequencing from the bubble linker back into the YAC insert end-fragment.

5. Prepare the following ligation mix (50 μl total):

- 2 μl (250 ng) digested DNA
- 1 μl (2 pmol) annealed bubble oligonucleotides (from step 2)
- 5 μl 10× ligase buffer
- 2 μl (2 U) T4 DNA ligase
- 40 μl H₂O.

Incubate 2 hr at 37°C or overnight at room temperature.

The blunt-ended bubble composed of the universal bubble-bottom oligonucleotide and the RsaI bubble-top oligonucleotide should be used with RsaI-digested YAC DNA. Likewise, the HinfI cohesive bubble composed of the universal bubble-bottom oligo-

Figure 6.10.3 Selective PCR amplification from the YAC insert end-fragment. **(A)** Result of ligation of the bubble linker to a random fragment from the internal portion of the YAC insert. Because this fragment is not derived from the end of the YAC genomic insert, it contains no sequences from the YAC vector and has no site for annealing any of the HYAC-C, HYAC-D, RA-2, or LS-2 primers or for annealing of the 224 primer. Consequently, no fragment is amplified by PCR. **(B)** Result of ligation of the bubble linker to a fragment derived from the end of the YAC genomic insert and containing its associated YAC vector sequences. During the first cycle of PCR, extension from the YAC vector priming site produces sequences complementary to the universal bubble-bottom primer. This extended fragment provides a template for annealing of the 224 primer, thus permitting successful amplification of the insert end-fragment.

*nucleotide and the *Hin*I bubble-top oligonucleotide should be used with *Hin*I-digested YAC DNA.*

6. Add 200 μ l water to bring the DNA concentration to 1 ng/ μ l final.

Amplify fragments containing YAC-insert end sequences

7. Prepare the following PCR on ice (10 μ l total):
 - 8 μ l PCR reaction mix
 - 1 μ l (2 μ M each) PCR primer pair mix
 - 1 μ l (1 ng) digested, bubble-ligated YAC DNA.

Carry out 35 cycles of amplification as follows: 1 min at 92°C, 2 min at 65°C, and 2 min at 72°C.

To amplify left end of YAC insert, use primer pair mix made from equal amounts of primers 224 and HYAC-C (Fig. 6.10.1). To amplify right end of YAC insert, use primer pair mix made from equal amounts of primers 224 and RA-2 (specific for the SUP4 region of pYAC4; Fig. 6.10.1).

These parameters were optimized using the Perkin-Elmer TC1 thermal cycler. If another instrument is used, some adjustment of parameters may be required.

8. Analyze a 1- μ l aliquot of PCR product on a 5% polyacrylamide gel. A single, clearly visible amplified fragment should be observed after staining the gel with ethidium bromide.

Produce end fragments using hemi-nested amplification

To amplify the left end (either RsaI- or HinfI-digested DNA):

- 9a. Amplify 1 μ l digested, bubble-ligated YAC DNA (from step 6) with primers 224 and HYAC-C, using 20 cycles of 1 min at 92°C, 2 min at 62°C, and 2 min at 72°C.
- 10a. Dilute the amplification product 1:100 with water and add 1 μ l to a new PCR reaction containing primers 224 and LS-2 (specific for the *SUP4* region of pYAC4; see Figs. 6.10.1 and 13.4.6). Carry out 30 cycles of 1 min at 92°C, 2 min at 65°C, and 2 min at 72°C.

To amplify the right end using RsaI-digested DNA:

- 9b. Amplify 1 μ l digested, bubble-ligated YAC DNA (from step 6) with primers 224 and HYAC-D, using 20 cycles of 1 min at 92°C, 2 min at 62°C, and 2 min at 72°C.
- 10b. Dilute amplification product 1:100 with water and add 1 μ l to a new PCR reaction (see step 7) containing primers 224 and RA-2. Carry out 30 cycles of 1 min at 92°C, 2 min at 65°C, and 2 min at 72°C.

Hemi-nesting of the right end cannot be performed with HinfI-digested DNA, because there is a HinfI site only 24 bp from the EcoRI YAC vector cloning site.

11. Analyze a 1- μ l aliquot of each final PCR reaction on a 5% polyacrylamide gel.
12. End label amplified fragments with ³²P and use as hybridization probes or for nucleotide sequencing to produce an end-specific STS. Alternatively, subclone by blunt-end ligation to a plasmid vector prior to further manipulation.

Blunt-end subcloning of DNA fragments that have been amplified by PCR must be preceded by "polishing" of the ragged PCR ends with S1 nuclease or T4 DNA polymerase (see UNIT 15.7).

ALTERNATE PROTOCOL

END-FRAGMENT ANALYSIS BY SUBCLONING INTO A BACTERIAL PLASMID VECTOR

This method (an alternative to the previous protocol for recovering end fragments from the YAC insert) uses the strategy of double digesting the YAC-containing DNA to enhance the efficiency of subcloning into a pUC19-based vector; the *SUP4* element containing the YAC *EcoRI* cloning site is located within a portion of the YAC vector derived from pBR322 (Figs. 1.5.2 and 6.10.5). The cloning strategy enriches for end-fragment-containing subclones because the restriction endonuclease used for digestion of YAC-containing DNA is either *ClaI* (for the left arm) or *SalI* (for the right arm). Both enzymes cut rarely in human or yeast genomic DNA; therefore, when one is combined with a more frequently cutting enzyme, the resulting doubly digested fragments will represent a minor portion of the total DNA pool. Size fractionation on an agarose gel prior to subcloning affords a still further enrichment for end fragments. Note that after the first step of the protocol, all steps are performed in duplicate to identify both the right and left end fragments of the YAC insert.

Additional Materials

*Cla*I, *Sal*I, and other appropriate restriction endonucleases and digestion buffers (UNIT 3.1)

Left- and right-vector-arm probes (Fig. 6.10.4)

pUC19-ES and pUC19-HS plasmid vectors (support protocol and Fig. 6.10.5)

Transformation-competent *Rec*⁻ strain of *E. coli* (e.g., DH5; Table 1.4.5)

2× TY or LB agar plates (UNIT 1.1) containing 50 to 100 µg/ml ampicillin

Additional reagents and equipment for agarose gel electrophoresis (UNIT 2.5A), subcloning of DNA fragments (UNIT 3.16), transformation of *E. coli* (UNIT 1.8), Southern blotting and hybridization (UNIT 2.9), labeling by random-primed synthesis (UNIT 3.5), isolation and purification of DNA fragments from agarose gels (UNIT 2.6), replica plating (UNIT 1.3), and purification of plasmid DNA (UNITS 1.6 & 1.7)

Perform an appropriate double digest and analyze by hybridization

- 1a. For left arm: Digest 5-µg aliquots of YAC-containing DNA with *Cla*I and then with each possible second cloning enzyme—*Sac*I, *Kpn*I, *Sma*I, *Bam*HI, *Xba*I, and *Sph*I.

In addition to SmaI, other blunt-cutters not represented within the ClaI-EcoRI interval of the YAC vector may be tested.

- 1b. For right arm: Digest 5-µg aliquots of YAC-containing DNA with *Sal*I and then with each of the following possible second cloning enzymes: *Sac*I, *Kpn*I, *Sma*I, *Bam*HI, *Xba*I, *Sph*I, or *Hind*III.

All of the above restriction endonucleases have compatible cleavage sites within the polylinker of the modified pUC19; AccI provides a cohesive site for ClaI.

Carry out all remaining steps in parallel for the left- and right-arm probes:

2. Electrophorese doubly digested DNA on an agarose gel and transfer to a filter for Southern hybridization.
3. Prepare left- and right-vector-arm probes by PCR as described in Fig. 6.10.4.

Probes can also be obtained by digestion and fractionation of pBR322 DNA with subsequent labeling.

4. Hybridize each probe to the appropriate filter from step 2.

Left arm:	5' ATCGATAAGCTTTAATGCGGTAGT 3' (pBR322 bases 23-46)
	5' GATCCACAGGACGGGTGTGGTCGC 3' (pBR322 bases 379-356)
Right arm:	5' GATCCTCTACGCCGGACGCATCGT 3' (pBR322 bases 375-399)
	5' GTCGACGCTCTCCCTTATGCGACT 3' (pBR322 bases 656-632)

Figure 6.10.4 Generation of left- and right-vector-arm probes. The 351-bp *Cla*I-*Bam*HI and 276-bp *Bam*HI-*Sal*I fragments of pBR322, which hybridize to sequences immediately flanking the *sup4* sequences of the YAC vector, are appropriate probes for the YAC left and right vector arms. These probes can be obtained by restriction digestion and gel fractionation of pBR322 plasmid DNA or generated by PCR using 10 ng pBR322 as template for the primers illustrated here. Perform PCR using 25 cycles of 1 min at 92°C, 1 min at 50°C, and 2 min at 72°C. Extract the amplified material once with phenol and once with chloroform, then precipitate with ethanol (UNIT 2.1). Label directly by random priming (UNIT 3.5) without further purification.

5. Examine autoradiogram and choose an enzyme combination that yields a hybridizing DNA fragment in the 2- to 7-kb size range. Digest a 50- μ g aliquot of YAC-containing DNA with these two enzymes.

This should yield ~5 times more size-fractionated DNA than needed.

Isolate the DNA

6. Electrophorese doubly digested DNA on an agarose gel. Using a scalpel or razor blade, cut out the segment of gel that should contain the doubly digested DNA fragment.

To avoid missing the critical portion of the gel, it may be useful to excise adjacent gel slices containing fragments larger than and smaller than the expected size, and to process them in parallel.

7. Purify size-fractionated DNA from gel slice and resuspend in a final volume of 20 μ l TE buffer, pH 8.0.

For purifying the DNA, the best results have been obtained by using the GeneClean II kit (BIO 101, La Jolla, CA).

Subclone the end fragments

8. Ligate 20% of the purified YAC-derived insert DNA with 0.2 μ g of gel-purified, compatibly digested pUC19-HS or -ES vector DNA overnight in a total volume of 20 μ l.

Because the pUC19 plasmid from which they are derived has no homology with the portion of pBR322 detected by the ClaI/BamHI and BamHI/SalI probes (Fig. 6.10.4), these probes can be used to detect YAC-insert end-fragment-containing subclones in pUC19, and will not cross-hybridize to the pUC vector.

9. Transform the ligated DNA into a transformation-competent *Rec*⁻ host strain of *E. coli*. Plate sufficient transformation mix on 2 \times TY/ampicillin or LB/ampicillin plates to obtain ~200 colonies, a sufficiently low density that individual colonies may be recovered following hybridization. Invert plates and incubate overnight at 37°C.
10. Prepare colony-lift filters and hybridize overnight with ~1–2 \times 10⁷ cpm of appropriate ³²P-labeled left- or right-arm probes. Wash and autoradiograph.

Because of the enrichment afforded by double digestion, 1% to 4% of colonies will contain the end fragment.

11. Purify plasmid DNA from hybridizing colonies.
12. Verify the structure of the plasmid by comparing its restriction map to the data obtained during the initial analytical double digests of the YAC (steps 1 to 3).

SUPPORT PROTOCOL

DESIGN AND PREPARATION OF pUC19-ES and pUC19-HS SUBCLONING VECTOR

This protocol describes the construction of two vectors for subcloning YACs (previous basic protocol). pUC19 is modified by insertion of a “stuffer” fragment in both possible orientations (see UNIT 3.16; Fig. 6.10.5). If a double digest is performed on the resulting construct (UNIT 3.1), using *AccI* (cohesive with *ClaI*) or *SalI* and any of the other enzymes in the pUC polylinker, the presence of the stuffer makes it possible to visualize whether the vector has been fully cut. Complete double digestion is critical to the success of the end-fragment subcloning described in the previous protocol. For example, digestion with *AccI* or *SalI* will linearize the pUC19-ES vector. Subsequent digestion with *EcoRI*, *SacI*, *KpnI*, *SmaI*, *BamHI*, or *XbaI* will result in a shift in vector size from 3161 bp to 2686 bp

Figure 6.10.5 Structure of the pUC19-ES and pUC19-HS plasmids.

and free stuffer fragment will be generated. The doubly digested vector can then be isolated by fractionation in an agarose gel (UNIT 2.5A) and purified (UNIT 2.6).

pUC19-ES: Modify the pUC19 (see Fig. 1.5.2) vector by inserting a stuffer consisting of 475-bp *TaqI* fragment of pBR322 (positions 653-1128) into the pUC19 polylinker *AccI* (*HincII*) site. In the resulting plasmid, the *AccI* (and *SalI* and *HincII*) site adjacent to the polylinker *PstI* site is preserved, but the *AccI* site previously found next to the polylinker *XbaI* site (which would now be at the other end of the stuffer) is lost (Fig. 6.10.5).

pUC19-HS: Insert the 475-bp *TaqI* fragment stuffer described above into the same pUC19 *AccI* site but in the opposite orientation. In the resulting plasmid, the polylinker *AccI* site adjacent to the *XbaI* site is preserved, but the *AccI* site adjacent to the *PstI* site is lost (Fig. 6.10.5).

**PREPARATION OF HIGH-MOLECULAR-WEIGHT YAC-CONTAINING
YEAST DNA IN SOLUTION**

This protocol describes the purification of YAC-containing DNA of sufficiently high molecular weight to provide a source of YAC insert material for subcloning in λ or cosmid vectors. This DNA is also suitable for restriction mapping or other genetic manipulations. A cell lysate is fractionated on a sucrose gradient; the DNA-containing fraction is subsequently dialyzed, concentrated, and examined by electrophoresis through a pulsed-field gel.

Materials

- Single colony of *S. cerevisiae* containing pYAC4 with insert (first basic protocol)
- AHC medium (*ura*⁻, *trp*⁻)
- SCEM buffer
- Lysis buffer
- Step-gradient solutions: 50%, 20%, and 15% (w/v) sucrose
- TE buffer, pH 8.0 (*APPENDIX 2*)
- Dry granular sucrose
- 30°C orbital shaking incubator (e.g., New Brunswick Scientific #G-24)
- 250-ml conical centrifuge bottles (e.g., Corning #25350)
- 65°C water bath
- 25 × 89-mm tube (e.g., Beckman #344058)
- Beckman JS-4.2 and SW-27 rotors (or equivalents)
- Dialysis tubing (*APPENDIX 3*)
- Pyrex baking dish
- CHEF pulsed-field gel apparatus or equivalent (*UNIT 2.5B*)
- Additional reagents and equipment for size fractionation using a sucrose gradient (*UNIT 5.3*) and estimating DNA concentration (*UNIT 2.6*)

Grow and prepare the cells

1. Inoculate a single red colony of a YAC-containing clone into 25 ml AHC medium in a 250-ml flask. Shake at 250 rpm, 30°C, until culture reaches saturation (~3 days).
2. Transfer 1 ml of saturated culture to 100 ml AHC medium in a 1-liter flask. Shake 16 to 18 hr at 250 rpm, 30°C.
3. Harvest yeast cells by centrifuging 10 min at 2000 × *g* (2800 rpm in Beckman JS-4.2 rotor), room temperature, using a 250-ml conical centrifuge bottle. Discard supernatant.
4. Resuspend cells in 50 ml water. Centrifuge 5 min at 2000 × *g*, room temperature. Discard supernatant.
A cell pellet of ~4 g should be obtained.
5. Resuspend cells in 3.5 ml SCEM buffer.

Lyse the cells

6. Incubate 2 hr at 37°C with occasional gentle mixing. The mixture will become highly viscous.
7. Gradually add cell mixture to 7 ml lysis buffer in a 250-ml Erlenmeyer flask by allowing viscous cell suspension to slide down side of flask.
8. Gently mix by swirling flask until mixture is homogeneous and relatively clear.
9. Incubate 15 min at 65°C, then cool rapidly to room temperature in a water bath.

Fractionate cell contents

10. Fractionate on a sucrose step gradient. In a 25 × 89–mm tube, prepare a step gradient consisting of:

- 3 ml 50% sucrose
- 12 ml 20% sucrose
- 12 ml 15% sucrose
- 11 ml lysed sample.

Centrifuge 3 hr at 125,000 × *g* (26,000 rpm in a Beckman SW-27 rotor), room temperature.

11. Discard ~25 ml from top of gradient using a 10-ml pipet.

Dialyze and analyze DNA

12. Collect viscous DNA-containing solution at the 20% to 50% sucrose interface (~5 ml total volume) and place in dialysis tubing, leaving room for volume to increase ≥2- to 3-fold. Dialyze overnight against 2 liters TE buffer, pH 8.0, at 4°C.
13. Reconcentrate dialyzed DNA by placing dialysis tubing in an autoclaved Pyrex baking dish and covering with granular sucrose. Recover dialysis tubing when volume of contents has been reduced to ~2 ml.
14. Squeeze DNA solution to one end of dialysis tubing and tie an additional knot to keep DNA in a small volume. Dialyze overnight against 1 liter of TE buffer, pH 8.0, at 4°C.
15. Recover dialyzed DNA and check a small aliquot by electrophoresing in a CHEF pulsed-field gel. Stain with ethidium bromide and estimate DNA content by comparison to a known amount of λ DNA.

The DNA sample will contain a substantial amount of yeast RNA but should also contain a population of YAC DNA fragments migrating at a size of >100 kb. The presence of the RNA may make it difficult to determine the DNA concentration accurately; the concentration may be estimated by comparison to known DNA standards in an ethidium bromide-stained gel. The RNA will not affect restriction digestion of the DNA.

PREPARATION AND ANALYSIS OF A YAC-INSERT SUBLIBRARY

Construction of a sublibrary of fragments of the YAC insert facilitates high-resolution analysis of the insert sequence. This protocol details the steps required to produce a cosmid library, followed by a series of screenings to identify regions of interest and “walking” to establish a contiguous map of the insert.

Materials

High-molecular-weight YAC-containing DNA (fifth basic protocol)

Vector DNA (e.g., SuperCos 1, Stratagene #251301)

³²P-labeled (UNIT 3.10) probes: total genomic DNA of the individual or species from which the library was made (e.g., UNITS 2.2, 2.3 & 5.3), end-specific DNA (UNIT 3.10) or RNA (UNIT 3.8), and end fragment from YAC (fourth basic protocol or alternate protocol)

Additional reagents and equipment for restriction endonuclease digestion (UNIT 3.1), genomic DNA library production (UNIT 5.7), plating and transferrin a cosmid library (UNIT 6.2), and hybridization with radioactive probes (UNITS 6.3 & 6.4)

BASIC PROTOCOL

Screening of Recombinant DNA Libraries

6.10.14

Construct the library

1. Partially digest 1 to 2 μg of YAC-containing DNA with restriction endonuclease(s) appropriate for cosmid vector to be used. For example, to clone into the *Bam*HI site of SuperCos 1, digest the YAC DNA with either *Mbo*I or *Sau*3A.

The quantity of restriction endonuclease should be adjusted to produce digested fragments with an average size of ~40 kb. Although only a small fraction of the YAC-containing DNA used as starting material is actual YAC DNA (the rest being yeast genomic DNA), because of the low complexity of the yeast genome (e.g., compared to the human genome), only 3000 to 5000 cosmid clones are required to yield 3 yeast genome equivalents. Thus, only 1 to 2 μg of yeast DNA are required to make an adequate library.

2. Perform a series of test ligations as described in UNIT 5.7. Using optimal conditions, ligate insert DNA to vector DNA.
3. Package cosmid recombinants; dilute packaged extract and determine the titer.
4. Plate and transfer the sublibrary as appropriate for the vector, and prepare resulting filters for hybridization.

Screen the sublibrary

5. Perform a preliminary screen of the library using a ^{32}P -labeled probe of total genomic DNA of the individual or species from which the library was made.

This probe is a source of repetitive sequences. Because these repetitive sequences are spaced frequently throughout the source genome, and are absent from yeast, this probe will identify most of the source-DNA insert cosmids from the excess of yeast insert cosmids.

6. Organize this first set of cosmid clones into contigs by analyzing shared restriction fragments and by hybridizing with probes contained in the YAC insert or prepared from the ends of individual cosmid inserts.

Cosmid end-fragment-specific probes can be generated by digesting cosmid DNA and end-labeling the purified restriction fragment(s) that contain(s) the cloning site. If the cloning vector is SuperCos 1 (or a comparable vector), end-specific RNA probes may also be transcribed from the ends of the cosmid clones using T3 and T7 polymerase (see critical parameters).

7. Establish a complete contiguous collection of cosmid clones of the original YAC insert by screening the library with specific YAC-derived probes and cosmid end-specific probes.

Note that nitrocellulose filters may be reused for hybridization in subsequent steps without further washing or removal of probe. Repeated hybridization with sequential "walking probes" should reveal new hybridizing colonies at each step.

REAGENTS AND SOLUTIONS

AHC medium and plates (*ura⁻, trp⁻*)

1.7 g yeast nitrogen base *without* amino acids and *without* ammonium sulfate (Difco)
5 g ammonium sulfate
10 g casein hydrolysate-acid, salt-free and vitamin-free (U.S. Biochemical #12852)
50 ml (for medium) or 10 ml (for plates) of 2 mg/ml adenine hemisulfate (Sigma #A-9126)
Dissolve in a final volume of 900 ml H₂O
Adjust pH to 5.8
Autoclave 30 min, then add 100 ml sterile 20% (w/v) glucose. For AHC plates, add 20 g agar prior to autoclaving. Store at 4°C for ≤6 weeks.

Lithium lysis solution

1% lithium dodecyl sulfate (Sigma # L-4632)
100 mM EDTA
10 mM Tris·Cl, pH 8.0 (*APPENDIX 2*)
Filter sterilize and store indefinitely at room temperature

Lysis buffer

0.5 M Tris·Cl, pH 8.0 (*APPENDIX 2*)
3% (v/v) *N*-lauroylsarcosine (Sarkosyl)
0.2 M EDTA, pH 8.0 (*APPENDIX 2*)
Store indefinitely at room temperature. Add 1 mg/ml proteinase K just before use.

100% NDS solution

Mix 350 ml H₂O, 93 g EDTA, and 0.6 g Tris base. Adjust pH to ~8.0 with 100 to 200 pellets of solid NaOH. Add 5 g *N*-lauroylsarcosine (predissolved in 50 ml water) and adjust to pH 9.0 with concentrated NaOH. Bring volume to 500 ml with water. Filter sterilize and store indefinitely at 4°C. Dilute 1:5 with H₂O (20% final) just before use.

PCR reaction mix

1.5 mM MgCl₂
50 mM KCl
10 mM Tris·Cl, pH 8.3 (*APPENDIX 2*)
0.2 mM each dATP, dCTP, dGTP, and dTTP
0.05 U AmpliTaq polymerase (Perkin-Elmer/Cetus)/μl reaction mixture
0.03 μl Perfect Match Enhancer (Stratagene)/μl reaction mixture
Store all components at -20°C and mix just before use

SCE buffer

0.9 M sorbitol (Fisher, molecular biology grade)
0.1 M sodium citrate
0.06 M EDTA, pH 8.0
Adjust pH to 7.0
Store at room temperature ≤3 months

SCEM buffer

4.9 ml SCE buffer (see above)
0.1 ml 2-mercaptoethanol (2-ME)
Add 1 to 2 mg Lyticase (Sigma #L-8137 or ICN Biomedicals #190123) just before use.

SEM buffer

1 M sorbitol
20 mM EDTA, pH 8.0
14 mM 2-ME
Filter sterilize
Store at 4°C for ≤6 weeks

SEMT buffer

1 M sorbitol
20 mM EDTA
14 mM 2-ME
10 mM Tris·Cl, pH 8.0 (*APPENDIX 2*)
Filter sterilize
Add 1 mg/ml Lyticase (Sigma #L-8137 or ICN Biomedicals #190123) just before use.

COMMENTARY

Background Information

An overview of strategies for screening YAC libraries and analyzing YAC clones is presented in *UNIT 6.9*.

Critical Parameters and Troubleshooting

The protocols provided in this unit are intended to describe the analysis and characterization of particular YAC clones of interest. It is initially desirable to assure the integrity of the clone; that is, to ensure that the YAC indeed carries the proper insert, that the insert is not chimeric or rearranged, and that it is stably maintained and propagated in the yeast host.

Growth of YAC-containing strains. In YAC clones, genomic DNA is inserted into a cloning site carried within the *SUP4* gene of the vector (see Figs. 6.10.1 and 13.4.6). In the parent vector, the *SUP4* product complements the *ade2-1* ochre mutation carried in the host AB1380. This mutation causes a block in purine biosynthesis, resulting in accumulation of red pigment in the culture. Thus, disruption of *SUP4* by insertional inactivation prevents complementation of the ochre mutation in the host. Before a strain is used, it is important to check that upon growth the colonies or cultures exhibit a red pigmentation. If not, another isolate should be used. Additionally, growth on selective AHC medium requires the presence of both arms of the YAC vector and favors stability of the clone through passage.

Analysis of YAC DNA. Restriction analysis of purified YAC DNA (second basic protocol) can be used to assess YAC structure. If fragments of unanticipated sizes are detected in the YAC, then it is likely that the YAC contains

sequences homologous to, but different from, the desired clone, or that the YAC insert has undergone some sort of rearrangement during cloning. Alternatively, lack of methylation of the YAC DNA at the restriction enzyme recognition site may give a digestion pattern not seen in uncloned genomic DNA. Determination of size and stability of the YAC clone is made by preparing chromosomes in agarose plugs and subsequent pulsed-field gel electrophoresis. The PFGE gel can be blotted and analyzed by hybridization with sequence-specific probes and end-fragment probes. The results should reveal hybridization to the same size chromosome in all isolates of a given YAC clone. Variation in the size of the artificial chromosome between yeast isolates derived from one clone indicates YAC instability. Hybridization of a YAC vector arm probe to more than one artificial chromosome may indicate multiple transformation of the strain at the time of library construction. Alternatively, it may represent strain instability, with the smaller chromosome(s) representing deletion products of the original YAC. When two or more artificial chromosomes are identified with a single-copy genomic insert-specific probe, instability of the YAC insert is the most likely cause.

Assessing chimerism. In most existing YAC libraries, chimeric clones are observed to represent from 5% to 50% of the total clones. One of the most reliable ways to identify a chimeric YAC insert is to isolate a small fragment from each end of the YAC insert and define its chromosome of origin and whether it is contained in overlapping YACs from the same chromosomal region. Two procedures are given for analyzing the end fragments of

the YAC clone, which can be used to identify chimerism in the YAC insert—one based upon subcloning (which for large-scale mapping projects can require prohibitive amounts of time and effort) and one based upon PCR. With the PCR strategy, the resulting amplified product should migrate as a single fragment in a polyacrylamide gel. If multiple bands are present, it may be possible to demonstrate that one is an appropriately amplified fragment because it should be digested by *EcoRI* to yield the vector-linker fragment plus the insert end fragment (see Fig. 6.10.3). If digestion by *EcoRI* cannot be confirmed or if no amplified band is observed, it is useful to try a “hemi-nested” PCR amplification in which the initially amplified product is reamplified using another primer that should be contained only in the properly amplified fragment.

Each end-fragment probe should be shown to be single-copy by hybridization to a Southern blot of total DNA from the species used to prepare the YAC library. If a smear of hybridization is obtained, repetitive sequences are present within the probe. In the case of fragments obtained by subcloning, it is usually possible to identify a single-copy probe by digesting the fragment into several smaller pieces using selected restriction enzyme. The end fragments recovered by PCR are usually small, so that it is generally impossible to salvage a single-copy probe. It may be possible to suppress the repetitive DNA hybridization by including in the hybridization reaction an excess of unlabeled denatured repetitive DNA fragments from the species used to prepare the YAC library. If this is unsuccessful, the alternate protocol (subcloning into a bacterial vector) is usually necessary.

Construction of a cosmid sublibrary. For further high-resolution analysis and mapping of the YAC insert, it is desirable to construct a sublibrary (final basic protocol) from the YAC-containing DNA (fifth basic protocol).

A number of cosmid and phage vectors are available that are suitable for subcloning YACs into bacterial vectors (*UNITS 3.16 & 5.7*). One excellent candidate is the SuperCos-1 cosmid vector (Stratagene), which can accommodate inserts in the 35- to 42-kb range. It contains a neomycin-resistance cassette that permits selection of transfected clones in mammalian cells. It also contains T3 and T7 phage promoters flanking the genomic insert, which facilitate generation of RNA probes from the ends of the genomic inserts. This feature is useful for verifying overlaps of clones or to permit chromo-

some walking if a complete cosmid contig is not established in the first round of screening.

Once a sublibrary has been constructed, it should be screened with a probe consisting of ³²P-labeled total genomic DNA from the individual or species that was originally used to construct the library (a source of repetitive sequences). This will identify most of the cosmids containing DNA inserts from the source genome. Individual clones can be analyzed by Southern blotting with probes from the YAC insert or with genomic repetitive sequences. This data, together with results of Southern blots using probes derived from the ends of the cosmid clones using T3 or T7 polymerase, can be used to organize the cosmids into contigs. If a complete contig is not established, the cosmid library can be screened again with probes representing the ends of the YAC inserts, or derived from the ends of cosmid clones. Empirically, different portions of the YAC insert have been found to be nonrandomly represented in the cosmid library. Consequently, it is common for one or more rounds of chromosome walking to be required to fill in gaps between cosmid contigs.

Anticipated Results

The basic protocol for preparation of DNA from YAC clones can be expected to yield ~1 to 1.5 μg of DNA in the size range of 50 to 200 kb from 10⁸ yeast cells. The yield of DNA obtained by purification using preparative CHEF gel electrophoresis is ≥10-fold lower. The basic protocol for preparation of yeast chromosomes in agarose plugs for PFGE should yield sufficient material for ~40 lanes of a pulsed-field gel from a 25-ml yeast culture. The basic and alternate protocols for analysis of the YAC insert end fragments (by PCR and by subcloning into a plasmid vector) should each yield DNA fragments that identify single hybridizing bands in genomic DNA when used as probes for Southern blots. The basic protocol for preparation of high-molecular-weight YAC-containing yeast DNA in solution should yield ~25 to 50 μg of DNA ≥100 kb in size from a 100-ml culture. Basic protocol for preparation of a YAC insert cosmid sublibrary should yield ~1500 colonies/μg of starting yeast DNA. From these, ~30 to 50 genomic DNA-containing cosmids should be recovered.

Time Considerations

Purifying YAC DNA using the first basic protocol requires ~3 days to grow the culture, 3.5 hr to isolate the DNA, and after an overnight

resuspension, ~2 hr to remove RNA and reprecipitate the DNA.

Preparation of yeast chromosomes in agarose plugs takes ~4 days to grow the yeast culture, ~1½ hr to form the yeast-containing plugs, ~6 hr to lyse the yeast, an overnight incubation, and ~6 hr to wash and prepare the plugs for electrophoresis.

Preparation of YAC insert end fragments by PCR takes from 6 hr to overnight to anneal the bubble primers, digest the YAC DNA, and ligate it to the bubbles. Another 3 to 5 hr are needed to amplify the end fragment by PCR.

Isolation of YAC end fragments by subcloning requires 2 to 3 days to perform the preliminary analytical Southern blot to identify the enzyme combination of choice for subcloning. Once this is identified, 1 day is required for preparative isolation of the doubly digested DNA fragments, followed by an overnight ligation to the modified pUC 19 vector. An additional day is needed to transform bacteria and grow colonies, and 1 to 2 days are required to identify the specific end-fragment

subclones by hybridization. Finally, 2 days are needed to purify the subcloned DNA and to verify its structure by restriction enzyme analysis.

Preparation of high-molecular-weight YAC-containing DNA requires ~4 days to grow the culture, 7 hr to lyse the cells and perform the sucrose-gradient fractionation, an overnight dialysis, and 2 to 3 hr to concentrate the DNA. Following an additional overnight dialysis, the DNA is ready for use.

YAC insert cosmid sublibrary preparation and analysis takes 2 days to perform test digestions and ligations. Another 2 days are required to perform the preparative digestion, ligation, packaging, and plating of the library. Two more days are required for preparation of filters, hybridization, washing, and autoradiography.

SPECIALIZED STRATEGIES FOR SCREENING LIBRARIES

Use of Monoclonal Antibodies for Expression Cloning

This unit details the use of transient expression in mammalian cells to screen cDNA libraries with monoclonal antibodies (MAB) to isolate cDNA clones encoding cell-surface and intracellular proteins. The first basic protocol describes the cloning of cDNAs encoding cell-surface antigens. Several steps in this protocol involve transfection procedures that are described in greater detail in *UNIT 16.12*. The second basic protocol is a modification that facilitates isolation of cDNAs encoding antigens that are expressed intracellularly. Both protocols are designed for use with the expression vector CDM8, which contains a polylinker for subcloning double-stranded cDNA (Fig. 16.12.1).

ISOLATION OF cDNA CLONES ENCODING CELL-SURFACE ANTIGENS

This protocol is designed to isolate cDNAs encoding cell-surface proteins by screening cDNA libraries transiently expressed in mammalian cells. The procedure requires multiple rounds of transfection and immunoselection and is divided into four sections: (1) COS cell transfection by the DEAE-dextran method, (2) immunoselection by panning, (3) plasmid recovery and *E. coli* transformation, and (4) COS cell transfection by the spheroplast fusion method. A total of four rounds of transfection and immunoselection (one using DEAE-dextran, three using spheroplast fusions; Fig. 6.11.1) are used. After the final round of immunoselection, plasmid DNA is prepared from individual bacterial colonies. COS cells are then transfected with this DNA by the DEAE-dextran method and examined for their ability to express the foreign protein of interest by immunofluorescence microscopy (*UNIT 14.6*) or flow cytometry analysis (Holmes and Fowlkes, 1991).

DEAE-dextran transfection is a highly efficient means of introducing the cDNA library into COS cells to ensure that the transfected cells receive as complete a library representation as possible. Typically, ten 100-mm tissue culture plates of COS cells are transfected (Fig. 6.11.1). The subsequent panning steps allow rapid and efficient culling of cells expressing the protein of interest from the bulk of the transfected cells (each 60-mm, antibody-coated plate can be used to pan $1-2 \times 10^7$ transfectants). Plasmid DNA can be rescued from the panned cells by obtaining a Hirt supernatant (Hirt, 1967) and following amplification in *E. coli*, the plasmid DNA can be reintroduced into COS cells using spheroplast fusion. This transfection procedure ensures that a single plasmid type is delivered into each transfectant, allowing greater enrichment in subsequent rounds of transfection and immunoselection. Each round of screening usually requires a set of six fusions and each set of six fusions requires 100 ml of cells in broth.

NOTE: All incubations are performed in a humidified 37°C, 5% CO₂ incubator unless otherwise noted. See Chapter 9 introduction for critical parameters concerning media components and preparation.

Materials

- Complete Dulbeccos minimum essential medium containing 10% (v/v) NuSerum or 10% (v/v) calf serum (complete DMEM-10 NS or complete DMEM-10 CS; *APPENDIX 3F*)
- 100-mm tissue culture plates seeded with COS cells (~50% confluent)

cDNA library: plasmid expression vector DNA containing $>10^6$ of cDNA clones (UNIT 5.8; see background information), CsCl-purified (UNITS 1.7 & 9.1)

Phosphate-buffered saline (PBS; APPENDIX 2)

DEAE-dextran/chloroquine solution: PBS containing 10 mg/ml DEAE-dextran (Sigma) and 2.5 mM chloroquine (Sigma)

10% (v/v) DMSO in PBS

Trypsin/EDTA solution: PBS containing 0.5 mg/ml trypsin + 0.2 mg/ml EDTA

0.5 mM EDTA/0.02% (v/v) azide in PBS

0.5 mM EDTA/0.02% (v/v) azide/5% (v/v) calf serum in PBS

1 μ g/ml purified monoclonal antibody (MAb) or 1:100 dilution of ascites fluid (UNIT 11.1)

0.5 mM EDTA/0.02% (v/v) azide/2% (w/v) Ficoll

60-mm antibody-coated plates (first support protocol)

5% (v/v) calf serum in PBS

0.6% (w/v) SDS/10 mM EDTA

5 M NaCl (APPENDIX 2)

Phenol (extracted twice with 1 M Tris·Cl, pH 7.5)

2 μ g/ μ l linear polyacrylamide

TE buffer, pH 7.5 (APPENDIX 2)

Electroporation-competent *E. coli* cells (UNIT 1.8)

LB medium (UNIT 1.1)

100 mg/ml spectinomycin or 35 mg/ml chloramphenicol in ethanol

20% (w/v) sucrose/50 mM Tris·Cl, pH 8.0, ice cold

5 mg/ml lysozyme (Sigma #L6876), freshly prepared in 250 mM Tris·Cl, pH 8.0

250 mM EDTA, ice cold (APPENDIX 2)

50 mM Tris·Cl, pH 8.0 (APPENDIX 2)

Figure 6.11.1 Isolation of a cDNA clone encoding a cell-surface antigen by transient expression in mammalian cells.

10% (w/v) sucrose/10 mM MgCl₂ in DMEM (GIBCO/BRL #320-1960AJ)
without serum, filter sterilized

60-mm tissue culture plates seeded with COS cells (~50% confluent)

50% (w/w) PEG 1000 or 1450 in DMEM (no serum), adjusted to pH 7 with
7.5% (w/v) sodium bicarbonate (Baker or Kodak)

DMEM without serum

Complete DMEM-10 CS (*APPENDIX 3F*) containing 15 µg/ml gentamycin sulfate

Nylon mesh, 100-µm pore size (Tetco)

Sorvall GSA rotor or equivalent

Swinging-bucket centrifuge (e.g., Sorvall RT-6000B)

Additional reagents and equipment for transformation of *E. coli* by electroporation
(*UNIT 1.8*), phenol extraction and ethanol precipitation (*UNIT 2.1*), alkaline lysis
miniprep (*UNIT 1.7*), and immunofluorescence (*UNIT 14.6*)

Transfect COS cells using DEAE-dextran

1. Add 5 ml complete DMEM-10 NS to each 100-mm plate of COS cells to be transfected.

Each 100-mm plate should be ~50% confluent the day of transfection (~5 × 10⁶ cells). This protocol is designed to be used with COS cells and is too harsh for WOP or MOP cells (see background information). If these murine lines must be used, it is important to reduce both the concentration of DEAE-dextran used to 200 µg/ml final and the time that the cells are exposed to the transfection medium to 2 hr, and to use IMDM (Iscoves modified Dulbeccos medium; GIBCO/BRL #430-2200) in place of DMEM (prepare complete IMDM media as for complete DMEM media, but omit amino acids).

2. To each dish, add 5 µg cDNA library and mix, then add 0.2 ml DEAE-dextran/chloroquine solution and mix. Incubate 4 hr.

Typically, libraries of >10⁶ clones are used to obtain plasmid DNA. It is important that the DNA and the DEAE-dextran form a fine, invisible precipitate. If the DNA is not diluted prior to addition of DEAE-dextran, a large DNA/DEAE-dextran precipitate forms (it is easily seen), which is not readily taken up by the cells.

Check the cells after ~3 hr exposure to the DEAE transfection mix, as their health can decline rapidly. This is particularly true of chloroquine transfections, and it is usually better to shorten the transfection than to allow too many cells to die.

3. Aspirate the medium and add 2 ml of 10% DMSO. Incubate ≥2 min at room temperature.

The time that the cells are exposed to the DMSO is not critical.

4. Remove DMSO and replace with 10 ml complete DMEM-10 CS. Incubate overnight.

5. Aspirate the medium, add PBS, then aspirate the PBS. Add 2 ml trypsin/EDTA to each plate and incubate 5 to 15 min until cells have lifted from the plate. Replate the cells on two new 100-mm plates and incubate overnight.

Replating the cells allows them to recover more effectively from the transfection. In addition, the DEAE-dextran transfection makes the cells sticky and replating allows them to be lifted from the plates with EDTA to initiate the panning step.

Immunoselect the cells by panning

6. Aspirate the medium, add 2 ml EDTA/azide solution, and incubate 10 to 20 min to detach cells from plates.

7. Pipet vigorously with a short Pasteur pipet to dislodge the cells, then transfer cells from each plate into a 15-ml centrifuge tube.

8. Centrifuge 4 min at $200 \times g$ (e.g., 1000 rpm in a Sorvall RT-6000B with GSA rotor or in a tabletop centrifuge) and discard supernatant.
9. Resuspend cells in 0.5 to 1.0 ml EDTA/azide/calf serum solution and add purified MAb to 1 $\mu\text{g}/\text{ml}$ final or ascites at a 1:100 dilution final. Incubate 30 to 60 min on ice.
10. Add an equal volume of EDTA/azide solution and carefully layer on 3 ml EDTA/azide/Ficoll solution. Centrifuge 4 min at $200 \times g$. Aspirate supernatant in one smooth movement.
11. Add 3 ml EDTA/azide/calf serum solution to each antibody-coated plate. Resuspend cells in 0.5 ml EDTA/azide solution, then add aliquots of the cells to these plates by pipetting them through a nylon mesh. Leave 1 to 3 hr at room temperature.

Four 6-mm antibody-coated plates are used in each round of panning. It is important to pass the cells through the nylon mesh to break up large clumps of cells which might contain both positive and negative cells. This ensures that individual antibody-coated cells bind to the panning plate.

12. Remove excess cells not adhering to the plate by gently washing two to three times with 3 ml of 5% calf serum (or complete DMEM-10 NS or complete DMEM-10 CS).

Washing gently means swirling the plate with a smooth motion for ~30 sec. The plate obtained after these washes is known as a panned plate.

Recover plasmid DNA and transform *E. coli*

13. Add 0.4 ml SDS/EDTA solution to the panned plate and leave 20 min at room temperature (to lyse the cells).

This incubation period can be as little as 1 min if there are only a few cells on the plate.

14. Pipet the viscous mixture into a microcentrifuge tube. Add 0.1 ml of 5 M NaCl, mix, and place ≥ 3 hr on ice or leave overnight at 4°C .

The viscosity is primarily due to the genomic DNA. It is important to avoid shearing the genomic DNA so that it will not contaminate the plasmid DNA. Keeping the mixture as cold as possible seems to improve the quality of the Hirt supernatant.

15. Microcentrifuge 4 min at top speed, 4°C , and remove supernatant carefully.
16. Extract with phenol (twice if the first interface is not clean) and add 5 μl (10 μg) of 2 $\mu\text{g}/\mu\text{l}$ linear polyacrylamide (or other carrier).
17. Fill the tube to the top with 100% ethanol and precipitate. Resuspend the pellet in 0.1 ml TE buffer, pH 7.5.
18. Add 10 μl of 3 M sodium acetate and 300 μl of 100% ethanol, and repeat precipitation. Resuspend the pellet in 0.1 ml TE buffer, pH 7.5.
19. Transform electroporation-competent *E. coli* cells by electroporation using DNA obtained from step 18. Incubate overnight at 37°C .

*Approximately 10^5 bacterial colonies should be obtained. It is advisable to transform *E. coli* with an aliquot of DNA to determine the amount necessary to obtain 10^5 colonies. Generally $1/10$ to $1/4$ of the recovered DNA will be used.*

Prepare the spheroplasts

20. Rinse the plate from step 19 several times with LB medium while scraping with a spreader to dislodge the bacteria. Use $\frac{1}{10}$ to $\frac{1}{5}$ of the pooled scrapings to inoculate 200 ml of LB medium. Grow to $OD_{600} = 0.5$ at 37°C with shaking.
21. Add 100 mg/ml spectinomycin to 100 $\mu\text{g}/\text{ml}$ or 35 mg/ml chloramphenicol to 150 $\mu\text{g}/\text{ml}$. Incubate with shaking 10 to 16 hr at 37°C .

Do not let the cells grow >16 hr or they will begin to lyse. If the cells lyse, do not proceed.

22. Centrifuge 100 ml of the culture in a 250-ml bottle, 5 min at $4000 \times g$ (e.g., 5000 rpm in a Sorvall with GSA rotor), room temperature or 4°C .
23. Drain well and resuspend pellet in 5 ml of ice-cold sucrose/Tris·Cl, pH 8.0.
24. Add 1 ml of 5 mg/ml lysozyme solution. Incubate 5 min on ice.
25. Add 2 ml of ice-cold 250 mM EDTA, pH 8.0, and incubate 5 min on ice.
26. Add 2 ml of 50 mM Tris·Cl, pH 8.0, and incubate 5 min in a 37°C water bath.
27. Place on ice. Check percent conversion to spheroplasts by microscopy.

A good spheroplast preparation gives about 80% to 90% conversion; anything <50% should not be used. Spheroplasts should appear as individual spheres, not as clumps.

28. In a tissue culture hood, slowly add 20 ml of ice-cold sucrose/ MgCl_2 solution dropwise at ~ 2 drops per second.

If this step is not carried out slowly, the spheroplasts will lyse. Lysis can easily be detected because the medium will become extremely viscous.

Transfect the COS cells by spheroplast fusion

29. Remove the medium from the COS cells plated the day before in 60-mm plates.

If the cells are confluent, they are more likely to lift from the plate.

30. Add 5 ml of the spheroplast suspension (from step 28) to each plate of cells (from step 29).
31. Place plates on top of tube carriers in a swinging-bucket centrifuge. Centrifuge 10 min at $100 \times g$ (e.g., setting 5.7 in a Sorvall RT-6000B with GSA rotor), room temperature. Aspirate the supernatant carefully from the plates.

Up to six plates can be prepared at once. Plates can be stacked on top of each other, but three in a stack is not advisable as the spheroplast layer on the top plate is often torn or detached after centrifugation.

32. Pipet 1.5 to 2 ml of 50% PEG solution into the center of the plate. If necessary, sweep the pipet tip around to ensure that the PEG spreads evenly and radially across the entire plate.

Use of PEG 1000 yields higher-efficiency transfections. This advantage is offset by the higher toxicity, requiring more careful timing of exposure; therefore, the use of PEG 1450 is advisable until the technique is mastered. WOP and MOP cells are more sensitive to PEG than are COS cells. When these cell lines are used, PEG 1450 is recommended and the procedure must be done as quickly as possible to prevent cell death.

33. After PEG has been added to the last plate, prop the plates up on their lids so that the PEG solution collects along the edge. Aspirate the PEG solution. Incubate 90 to 120 sec for PEG 1000 or 120 to 150 sec for PEG 1450 at room temperature.

The thin layer of PEG that remains on the cells is sufficient to promote fusion; the PEG is

easier to wash off and better cell viability is obtained than if the bulk of the PEG is left behind.

34. Pipet 1.5 ml of serum-free DMEM into the center of the plate to sweep the PEG layer radially across the plate. Tilt plates and aspirate medium. Repeat this DMEM wash.
35. Add 3 ml complete DMEM-10 CS containing gentamycin sulfate. Incubate 4 to 6 hr.
36. Remove medium and replace with 3 ml of complete DMEM-10 CS containing gentamycin sulfate. Incubate 2 to 3 days.
37. Repeat steps 6 to 36 two times using the transfected cells obtained in step 36.
38. Repeat steps 6 to 19 using the cells obtained in step 37. Prepare DNA from a single bacterial colony and transfect COS cells as in steps 1 to 4.

Approximately 1/4 of the DNA obtained from a 1.5-ml saturated bacterial culture is used for the transfection of a 100-mm plate.

39. Analyze the transfected cells by immunofluorescence microscopy or flow cytometry analysis.

One day after transfection, cells may be trypsinized (step 5) and replated in smaller plates to conserve materials used in staining. Flow cytometry analysis is beyond the scope of this book; the reader may consult Holmes and Fowlkes (1991) for a detailed description of this procedure.

SUPPORT PROTOCOL

PREPARATION OF ANTIBODY-COATED PLATES

This protocol describes a method for preparing plates coated with antibody to be used in the panning procedure of the first basic protocol.

Additional Materials

Anti-mouse affinity-purified antibody, sheep or goat (e.g., Cappel)

50 mM Tris·Cl, pH 9.5

0.15 M NaCl

1 mg/ml BSA in PBS (*APPENDIX 2*)

60-mm bacteriological plates

(e.g., Falcon #1007) or 100-mm plates (e.g., Fisher #8757-12)

1. Dilute anti-mouse antibody to 10 µg/ml in 50 mM Tris·Cl, pH 9.5. Add 3 ml diluted antibody per 60-mm plate or 10 ml per 100-mm plate and swirl. Incubate 1.5 hr at room temperature.

This antibody solution can be used on two more plates.

2. Wash plates three times with 0.15 M NaCl at room temperature.
3. Add 3 ml of 1 mg/ml BSA and incubate overnight at room temperature.
4. Aspirate the BSA and store plates at -20°C until used in step 11 of the first basic protocol.

ISOLATION OF cDNA CLONES ENCODING INTRACELLULAR ANTIGENS

One day after transfection with a cDNA library, COS cells are replated onto a polyvinylidene film. The following day, the cells are fixed with methanol. Cells expressing the target protein are radiolabeled by incubation with the appropriate antibody, followed by incubation with radioactive protein A or anti-Fc-antibody (alternatively, a radiolabeled primary antibody may be used). Autoradiography is used to identify the location of positive cells. Plasmid DNA is recovered by cutting the polyvinylidene wrap into squares and incubating them in SDS/EDTA and is then amplified by transforming *E. coli*. The COS cell transfection and screening procedure is repeated using plasmid DNA prepared from pools of bacterial colonies. Individual colonies from the pools enriched with the target gene are screened until the gene is clonally isolated. This strategy is illustrated in Figure 6.11.2.

**BASIC
PROTOCOL**

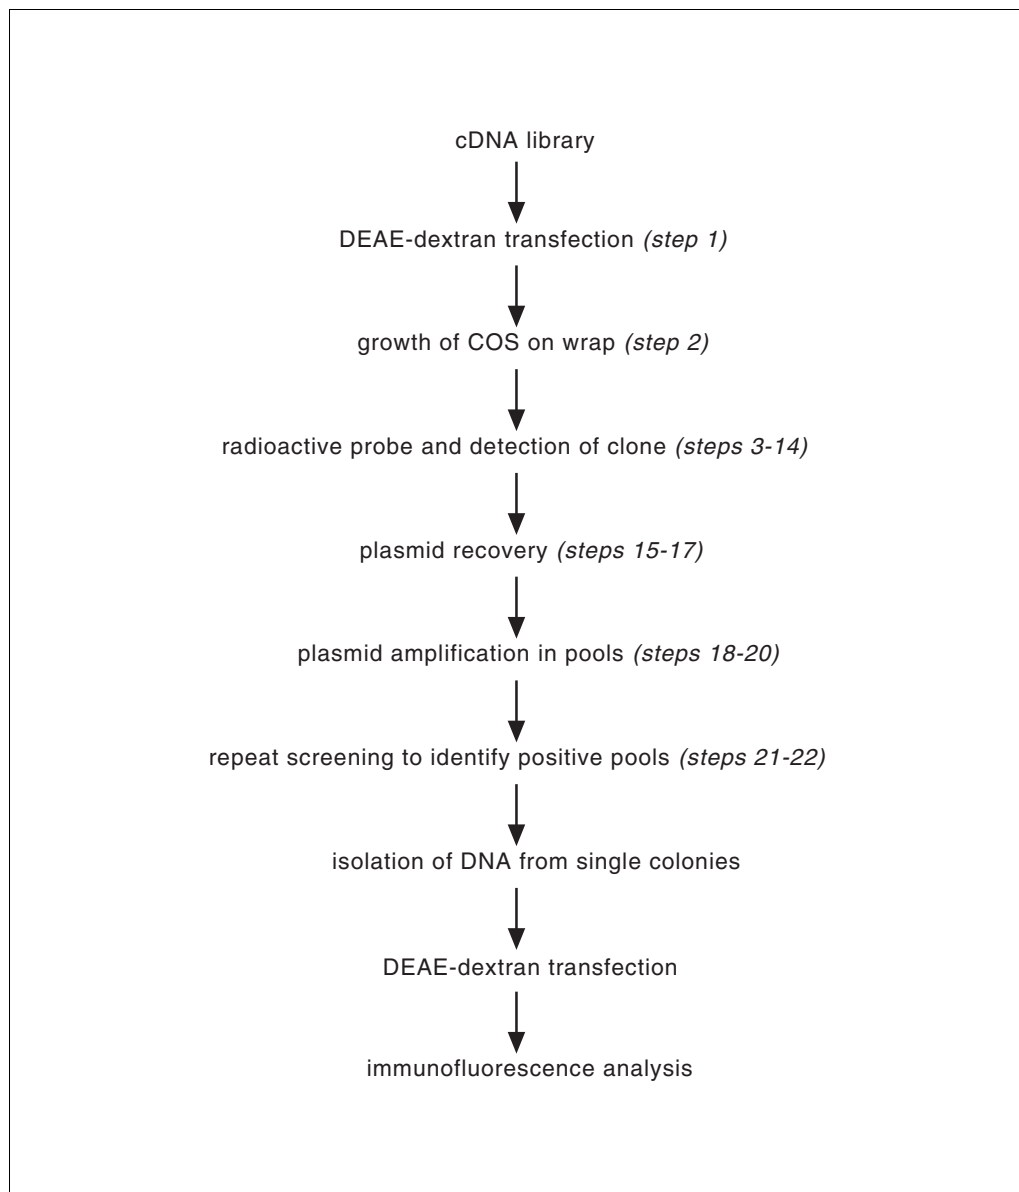

Figure 6.11.2 Sequence of steps for isolation of a cDNA clone encoding an intracellular antigen by transient expression in mammalian cells.

**Screening of
Recombinant
DNA Libraries**

6.11.7

Materials

100-mm tissue culture plates seeded with COS cells
cDNA library: plasmid DNA containing $>10^6$ cDNA clones (*UNIT 5.8*; see background information), CsCl purified (*UNITS 1.7 & 9.11*)
Trypsin/EDTA solution: PBS containing 0.5 mg/ml trypsin + 0.2 mg/ml EDTA
Phosphate-buffered saline (PBS; *APPENDIX 2*)
Methanol
1% (w/v) nonfat dry milk in PBS with and without monoclonal antibody (MAb)
1% (w/v) nonfat dry milk in PBS containing 0.25 μ Ci/ml of 125 I-labeled protein A
0.6% (w/v) SDS/10 mM EDTA buffer
LB medium (*UNIT 1.1*)

Polyvinylidene-wrapped plates (second support protocol)
X-ray film
Polyvinylidene wrap (e.g., Saran Wrap)
Rubber cement
Luminescent stickers

Additional reagents and equipment for alkaline lysis miniprep (*UNIT 1.7*) and autoradiography (*APPENDIX 3*)

Transfect cells and fix with methanol

1. Transfect ten 100-mm plates of COS cells with the cDNA library using the DEAE-dextran method as described in steps 1 to 4 of the first basic protocol.
2. Trypsinize each plate of transfected COS cells using trypsin/EDTA as described in step 5 of the first basic protocol and replate onto polyvinylidene-wrapped plates. Incubate 1 to 2 days.

Cells should be split at a ratio that will provide 50% to 75% confluency the following day. Complete DMEM containing penicillin and streptomycin should be used to avoid minor contamination that may occur because the plates are not sterile.

3. Remove medium from transfected COS cells. Wash plates by adding 5 ml PBS and aspirating at room temperature. Repeat wash one time.

Generally, 15 to 20 plates are used.

4. Add ~6 ml methanol and incubate 5 min at room temperature.
5. Wash plates three times with PBS, leaving the first addition of PBS on the plate for 2 to 3 min before aspirating.
6. Add 4 ml of 1% dry milk containing MAb to each plate. Incubate 30 to 60 min at room temperature.
7. Wash plates twice by adding 5 ml of 1% dry milk (without MAb), swirling gently, and removing solution.

Radiolabel and locate positive cells

8. Add 4 ml of 1% dry milk in PBS containing 125 I-labeled protein A to each plate. Incubate 30 min at room temperature.
9. Rinse plates four times with 1% dry milk in PBS and one time with PBS at room temperature. Remove all excess liquid.

It is helpful to prop the plates on edge to remove the excess liquid.

10. Completely cover a piece of X-ray film with polyvinylidene wrap and tape the edges

of the wrap to the film. Paint the wrap with a thin layer of rubber cement. Allow rubber cement to dry briefly.

The X-ray film acts as a support and may be a used piece that would otherwise be discarded. The presence of rubber cement does not appear to affect DNA recovery. Five plates will fit on an 8 × 10-inch (20.3 × 25.4-cm) film or 15 plates will fit on a 14 × 17-inch (35 × 43-cm) film.

11. Paint the bottom surface of the polyvinylidene-wrapped plate with a thin layer of rubber cement and allow the rubber cement to dry briefly.
12. Place the plates on the support. Lift the plate slightly and cut the wrap away from the edge of the plate.

The wrap with the cells will be left on the X-ray film. By slightly lifting the plate, a scalpel held nearly horizontal along the inside of the plate can be used to cut the wrap from the plate without cutting the wrap on the support. While this technique is not difficult, it is advisable to practice it on nonradioactive samples.

13. Affix luminescent stickers to the support. Cover the support and samples with polyvinylidene wrap.

There are now three layers of wrap on the support. Without the luminescent stickers, the film cannot be aligned over the samples to recover positive cells. Careful alignment is necessary to recover positive cells (there will be insufficient background to use the location of the samples for alignment).

14. Autoradiograph with an intensifying screen for 1 to 2 days at -70°C . Develop the film.
15. Align the film over the support using the luminescent stickers. Mark the location of positive cells by piercing the film alongside the spot with a needle (this leaves a mark on the polyvinylidene wrap).

A light box is helpful for locating the positive cells on the film.

16. Remove the film. Cut small squares of ~3 mm in the polyvinylidene wrap at the places it is marked.

Recover plasmid DNA and isolate the positive clone

17. Add 400 μl of SDS/EDTA buffer to a microcentrifuge tube. Place squares in tube (10 to 25 squares per tube) and incubate 30 min at room temperature.

All three layers of wrap are placed in the tube.

18. Recover plasmid DNA and transform *E. coli* as in steps 14 to 19 of the first basic protocol, plating transformed bacteria on separate LB plates to form pools of appropriate numbers of clones. Incubate overnight at 37°C .
19. Collect the bacteria from the LB plates by rinsing several times with LB medium while scraping with a spreader to dislodge the bacteria.
20. Prepare plasmid DNA from the scraped colonies using an alkaline lysis miniprep.
21. Transfect COS cells with the pools of plasmid DNA by the DEAE-dextran method as described in steps 1 to 4 of the first basic protocol.

In general, $1/10$ to $1/5$ of the DNA obtained from 1000 colonies is used to transfect one 100-mm plate of COS cells.

**SUPPORT
PROTOCOL**

22. Repeat steps 2 to 14 above to identify pools enriched with the gene of interest. Store the appropriate plasmid DNA in TE buffer at -20°C .

When screening pools, it is possible to use 60-mm plates (reduce all volumes to $\frac{1}{3}$).

23. Prepare DNA from a single bacterial colony, transfect COS cells, and analyze as in steps 38 and 39 of the first basic protocol.

PREPARATION OF POLYVINYLIDENE-WRAPPED PLATES

Plates are prepared in which the growth surface is a polyvinylidene wrap (to be used in the second basic protocol). The plates are quite sturdy and can be used in the same manner as standard tissue culture plates. Plates may be prepared a day or two in advance but the wrap will stretch and become floppy on prolonged storage.

Additional Materials

Chloroform
70% ethanol
0.1 mg/ml poly-L-lysine HCl (Sigma) in 50 mM Tris·Cl, pH 8.0, freshly prepared
100-mm or 60-mm tissue culture plates

1. Break the bottoms out of a 100- or 60-mm tissue culture plate with a blunt object.

Safety glasses are advisable. Strike the plate near the sides of the plate rather than in the center. If too much force is used, the sides of the plate will break as well. Structural stability is increased if the outer edges of the bottoms are not removed.

2. In a fume hood at room temperature, dip the top rim of the plate in chloroform to a depth of ~ 3 mm.
3. Shake off excess chloroform and place plate on a piece of polyvinylidene wrap laid flat. Place the plate and attached film into the lid of the plate to force the wrap into contact with the edges of the plate.
4. Remove the lid and gently but firmly pull the film tight to form a smooth surface.

Adhesion of the film to the outside of the plate helps maintain the strength of the seal.

5. Cut excess wrap from the plate with a razor blade.

The plate is now essentially inverted. The lid is placed over the opening that had been the bottom of the plate. When using 100-mm plates, a second lid is used to support the new wrap bottom.

6. Wash the plate two times with 70% ethanol. Allow the wrap to soak in the ethanol ~ 30 min.
7. Wash the plate with water.
8. Add 0.1 mg/ml poly-L-lysine to the plate—11 ml for a 100-mm plate and 4 ml for a 60-mm plate. Incubate 2 hr to overnight at room temperature.
9. In a tissue culture hood, rinse the plates twice with PBS.

Dishes should not be stored more than a few days because the wrap will stretch and become loose.

COMMENTARY

Background Information

Transient expression in mammalian cells has emerged as a powerful method for isolating cDNA clones that encode secreted cell-surface and intracellular proteins. It was first used to isolate cDNA clones encoding the lymphokine granulocyte/macrophage colony stimulating factor (GM-CSF; Lee et al., 1985; Wong et al., 1985). This cloning strategy is well suited for isolating any secreted proteins for which a rapid and sensitive bioassay exists, and has since been applied to isolate cDNA clones encoding a number of different lymphokines. Transient expression cloning was combined with the simple but powerful immunoselection technique of panning (Wysocki and Sato, 1978) to isolate a cDNA encoding the T cell-surface proteins CD2 and CD28 (Seed and Aruffo, 1987; Aruffo and Seed, 1987). This procedure has since been used to isolate cDNA clones encoding a number of different cell-surface proteins when antibodies against them were available. When antibodies against a cell-surface receptor of interest are not available, but its ligand is, transient expression in mammalian cells has been combined with ligand-binding assays to isolate cDNA clones encoding the receptor. This strategy was first used to isolate a cDNA clone encoding the receptor for the lymphokine interleukin 1 (Sims et al., 1988). Modifications to this protocol (Gearing et al., 1989) have since allowed the use of this strategy to isolate a number of receptors.

Recent improvements have allowed the use of transient expression in mammalian cells to isolate cDNA clones encoding intracellular proteins, including the major DNA-binding protein of the erythroid lineage (Tsai et al., 1989), the lysosomal membrane glycoprotein CD63 (Metzelaar, 1991), and fucosyltransferase, which adds fucose to *N*-acetylglucosamine with $\alpha(1,3)$ linkages, allowing the expression of the sialyl CD15 antigen (Goelz et al., 1990).

Transient expression in mammalian cells. Mammalian cells are ideal hosts for screening cDNA libraries prepared using mRNA isolated from higher eukaryotes. These cells are able to synthesize transcripts correctly from the cDNA clones in the library and are likely to process the proteins that they encode appropriately, thus maximizing the likelihood that the foreign proteins will be present in their native state and will be detectable using functional or immunological assays.

Mammalian cells were initially used as the host for isolation of genomic DNA fragments encoding oncogenes by stably introducing genomic DNA fragments derived from human tumors into murine cells (Goldfarb et al., 1982; Shih and Weinberg, 1982). The gene encoding the oncogene was then rescued from the transfected cells that had acquired the transformed phenotype. Stable transfections of mammalian cells were subsequently combined with immunoselection procedures to isolate genomic DNA fragments encoding the human HLA and β_2 microglobulin genes (Kavathas and Herzenberg, 1983) and cDNA clones encoding the T cell-surface proteins CD8 (Kavathas et al., 1984; Littman et al., 1985) and CD4 (Maddon et al., 1985).

The time involved in obtaining stable transfectants expressing the gene of interest and the difficulties associated with recovering the transfected DNA from the host's chromosomal DNA has limited the number of genes isolated using this cloning strategy. These difficulties prompted the development of transient expression systems for use in cloning with mammalian cells as the screening host. Unlike stable transfectants, these methods permit rapid preparation and detection of transfectants expressing the protein of interest and efficient recovery of the DNA encoding it.

Many technical advances have permitted efficient and routine screening of cDNA libraries in transiently expressing mammalian cells. These include the following developments: shuttle vectors that contain the appropriate eukaryotic transcription elements for high-level protein expression in transfected mammalian cells, mammalian cell lines that can act as effective heterologous expression hosts, and transfection protocols that allow efficient introduction of plasmid DNA into mammalian cells.

Expression vectors. A number of mammalian expression vectors permit screening of cDNA libraries by transient expression in mammalian cells (Chapter 16; Kaufman, 1990). These plasmids contain at least four basic elements: an efficient eukaryotic transcription unit, a viral-derived origin of replication, a prokaryotic origin of replication, and a prokaryotic selectable marker. One particular expression vector, CDM8 (Seed, 1987; Fig. 16.12.1; available from Invitrogen #V308-20) is especially engineered for these purposes, and is described in detail in *UNIT 16.12*. CDM8 con-

tains origins of replications derived from polyoma and SV40 viruses that allow for plasmid replication in cell lines expressing either the polyoma or SV40 large T antigens, respectively; usually, WOP (Dailey and Basilico, 1985) and COS (Gluzman, 1981) cells, respectively. Bacterial and M13 origins of replication (*ori*) are also present, allowing for plasmid amplification in bacteria and production of single-stranded DNA, respectively. The plasmid contains a *supF* gene as a prokaryotic selectable marker and a T7 RNA polymerase promoter for the preparation of mRNA in vitro from the subcloned cDNAs.

Mammalian cell lines. A number of cell lines have been developed that are excellent hosts for screening cDNA libraries prepared in the vector described above. Perhaps the most popular is the COS cell line (Gluzman, 1981), which was derived from the African green monkey kidney cell line CV-1 by transformation with an origin-defective SV40 virus. This cell line produces wild-type SV40 large T antigen but no viral particles. When plasmids containing an SV40 virus-derived *ori* are transfected into COS cells, the plasmid is replicated to a high copy number 48 hr posttransfection (10,000 to 100,000 copies/cell). This high-level replication has two important consequences. First, it allows for amplification of all DNA templates available for transcription. Second, it allows for recovery of the plasmid encoding the protein of interest from the immunoselected cells. This last point is of importance in the two basic cloning protocols because each cycle of transfection and immunoselection is followed by a plasmid-rescue step.

Other cell lines that have been used for expression cloning include the murine cell lines WOP (Dailey and Basilico, 1985) and MOP (Muller et al., 1984). These two cell lines express the polyoma large T antigen allowing the replication of plasmids containing a polyoma origin of replication in the transfected cells (1,000 to 10,000 copies/cell, 48 hr posttransfection). Another cell line, CV-1/EBNA, has been developed for screening cDNA libraries in conjunction with the expression vector pDC406, which contains an Epstein-Barr virus *ori* (McMahan et al., 1991).

The ability of COS cells to endure the transfection protocols and their ability to replicate the transfected plasmid to a very high copy number make them the cells of choice when screening a cDNA library with the methods described here. However, when the antibodies to be used in the immunoselection step cross-

react with proteins expressed by COS cells, another cell line must be used. In these cases, WOP or MOP cells can be used successfully, in spite of their more delicate nature and lower copy numbers of transfected plasmid.

Mammalian cell transfection. A number of transfection protocols have been developed for efficient introduction of foreign DNA into mammalian cells, including calcium phosphate, DEAE-dextran, spheroplast fusion, lipofection, and electroporation (*UNITS 9.1-9.5*). Two factors determine which transfection procedure should be used when screening a cDNA library by transient expression in mammalian cells: first, the efficiency of transfection, and second, the number of different plasmids that are introduced into each cell during transfection. Two transfection protocols, DEAE-dextran (McCutch and Pagano, 1968) and spheroplast fusion (Sandri-Goldin et al., 1981), are discussed below.

The mechanism by which DEAE-dextran transfections allow for introduction of foreign DNA into cells is poorly understood. It is believed that the positive charge of the DEAE-dextran polymer neutralizes the negative charge of the DNA polymer, forming a fine precipitate that can come into contact with the plasma membrane of the host cell. The DEAE-dextran/DNA complex is then internalized by pinocytosis. Some of this DNA makes its way to the host-cell nucleus, where it is replicated and transcribed. Because the foreign DNA enters the cell via endosomes, DNA integrity is enhanced by the addition of chloroquine to the transfection medium to prevent endosome acidification. DEAE-dextran transfections are very efficient, allowing for transfection of up to 70% of the host cells and delivery of up to 200 different plasmids into each transfected cell.

Introducing foreign DNA into mammalian cells by spheroplast fusion is very inefficient, allowing for transfection of only 1% to 2% of the host cells. Bacteria containing the foreign DNA are treated with lysozyme to remove their cell walls. The resulting spheroplasts are then fused with the host mammalian cell using polyethylene glycol (PEG), allowing introduction of the foreign DNA directly into the host cell cytoplasm. The DNA is then replicated and transcribed in the nucleus. Because of the inefficiency of the procedure, each host cell fuses with only one spheroplast, on average, introducing only a single plasmid type into each transfected cell.

The immunoselection screening method de-

scribed in the first basic protocol involves multiple rounds of mammalian cell transfection, immunoselection, and plasmid rescue steps. The rescued plasmids are amplified in *E. coli* and reintroduced into mammalian cells to initiate additional rounds of enrichment. To take full advantage of immunoselection, the two methods of transfection are used. When the cDNA library is first introduced into mammalian cells, it is important to obtain a complete representation of the library in the transfected host cells, ensuring that the protein of interest is expressed by the transfectants. For this reason, the first round of enrichment is initiated using DEAE-dextran transfection. In subsequent cycles of enrichment, it is important that a single plasmid type be delivered into each of the transfected cells to maximize the level of enrichment obtained in the subsequent immunoselection steps. This is accomplished using the spheroplast fusion transfection.

Immunoselection procedures. Two immunoselection techniques designed to rapidly select and enrich for plasmids encoding proteins of interest from a cDNA library transfected into mammalian cells are described. The first strategy is designed to isolate cDNA clones encoding surface proteins. A cDNA library prepared in a mammalian expression vector is transfected into COS cells using DEAE-dextran transfection. Forty-eight hours posttransfection, the cells are lifted from the plate and incubated with antibodies directed against the protein of interest. Cells expressing the foreign protein on their cell surface are easily culled from the bulk of the transfected cells by panning on plastic plates coated with anti-antibody antibodies (Wysocki and Sato, 1978). Plasmid DNA is then recovered from the transfected cells by the method of Hirt (Hirt, 1967), amplified in *E. coli*, and reintroduced into COS cells by spheroplast fusion. Two additional rounds of spheroplast fusion and panning are usually required to enrich for the plasmid encoding the protein of interest.

Panning has many advantages over other immunoselection procedures. It is fast, efficient (10^7 cells can easily be panned on two 60-mm plastic plates in 30 min), and very inexpensive. Other immunoselection techniques, such as sorting of fluorescence-labeled cells (Holmes and Fowlkes, 1991), may be used to screen cDNA libraries in transiently expressing mammalian cells (Yamasaki et al., 1988); but the greater demands on time, equipment, and technical expertise make these methods much less attractive.

The second strategy is designed to isolate cDNA clones encoding intracellular antigens. This method is a combination of the techniques described by Munro and Maniatis (1989) and Metzelaar et al. (1991). COS cells are transfected with a cDNA library by DEAE-dextran transfection. The day after transfection, they are replated onto poly-L-lysine-coated polyvinylidene wrap and allowed to grow for 1 to 2 additional days. They are then washed and fixed with methanol. The permeabilized cells are incubated with antibodies directed against the protein of interest, washed, and incubated with radiolabeled protein A (^{125}I). After washing, they are exposed to film to identify radiolabeled cells, which are then recovered by cutting the polyvinylidene wrap. The plasmid DNA is recovered from these cells by the method of Hirt, amplified in *E. coli*, and subjected to additional rounds of transfection and immunoselection.

Critical Parameters

The cloning strategy described in the first basic protocol is well suited for isolating cDNA clones encoding cell-surface proteins (see discussion above). If a cDNA library is thought to contain cDNA clones encoding a number of proteins of interest, it is possible to isolate all of them simultaneously by simply using a mixture of antibodies against all of the proteins of interest in the panning steps of the first three rounds of enrichment. The last cycle of immunoselection is carried out independently with antibodies against each of the different proteins.

Many times antibodies directed against the protein(s) of interest are of multiple isotypes. It is important, in this case, to use panning plates that have been coated with anti-Ig antibodies that bind to each of the isotypes present in the initial antibody pool. Alternatively, individual panning plates can be prepared for each of the antibody isotypes present in the initial antibody pool, but no significant advantage is achieved.

Although this cloning strategy has allowed isolation of a large number of cDNA clones encoding cell-surface proteins, it has some serious limitations. As with any expression cloning system, the gene of interest must initially be present in the library, the target protein must be functional or immunoreactive as a single chain, and the host system must posttranslationally modify the protein appropriately when these modifications are required for function or immunoreactivity. Compared with earlier bacterial expression cloning systems, the mam-

malian expression systems presented here are more likely to appropriately modify the gene products of higher eukaryotes. However, these methods require the host mammalian cell to express the target protein on its surface as a single molecule. This may not occur in cases where the target protein is part of a heterocomplex that requires more than one member for surface expression.

Several factors contribute to the successful application of this cloning strategy. The most critical parameter when screening a cDNA library by expression in mammalian cells is the quality of the cDNA library (for a more complete discussion, see *UNIT 5.8*). In addition, the quality of the COS cells and transfectability is of utmost importance. COS cells maintained in culture for prolonged periods tend to become refractory to transfection. For this reason, it is important to check the cells periodically for transfectability and replace them with cells from frozen stocks when necessary.

The competency level of the bacterial cells used to amplify the DNA rescued from the immunoselection step is very important and should be determined prior to the start of the experiment. If only a few positive cells are immunoselected by panning, it is of utmost importance that this plasmid DNA work its way into the bacteria so that it can potentially be amplified and thus be available for subsequent rounds of transfection and immunoselection. Ideally, only cells whose competency level is $\geq 10^9$ cfu/ μ g DNA should be used. For most bacterial strains, this can be achieved using electroporation.

When using panning to immunoselect the transfected cells, it is important to check that the antibody directed against the protein of interest does not bind to COS cells. If it does, another cell line should be used for screening. The researcher must also be mindful that DEAE-dextran treatment of cells changes their phenotype and thus the antibodies to be used in the panning step should be tested for cross-reactivity with mock-transfected cells.

The most difficult step, technically, is the spheroplast-fusion step. Careful timing of cell exposure to PEG is necessary to promote fusion while minimizing cell death. Although lower-molecular-weight PEG (PEG 1000) results in more efficient fusion, it is more toxic to the cells.

The cloning strategy described in the second basic protocol will not be effective if the antibodies used recognize epitopes that are sensitive to methanol treatment. Testing of the target

cells may reveal this limitation. If methanol sensitivity cannot be assayed, multiple antibodies against a given protein should be used when available.

Anticipated Results

In the first basic protocol, the authors typically use DNA prepared from a cDNA library of $\geq 10^6$ clones for screening. After four rounds of transfection, immunoselection, and plasmid rescue, 12 individual colonies are picked and plasmid DNA prepared from them. If the cloning procedure has been successful, at least one DNA preparation directs the expression of the protein of interest. In general, if the screening is unsuccessful, this indicates that the clone of interest may not be present in the library. In this case, screening of a new cDNA library may be successful. Unsuccessful screening may indicate that the target gene is refractory to cloning using this strategy. Possible alternative methods are described in Chapter 5.

In the second basic protocol, three to five spots are generally obtained on each 100-mm plate. It is possible to enrich a mixture that is 1:10,000 in the desired clone to 1:100 with a single immunoselection step.

Time Considerations

In the first basic protocol, the cloning strategy involves multiple steps. Each cycle of transfection, immunoselection, plasmid rescue, and amplification can be comfortably accommodated in 1 week. On this schedule, it is possible to screen a cDNA library in 1 month. However, the more ambitious can screen a library in 3 weeks.

In the second basic protocol, successful application allows identification of positive pools in 1½ weeks. The screening of subsets of the pool can be accelerated by using 60-mm plates. When screening individual clones, transfectants may be assayed by immunofluorescence. The length of time required to obtain a single isolated positive clone will depend on the pool sizes used.

Recombination-Based Assay (RBA) for Screening Bacteriophage Lambda Libraries

The recombination-based assay represents a convenient way to screen a complex library constructed in bacteriophage λ for homology to a given sequence cloned into a specially designed plasmid. The technique serves to screen a bacteriophage library rapidly and efficiently with a sequence cloned into a plasmid; counterselection then yields the gene product of interest with its plasmid carrier deleted. Because 10^6 to 10^7 plaque-forming units (pfu) may be screened using several petri dishes, and the homology for crossing-over need only be >25 bp, the RBA represents an efficient way to screen complex λ libraries rapidly for homology to a given sequence.

In this procedure (outlined in Fig. 6.12.1), a λ library is screened using a specially designed R6K *supF* plasmid, pAD1 (Fig. 6.12.2), carrying the desired target sequence. Recombinants arising from cross-over events between the plasmid and a bacteriophage carrying a corresponding region of homology are selected by their ability to grow on strain DM21 (Fig. 6.12.3). Growth of λ on DM21 requires the presence of the *supF* allele encoded on the plasmid to suppress an amber mutation in the host strain that prevents λ propagation. Recovery of the original phage carrying the target sequence requires a reversal of the homologous recombination event. This reversal occurs spontaneously, and is detected by PCR amplification using primers that flank the cloning site in the λ vector (Fig. 6.12.4).

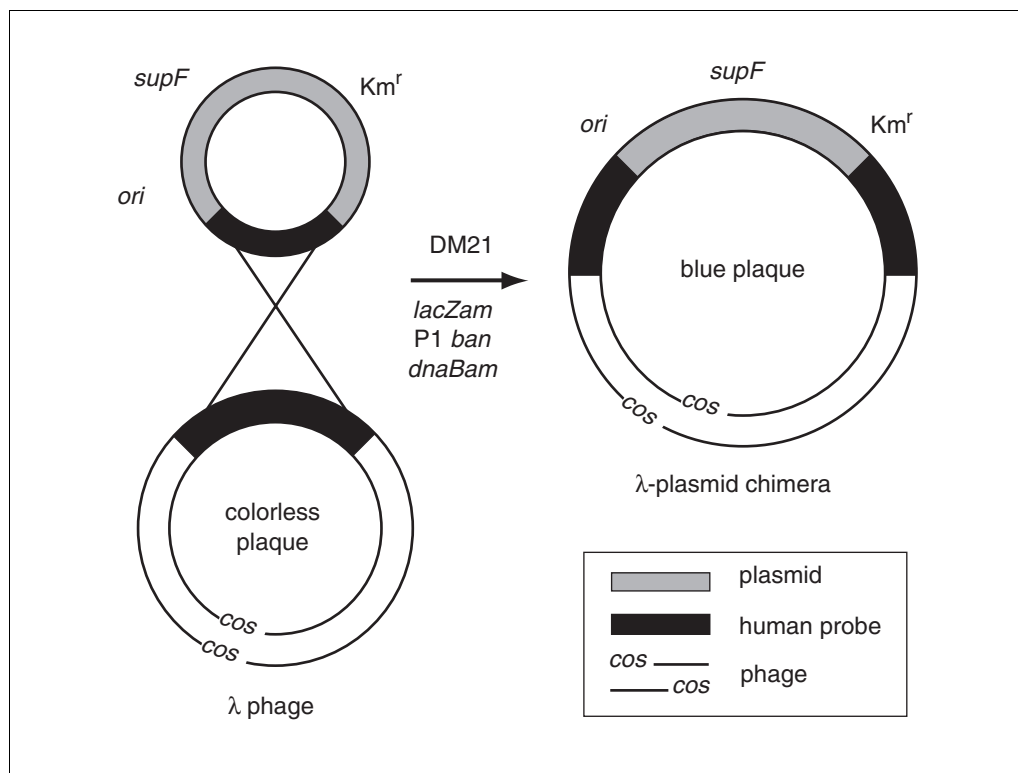

Figure 6.12.1 The recombination-based assay (RBA). Homology between sequences in a plasmid and a bacteriophage >25 bp long (Watt et al., 1985; Shen and Huang, 1986, 1989; King and Richardson, 1986) mediates a recombination event between the two vectors. As a result *supF* is integrated into the bacteriophage, allowing it to plate on the *dnaBam* host DM21 (see Table 6.12.1). The cointegrate yields a blue plaque in the presence of IPTG and Xgal on the *lacZam* host DM21, as *supF* suppresses the amber mutations in both the *dnaB* and *lacZ* genes. Different shadings indicate origins of DNA regions.

Materials

For recipes, see **Reagents and Solutions** in this unit (or cross-referenced unit); for common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.

DNA fragment encoding sequence of interest
Plasmid pAD1 (Fig. 6.12.2; available from Dr. D. Kurnit)
recA⁺ *E. coli* strain (Table 1.4.5 or commercial suppliers)
L broth (see recipe) with 50 µg/ml kanamycin (Table 1.4.1)
Bacteriophage λ library (UNIT 5.8)
Lambda top agar (see recipe)
Lambda plates (see recipe), some with 50 µg/ml kanamycin and some with 100 µg/ml streptomycin (Table 1.4.1)
Suspension medium (SM; see recipe)
Chloroform
E. coli DM21, DM75, DM392, and DM1061 (Fig. 6.12.3 and Table 6.12.1), saturated overnight cultures freshly grown in LB medium (UNIT 1.1) with 100 µg/ml streptomycin
100 mM IPTG (isopropyl thiogalactoside; Table 1.4.2)
2% Xgal in DMF (see recipe)
Additional reagents and equipment for subcloning DNA into plasmids (UNIT 3.16), culturing (UNIT 1.1) and transformation (UNIT 1.8) of bacteria, plating and titering λ phage (UNIT 1.11), β-galactosidase assay (UNIT 1.4), and PCR amplification (UNIT 15.1)

NOTE: All incubations are at 37°C unless otherwise specified.

Screen library and select recombinants

1. Clone the sequence of interest into a pAD1 plasmid and transform into *recA*⁺ *E. coli* strain yielding a kanamycin-resistant *recA*⁺ strain. Prepare a saturated overnight culture grown with aeration in L broth containing 50 µg/ml kanamycin.

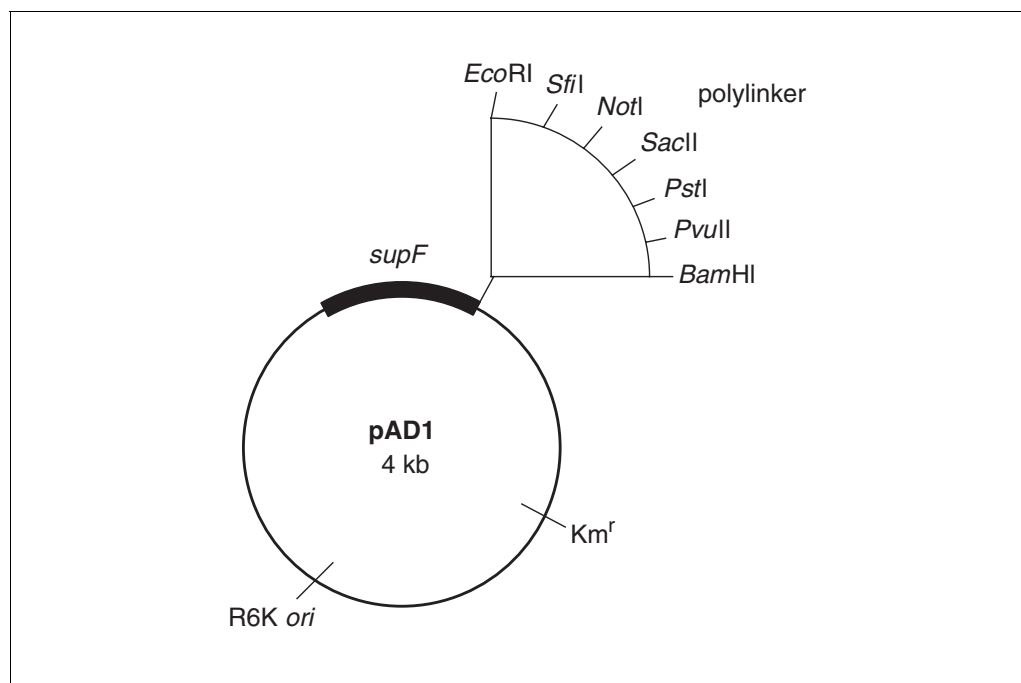

Figure 6.12.2 Structure of pAD1. This plasmid incorporates the R6K replicon, *Km*^r, *supF*, and a polylinker. It is not homologous to ColE1 plasmids.

- Mix 3 ml lambda top agar, 200 μ l of overnight culture, and 10^6 to 10^7 pfu of a bacteriophage λ library. Mix well and pour mixture onto a lambda/kanamycin plate. Incubate 7 hr to overnight until total lysis occurs.

If more convenient, incubation overnight is perfectly acceptable, because there is no need to harvest the plates just as lysis occurs.

- Add 3 ml SM and 0.5 ml chloroform to each plate. Swirl lightly. Incubate 2 hr to overnight at room temperature to allow the plates to elute.

SM and chloroform are immiscible; swirling them together ensures that the SM is saturated with chloroform, killing any eluted bacteria and minimizing phage adsorption to bacterial debris. The easiest method is to rotate a stack of plates slowly by hand after adding the liquid. Care should be taken not to get chloroform on the petri dish cover, as this can cause fusion of the cover and the plate bottom. If fusion occurs, the cover can be pried from the bottom (e.g., with a screwdriver).

- Using a nonsterile disposable transfer pipet, harvest the eluate from each plate into a 1.5-ml polypropylene microcentrifuge tube.

Although the transfer pipets are polyethylene, they hold chloroform-saturated SM for too short a time-span to be damaged by the solvent.

At this stage harvested eluates can be stored ≤ 1 week at 4°C before continuing the procedure.

- Add 50 μ l of eluate (5×10^8 to 1×10^9 pfu) to 200 μ l DM21 culture. Add 3 ml lambda top agar and pour mixture onto a lambda/streptomycin plate. Incubate 7 hr to overnight until plaques form.

*DM21 is selective (*dnaBam lacZam*) and resistant to streptomycin. DM75, DM1061, and DM392 (used in later steps) are also streptomycin-resistant, with growth and plating conditions identical to those for DM21.*

Figure 6.12.3 Bacterial strain DM21 (outer rectangle) containing λ plasmid chimera with *supF* integrated (inner circle). DM21 has the genotype *lacZ_{YA536}(am)*, *dnaB266(am)*, *Sm^r*, *hsdR⁺*, *hsdM⁺*, *tonA⁻* (λ *imm21 b515 b519 nin5 att⁺P1 ban*), *supO lacZ(am) dnaB(am)*. The *dnaB* amber allele selects for λ phage that have *supF* integrated as shown. *SupF* also suppress the *lacZ* amber mutation, yielding blue plaques. Different shadings indicate origins of DNA regions.

Titer eluates on permissive strain

6. Add 10 μl of each eluate to be titered to 990 μl SM to obtain a 1/100 dilution. Prepare a 100-fold dilution series (to 10^{-8}) in SM.

Several random eluates should be titered on the permissive (*supF*-bearing) strain DM392 to ensure that an appropriate number of phage have been added to the DM21 lawn.

7. Pour a lawn of DM392 (200 μl culture in 3 ml top agar) on a lambda/streptomycin plate. Drop 10- μl aliquots of each eluate dilution onto lawn. Dry 15 min in a forced-air hood (or for longer on bench or in incubator). Incubate 7 hr to overnight until total lysis occurs.

This drop-titer procedure is the most convenient method of titering the eluates.

8. Count plaques in the lowest dilution that yields plaques. Convert the result to pfu/ml by multiplying it by the appropriate dilution factor and by a factor of 10^2 .

Titration ensures that sufficient phage have been added to the DM21 lawn. Should too many be added (more pfu than cells), the lawn will not materialize due to lysis from without. This phenomenon occurs because every cell that is infected with a bacteriophage will die, even though only cells infected by a phage carrying *supF* will yield a productive burst that then goes on to infect other cells. In rare cases of lysis from

Figure 6.12.4 Counterselection. Reversal of the recombination event (which is an equilibrium event) occurs spontaneously. PCR using primers abutting the cloning site of the bacteriophage is employed preparatively to obtain the cDNA without the genomic sequence in pAD1 that was used to retrieve it. The cDNA insert + pAD1 + genomic insert is too large to be amplified by PCR; in contrast, the cDNA insert alone can be amplified. Because there is an equilibrium between the selected and the counterselected phage, the counterselected insert can be amplified directly from the selected blue plaque, which contains a mixture of the two phages. Different shadings indicate origins of DNA regions.

without, the plating should be repeated; either the eluate should be titered or less eluate used.

Plaques on DM21 are very small, because suppression of the *dnaBam* mutation (which is not fully efficient) is required for growth. This makes it difficult to confirm that *supF* is present via simultaneous suppression of the *lacZam* mutation by *supF*; therefore, phage must be transferred to another strain as described in the following steps.

Confirm phages have integrated *supF*

9. Elute plaques on DM21 (from step 5) into 100 μ l SM. Mix:

- 10 μ l eluate
- 200 μ l DM75 culture
- 3 ml lambda top agar
- 10 μ l 100 mM IPTG
- 100 μ l 2% Xgal in DMF.

Plate on lambda/streptomycin plates. Incubate 7 hr to overnight until total lysis occurs.

To mix water and DMF, the tubes of top agar must be inverted and righted several times, taking care not to create bubbles. It is best not to prepare more than several tubes at once, because cells do not tolerate the heating block for very long.

*Light blue plaques are the desired phage containing *supF*. A larger number of colorless plaques that have not integrated *supF* will also plate on this strain; these correspond to phage that were not adsorbed originally on DM21 and therefore remain viable. In addition, for a phage such as λ gt11, in which interruption of an intact *lacZ* gene serves as evidence of successful cloning, blue color can result from an intact *lacZ* gene in the phage. To differentiate between the two, note that the desired *supF* suppression of the single-copy chromosomal *lacZ* locus results in a light blue color that extends only to the plaque margins, whereas the high-copy-number *lacZ* gene on λ gt11 yields a dark blue halo that extends past the plaque margins.*

10. Elute each plaque thought to contain an integrated *supF* (from step 9) into 100 μ l SM. Pour lawns of DM75 and DM1061 (200 μ l culture in 3 ml top agar/IPTG/Xgal, as in previous step) onto separate lambda/streptomycin plates. Drop 10- μ l aliquots of each phage eluate onto a lawn of each strain. Incubate 7 hr to overnight until total lysis occurs.

*This serves to confirm that plaques result from phage with *supF* rather than *lacZ*. Phage with *supF* will be blue on DM75 (*lacZam*) but colorless on DM1061 (which contains a *lacZ* deletion), whereas phage carrying an intact *lacZ* gene will be blue on both strains.*

Counterselect with PCR

11. Pour a lawn of 200 μ l DM75 in 3 ml top agar onto lambda/streptomycin plate. Drop 10- μ l aliquots of phage eluate onto lawn. Incubate 7 hr to overnight, until a single large plaque (“macroplaque”) appears.

12. PCR amplify the cloned product from the macroplaque using primers that abut the *EcoRI* cloning site of the λ phage vector used to construct the library.

This reverses the selection process and accomplishes counterselection (see Fig. 6.12.4). Using the large macroplaque ensures that sufficient template is present.

*Because the recombination reaction is an equilibrium reaction, a small fraction of phage within a blue macroplaque represent colorless revertants that have excised the *pAD1* plasmid and its insert. In contrast, the major product in the macroplaque carries the phage insert, the plasmid, and the insert. Because this is too large to be amplified efficiently by PCR, the technique preferentially yields the desired genic insert from the phage without the unwanted plasmid and its insert.*

13. If desired, sequence the isolated genic clone (*UNITS 7.1-7.5*) and compare it to a database of known expressed sequences (*UNIT 7.7*) to obtain information about its possible significance, if available.

Repeatedly performing this protocol with different cDNA libraries allows determination of the timing of development and the tissue(s) in which the gene of interest is expressed. The latter can also be determined by using PCR primers specified by the sequence to see if amplification of different cDNA libraries occurs; given the sensitivity of this method, only cDNA library eluates, rather than DNA preparations, need be screened.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Lambda plates

10 g tryptone
5 g NaCl
13 g agar
3 ml 1 M MgCl₂
H₂O to 1 liter

Sterilize by autoclaving. Allow to cool until comfortable to touch. Add antibiotics as needed, mix gently to avoid bubbles, and pour plates. Store up to several months at 4°C.

Lambda top agar

10 g tryptone
5 g NaCl
8 g agar
3 ml 1 M MgCl₂
H₂O to 1 liter

Sterilize by autoclaving. Maintain ≤1 month molten at 60°C.

L broth

10 g tryptone
5 g NaCl
5 g yeast extract
5 g MgSO₄·7H₂O
1 g glucose
160 ml 12.5 M NaOH (to pH 7.2)
H₂O to 1 liter

Sterilize by autoclaving. Allow to cool until comfortable to touch. Add antibiotics as needed and mix. Store up to several months at 4°C.

Suspension medium (SM)

5.8 g NaCl
2 g MgSO₄·7H₂O
50 ml 1 M Tris·Cl, pH 7.5 (APPENDIX 2)
5 ml 2% (w/v) gelatin
H₂O to 1 liter

Sterilize by autoclaving. Store up to several months at 4°C.

Gelatin is prepared by adding 2 g gelatin to 100 ml H₂O, then autoclaving to dissolve when needed.

Xgal, 2% (v/v) in DMF

Dissolve 2% Xgal (5-bromo-4-chloro-3-indolyl-β-D-galactoside; see Table 1.4.2) in dimethylformamide (DMF). Place in polypropylene tube (not polystyrene, which will be dissolved by DMF), wrapped in aluminum foil. Store indefinitely at -20°C (solution will not freeze).

COMMENTARY

Background Information

The recombination-based assay (RBA) permits screening of a complex library or group of libraries with a given probe using only two petri dishes. As a result, the RBA is unparalleled in its efficiency and speed. The crux of the RBA is the insertion of a DNA fragment into a plasmid containing *supF*, followed by screening of a complex λ library (10⁶ to 10⁷ recombinants) for homology to the fragment. If such homology exists, a recombination event ensues between the inserts in the plasmid and homologous phage at a frequency of 10⁻² to 10⁻³ (see Fig. 6.12.1). As a result of this homology-mediated recombination event, the plasmid with *supF* is integrated into λ. Genetic selection for λ phage carrying the plasmid with *supF* results in the isolation of λ phage carrying an insert homologous to the insert in the plasmid. Given the high frequency of homologous recombination (10⁻² to 10⁻³), and the fact that 5 × 10⁸ to 10⁹ pfu can be plated onto a single petri dish, it is feasible to screen rapidly a λ library with a complexity of 10⁶ to 10⁷.

Bacterial host characteristics

This assay employs a bacterial strain, DM21 (see Figs. 6.12.1 and 6.12.3), that has been constructed to require the presence of *supF* in λ for phage propagation. As a result, sequences from a λ library that are homologous to a sequence cloned into the *supF*-bearing plasmid can be isolated on this strain. By screening a λ library carrying human genomic DNA sequences (Lawn et al., 1978), the copy number of a given sequence can be determined analytically. Plasmids carrying repetitive sequences rescue more phage clones from a human

genomic library than do plasmids carrying non-repetitive sequences (Neve and Kurmit, 1983). By screening a λ library corresponding to the genes encoded by a given tissue with single-copy sequences, the tissue and time in which a single-copy sequence is transcribed can be determined analytically. Selection for the desired *supF*-bearing phage is done using the *dnaB*/P1 *ban* balanced lethal system. In constructing the host, the *dnaB* unwinding protein that is normally essential for λ phage growth was replaced by the related, but not identical, P1 *ban* gene for *E. coli* growth. The resulting streptomycin-resistant *dnaBam* P1 *ban lacZam* host, DK21 (Kurmit and Seed, 1990), was then protected against a contaminating large (?T1) phage infection by a *tonA* mutation to yield the strain DM21 that is used in the protocol (the question mark notes characteristics that are likely but not definite). Analogously, strains LE392, LG75, and MC1061 have each been altered to carry a *tonA* mutation and resistance to streptomycin for use in the protocol, and have been renamed DM392, DM75, and DM1061, respectively (Table 6.12.1). DM21 selects for the plasmid-borne *supF* by requiring the suppression of an amber mutation in the *dnaB* gene to permit λ propagation. Furthermore, *supF* also suppresses the amber mutation in the *lacZ* gene of DM21, yielding a blue plaque upon addition of the chromogenic substrate Xgal in the presence of IPTG. This makes it possible to discard rare (<10⁻⁹) mutant λ phages (probably P-gene mutants) that lack *supF* but can be successfully plated on the *dnaBam* P1 *ban* host DM21, because these contaminating phages will yield colorless plaques.

^aA question mark denotes characteristics that are likely, but not definite.

Counterselection

Regeneration of the phage as it existed before the recombination-based retrieval event requires deletion of the *supF*-bearing plasmid and its insert by reversal of the original homologous recombination event. Reversal of the selection event by PCR counterselection (Saiki et al., 1985; *UNIT 15.1*) allows preparative isolation of the transcribed sequence free of the sequence originally used to screen for it (Fig. 6.12.4). Fortunately, the frequency of this excision event is high in the presence of the *λ red* or *rap* genes: on the order of 10⁻² to 10⁻³ per generation where perfect homology exists between the genomic insert in the plasmid and the cDNA insert in the phage. Following selection on DM21 and amplification on DM75, counterselection is employed to delete the screening DNA sequence, leaving only the DNA sequence obtained by selection. This counterselection is achieved by PCR using primers that about the *EcoRI* cloning site in phage vectors (a specific set of primers is used for each phage vector; see Fig. 6.12.4). Each blue plaque contains both the selected sequence and a small proportion (~0.1%) of the counterselected sequence, which exists in equilibrium with the selected sequence (see Figs. 6.12.1 and 6.12.4). The selected sequence, which contains the R6K-derived *supF*-bearing pAD1 plasmid and its sequence as well as the (at least partially) homologous sequence in *λ*, is too large to be amplified efficiently by PCR, whereas the

shorter counterselected cDNA sequence can be amplified. Thus, PCR counterselection yields the desired cDNA sequence free of pAD1 and of the genomic sequence originally used to retrieve the cDNA sequence.

Another useful aspect of counterselection (Hanzlik et al., 1993) is that it distinguishes legitimate from illegitimate recombinants (Kurnit and Seed, 1990): legitimate recombinants will reverse the recombination reaction at a high frequency (10⁻²), whereas illegitimate recombinants will reverse the recombination reaction at a much lower frequency (10⁻⁹; Ikeda et al., 1982; Marvo et al., 1983). On an analytical basis, a rough indication of which category a recombinant belongs to is provided by the number of plaques arising during selection: the existence of multiple plaques (indicating multiple events) rules out rare nonhomologous events as the cause of recombination. This differential in reversal frequency allows recombination mediated by full homology to be distinguished from that mediated by partial or no homology, as the latter reverses at a much lower frequency due to mismatching or absence of matching (Watt et al., 1985; King and Richardson, 1986; Shen and Huang, 1986; 1989). When counterselection is performed, this large difference results in the isolation of PCR product in the case of recombination mediated by legitimate homology versus no product in the case of poorly-matched or illegitimate recombination. Thus, in addition to yield-

ing a desired clone, reversal of the recombination reaction (counterselection) allows one to distinguish legitimate from the rarer and undesired illegitimate recombinants.

Avoiding plasmid–phage library homology

For recombination-based screening, there can be no homology between the screening plasmid and the library to be screened lest this homology yield false positives. As a result, the plasmid used must have no homology to sequences present in a recombinant library to be screened. To permit recombination-based screening of common cDNA libraries that contain ColE1 sequences, *supF* has been inserted into a R6K plasmid origin of replication that is not homologous to ColE1. The ColE1 origin is present in a number of common plasmid vectors, including pBR– and pUC–derivatives and the author's π *supF* vectors (Bolivar et al., 1977; Seed, 1983; Yanisch-Perron et al., 1985; Lutz et al., 1987; Kurnit and Seed, 1990; Stewart et al., 1991). The R6K replicon chosen in this case lacks homology with ColE1 and therefore with λ libraries carrying ColE1 sequences (Poustka et al., 1984; Stewart et al., 1991).

ColE1 sequences are present in a variety of desirable cDNA libraries that have been constructed to date. By necessity, λ gt11 is propagated on a strain that contains *lac* sequences on the ColE1 replicon plasmid pMC9 to ensure repression of sequences downstream from the *lac* promoter in the λ phage. pMC9 thereby shares *lac* homology with λ gt11, fostering recombination between the two mediated by that shared homology. As a result, phage incorporate pMC9 at a low, but for these purposes appreciable, frequency of $\sim 10^{-4}$. Once internalized, the pMC9 integrated in the phage can recombine with ColE1-derived *supF*-bearing plasmids because they share homology at the ColE1 *ori*. This shared homology prevents the use of ColE1-derived plasmids for background-free recombination-based screening of λ gt11 libraries. Although theoretically λ gt10 libraries do not suffer this problem, many λ gt10 libraries do contain ColE1-derived sequences (Jankowski et al., 1990), indicating that these libraries have been passaged in strains intended for λ gt11 or that accidental contamination with ColE1 sequences has occurred. The vector pYAC4 contains pBR322 (ColE1) sequences, which can be used to clone end fragments. This prevents background-free screening by recombination with a probe cloned in a ColE1 origin vector of λ libraries made from pYAC4 recombinants. Furthermore, the ColE1 replicon in

phasmid vectors (i.e., recombinants arising from phage and plasmids) such as λ ZAP (Short et al., 1988) and CharonBS prevents recombination-based screening of libraries constructed in these vectors with inserts cloned in ColE1-based *supF*-bearing plasmids due to the shared ColE1 homology. To avoid these difficulties, we constructed a plasmid, pAD1 (Stewart et al., 1991; Fig. 6.12.2), based on the R6K replicon that is not homologous with ColE1 plasmids (Poustka et al., 1984). The sequences cloned in this plasmid may be used to screen all of the above λ libraries regardless of the presence of ColE1 sequences.

Other plasmid characteristics

Construction of the 4-kb plasmid pAD1 (Stewart et al., 1991) entailed cloning the R6K γ *ori*, *supF*, a kanamycin-resistance gene, and a polylinker containing sites for *Bam*HI, *Eco*RI, *Mlu*I, *Not*I, *Pst*I, *Pvu*II, *Sal*I, and *Sfi*I (Fig. 6.12.2). To confirm that the final vector, pAD1, indeed lacks homology to ColE1 sequences, it has been demonstrated by recombination (Seed, 1983; Kurnit and Seed, 1990) that this plasmid does not recombine with ColE1 DNA sequences. This lack of homology is consistent with the known sequence of R6K and with the finding that R6K-based cosmids do not recombine with ColE1-based plasmids (Poustka et al., 1984).

Recombination genes in host strain and phage

For recombination to function at a useful level of 10^{-2} to 10^{-3} if there is perfect homology, there must be genes promoting recombination in both the bacterial host and the bacteriophage. Thus, the bacterial host must be *recA*⁺ and the bacteriophage must be either *red*⁺ or *rap*⁺. In the case where the bacteriophage is neither *red*⁺ nor *rap*⁺, the *rap* gene can be supplied in *trans* from the pACYC-derived plasmid, pOM-PRAP2, constructed by Kurnit and Seed (1990). Most λ vectors are *rap*⁻, because *rap* lies within the *nin5* region deleted in most λ vectors.

Uses of the RBA

The RBA has special utility for two purposes:

1. *Isolating single-copy sequences.* A fragment whose copy number in the genome is to be elucidated is cloned into a plasmid with *supF*. Because cloning sequences into *supF*-bearing plasmids is also required for step (2) below, this procedure satisfies both require-

ments simultaneously. Sequence repetitiveness is assayed by the frequency with which a given insert in a *supF*-bearing plasmid mediates recombination between the plasmid and a recombinant bacteriophage library constructed from large random human genomic fragments (Neve et al., 1983; Neve and Kurnit, 1983). This author uses the library of Lawn et al. (1978) for this purpose, because it was constructed fortuitously (and unbeknownst at the time) in a Charon 4A λ vector that contains the $\phi 80$ *rap* gene (Kurnit and Seed, 1990). Although this older human genomic library is incomplete for single-copy sequences, this does not pose a problem because it is used merely to assay sequence repetitiveness, for which it is adequate. Subsequent human genomic libraries have been constructed in *red⁻ rap⁻* vectors, which cannot be screened without the awkward placement of a *rap* gene in *trans* (Kurnit and Seed, 1990). The amount of recombination correlates with the degree of repetitiveness in the genome, with the understandable and benign caveat that more highly repetitive sequences, which manifest significant mismatching, show some depression of the recombination frequency (Neve and Kurnit, 1983). This depression does not interfere with the ability of the assay to sort out the desired single-copy sequences; it merely results in the finding that *Alu* sequences (Rubin et al., 1980), which are actually reiterated 10^6 times in the genome, behave in the RBA as if they are repeated only 10^3 to 10^4 times (Neve et al., 1983; Neve and Kurnit, 1983). The salient point is that the methodology allows rapid analysis and isolation of sequences of a given copy number in the genome: "single" (1 to 10 copies), low-order-repeated (10 to 100 copies), and more highly repeated (>100 copies; Neve and Kurnit, 1983).

2. *Determining tissue- and time-specific transcriptional activity of single-copy fragments and isolating genes.* Gene libraries containing $>10^6$ independent recombinants are constructed: each corresponds to the totality of genes made in a given tissue at a given time in development. Screening a pool of 10^6 recombinants from a cDNA library requires only two petri dishes. The phage are first plated on a bacterial lawn carrying the sequence to be tested cloned in a *supF*-bearing plasmid. Following confluent lysis, 5×10^8 to 5×10^9 pfu are eluted and plated on DM21 to select for phage that have integrated *supF*. If no phage plaques are observed on DM21, this indicates that the sequence is not transcribed in the tissue

at the developmental stage present when the cDNA libraries were made. If plaques are observed on DM21, this indicates that the sequence is transcribed at that stage. The transcribed sequence is isolated free of the genomic sequence initially used to screen for it by reversing the recombination event (Fig. 6.12.4). In all the libraries used to date— λ gt10 (Huynh et al., 1985), λ gt11 (Young and Davis, 1983), and Sumo 15A (Kurachi et al., 1989)—the desired sequence is liberated as an *EcoRI* fragment that can be subcloned. As well as liberating the sequence, the reversal also makes it possible to discard rare nonhomologous (or imperfect) recombination events, which are identified by the fact that they reverse at the same low 10^{-9} frequency that they occur (for nonhomologous events) and at an intermediate frequency (for partially homologous events). In contrast, homologous recombination events, which can occur in a forward direction at a similar 10^{-8} frequency (assuming a worst case where a sequence is present only once per genome equivalent in a phage library of 10^6 recombinants, which is multiplied by a 10^{-2} chance of recombining if there is homology), reverse at a much higher 10^{-2} frequency. Thus, reversal of the recombination reaction will yield the cDNA free of the genomic sequence and will simultaneously allow rarer nonhomologous or partially homologous exchange events to be identified and discarded.

The RBA can be employed to determine the tissue and time of transcription of candidate genes discovered by other technologies as well as to obtain the gene of interest (in the form of the larger gene sequence that is transcribed). The technique is useful either alone or in combination with other methods for defining single-copy transcribed sequences. If DNA sequencing (as part of the genome initiative) or techniques to define transcribed sequences are used to identify genes, the RBA is still useful for determining the tissue and developmental timing of transcription, as well as for isolating a larger gene of interest. Technologies for defining transcribed sequences include exon trapping/amplification (Nisson and Watkins, 1994; Duyk et al., 1990; Buckler et al., 1991), use of somatic cell hybrids (Liu et al., 1989), and the use of hybridization-based schemes (Hochgeschwender and Brennan, 1994; Hochgeschwender et al., 1989; Kao and Yu, 1991), including hybrid selection (Lovett, 1994; Lovett et al., 1991; Parimoo et al., 1991). The RBA will proceed cooperatively, rather than competitively, with these other methods be-

cause it efficiently accomplishes two necessary tasks: identifying the timing and tissue of gene transcription and isolating a large transcribed sequence.

Critical Parameters

Plaque size is a major issue in this assay because plaques on the *dnaB am* strain DM21 are so small. Fresh λ plates should be used to maximize plaque size, because plaques will be smaller on older (drier) plates; likewise, it is important to plate cells on lambda plates, because plaques will be smaller on richer (e.g., LB) plates.

It is essential that there be no homology between the screening plasmid and sequences in the λ libraries (see Background Information). Therefore, screening should be performed solely with R6K *supF* plasmids, not with ColE1 *supF* plasmids.

Although titering all eluates would be too time-consuming, a few eluates should be titered to ensure that lysis and elution are occurring as expected. This is especially important because a lysed plate may vary from clear to grainy, rendering it difficult to determine visually whether complete lysis has occurred. Eluates should be saved until the DM21 plates have been scored as a precaution in case too many phage have been added, resulting in lysis from without. If this happens, the eluate may be titered or a lesser amount plated on DM21.

Anticipated Results

The abundance of sequences in screened λ libraries should be reflected in the number of phage that plate on DM21. Assuming a recombination rate of 1/500 (the exact number that will depend on the extent of homology), a sequence abundance of 1/10⁶ should yield one plaque on DM21 per 5 × 10⁸ phage plated. A higher abundance should yield a correspondingly greater number of plaques on DM21. If mismatching occurs in an interspersed "salt-and-pepper" manner (as for *Alu* sequences), recombination will be depressed (e.g., ~1000-fold for *Alu* sequences; Neve et al., 1983).

Time Considerations

The major advantage of the RBA is its rapidity: selection can be completed in four days using the following schedule. Day 1, grow bacterial cultures; day 2, add λ library and perform lysis; day 3, elute and plate on DM21; and day 4, identify plaques on DM21.

Counterselection takes an additional four days. One day is necessary for elution of

plaques from DM21 that are plated on DM75 with IPTG and Xgal in top agar. A second day is required for elution of putative light blue plaques and confirmatory macroplaque plating on DM75 and DM1061 with IPTG and Xgal. PCR counterselection of macroplaques that are blue on DM75 and colorless on DM1061 takes one day and a final day is necessary to isolate the counterselected PCR band from the gel.

CHAPTER 7

DNA Sequencing

INTRODUCTION

For many recombinant DNA experiments, knowledge of a DNA sequence is a prerequisite for its further manipulation. DNA sequencing followed by computer-assisted searching for restriction endonuclease cleavage sites is often the fastest method of obtaining a detailed restriction map (*UNITS 3.1-3.3*). This information is particularly useful when vectors designed to overexpress proteins or to generate protein fusions are used to subclone a gene of interest (Chapter 16). Computer-assisted identification of protein-coding regions (open reading frames, or ORF) within the DNA sequence, followed by computer-assisted similarity searches of DNA and protein data bases, can lead to important insights about the function and structure of a cloned gene and its product (*UNIT 7.7*). In addition, the DNA sequence is a prerequisite for a detailed analysis of the 5' and 3' noncoding regulatory regions of a gene. DNA sequence information is essential for site-directed mutagenesis (*UNIT 8.1*). Small amounts of DNA sequence information (sequence tagged sites, or STS; or expressed sequence tags, or ESTs) are the basis of methods for mapping and ordering large DNA segments cloned into yeast or bacterial artificial chromosomes (CYACs; BACs) or cosmids (Olson et al., 1989; Stephens et al., 1990; Green and Olson, 1990; Adams et al., 1991; Shizuya et al., 1992). EST databases are extremely valuable in gene discovery.

DNA sequencing techniques are primarily based on electrophoretic procedures using high-resolution denaturing polyacrylamide gels. These so-called sequencing gels are capable of resolving single-stranded oligonucleotides up to 800 bases in length that differ in size by a single deoxynucleotide. In practice, for a given region to be sequenced, a set of labeled, single-stranded oligonucleotides is generated whose members have one fixed end, and which differ at the other end by each successive deoxynucleotide in the sequence. The key to determining the sequence of deoxynucleotides is to generate, in four separate enzymatic or chemical reactions, all oligonucleotides that terminate at the variable end in

A, T, G, or C. The oligonucleotide products of the four reactions are then resolved on adjacent lanes of a sequencing gel. Because all possible oligodeoxynucleotides are represented among the four lanes, the DNA sequence can be read directly from the four "ladders" of oligonucleotides as shown in Figure 7.0.1. In automated four-color fluorescent DNA sequencers, the oligonucleotide products terminated from each of the four bases (A, C, G, T) are run in a single lane and resolved on the basis that the DNA fragments ending with each of the four bases are labeled with four different fluorescent tags.

The practical limit on the amount of information that can be obtained from a set of sequencing reactions is the resolution of the sequencing gel (see *UNIT 7.6* for protocols on setting up and running sequencing gels). Current technology allows ~500 nucleotides of sequence information to be reliably obtained in one set of sequencing reactions, although more information (up to 800 nucleotides) is often obtained using an automated sequencer. Thus, if the region of DNA to be sequenced is <500 nucleotides, a single cloning into the appropriate vector is all that is usually necessary to produce a recombinant molecule that can easily be sequenced in a single set of reactions.

For a larger region of DNA, it is generally necessary to break a large fragment into smaller ones that are then individually sequenced. This can be done in a random or an ordered fashion. *UNIT 7.1* contains a discussion of strategies for sequencing large regions of DNA. Two protocols for subdividing large regions of DNA are provided in *UNIT 7.2*. These protocols are used to create a set of ordered, or nested, deletions for DNA sequencing using exonuclease III or *Bal* 31 nuclease.

The two methods that are widely used to determine DNA sequences, the enzymatic dideoxy method and the chemical method, differ primarily in the technique used to generate the ladder of oligonucleotides. In the enzymatic dideoxy sequencing method, a DNA polymerase is utilized to synthesize a labeled, complementary copy of a DNA template. In the

chemical sequencing method, a labeled DNA strand is subjected to a set of base-specific chemical reagents. These two techniques are further described below.

DIDEOXY (SANGER) SEQUENCING

Sequencing Method

The dideoxy or enzymatic method, originally developed by F. Sanger and co-workers (1977, 1980), utilizes a DNA polymerase to synthesize a complementary copy of a single-stranded DNA template. DNA polymerases cannot initiate DNA chains; rather, chain elongation occurs at the 3' end of a primer DNA that is annealed to "template" DNA (Fig. 7.0.2). The deoxynucleotide added to the growing primer chain is selected by base-pair matching to the template DNA. Chain growth involves the formation of a phosphodiester bridge between the 3' hydroxyl group at the growing end of the primer and the 5' phosphate group of the incoming deoxynucleotide (see Fig. A.1.7 for line

drawings of the nucleotides). Thus, overall chain growth is in the 5'→3' direction.

Dideoxy sequencing capitalizes on the ability of the DNA polymerase to use 2',3'-dideoxynucleoside triphosphates (ddNTPs) as substrates. When a ddNMP is incorporated at the 3' end of the growing primer chain, chain elongation is terminated at G, A, T, or C because the primer chain now lacks a 3' hydroxyl group. To generate the four sequencing ladders shown in Figure 7.0.1, only one of the four possible ddNTPs is included in each of the four reactions (see below). The ddNTP/dNTP ratio in each reaction is adjusted such that a portion of the elongating primer chains terminates at each occurrence of the base in the template DNA corresponding to the included complementary ddNTP. In this way, each of the four elongation reactions contains a population of extended primer chains, all of which have a fixed 5' end determined by the annealed primer and a variable 3' end terminating at a specific dideoxynucleotide.

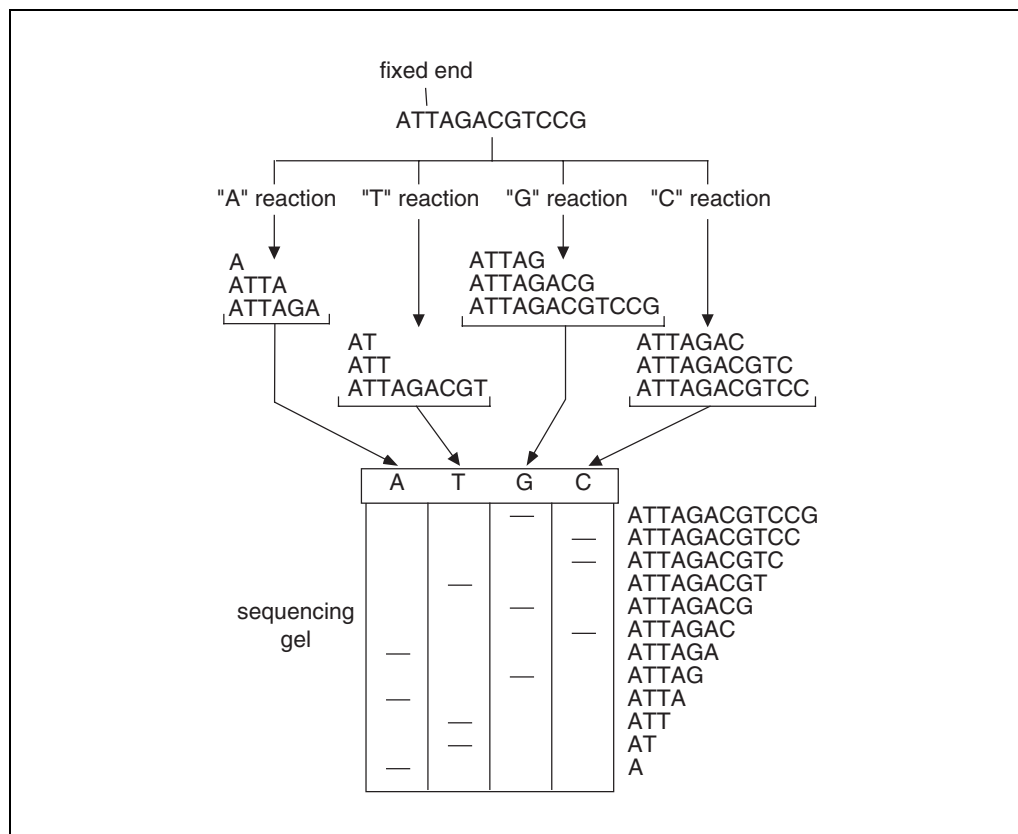

Figure 7.0.1 General strategy for DNA sequencing. To sequence a fragment of DNA, a set of radiolabeled single-stranded oligonucleotides is generated in four separate reactions. In each of the four reactions, the oligonucleotides have one fixed end and one end that terminates sequentially at each A, T, G, or C, respectively. The products of each reaction are fractionated by electrophoresis on adjacent lanes of a high-resolution polyacrylamide gel. After autoradiography, the DNA sequence can be "read" directly from the gel.

Two protocols for dideoxy sequencing using radiolabeled ddNTPs are provided in *UNIT 7.4A*. The original dideoxy method, which in this chapter is referred to as the Sanger procedure (Sanger et al., 1977, 1980), was developed for use with the large fragment of *E. coli* DNA polymerase I known as the Klenow fragment. A synthetic oligonucleotide primer is annealed to the 3' end of the region to be sequenced on a single-stranded DNA template (Fig. 7.0.2). The annealed template + primer is then divided into four reaction mixtures, each of which contains DNA polymerase, all four deoxynucleoside triphosphates (dNTPs)—one of which is radiolabeled—and one of the four ddNTPs (Fig. 7.0.2, right side). Under these conditions, the primer is extended and labeled until incorporation of a specific dideoxynucleotide causes termination. In a subsequent chase reaction, high concentrations of all four dNTPs are added so that all chains not terminated by a dideoxynucleotide will be elongated into high-molecular-weight DNA that remains unresolved at the top of the sequencing gel.

In the “labeling/termination” method, developed for use with modified T7 DNA polymerase (Sequenase; *UNIT 3.5*; Tabor et al., 1987; Tabor and Richardson, 1987a, 1987b, 1989a, 1989b, 1990), labeling of the primer and termination by incorporation of a dideoxynucleotide occur in two separate reactions (Fig. 7.0.2, left side). After annealing of the primer to the template, the labeling reaction occurs when the primer is elongated and labeled in the presence of a low concentration of all four dNTPs, one of which is radiolabeled. DNA synthesis continues until one or more of the nucleotide pools is exhausted, leading to almost complete incorporation of the labeled nucleotide. The termination step takes place in four separate reactions, each of which contains additional dNTPs and one of the four ddNTPs. In the termination step, a high concentration of dNTPs ensures processive DNA synthesis until the growing chains are terminated by the incorporation of a ddNMP.

In the Sanger procedure, the average length of the sequencing products is controlled by the ddNTP/dNTP ratio, where a higher ratio leads to shorter products. In the labeling/termination protocol, the average length of the sequencing products can be modulated either by the concentration of dNTPs in the labeling reaction (a higher concentration leads to longer products) or by the ddNTP/dNTP ratio in the termination reaction.

If Sequenase is used, the labeling/termination method is capable of yielding longer sequencing products, on average, than those obtained using the original Sanger protocol. Therefore, the labeling/termination method is advantageous for obtaining the maximum amount of sequence information per template. For applications where large amounts of sequence information are not needed (such as verifying constructions or sequencing small regions of DNA), the Sanger procedure is usually adequate. The Sanger procedure may be more reliable for obtaining the first few nucleotides of sequence information after the primer.

A variety of DNA polymerases are commercially available for sequencing. A description of these polymerases and their appropriate uses can be found in *UNIT 7.4A*. Thermostable DNA polymerases are the newest class of enzymes available for DNA sequencing. They are useful because they can carry out a sequencing reaction at high temperatures, allowing thermal cycling to increase the yield of sequencing fragments, and therefore enhanced detection sensitivity. This property provides a way of destabilizing secondary structures of the DNA template, which can interfere with the elongation reaction.

Vectors and Templates for Dideoxy Sequencing

Dideoxy sequencing requires a single-stranded template to which the primer can anneal. Single-stranded templates can be easily generated using specialized vectors derived from M13, an *E. coli* filamentous phage that contains a single-stranded circular DNA molecule (*UNITS 1.14 & 1.15*; Messing, 1983, 1988). Dideoxy sequencing can also be readily carried out using double-stranded DNA with a cycle sequencing procedure involving denaturation of the double-stranded DNA in each cycle (Chen and Seeburg, 1985; Haltiner et al., 1985; Zagursky et al., 1985; Hattori and Sakaki, 1986). Dideoxy sequencing of a double-stranded template is particularly useful when DNA sequencing is the only rapid method available for verifying a particular plasmid construction. For large-scale sequencing projects, the use of a single-stranded DNA vector system, such as the M13mp series, is recommended, because the preparation of high-quality generation of sequencing-quality, single-stranded DNA templates is somewhat more reliable than for plasmid DNA templates. However, plasmids offer the advantage of being able to obtain sequence from both the 5' and 3' ends.

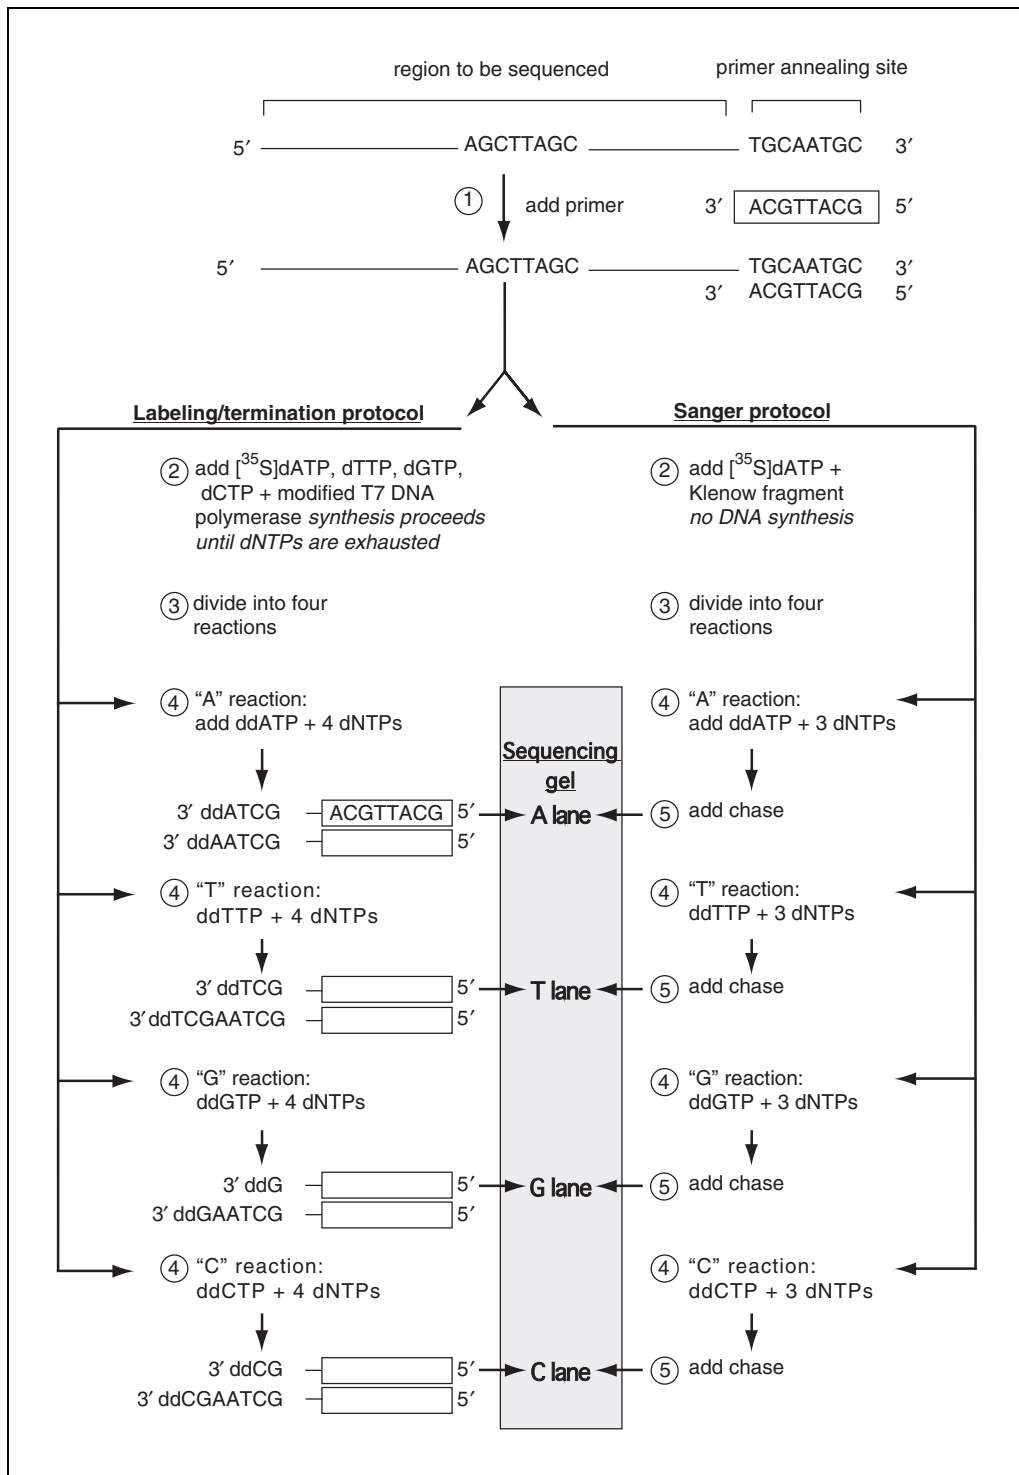

Figure 7.0.2 Dideoxy sequencing methods. In each method, a single-stranded DNA fragment is annealed to an oligonucleotide primer for polymerization (**step 1**). In the Sanger protocol (right side), the Klenow fragment and radiolabeled dATP are added (**step 2**). The reaction is divided into four aliquots (**step 3**) and the other three dNTPs and either ddATP, ddTTP, ddGTP, or ddCTP are added (**step 4**). DNA synthesis occurs until terminated by the incorporation of a ddNTP. A “chase” of all four dNTPs (**step 5**) elongates chains not terminated by a ddNMP into higher-molecular-weight DNA. In the labeling/termination protocol (left side), after the first step, a limiting amount of the four dNTPs—one of which is radiolabeled—and Sequenase are added (**step 2**). DNA synthesis proceeds until the dNTPs are exhausted. The reaction mix is divided into four aliquots (**step 3**) and all four dNTPs plus either ddATP, ddTTP, ddGTP, or ddCTP are added (**step 4**). Synthesis resumes, but termination specifically occurs when a ddNMP is incorporated. In each method, after the reactions are terminated, samples are loaded on adjacent lanes of a sequencing gel.

This feature is very valuable for genomic sequencing using randomly generated DNA fragments (the “shotgun” approach). A more detailed discussion of vectors used for dideoxy sequencing is provided in *UNIT 7.1*, and protocols for preparation of DNA templates derived from M13, plasmid, and bacteriophage λ vectors are provided in *UNIT 7.3*. The products of the polymerase chain reaction (PCR) can also be sequenced by the dideoxy method, and several protocols for generating these templates are provided in *UNITS 15.2 & 15.5*.

Radiolabels for Dideoxy Sequencing Reactions

$[\alpha\text{-}^{35}\text{S}]\text{dATP}$. The dideoxy sequencing protocols in *UNIT 7.4A* involve radiolabeling nascent DNA chains with $[\alpha\text{-}^{35}\text{S}]\text{dATP}$ rather than with $[\alpha\text{-}^{32}\text{P}]\text{dATP}$, for the following reasons. First, the low-energy β emissions of ^{35}S result in sharper autoradiographic bands compared to those generated by ^{32}P , allowing more sequence to be read from the upper portion of a gel. Second, the lower-energy emissions of ^{35}S cause fewer breaks in the sugar-phosphate backbone of the DNA. In practice, this means that ^{35}S -labeled reaction products can be stored at -20°C for several weeks without significant degradation; by contrast, ^{32}P products should be electrophoresed within a day. Third, users receive a lower radiation dose with ^{35}S than with ^{32}P .

$[\alpha\text{-}^{32}\text{P}]\text{dATP}$. In contrast to ^{35}S however, ^{32}P offers the advantage of short exposure times and is particularly useful in situations, such as verification of plasmid constructions, where maximizing resolution in the higher region of the sequencing gel is not a priority.

$[\alpha\text{-}^{33}\text{P}]\text{dATP}$. ^{33}P has a maximum β -emission energy that is 50% stronger than ^{35}S , but 5-fold weaker than ^{32}P . Sequences generated using $[\alpha\text{-}^{33}\text{P}]\text{dATP}$ have short exposure times like ^{32}P but band resolution comparable to that of ^{35}S (Zagursky et al., 1991).

5' end labeling. An alternative to labeling the nascent oligonucleotide with $[\alpha\text{-}^{35}\text{S}]\text{dATP}$ is to use a 5'-end-labeled primer generated by T4 polynucleotide kinase and $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ or $[\gamma\text{-}^{35}\text{S}]\text{ATP}$ (*UNIT 3.10*). Sequencing of large double-stranded DNA templates (such as $\lambda\text{gt}11$) with 5'-end-labeled primers has been found to give better results than standard labeling techniques. Protocols for sequencing using end-labeled primers are provided in *UNIT 7.4A*.

CHEMICAL (MAXAM-GILBERT) SEQUENCING

Sequencing Method

In the chemical method of DNA sequencing developed by A. Maxam and W. Gilbert (Maxam and Gilbert, 1977, 1980; Rubin and Schmid, 1980; Ambrose and Pless, 1987), the four sets of deoxyoligonucleotides are generated by subjecting a purified 3'- or 5'-end-labeled deoxyoligonucleotide to a base-specific chemical reagent that randomly cleaves DNA at one or two specific nucleotides. Because only end-labeled fragments are observed following autoradiography of the sequencing gel, four DNA ladders are observed as shown in Figure 7.0.3.

The Maxam and Gilbert chemical sequencing method is based on the ability of hydrazine, dimethyl sulfate (DMS), or formic acid to specifically modify bases within the DNA molecule. Piperidine is then added to catalyze strand breakage at these modified nucleotides. The specificity resides in the first reaction with hydrazine, DMS, or formic acid, which react with only a few percent of the bases. The second reaction, piperidine strand cleavage, must be quantitative. The chemical mechanisms of the first reactions are as follows:

G: DMS methylates nitrogen 7 of G, which then opens between carbon 8 and nitrogen 9. Piperidine then displaces the modified guanine from its sugar.

G+A: Formic acid weakens A and G glycosidic bonds by protonating purine-ring nitrogens. The purines can then be displaced by piperidine.

T+C: Hydrazine splits the rings of T and C. The fragments of these bases can then be displaced by piperidine.

C: In the presence of NaCl, only C reacts with hydrazine. The modified C can then be displaced with piperidine.

In all four reactions, piperidine also catalyzes phosphodiester bond cleavage at the position where the modified base has been displaced by piperidine.

Vectors for Chemical Sequencing

Chemical sequencing reactions can be performed on either single- or double-stranded DNA, as long as only one end is labeled. Specialized vectors have been developed (Eckert, 1987; Volckaert et al., 1984; Arnold and Puhler, 1988) that allow unique labeling of only one

strand of the cloned target DNA using *Tth*1111 or other restriction enzymes that have asymmetric recognition sites adjacent to the cloned DNA. These vectors are described more fully in *UNIT 7.1* and a protocol for their use is provided in *UNIT 7.5*.

CHOOSING BETWEEN DIDEOXY AND CHEMICAL SEQUENCING METHODS

As described above, the dideoxy chain-termination method is based on the ability of DNA polymerase to synthesize DNA 5'→3' from a defined primer annealed to the vector DNA at a site adjacent to the DNA being sequenced. Each reaction contains one of the four ddNTPs, which terminates synthesis selectively at G, A, T, or C.

Dideoxy sequencing is rapid. The primer-annealing and sequencing reactions can be completed within 60 to 90 min. A large number of single- or double-stranded samples can be

prepared for sequencing simultaneously. The method also offers excellent band resolution if ³⁵S-labeled nucleoside triphosphates are used to label the DNA.

The major disadvantage of dideoxy sequencing is that composition or secondary structure of the template can sometimes cause premature termination by DNA polymerase. Klenow fragment is more prone to this problem than are T7 DNA polymerase or the other alternative polymerases discussed in *UNIT 7.4A*. Despite these alternative polymerases, DNA is sometimes encountered that cannot be accurately sequenced by the dideoxy method.

The second method, chemical cleavage, is based on the ability of various chemicals to cleave DNA with a high specificity. The major advantage of the chemical method is that problems associated with polymerase synthesis of DNA (i.e., premature termination due to DNA sequence or structure) are eliminated, permitting sequencing of stretches of DNA that cannot

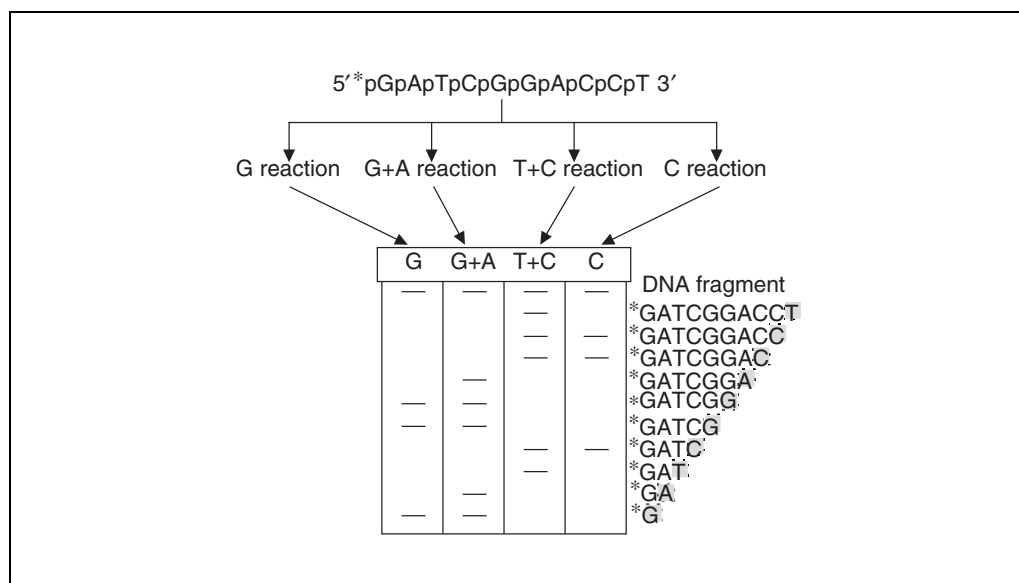

Figure 7.0.3 Chemical sequencing strategy. The ladder of oligonucleotides after gel electrophoresis of the products from the four chemical cleavage reactions is shown. The asterisk (*) indicates the position in the DNA fragment of the ³²P label, which is placed on the 5' end in this example. The direction of fragment migration is downward; smaller DNA oligonucleotides migrate faster in the sequencing gel than larger oligonucleotides. The shaded bases at the 3' end of the fragments to the right of the gel indicates bases that have been chemically modified and then displaced from the oligonucleotide during piperidine-mediated strand scission. For example, after a limited reaction with dimethyl sulfate (DMS), which is specific for G's, followed by quantitative release of the modified G residue by piperidine, a set of oligonucleotides are generated that terminate at the base immediately 5' of each G in the sequence. In this example, the oligonucleotide products are *pGpApTpCpGp and *pGpApTpCp. Each of these products forms a band in the G lane. For *pG, the product is *p, which would most likely run off the gel, making it difficult to determine the identity of the 5'-terminal base. Because formic acid is specific for purines (G's and A's), a fragment that terminates in G or A will produce a band in the G + A lane. Hydrazine in the absence of NaCl cleaves T's and C's resulting in a band in the T + C lane. Hydrazine in the presence of NaCl cleaves only C's; thus, a band is observed in the C lane.

be sequenced by the enzymatic method. In addition, obtaining the sequence of shorter regions of DNA using the chemical method does not require subcloning into an appropriate sequencing vector, such as is required for dideoxy sequencing. Finally, chemical cleavage is the only sequencing method available for small oligonucleotides.

Before the development of specialized cloning vectors, such as pSP64CS and pSP65CS, the major disadvantage of the chemical sequencing method was that preparation of the DNA prior to sequencing was very time-consuming. The fragment to be sequenced had to be end labeled and then the end of interest had to be isolated from all other labeled ends. This required several gel electrophoresis steps and often entailed a significant loss of the ^{32}P -labeled DNA fragment. However, vectors such as pSP64CS or pSP65CS allow direct subcloning of the DNA fragment of interest and end-labeling of a single predetermined terminus adjacent to the sequence, and they eliminate the time-consuming gel purification steps otherwise necessary. These vectors also make it possible to sequence a large number of samples simultaneously, because each recombinant plasmid to be sequenced is processed in a systematic manner (UNIT 7.1).

ALTERNATIVES TO RADIOLABELED SEQUENCING REACTIONS

Chemiluminescence

Chemiluminescence is a newer detection method that is comparable in sensitivity to traditional radiolabeling. Detection of the sequencing products occurs by a chemiluminescent reaction that can be monitored by autoradiography (UNIT 7.4B). A biotinylated primer is used in the dideoxy sequencing reactions. After electrophoresis of the biotinylated sequencing products on a sequencing gel, the products are transferred and cross-linked to a nylon membrane. The sequencing products are detected using streptavidin, biotinylated alkaline phosphatase, and a dioxetane substrate for alkaline phosphatase. The multivalent streptavidin cross-links the biotinylated sequencing product to the biotinylated alkaline phosphatase, immobilizing the phosphatase. Upon dephosphorylation by alkaline phosphatase, the dioxetane substrate emits light that is detected by autoradiography (Beck et al., 1989; Tizard et al., 1990; Creasey et al., 1991; Evans, 1991; Martin et al., 1991). Technology for end labeling DNA

fragments with biotin allows this detection method to also be used in chemical sequencing reactions (Tizard et al., 1990).

Alternatively, the dideoxy sequencing reactions can be carried out with a standard, nonbiotinylated primer without radioactivity. After electrophoresis, transfer, and cross-linking to a membrane, the sequencing products are hybridized with a biotinylated probe complementary to the primer before performing the detection described above. This method can be used with the products of chemical sequencing.

Multiplex Sequencing

Multiplex sequencing uses hybridization to a specific probe to detect an individual sequencing ladder in a mixture of ladders. In this method, sequencing products derived from a mixture of templates are subjected to electrophoresis on a sequencing gel, transferred to a membrane, and hybridized with a probe specific for one template. After hybridization and detection of the sequencing ladder derived from a single template, the probe is removed at a high temperature and the membrane is rehybridized to a different probe, complementary to an independent set of sequencing products that have been subjected to electrophoresis in the same lanes of the sequencing gel. Thus, the amount of sequence information available from one gel is multiplied by the number of times the membrane can be rehybridized (in practice, up to 20 times). Multiplex sequencing originally used radioactive probes and chemical sequencing technology (Church and Gilbert, 1984; Church and Kiefer-Higgins, 1988) but it is equally well adapted to chemiluminescent detection and/or dideoxy reactions.

A set of sequencing vectors is commercially available (Millipore) for multiplex sequencing using the dideoxy method. They have the identical priming region but contain unique sequences between the primer locus and the cloning site for the target DNA. These unique sequences are incorporated into the sequencing reaction products. Thus, sequencing reactions using several templates and the same primer can be performed in one set of reactions and later differentiated by successive hybridizations with probes for each unique sequence.

DEVELOPMENTS IN SEQUENCING TECHNOLOGY

Commercial Kits for Sequencing

Commercially available kits eliminate the need to assemble and calibrate numerous mixes

and can save a significant amount of startup time, although they are somewhat less flexible and can limit the ability to troubleshoot reactions when necessary. Nevertheless, these kits offer an excellent option for the novice at a reasonable cost. Kits are available for constructing nested deletions (see Table 7.2.1 for suppliers) as well as for dideoxy sequencing reactions using radiolabeling or chemiluminescent detection (Table 7.4.1) and for chemical sequencing using radiolabeling (UNIT 7.5).

Automated Sequencers and Automation of Sequencing Reactions

Automated sequencing machines automate the gel electrophoresis step, detection of DNA band pattern, and analysis of bands. Currently, all commercially available automated sequencers are designed for enzymatic sequencing reactions. The four sets of oligonucleotides generated by the sequencing reactions are loaded onto the gel manually and electrophoresis is then controlled automatically. Detection occurs at a point near the bottom edge of the gel in one of two ways. In one method, applicable to either fluorescently or radioactively labeled DNA, the bands of DNA moving sequentially past a detector are recorded. In the second method, the banding pattern of fluorescently labeled DNA is detected using an imaging camera. All automated sequencers possess data-collection capabilities, and either include further analysis programs or provide portability to external data-analysis software programs.

Fluorescent label can be incorporated into the sequencing products either through the primer or the ddNTPs. In the simplest system, a single fluorescently labeled primer is used and the four reaction products are run in separate lanes (Ansorge et al., 1987; Brumbaugh et al., 1988; Kambara et al., 1988; Middendorf et al., 1988; Fujita et al., 1990; Rosenthal et al., 1990; Sears et al., 1992). Other systems use either identical primers labeled with four different fluors (Smith et al., 1985, 1986; Connel et al., 1987; Johnston-Dow et al., 1987; Wilson et al., 1988; Mardis and Roe, 1989), or a different fluorescent tag for each ddNTP (Prober et al., 1987; Zagursky and McCormick, 1990). In these latter systems, because the primers or ddNTPs fluoresce at different wavelengths, all four reaction products are run in a single lane and the fragments terminating at the four different bases (A, C, G, T) are identified by four distinct emission colors of the fluorescent tags upon laser excitation. This quadruples the throughput compared to sequencing with radi-

olabels. Figure 7.0.4 shows a four-color sequencing gel image from the automated ABI 377 DNA sequencer. Among the various fluorescence detection methods, four-color DNA sequencing based on the Sanger dideoxy chain-termination method is now accepted as the technique of choice for large-scale sequencing projects.

Another promising approach is automation of the sequencing reaction by the use of robotics (Martin et al., 1985; Frank et al., 1988; Wilson et al., 1988; Mardis and Roe, 1989; Zimmerman et al., 1989; D’Cunha et al., 1990; Fujita et al., 1990; Smith et al., 1990). As this technology and that of automated sequencers is further developed, more rapid and less tedious sequence-data acquisition for large projects should be possible. For example, a fully automated sequencing system has been reported for genomic-scale sequencing (Hawkins et al., 1997).

Capillary Array DNA Sequencer

The most recent innovation in automated DNA sequencers utilizes capillary electrophoresis (CE; UNIT 2.8) and laser-induced fluorescence detection. CE using gel-filled narrow-bore (10- to 100- μm internal diameter) capillaries provides rapid, high-field, high-resolution separation of DNA fragments without heating artifacts. The use of multiple capillaries coupled with confocal laser-induced fluorescence for DNA sequencing was first reported in 1992 (Huang et al., 1992). Capillary array DNA sequencers (MegaBACE 1000 and ABI 3700) allow automated loading of 96 samples simultaneously as well as automated sample tracking and analysis (Khetarpal and Mathies, 1999). Currently, the separation matrix linear polyacrylamide (LPA) provides the best resolution and longer read-length in CE sequencers. Using LPA on CE sequencers with close to single-base resolution, read-length of 1000 bp with an electrophoresis time of 1 hr has been reported (Salas-Solano et al., 1998). This is an order-of-magnitude increase in speed compared to traditional slab gel sequencing. This new generation of automated DNA sequencer coupled with separation matrix development and improved fluorescent tags has the potential to substantially improve the throughput, speed, and overall process of larger sequencing projects.

Thermal Cycle Sequencing

Thermal cycle sequencing is a method of dideoxy sequencing in which a small number of template DNA molecules are repetitively

utilized to generate a sequencing ladder. A dideoxy sequencing reaction mixture (consisting of template, primer, dNTPs, ddNTPs, and a thermostable DNA polymerase) is subjected to repeated rounds of denaturation, annealing, and synthesis steps, similar to PCR (Chapter 15), using a commercially available thermal cycling machine. In this manner, linear amplification of the sequencing products occurs, allowing much less template DNA to be used than is usually required. In addition, thermal cycle sequencing eliminates the requirements for a separate annealing reaction preceding the sequencing reaction itself and for denaturing double-stranded DNA templates, and is compatible with automation processes. Various protocols have been developed for thermal cycle sequencing reactions (Applied Biosystems, 1989; Carothers et al., 1989; Murray, 1989; Adams and Blakesley, 1991; Craxton, 1991; Krishnan et al., 1991; Young and Blakesley, 1991; Sears et al., 1992); two such protocols are included in *UNIT 7.4A*. In addition, several thermal cycle sequencing kits are now commercially available utilizing each of the detection methods described above (Table 7.4A.1).

Energy Transfer Fluorescent Labeling Technology for Four-Color DNA Sequencing

Ideally, the fluorophores used for four-color DNA sequencing should have a similar high

molar absorbance at a common excitation wavelength as well as high fluorescence quantum yields, exhibit strong and well-separated fluorescence emissions, and introduce the same relative mobility shift. These criteria cannot be met optimally by the spectroscopic properties of single fluorescent dye molecules, and indeed were poorly satisfied by the fluorescent tags initially used for automated DNA sequencing. By exploiting resonance energy transfer (ET), the constraints imposed by the use of single dyes were overcome and fluorescent tags for DNA sequencing that met the performance criteria set out above were developed (Ju et al., 1995). Figure 7.0.5 shows how the energy transfer principle is utilized to construct ET primers that exhibit much enhanced fluorescence compared to single-dye fluorescent tags. The ET primer is labeled with two fluorophores that are separated by a spacer and coupled by resonance fluorescence energy transfer. The excitation energy that is captured by the fluorophore that absorbs at the shorter wavelength (the “donor”) is transferred to the longer wavelength-absorbing chromophore (the “acceptor”) located some distance away. This transfer results in a loss of donor fluorescence and the appearance of enhanced acceptor fluorescence emission even though the acceptor has only weak absorbance at the excitation wavelength. For resonance energy transfer to take place, the emission spectrum of the donor must

Figure 7.0.4 Gel image of 48 sequencing samples from the four-color ABI 377 automated DNA Sequencer. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to <http://www.currentprotocols.com/colorfigures>*

overlap the absorption spectrum of the acceptor. The efficiency of energy transfer is proportional to the inverse sixth power of the distance separating the donor and acceptor. Thus, the transfer efficiency and consequently the ratio of acceptor to donor emission can be controlled through changes in the spacing between the donor and acceptor. The ET dye-labeled primers and terminators can be efficiently excited at a common wavelength and exhibit strong and distinct fluorescent emissions (Ju et al., 1996; Lee et al., 1997). They are markedly superior to single dye-labeled primers and terminators for DNA sequencing and PCR fragment analysis. The ability to sequence directly from large-insert clones (>30 kb), such as BAC clones, is very important for closing the gaps in large genomic sequencing and mapping projects. Such large templates are very difficult to

sequence due to the smaller number of available priming sites (fewer molecules) compared with plasmid templates of the same mass. The higher sensitivity provided by primers/terminators tagged with ET dyes make it possible to sequence these large-template DNAs directly, which is a significant advantage for large-scale sequencing and mapping projects (Marra et al., 1996; Heiner et al., 1998). The sequencing protocol for large DNA templates are provided in *UNIT 7.4*

Solid-Phase Sequencing

Another recent innovation that is applicable to both manual and automated DNA sequencing is the use of solid-phase capture strategy to generate single-stranded DNA templates (Hultman et al., 1989, 1991; Jones et al., 1991; Kaneoka et al., 1991; Zimmerman et al., 1992).

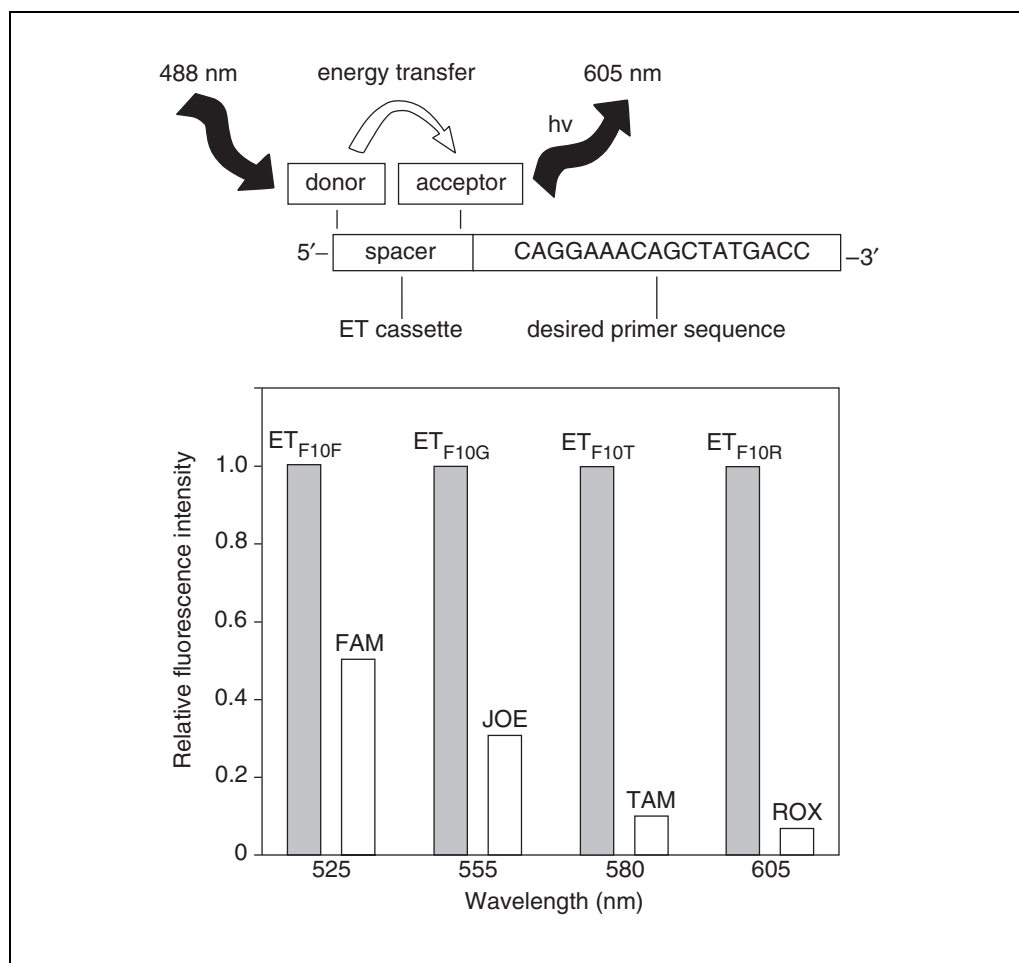

Figure 7.0.5 In ET primers, a common donor with a high absorbance at the excitation wavelength harvests energy and transmits it efficiently to acceptor fluorophores that emit in distinct wavelength regions. To avoid fluorescence quenching, the donor and acceptor are separated by a spacer that can be an oligonucleotide or other chemical functionality. The fluorescence emission intensity of current ET primers is 2- to 24-fold higher than that of conventional single dye-labeled primers, leading to high-quality DNA sequencing data.

In this approach, one strand of a double-stranded DNA molecule is biotinylated (e.g., by amplification using PCR in which one of the two primers is biotinylated; Chapter 15). The hemibiotinylated DNA molecule is then bound to streptavidin-ferromagnetic beads. The strands are denatured by treating the beads with alkali and the biotinylated strands are separated from the nonbiotinylated strands using a magnet that traps the bead complex to which the biotinylated strands are bound. Sequencing reactions can be performed using either the biotinylated strand-bead complex or the nonbiotinylated strand preparation as the template.

Fluorescent sequencing procedures (both dye primer and dye terminator methods) have disadvantages, most notably false termination and background noise. In the dye primer method, all the extended DNA fragments—including false-terminated fragments—from the primer carry a fluorescent dye, and thus all are detected by the fluorescent sequencer. This causes background noise and results in inaccurate sequencing data. In the dye terminator method, the excess dye-labeled dideoxynucleotides need to be cleaned up completely. Furthermore, if RNAs and nicked DNAs are present in the DNA templates, they will act as primers to generate false termination or high background noise. Thus, a DNA sequencing method that overcomes these disadvantages is desirable.

A sequencing chemistry using solid-phase-capturable dideoxynucleotides was recently developed that produces much cleaner sequencing data on both slab gel and capillary array sequencers, eliminating the disadvantages of current dye primer and dye terminator chemistries (Ju et al., 1997; Ju, 1999). The procedure involves coupling fluorescent ET primers that produce high fluorescent signals with solid phase-capturable terminators such as biotinylated dideoxynucleotides. After the sequencing reaction, the extension DNA fragments are captured with magnetic beads coated with streptavidin, while the other components in the sequencing reaction are washed away. Only the pure dideoxynucleotide terminated extension products are released from the magnetic beads and loaded on the sequencing gel, producing high-quality data.

Sequencing with Mass Spectrometry

Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS; *UNITS 10.21 & 10.22*) has recently been explored for DNA sequencing (Koster et al.,

1996; Monforte et al., 1997; Fu et al., 1998). The Sanger dideoxy procedure is used to generate the DNA sequencing fragments and no labels are required. The fragments are mixed with a matrix compound, 3-hydroxypicolinic acid, forming microcrystals on a flat plate. The sample plate is then placed in the vacuum chamber of the mass spectrometer. Upon irradiation by a laser light, a microscopic portion of the matrix molecules desorbs off the plate, entraining the DNA fragments. In an electric field, the charged DNA molecules (ions) are accelerated toward the detector, which measures the mass of the fragments based on their time of flight, which is inversely proportional to their mass. Since the mass of each nucleotide (A, C, G, T) is different, the mass difference between adjacent peaks in the mass spectrum is used to establish the sequence of the DNA templates. For example, if the mass difference between the two adjacent peaks in a mass spectrum of an unknown DNA is the mass of “A” base, then the peak with the higher mass is identified as an “A”. Thus simple computation software is all that is needed to assemble the sequence of the DNA from its mass spectrum. Compared to gel-based sequencing systems, MS produces very high resolution of the sequencing fragments (sometimes as good as 1 Da) and extremely fast separation, on a time scale of microseconds. The high resolution allows accurate detection of mutations and heterozygosity.

Another advantage of sequencing with mass spectrometry is that the compressions associated with gel-based systems are completely eliminated. However, in order for accurate measurements of the masses of the sequencing DNA fragments to be obtained, the sample must be free from alkaline and alkaline earth salts. The samples must therefore be desalted before the MS analysis. Solid-phase procedures using either biotinylated primer or immobilized templates are generally used for desalting (Koster et al., 1996; Monforte and Becker, 1997). Both approaches introduce false-terminated DNA fragments into the mass detector. An elegant method to obtain pure sequencing fragments is to use solid phase-capturable dideoxynucleotides—such as biotinylated terminators—in the Sanger reactions to generate sequencing fragments. In this procedure, only the correctly terminated DNA fragments are isolated by streptavidin-coated beads, which are subsequently released and loaded on the mass spectrometer, resulting in accurate sequencing data (Ju et al., 1997; Ju, 1999). The current limit of mass spectrometry for sequenc-

ing is in the 100-bp range. Optimized solid-phase sequencing chemistry plus improvement in detector sensitivity for large DNA fragments will further improve mass spectrometry for DNA sequencing.

Sequencing by Hybridization

Sequencing by hybridization (SBH) makes use of an array of all possible short oligonucleotides to identify a segment of sequences present in an unknown DNA (Drmanac et al., 1989, 1993). This can be clearly explained by the following example. A pentanucleotide 5' CAGTA-3', with a complementary sequence of 5'-TACTG-3' is the sequence that need to be determined from a pool of all possible trinucleotides ($4^3 = 64$). This pentanucleotide will specifically hybridize only with the complementary trinucleotides TAC, ACT, and CTG, revealing the presence of these blocs in the complementary sequence. From this the sequence 5'-TACTG-3' can be reconstructed. Thus with a library of 8- to 10-mer oligonucleotides, much larger segments of DNA sequences can be established. Computational approaches are then used to assemble the complete sequence. In the current state of the art of this technology, SBH has been used for detecting mutations and for resequencing a genome as well as for detecting polymorphisms (Chee et al., 1996; Drmanac et al., 1998). Robust de novo sequencing has not yet been demonstrated. Potential applications of SBH include physical mapping (ordering) of overlapping DNA clones, sequence checking, DNA fingerprinting comparisons of normal and disease-causing genes, and identification of DNA fragments with particular sequence motifs in complementary DNA and genomic libraries.

COMPUTER ANALYSIS

Once the gels are run and autoradiograms are obtained, computer software is practically indispensable for analysis of the sequence information. Computer software can assist at three stages. First, DNA sequence data can be entered into a computer data base either by "reading" the sequencing gels manually with a digitizer system or by using an automated gel scanner. Second, several software packages are available for detecting overlaps in sequence data and then assembling contiguous DNA sequences (contigs) from individual templates. Third, computer assistance is indispensable for analyzing final sequence data, e.g., in finding open reading frames or finding homologies to other sequences present in the nucleotide (UNIT

19.2) or protein databases (UNIT 19.3). UNIT 7.7 provides an overview of software and technology currently available.

This unit contains a general discussion of factors that should be considered before embarking on a DNA sequencing project. In general, any sequencing strategy should include plans for sequencing both strands of the DNA fragment. Complementary strand confirmation leads to higher accuracy, especially when sequencing regions where artifacts such as “compressions” are a problem. Sequencing the opposite strand is often required to obtain accurate data for such regions.

The most commonly used methods for generating appropriately sized DNA fragments for dideoxy and chemical sequencing are discussed below. The biochemistry underlying these procedures, as well as how to choose between these and alternative sequencing methods, are discussed in the introduction to this chapter.

DIDEOXY SEQUENCING

Planning for Dideoxy Sequencing

Sequencing determination of a fragment of <500 nucleotides is usually straightforward because this amount of sequence information can reliably be determined from a single set of sequencing reactions. Fragments of this size can usually be subcloned directly into an appropriate single- or double-stranded DNA sequencing vector. If the vector generates single-stranded DNA, such as the M13mp vectors described below, the fragment should be cloned in both orientations so that both strands of the insert are produced as single-stranded DNA. A primer that hybridizes to a site on the vector adjacent to the insert DNA is then used to sequence both clones, generating the sequence of each strand. When sequencing double-stranded plasmid DNA, there are two options for obtaining the sequence of each strand. A single primer can be used if the insert DNA is cloned in both orientations. Alternatively, two primers that hybridize to plasmid sequences on opposite sides (and opposite strands) of the insert DNA can be used to sequence a single clone.

To sequence larger regions of DNA completely, it is generally necessary to subdivide a large fragment into smaller ones that can then be individually sequenced. Three general approaches are currently used. In the first approach, known as “shotgun cloning,” random

fragments are created from longer DNA fragments by physical shear, digestion by nucleases, (e.g., DNase I) or by restriction digests with endonucleases that make frequent cuts in the fragment (e.g., those with four-base recognition specificity; Frischauf et al., 1980; Anderson, 1981; Bankier and Barrell, 1983; Bankier et al., 1988; Hong, 1982; Messing, 1983, 1988; Deininger, 1983a, 1983b; Bankier, 1984; Lin et al., 1985). These fragments are combined and the entire pool is ligated into the appropriate sequencing vector. After the DNA sequence of the various cloned fragments has been determined, the final sequence is compiled by computer using overlapping information from the individual fragments (UNIT 7.7). However, with more complex (i.e., longer) sequences, this approach becomes tedious since it requires purifying, ligating, and cloning numerous individual fragments. In addition, finding the final few percent of a sequence by this procedure can consume a disproportionately large amount of time.

A second subcloning strategy for sequencing large DNA fragments is to generate an ordered set of subclones from a large DNA molecule. This is usually done by making progressive (nested) sets of deletions from a clone containing the entire DNA fragment to be sequenced. Numerous protocols exist for making nested deletions by enzymatic means; two such protocols using exonuclease III (Henikoff, 1984; Guo and Wu, 1982; Okita, 1985; Ozkaynak and Putney, 1987; Smith, 1979, 1980; Strauss and Zagurski, 1991) and nuclease *Bal* 31 (Guo and Wu, 1982; Guo et al., 1983; Vocke and Bastia, 1983; Yanisch-Perron et al., 1985; Poncz et al., 1982; Misra, 1985) are presented in UNIT 7.2. Another enzymatic method for making nested deletions utilizes T4 DNA polymerase (Dale et al., 1985). Other methods for isolating nested sets of deletion fragments include size-selection of inserts (Barnes, 1987; Barnes and Bevan, 1983; Barnes et al., 1983; Vocke and Bastia, 1983), oriented restriction fragment subcloning (Yanisch-Perron et al., 1985; Lee and Lee, 1989; Hoheisel and Pohl, 1986), transposon-mediated deletions (Ahmed, 1987a, 1987b; Nag et al., 1988; Peng and Wu, 1986), progressive synthesis (Burton et al., 1988; Liu and Hackett, 1989), and oligonucleotide-directed mutagenesis (Shen and Wayne, 1988; Wang et al., 1989). Commercial kits for

making nested deletions are currently available from a variety of sources (see Table 7.2.1 for a list of suppliers).

A third strategy for sequencing large DNA fragments, known as “primer walking,” is uniquely suited to dideoxy DNA sequencing and bypasses the need for subcloning smaller pieces of DNA. Initial sequence data is obtained using a vector-based primer. As new sequence is ascertained, an oligonucleotide is synthesized that hybridizes near the 3′ end of the newly obtained sequence and primes synthesis in a subsequent set of dideoxy reactions (Strauss et al., 1986). The widespread introduction of automated oligonucleotide synthesizers and advances in oligonucleotide purification techniques have made this approach widely accepted and cost effective. Primer walking is also effective as a way to fill gaps in sequence information left by the shotgun cloning or nested deletion approach.

Vectors for Dideoxy Sequencing

A wide variety of vectors are suitable for preparing template DNA for dideoxy sequencing. The decision as to vector choice is subject to the following general constraints:

1. Protocols involving construction of nested deletions generally require particular restriction endonuclease sites in the vector that permit generation of deletions or subsequent cloning of deletion products. For instance, the *exo III* deletion protocol (UNIT 7.2) generally requires the presence of restriction endonuclease sites which allow the generation of a 3′ overhang and a 5′ overhang or blunt end at either end of a DNA fragment.

2. For deletion strategies that require subcloning of deletion products into a secondary vector, such as the *Bal 31* procedure (UNIT 7.2), it is essential that the secondary vector utilize a positive screening method for inserts. For example, many vectors utilize a blue-versus-white screen for inserts into the *E. coli lacZ* gene using Xgal and α -complementation of β -galactosidase (UNIT 1.4 and below).

3. Synthetic oligonucleotides suitable for priming dideoxy sequencing reactions must be available either commercially or through custom synthesis. Primers are also commercially available for many vectors that are not used primarily for sequencing.

4. For large sequencing projects, it is most efficient to use a vector designed to produce single-stranded DNA, such as the phage-based M13mp vectors described below. For projects that require a plasmid-based vector (usually for

reasons other than sequencing), it is often still advantageous to have the capability to generate single-stranded DNA for sequencing templates. Many plasmid vectors contain an M13, *f1*, or *fd* origin of replication that can be activated for production of single-stranded DNA using helper phage (UNIT 1.14 and below).

5. If the sequencing strategy involves sequencing double-stranded templates, a high-copy-number plasmid is advantageous for sequencing minipreps of plasmid DNA.

M13 vectors. The dideoxy sequencing method has been greatly facilitated by the development of the filamentous *E. coli* phage M13 as a cloning vector (Sanger et al., 1980; Messing, 1988). Each M13 phage contains a single-stranded circular DNA molecule that replicates as a double-stranded circular replicative form (RF; UNIT 1.14). The RF can be isolated as a plasmid which can then be transformed into competent *E. coli* cells to yield either phage, which contain single-stranded DNA molecules, or additional double-stranded circular RF molecules. Therefore, a DNA fragment of interest can be cloned into the RF of M13 and then single-stranded DNA for sequencing can be readily produced in large quantities.

The M13 vectors most widely used for dideoxy sequencing are a series called M13mp constructed by J. Messing and his collaborators (Messing and Vieira, 1982; Messing, 1983, 1988; Norrander et al., 1983; Yanisch-Perron et al., 1985). The M13mp series contains the *lacZ* promoter and a partial *lacZ* gene, encoding the α -fragment of β -galactosidase (UNIT 1.14). After infection of an *E. coli* F′ host containing another partial *lacZ* gene encoding the ω -fragment of β -galactosidase and induction by IPTG, M13mp phage produce blue plaques on Xgal agar (see UNIT 1.4 for a discussion of α -complementation and the use of Xgal for assaying β -galactosidase). In addition, each vector in the M13mp series contains a synthetic polylinker inserted into the fifth codon of *lacZ*. Because these polylinkers do not alter the *lacZ* reading frame, M13mp vectors still produce blue plaques on Xgal agar. However, insertion of a DNA fragment into one of the unique polylinker cloning sites has a high probability of disrupting the *lacZ* reading frame, thus generating a recombinant phage that produces colorless plaques.

The more recent members of the M13mp series come as pairs with the polylinker inserted in each orientation. Using these vectors, restriction fragments with different ends (generated by restriction endonucleases whose sites are

present in the polylinker) can be readily cloned in either orientation with respect to the *lacZ* gene (i.e., forced cloning). This procedure permits preparation of opposite strands of the insert from the two recombinant phages, a feature that is particularly important for dideoxy sequencing.

Thus, the use of the M13mp vectors for sequencing involves the following steps. A DNA fragment of interest is ligated into the polylinker in opposite orientations or into an appropriate pair of M13mp vectors. Phage that produce white plaques are picked and used individually to infect a culture of *E. coli* F' cells. Following an incubation period, the supernatant containing the recombinant M13 phage is collected and single-stranded phage DNA is purified for use directly as template DNA in dideoxy sequencing. Because the polylinker is inserted into the same site in *lacZ* in all M13mp

derivatives, a synthetic oligonucleotide—complementary to a region of *lacZ* just downstream on the 3' side of the polylinker—is used as a “universal” primer for all sequencing reactions. If the insert is cloned in both orientations, both strands can be sequenced from the same primer site. It is routine to sequence 300 to 400 nucleotides in M13 vectors in a single set of reactions. The M13mp series of vectors are amenable to all deletion strategies described above. For dideoxy sequencing using single-stranded DNA templates we recommend M13mp18 or M13mp19 (see Table 7.1.1 for suppliers).

Plasmid sequencing vectors. Numerous plasmid vectors, most available commercially, can be used for double-stranded dideoxy sequencing (see Table 7.1.1). Each of these plasmids replicates to a high copy number in *E. coli*, each features a blue-versus-white screen for inserts, and for each plasmid, primers are com-

See APPENDIX 4 for locations and phone numbers. Suppliers' catalogues contain citations of original literature describing these vectors, if available.

^cThese vectors produce both double-stranded RF DNA and packaged single-stranded DNA.

^dThese vectors replicate as plasmids but produce single-stranded DNA upon infection with helper phage.

^eThese vectors produce only double-stranded DNA.

mercially available for sequencing both strands of insert DNA. Several of these vectors also contain an M13, f1, or fd origin of replication that can be activated to produce single-stranded copies of the plasmid by infection with helper phage (*UNITS 1.14 & 1.15*). Several of these hybrid phage/plasmid vectors (designated “ ϕ ” in Table 7.1.1) come as pairs with the phage origin of replication in both orientations such that helper phage directs the synthesis of opposite strands on the hybrid vector.

The design of the polylinker is the most important feature of the vectors listed in Table 7.1.1. The M13mp18/19 polylinker is found in many of these vectors, a feature that is often but not always indicated by the “18/19” designation in the plasmid name. Several other vectors, including Bluescript (which is commonly used in procedures for making nested deletions) have polylinkers containing several useful sites not present in the M13mp18/19 polylinker, as well as a different configuration of these sites. We recommend obtaining information about specific polylinkers from the supplier to determine which vector is best suited for a particular sequencing project.

CHEMICAL SEQUENCING

Planning for Chemical Sequencing

Chemical sequencing requires a DNA fragment that is labeled at only one end (*UNITS 3.5 & 3.10*). Traditionally, chemical sequencing strategies required relatively detailed knowledge of the restriction map for the fragment to be sequenced. This permitted generation of a series of subfragments that could be labeled at both ends by polynucleotide kinase or by the *E. coli* DNA polymerase I large fragment (Klenow fragment; *UNIT 3.5*). These labeled fragments would then be cut asymmetrically to produce two fragments labeled at each end, which could be purified individually by gel electrophoresis. However, specially designed vectors (described below) circumvent the requirement for purifying and labeling individual restriction

fragments and greatly facilitate chemical sequencing projects. These vectors contain asymmetric sites (see below) that permit labeling only one end of the target DNA to be sequenced; this strategy can be thought of as the chemical sequencing analog to the universal priming site. These vectors are particularly suited for cloning a set of nested deletions generated by *Bal 31*. We recommend using the nested deletion strategy for large chemical sequencing projects. For small fragments of DNA, the traditional end-labeling strategy is as efficient as subcloning into specialized vectors.

Vectors for Chemical Sequencing

Eckert (1987) has described the construction of specialized vectors that make it possible to rapidly and simultaneously sequence a large number of samples by the chemical cleavage method. These vectors, pSP64CS and pSP65CS (CS refers to chemical sequencing) are high-copy-number plasmids that confer ampicillin resistance and carry a synthetic polylinker containing two *Tth111I* sites flanking a *SmaI* site (Table 7.1.2). *Tth111I* cleaves at the sequence GACNNGTC leaving a single protruding 5' base. The two *Tth111I* sites were synthesized so it would be possible to selectively label one end of a *Tth111I* fragment using Klenow fragment in an end-labeling reaction as shown in Figure 7.1.1, bottom (Volckaert et al., 1984). End labeling of DNA fragments using Klenow fragment is simple and efficient and, since gel purification of labeled fragments is eliminated, the DNA can be sequenced directly after labeling. Since the plasmids are high-copy-number, a small (1.5 ml) bacterial culture yields enough plasmid DNA to repeat the sequencing reactions five to ten times, once the DNA is radiolabeled. The vectors allow for sequencing of a large number of fragments bordered by any of the unique restriction sites in the polylinker provided that at least one of the *Tth111I* labeling sites is retained. The sequence of the polylinker region of pSP64CS and pSP65CS is shown in Figure 7.1.1, top. The

^aSuppliers' abbreviations are listed in Table 7.1.1.

two vectors differ only in the orientation of the polylinker relative to an SP6 promoter element, a feature of the plasmids not relevant to DNA sequencing (UNIT 3.8). Thus, it is necessary to use only one of the plasmids for DNA sequencing. (The SP6 promoter can be utilized to synthesize RNA complementary to the cloned DNA; thus, exon/intron mapping and other types of nuclease protection/mapping experiments can be carried out using the same plasmid construction as for sequencing.)

To use these vectors, the DNA fragment to be sequenced is subcloned into pSP64CS or pSP65CS and recombinant colonies are selected on ampicillin plates. Recombinant plasmid is prepared, digested with *Tth111I*, and the 5' single-base overhang created by *Tth111I* is filled in using the appropriate ³²P-labeled dNTP and Klenow fragment, such that the label is incorporated only at the end adjacent to the DNA to be sequenced (Fig. 7.1.1). Protocols for preparing pSP64/65CS-derived clones are presented in UNIT 7.3; protocols for *Tth111I* end labeling and chemical sequencing are provided in UNIT 7.5.

The *Bal* 31 procedure (UNIT 7.2) can be used to generate a set of nested deletions for subcloning into pSP64CS or pSP65CS. The blunt end generated by *Bal* 31 is ligated to the *Sma*I site in pSP64/65CS. This places the deleted end of each fragment next to a *Tth111I* site for end labeling (see Figs. 7.1.1 & 7.2.3 for strategy and protocol for constructing *Bal* 31 deletions).

Tth111I is an ideal site to utilize in an end-labeling vector because (1) it leaves a single protruding 5' base, assuring that the filling reaction will add only a single base per end; (2) *Tth111I* sites are rare, and thus sites present in the DNA being sequenced rarely complicate the labeling reaction; (3) the protruding base is G, A, T, or C, allowing a single DNA terminus to be selectively labeled (Fig. 7.1.1); and (4) the presence of two *Tth111I* sites in the vector makes it possible to selectively label either side of a fragment cloned between them. Together with *Tth111I*, other asymmetric sites (*Bst*EII and *Eco*81I) are incorporated in an additional family of plasmid vectors for chemical sequencing that utilize the same basic end-labeling strategy as pSP64CS/65CS (Table 7.1.1; Arnold and Puhler, 1988).

Constructing Nested Deletions for Use in DNA Sequencing

Nested deletions useful for dideoxy DNA sequencing (UNIT 7.4) are a set of deletions originating at one end of a target DNA fragment and extending various lengths along the target DNA. Each successively longer deletion brings “new” regions of the target DNA into sequencing range (about 300 bp for normal sequencing gels) of the primer site (see UNIT 7.1 for a general discussion of nested deletions in DNA sequencing).

Two protocols for generating nested subclones via enzymatic digestion are included in this unit. In the basic protocol, a set of nested deletions is generated by exonuclease III. The primary advantage of this method is that the deletion products generated from the original clone can be recircularized to generate functional plasmids and thus do not require subcloning into another vector. An alternate method utilizes *Bal* 31 nuclease to generate the deletions. This method requires subcloning of the deletion fragments into a separate vector for subsequent use. Both the *exo* III and *Bal* 31 methods require the presence of unique restriction sites in the vector that are not present in the insert DNA. *Bal* 31 can also be used to generate nested deletions for chemical sequencing (UNIT 7.5) in conjunction with specialized chemical sequencing vectors (UNIT 7.1).

Commercially available kits for making nested deletions using a number of methods are described in UNIT 7.1 and listed in Table 7.2.1.

USING EXONUCLEASE III TO CONSTRUCT UNIDIRECTIONAL DELETIONS

BASIC PROTOCOL

This method is based on the enzymatic properties of *exo* III, a 3′ exonuclease specific for double-stranded DNA (UNIT 3.11). Exonuclease III can initiate digestion at blunt ends or ends with a 5′ overhang, but cannot efficiently initiate digestion at a 3′ overhanging end. The protocol contains the following steps: (1) cloning of target DNA into a polylinker in a suitable sequencing vector (see strategic planning, below, and UNIT 7.1 for a discussion of useful vectors); (2) double digestion of this plasmid at a site adjacent to the cloned target DNA with an enzyme that leaves a 5′ overhanging or blunt end and an enzyme that leaves a 3′ overhanging end of four bases; (3) exonucleolytic attack with *exo* III for varying lengths of time to create unidirectional digestion of the target sequence; (4) treatment with a single-stranded nuclease (*S*1 or mung bean nuclease) to remove the 5′ single strand, and repair of ends with Klenow fragment of *E. coli* DNA polymerase I; and (5) circularization and ligation with T4 DNA ligase and transformation of competent *E. coli* cells.

Materials

DNA fragment to be sequenced (insert DNA)
Appropriate sequencing vector (strategic planning and Table 7.1.1)
Restriction endonucleases and corresponding buffers (UNIT 3.1)
Buffered phenol (UNIT 2.1)
25:24:1 phenol/chloroform/isoamyl alcohol (UNIT 2.1)
Ice-cold 100% and 70% ethanol
3 M sodium acetate
Exonuclease III (UNIT 3.11) and 1× exonuclease III buffer
1 U/μl S1 nuclease (UNIT 3.12) and S1 nuclease buffer
S1 nuclease stop buffer
10× loading buffer (UNIT 2.5A)
2 U/μl Klenow fragment of *E. coli* DNA polymerase I (UNIT 3.5)
0.25 mM 4dNTP mix (dATP, dCTP, dGTP, and dTTP at 0.25 mM each; UNIT 3.4)
Exo III ligation buffer
10 mM ATP
1 U/μl T4 DNA ligase (measured in Weiss units; UNIT 3.14)

If plasmid vector is used

E. coli DK1 (*recA*; available from BRL) or DH5αF' (*recA*) made competent for transformation (Table 1.4.5 and UNIT 1.8)
LB plates and medium (UNIT 1.1) containing appropriate antibiotic

If one of the M13mp plasmids is the cloning vector

E. coli JM109 (*recA*) or DH5αF' (*recA*; BRL) made competent for transformation (Table 1.4.5 and UNIT 1.8)
LB plates (UNIT 1.1), prewarmed
H top agar (UNIT 1.1)
Xgal/IPTG mixture [30 μl Xgal stock and 30 μl IPTG stock (Table 1.4.2) for each 3 ml H top agar]
2× TY medium (UNIT 1.1)
Phage loading buffer

Additional reagents and equipment for subcloning DNA fragments (UNIT 3.16), CsCl/EtBr purification of plasmid DNA (UNIT 1.7), restriction enzyme digestion (UNIT 3.1), phenol extraction and ethanol precipitation (UNIT 2.1), agarose gel electrophoresis (UNIT 2.5A), transforming *E. coli* (UNIT 1.8), plasmid minipreps (UNIT 1.6), preparation of frozen glycerol stocks (UNITS 1.3 & 1.6), and dideoxy DNA sequencing (UNIT 7.4)

Strategic Planning

Figure 7.2.1 gives an overview of the experimental strategy for constructing a nested set of unidirectional deletions with exo III. Between the target DNA and the sequencing primer site there must be a recognition site for a restriction enzyme that generates a 5' overhanging end or a blunt end; between that restriction site and primer site there must be a recognition site for a restriction enzyme that generates a four-base 3' overhanging end that will be protected from exo III digestion. Incorporation of α-thio nucleotide analogs by filling in a 5' overhanging end adjacent to the primer site provides an alternative means of protection (see support protocol in this unit). Recently it has been shown that the *lac* repressor bound at *lac* operator site can also protect DNA from exo III digestion (Johnson et al., 1990).

To sequence both strands of the target DNA, deletions must be made from each end. Since exo III deletions of target DNA do not require subcloning into another vector, the vector into which the target DNA is initially cloned is also the one that will eventually

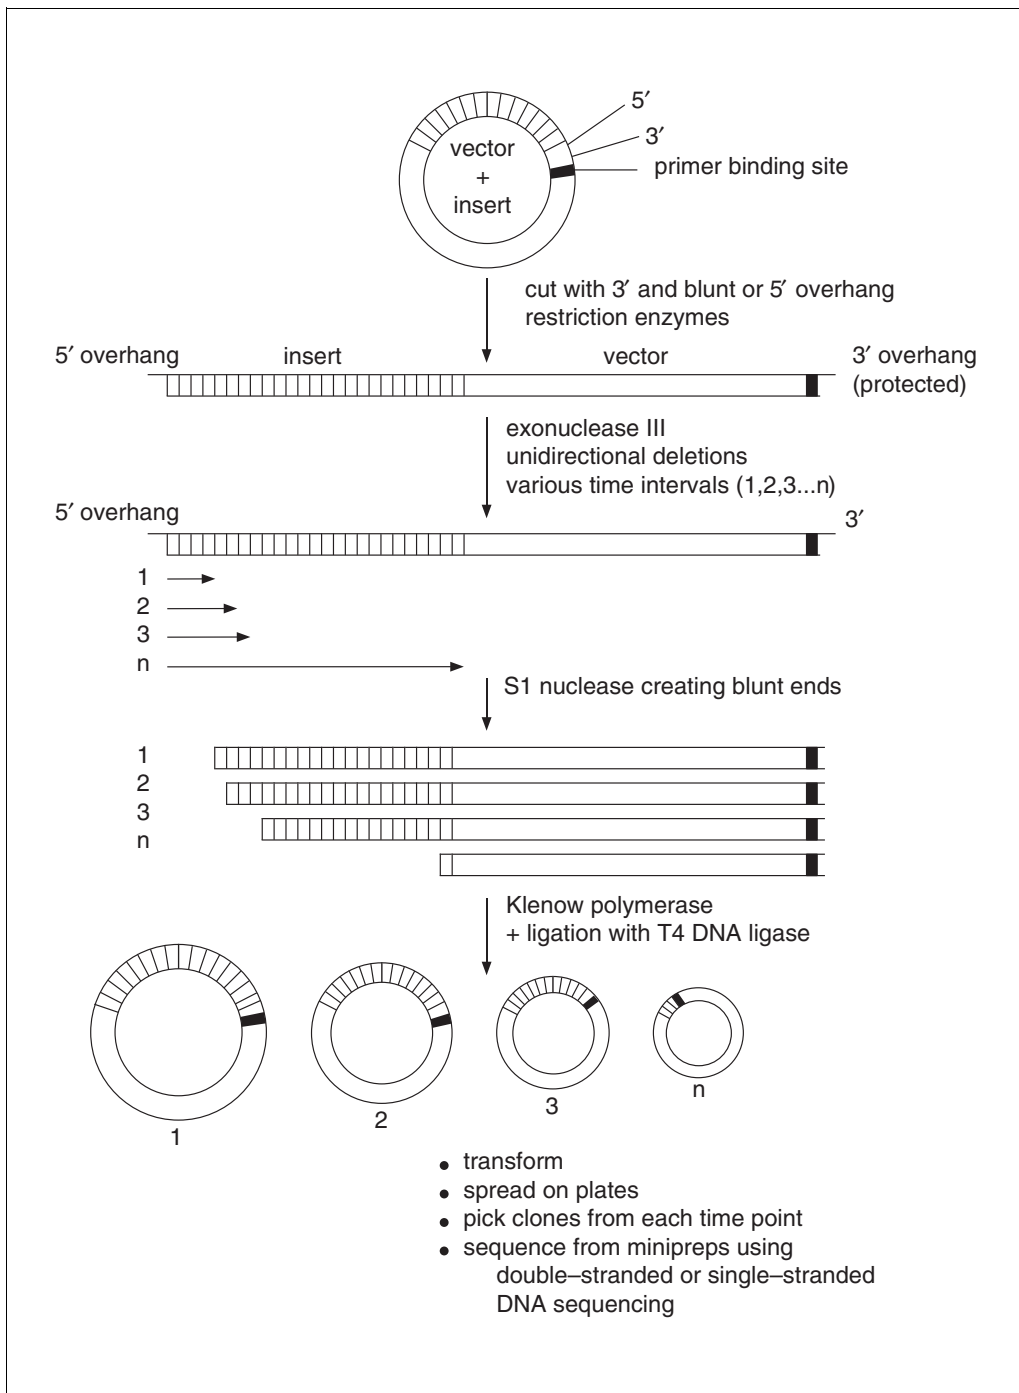

Figure 7.2.1 Construction of unidirectional deletions using *exo III*. The vector::insert DNA is digested with restriction endonucleases which generate a 3' overhang next to the sequencing primer site and a 5' overhang next to the insert DNA. Digestion with *exo III* generates unidirectional deletions from the end with the 5' overhang. Treatment with S1 nuclease and repair with Klenow fragment create blunt ends from both the *exo III*-treated ends and the 3' overhang which was protected from *exo III* digestion. The deleted plasmids are treated with DNA ligase and used to transform *E. coli*. Plasmids which have deletions are identified by gel electrophoresis of minipreparations of DNA.

provide sequencing templates. Thus, the DNA to be sequenced should be situated adjacent to restriction sites suitable for creating exo III deletions; in addition, priming sites for dideoxy sequencing should be located next to each end of the target DNA (Fig. 7.2.1). If the target DNA will be sequenced using double-stranded DNA templates, it is possible to construct deletions from each end of the fragment if both sequencing priming sites and suitable restriction sites are present in the vector on both sides of the target fragment. If the target fragment will be sequenced using single-stranded M13mp DNA templates, the target DNA must be cloned in both orientations with respect to the primer sequencing site using a pair of M13mp vectors. Refer to *UNIT 7.1* and Table 7.1.1 for information about sequencing vectors.

This protocol is written for constructing deletions in a ~2.0-kb fragment. However, we have successfully constructed nested sets of deletions in fragments as long as 7.0 kb, and it is likely that even longer insert fragments can be used. The protocol should be scaled up proportionately for longer fragments.

Preliminary Steps

1. Clone the DNA fragment to be sequenced (insert DNA) in the polylinker of an appropriate sequencing vector (see Fig. 7.2.1).

Refer to strategic planning above and to UNIT 7.1 for information regarding vector requirements for this procedure.

2. Prepare DNA twice-purified by CsCl/EtBr equilibrium centrifugation of the recombinant plasmids constructed in step 1.

It is important that the DNA be supercoiled; nicks in the vector DNA may cause degradation in the exonucleolytic step. Approximately 5 µg of plasmid DNA are required per experiment.

Exo III Procedure

DAY ONE: Linearize vector::insert DNA

3. Completely linearize 5 µg vector::insert DNA by double digestion with restriction enzymes that leave a 3' overhang adjacent to the primer site and a 5' overhang or blunt end adjacent to the insert DNA (see Fig. 7.2.1).

The 5' or blunt restriction site must be positioned between the 3' restriction site and the insert. Verify that digestion is complete by running a small aliquot on an agarose minigel (UNIT 2.5A).

4. Extract with buffered phenol, extract with phenol/chloroform/isoamyl alcohol, add $\frac{1}{10}$ vol of 3 M sodium acetate, and precipitate with ethanol (see *UNIT 2.1*). Wash the pellet in ice-cold 70% ethanol and dry it.
5. Dissolve the dried pellet in 1× exo III buffer for a final concentration of 0.1 µg/µl.

Create a nested set of unidirectional deletions

The extent of digestion of exo III is regulated by the reaction temperature and the time of incubation. Rates of 250 bp/min at 37°C and 120 bp/min at 30°C were obtained using the conditions outlined in the following steps.

6. Remove 25 µl (2.5 µg) of the linearized DNA (from step 5) and incubate 2 min at 37°C.
7. Add 150 U exo III per pmol susceptible 3' ends. Continue the 37°C incubation.

Conversion factor: 1 µg of 1-kb DNA = 1.5 pmol susceptible 3' ends.

Figure 7.2.2 Ethidium bromide–stained agarose gel depicting exo III digestion. Bluescript vector (10 μg with a 3-kb insert) was cut with *Xba*I, which leaves a 5' overhanging end, and with *Bst*XI, which leaves a 3' overhanging end. The vector was then subjected to exo III digestion for eight different time intervals, followed by S1 nuclease digestion. Approximately 1 μg of each DNA sample was loaded on the gel. The DNA fragments in the lanes labeled “M” are molecular weight markers.

8. Remove 3- μl aliquots at 1-min intervals to individual microcentrifuge tubes (giving a total of eight samples) and place immediately on dry ice for 5 min. Add 3 μl water and inactivate the exo III by incubating 10 min at 70°C. Put the samples on ice.
9. Add 15 μl S1 nuclease buffer and 4 μl (4 U) S1 nuclease to each sample. Incubate 20 min at room temperature.
10. Stop the S1 nuclease reaction (via pH shift) by adding 5 μl S1 nuclease stop buffer to each sample.

Subject deleted DNA samples to electrophoresis

11. Add 2 μl of 10 \times loading buffer to an 8- μl aliquot of each sample and subject to electrophoresis on a 1% agarose gel, including ethidium bromide in the gel and buffer. Also run a lane of molecular weight markers (e.g., bacteriophage λ DNA, cut with *Hind*III) to determine the actual rate of exonuclease degradation. Decide which aliquots are worth saving.

Figure 7.2.2 illustrates the extent of deletions created on a Bluescript vector with a 3-kb insert starting with 10 μg DNA.

Create blunt ends for ligation

12. Add to each remaining 22 μl of the selected samples 1 μl (2 U) Klenow fragment. Incubate ~2 min at 37°C. Then add 1 μl of 0.25 mM 4dNTP mix and continue incubation at 37°C for 10 min to create blunt ends.

Recircularize the deleted molecules by ligation

13. Add 20 μl exo III ligation buffer, 3 μl of 10 mM ATP, 14 μl water, and 1 μl (1 U) T4 DNA ligase. Incubate 5 hr at room temperature or overnight at 15°C.

If using a plasmid vector and planning to carry out dideoxy sequencing with double-stranded plasmid template, proceed with steps 14 to 18. If using an M13mp vector and planning to carry out dideoxy sequencing with single-stranded templates, proceed to step 19.

DAY TWO (DOUBLE-STRANDED TEMPLATE): Transform ligated DNAs into competent *E. coli*

14. Transform 100 μ l of competent cells (*E. coli* DK1 or DH5 α F'; Table 1.4.5) with 10 μ l of each ligation reaction. Following heat-shock in the transformation protocol, spread $\frac{1}{5}$ of each of the cultures on LB plates containing antibiotic appropriate for the plasmid and incubate overnight at 37°C.

*Any competent *E. coli* recA strain can be used for transformation. About 2000 colonies are expected for each sample.*

DAY THREE (DOUBLE-STRANDED TEMPLATE): Characterize deleted plasmid clones

15. Pick two to four colonies from each plate and inoculate 5 ml LB medium containing appropriate antibiotic and grow overnight. Isolate DNA from 1.5 ml of each overnight culture using one of the miniprep procedures described in UNIT 1.6. Make a frozen glycerol stock with 1 ml of each culture (see UNIT 1.3) and store the remainder of each overnight culture at 4°C for DNA sequencing template preparation.

16. Add 2 μ l of 10 \times loading buffer and 10 μ l water to each 2.5- μ l aliquot of the plasmid DNA from step 15 and run on a 1% agarose gel. As size markers, also load 0.1 μ g each of the undeleted plasmid and parent vector on the gel. It should be possible to discern a ladder of deletions from full insert size to ~300 bp.

If it is difficult to size double-stranded circular molecules in increments of 200 bp, linearize the DNA at a common polylinker site before electrophoresis.

DAY FOUR (DOUBLE-STRANDED TEMPLATE): Prepare double-stranded plasmid templates for DNA sequencing

17. Choose a set of clones (from step 16) that differ from each other by intervals of 250 to 300 bp, spanning the complete region of the target DNA. Prepare plasmid DNA from the overnight cultures stored at 4°C (step 15) suitable as template for dideoxy sequencing (UNIT 7.3).

18. Subject the plasmid DNA of the deleted clones to nucleotide sequencing analysis, as described in UNIT 7.4.

The clones can initially be characterized by T-track analysis, in which each template is used in a dideoxy-T sequencing reaction. Whether or not overlapping regions occur in the chosen clones can be determined by the sequencing pattern.

Follow steps 19 to 26 if using an M13mp vector and planning to carry out dideoxy sequencing using single-stranded templates.

DAY TWO (SINGLE-STRANDED TEMPLATE): Transform ligated DNAs into competent *E. coli*

19. Transform 100 μ l of competent JM109 or DH5 α F' *E. coli* cells with 10 μ l of each reaction mix (from step 13). Also transform with 0.5 ng of the M13mp RF vector DNA and 0.5 ng of the M13mp::insert RF DNA that carries the nondeleted fragment.

**E. coli* DH5 α F' (Table 1.4.5) can be maintained on rich media without loss of the F' factor, is suppressor plus, restriction minus, modification plus, recombination deficient (recA1), and exhibits a higher transformation efficiency than JM109.*

20. Following the heat shock step in the transformation protocol, add 0.2 ml of an overnight culture of *E. coli* JM109 or DH5 α F', pipet contents into 3 ml of room

temperature H top agar containing 60 μ l Xgal/IPTG mixture, mix, and pour on LB plates. Incubate overnight at 37°C.

About 2000 plaques are expected for each sample. All plaques should be white except for those from the M13mp RF vector DNA, which should be blue.

DAY THREE (SINGLE-STRANDED TEMPLATE): Characterize deleted phages

21. Picking two to four M13 plaques from each transfection plate (i.e., two to four per exonuclease time point), grow individual M13mp phage stocks as described in steps 1 through 4 in the protocol for preparing single-stranded templates in UNIT 7.3. Grow stocks of the M13mp vector and M13mp::insert as controls. Store supernatants at 4°C.

Following sequencing, particular deletion intervals may be missing. For this reason, it is useful to be able to examine additional phage from a particular time point. Because phage diffuse within the agar, we advise picking several additional colorless plaques from each time point into individual wells in a 96-well microtiter plate containing 200 μ l of 2 \times TY medium plus 15% glycerol, growing them at 37°C for 6 hr, and freezing at -20°C for future use, if necessary.

If further small-scale manipulations with RF DNA from the deleted phage are desired, harvest cells in addition to the phage supernatants and isolate RF DNA by the alkaline lysis method described in UNIT 1.6.

22. Place 20 μ l of each phage supernatant into 4 μ l of phage loading buffer and load on a 1% agarose gel. Also load M13mp vector(s) and M13mp::inserts (undeleted) supernatants as size markers. It should be possible to discern a ladder of deletions from full insert size to ~300 bp.

Optional test for detecting small inserts: "C testing" entails mixing 10 μ l of a phage supernatant carrying a presumptive insert with 10 μ l of the supernatant from the M13 control carrying the full-length, undigested opposite strand. Add 4 μ l phage loading buffer and incubate 30 min at 65°C prior to electrophoresis. Annealing between the phage DNAs causes significant retardation in the gel compared to the single-stranded circular forms.

C testing can also be used to determine the orientation of an insert.

DAY FOUR (SINGLE-STRANDED TEMPLATE): Prepare single-stranded phage templates for DNA sequencing, choosing phage that contain appropriate deletions from previous step

23. Choose clones from step 22 that differ from each other by intervals of 250 to 300 bp, spanning the complete insert DNA.
24. Respin the stored phage supernatants from step 21 (there will be some cell growth, even at 4°C) and transfer supernatants to fresh 1.5-ml microcentrifuge tubes.

The presence of chromosomal DNA will interfere with sequencing reactions.

25. Proceed immediately to step 5 of the protocol in UNIT 7.3 for preparing single-stranded template DNA for sequencing.
26. Subject the prepared single-stranded DNA templates to dideoxy sequencing as described in UNIT 7.4. Also perform sequencing reactions on the vector containing the undeleted fragment.

See annotation to step 18 concerning characterization of clones by T-track analysis.

**PROTECTION OF DNA FROM EXONUCLEASE III DIGESTION
USING [α -³⁵S]dNTPs**

Creating unidirectional deletions for DNA sequencing using exonuclease III requires that the end of the molecule adjacent to the sequencing primer site be protected from digestion. This is typically accomplished using restriction endonucleases that provide four-base, 3' overhanging ends. Incorporating α -thio nucleotide analog, [α -³⁵S]dNTP, adjacent to the primer site provides an alternative means of protecting against exo III digestion (Putney et al., 1981). Restriction sites adjacent to the primer site that leave a 5' overhang can be filled in with Klenow fragment using the appropriate thio nucleotide analog to cap the 3' end. This increases flexibility in designing a deletion strategy, as any restriction site that leaves a 5' overhang can be appropriately modified to provide the necessary protection from digestion by exo III (Ozkaynak and Putney, 1987).

Additional Materials

- 5 mM appropriate dNTPs (UNIT 3.4)
- 5 mM appropriate [α -³⁵S]dNTPs (Pharmacia)

1. In a 20- μ l reaction mixture, completely linearize 5 μ g vector::insert DNA by digesting with a restriction endonuclease that leaves a 5' overhanging end adjacent to the sequencing primer site.

Verify that the digestion is complete by running a small aliquot on an agarose minigel (UNIT 2.5A).

2. Add 1 μ l of each of the appropriate 5 mM [α -³⁵S]dNTPs and 5 mM dNTPs, and 1 U Klenow fragment (UNIT 3.5). Incubate 30 min at room temperature.

The [α -³⁵S]dNTPs and dNTPs required depend upon the sequence of the 5' overhang left by the restriction endonuclease. Adequate protection from exo III digestion will be obtained for both partially and completely filled-in restriction sites, providing that the 3'-most nucleotide added by Klenow fragment contains the thio group.

Ozkaynak and Putney (1987) used higher concentrations of [α -³⁵S]dNTPs; however we have found that the above concentration will provide adequate incorporation.

3. Stop the Klenow polymerase reaction by incubating 10 min at 75°C. Digest the DNA with a second restriction endonuclease that generates a 5' overhanging or blunt end adjacent to the insert DNA.

Be sure to adjust the salt concentration of the reaction mix to that appropriate for the second enzyme (see UNIT 3.1). Do not exceed 20% glycerol in the final restriction endonuclease reaction mix.

4. Proceed with step 4 of the protocol for constructing nested deletions with exo III.

USING BAL 31 NUCLEASE TO CONSTRUCT NESTED DELETIONS

This method is based on the properties of Bal 31 nuclease, a single strand-specific endonuclease that can degrade the ends of duplex linear DNA from both the 5' and 3' termini (see UNIT 3.12). As illustrated in Figure 7.2.3 (left side), the Bal 31 procedure involves linearizing vector::insert DNA at one end of the region to be sequenced. In a second step, a series of deletions are created that extend various amounts into the desired region using Bal 31. Because Bal 31 will shorten both ends of the linearized vector::insert, the third step separates the deleted insert from the vector component by digestion with a second restriction endonuclease at the opposite end of the insert DNA. Finally, the deleted insert fragments are subcloned into an appropriate dideoxy sequencing vector such that the deleted Bal 31 ends are adjacent to the sequencing priming site. Alternatively, for chemical sequencing, the deleted fragments can be cloned into

chemical sequencing vectors, such as pSP64CS/65CS, so that the deleted *Bal* 31 ends are adjacent to a universal site for end-labeling. To sequence both strands of the insert DNA, a nested set of deletions from each side of the insert must be generated. To do this, the *Bal* 31 digestion and subcloning procedures are repeated using a separate aliquot of the plasmid that has been linearized at the other end of the region to be sequenced (Fig. 7.2.3, right side).

A nested set of deletions spanning a 1.5- to 2.0-kb region can be reliably generated using this procedure. If a larger region is to be sequenced, it is best to choose two large deletions (one from each end of the fragment) from the first set of *Bal* 31 digestions and then to repeat the procedure with these deleted fragments. Alternatively, a series of ~2.0-kb fragments spanning the region to be sequenced can be cloned individually. If this latter procedure is adopted, choose a set of overlapping rather than adjacent fragments to avoid the problem of overlooking very small restriction fragments.

This protocol is written for generating a set of deletions from only one end of the DNA (i.e., the left half of Fig. 7.2.3). The protocol can be duplicated and performed simultaneously to generate the second set of deletions (i.e., the right half of Fig. 7.2.3).

Materials

DNA fragment to be sequenced (insert DNA)
Appropriate “source” and “sequencing” vectors (see strategic planning below and Table 7.1.1)
Buffered phenol (UNIT 2.1)
Ice-cold 70% ethanol
3 M sodium acetate
TE buffer (APPENDIX 2)
10× and 1× *Bal* 31 nuclease buffer
Bal 31 nuclease (UNIT 3.12)
200 mM EGTA
1 mg/ml yeast tRNA
Restriction endonucleases and corresponding buffers (UNIT 3.1)
10× loading buffer (UNIT 2.5A)
Low gelling/melting temperature agarose (UNIT 2.6)
Ethidium bromide
50× TAE buffer (optional; APPENDIX 2)
95% ethanol (optional)
10× T4 DNA ligase buffer (UNIT 3.4)
400 U/μl T4 DNA ligase (measured in cohesive-end units; UNIT 3.14)

If plasmid vector is used

E. coli JM109, DH5αF', or equivalent made competent for transformation (Table 1.4.5 and UNIT 1.8)
LB plates and medium (UNIT 1.1) containing appropriate antibiotic

If one of the M13mp plasmids is the cloning vector

E. coli MC1061, DH5αF', JM109, or equivalent made competent for transformation (Table 1.4.5 and UNIT 1.8)
Overnight cultures of *E. coli* JM101, JM107, JM109 or equivalent (Table 1.4.5) in LB or 2× TY medium (UNIT 1.1)
H top agar (UNIT 1.1)
Xgal/IPTG solution [30 μl Xgal stock and 30 μl IPTG (Table 1.4.2) for each 3 ml of H top agar]
LB plates (UNIT 1.1), prewarmed
2× TY medium (UNIT 1.1)
Phage loading buffer

Figure 7.2.3 Strategy for making a nested set of deletions with *Bal*31 nuclease. The source vector containing a fragment to be deleted (in this example RF DNA of an M13mp vector) is linearized at each end of the fragment in separate reactions (**step 1**) and a nested set of deletions is generated with *Bal* 31 nuclease (**step 2**). The source vector and insert DNA are separated by restriction endonuclease digestion (**step 3**) and agarose gel electrophoresis (**step 4**). The deleted fragments are eluted from the gel and ligated to a sequencing vector (in this example, an M13mp vector) that has been digested with a restriction enzyme generating a blunt end (compatible with ends digested by *Bal* 31; in this example, *Sma*I) and another restriction enzyme corresponding to the site at the other end of the insert (RE1 or RE2). "RE2" and "RE2" refer to two different restriction endonucleases or their respective recognition sites.

Additional reagents and equipment for subcloning DNA fragments (*UNIT 3.16*), CsCl/EtBr purification of plasmid DNA (*UNIT 1.7*), phenol extraction and ethanol precipitation (*UNIT 2.1*), preparing and transforming competent *E. coli* (*UNIT 1.8*), agarose gel electrophoresis (*UNIT 2.5A*), isolating fragments using low gelling/melting temperature agarose (*UNIT 2.6*), plasmid minipreps (*UNIT 1.6*), and preparing single-stranded phage DNA templates (*UNIT 7.3*)

Strategic Planning

Refer to Figure 7.2.3 for an overview of the experimental strategy that can be employed for constructing a nested set of deletions with *Bal* 31 nuclease.

Because *Bal* 31–deleted fragments are subcloned into a separate sequencing vector, two vector selections must be made prior to generating the nested set of deletions: one that will serve as a source of DNA to be subjected to *Bal* 31 digestion (“source” vector), and one that will accept the deleted fragments and ultimately generate sequencing templates (“sequencing” vector).

Source vector. Two factors are important in selecting the source vector for the initial cloning of the insert to be subjected to *Bal* 31 digestion:

- The source vector::insert must be constructed such that the region to be deleted has a unique restriction site at each end. For each set of *Bal* 31 deletions, one site is required for DNA cleavage where the deletions will begin and a second site (at the opposite end of the insert) serves to separate the deleted insert from the vector. These restriction sites flanking the insert must be compatible with polylinker sites in the sequencing vector.
- In this procedure, the *Bal* 31–digested insert DNA is purified from vector DNA by agarose gel electrophoresis. In theory, any insert that is minimally 80% different (either larger or smaller) than the vector can be differentiated on a standard agarose gel. For example, if the source vector is one of the pUC series of plasmids that are ~2.7 kb, the insert should be ≤ 2.3 kb or ≥ 3.2 kb.

A wide variety of vectors meet the above criteria (see Table 7.1.1). One advantage of using an M13mp vector as source vector is that M13 is generally considerably larger than the region to be sequenced and can be readily separated from the insert by gel electrophoresis.

NOTE: Inserts >2.5 kb are often unstable in M13mp vectors and may delete spontaneously. JM109 (*recA*; Yanisch-Perron et al., 1985) may stably propagate larger inserts.

An alternative strategy for subcloning the *Bal* 31–deleted fragments is to omit the gel electrophoresis step after the second restriction enzyme digestion (Fig. 7.2.3, step 4) and simply subclone everything into an appropriate sequencing vector. Those subclones that contain insert DNA can be differentiated from those containing source vector DNA via plaque lift or colony blot analysis (*UNITS 6.1-6.4*). In this case, size difference between source vector and insert is not important. It is advantageous to use a high-copy-number source vector, such as the pUC series, to easily prepare sufficient quantities of DNA for *Bal* 31 digestion (5 μ g of DNA is required per 150 to 200 bp of DNA to be deleted).

Sequencing vector. Choice of sequencing vector depends on the method that will be used to sequence the nested set of deletions. See *UNIT 7.1* and Tables 7.1.1 and 7.1.2 for a description of vectors suited to dideoxy and chemical sequencing and the factors involved in their selection. The major constraint on the sequencing vector is that it have a polylinker-site configuration that can accept the *Bal* 31–deleted fragments so that the blunt end created by *Bal* 31 digestion is next to a priming site for dideoxy sequencing (or an end-labeling site for chemical sequencing).

If M13mp sequencing vectors are chosen, (UNIT 7.1) it may be necessary to use a pair of complementary M13mp vectors, each of which will accept fragments with deletions from one end. This will be the case if, in the sequencing vector polylinker, the two restriction sites flanking the insert DNA to be sequenced are located on opposite sides of the restriction enzyme site used to provide a blunt end. This case is illustrated in Figure 7.2.3.

Preliminary Steps

Prepare source vector::insert double-stranded DNA as starting material

1. Clone the fragment to be sequenced in an appropriate source vector, choosing a vector according to the criteria in strategic planning, above.

If an M13mp vector is chosen as source vector, clone the insert DNA in both orientations with respect to the sequencing priming site so that the sequence at each end of the undeleted insert can be obtained. However, prepare CsCl-purified DNA for only one of the orientations to use for Bal 31 digestion.

2. Prepare 5 μ g of CsCl-purified double-stranded DNA of the clone constructed in step 1 for each 150 bp to be deleted (e.g., 50 μ g for a 1.5-kb fragment; this is a two-fold excess to allow for repetition if necessary).

RNA will interfere with digestion by Bal 31 nuclease; if RNA contaminates the DNA preparation after one CsCl gradient, purify the DNA through a second gradient.

Prepare sequencing vector to accept Bal 31-digested fragments

Two separate preparations of sequencing vector DNA are required, each for a set of deletions from one end (see Fig. 7.2.3, step 5). For each set of deletions, the sequencing vector should have a blunt end (compatible with *Bal* 31-digested ends) adjacent to a dideoxy sequencing priming site (or chemical sequencing end-labeling site) and a sticky end compatible with the restriction site on the opposite side of the insert from which *Bal* 31 digestion was initiated in that set of deletions (and which was therefore protected from *Bal* 31 digestion). It can be prepared anytime in advance and stored at -20°C .

3. For each set of *Bal* 31 deletions, digest ≥ 2 μ g of CsCl-purified double-stranded DNA of the chosen sequencing vector with the appropriate restriction endonucleases.

A typical protocol for preparing M13mp sequencing vector DNA is described in the second support protocol.

Prepare competent recipient cells

4. For subcloning *Bal* 31-deleted fragments, prepare cells competent for transformation and store at -70°C . If fragments are to be subcloned into sequencing templates that feature *lac* α -complementation or into M13mp vectors, use *E. coli* JM109, DH5 α F', or equivalent host strain. Alternatively, MC1061 can be initially transformed, then mixed with DH5 α F' or equivalent host, which will allow formation of plaques.

Strain MC1061 helps the efficiency of this procedure because of its high transformation frequency, but cannot be used for M13mp7, 8, 9, 10, and 11 because amber mutations in these vectors are not suppressed by MC1061.

Bal 31 Procedure

DAY ONE: Linearize source vector::insert DNA (Fig. 7.2.3, step 1)

5. Completely linearize 2 μg of source vector::insert DNA for each 150 bp to be deleted plus an additional 2 μg (e.g., 22 μg for a 1.5-kb fragment) using a restriction endonuclease that cuts at one end of region to be deleted.

Two separate preparations of linearized source vector::insert DNA are required, each for deletions from one end.

6. Verify that digestion went to completion by running a small aliquot on an agarose minigel.

For each set of deletions, the maximum amount of DNA that should be linearized is 28 to 30 μg , i.e., sufficient to construct deletions in a 2.0-kb fragment.

7. Clean up the restriction digest from step 5 by extracting with buffered phenol; add $\sim 1/10$ vol 3 M sodium acetate and precipitate with ethanol. Wash the pellets with ice-cold 70% ethanol, and dry. Resuspend the pellets in TE buffer at 1 $\mu\text{g}/\mu\text{l}$ and store at 4°C.

The final concentration of the DNA can be checked by reading the A_{260} of a sample diluted $\sim 1:200$ (APPENDIX 3).

Determine the sensitivity of each batch of linear source vector::insert DNA to digestion using Bal 31 nuclease

The following steps are necessary because base composition of the DNA and impurities (such as RNA) can affect the rate of Bal 31 digestion and because Bal 31 may lose activity during storage.

8. Mix 2 μl (2 μg) linearized DNA, 38 μl water, and 5 μl of 10 \times Bal 31 nuclease buffer, and aliquot 9 μl of resulting mixture into five microcentrifuge tubes. To each tube add 1 μl of either 1 \times Bal 31 buffer or Bal 31 nuclease diluted $1/5$, $1/10$, $1/20$, or $1/40$ in 1 \times Bal 31 buffer.
9. Incubate each reaction 30 min at 37°C, then stop the reactions by adding 1 μl of 200 mM EGTA to each and heating 5 min at 65°C.

EGTA chelates Ca^{++} required by Bal 31.

10. Analyze the samples by agarose gel electrophoresis (a minigel is acceptable; see UNIT 2.5A) to determine the dilution of Bal 31 nuclease that completely digests the DNA in the 30-min incubation.

DNA samples typically require 0.03 to 0.10 U Bal 31 nuclease per μg linearized DNA. As the digestion proceeds, the DNA bands first decrease uniformly in size, but gradually become increasingly diffuse before becoming completely digested. Electrophoresing in the presence of ethidium bromide saves time.

DAY TWO: Create a nested set of deletions (Fig. 7.2.3, step 2)

Perform Bal 31 digestions on each of the linearized source vector::insert DNA preparations (from step 5). Use 2 μg DNA of each for each 150 bp to be deleted. Use the amount of Bal 31 nuclease previously determined (steps 8 to 10) to completely digest the DNA. The protocol assumes that 1-min time points will be taken.

11. For each 150 bp to be deleted, mix 2 μl (2 μg) linearized DNA, 43 μl water, and 5 μl of 10 \times Bal 31 nuclease buffer.
12. Preheat diluted DNA by incubating 10 min at 37°C.
13. For each linearized DNA preparation, set aside a 1.5-ml microcentrifuge tube for each time point (i.e., one tube for each 2 μg DNA to be subjected to Bal 31 digestion).

Add 5 μ l of 200 mM EGTA to each tube and label tubes to indicate the linearized species and the *Bal* 31 digestion time.

14. Add *Bal* 31 nuclease of the determined amount to the tube of linearized DNA, vortex gently, and incubate at 37°C. Every minute, transfer 45 μ l to the appropriately labeled tube from step 13 containing 200 mM EGTA and place at room temperature.

The digestion described should generate 150- to 200-bp deletions; the time interval or the amount of enzyme can be adjusted. We recommend taking time points for no longer than 10 to 12 min. At longer digestion times, the DNA bands that form following electrophoresis (see step 18 annotations below and Fig. 7.2.4) become too diffuse to be eluted efficiently from an agarose gel.

Repeat steps 11 to 14 for each preparation of linearized source vector::insert DNA, one set of deletions from each end of the insert DNA.

15. After all *Bal* 31 digestions have been collected, incubate them 5 min at 65°C.

Figure 7.2.4 Ethidium bromide–stained agarose gel depicting successive digestion of a linearized M13mp vector::insert with *Bal* 31 nuclease. Following *Bal* 31 digestion for increasing amounts of time (1-min time points, left to right), the M13mp vector::insert was digested with a restriction enzyme that separated the vector (upper band) from the DNA fragment of interest (lower band). Digested fragments appear as increasingly diffuse bands with increased digestion time. The molecular weight markers on the right are the 1-kb ladder available from Gibco/BRL; the size of the deleted insert varied from ~2.0 kb to ~1 kb.

Separate digested insert and vector sequences (Fig. 7.2.3, step 3)

16. Add 2 μ g of 1 mg/ml yeast tRNA to each tube and ethanol precipitate the samples using 3 M sodium acetate. Dissolve the washed and dried pellets in 20 μ l of the appropriate restriction endonuclease buffer for the next step.

*Optional: Before digestion with the second restriction endonuclease, the *Bal* 31–treated ends can be repaired with Klenow fragment of DNA polymerase to create blunt ends (see UNIT 3.5). This will increase the efficiency of ligations for subcloning. The reaction can take place in most restriction endonuclease buffers. Inactivate the Klenow fragment by heating the reaction mix at 75°C for 10 to 15 min before proceeding to the next step.*

17. Digest each of the DNA samples with the restriction endonuclease whose recognition site was protected from *Bal* 31 digestion (i.e., flanking the insert opposite the site used for linearization).

Subject digested DNA samples to electrophoresis (Fig. 7.2.3, step 4)

18. Add 2 μ l of 10 \times loading buffer to each digested DNA sample and subject to electrophoresis on low gelling/melting temperature agarose, including ethidium bromide in the gel and buffers. Also run a lane of molecular weight markers spanning the size of the fragment to be sequenced.

This gel can be run overnight at low voltage. If an M13mp source vector has been used, run a 1% gel and allow bromphenol blue dye to migrate ~4 cm. This gives good separation between vector and insert.

Because electrophoresis buffer and chambers can develop nuclease contamination, when fragments will be isolated from gels for subsequent cloning it is desirable to use autoclaved 50 \times TAE for preparing buffers and casting gels.

The digested fragments should appear as increasingly diffuse bands with increased digestion time (see Fig. 7.2.4).

DAY THREE: Elute Bal 31–digested fragments from gel

19. Using a longwave UV (354-nm) lamp and the molecular weight markers as a guide (and minimizing exposure to UV light), cut out a series of DNA fragments (usually the entire band of digested insert DNA) differing in molecular weight by 150 to 200 bp from each lane (Fig. 7.2.4) and place in individual microcentrifuge tubes.
20. Add TE buffer to ~400 μ l total volume for each tube, incubate at 65 $^{\circ}$ C until all the agarose melts (about 5 to 10 min), and extract with 1 ml buffered phenol by vortexing at low speed for 30 sec.

When extracting agarose, it is important to obtain sufficient mixing for equilibration between the phenol and water (i.e. vortex vigorously for 2 full min). Do not use phenol/chloroform or phenol/chloroform/isoamyl alcohol; they will not extract efficiently.

21. Repeat the phenol extraction on the aqueous phase combined with its milky interface which, after the second extraction, will become much less abundant. If a significant amount of interface remains, repeat extraction a third time.
22. Precipitate with 95% ethanol. Add 2 μ g of 1 mg/ml yeast tRNA, if desired. Dissolve the washed and dried pellets in 30 μ l TE buffer and store at 4 $^{\circ}$ C.

Low gelling/melting temperature agarose is very reliable for isolating fragments for subsequent ligations. It is sometimes possible to save time by diluting melted slices to <0.1% agarose and ligating without extraction and precipitation of the DNA. Refer to UNIT 2.6 for alternative methods of purifying DNA from agarose gels.

Ligate eluted Bal 31–digested fragments to sequencing vector (Fig. 7.2.3, step 6)

23. Add 3 to 8 ml of each DNA sample eluted from the agarose gel to appropriate sequencing vector DNA prepared in step 3. Include as a control one sample which contains vector DNA alone. Add 1 ml of 10 \times T4 DNA ligase buffer and adjust the final reaction volume to 10 ml. Add ~0.5 ml T4 DNA ligase and incubate overnight at 4 $^{\circ}$ C.

20 to 40 ng of M13mp and pUC sequencing vectors is sufficient. A convenient concentration of sequencing vector DNA is 20 μ g/ml; therefore, 1 to 2 μ l would be added to the Bal 31–digested DNA. The sample containing vector DNA alone controls for the amount of vector DNA that was not fully digested with both restriction endonucleases; such molecules can recircularize and be ligated.

The amount of Bal 31–digested DNA used in this ligation should be chosen according to the recovery of the DNA from the agarose gel. Three microliters would be used for >90% recovery.

A large amount of ligase is required for the blunt-end ligation.

If planning to sequence double-stranded templates, follow steps 24 and 25. If using M13mp vector, proceed to step 26.

DAY FOUR (DOUBLE-STRANDED TEMPLATE): Transform ligated DNAs into competent *E. coli*

24. Transform 100 μ l of competent cells (JM109, DH5 α F' or equivalent from step 4) with 5 to 10 μ l of each ligation reaction (from step 23). In addition, transform with sequencing vector DNA untreated with ligase, as described in step 25. Following heat-shock of transformation protocol, spread $\frac{1}{5}$ of each of the cultures on LB plates containing the appropriate antibiotic and incubate overnight at 37°C.

The hosts described above are appropriate for sequencing vectors that allow a positive screen for inserts using alpha-complementation of β -galactosidase. In this case, include Xgal/IPTG in the LB plates (UNIT 1.1).

DAYS FIVE AND SIX (DOUBLE-STRANDED TEMPLATE): Characterize recombinant plasmid clones and prepare double-stranded plasmid templates for DNA sequencing.

25. If there are many colorless (not blue) colonies, proceed with steps 15 to 18 in the first basic (exo III) protocol. Pick two to four colorless colonies from each time point and grow in LB medium containing the appropriate antibiotic.

If using an M13mp sequencing vector and planning to carry out dideoxy sequencing using single-stranded templates, proceed with steps 26 to 30.

DAY FOUR (SINGLE-STRANDED TEMPLATE): Transform ligated DNAs into *E. coli* MC1061 Strain MC1061 is recommended because of its high transformation frequency; however, other hosts can be used (see step 4).

26. Mix each of the ligation reactions with 40 μ l of competent cells.

If the vector was not treated with phosphatase, many more plaques—predominantly blue—may result. Under these circumstances, transform with $\leq \frac{1}{4}$ of each ligation reaction.

27. In addition, transform with M13mp sequencing vector (Fig. 7.2.3, step 6) cut with *Sma*I and additional enzyme, untreated with ligase.

The sample not treated with ligase controls for the amount of undigested M13mp sequencing vector molecules that will form blue plaques.

Other controls: Also transform with 0.5 ng of the M13mp RF sequencing vector used to subclone the Bal 31-deleted fragments and the source vector::insert clones carrying the undeleted fragment. Expect nearly a lawn of M13 plaques with the RF control DNA.

28. Following the heat shock step in the transformation protocol, add 0.2 ml of an overnight culture of *E. coli* JM109, DH5 α F', or equivalent in LB medium or 2 \times TY medium. Pipet contents into 3 ml of room temperature H top agar containing 60 μ l Xgal/IPTG solution, mix, and pour on LB plates.

Prior to pouring top agar, it is essential to prewarm LB plates to at least room temperature to retard setting of the top agar.

29. After the top agar hardens, incubate plates upside down overnight at 37°C.

It is essential to incubate plates at 37°C for plaques to form.

Each transformation should result in ~100 colorless plaques. Depending on the fidelity of vector preparation, these will be accompanied by zero to many blue plaques.

DAYS FIVE AND SIX (SINGLE-STRANDED TEMPLATE): Characterize recombinant phage and prepare single-stranded templates for DNA sequencing

30. If there are many colorless (not blue) plaques, proceed as in steps 21 to 26 in the previous basic (exo III) protocol. Picking two plaques for each time point and two plaques from each of the control plates is usually sufficient.

If only a few colorless plaques are present, they may not be the desired recombinants. The presence of inserts detected by electrophoresis will resolve the issue, as will "C testing" (see step 22 in the exo III protocol).

PREPARATION OF M13mp SEQUENCING VECTOR DNA FOR SUBCLONING OF BAL 31-DIGESTED DNA FRAGMENTS

**SUPPORT
PROTOCOL**

This protocol provides an example of the preparation of M13mp 18 or M13mp 19 vector DNA for subcloning *Bal* 31-digested DNA fragments. The vector DNA is first digested with a restriction endonuclease generating a blunt end (in this example *Sma*I) which is compatible with *Bal* 31-digested ends. In a second step, the vector DNA is digested with a restriction endonuclease generating a sticky end which is compatible with the sticky end on the opposite end of the *Bal* 31-digested fragment.

Materials

M13mp18 or M13mp19 (UNITS 1.14 & 1.15)

*Sma*I restriction endonuclease and buffer (UNIT 3.1)

Buffered phenol

Ice-cold 100% ethanol

70% ethanol

Appropriate restriction endonuclease (Fig. 7.2.3) and buffer

Calf intestine phosphatase (CIP; UNIT 3.10; optional)

TE buffer (APPENDIX 2)

Additional reagents and equipment for restriction enzyme digestion (UNIT 3.1) and phenol extraction and ethanol precipitation (UNIT 2.1)

1. For each 10 µg of DNA that will be subjected to *Bal* 31 digestion, digest 1 µg of mp18 and/or mp19 with *Sma*I.

It is important to determine the minimal amount of SmaI needed to linearize the vector; too much SmaI can damage ends and prevent subsequent ligation. Usually, ~2 U SmaI per microgram of mp18 or mp19 DNA for 60 min at 37°C is sufficient.

Alternatively, DNA polymerase (UNIT 3.5) or single-stranded nuclease (UNIT 3.12) can be used to convert a sticky end to a blunt end.

2. Extract with buffered phenol and precipitate with ethanol as in UNIT 2.1.

If the DNA preparations are really clean, it may be necessary to add 1 to 2 µg yeast tRNA before precipitation to see the pellets.

3. Digest the *Sma*I-linearized sequencing vector with the restriction enzyme whose site flanks the insert DNA and which will be protected from *Bal* 31 digestion in that set of deletions (Fig. 7.2.3, step 5). Use the minimum amount of enzyme necessary. If desired, remove phosphate groups by adding ≤0.2 µl CIP (~5 U) for the last 20 min of the digestion with the chosen restriction endonuclease.

Two separate preparations of sequencing vector DNA are required, each for a set of deletions from one end.

The following restriction buffers work for this procedure: 10 mM Tris·Cl (pH 7.5), 10 mM MgCl₂, and 10 to 150 mM NaCl. A vast excess of phosphatase is used, allowing the use of a suboptimal buffer. Phosphatase treatment sometimes results in a nonfunctional vector. If

DNA Sequencing

7.2.17

dephosphorylation is omitted, transform with less DNA in the second basic protocol (steps 25 or 29).

4. Extract with buffered phenol, precipitate with ethanol, and dissolve in 50 μ l TE buffer. Stored at -20°C , such vectors last months.

REAGENTS AND SOLUTIONS

1 \times exonuclease III buffer

15 mM Tris·Cl, pH 8.0
0.66 mM MgCl_2

Exo III ligation buffer

80 mM Tris·Cl, pH 7.5
30 mM dithiothreitol (DTT)
20 mM MgCl_2
Store at -20°C

Phage loading buffer

0.25% bromphenol blue
15.0% Ficoll 400
2.0% sodium dodecyl sulfate (SDS)
10 mM EDTA
Store at room temperature

S1 nuclease buffer

16 mM sodium acetate, pH 4.6
400 mM NaCl
1.6 mM ZnSO_4
8% glycerol

S1 nuclease stop buffer

0.8 M Tris·Cl, pH 8.0
20 mM EDTA, pH 8.0
80 mM MgCl_2

10 \times Bal 31 buffer

2.0 M NaCl
0.2 M Tris·Cl, pH 8.0
0.12 M MgCl_2
0.12 M CaCl_2
0.02 M EDTA

COMMENTARY

Background Information

Exonuclease III. The experimental strategy of the exo III method is based on the unique properties of *E. coli* exo III, which is a 3'→5' double-stranded, specific exonuclease that catalyzes release of 5' nucleotides from the 3' hydroxy end of double-stranded DNA (see UNIT 3.11 and Fig. 3.11.3). Blunt DNA ends (e.g., created by *Sma*I) or overhanging 5' ends (e.g., created by *Hind*III, *Xba*I, *Bam*HI) are substrates for an exo III attack. However, exo III will not efficiently initiate digestion at an overhanging 3' end of four bases created

by restriction enzymes such as *Apa*I, *Sac*I, *Kpn*I, and *Bst*XI. The 3' overhang generated by *Pst*I digestion is not adequately protected from exo III digestion. Exo III also will not digest ends of DNA that contain an [α - ^{35}S]dNMP (see first support protocol). Thus, a cloned fragment of DNA can be specifically digested with exo III if it is adjacent to a 5' overhanging end or blunt end, whereas a primer sequencing site and vector DNA can be protected from digestion if they are adjacent to a 3' overhanging end or an end "capped" with a-thio nucleotide analog. A third method of protecting DNA from exo III digestion by *lac* repressor bound at *lac* operator site has recently

been shown (Johnson et al., 1990).

Exo III is particularly suited for generating nested sets of deletions because of the synchrony and uniformity of its exonucleolytic activity (see Fig. 7.2.2).

The exo III method has one major advantage over the *Bal* 31 nuclease method (Poncz et al., 1982; Guo and Wu, 1982) for constructing nested sets of deletions. The *Bal* 31 procedure requires subsequent recloning of the set of digested fragments; in contrast, the exo III procedure is carried out on a single linearized plasmid and is followed by relegation. Double digestion of the DNA, exo III treatment, and relegation can be accomplished in 3 hr (Hoheisel and Pohl, 1986). Another advantage of the exo III procedure over the *Bal* 31 procedure is that larger DNA fragments (up to 14 kb; Henikoff, 1984) can be easily subjected to construction of progressive deletions. On the other hand, the exo III procedure depends on the availability of appropriate restriction sites between the insert and primer site. If the required sites are not available for the exo III procedure, the *Bal* 31 procedure can be used.

***Bal* 31 exonuclease.** The basis of this method is the ability of *Bal* 31 nuclease to progressively shorten a DNA restriction fragment, generating blunt ends that can be ligated with phage T4 DNA ligase. Because *Bal* 31 digestion continues in a nearly linear fashion for up to 10 to 15 min, a nested set of deletions can be easily created. This method is appropriate for DNA fragments that do not have the required arrangement of restriction sites for exo III digestion. All that is needed is that the DNA fragment be flanked by unique restriction sites.

Critical Parameters and Troubleshooting

For phage preparations of M13mp clones and DNA preparations of M13mp or plasmid sequencing templates, refer to *UNIT 7.3*. When examining M13mp phage DNA for inserts, optimum resolution is achieved when large gels are run for 10 to 15 hr at low voltage.

Exonuclease III. It is important to start with a highly purified DNA preparation that has been subjected to two rounds of CsCl/ethidium bromide centrifugation. Preexisting nicks in the DNA will create a substrate for exo III and S1 nuclease, leading to nonspecific degradation. During the double-digestion step, it is very important that the DNA is completely digested. Choosing restriction sites as far apart as possible increases the probability of obtaining a complete digestion.

If the yield of DNA from longer digestion times turns out to be disproportionately low, the exo III is probably contaminated with other nucleases. A high background of randomly deleted clones is another sign of nuclease contamination in the exo III, the restriction enzymes, or the S1 nuclease. Because the activity of exo III is very sensitive to temperature, the temperature of the reaction can be varied between 30° and 40°C to achieve a satisfactory rate of digestion. It is advantageous to fix time points (30 to 60 sec) and adjust the temperature to obtain the desired deletion interval. The rate of exo III digestion can also be regulated by including NaCl in the digestions (Tomb and Barcak, 1989).

The final concentration of NaCl in the ligation reaction is somewhat inhibitory for T4 ligase, but a sufficient number of deleted clones should be obtained. If poor ligation efficiency results in few transformants, the DNA can be precipitated from 3.75 M ammonium acetate and two vol of ethanol. Alternatively, the ligation volume can be increased to dilute the NaCl.

***Bal* 31 exonuclease.** It is important to start with a highly purified DNA preparation, because *Bal* 31 is very sensitive to RNA contamination. If RNA contamination is suspected after one round of CsCl-ethidium bromide centrifugation, the DNA should be purified through a second gradient. Complete linearization of the plasmid DNA—by excessive treatment with the appropriate restriction endonuclease to the extent that the ends are damaged—should theoretically not be a problem, as *Bal* 31 will convert a damaged end into a blunt end suitable for ligation.

The number of nucleotides separating the ends of the deletions can be varied by adjusting the amount of *Bal* 31 used and the time of digestion, and by the use of commercially available preparations of *Bal* 31 that are characterized as “fast” or “slow.” If insufficient digestion occurs with *Bal* 31, repeat the procedure using a higher concentration of enzyme.

Some researchers improve the quality of the *Bal* 31-generated ends by filling out with Klenow fragment (see annotation to step 16) or by digestion with S1 nuclease or mung bean nuclease before digestion with the second restriction enzyme (*UNIT 3.12*). Using MC1061 seems to eliminate this requirement, because of its high transformation frequency. If low numbers of transformants are obtained, that optional step can be performed.

EGTA very effectively stops *Bal* 31 digestion by chelating Ca⁺⁺; however, it also inhibits

subsequent digestion with a variety of restriction enzymes. Therefore, it is very important to ethanol precipitate samples carefully after the addition of EGTA. This will allow digestion with minimal amounts of restriction enzymes, thus providing high-quality ends for subsequent ligation reactions.

Successful cloning of *Bal 31*-digested fragments into sequencing vectors also depends on using the minimal amount of restriction endonuclease treatment to prepare the sequencing vector for ligation. Unfortunately, because the sequencing vector is first cut with *Sma*I (or other restriction enzyme generating a blunt end) and then with a second enzyme that cuts only a few bases away in the polylinker, it is difficult to determine the extent of cleavage of the second enzyme. Sequencing vectors suitable for ligation are best prepared by individually titrating each restriction enzyme with uncut sequencing vector to determine the minimal amount to completely digest the DNA. If necessary, check the ability of ligase to circularize the cut sequencing vector following *Sma*I digestion and again following digestion with the second enzyme. There should be a dramatic decrease in the sequencing vector's ability to be self-ligated following treatment with the second enzyme. The doubly-digested sequencing vector can be treated with calf intestine phosphatase (*UNIT 3.10*) to further reduce self-ligation. Alternatively, it can be separated from the small piece of DNA between the two restriction sites by electrophoresis on low gelling/melting temperature agarose (see steps 18 to 22). Excess prepared sequencing vector should last for months or years if kept frozen.

Time Considerations

Exonuclease III. Starting with CsCl/ethidium bromide-purified plasmid DNA, it takes 3 or 4 days to generate and characterize a set of 30 overlapping fragments of a 3.0-kb target DNA.

Bal 31 exonuclease. Starting with CsCl/ethidium bromide-purified plasmid DNA, it takes ~6 days to generate a set of 20 ordered fragments for a 2.0-kb insert of interest.

Preparation of Templates for DNA Sequencing

UNIT 7.3

This unit contains protocols for preparing DNA suitable for use as dideoxy sequencing templates and as material for end labeling and chemical sequencing. In all protocols, the starting material contains the recombinant molecule to be sequenced. DNA from M13mp-derived phage is easily prepared (first basic protocol) and is currently the most reliable source of template for large-scale dideoxy sequencing projects. Because it is occasionally necessary or convenient to use a λ -derived phage as a source of DNA, a protocol for preparing λ phage DNA from plate lysates is provided (second basic protocol). Two protocols for minipreps of plasmid DNA are provided, one intended for dideoxy sequencing, the other for end labeling and chemical sequencing (third and fourth basic protocols); they differ primarily in the way in which cellular RNA is removed. Protocols for preparing the products of the polymerase chain reaction (PCR) for dideoxy sequencing are provided in *UNIT 15.2*.

Any double-stranded template used in dideoxy sequencing should be denatured before being annealed to the primer. In general practice, alkali denaturation of plasmid DNA works better for sequencing than heat denaturation (Chen and Seeburg, 1985; Zagursky et al., 1985; Hattori and Sakaki, 1986; Zhang et al., 1988); thus, alkali denaturation of double-stranded DNA is described in this unit (fifth basic protocol). In contrast, heat denaturation of PCR products can be important in generating reliable sequencing templates (*UNIT 15.2*). A final protocol describes the preparation of template for thermal cycle sequencing from a single phage plaque or bacterial colony.

PREPARATION OF SINGLE-STRANDED M13 PHAGE DNA

Single-stranded M13mp DNA to be sequenced by the dideoxy method is prepared from *E. coli* DH5 α F' (or equivalent *E. coli* F' host) infected with an M13mp plaque. Because M13mp clones are sometimes susceptible to DNA rearrangements, we recommend preparing the template DNA from a single isolated plaque. The plaque should be purified shortly before use by transformation of competent *E. coli* cells with a ligation mixture (such as would come from construction of nested deletions, *UNIT 7.2*) or M13 RF DNA or single-stranded DNA. A stock of M13 phage can be replated to give individual plaques. An alternative to plaque purification is to infect the *E. coli* host with a phage suspension. Because this method bypasses the plaque purification step, it should be kept in mind as a source of background bands in sequencing ladders generated from such DNA templates (see *UNIT 7.4*, troubleshooting).

Cells are harvested and phage are precipitated from the culture supernatant with polyethylene glycol and high salt. Single-stranded viral DNA is then extracted from the phage with phenol and ethanol precipitated. If the single-stranded M13mp DNA obtained using the procedure described below is not clean enough (i.e., insufficient label is incorporated during the sequencing reactions or the sequencing gels have a high background), the optional annotations to the steps should be followed.

Materials

- E. coli* DH5 α F' (or equivalent; Table 1.4.5), competent (*UNIT 1.8*) and overnight cultures in LB medium (*UNITS 1.1 & 1.2*)
- Recombinant M13mp RF DNA or M13mp single-stranded DNA (*UNIT 1.15*)
- H top agar (*UNIT 1.1*)
- LB plates (*UNIT 1.1*), 37°C
- 2 \times TY medium (*UNIT 1.1*)
- M13 polyethylene glycol (PEG) solution

**BASIC
PROTOCOL**

DNA Sequencing

7.3.1

TE buffer (*APPENDIX 2*)
Buffered phenol (*UNIT 2.1*)
3 M sodium acetate, pH 5.2 (*APPENDIX 2*)
100% ethanol and 70% ethanol, ice-cold
Pasteur pipets, regular and drawn-out (sterile)
18 × 150–mm tubes
Additional reagents and equipment for transformation (*UNIT 1.8*), cell growth (*UNIT 1.2*), and agarose gel electrophoresis (*UNIT 2.5*)

Grow M13mp phage

1. If starting with M13 RF DNA or M13 single-stranded DNA, transform 40 μ l competent *E. coli* DH5 α F' with ~0.5 ng recombinant M13mp RF DNA or with 5 to 10 ng single-stranded DNA. Following the heat-shock step, add 0.2 ml of an overnight *E. coli* DH5 α F' culture to the transformed cells. Pipet the cells into 3 ml of H top agar, mix, and pour onto 37°C LB plates. Incubate upside-down overnight at 37°C.

It is essential to incubate plates at 37°C for plaques to form. Xgal and IPTG can be added to the top agar to detect contaminating wild-type plaques (which will be blue; recombinant plaques will be clear).

Single-stranded DNA transforms much less efficiently than double-stranded DNA.

*If transforming with a ligation mixture for creating nested deletions (UNIT 7.2), follow steps 19 and 20 in the exo III protocol or steps 26 through 29 in the Bal 31 procedure, using appropriate *E. coli* host.*

*To purify individual plaques from a previously prepared phage stock, titer stock on an overnight culture of *E. coli* F' cells (UNIT 1.15).*

2. Dilute an overnight *E. coli* DH5 α F' culture 100-fold with 2× TY medium and dispense 1.5-ml aliquots into loosely capped 18 × 150–mm tubes.
3. Pick one M13mp plaque with a sterile Pasteur pipet and expel it into one of the cultures. Be sure that a plug of agar is transferred. Repeat for each plaque.

Alternatively, each culture can be inoculated with a “loopful” of phage from a previously prepared M13 phage stock that has been stored in 15% glycerol at –20°C.

4. Grow cells 5 to 6 hr at 37°C (preferably on a roller drum).

To decrease the chance of defective phage production, do not incubate >8 hr. Defective phage, which arise spontaneously, are secreted into the medium and can reinfect cells in which the recombinant clone is growing, thereby creating a mixed population of template DNA.

Harvest cells and precipitate phage

5. Transfer cells to a 1.5-ml microcentrifuge tube and microcentrifuge at high speed for 5 min at 4°C to room temperature. Transfer supernatant to a clean 1.5-ml microcentrifuge tube.

*Supernatants can be stored at 4°C for several weeks. If this is done, microcentrifuge the stored supernatants at high speed (there will be some cell growth, even at 4°C) before proceeding to the next step, and transfer supernatant to a clean 1.5-ml microcentrifuge tube. The presence of *E. coli* chromosomal DNA in the stored supernatants interferes with sequencing reactions.*

6. Add 200 μ l of M13 PEG solution to the phage supernatant, mix, and incubate 15 min at room temperature.
7. Microcentrifuge 5 min at high speed and discard the supernatant.

A white pellet should be visible. The pellet will not be disturbed by vigorous shaking.

8. Microcentrifuge 30 sec at high speed and remove any remaining supernatant with a drawn-out Pasteur pipet.

It is critical to remove all traces of the PEG supernatant.

It is optional to resuspend pellet in 500 μ l TE buffer; this provides further purification of phage particles from cellular contaminants. Add 100 μ l of M13 PEG solution, mix well, and leave 15 min at room temperature. Repeat steps 7 and 8.

Prepare single-stranded DNA from phage

9. Resuspend phage pellet in 100 μ l TE buffer.

If many samples are being prepared, PEG pellets can be resuspended in TE buffer by placing all tubes in a suitable rack and vigorously shaking rack by hand.

10. Extract with 100 μ l buffered phenol by vortexing 15 to 20 sec at low speed. Microcentrifuge at high speed 5 min at 4°C to room temperature and transfer upper (aqueous) phase to a clean microcentrifuge tube.

It is optional to extract upper phase with 100 μ l chloroform.

11. Add 11 μ l of 3 M sodium acetate, pH 5.2, and 250 μ l of 100% ethanol. Freeze 20 min at -70°C.

12. Microcentrifuge at high speed 10 min, 4°C, and discard supernatant.

13. Add 100 μ l ice-cold 70% ethanol, microcentrifuge, and remove supernatant. Repeat this 70% ethanol wash once.

It is optional to wash the ethanol precipitate with 100% ethanol to remove phenol remaining in the aqueous phase.

14. Dry DNA pellet in a Speedvac evaporator.

Single-stranded DNA pellets as an arched film, most readily seen after tubes are dry.

15. Resuspend pellet (2 to 3 μ g) in 20 μ l TE buffer. Electrophorese 0.5 μ l on a minigel to confirm the DNA concentration. Store the remainder at -20°C until used as template for sequencing reactions (UNIT 7.4).

Dissolve the DNA film in TE buffer by simply pipetting buffer over the film until the drop moves freely over the tube surface.

PREPARATION OF λ DNA FROM SMALL-SCALE LYSATES

Phage are prepared from a plate lysate using agarose in place of agar in both the top agarose and plates. The phage are precipitated with polyethylene glycol and high salt, then lysed in SDS and EDTA. Phage DNA is then extracted with phenol and chloroform and precipitated with isopropanol.

Materials

Recombinant λ phage

E. coli strain appropriate for λ phage of interest

Lambda top agarose and agarose plates (i.e., substitute agarose for agar; UNIT 1.1), freshly prepared on the day of use

1 mg/ml DNase I (UNIT 3.12)

1 mg/ml RNase A, heat-inactivated (see reagents and solutions)

Lambda polyethylene glycol (PEG) solution

SM medium (UNIT 1.11)

10% sodium dodecyl sulfate (SDS)

Buffered phenol (UNIT 2.1)

0.5 M EDTA

BASIC PROTOCOL

DNA Sequencing

7.3.3

1:1 phenol/chloroform
Chloroform
3 M sodium acetate, pH 7.0
Isopropanol
TE buffer, pH 8.0 (*APPENDIX 2*)
Pasteur pipets, drawn out (sterile)

Additional reagents and equipment for preparing and titering a λ phage plate lysate (*UNITS 1.11 & 1.12*)

Prepare λ phage stock

1. Prepare the recombinant λ phage stock on an *E. coli* strain appropriate for the λ phage by plate lysis using freshly prepared lambda top agarose and lambda agarose plates.

It is critical to use agarose in place of agar to yield DNA suitable for sequencing and restriction endonuclease analysis. Use one freshly prepared lambda agarose plate per phage stock. If freshly prepared agarose plates are unavailable or inconvenient, older plates may be substituted. Add 5 ml sterile SM buffer to the plate and allow the buffer to soak into the plate for 15 min. Remove excess buffer with a sterile pipet. Take care after pouring the top agarose, since it is loosely attached to the bottom agarose; incubate the plates right-side up.

2. Titer the λ phage stock—the titer should be $>10^9$ pfu/ml.
3. Place 700 μ l of phage stock in a sterile 1.5-ml microcentrifuge tube. Add 1 μ l of 1 mg/ml DNase I and 1 μ l of 1 mg/ml heat-inactivated RNase A. Incubate 30 min at 37°C.

This step removes cellular DNA and RNA that might remain in the medium.

Precipitate the phage

4. Add 700 μ l lambda PEG solution and incubate 1 hr on ice.

Do not incubate >4 hr or contaminating chromosomal DNA will precipitate.

5. Microcentrifuge at high speed 10 min at 4°C and pour off supernatant.
6. Microcentrifuge at high speed 2 min at 4°C and remove any remaining supernatant with a drawn-out Pasteur pipet.
7. Resuspend phage pellet in 500 μ l SM medium.

If the pellet remains undissolved, it will dissolve in the next step.

Prepare DNA from phage

8. Add 5 μ l of 10% SDS and 0.5 μ l of 0.5 M EDTA to the solution and mix gently. Incubate 15 min at 65°C. Periodically mix gently to dissolve any remaining pellet.
9. Extract with 500 μ l buffered phenol by vigorous vortexing. Microcentrifuge at high speed 2 min at room temperature and transfer upper (aqueous) phase to a clean microcentrifuge tube.
10. Repeat step 9 using 500 μ l of 1:1 phenol/chloroform.
11. Repeat step 9 using 500 μ l chloroform.
12. Add 50 μ l of 3 M sodium acetate, pH 7.0, followed by 550 μ l isopropanol. Freeze 30 min at -20°C .
13. Microcentrifuge at high speed 15 min at 4°C and aspirate and discard supernatant.

14. Air dry the DNA pellet.

The pellet will be invisible.

15. Resuspend pellet (~20 µg) in 50 µl TE buffer, pH 8.0.

16. For sequencing, denature 0.1 to 0.3 pmol (2 to 4 µg) in alkali as described in the fifth basic protocol.

MINIPREP OF RECOMBINANT pSP64CS OR pSP65CS PLASMID DNA FOR CHEMICAL SEQUENCING

**BASIC
PROTOCOL**

Recombinant DNA from pSP64CS or pSP65CS is prepared from a saturated culture after lysis, phenol extraction, and isopropanol precipitation. This miniprep procedure yields DNA suitable for end labeling and chemical sequencing. The method is simple, rapid, requires a minimum number of reagents (lysozyme digestion is eliminated), and conserves tubes. Other miniprep methods such as the boiling protocol (*UNIT 1.6*) may be used if the final plasmid preparation is free of bacterial genomic DNA (which can interfere with the end-labeling reaction).

Materials

LB medium containing 40 µg/ml ampicillin (*UNIT 1.1*)
E. coli strain carrying recombinant pSP64CS or pSP65CS
Tris/EDTA/glucose buffer
2 N NaOH
4% SDS
3 M sodium acetate, pH 6.0
10 µg/ml RNase A, heat-inactivated (see reagents and solutions)
25:24:1 phenol/chloroform/isoamyl alcohol (*UNIT 2.1*)
Isopropanol
70% ethanol
18 × 150–mm tubes

1. Inoculate 5 ml LB medium containing 40 µg/ml ampicillin in 18 × 150–mm tubes with an *E. coli* strain carrying recombinant pSP64CS or pSP65. Grow until saturated (usually overnight) at 37°C.
2. Transfer 1.5 ml to a microcentrifuge tube. Microcentrifuge 2 min and discard supernatant.
3. Resuspend pellet in 120 µl Tris/EDTA/glucose buffer by vigorously vortexing.

It is important to resuspend the entire pellet because the reagents used in subsequent steps will not penetrate clumps of bacteria.

4. To the pellet, add 8 µl of 2 N NaOH and 8 µl of 4% SDS and shake vigorously (but do not vortex).
5. Immediately add 22 µl of 3 M sodium acetate, pH 6.0, and shake as in step 4. Immediately microcentrifuge 10 min.
6. Use a pipettor tip to remove and discard the pellet. Microcentrifuge supernatant 2 min and transfer supernatant to a clean microcentrifuge tube.
7. Add 2 µl of 10 µg/ml heat-inactivated RNase A and incubate 10 min at 37°C.
8. Extract twice with 100 µl phenol/chloroform/isoamyl alcohol.
9. Add 1 vol isopropanol to the upper (aqueous) phase, mix, and wait 5 min.

DNA Sequencing
7.3.5

10. Microcentrifuge 5 min at high speed and discard supernatant.
11. Wash pellet twice with 1 ml of 70% ethanol, microcentrifuging each time before removing ethanol, then dry the pellet.
12. Resuspend in 20 μ l sterile water for use in end labeling and sequencing (UNIT 7.5).

**BASIC
PROTOCOL**

**MINIPREP OF DOUBLE-STRANDED PLASMID DNA FOR
DIDEOXY SEQUENCING**

CsCl/ethidium bromide-purified closed-circular DNA (UNIT 1.7) can be used directly as a template for double-stranded sequencing. If such purified DNA is available, proceed directly to the fifth basic protocol for denaturation of plasmid DNA.

Plasmid DNA prepared from log-phase cultures by various miniprep procedures is also suitable as a template if treated to remove excess RNA. This can be accomplished by precipitating the RNA and single-stranded DNA with LiCl as described in this protocol. Alternatively, plasmid DNA can be treated with RNase A (UNIT 3.13), followed by phenol extraction and ethanol precipitation (UNIT 2.1), or treated as in the previous protocol.

Materials

- LB medium containing appropriate antibiotic (UNIT 1.1)
- E. coli* strain carrying recombinant plasmid
- Tris/EDTA/glucose buffer
- 1.0% SDS/0.2 N NaOH
- 3 M sodium acetate, pH 4.8 (APPENDIX 2)
- Isopropanol
- TE buffer, pH 8.0 (APPENDIX 2)
- 4 M LiCl
- Buffered phenol (UNIT 2.1)
- Chloroform
- Isopropanol
- 70% ethanol, ice-cold
- TE buffer, pH 8.0 (APPENDIX 2)

Additional reagents and equipment for agarose gel electrophoresis (UNIT 2.5)

1. Inoculate 5 ml LB containing appropriate antibiotic with *E. coli* strain carrying the recombinant plasmid. Grow until culture is in mid-log phase at 37°C.

It is very important to use a mid-log-phase culture ($OD_{560} \cong 1$). Do not use saturated or overnight cultures.
2. Transfer 1.5 ml to a microcentrifuge tube. Microcentrifuge 2 min and discard supernatant.
3. Resuspend pellet in 150 μ l Tris/EDTA/glucose buffer and leave 5 min at room temperature.
4. Add 300 μ l of 1.0% SDS/0.2 N NaOH and mix by inverting ~15 times (do not vortex). Leave 5 min at room temperature.
5. Add 225 μ l of 3 M sodium acetate, pH 4.8, and mix by inverting ~15 times (do not vortex). Leave 45 min on ice.
6. Microcentrifuge at high speed 5 min. Transfer 650 μ l of supernatant to a clean microcentrifuge tube.
7. Add 650 μ l isopropanol. Mix and let sit 10 min at room temperature.

8. Microcentrifuge at high speed 5 min at room temperature, then decant and discard supernatant. Dry pellet in desiccator.
9. Resuspend pellet in 125 μ l TE buffer, pH 8.0, by vortexing. Add 375 μ l of 4 M LiCl and let stand 20 min on ice.
10. Microcentrifuge 5 min at 4°C. Transfer supernatant to a clean microcentrifuge tube.
11. Extract with 500 μ l buffered phenol by vigorous vortexing. Microcentrifuge at high speed 2 min at room temperature and transfer upper (aqueous) phase to a clean microcentrifuge tube. Repeat this extraction using 500 μ l chloroform.
12. Precipitate DNA with 2 vol isopropanol for 30 min at room temperature.
13. Microcentrifuge 5 min at high speed and decant and discard supernatant.
14. Vortex pellet in ~1 ml ice-cold 70% ethanol. Microcentrifuge at high speed 5 min, then decant and discard supernatant. Dry pellet.
15. Resuspend pellet in 50 μ l TE buffer, pH 8.0. Electrophorese 5 to 10 μ l on an agarose gel to verify purity and approximate DNA concentration.
16. For sequencing, denature ~0.5 pmol (10 to 45 μ l) in alkali as described in the fourth basic protocol.

ALKALI DENATURATION OF DOUBLE-STRANDED PLASMID DNA FOR DIDEOXY SEQUENCING

**BASIC
PROTOCOL**

Theoretically, it should be possible to denature double-stranded templates either by treating with alkali or by boiling and achieve equal results in sequencing. In practice, however, alkali denaturation of closed-circular double-stranded templates and λ templates usually gives superior results for dideoxy sequencing. In contrast, for PCR products heat denaturation seems to yield better results in dideoxy sequencing reactions (see *UNIT 15.2*).

In the procedure described below, a recombinant plasmid is denatured using NaOH. After adjusting the pH to ≤ 7.0 , the DNA is precipitated with ethanol, washed, and dried. The dried pellet is suitable to be added to annealing reactions prior to DNA sequencing reactions (*UNIT 7.4*).

Materials

Recombinant plasmid DNA (third and/or fourth basic protocol)
 2 M NaOH/2 mM EDTA
 3 M sodium acetate, pH 6.0
 95% and 70% ethanol
 0.5-ml microcentrifuge tubes

1. Add ~0.5 pmol of recombinant plasmid DNA to a 0.5-ml microcentrifuge tube. If the volume is >20 μ l, ethanol precipitate the DNA (*UNIT 2.1*) and redissolve in 20 μ l water. If the volume is ≤ 20 μ l, add water to bring the volume to 20 μ l.
0.5 pmol of a 5-kbp plasmid is ~1.6 μ g.
2. Add 2 μ l of 2 M NaOH/2 mM EDTA and gently mix by drawing up and down with a pipet. Incubate 5 min at 25° to 37°C.
3. Place sample on ice, add 7 μ l water, and mix thoroughly by drawing solution up and down with the pipettor.
4. Add 7 μ l of 3 M sodium acetate, pH 6.0 (to neutralize DNA solution). Mix thoroughly by drawing solution up and down with the pipettor. Check the pH of the solution by

DNA Sequencing
7.3.7

spotting 1 μ l on pH paper. Add 3 M sodium acetate, pH 6.0, in 1- μ l increments until the pH is \leq 7.0.

5. Add 75 μ l of 95% ethanol and place 10 min on dry ice.
6. Microcentrifuge 10 min, 4°C, and carefully remove and discard the supernatant.
Use caution when removing the ethanol because the DNA pellet may also be removed.
7. Add 400 μ l 70% ethanol. Microcentrifuge 10 min at 4°C, then carefully remove and discard the ethanol layer.
8. Dry pellet 10 min in a Speedvac evaporator. Store the pellet at 20°C (up to several weeks) until used as template for dideoxy sequencing reactions (UNIT 7.4).

BASIC PROTOCOL

PREPARATION OF PLASMID DNA FROM AN *E. COLI* COLONY OR PHAGE DNA FROM A PLAQUE FOR THERMAL CYCLE SEQUENCING

Plasmid DNA is prepared from a single *E. coli* colony or phage DNA from a single plaque after resuspension in Tris/EDTA/proteinase K. The supernatant contains enough DNA for one set of thermal cycle sequencing reactions using a 5'-end-labeled primer (Krishnan et al., 1991; Young and Blakesley, 1991; Sears et al., 1992).

Materials

Agar plate containing *E. coli* colonies carrying a recombinant plasmid *or* λ
or M13 recombinant phage plaques
Tris/EDTA/proteinase K
Sterile toothpick or glass rod

- 1a. *For E. coli colony:* add 12 μ l of Tris/EDTA/proteinase K mix to a 1.5-ml microcentrifuge tube. With a sterile toothpick or glass rod, transfer a single *E. coli* colony carrying a recombinant plasmid to this solution and vortex 15 sec.
- 1b. *For phage plaque:* add 12 μ l of Tris/EDTA/proteinase K mix to a 1.5-ml microcentrifuge tube. With a sterile toothpick, transfer a single plaque to this solution and vortex 15 sec.

Try to remove as little top agar as possible.

2. Incubate 15 min at 55°C, then 15 min at 80°C.
3. Place 1 min on ice.
4. Microcentrifuge 3 min and immediately transfer supernatant to a clean 1.5-ml microcentrifuge tube.
5. Use 9 μ l as the template DNA in the end-labeled thermal cycle sequencing protocols (UNIT 7.4). Store remainder at -20°C.

REAGENTS AND SOLUTIONS

Lambda PEG solution

20% (w/v) PEG 6000
2.5 M sodium acetate, pH 6.0

M13 PEG solution

20% (w/v) PEG 800
2.5 M NaCl

RNase A, heat-inactivated

Dissolve RNase A at 10 mg/ml in 10 mM Tris·Cl (pH 7.5)/15 mM NaCl. Heat 10 min at 80°C, slowly cool to room temperature, and store in aliquots at 20°C. Dilute to 1 mg/ml or 10 µg/ml as required.

Tris/EDTA/glucose buffer

25 mM Tris·Cl, pH 8.0
10 mM EDTA
50 mM glucose

Tris/EDTA/proteinase K

10 mM Tris·Cl, pH 7.5
1 mM EDTA
50 µg/ml proteinase K

Prepare fresh for each use at the final concentrations listed above using stock solutions of 1 mg/ml proteinase K and TE buffer, pH 7.5 (APPENDIX 2).

COMMENTARY

Background Information

Each protocol in this unit provides a specific application of a general method for preparing DNA that has been proven to be effective for DNA sequencing. *UNITS 1.15, 1.13 & 1.6* provide information about M13-, λ-, and plasmid-based vector systems, respectively, and preparation of each type of vector DNA.

Critical Parameters and Troubleshooting

General troubleshooting information is provided in the units referred to above. When preparing phage from M13mp clones, vigorous aeration during phage growth is required to obtain high titers. If low phage titers are a problem, 100 mM MOPS buffer, pH 6.5, may be added to the 2× TY medium used for growing the phage. High titers of λ phage (>10⁹ pfu/ml) are also crucial for a good DNA yield.

Following precipitation of the M13mp or λ phage with PEG, it is very important to remove as much PEG as possible before resuspending the phage pellet. Contaminating PEG will result in high background in sequencing gels. Phenol remaining in the aqueous phase is readily removed by washing the ethanol precipitates with 100% ethanol. This also hastens drying

and reveals the single-stranded DNA as an arched film.

In addition to PEG, many other cellular and reagent contaminants can interfere with dideoxy sequencing reactions and with the end-labeling reaction for chemical sequencing. In general, it is crucial to avoid contamination by cellular chromosomal DNA and RNA and to thoroughly wash all ethanol pellets. The M13mp protocol contains an optional PEG precipitation and chloroform extraction, which should be added to the procedure if DNA of insufficient quality for sequencing is obtained.

A common problem with double-stranded DNA preparations is the occurrence of nicks in the DNA, which appear to act as priming sites for DNA polymerase in dideoxy sequencing reactions. This may result in a background of “shadow” or “ghost” bands. Plasmid preparations can be checked for nicked or linear molecules by agarose gel electrophoresis (*UNIT 2.5*). By using an *E. coli* host, which is EndoI⁻, and being careful to prevent nuclease contamination during and after the DNA preparation, nicks in the DNA may be avoided. However, some plasmids, because of their size or origin of replication, appear to be more susceptible to nicking. If this occurs during the preparations

described in this unit, CsCl/ethidium bromide centrifugation (UNIT 1.7) can be used to purify the DNA. An alternative procedure, particularly useful for λ DNA templates, is to use 5'-end-labeled primers so that the only labeled oligonucleotides are those primed by the end-labeled primer (see UNIT 7.4). Linearization of supercoiled plasmid preparations before alkali denaturation has been reported to improve the quality of the sequencing ladder (Wang and Sodja, 1991).

When preparing DNA from a plaque for use in thermal cycle sequencing, it is important to use agar that does not contain inhibitors of thermostable DNA polymerases (GIBCO/BRL #M29450 Luria agar has given satisfactory results). In addition, plaque size is critical for obtaining a strong sequencing signal from one plaque. A large plaque (e.g., 2 mm from λ gt10) is required for an overnight exposure; a small plaque (e.g., from λ gt22A) may require a longer exposure.

For use as templates in thermal cycle sequencing, plasmid DNA should be purified by CsCl gradient, miniprep methods (UNITS 1.6 & 1.7), or mini-column chromatography (UNITS 2.1 & 2.10). DNA obtained from single-stranded M13 should be purified by PEG precipitation (UNIT 1.15), mini-column chromatography, or solid support purification procedures (Hultman et al., 1991; Kaneoka et al., 1991; Zimmerman et al., 1989). λ and cosmid DNA should be purified using CsCl gradient protocols or miniprep methods (UNIT 1.13). To use PCR products as templates, remove excess primers and nucleotides from double- and single-stranded products after completing the reaction by glass bead procedures or exclusion methods (UNIT 2.1), gel purification (UNIT 2.6), or the drop dialysis method (Silhavy et al., 1984).

Anticipated Results and Time Considerations

UNITS 1.15, 1.13 & 1.6 provide general information about anticipated results and time considerations for preparation of M13, λ , and plasmid DNA, respectively. Double-stranded plasmid DNA can be denatured with alkali and prepared for annealing reactions in ~1 hr.

DNA Sequencing by the Dideoxy Method

In the basic dideoxy sequencing reaction, an oligonucleotide primer is annealed to a single-stranded DNA template (prepared by one of the methods described in *UNIT 7.3*) and extended by DNA polymerase in the presence of four deoxyribonucleoside triphosphates (dNTPs), one of which is ^{35}S -labeled. The reaction also contains one of four dideoxyribonucleoside triphosphates (ddNTPs), which terminate elongation when incorporated into the growing DNA chain (see introduction to Chapter 7 for a general overview of dideoxy sequencing). After completion of the sequencing reactions, the products are subjected to electrophoresis on a high-resolution denaturing polyacrylamide gel and then autoradiographed to visualize the DNA sequence (protocols for pouring, running, and processing sequencing gels are provided in *UNIT 7.6*). Reading and interpretation of sequencing gels are discussed (see Commentary).

Three variations of the dideoxy sequencing procedure are currently in use and are presented in this unit. In the “labeling/termination” procedure (see Basic Protocol 1), primer chains are initially extended and labeled in the absence of terminating ddNTPs, whereas in the traditional “Sanger” procedure (see Basic Protocol 2), labeling and termination of primer chains occur in a single step (see Fig. 7.0.2). The Commentary provides a more detailed comparison of the two protocols and recommendations for their use. A variety of DNA polymerases, including modified T7 DNA polymerase (Sequenase), *E. coli* DNA polymerase I large fragment (Klenow fragment), and thermostable enzymes are commercially available and may be used with either protocol (see Commentary). Instructions for substituting one polymerase for another are provided in Alternate Protocols 2 and 3.

A recent variation of the dideoxy sequencing method is thermal cycle sequencing (see Basic Protocol 3 and Alternate Protocol 6). In this procedure, the reaction mixture, containing template DNA, primer, thermostable DNA polymerase, dNTPs, and ddNTPs, is subjected to repeated rounds of denaturation, annealing, and elongation steps. The resulting linear amplification of the sequencing products allows much less template DNA to be used and eliminates independent primer annealing and template denaturation steps, which are required for the labeling/termination or Sanger procedures (see Commentary for a detailed discussion of thermal cycle sequencing).

In each of the basic protocols, substitution of a nucleotide analog, such as 7-deaza-dGTP, 7-deaza-dATP, or, in some cases, dITP, for dGTP in the nucleotide mixes can help to destabilize structures that can otherwise form in the sequencing products during electrophoresis to cause gel “compressions” (see Commentary). In addition, in some protocols manganese can be substituted for magnesium in the labeling/termination reaction (Alternate Protocol 1). Manganese increases the band uniformity exhibited by Sequenase and can increase the intensity of the sequencing ladder near the primer.

Each of the basic protocols utilizes [α - ^{35}S]dATP to label the nascent chain. A 5'-end-labeled primer can be used in either a one-step noncycling procedure (Alternate Protocol 4) or in a thermal cycling procedure (Alternate Protocols 5 and 6). Nonradioactive detection methods are described in the Chapter 7 introduction.

Commercially available DNA sequencing kits provide most of the reagents required for the abovementioned protocols. These kits save a significant amount of startup time, although they may limit flexibility in troubleshooting and are somewhat more expensive than assembling components individually (see Table 7.4A.1). Automated fluorescent sequencers, which are used in four-color dideoxy DNA sequencing (Alternate Protocols 7 and 8), are also commercially available (see Table 7.4A.1).

An alternative to radioisotope labeling (chemiluminescent detection) can be found in *UNIT 7.4B*.

**BASIC
PROTOCOL 1**

**LABELING/TERMINATION SEQUENCING REACTIONS
USING SEQUENASE**

The labeling/termination sequencing protocol involves two steps (Tabor and Richardson, 1987b, 1990). In the labeling step, primed DNA synthesis is initiated in the presence of limiting concentrations of all four dNTPs, including [α - ^{35}S]dATP, and continues until one of the dNTP pools is depleted. At this point, the uniformly labeled DNA chains are distributed randomly in length from a few nucleotides to hundreds of nucleotides. In the second step, synthesis resumes in the presence of additional dNTPs and one ddNTP. Elongation of the DNA chains in this step is rapid and processive until termination occurs at specific bases after incorporation of the corresponding dideoxynucleotide. In this protocol, the average length of the radioactively labeled oligonucleotide products is modified by altering the concentration of dNTPs in the first step; however, it can also be regulated by altering the dNTP:ddNTP ratio in the termination reaction (see Critical Parameters).

This protocol uses Sequenase. The labeling/termination procedure can also be used with other polymerases; however, because each polymerase has different buffer and Mg^{2+} concentration optima, and each discriminates to a different extent against ddNTPs, the concentrations of these components must be modified in each case (see Commentary). Conditions for substitution of *Taq* DNA polymerase and Klenow fragment are provided in the alternate protocols that follow (see Alternate Protocols 2 and 3).

Materials

- 0.5 pmol single-stranded *or* denatured double-stranded DNA template (*UNIT 7.3*)
- 0.5 to 1 pmol/ μl oligonucleotide primer in water (store at -20°C ; *UNIT 2.11*)
- 10 \times Sequenase buffer (see recipe)
- Sequenase termination mixes (see recipe)
- Sequenase/pyrophosphatase mix (see recipe)
- Sequenase diluent (see recipe)
- Labeling mixes (see recipe)
- 10 mCi/ml [α - ^{35}S]dATP (500 to 1200 Ci/mmol)
- Stop/loading dye (see recipe)
- 65 $^\circ$ and 95 $^\circ\text{C}$ water baths

- 0.5-ml microcentrifuge tubes
- Heat-resistant microtiter plates (optional; Table 7.4A.1)

Anneal primer and template

For each single-stranded DNA template

1a. Mix the following in a 0.5-ml microcentrifuge tube:

- 0.5 pmol single-stranded DNA template
- 0.5 pmol primer
- 1 μl 10 \times Sequenase buffer
- H_2O to 10 μl .

Mix gently by pipetting up and down (avoid creation of bubbles). Incubate 6 min at 65 $^\circ\text{C}$, then 20 min at 37 $^\circ\text{C}$. Proceed to step 2.

1.6 μg of single-stranded DNA 10,000 nucleotides long corresponds to 0.5 pmol of template molecules. Approximately 2.8 ng of a 17-mer is 0.5 pmol of primer molecules. Incubation

at 65°C destabilizes secondary structures that may be present in the single-stranded DNA template preparation. For more stringent annealing conditions, incubate at 42° to 50°C after the 65°C incubation (see Critical Parameters).

For each double-stranded DNA template

1b. Resuspend a dried pellet containing 0.5 pmol denatured double-stranded DNA in the following mixture:

1 pmol primer
1 µl 10× Sequenase buffer
H₂O to 10 µl.

Mix gently by pipetting up and down (avoid creation of bubbles). Incubate 30 min at 37°C, then keep at this annealing temperature until ready to proceed to step 2.

1.6 µg of 5000-bp double-stranded DNA molecule corresponds to 0.5 pmol of template molecules. For a λgt11-derived template (50,000 bp), 0.2 to 0.3 pmol (6 to 10 µg) is sufficient (see Critical Parameters). Double-stranded DNA templates require twice as much primer as single-stranded DNA templates. For more stringent annealing conditions, incubate at 42° to 50°C instead of 37°C (see critical parameters).

Set up termination reactions

2. While the primer is being annealed to the template, label four microcentrifuge tubes A, C, G, and T for each template to be sequenced.

For simultaneous sequencing of a large number of templates, the reactions can be carried out in heat-resistant, round-bottom, 96-well microtiter plates with heat-resistant lids (Table 7.4A.1).

3. Add 2.5 µl each of A, C, G, and T Sequenase termination mixes to the bottom of the A, C, G, and T tubes, respectively.

Keep tubes closed because the small volumes evaporate rapidly when open to the air.

Carry out labeling reaction

4. Immediately before use, dilute the Sequenase/pyrophosphatase mix in Sequenase diluent to 1 to 2 U Sequenase/µl and keep on ice.

5. Add the following to the annealed primer and template:

2 µl labeling mix
0.5 to 1.5 µl 10 mCi/ml [α -³⁵S]dATP
2 µl diluted Sequenase/pyrophosphatase mix.

Table 7.4A.1 Suppliers of DNA Sequencing Kits, Reagents, and Equipment^a

Product	Supplier ^b
Automated fluorescent DNA sequencers	APB, BK, LI, MD, MJ, PE, VG
Heat-resistant microtiter plates (round-bottom, 96-well)	APB, BK, CO, SA, ST
Nucleotides, nucleotide analogs	BM, BR, ICN, LT, NEB, PR, USB
Radiolabeled nucleotides	APB, ICN, NEN
Sequencing kits	APB, BM, BR, IBI, LT, NEB, NEN, PE, PR, ST, USB

^aModified from Slatko, 1991b.

^bAbbreviations: APB, Amersham Pharmacia Biotech; BK, Beckman; BM, Boehringer-Mannheim; BR, Bio-Rad; CO, Costar; IBI, International Biotechnologies; ICN, ICN Biomedicals; LI, LICOR; MD, Molecular Dynamics; MJ, MJ Research; NEB, New England Biolabs; NEN, NEN Life Sciences; PE, Perkin-Elmer; PR, Promega; SA, Sarstedt; ST, Stratagene; USB, U.S. Biochemical; VG, Visible Genetics. Addresses of suppliers are listed in APPENDIX 4.

The total volume is 14.5 to 16 μl . Incubate 5 min at 25°C (room temperature).

Choose the labeling mix (see Reagents and Solutions) appropriate for the lengths of sequencing products that are desired (see Critical Parameters). The short labeling mix is formulated to generate sequences closer to the primer annealing site, while the long labeling mix is formulated to generate sequences further away from the primer annealing site. Reaction times can be extended to 20 min without detriment, although the reaction is complete within 5 min, by which time the nucleotide pools are exhausted. This step can be performed at 37°C; however, 25°C limits the processivity of the Sequenase, an advantage during the labeling step, and maximizes its half-life during the sequencing reaction.

At least 3 pmol of [α -³⁵S]dATP are required for reactions containing the short labeling mixes whereas 15 pmol must be added to reactions containing the long labeling mixes. Amounts greater than these are not incorporated during the labeling step, because the other three dNTPs become limiting. The concentration of [α -³⁵S]dATP at 10 mCi/ml with a specific activity of 1000 Ci/mmol is 10 μM . Thus for such a preparation, 0.3 and 1.5 μl are sufficient for the labeling step with the short and long labeling mixes, respectively (see Critical Parameters).

Carry out termination reaction

6. Add 3.5 μl of the labeling reaction mixture (from step 5) to the tube containing Sequenase termination mix A (from step 3). Mix the solution by gently pipetting up and down. Repeat this addition to the C, G, and T tubes, changing pipet tips each time. Incubate 5 to 10 min at 37°C.

Reactions are complete within 2 to 3 min but incubations can be extended to 30 min without problems, except when using dITP under some conditions (see discussion of pyrophosphorolysis in the Commentary).

7. Add 4 μl stop/loading dye.

³⁵S sequencing reactions may be stored for up to one week at -20°C before electrophoresis.

8. Heat samples 2 min in a 95°C water bath, then place on ice. Load 2 to 3 μl of each sample on a sequencing gel. Electrophorese the gel (UNIT 7.6) and read the sequence (see commentary).

Excessive boiling of the completed reactions in formamide/dye solution may cause DNA chain breakage and smeared bands on the sequencing gel. If repeated loadings are planned, remove a 3- μl aliquot of each reaction to heat before each loading.

ALTERNATE PROTOCOL 1

USING Mn²⁺ IN THE LABELING/TERMINATION REACTIONS

In the presence of Mn²⁺, Sequenase incorporates deoxynucleotides and dideoxynucleotides at the same rate (Tabor and Richardson, 1989b, 1990). The addition of Mn²⁺ to a sequencing reaction has two effects. First, dideoxynucleotides are incorporated at the same rate at each position, resulting in bands of nearly uniform intensity. This high degree of band uniformity is most advantageous for automated sequencing procedures. Second, the relative incorporation of dideoxynucleotides to deoxynucleotides is about four times higher in the presence of Mn²⁺ than in the presence of Mg²⁺. The effect is the same as increasing the ddNTP:dNTP ratio 4-fold, resulting in an increase in the intensity of bands near the primer.

The Mn buffer specified in this protocol should be used only with Sequenase. Using the short labeling mixes and Mn buffer, it should be possible to read from near the primer up to ~200 nucleotides. To read further, it is necessary to increase the amount of dNTPs in the labeling reaction (by using the long mixes) or to increase the ratio of dNTP:ddNTP in the termination mixtures (see Critical Parameters).

Mn buffer is effective with the mixtures described in the labeling/termination basic protocol when dGTP or the analog 7-deaza-dGTP are employed. However, when sequencing with dITP, the lane will be faint near the bottom of the gel, as Mn^{2+} reduces the discrimination against dITP to a greater extent than it does ddGTP. To use Mn buffer with the dITP mixes, the amount of ddGTP should be increased 5-fold (to 8 μM); all the other nucleotides should be kept at the same concentration. The bromphenol blue in the lanes containing Mn buffer will be more diffuse than in the absence of Mn buffer. This does not interfere with the resolution of the sequencing ladder.

Additional Materials (also see *Basic Protocol 1*)

Mn buffer: 0.15 M sodium isocitrate/0.1 M $MnCl_2$ (store up to 3 months at $-20^\circ C$)

To sequence using Mn buffer, carry out the labeling/termination basic protocol, making the addition at the step indicated below.

5. After adding labeling mix and label to the annealed primer and template, add 1 μl Mn buffer to the primer/template/labeling mixture prior to adding Sequenase.

10 \times Sequenase buffer is still used; the effect of Mn^{2+} is dominant. The amount of Mn buffer added is not critical; comparable results will be observed if 0.2 to 2.0 μl are added (i.e., the effects are “all-or-none”; intermediate results are not observed). Do not mix Mn buffer with other reagents prior to use because Mn^{2+} is prone to oxidation, forming a yellow-brown precipitate.

USING OTHER POLYMERASES IN THE LABELING/TERMINATION REACTIONS

Labeling/Termination Reactions Using *Taq* DNA Polymerase

Taq DNA polymerase is useful for templates exhibiting secondary structures that may inhibit elongation by Sequenase (see Troubleshooting). Using *Taq* DNA polymerase, the reactions can be performed at temperatures high enough to destabilize many secondary structures (see Background Information).

Additional Materials (also see *Basic Protocol 1*)

10 \times *Taq* sequencing buffer: 500 mM Tris·Cl, pH 9.0 (APPENDIX 2)

Taq termination mixes (see recipe)

Taq DNA polymerase

45 $^\circ C$ water bath

To use *Taq* DNA polymerase in the labeling/termination reactions, modify the steps in Basic Protocol 1 as indicated below.

1. Substitute 10 \times *Taq* sequencing buffer for Sequenase buffer in the annealing reaction.
3. Add A, C, G, and T *Taq* termination mixes to the labeled tubes.
4. Immediately before use, dilute *Taq* DNA polymerase to 1 U/ μl in 1 \times *Taq* sequencing buffer and keep on ice.
5. Substitute *Taq* DNA polymerase for Sequenase; incubate labeling reactions at 45 $^\circ C$.

The initial 30 sec of the labeling reaction should not be carried out at a higher temperature than the maximum annealing temperature for the specific primer (see Critical Parameters and see Troubleshooting).

6. After adding aliquots of the labeling reaction mixture to each tube containing the termination mix, incubate the termination reactions at 65 $^\circ C$.

**ALTERNATE
PROTOCOL 2**

DNA Sequencing

7.4A.5

Labeling/Termination Reactions Using Klenow Fragment

Klenow fragment can be substituted for Sequenase (Stambaugh and Blakesley, 1988; Mardis and Roe, 1989) in the labeling/termination protocol (see Basic Protocol 1) as described in the modified steps below.

Additional Materials (also see Basic Protocol 1)

- 10× Klenow sequencing buffer (see recipe)
- Klenow termination mixes (see recipe)
- Klenow fragment (UNIT 3.5)
- 37° to 42°C water bath

1. Substitute 10× Klenow sequencing buffer for Sequenase buffer in the annealing reaction.
3. Add A, C, G, and T Klenow termination mixes to the labeled tubes.
4. Immediately before use, dilute Klenow fragment to 1 to 2 U/μl in 1× Klenow sequencing buffer and keep on ice.
5. Substitute Klenow fragment for Sequenase and incubate the labeling reactions at 37° to 42°C for 5 to 10 min.

Both the labeling reactions and the termination reactions (step 6) can be carried out at temperatures up to 50°C. The initial 30 sec of the labeling reaction should not be greater than the maximum annealing temperature for the specific primer (see Critical Parameters and see Troubleshooting).

6. Incubate the termination reactions at 37° to 42°C for 5 to 10 min.

SEQUENCING BY THE SANGER PROCEDURE USING KLENOW FRAGMENT

The traditional Sanger method proceeds in two stages. First, primed DNA synthesis occurs in the presence of a mixture of dNTPs and ddNTPs; termination occurs when a ddNMP is incorporated. Second, a chase with high concentrations of dNTPs ensures that oligonucleotides that have not specifically terminated by incorporation of a dideoxynucleotide are elongated past the region of interest. This protocol is written for use with Klenow fragment. Other DNA polymerases can be substituted along with appropriate buffer and reaction mixes (see Commentary). Conditions for *Taq* DNA polymerase are provided in Alternate Protocol 2.

Materials

- 0.5 to 1 pmol single-stranded *or* denatured double-stranded DNA (UNIT 7.3)
- 0.5 to 1 pmol/μl oligonucleotide primer in water (store at -20°C; UNITS 2.11 & 2.12)
- 10× and 1× Klenow sequencing buffer (see recipe)
- Klenow Sanger mixes (see recipe)
- Klenow fragment (UNIT 3.5)
- 10 mCi/ml [α -³⁵S]dATP (500 to 1200 Ci/mmol)
- dNTP chase (see recipe)
- Stop/loading dye (see recipe)
- 0.5-ml microcentrifuge tubes
- 37° to 42°C water bath
- Additional reagents and equipment for labeling/termination sequencing reactions (see Basic Protocol 1)

1. Anneal primer to single-stranded or denatured double-stranded DNA template as described in steps 1a and 1b in the labeling/termination protocol (see Basic Protocol 1), using 10× Klenow sequencing buffer in place of 10× Sequenase buffer.
2. Prepare labeled tubes as in step 2 of the labeling/termination protocol (see Basic Protocol 1).
3. Add 3 μl each of A, C, G, and T Klenow Sanger mixes to the bottom of the A, C, G, and T tubes, respectively.
4. Immediately before use, dilute Klenow fragment in 1× Klenow sequencing buffer to 2.5 to 5 U/μl and keep on ice.
5. Add the following to the annealed primer and template:

2 μl 10 mCi/ml [α -³⁵S]dATP
1 μl diluted Klenow fragment.

Mix by pipetting the solution up and down. The total volume is 13 μl.

6. Add 2.5 μl of primer/template/Klenow polymerase mixture to the tube containing the A Klenow Sanger mix (from step 3). Mix by gently pipetting the solution up and down. Repeat the addition to the C, G, and T tubes with the appropriate Klenow Sanger mix, changing pipet tips each time. Incubate 10 min at 37° to 42°C.
7. Add 1.0 μl dNTP chase to each A, C, G, and T reaction and mix as above. Incubate 10 min at 37° to 42°C.
8. Carry out steps 7 and 8 of the labeling/termination protocol (see Basic Protocol 1), except add 6 μl stop/loading dye.

USING *TAQ* DNA POLYMERASE IN THE SANGER PROCEDURE

Sequencing reactions using *Taq* DNA polymerase can be carried out at temperatures high enough to destabilize many secondary structures that would otherwise inhibit elongation of the polymerase (see Commentary).

Additional Materials (also see Basic Protocol 2)

10× *Taq* sequencing buffer: 500 mM Tris·Cl, pH 9.0 (APPENDIX 2)
Taq Sanger mixes (see recipe)
Taq DNA polymerase
50° to 75°C water bath

To use *Taq* DNA polymerase in the Sanger procedure (see Basic Protocol 2), modify the steps in that protocol as indicated below.

1. Use 10× *Taq* sequencing buffer in the annealing reaction.
3. Add A, C, G, and T *Taq* Sanger mixes to the labeled tubes.
4. Immediately before use, dilute *Taq* DNA polymerase to 2.5 U/μl in 1× *Taq* sequencing buffer and keep on ice.
5. Substitute *Taq* DNA polymerase for Klenow fragment in the reaction mixture.
6. Incubate the sequencing reactions 10 min at 50° to 75°C.
The initial 30 sec of this sequencing reaction should be at a temperature no greater than the maximum annealing temperature of the primer to the template (see Critical Parameters).
7. Incubate the chase reactions 10 min at 50° to 75°C.

**ALTERNATE
PROTOCOL 4**

DNA Sequencing

7.4A.7

ONE-STEP SEQUENCING REACTIONS USING 5'-END-LABELED PRIMERS

5'-end-labeled primers are used primarily for sequencing very large double-stranded DNA templates (such as λ gt11) or for templates that have given less than optimum results with nascent chain labeling (Slatko, 1991a). Nicks in larger or partially degraded templates can act as priming sites in the labeling reaction, resulting in a high background on the sequencing gel. When a 5'-end-labeled primer is used, only bona fide products from elongation of the primer will be detected by autoradiography.

Because the primer is labeled prior to the sequencing reaction, only one step is required for extension of the primer in the presence of ddNTPs. Nucleotide mixes vary depending on the DNA polymerase used in the reaction. A chase reaction containing high levels of all four dNTPs is recommended when utilizing Klenow fragment. Sequencing ladders from 5'-end-labeled primers generally have a clean background and band uniformity that is limited by variations caused by polymerase-specific artifacts. Because radiolysis of a 5'-end-labeled primer results only in a nonradioactive fragment, the sequencing reactions and end-labeled primers are relatively stable, and can be stored for up to 1 month with good results.

Primers may be 5' end-labeled with ^{32}P or ^{35}S using T4 polynucleotide kinase. The following protocol provides enough end-labeled primer for ten double-stranded DNA templates. If more end-labeled primer is desired, add at least as many pmol of ATP as pmol of primer to the end-labeling reaction.

Additional Materials (also see Basic Protocol 1)

$[\gamma\text{-}^{32}\text{P}]\text{ATP}$ (3000 Ci/mol) or $[\gamma\text{-}^{35}\text{S}]\text{ATP}$ (1300 Ci/mmol)

Sequenase termination mixes (see recipe), *Taq* termination mixes (see recipe), or Klenow one-step sequencing mixes (see recipe)

DNA polymerase and appropriate 10 \times buffer: Sequenase (see Basic Protocol 1), *Taq* DNA polymerase (see Alternate Protocol 2), or Klenow fragment (see Alternate Protocol 3)

dNTP chase (for Klenow fragment; see recipe)

37 $^{\circ}$ to 42 $^{\circ}$ C water bath (for Klenow fragment or 50 $^{\circ}$ to 75 $^{\circ}$ C water bath (for *Taq* polymerase)

Additional reagents and equipment for end labeling (UNIT 3.10)

End label primer

Carry out 5'-end-labeling of the primer using $[\gamma\text{-}^{32}\text{P}]\text{ATP}$

- 1a. End label ~10.5 pmol primer in a 25- μl reaction as described in UNIT 3.10 for labeling by the forward reaction. Use ~11.5 pmol $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ (3000 Ci/mmol) and 10 U of T4 polynucleotide kinase (BSA may be omitted from reaction). Incubate 30 min, 37 $^{\circ}$ C.
- 2a. Terminate the reaction by incubating 5 min at 95 $^{\circ}$ C. Briefly microcentrifuge at high speed, room temperature. Proceed to step 3.

It is not necessary to remove the unused ATP from the reaction; it will not interfere with the sequencing reaction.

Carry out 5'-end-labeling of the primer using $[\gamma\text{-}^{35}\text{S}]\text{ATP}$

- 1b. End label ~10.5 pmol primer in a 25- μl reaction as described in UNIT 3.10 for labeling by the forward reaction. Use ~13 pmol $[\gamma\text{-}^{35}\text{S}]\text{ATP}$ (1300 Ci/mmol) and 5 U of T4 polynucleotide kinase (BSA may be omitted from the reaction). Incubate 4 hr at 37 $^{\circ}$ C, adding an additional 5 U of T4 polynucleotide kinase every hour.

$[\gamma\text{-}^{35}\text{S}]\text{ATP}$ is not used efficiently by T4 kinase.

- 2b. Terminate the reaction by incubating 5 min at 95°C. Briefly microcentrifuge at high speed, room temperature. Proceed to step 3.

It is not necessary to remove the unused ATP from the reaction.

Carry out sequencing reactions using 5'-end-labeled primers

3. Anneal the 5' end-labeled primer to the DNA template as described in steps 1a or 1b of the labeling/termination protocol (see Basic Protocol 1), using ~2.4 µl of the 25-µl end-labeling reaction (~1 pmol primer) per denatured double-stranded DNA template, and 10× buffer appropriate for the DNA polymerase being utilized.
4. Place 3.5 µl each of the appropriate A, C, G, and T mixes in the bottom of four microcentrifuge tubes labeled A, C, G, and T, respectively—use Sequenase termination mixes, *Taq* termination mixes, or Klenow one-step sequencing mixes.

For Sequenase, these termination mixes will yield a readable sequencing ladder of up to ~150 nucleotides from the primer. To sequence further (up to ~300 nucleotides), increase the ratio of dNTP:ddNTP in the termination mixes from 10:1 (as described) to 20:1, by either increasing the concentration of all four dNTPs or reducing the concentration of ddNTPs by one-half and keeping the dNTP concentration the same. To sequence even further, the dNTP:ddNTP ratio should be increased to 40:1 (see Critical Parameters for further discussion of factors affecting extension lengths).

5. Add ~2.5 µl of the annealed labeled primer/DNA mix from step 4 to each tube. Incubate 30 sec to 1 min at 37°C.
6. Dilute enzymes in appropriate diluent as follows:
 - Sequenase—1 to 2 U/µl final
 - Taq* DNA polymerase—1 to 2.5 U/µl final
 - Klenow fragment—2.5 to 5 U/µl final.
7. Add 1 to 2 µl diluted DNA polymerase to each of the tubes from step 5. Incubate 5 to 10 min at the temperature appropriate for the DNA polymerase being utilized:
 - Sequenase—37°C
 - Taq* DNA polymerase—50° to 75°C
 - Klenow fragment—37° to 42°C.
8. If using Klenow fragment, add 1 µl dNTP chase to each tube after carrying out step 7. Incubate 5 min at 37° to 42°C.

*A chase step is not necessary when using Sequenase or *Taq* DNA polymerase.*
9. Carry out steps 7 and 8 of the labeling/termination protocol (see Basic Protocol 1).

THERMAL CYCLE SEQUENCING REACTIONS USING α-LABELED NUCLEOTIDES

This method is useful for situations where 100 to 200 ng of M13-derived or plasmid DNA or 2 µg of λ DNA is available. The DNA is combined with an oligonucleotide primer, all four dNTPs (one of which is labeled), and appropriate ddNTP for each reaction. Thermal cycle sequencing is then carried out in the presence of Vent_R (exo⁻) DNA polymerase, and the products are resolved on a sequencing gel.

This protocol and Alternate Protocol 6 were developed for use with the thermostable Vent (exo⁻) DNA polymerase (Sears et al., 1992). *Taq* DNA polymerase or modified *Taq* DNA polymerase can also be used in a thermal cycle sequencing protocol with the appropriate buffer and nucleotide mixes. Kits are commercially available with each of these DNA polymerases (Table 7.4A.1).

**BASIC
PROTOCOL 3**

DNA Sequencing

7.4A.9

Materials

Vent_R (exo⁻) sequencing mixes (see recipe)
0.04 to 0.1 pmol single-stranded or double-stranded DNA template (UNIT 7.3)
0.6 to 1.2 pmol oligonucleotide primer (UNIT 2.11)
10× Vent_R (exo⁻) DNA sequencing buffer (see recipe)
3% (v/v) Triton X-100
10 mCi/ml [α -³⁵S]dATP, [α -³²P]dATP, or [α -³³P]dATP (500 to 3000 Ci/mmol)
2000 U/ml Vent_R (exo⁻) DNA polymerase
Mineral oil, sterile
TCS stop/loading dye (see recipe)
Thermal cycling apparatus

Set up sequencing reactions

1. Label four microcentrifuge tubes A, C, G, and T for each template to be sequenced.
2. Add 3 μ l each of A, C, G, and T Vent_R (exo⁻) sequencing mixes to the bottom of the A, C, G, and T tubes, respectively.

Combine template and primer

For each single-stranded DNA template

- 3a. Mix the following in a 0.5-ml microcentrifuge tube:

0.04 pmol single-stranded DNA template
0.6 pmol primer
1.5 μ l 10× Vent (exo⁻) sequencing buffer
1 μ l Triton X-100
H₂O to 12 μ l.

Mix the solution gently by pipetting up and down.

For each double-stranded DNA template

- 3b. Mix the following in a 0.5-ml microcentrifuge tube:

0.1 pmol double-stranded DNA template
1.2 pmol primer
1.5 μ l 10× Vent_R (exo⁻) sequencing buffer
1 μ l 3% Triton X-100
H₂O to 12 μ l.

Mix the solution gently by pipetting up and down.

It is not necessary to denature a double-stranded DNA template in this procedure.

Carry out sequencing reactions

Individually process each template/primer mixture through step 6. When all sets of reaction mixtures are complete, proceed to step 7.

4. Add to each template/primer mix:

1 to 2 μ l 10 mCi/ml [α -³⁵S]dATP, [α -³²P]dATP, or [α -³³P]dATP

Mix the solution gently by pipetting up and down.

5. Add 1 μ l of 2000 U/ml Vent_R (exo⁻) DNA polymerase to the tube from step 4.
6. Immediately add 3.2 μ l of the mix from step 5 to the tube containing Vent (exo⁻) sequencing mix A from step 2. Mix the solution by gently pipetting up and down.

Repeat this addition to the C, G, and T tubes, changing pipet tips each time. Place the reaction mixtures on ice.

- Overlay each reaction mixture with 1 drop of sterile mineral oil.
- Set thermal cycle apparatus for the following thermal cycle conditions:

20 cycles:	20 sec	95°C
	20 sec	55°C
	20 sec	72°C

Place the tubes in the thermal cycler.

See Commentary for more discussion of thermal cycle temperature settings.

Terminate sequencing reactions

- Add 4 μl TCS stop/loading dye to each tube beneath the mineral oil.

³⁵S and ³³P reactions may be stored at -20°C for several weeks, ³²P reactions up to 1 week.

- Heat samples 3 min at 85°C . Insert pipet tip underneath the oil covering the reaction and load 2 μl on a sequencing gel. Electrophorese the gel (UNIT 7.6) and read the sequence (see Commentary).

A (5-sec) microcentrifugation will help to fully separate the aqueous layer from the oil layer. If necessary, briefly touch the pipet tip to a tissue to remove residual oil before loading. Alternatively, remove the oil by using silicone oil to cover the reactions followed by precipitation of the reaction products from the oil (Ross and Leavitt, 1991) or by using Parafilm to remove the oil (Whitehouse and Spears, 1991). Another alternative is to use a "hot-top" apparatus, set 15°C hotter than the warmest step in the cycle reaction ($\sim 115^{\circ}\text{C}$), which eliminates evaporation and precludes the requirement for oil on the reactions. A "hot-top" apparatus may be a clothes iron (set just to "steam" setting) or an upside-down heat-block or heating-stirring apparatus. The authors emphasize that no sequence aberration has been observed due to overlay oil contaminating the reaction in the sequencing gel lane.

THERMAL CYCLE SEQUENCING REACTIONS USING 5'-END-LABELED PRIMERS

ALTERNATE PROTOCOL 6

This method allows detection of a few nanograms of M13-derived or plasmid DNA or 300 ng of λ DNA, much less than required in Basic Protocol 3. PCR products must have excess primers and nucleotides removed after completion of the PCR reaction by drop dialysis, gel purification, glass bead procedures, or by spin columns.

Additional Materials (also see Basic Protocol 3)

10 mCi/ml [γ -³²P]ATP or [γ -³³P]ATP (3000 Ci/mmol), or biotin or fluorescent conjugates (see Commentary)

Additional reagents and equipment for end-labeling as described for one-step sequencing reactions (see Alternate Protocol 5, steps 1a and 2a)

Preliminary step

- End label primer using [γ -³²P]ATP or [γ -³³P]ATP (3000 Ci/mmol) as described in steps 1a and 2a of Alternate Protocol 5.

Set up sequencing reactions

- Set up tubes and sequencing mixes as described in steps 1 and 2 of the basic thermal cycle sequencing protocol (see Basic Protocol 3).

Carry out sequencing reactions

Individually process tubes as described in the thermal cycle sequencing protocol (see Basic Protocol 3).

For each single-stranded DNA template

3a. Mix the following in a 0.5-ml microcentrifuge tube:

- 0.004 pmol single-stranded DNA template
- 0.6 pmol 5'-end-labeled primer
- 1.5 μ l 10 \times Vent_R (exo⁻) sequencing buffer
- 1 μ l 3% Triton X-100 solution
- H₂O to 14 μ l.

Mix gently by pipetting up and down.

For each double-stranded DNA template

3b. Mix the following in a 0.5-ml microcentrifuge tube:

- 0.01 pmol double-stranded DNA template
- 1.2 pmol 5'-end-labeled primer
- 1.5 μ l 10 \times Vent_R (exo⁻) sequencing buffer
- 1 μ l 3% Triton X-100 solution
- H₂O to 14 μ l.

Mix gently by pipetting up and down.

Carry out and terminate sequencing reactions

4. Add 1 μ l of 2000 U/ml Vent_R (exo⁻) DNA polymerase to the tube from step 3a or 3b. Mix gently by pipetting up and down.
5. Complete the sequencing reactions as described in steps 6 to 10 of the basic protocol for thermal cycle sequencing (see Basic Protocol 3).

CYCLE SEQUENCING USING FLUORESCENCE DYE-LABELED PRIMER (DYEPRIMER) OR TERMINATOR (DYETERMINATOR)

The following two protocols are provided as examples of automated fluorescent sequencing. Although the methods described here are for direct sequencing of large template DNA, such as bacterial artificial chromosome clones (BAC), protocols for sequencing M13 clones, plasmids, or PCR products are performed in the same format with reduced amounts of sequencing reagents and DNA templates. The protocols for these latter applications are readily available from the sequencing reagent provider with nucleotide termination mix, DNA polymerase, and reaction buffer already mixed together as a cocktail (see Table 7.4A.1).

ALTERNATE PROTOCOL 7

Sequencing with Energy Transfer Dye-Labeled Primers (ET Primer)

The DyePrimer sequencing system uses four reactions, each for a particular dideoxynucleotide, generating data with uniform peaks. Since all the DNA fragments extended from the primer carry a fluorescent tag, the fragments prematurely terminated at dNTPs will be detected by the automated sequencer as false stops in the DyePrimer procedure.

The ET Primer Sequencing Kit is available from Amersham Pharmacia Biotech.

Materials

ThermoSequenase reaction buffer: 260 mM Tris·Cl/65 mM MgCl₂, pH 9.5
ThermoSequenase nucleotide mix: 750 μM each dNTP + 2.5 μM of specific ddNTP
ET primer: 0.5 μM dye-labeled A or C primer; 1.0 μM dye-labeled G or T primer
1.5 U/μl ThermoSequenase (Amersham Pharmacia Biotech)
0.25 μg/μl BAC DNA
Formamide loading buffer (see recipe)
0.2-ml strip tubes
Thermal cycler
Automated DNA sequencer (e.g., Perkin-Elmer)

1. Combine the following reagents (per reaction) to make a cocktail:

0.4 μl ThermoSequenase reaction buffer
1.6 μl ThermoSequenase nucleotide mix
1.0 μl ET primer
1.0 μl ThermoSequenase.

Multiply the amount of reagents per reaction by the number of reactions planned.

2. Dispense 4 μl of each cocktail into 0.2-ml microcentrifuge tubes with rows labeled A, T, G, and C. Add 4 μl (~1 μg) of DNA/reaction to each tube.
3. Microcentrifuge samples 30 sec at 2500 × g to bring the reagents to the bottom of the tube. Set up the following thermal cycles:

1 cycle:	2 min	95°C
20 cycles:	5 sec	95°C
	10 sec	55°C
	60 sec	72°C

Cool to 4°C and hold.

4. Remove samples from thermal cycler and add 1 μl of glycogen and 100 μl of 100% ethanol to the “A” row only. Pool samples from the A, C, and G reactions down into the “T” row reaction for precipitation.
5. Centrifuge samples 30 min at 3000 × g, 4°C. Decant ethanol supernatant and vacuum-dry samples, then resuspend in 3 μl formamide loading buffer for running on the automated DNA sequencer.

For large scale sequencing, carry out cycle sequencing reactions in 96-well or 384 microplates (Automated DNA Sequencing: Chemistry Guide, Perkin-Elmer Applied Biosystems, 1998).

Sequencing with Energy Transfer Dye-Labeled Terminators (BigDye Terminators)

The DyeTerminator procedure uses a one-tube reaction, and false stops (i.e., the fragments terminated at dNTPs) do not carry a fluorescent tag and therefore are not detected by the automated sequencer. The sequencing peaks, however, are less uniform as compared to DyePrimer data, due to the discrimination of the polymerase with respect to the dye-labeled dideoxynucleotides.

The BigDye terminator sequencing kit is available from Perkin-Elmer Applied Biosystems and the ET terminator kit is available from Amersham Pharmacia Biotech.

**ALTERNATE
PROTOCOL 8**

DNA Sequencing

7.4A.13

Materials

Termination nucleotide mix (see recipe)
5× sequencing buffer: 400 mM Tris·Cl, pH 9.0/10 mM MgCl₂
AmpliTaq FS for terminators (Perkin-Elmer)
Primer
0.25 µg/µl BAC DNA
Centri-Sep spin columns (Princeton Separations)
Thermal cycler
Automated DNA sequencer (e.g., Perkin-Elmer)

1. Combine the following reagents (per reaction) to make a cocktail:

8.0 µl termination nucleotide mix
4.0 µl 5× sequencing buffer
0.5 µl AmpliTaq FS for terminators
4.0 pmol primer
~400 ng BAC DNA
Water to 40.0 µl final volume.

Multiply the amount of reagents per reaction by the number of reactions planned.

2. Set up the following thermal cycles:

1 cycle:	5 min	95°C
30 cycles:	30 sec	95°C
	20 sec	55°C
	4 min	60°C

Cool to 4°C and hold.

3. Remove excess terminators with Centri-Sep spin columns. Vacuum dry samples and resuspend in 2 or 4 µl formamide loading buffer for running on the automated DNA sequencer.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

NOTE: Unless otherwise specified, the sources for recipes for each protocol are as follows: Klenow labeling/termination reactions, modified from Stambaugh and Blakesley (1988) and Mardis and Roe (1989); Sequenase labeling/termination reactions, U.S. Biochemical; *Taq* labeling/termination reactions, modified from Promega Biotech; Klenow Sanger and Klenow one-step reactions, modified from New England Biolabs; *Taq* Sanger reactions, Slatko, 1991a; Vent_R thermal cycle sequencing reactions, modified from New England Biolabs (Sears et al., 1992). See APPENDIX 4 for addresses and phone numbers of suppliers.

dNTP chase

Prepare 0.25 mM each dATP, dCTP, dGTP, and dTTP in 10 mM Tris·Cl, pH 7.5 (APPENDIX 2)/0.1 mM EDTA using nucleotide stock solutions (see recipe). Store up to 1 year at -20°C

Formamide loading buffer

95% (v/v) formamide
0.09% (w/v) bromphenol blue
0.09% (w/v) xylene cyanol FF
Store up to 3 months at 4°C

Klenow one-step sequencing mixes

Concentrations of dNTPs and ddNTPs in the A, C, G, and T mixes are listed below in μM . Prepare all mixes in 10 mM Tris·Cl, pH 7.5 (*APPENDIX 2*)/0.1 mM EDTA using nucleotide stock solutions (see recipe). Store up to 1 year at -20°C .

	A	C	G	T
dATP	4.4	44	44	44
dCTP	44	4.4	44	44
dGTP	44	44	4.4	44
dTTP	44	44	44	4.4
ddATP	50	—	—	—
ddCTP	—	50	—	—
ddGTP	—	—	50	—
ddTTP	—	—	—	50

Klenow sequencing buffer, 10 \times

100 mM Tris·Cl, pH 7.5 (*APPENDIX 2*)

150 mM MgCl_2

75 mM dithiothreitol (DTT)

Store up to 1 year at -20°C

Klenow Sanger mixes

Concentrations of dNTPs and ddNTPs in the A, C, G, and T mixes are listed below in μM . Prepare all mixes in 10 mM Tris·Cl, pH 7.5 (*APPENDIX 2*)/0.1 mM EDTA using nucleotide stock solutions (see recipe). Store up to 1 year at -20°C .

	A	C	G	T
dATP	—	—	—	—
dCTP	56	5.6	56	56
dGTP	56	56	5.6	56
dTTP	56	56	56	5.6
ddATP	22	—	—	—
ddCTP	—	300	—	—
ddGTP	—	—	300	—
ddTTP	—	—	—	450

To substitute dITP for dGTP, Bankier and Barrell (1983) recommend replacing dGTP with 4 \times as much dITP in each of the Klenow Sanger mixes and reducing ddGTP to 20 μM in the G mix. However, the authors have successfully substituted an equimolar concentration of dITP with no change in the ddGTP concentration (B.E. Slatko, unpub. observ.).

To substitute 7-deaza-dGTP for dGTP, replace dGTP with an equimolar concentration of 7-deaza-dGTP in each of the Sanger mixes (Mizusawa et al., 1986). The ddGTP concentration remains unchanged.

Klenow termination mixes

Concentrations of dNTPs and ddNTPs in the A, C, G, and T mixes are listed below in μM . Prepare all mixes in 10 mM Tris·Cl, pH 7.5 (APPENDIX 2)/0.1 mM EDTA using nucleotide stock solutions (see recipe). Store up to 1 year at -20°C .

	A	C	G	T
dATP	25	250	250	250
dCTP	250	25	250	250
dGTP	250	250	25	250
dTTP	250	250	250	25
ddATP	240	—	—	—
ddCTP	—	100	—	—
ddGTP	—	—	120	—
ddTTP	—	—	—	400

To substitute dITP or 7-deaza-dGTP for dGTP, replace dGTP with an equimolar concentration of dITP or 7-deaza-dGTP, respectively, in each termination mix; do not alter the concentration of ddGTP in the G mix.

Labeling mixes

To obtain sequencing reaction products that are relatively short (<350 bases), use the short mix. Prepare the long mix when relatively long (>150 bases) products are desired. Prepare labeling mixes for Sequenase and Klenow fragment in 10 mM Tris·Cl, pH 7.5 (APPENDIX 2)/0.1 mM EDTA using nucleotide stock solutions (see below). Prepare labeling mixes for *Taq* DNA polymerase in 0.1 mM EDTA. Store mixes up to 1 year at -20°C .

Short mix: 1.5 μM each dCTP, dGTP, and dTTP

Long mix: 7.5 μM each dCTP, dGTP, and dTTP

To substitute 7-deaza-dGTP for dGTP, replace dGTP with an equimolar concentration of 7-deaza-dGTP in each mix.

*To substitute dITP for dGTP in Sequenase labeling mixes, replace dGTP with 3 μM dITP in the short mix and 15 μM dITP in the long mix. To substitute dITP for dGTP in the Klenow labeling mixes, replace dGTP with an equimolar concentration of dITP in each mix (B. Slatko, unpub. observ.). Substitution of dITP is not recommended when using *Taq* DNA polymerase.*

Nucleotide stock solutions

Purchase (Table 7.4A.1) or prepare sequencing grade dNTPs (including dITP and 7-deaza-dGTP) and ddNTPs as concentrated 20 mM stock solutions in 0.1 mM EDTA. Determine the actual concentrations spectrophotometrically using the extinction coefficients in Table 3.4.3; the extinction coefficient for each ddNTP is the same as that of the corresponding dNTP. Store up to 1 year at -20°C .

10 \times Sequenase buffer

400 mM Tris·Cl, pH 7.5 (APPENDIX 2)

200 mM MgCl_2

500 mM NaCl

50 mM dithiothreitol (DTT)

Store up to 1 year at -20°C

Sequenase diluent

10 mM Tris·Cl, pH 7.5 (*APPENDIX 2*)
5 mM dithiothreitol (DTT)
0.5 mg/ml bovine serum albumin (BSA)
Store up to 1 year at -20°C .

Sequenase/pyrophosphatase mix

Pyrophosphorolysis, the reversal of the polymerase reaction, is a problem when sequencing with Sequenase under some conditions, particularly when dITP is used (see Commentary). Inorganic pyrophosphatase prevents pyrophosphorolysis, and thus should be included in all sequencing reactions using Sequenase, particularly when dITP is present.

Pyrophosphatase is included with U.S. Biochemical's Sequenase sequencing kit. A mixture of the two enzymes can be prepared and stored in 20 mM KPO_4 buffer (pH 7.4)/0.1 mM DTT/0.1 mM EDTA/50% glycerol at -20°C . Mix 10 ng of sequencing grade yeast inorganic pyrophosphatase (0.005 U) per 2 to 4 U of Sequenase (i.e., per set of reactions), keeping the Sequenase stock as concentrated as possible. These enzymes are stable together at least 1 year.

Sequenase termination mixes

Concentrations of dNTPs and ddNTPs in the A, C, G, and T mixes are listed below in μM . Prepare all mixes in 10 mM Tris·Cl, pH 7.5 (*APPENDIX 2*)/0.1 mM EDTA using nucleotide stock solutions (see recipe). Store up to 1 year at -20°C .

	A	C	G	T
dATP	80	80	80	80
dCTP	80	80	80	80
dGTP	80	80	80	80
dTTP	80	80	80	80
ddATP	8	—	—	—
ddCTP	—	8	—	—
ddGTP	—	—	8	—
ddTTP	—	—	—	8
NaCl (mM)	50	50	50	50

To substitute dITP for dGTP, replace dGTP with 160 μM dITP in each termination mix and use 1.6 μM ddGTP in the G termination mix. Inorganic pyrophosphatase should be used in reactions with dITP (see Commentary).

To substitute 7-deaza-dGTP for dGTP, replace dGTP with 80 μM 7-deaza-dGTP in each termination mix; do not alter the concentration of ddGTP in G termination mix.

Stop/loading dye

Prepare in deionized formamide:

0.05% (w/v) bromphenol blue
0.05% (w/v) xylene cyanol
20 mM EDTA

A high-quality grade of formamide that does not require deionization is available from Fluka.

Taq Sanger mixes

Concentrations of dNTPs and ddNTPs in the A, C, G, and T mixes are listed below in μM . Prepare all mixes in 0.1 mM EDTA using nucleotide stock solutions (see recipe). Store up to 1 year at -20°C .

	A	C	G	T
dATP	2	2	2	2
dCTP	20	20	20	20
dGTP	20	20	20	20
dTTP	20	20	20	20
ddATP	150	—	—	—
ddCTP	—	500	—	—
ddGTP	—	—	222	—
ddTTP	—	—	—	520

To substitute 7-deaza-dGTP for dGTP, replace dGTP with an equimolar concentration of 7-deaza-dGTP in each termination mix (Brow, 1990; B.E. Slatko, unpub. observ.); do not alter the concentration of ddGTP in the G mix.

Taq termination mixes

Concentrations of dNTPs and ddNTPs in the A, C, G, and T mixes are listed below in μM . Prepare all mixes in 0.1 mM EDTA using nucleotide stock solutions (see recipe). Store up to 1 year at -20°C .

	A	C	G	T
dATP	8	80	80	80
dCTP	80	8	80	80
dGTP	80	80	8	80
dTTP	80	80	80	8
ddATP	120	—	—	—
ddCTP	—	55	—	—
ddGTP	—	—	16	—
ddTTP	—	—	—	100

To substitute 7-deaza-dGTP for dGTP, replace dGTP with an equimolar concentration of 7-deaza-dGTP in each termination mix; reduce the concentration of ddGTP in the G mix to 8 μM .

TCS stop/loading dye

Prepare in deionized formamide:

0.3 (w/v) bromphenol blue

0.3 (w/v) xylene cyanol

12 mM EDTA

Store up to 1 year at -20°C .

A high-quality grade of formamide that does not require deionization is available from Fluka.

Termination nucleotide mix for cycle sequencing

For use with BigDye terminator (Perkin-Elmer Applied Biosystems). Concentrations are 100 μM for dATP, dCTP, and dUTP (replace dTTP), 500 μM for dITP (replace dGTP). Concentrations for dye-labeled terminators are 0.11 μM ddATP, 0.16 μM ddCTP, 0.10 μM ddGTP, and 1.12 μM ddTTP.

10× Vent_R (exo⁻) sequencing buffer

100 mM KCl
100 mM (NH₄)₂SO₄
200 mM Tris·Cl, pH 8.8 (APPENDIX 2)
50 mM MgSO₄
Store up to 1 year at -20°C

Vent_R (exo⁻) sequencing mixes

Concentrations of dNTPs and ddNTPs in the A, C, G, and T mixes are listed below in μM. Prepare all mixes in 1× Vent_R (exo⁻) sequencing buffer using nucleotide stock solutions (see recipe). Store up to 1 year at -20°C.

	A	C	G	T
dATP	30	30	30	30
dCTP	100	37	100	100
dGTP	100	100	37	100
dTTP	100	100	100	33
ddATP	900	—	—	—
ddCTP	—	480	—	—
ddGTP	—	—	400	—
ddTTP	—	—	—	720

To substitute 7-deaza-dGTP for dGTP, replace dGTP with an equimolar concentration of 7-deaza-dGTP in each of the Vent_R (exo⁻) sequencing mix (Sears et al., 1992); do not alter the ddGTP concentration.

dITP is not recommended for use with Vent_R (exo⁻) DNA polymerase.

COMMENTARY

Background Information

Refer to the introduction to Chapter 7 and to UNIT 7.1 for a general discussion of dideoxy sequencing. For automated fluorescent sequencing (Alternate Protocols 7 and 8), refer to Automated DNA Sequencing: Chemistry Guide 1998, from Perkin-Elmer Applied Biosystems, which is available at <http://www2.perkin-elmer.com/ab/techsupp/377.html>. This guide contains detailed steps for performing fluorescent sequencing.

Important differences between the labeling/termination and Sanger procedures

Labeling/termination sequencing reactions are carried out in two steps. In the first step, the primer is extended in the presence of low concentrations of dNTPs, including [α -³⁵S] dATP, until one or more of the dNTP pools is depleted (labeling step). The limiting levels of dNTPs and a low reaction temperature reduce the processivity (see below) of Sequenase, increasing the number of chains that are extended and labeled. At the end of the labeling reaction the uniformly labeled fragments range in size from a few to several hundred nucleotides. In the

second step, synthesis resumes in the presence of additional dNTPs and ddNTPs (termination step). In the termination reaction, the high dNTP concentration and an increased reaction temperature render Sequenase processive, ensuring that the polymerase extends each chain without dissociation until the incorporation of a dideoxynucleotide (an average of ~120 nucleotides).

Two steps are also employed in the Sanger dideoxy sequencing reaction, but the purposes of the steps are different. In the first step, a pulse reaction extends the primer in the presence of [α -³⁵S]dATP, unlabeled dNTPs, and ddNTPs. Thus, both labeling and termination occur in the pulse. The second step, a chase, employs a high concentration of all four dNTPs and ensures that all extended primers that have not incorporated a ddNMP are extended past the region to be sequenced.

In the labeling/termination protocol, extension lengths can be modulated by altering the dNTP concentrations in the first step independently of reaction conditions in the termination step. As a consequence, this method provides a capability of producing longer prod-

ucts, on average, than the Sanger protocol, particularly when Sequenase is employed. This is an advantage when trying to maximize the amount of sequence information obtained from each template. It can be a disadvantage, however, when only the first few nucleotides of sequence information after the primer are desired, although this problem can be overcome by altering labeling mixes and/or sequencing buffer (see Critical Parameters).

Another advantage of the labeling/termination protocol is that only a single reaction is used for the labeling step. Two conditions of the labeling step (low temperature and a low concentration of dNTPs) reduce the processivity of the polymerase (see below), resulting in some dissociation of the enzyme from the primer. When dissociation occurs at a site where reinitiation during the termination step is impeded, an artifactual band will occur at an equal intensity in all four lanes, and is readily identifiable as an artifact. In the Sanger protocol, by contrast, because four separate sequencing reactions are used, artifactual bands due to pausing of the polymerase sometimes occur in only one or two lanes, due to slight differences in the amount of enzyme or mixture in each reaction. This may result in artifactual bands being erroneously interpreted as dideoxy termination sites.

For most sequencing projects, where maximizing the amount of sequence information obtained per template is desirable, the labeling/termination protocol is recommended. For situations where limited amounts of sequence information are required (such as verifying constructions, confirming mutations from oligonucleotide-directed mutagenesis, or confirming overlapping clones), the Sanger protocol is appropriate.

Thermal cycle sequencing

In thermal cycle sequencing, the reaction mixture containing template, a large excess of primer, dNTPs, ddNTPs, and a thermostable DNA polymerase is subjected to 20 to 30 cycles of denaturation, annealing, and elongation steps. Because the template DNA is utilized repeatedly, linear amplification of the sequencing products occurs, and only femtomoles of template DNA are required in the reaction. Thus, thermal cycle sequencing is particularly useful in situations where minimal amounts of DNA template are available. Sequence information can be obtained from individual bacterial colonies or phage plaques using 5'-end-la-

beled primers in the thermal cycle sequencing procedure (UNIT 7.3). Thermal cycle sequencing has been particularly useful for automated sequencing, which normally requires larger reaction mixtures than manual sequencing.

Thermal cycle sequencing eliminates the requirement for a separate annealing reaction as well as the requirement for denaturing double-stranded DNA templates prior to the sequencing reaction, saving considerable amounts of time. In addition, much less template DNA is required in the sequencing reaction than in traditional methods, because the template is amplified in the reaction. Finally, the rapid thermal cycling helps prevent sequencing problems due to reannealing of linear double-stranded templates such as PCR products. Because a thermostable DNA polymerase is required, this method offers the option of performing the elongation reaction at a high temperature to destabilize secondary structures that may be present in the DNA template (see discussion of premature termination below).

Thermal cycle sequencing is compatible not only with traditional radiolabeling methods as described in this unit, but also with nonradioactive labeling methods such as chemiluminescence (using 5'-end-biotinylated primers; see UNITS 3.18 & 3.19) or fluorescence (in automated sequencers using fluorescently end-labeled primers or ddNTPs; Sears et al., 1992). In the latter case, the mutant form of *Taq* DNA polymerase for DNA sequencing is the preferred enzyme to use, because it incorporates fluorescently tagged ddNTPs more efficiently than does Vent_R (exo⁻) DNA polymerase.

DNA polymerases for sequencing

The original Sanger protocol was developed utilizing the Klenow fragment of *E. coli* DNA polymerase I (Sanger and Coulson, 1978; Sanger et al., 1977, 1980). The labeling/termination protocol is a modification of the Sanger procedure designed to take advantage of the high processivity and elongation rate of Sequenase (Tabor and Richardson, 1987a, 1987b, 1989a, 1989b, 1990). Other DNA polymerases can be used in either protocol. The following discussion and Table 7.4A.2 and Table 3.5.1 contain a brief summary of the relevant properties of the DNA polymerases used for DNA sequencing. In addition to Sequenase and Klenow fragment, these include *Taq* and Vent DNA polymerases and other thermophilic DNA polymerases, and avian or murine reverse transcriptase.

Properties of DNA polymerases relevant for sequencing

3'→5' exonuclease. Some DNA polymerases, such as *E. coli* DNA polymerase I, native T7 DNA polymerase, and Vent DNA polymerase, have an inherent 3'→5' exonuclease activity that acts as an editor to remove misincorporated nucleotides or nucleotide analogs (Table 3.5.1). A 3'→5' exonuclease activity can be a problem for several reasons. First, it can make it difficult to label efficiently the synthesized fragments, since in the presence of low concentrations of dNTPs the exonuclease activity can operate more efficiently than the polymerase activity, resulting in degradation of the primer. Second, because the 3'→5' exonuclease activity serves a proofreading function, it can increase the discrimination against nucleotide analogs (e.g., dITP and 7-deaza dGTP) that are used in DNA sequencing by preferentially degrading primers that have incorporated the analogs. Third, it can increase the variability in band intensity because a polymerase will pause at some sequences, cycling between its polymerase and exonuclease activities, resulting in a turnover of dNTPs. This gives ddNMPs repeated opportunities to be incorporated, increasing the probability that they will be incorporated at such sites. Fourth, the 3'→5' exonuclease activity has sequence preferences for where it will remove a dideoxynucleotide, which will also result in an increase in the variability of bands on a sequencing gel.

5'→3' exonuclease. Some DNA polymerases, such as *Taq* and *E. coli* DNA polymerase I, also have a 5'→3' exonuclease activity. This can be a problem for DNA sequencing because with uniform labeling it will result in a heterogeneous 5' end (thus multiple bands). With 5' end-labeling, it will result in the loss of some labeled material altogether. The 5'→3' exonuclease activity of *E. coli* DNA polymerase I is not present in the Klenow fragment. In addition, several commercial versions of *Taq* DNA polymerase have the 5'→3' exonuclease activity removed by mutagenesis or posttranslational modification.

Processivity. Processivity refers to the ability of the enzyme to polymerize nucleotides on a DNA chain without dissociating from the chain (or the number of nucleotides polymerized per polymerase binding event). A nonprocessive polymerase undergoes many dissociation and reassociation cycles during chain growth; this can lead to a population of fragments terminated not by the incorporation of a dideoxynucleotide but rather by dissociation of

the polymerase at a site where reinitiation is impeded. This results in a background of radioactivity on the gel at positions that do not correspond to incorporation of a dideoxynucleotide. In contrast, with a highly processive polymerase, a greater percentage of chains will terminate with the incorporation of a dideoxynucleotide, increasing the signal-to-noise ratio in the sequencing gel.

Elongation rate. Elongation rate is the rate at which DNA synthesis occurs. A rapid rate of elongation is advantageous because if a polymerase synthesizes DNA at a slow rate (as does AMV reverse transcriptase), pause sites that are difficult to synthesize through are more likely to be a problem in the time frame of the sequencing reactions, leading to background bands on the sequencing gel.

Incorporation of nucleotide analogs. To be useful for sequencing, the DNA polymerase must be able to incorporate dideoxynucleotides. Polymerases differ dramatically in their ability to use ddNTPs. The degree of discrimination against ddNTPs determines the ddNTP:dNTP ratio required in the nucleotide mixes to achieve a sequencing ladder in the region of the gel that resolves fragments that differ by a single nucleotide. Klenow fragment and *Taq* DNA polymerase discriminate about 100-fold more strongly against ddNTPs than does Sequenase. As a consequence, these two enzymes require proportionally greater amounts of ddNTPs in the sequencing reactions. This is a factor to be considered in comparing the cost of DNA sequencing using the different protocols and enzymes. Other nucleotide analogs, such as dITP, 7-deaza-dATP (Pharmacia, 1991; Barr et al., 1986; Seela et al., 1989), 7-deaza-dITP, and 7-deaza-dGTP, are useful in destabilizing secondary structures that can cause “compressions” on the sequencing gel (see below); therefore the ability to efficiently incorporate these analogs is an advantage. In addition, the DNA polymerase must be able to incorporate α -thio-analogs (such as [α -³⁵S]dATP) to label the sequencing products with ³⁵S (see introduction to Chapter 7 for a discussion of the advantages of labeling sequencing products with ³⁵S compared to ³²P).

Band uniformity. If ddNTPs are discriminated against in a sequence-dependent manner, the intensity of adjacent bands in a sequencing ladder will vary. This is a problem for three reasons. First, it decreases the sensitivity of the sequencing method, which is limited by the ability to detect the faintest bands. Second, it can make it difficult to interpret whether a

Table 7.4A.2 Characteristics of DNA Sequencing Enzymes^a

Characteristic	T7	Klenow	<i>Taq</i>	Bst	Vent	AMV RT

^aModified from U.S. Biochemical. This information is meant to serve as a guideline, not as a reference source. Some characteristics depend strongly on reaction conditions. Enzyme abbreviations: T7, genetically modified T7 DNA polymerase (Sequenase Version 2.0); Klenow, *E. coli* DNA polymerase I, large fragment; *Taq*, *Thermus aquaticus* DNA polymerase; Bst, *Bacillus stearothermophilus* DNA polymerase; Vent, *Thermococcus litoralis* DNA polymerase, exo⁻; AMV RT, avian myeloblastosis virus reverse transcriptase. Other abbreviations used in the table are: inter., intermediate; Y, yes; N, no; ND, not determined.

^bMutants of Klenow are available that lack a 3'→5' exonuclease (Derbyshire et al., 1988); however, sequencing results identical to that of normal Klenow fragment are obtained.

^cSome versions of *Taq* DNA polymerase have the 5'→3' exonuclease genetically or chemically removed.

^dThis entry refers to whether the enzymes use dITP and dGTP efficiently.

^eTermination reactions; labeling reactions <37°C.

relatively weak band results from artifactual dissociation of the polymerase from the growing chain before a dideoxynucleotide is incorporated or from a correct stop due to inefficient incorporation of a ddNMP. Third, it makes it more difficult to read DNA sequences several hundred bases from the primer, where bands become increasingly close together. A large difference in radioactive intensity of adjacent dideoxy-terminated fragments increases the difficulty in determining whether the bands are due to single or multiple termination sites.

Temperature range. There are several situations in which it is advantageous for a DNA polymerase to be active at high temperatures. First, performing sequencing reactions at high temperatures makes it possible to increase the stringency of the primer annealing reaction to reduce priming at secondary hybridization sites on the template. Second, if the secondary structure of the template impedes the progress of the polymerase, resulting in incorrectly terminated chains, sequencing reactions can be performed at a high temperature to destabilize the secondary structure. Third, protocols for “thermal cycle sequencing,” which allow sequencing of nanogram amounts of template (see introduction to Chapter 7), require a thermostable DNA polymerase.

Sequenase

A high level of 3'→5' exonuclease activity in the native form of T7 DNA polymerase makes it ineffective for DNA sequencing. However, the exonuclease activity can be selectively removed without affecting the polymerase activity, either by a chemical reaction that oxidizes amino acid residues essential for exonuclease but not polymerase activity (Sequenase Version 1; Tabor and Richardson, 1987a) or genetically by deleting 28 amino acids essential for the exonuclease activity (Sequenase Version 2; Tabor and Richardson, 1989a). The chemically modified T7 DNA polymerase has 0.1% to 1.0% the level of exonuclease activity of the native enzyme, while the genetically modified T7 DNA polymerase has <10⁻⁷% the exonuclease activity of the native enzyme. While either can be used, the genetically modified enzyme has a higher specific activity than the chemically modified enzyme and yields more stable dideoxynucleotide-terminated fragments. T7 DNA polymerase does not have a 5'→3' exonuclease activity.

Sequenase synthesizes DNA at a rapid elongation rate by a highly processive mechanism (Table 7.4A.2). Under the termination reaction conditions, it discriminates against ddNTPs by ~4-fold compared to dNTPs. Thus, although Sequenase produces bands of higher uniformity than those produced by Klenow fragment or

Taq DNA polymerase, there is about a 10-fold variation in the intensity of adjacent bands (Fig. 7.4A.1). When Mn^{2+} is included in the reaction mixture, Sequenase incorporates dideoxynucleotides at the same rate as deoxynucleotides and the bands are almost completely uniform (see Alternate Protocol 1; Tabor and Richardson, 1989b, 1990). This high degree of uniformity is most advantageous for automated sequencing procedures.

Sequenase utilizes dITP and 7-deaza-dGTP efficiently (Fig. 7.4A.1). Sequenase has a tendency to stall in sequencing reactions using dITP, resulting in sequencing ladders which have a higher frequency of bands in all four lanes, typically at G positions. (However, this should not be used as a criterion for identifying G residues in ambiguous cases.) One group has reported successful removal of these inappropriately terminated products by reaction with terminal deoxynucleotidyl transferase (see troubleshooting; Fawcett and Bartlett, 1990). Labeling reactions using modified T7 DNA polymerase should be kept below 25°C, both to reduce the processivity of the enzyme and to maintain its activity in the termination reaction.

However, termination reactions using Sequenase can be performed from 37° to 55°C.

Klenow fragment

Klenow fragment has a 3'→5' exonuclease activity. However, it is a much weaker activity than that found in the native T7 DNA polymerase (Tabor and Richardson, 1989a) and does not interfere with the use of Klenow fragment for DNA sequencing. The 5'→3' exonuclease activity present in native *E. coli* DNA polymerase I is absent from Klenow fragment. Klenow fragment is relatively nonprocessive and has an intermediate elongation rate (Table 7.4A.2). The low processivity contributes to a somewhat higher background and lower signal-to-noise ratio than that found in reactions carried out using Sequenase. Occasionally, Klenow fragment encounters difficulty in reinitiating DNA synthesis at particular sites, resulting in "ghost" or "shadow" bands. The most common examples of this are: authentic T bands accompanied by faint shadow bands in the G and C tracks; authentic A bands accompanied by faint shadow bands in the G and C tracks; authentic A bands accompanied by faint shadow bands in the T track; and occasionally,

Figure 7.4A.1 Sequencing reactions using the labeling/termination protocol, Sequenase, [α -³⁵S]dATP labeling, and dGTP, dITP, or 7-deaza-dGTP (dc⁷GTP). Several compressions are present in the sequencing ladder produced with dGTP; each compression is bracketed, and the corresponding sequence is shown at the bottom of the figure. Regions of dyad symmetry are underlined, asterisks are above nucleotides corresponding to bands compressed in the presence of dGTP, and arrows are above "expanded" nucleotides. Electrophoresis was in a 7% acrylamide sequencing gel with wedge spacers (from Tabor and Richardson, 1987b; reprinted with permission of the authors).

authentic A bands accompanied by dark shadow bands in the other three lanes.

Klenow fragment discriminates strongly against ddNTPs, having a several-thousand-fold preference for a dNTP over the corresponding ddNTP. In addition, Klenow fragment exhibits a sequence-dependent variability in discrimination: adjacent dideoxy-terminated fragments can differ by as much as 50-fold in intensity. Listed below are the three most common examples of sequence-dependent discrimination in reactions using Klenow fragment: (1) The first A in a run of A's is usually the darkest (Fig. 7.4A.2, position 115). (2) The second C in a run of C's is always the most intense and the first C is very light; the third C is frequently dark as well (Fig. 7.4A.2, positions 59, 78, 90, and 106). (3) The second G in a run of G's is always very dark when the run of G's is preceded by a T (Fig. 7.4A.2, position 130).

Although the discrimination against ddNTPs is reduced over 100-fold by inclusion of Mn^{2+} (Tabor and Richardson, 1989b), a significant degree of sequence-dependent discrimination persists, producing bands that are still more variable in intensity than those resulting from reactions with Sequenase. 7-deaza-dGTP and dITP can each be used in sequencing

reactions with Klenow fragment. Sequencing reactions using Klenow fragment can be performed as high as 50°C.

Thermus aquaticus (Taq) DNA polymerase

Taq DNA polymerase lacks a 3'→5' exonuclease activity. Native *Taq* DNA polymerase has a 5'→3' exonuclease activity; however, a number of genetically engineered or posttranslationally modified versions of *Taq* DNA polymerase have recently been made commercially available in which the 5'→3' exonuclease activity has been removed. *Taq* DNA polymerase synthesizes DNA at an intermediate elongation rate with a moderate degree of processivity (Table 7.4A.2). It discriminates strongly against ddNTPs and requires ddNTP/dNTP ratios comparable to Klenow fragment. It exhibits band uniformity better than that of Klenow fragment but worse than that of Sequenase. Sequencing reactions carried out with *Taq* DNA polymerase generally produce a very clean background on the sequencing gel (Fig. 7.4A.3). 7-deaza-dGTP or 7-deaza-dATP can each be used in sequencing reactions with *Taq* DNA polymerase; however, dITP is usually not recommended for use with *Taq* DNA polymerase because of an unacceptably high frequency of inappropriately terminated chains

Figure 7.4A.2 Sequencing reactions using the Sanger procedure, Klenow fragment, and [α - 35 S]dATP labeling. The right panel was exposed for three times as long as the left panel. Electrophoresis was in an 8% sequencing gel at 60 W constant power for 1 hr (from Williams et al., 1986; reprinted with permission of *BioTechniques*).

(Fig. 7.4A.3). Sequencing reactions using *Taq* DNA polymerase can be performed at 55° to 70°C in low salt-buffer, conditions which promote destabilization of many template secondary structures (see troubleshooting; Innis et al., 1988; Peterson, 1988; Gyllensten, 1989; Brown, 1990).

Recent improvements on thermostable DNA polymerase have led to the development of mutant forms of *Taq* DNA polymerase—ThermoSequenase and AmpliTaq DNA polymerase FS (Tabor and Richardson, 1995)—which provide uniform termination efficiency and high-quality sequencing data in fluorescent cycle sequencing. ThermoSequenase contains a point mutation at the active site, in which phenylalanine is replaced with tyrosine at residue 667 (F667Y). This mutation results in less discrimination against dideoxynucleotides, and leads to a more even peak-intensity pattern. AmpliTaq DNA polymerase FS also contains a point mutation in the amino-terminal domain, in which glycine is replaced with aspartate at residue 46 (G46D), which removes almost all of the 5'→3' nuclease activity. This eliminates artifacts that arise from exonuclease activity.

Vent DNA polymerase

Vent_R DNA polymerase is purified from *E. coli* carrying the Vent DNA polymerase gene from the archaeobacterium *Thermococcus litoralis* (Perler et al., 1992; Kong et al., 1993). It lacks a 5'→3' exonuclease activity but has a 3'→5' exonuclease activity, giving it a high degree of fidelity that is useful for cloning. Vent_R (exo⁻) DNA polymerase is a genetically modified form of Vent_R DNA polymerase that has the 3'→5' exonuclease activity removed. This is the preferred form of the enzyme for sequencing. Like *Taq*, Vent_R (exo⁻) DNA polymerase synthesizes DNA at an intermediate elongation rate with a low degree of processivity (Table 7.4A.2; Jack et al., 1992). Vent (exo⁻) DNA polymerase has a relatively high *K_m* for dNTPs (~50 μM) and a relatively low *K_m* for DNA (~0.1 nM). Although the processivity of the enzyme is relatively low, under conditions of enzyme excess and appropriate concentrations of dNTPs and ddNTPs, the enzyme quickly binds and extends primers to create nascent dideoxy-terminated DNA chains (Sears et al., 1992; Jack et al., 1992; Kong et al., 1993).

Figure 7.4A.3 The left side of the figure shows the sequence of the polylinker region of M13mp7, which includes a 48-base inverted repeat (palindrome). The right side of the figure shows the products of sequencing reactions using M13mp7 DNA template, *Taq* DNA polymerase (Δ *Taq* Version 2.0), the protocol and reagents from the TAQuence Version 2.0 DNA sequencing kit (U.S. Biochemical), and dGTP, 7-deaza-dGTP (dc⁷GTP), or dITP. The secondary structure of the template DNA may inhibit elongation of the DNA polymerase under some conditions; synthesis in the presence of dITP is stopped completely within the palindromic region. No such stopping is seen on other templates lacking inverted repeat sequences. The palindromic region can also exhibit strong compression artifacts on sequencing gels; electrophoresis in these examples was in the presence of 40% formamide and 7 M urea. A mild compression near the 3' end of the palindrome (GGGGAATTC) is still evident in lanes with samples from dGTP-containing reactions (compare to samples from 7-deaza-dGTP-containing reactions). (Photo courtesy of Carl Fuller, U.S. Biochemical.)

Vent_R (exo⁻) DNA polymerase discriminates strongly against ddNTPs and requires ddNTP/dNTP ratios comparable to those of Klenow fragment. Although it exhibits better band uniformity than with Klenow fragment, the following effects of sequence-dependent discrimination against ddNTPs (illustrated in Fig. 7.4A.4) are generally seen: (1) The second A of a run of A's is darker than the preceding (and/or following) A's. (2) The first C of a run of C's is darker than the following C's. (3) G following an A tends to be darker than other G's. (4) T following an A tends to be darker than other T's.

In sequencing reactions, 7-deaza-dGTP or 7-deaza-dATP can each be used with Vent_R (exo⁻) DNA polymerase; however, dITP is not efficiently utilized by the enzyme. Sequencing reactions using Vent_R (exo⁻) DNA polymerase can be performed at temperatures up to 80°C, and the enzyme is stable for several hours at temperatures up to 100°C (Kong et al., 1993; Perler et al., 1992).

Vent_R (exo⁻) activity is distinguished from that of *Taq* by three major differences. First, although both enzymes exhibit a comparable temperature optimum between 75° and 80°C, Vent_R demonstrates increased thermostability at higher temperature over extended periods of time compared with *Taq* (e.g., at 95°C, the

half-life of Vent_R is 7 hr versus 1.6 hr for *Taq*), thereby allowing the use of high denaturation temperatures and extended reaction times without significant loss of enzyme activity. Second, Vent_R exhibits lower processivity than *Taq*, although limiting the size of extension products in sequencing reactions with Vent_R has not been a problem. Third, the 3'→5' exonuclease activity associated with Vent_R (and lacking in *Taq*) confers a "proofreading" activity that allows the removal of a misincorporated nucleotide at the 3' end of the growing strand. Polymerases such as *Taq* that lack this activity make many (up to ten-fold) more errors during DNA synthesis. However, even without the 3'→5' exonuclease activity, Vent_R (exo⁻) exhibits an error rate that is two-fold lower than that of *Taq*.

Bst polymerase

Bst polymerase is isolated from the mesophilic bacterium *Bacillus stearothermophilus*. The large fragment of the enzyme, used for sequencing, is prepared by subtilisin digestion of the *B. stearothermophilus* holoenzyme, DNA polymerase I (Ye and Hong, 1987). The enzyme rapidly synthesizes dideoxy-terminated fragments and is very efficient at primer and template utilization; polymerization rate is rapid, and while processivity rates have not yet been determined, they are likely low to moder-

Figure 7.4A.4 The results of thermal cycle sequencing of a double-stranded PCR DNA template utilizing the Vent_R (exo⁻) DNA polymerase followed by chemiluminescent detection. The lane order is A, C, G, T. The effects of sequence-dependent discrimination against ddNTPs are shown: (1) in the A lane, position marker shows an example of the second A in a run of A's darker than the preceding (and/or following) A's; (2) in the C lane, position marker shows that the first C in a run of C's is darker than the following C's; (3) in the G, C, or T lanes, position markers show that a nucleotide following an A tends to be darker than other nucleotides. (Photo courtesy of Millipore Corp./New England Biolabs, Inc.)

ate, as has been observed for other thermostable polymerases (Jack et al, 1992). *Bst* polymerase has also been shown to be useful in both robotic and automated sequencer formats (Mardis and Roe, 1989). *Bst* polymerase, similar to other thermostable enzymes and *E. coli* DNA polymerase I Klenow (or large) fragment, discriminates strongly against ddNTPs, requiring an excess of ddNTPs relative to dNTPs in the respective sequencing mixes. The heat-stable enzyme permits DNA sequencing at elevated temperatures and provides a highly uniform distribution of band intensities, using either a Sanger (“one-step”) protocol or a labeling-termination type protocol (Mardis and Roe, 1989; McClary et al., 1991; Mead et al., 1991). While the temperature maximum for the sequencing reaction is about 70°C, the enzyme does not have the inherent heat stability to be useful for thermal cycling protocols. Nevertheless, *Bst* polymerase has been shown to be useful for sequencing templates with difficult G+C and “hairpin” palindromic regions (Ye and Hong, 1987). The higher reaction temperature helps alleviate problems due to premature termination (nondideoxy terminated fragments; see above). *Bst* polymerase is also able to incorporate base analogs such as 7-deaza dGTP and dITP to aid in the relief of gel compressions (see above), although the ratios of these nucleotides to ddGTP must be doubled, relative to that of dGTP.

Reverse transcriptase

Avian myeloblastosis virus (AMV) reverse transcriptase has been used for DNA sequencing in the past but is not now widely used. This enzyme lacks both 3'→5' and 5'→3' exonuclease activities. Compared to the other polymerases used for sequencing (Table 7.4A.2), it has an intermediate level of processivity and a low rate of elongation. The slow rate of elongation is a disadvantage for DNA sequencing as it is more difficult to obtain as incorporation of radioactivity into the fragments and background bands due to sites where the polymerase has paused are more frequent. AMV reverse transcriptase uses ddNTPs efficiently and requires ddNTP:dNTP ratios comparable to those for Sequenase. It exhibits slightly better band uniformity than does Klenow fragment. 7-deaza-dGTP can be used in sequencing reactions with reverse transcriptase. Sequencing reactions using AMV reverse transcriptase can be performed at 37° to 42°C (Mierendorf and Pfeffer, 1987; Stoflet et al., 1988; Zagursky et al., 1985; Bartlett et al., 1986; Krawetz, 1987).

Choosing a DNA polymerase for sequencing

Deciding which DNA polymerase to use for a sequencing project is sometimes as much a matter of convenience or personal preference as it is a decision based upon enzyme characteristics; in general, more than one polymerase can give reliable sequence information when used properly in a given protocol with clean templates. Conversely, since any of the DNA polymerases can produce artifactual sequence data under certain conditions, as the size of a sequencing project increases, so does the likelihood that no single enzyme will give 100% unambiguous data. A strategy that is usually effective consists of choosing one enzyme to generate the bulk of the sequence data and then switching to an alternate enzyme and/or protocol to resolve ambiguities.

For sequencing projects that do not require thermal cycling, use of Sequenase with the labeling/termination basic protocol is recommended because of its high degree of band uniformity, low background, and efficient use of ddNTPs and other nucleotide analogs. The only drawback is that Sequenase is not thermophilic. In situations where a thermostable DNA polymerase is required, *Taq* DNA polymerase or one of the other thermophilic DNA polymerases should be used.

Klenow fragment can also be used in the labeling/termination protocol. Klenow fragment is readily available from a large number of sources and has a long (and strong) track record of use in DNA sequencing.

In the Sanger protocol, Klenow fragment is generally the most appropriate enzyme to use; *Taq* DNA polymerase is a good alternative when template secondary structure causes premature termination of Klenow fragment. Template secondary structure most commonly occurs in stretches of DNA that are rich in G+C or A+T or that are extensively palindromic (see Troubleshooting). Reverse transcriptase has proven to be effective at sequencing through G-C-rich regions, while Klenow fragment has been effective at A-T-rich regions.

Using *Taq* DNA polymerase with a 5'-end-labeled primer in the one-step alternate protocol at 70°C is a good method for sequencing templates that are the products of the polymerase chain reaction (PCR; Chapter 15). In this case, the high temperature of the sequencing reactions not only destabilizes template secondary structure but also provides increased priming specificity. Vent_R (exo⁻) DNA polymerase, with the appropriate buffer and nucleotide mixes, can be used in place of *Taq* DNA po-

lymerase for sequencing reactions that require a high reaction temperature. [Nonthermal cycling protocols using Vent_R (exo⁻) DNA polymerase are available (Sears et al., 1992).]

For large sequencing projects, use of fluorescent cycle sequencing (Alternate Protocols 7 and 8) is recommended because of the simplicity of the procedure and the automation of data analysis.

Thermal cycle sequencing protocols obviously require a thermostable polymerase such as Vent_R (exo⁻)—as described in this unit—or the mutant forms of *Taq* DNA polymerase ThermoSequenase or AmpliTaq FS. Thermal cycle sequencing is particularly useful for sequencing small amounts of DNA or templates that tend to have secondary structures, such as PCR products (UNIT 15.2) or large double-stranded templates such as λ gt10, λ gt11, or cosmids.

Critical Parameters

For automated fluorescent sequencing (Alternate Protocols 7 and 8), refer to Automated DNA Sequencing: Chemistry Guide 1998, from Perkin-Elmer Applied Biosystems, which is available at <http://www2.perkin-elmer.com/ab/techsupp/377.html>. This guide contains detailed steps for performing fluorescent sequencing, as well as Critical Parameters and Troubleshooting information.

Primer/template ratio

In the labeling/termination and Sanger procedures, the optimal primer/template molar ratios are 1:1 for a single-stranded DNA template and 2:1 for a double-stranded DNA template. Increasing the ratio to >5:1 can result in the primer annealing to secondary sites on the template, resulting in extra “ghost” or “shadow” bands. However, a higher ratio of primer to template can be used with λ templates without detriment, possibly because the complexity of λ -derived vectors is generally greater than that of most plasmid-based templates, providing a larger pool of potential secondary annealing sites.

In the thermal cycle sequencing procedure, less template is required than in the labeling/termination or Sanger protocols because it is repetitively utilized during the reaction. However, primers are elongated into sequencing products and thus removed from the reaction, so primer is required in amounts comparable to those in a noncycling protocol. Thus the initial molar ratio of primer to template is much higher (15:1).

Annealing temperature

The maximum annealing temperature for primers that are 15 to 25 nucleotides long and that are used in the sequencing buffers in this unit can be approximated as $4 \times (\text{number of G and C residues}) + 2 \times (\text{number of A and T residues}) - 5$ (Van Zeeland et al., 1990). Thus, the maximum annealing temperature for a 20-mer, 50% G+C, is 55°C. If annealing times are longer than recommended in the sequencing protocols, the authors recommend annealing close to the maximum annealing temperature to prevent hybridization of the primer at secondary sites on the template. When sequencing reactions are performed at high temperatures with thermophilic DNA polymerases, the initial 30 sec of the labeling reaction in the labeling/termination protocol, or the sequencing reaction in the Sanger protocol, should not be at a temperature greater than the maximum annealing temperature for the specific primer.

In the thermal cycle sequencing procedure, the standard annealing temperature setting is 55°C; however, for primers that have a high A+T content or that are <20 bases, it may be necessary to adjust the primer annealing temperature to 50°C. Conversely, for primers have a high G+C content or that are >24 bases, it may be possible to skip the annealing step.

Thermal cycling conditions

If the amount of template DNA used in the thermal cycling protocol is larger than recommended, the number of cycles in the reaction may be reduced. However, when smaller amounts of DNA are used, increasing the number of cycles to >30 has not been successful; often “ghost” or “shadow” bands become more prominent.

The cycling regime may also be varied. The authors have performed the thermal cycling protocol using a two-step cycle, a 95°C denaturation step, and a 72°C annealing and extension step using primers with apparent melting temperatures as low as 55°C. The signal intensities under these conditions may be weaker than with the standard three-step protocol. Another way to perform two-step cycling is to lower the extension temperature to that of the annealing step, i.e., a 95°C denaturation and 55°C annealing and extension. Because of their high efficiency at ramping from one temperature to another, some thermal cycler machines may need to be set for longer reaction times (increasing each step from 20 sec to 1 min in each cycle) to achieve optimal results.

Factors affecting extension lengths in the labeling/termination protocol

For a given polymerase, three major parameters determine the average extension length of the synthesis reactions. The first factor is the concentration of dNTPs in the labeling reaction. Longer sequencing reaction products can be obtained simply by increasing the concentrations of nucleotides in the labeling mix. The two types of labeling mixes that have been provided in this unit are calibrated to give shorter (<350 bases) or longer (>150 bases) sequencing products.

The second factor determining the average extension length is the dNTP:ddNTP ratio in the termination reaction mixtures. Thus, the ratio of dNTP:ddNTP will determine in a predictable, statistical manner the average length of the extensions, depending upon the ability of the DNA polymerase to discriminate against the incorporation of dideoxynucleotides. Basic Protocol 1 uses a 10:1 ratio of dNTP to ddNTP. In the presence of Mg^{2+} , which is the metal ion used in the labeling/termination basic protocol, Sequenase discriminates ~4-fold against ddNTPs (Tabor and Richardson, 1989b). Thus, each chain is extended during the termination reaction an average of 120 nucleotides before incorporation of a dideoxynucleotide, although the range of extension lengths is quite wide. A higher dNTP/ddNTP ratio will result in correspondingly longer extensions while a lower ratio will result in terminations nearer the start of the primer.

The third factor is the amount of template DNA. During the labeling reaction, the primers are extended until the nucleotide pool is exhausted. Thus, the smaller the amount of template present in the reaction mixture, the further each primer will be extended on average. For M13 DNA templates or double-stranded plasmid DNA templates, ~0.5 pmol of template gives a broad distribution of radioactive fragments from near the primer to several hundred bases in length.

In summary, for normal labeling/termination reactions, the short labeling mixes are usually adequate. If only the first 100 nucleotides from the primer are of interest, four factors can be varied, to produce a greater percentage of terminations in this region: (1) the concentration of the three dNTPs in the short labeling mix can be reduced (e.g., 3- to 5-fold); (2) the time of the labeling reaction can be reduced (e.g., to 2 min); (3) the dNTP/ddNTP ratio in the termination mixes can be decreased (e.g., ~5-fold) by raising the ddNTP concentration);

and (4) the DNA concentration can be increased (e.g., 2-fold). It is not necessary to vary all of these factors; in most cases the size range of sequencing products can be closely regulated by varying just the concentration of the three dNTPs in the labeling reaction.

If the sequence just after the primer is the major region of interest, the intensity of the bands corresponding to this region can be increased by the addition of Mn^{2+} to the labeling/termination reactions (Alternate Protocol 1; Tabor and Richardson, 1989b, 1990). Use of Mn^{2+} reduces the discrimination against ddNTPs by Sequenase by ~4-fold and thus has the same effect as increasing the ddNTP to dNTP ratio by a factor of four. As a consequence, the average extension of each radioactive fragment in the termination reaction is reduced proportionately.

If sequences 300 to 1000 nucleotides from the primer are of primary interest, then either the concentration of the four dNTPs in the labeling reaction can be raised (by using the long labeling mixes and increasing the amount of [α - ^{35}S]dATP) or the dNTP:ddNTP ratio in the termination mixes can be increased (e.g., by a factor of 2 to 3).

Using the short and long labeling mixes, respectively, 3 pmol and 15 pmol of each nucleotide are added to the labeling reaction. The amount of [α - ^{35}S]dATP included should not be lower than these values so that it will not become the limiting nucleotide. Amounts greater than these are not incorporated in the labeling reaction since the other three dNTPs become limiting. However, the authors have found empirically that adding an excess of [α - ^{35}S]dATP (such as 40 pmol, or 2 μ l of 500 Ci/mmol at 10 mCi/ml) to the labeling reactions containing the short mixes results in darker bands on the sequencing gel. This is probably because the [α - ^{35}S]dATP unused in the labeling reaction contributes a significant proportion of the dATP in the termination reactions. It is recommended that only the appropriate amount of [α - ^{35}S]dATP be used in the labeling reactions to avoid generating more radioactive waste than necessary, and because the labeled nucleotide is a significant fraction of the cost of sequencing reagents.

Factors affecting extension length in the Sanger and thermal cycle sequencing procedures

Because extension and termination occur in the same step in the Sanger and thermal cycle sequencing procedures, the average length of

Table 7.4A.3 General Troubleshooting Guide for Dideoxy Sequencing

Problem	Possible cause	Solution
Blank autoradiogram	Inactive polymerase	Test using control primer, template, and reagents.
	Old label Old reagents Incorrect or defective primer Incorrect or defective template	Replace defective reagent.
Entire autoradiogram too light/poor incorporation of label	Incorrect exposure procedure (plastic wrap left on, gel facing backwards, etc.)	Correct error
	Old label	Obtain new label
	Low enzyme activity	Obtain fresh preparation of enzyme. Dilute immediately before use and keep on ice.
	Primer did not anneal well to template	See critical parameters for calculating maximum annealing temperature for primers. If template is double-stranded, remember to denature it in alkali before annealing (<i>UNIT 7.3</i>).
	Not enough primer	Test using control DNA and primer. Check concentration of primer. Use 0.5 pmol/single-stranded template, 1 pmol/double-stranded template.
	Not enough template	Test using control DNA and primer. Check template concentration on gel or by other method. Use ~0.5 pmol template DNA per set of reactions.
High background in all lanes	Incorrect exposure or development of autoradiogram	Reexpose gel. Change developing reagents, if necessary.
	Failure to remove plastic wrap from gel if using ³⁵ S	Remove plastic wrap
	Impure template DNA	See if problem persists with control DNA. If not, make new template DNA. For single-stranded templates, try optional annotations in <i>UNIT 7.3</i> . For double-stranded templates, treat with RNase A (<i>UNIT 3.13</i>), phenol extract and ethanol precipitate (<i>UNIT 7.3</i>). If necessary, CsCl-purify DNA.

continued

dideoxy-terminated fragments can only be adjusted by changing the ddNTP/dNTP ratio in the sequencing mixes. Changing the extension length in the Sanger reaction is most common when sequence information close to the primer is of interest. In this case the ddNTP:dNTP ratios can be increased ~5-fold, usually by increasing ddNTP concentrations. Conversely, decreasing the ddNTP concentration will effectively lengthen the sequence that can be read, while decreasing the frequency of stops at the bottom part of the sequence. If the template is particularly rich in one nucleotide, depletion of

the complementary nucleotide in that reaction can occur (because the dNTP concentration is lower in that reaction mix) and the sequencing ladder for that reaction may “fade out” at the top. In these cases, the ddNTP/dNTP ratio can be individually adjusted (e.g., by raising the dNTP concentration in that mix).

Troubleshooting

For automated fluorescent sequencing (Alternate Protocols 7 and 8), refer to Automated DNA Sequencing: Chemistry Guide 1998, from Perkin-Elmer Applied Biosystems, which

Table 7.4A.3 General Troubleshooting Guide for Dideoxy Sequencing, continued

Problem	Possible cause	Solution
Bands throughout the lanes are diffuse or fuzzy	Impure template DNA	See if problem persists with control DNA. If not, make new template DNA. For single-stranded templates, try optional annotations in protocol, <i>UNIT 7.3</i> . For double-stranded templates, treat with RNase A, phenol extract and ethanol precipitate as described in <i>UNIT 7.3</i> . If necessary, CsCl-purify the DNA.
	Poor quality of acrylamide gel	Prepare fresh acrylamide, bisacrylamide, and buffers using only high-quality reagents. Store stock solutions at 4°C in dark (<i>UNIT 7.6</i>).
	Gel used too soon after pouring	Let gel set up longer
	Buffer concentration in gel differs from concentration in reservoirs	Prepare gel and reservoir solutions from same 10× TBE stock
	Excessive boiling of samples	If samples are to be loaded on multiple gels, remove 3-μl aliquot of each reaction for heating and loading on gel
	Samples not denatured before running on gel	Heat samples in 95°C water bath 2 to 3 min
	Gel electrophoresis at too high a temperature	Monitor gel temperature with thermometer, keep temperature below 65°C. If necessary, run gel at lower wattage to keep temperature lower.
Areas on gel where bands are fuzzy	Gel or plastic wrap on top of gel dried with wrinkle	See <i>UNIT 7.6</i> , processing sequencing gels, for suggestions to avoid wrinkles
	Film was not clamped tightly to the gel	Insert filter paper behind gel to take up any extra space in X-ray cassette. Use more clamps, if necessary.
Distortion of all bands in 450-550-nucleotide region of the gel	>0.5% glycerol in samples (Tabor and Richardson, 1987b)	Dilute DNA polymerase in diluent without glycerol
Bands in all four lanes over entire gel	Low enzyme activity	Use fresh enzyme preparation; dilute immediately before use in appropriate diluent or 1× sequencing buffer
	Incorrect buffer or nucleotide mixes	Prepare new mixes
	Contaminated reagents	Prepare fresh reagents
Anomalous spacing of bands, missing bands, or bands at the same position in two or three lanes only at specific regions	Compression (due to secondary structure of newly synthesized DNA strands under conditions of gel electrophoresis)	See Commentary for a discussion of various methods for eliminating compressions
Bands at the same position in more than one lane throughout the gel	DNA preparation contains two different DNAs that are producing overlapping sequences	Prepare new DNA starting from a single plaque or colony
	Primer has annealed to secondary sites on template	See Critical Parameters for discussion of primer/template ratio and annealing temperature

Table 7.4A.4 Guide to Troubleshooting in the Labeling/Termination Protocol

Problem	Possible cause	Solution
Bands at the same position in all four lanes, especially near the primer	Impure template DNA ^a	See if problem persists with control DNA. If not, make new template DNA.
	Impure or old reagents; not enough dNTPs ^a	Prepare fresh reagents
	DNA polymerase activity low ^a	(1) Use fresh enzyme preparation. (2) Add more enzyme, e.g., four times as much per reaction. (3) Dilute enzyme immediately before use. (4) Reduce labeling reaction to 2 min to minimize the chance of T7 DNA polymerase dissociating from template.
Bands below a certain site on the gel are very dark, and bands above that are very faint	Secondary structure of the template impeding the extensions in the labeling step	Alter the conditions of the labeling reaction so that the extensions in the labeling reaction do not reach the secondary structure: (1) lower the concentration of the 3 dNTPs in the labeling mix, e.g., dilute 4-fold; (2) reduce the time of the labeling reaction to 1 or 2 min; (3) raise the DNA concentration 2- to 3-fold Use higher reaction temperature with alternate polymerase (and maybe alternate protocol) such as thermophilic polymerase. Refer to Commentary for discussion of alternate polymerases. Add 0.5 µg <i>E. coli</i> single-stranded DNA binding protein to the labeling reaction to help the polymerase synthesize through regions of secondary structure. The binding protein must be removed by treating with 0.1 µg of proteinase K at 65°C for 20 min after adding formamide/dye stop solution.
Intensity of bands at the bottom of gel is too low	Proportion of extensions that have terminated near the bottom of the gel is too low	Reduce the concentration of the labeling mix in the labeling reaction, e.g., dilute an additional 3- to 5-fold Reduce labeling time to 1 to 2 min Raise DNA concentration 2- to 3-fold Decrease ratio of dNTP to ddNTP in the termination reaction, e.g., raise the ddNTP concentration 2-fold Use a primer that lies further upstream of the site to be sequenced
Intensity of bands at the top of the gel is too low	The polymerase is incorporating a ddNMP before the DNA fragments have reached the appropriate length	Raise the concentration of the labeling mix in the labeling reaction (e.g. by using “long” mixes) Increase the dNTP/ddNTP ratio in the termination, e.g., reduce the ddNTP concentration in each termination mix 2-fold
Range of bands that can be sequenced is narrow (radioactivity is restricted to bands spanning 200 nucleotides)	DNA concentration in the sequencing reaction is low	Increase the DNA concentration in the sequencing reaction to 2 µg

^aThis may occur because of enzyme pausing during the labeling reaction and not reinitiating synthesis efficiently.

Table 7.4A.5 Guide to Troubleshooting in the Sanger Procedure

Problem	Possible cause	Solution
High background in “A” track, especially when [³⁵ S]dATP is older than one half-life	Old label	Replace with fresh label, or reduce label in reactions
Intensity of bands is too low at top of gel	Ratio of ddNTP to dNTP is too high	If problem is specific to one mix make up new nucleotide mix; otherwise decrease ddNTP/dNTP ratio by lowering ddNTP in each mix
Intensity of bands is too low at bottom of gel	Ratio of ddNTP to dNTP is too low	If problem is specific to one mix, make up new mix; otherwise increase ddNTP/dNTP ratio by increasing ddNTP in each mix

is available at <http://www2.perkin-elmer.com/ab/techsupp/377.html>. This guide contains detailed steps for performing fluorescent sequencing, as well as Critical Parameters and Troubleshooting information.

Refer to Table 7.4A.3 for a guide to troubleshooting general problems that are encountered with dideoxy sequencing, and to Table 7.4A.4, Table 7.4A.5, and Table 7.4A.6 for problems specific to the labeling/termination, Sanger, and thermal cycle sequencing procedures, respectively.

DNA preparations of poor quality are the most common problem encountered with sequencing reactions. Template impurities reduce the effectiveness of DNA polymerase in the sequencing reactions, resulting in higher levels of artifactual bands caused by premature termination. It is important to have highly purified control DNA for testing or troubleshooting reactions.

Denatured double-stranded DNA templates can give particularly troublesome backgrounds because these preparations are often contaminated with residual salts, proteins, and RNA. Moreover, nicks in the DNA can act as priming sites during the sequencing reaction. Using a 5′-end-labeled primer rather than uniform labeling with [α -³⁵S]dATP often overcomes the background problems associated with nicked templates because only elongated primers are detected (see Alternate Protocol 5). Empirically, the authors have found that the greater the percentage of supercoiled molecules in a plasmid preparation, the lower the background on the sequencing gel. Thus, for example, it is recommended that an *E. coli* strain which is

EndoI⁻ be used to propagate the plasmid. Somewhat paradoxically, there are several reports in the literature that linearization of circular double-stranded DNA templates reduced artifactual bands (Gravel et al., 1985; Mierendorf and Pfeffer, 1987; Wallace et al., 1981).

Interpretation of sequencing gels

Refer to Figures 7.4A.1 and 7.4A.3 for examples of how to “read” dideoxy sequencing gels. Autoradiograms are read from bottom to top, i.e., in the direction of synthesis (5′→3′). The spacing between oligodeoxynucleotides that differ in length by only one nucleotide gradually becomes narrower towards the top of the gel. To read more sequence data at the top of the gel, a shorter exposure time is often best, as this results in finer bands and a cleaner background. Use of a higher-contrast film such as Kodak OM-1, rather than the Kodak XAR-5 recommended in *UNIT 7.6* can also help; however, the exposure time is about three times longer for OM-1 than for XAR-5 for a comparable exposure.

Dark “shadow” or “ghost” bands may become more of a problem with long exposure times. By paying careful attention to spacing between oligodeoxynucleotides and considering enzymatic artifacts described in the previous section, it is usually possible to determine what is a shadow band and what is not.

Compressions

The largest single problem encountered in both the dideoxy and chemical sequencing methods is that of compressions in the banding pattern. Compressions are electrophoretic arti-

Table 7.4A.6 Guide to Troubleshooting in the Thermal Cycle Sequencing Protocols

Problem	Possible cause	Solution
Bands are seen at same position in all four lanes, especially near primer.	Impure template DNA	See if problem exists with control DNA. If not, repurify DNA.
	Incorrect primer annealing temperature	Reduce primer annealing temperature; use longer (more stable) primer; increase annealing and extension steps to 1 min each
	Impure or old reagents; ddNTP amount too high or dNTP amount too low	Prepare fresh reagents and readjust dNTP/ddNTP ratios
Bands below a certain site on gel are very dark, and bands above that are very faint.	Secondary structure of template impeding extensions	Use higher reaction temperatures
A dark band is present across all 4 lanes of gel; bands below and above it are equally dark.	Secondary structure of reaction products causing anomalous electrophoresis position of products in gel	Use higher gel temperatures or formamide gel; use base analogs or TdT in reaction; for PCR products, check purification procedure
Intensity of bands at bottom of gel is too low.	Proportion of reaction products terminating near bottom of gel too low	Increase ddNTP:dNTP ratio in sequencing mixes
Intensity of bands at top of gel is too low.	Proportion of reaction products terminating near top of gel too low	Decrease ddNTP:dNTP ratio in sequencing mixes
One lane of reaction failed or is weak or smeary.	Possible cyclor fault in one reaction slot	Check cyclor performance
	Pipetting error	Review chemistry procedure
All lanes are smeary or show high backgrounds.	Template impurity	Review template preparation; run control DNA template
	Primer impurity	Check primer purity
	Cyclor problem	Check cyclor function
	Reagent problem	Review chemistry procedure; make fresh reagents
	Primer/template ratio too high Incorrect priming temperature	Review chemistry procedure Calculate T_m as guideline for reaction
Entire sequence is light.	Insufficient template or primer in reaction	Double DNA and primer quantities in reaction
	Cyclor error; incorrect or inadequate cycling conditions	Check cyclor performance; make steps 1 min instead of 30 sec; increase cycles to 30
Oil covering reaction makes it difficult to load gel.	Excess oil present	Remove oil or use hot top-apparatus (see commentary); microcentrifuge reaction before loading gel

facts that occur when the bases of the single-stranded product of the sequencing reaction interact to form secondary structures, such as hairpins, that are stable even in the 7 M urea that is included in the sequencing gel. Secondary structures are most likely to form in regions of DNA that contain extended palindromic sequences or that are rich in G and C residues.

In practice, the migration of an oligonucleotide in a sequencing gel is affected by secondary structure only when the region of DNA capable of forming that structure is found at the 3' end of the oligonucleotide. This explains the observation that the migration of only a few adjacent fragments in the sequencing ladder is altered by a sequence that can form a secondary structure. The result is that any given compression occurs only in a limited region of the gel. Anomalous spacing of bands, extra bands, or missing bands are all important clues that a compression has occurred. A typical compression pattern consists of comigration of bands in different lanes and anomalously wide spacing of bands above this region (Fig. 7.4A.1). However, it is sometimes nearly impossible to identify a compression from the sequence of one strand alone.

A compression does not typically occur at the same site on both strands. When a compression does occur, the region that will be compressed on the opposite strand (if the complementary secondary structure is stable) will be on the other side of the secondary structure. This is because the secondary structure cannot form until the nucleotides involved in forming the secondary structure have been added to the growing oligonucleotide chain. Thus, the best criterion for identifying compressions is any discrepancy in the sequence between the two strands. Analysis of the discrepancies and the potential secondary structure of the neighboring sequence often reveals the site of compression and the true sequence of the region.

A variety of methods have been used to eliminate compressions. A very simple solution that may resolve some compressions is to run the gels at the highest possible temperature. This approach is limited, however, by the tendency of the glass gel plate to crack at high temperatures and by reduction in the resolution of the gel at high temperatures, leading to "fuzzy" bands.

Inclusion of formamide in the sequencing gel promotes denaturation of secondary structures and often solves many compression problems (Fig. 7.4A.3; Martin, 1987; Brown, 1984;

U.S. Biochemical, 1990). If this approach is tried, include 25% to 40% formamide in the acrylamide gel solutions (see UNIT 7.6).

A third method for eliminating compressions, not widely used, is to chemically modify C residues so that they can no longer engage in the formation of G-C base pairs. This can be accomplished by treating the synthesized oligonucleotides with either bisulfite or a mixture of bisulfite and methoxyamine (Ambartsumyan and Mazo, 1980; Hayatsu, 1976). These three procedures for eliminating compressions are equally applicable to enzymatic or chemical sequencing methods (UNIT 7.5).

For enzymatic sequencing, the use of nucleotide analogs that have a lower tendency to form secondary structures is frequently an effective method for eliminating compressions (Fig. 7.4A.1). Deoxyinosine-5'-triphosphate (dITP) has been used traditionally for this purpose (Mills and Kramer, 1979). Inosine is an analog of guanosine that bonds considerably more weakly to cytidine. The concentrations in the nucleotide mixes must be adjusted to compensate for the fact that DNA polymerases use dITP less efficiently than dGTP. dITP is substituted for dGTP in the nucleotide mixes but ddGTP is still used (not ddITP; see Alternate Protocols; Bankier and Barrell, 1983).

When Sequenase is used in sequencing reactions containing dITP, some fragments are susceptible to degradation by a reaction called pyrophosphorolysis (see below). The presence of inorganic pyrophosphatase prevents this degradation (Tabor and Richardson, 1990). Pyrophosphatase should always be present when dITP is used in the labeling/termination procedure with modified T7 DNA polymerase. A mixture of modified T7 DNA polymerase and yeast inorganic pyrophosphatase can be mixed together and stored in 50% glycerol at -20°C (see reagents and solutions). These enzymes are stable together for several years. Sequencing reactions using dITP should be performed in parallel with reactions containing dGTP because dITP-containing reactions tend to have banding artifacts caused by premature termination of the polymerase.

An alternative to dITP that is effective in reducing band compressions in some cases is 7-deaza-dGTP (7-deaza-2'-deoxyguanosine-5'-triphosphate; Seela et al., 1982; Mizusawa et al., 1986; Barr et al., 1986). 7-deaza-dGTP, which has a methine moiety at the N-7 position of the guanine nucleus, has been suggested to reduce compressions by disrupting the formation of alternative Hoogsteen base pairs

(Mizusawa et al., 1986; Sarecchi et al., 1970). However, it is possible that 7-deaza-dGTP also interferes with standard Watson-Crick base pairing by base pairing more weakly with cytidine. 7-deaza-dGTP is used by Sequenase, Klenow fragment, *Taq* polymerase, Vent_R polymerase, and reverse transcriptase more efficiently than dITP; it can be substituted at a 1:1 molar ratio for dGTP in the sequencing reactions (see alternate protocols). However, it may not be as effective as dITP at removing many compressions (Fig. 7.4A.1; Tabor and Richardson, 1987b). 7-deaza-dATP in combination with 7-deaza-dGTP may also be useful in resolving compressions (Pharmacia, 1991).

Premature termination

Stretches of single-stranded DNA that are rich in G + C or A + T or that are extensively palindromic can be particularly difficult to sequence accurately, not only because of stable secondary structure formation in the products on the gel (compressions) but also because of stable secondary structure in the template during the sequencing reaction. When bands in all four lanes are seen at or shortly before such a sequence and the sequencing ladder is very faint after that point, it is likely that the template secondary structure in the sequencing reaction has prevented the DNA polymerase from advancing past the “foldback” position (Fig. 7.4A.3). In such cases, using more polymerase can be helpful. Another strategy is to perform sequencing reactions at a higher temperature to destabilize the template secondary structure. The thermophilic DNA polymerases, such as *Taq* DNA polymerase, are the enzymes of choice in this situation (see above). An alternative strategy is to include *E. coli* single-stranded DNA binding protein in the sequencing reactions to destabilize the secondary structures (Table 7.4A.4). For templates with severe secondary structure problems, chemical sequencing (UNIT 7.5) can be employed.

Premature termination can also result in “ghost” or “shadow” bands or bands in all four lanes. This can arise from a variety of causes, such as impure template DNA, use of dITP (Fig. 7.4A.3), or performing reactions at a temperature at which the polymerase rapidly loses activity. One group has reported improvement of “shadow” bands when using Sequenase in the labeling/termination protocol by addition of terminal deoxynucleotidyl transferase (TdT; UNIT 3.6) to the sequencing reactions (Fawcett and Bartlett, 1990). TdT, in the presence of dNTPs, extends chains which have not been

terminated by incorporation of a ddNMP in a template-independent process to higher-molecular-weight DNA.

Pyrophosphorolysis

During DNA synthesis, the incorporation of dNMPs results in the accumulation of inorganic pyrophosphate. At a high enough level, the inorganic pyrophosphate can drive the reverse reaction of polymerization, called pyrophosphorolysis. Pyrophosphorolysis can lead to the disappearance of specific fragments on a DNA sequencing gel with some DNA polymerases (e.g., Sequenase; Tabor and Richardson, 1990). The removal of a dideoxynucleotide by pyrophosphorolysis leaves a chain with a normal 3'-hydroxyl group that is then rapidly extended by the DNA polymerase. This results in bands that are missing from the sequencing ladder or whose intensity is weak. Pyrophosphorolysis is most noticeable when using Sequenase, and particularly in reactions in which dITP has been substituted for dGTP. A simple solution to this problem is the inclusion of inorganic pyrophosphatase in the sequencing reaction. It is strongly recommended that inorganic pyrophosphatase be present in all sequencing reactions using Sequenase; under these conditions, all bands are stable to incubation of the sequencing reactions for at least 1 hr (Tabor and Richardson, 1990). Alternatively, when using Sequenase in the absence of inorganic pyrophosphatase, incubation of the termination reactions should be kept to a minimum (5 min), particularly when using dITP. Pyrophosphorolysis has also been observed with AMV reverse transcriptase-catalyzed sequencing reactions (Ruan et al., 1990).

Time Considerations

The dideoxy sequencing protocol can be carried out in a single long day. In general, the authors recommend that if a large region of DNA is to be sequenced, the sequencing should be carried out in a concerted effort. DNA sequencing is easier, more efficient, and more successful when a daily rhythm has been established.

A day's work usually starts with pouring the sequencing gels. Then, template-primer annealing reactions are set up. During the annealing reactions, there is usually time to develop the autoradiograms of the sequencing gels from the previous day. Next, the primer extension reactions are started. When these are complete, the reactions are loaded onto the gels. After lunch, the gels are stopped, dried down, and put on film overnight. The day ends by cleaning the

gel plates and setting them up for the next day. The whole procedure takes 7 to 8 hr for 10 templates, 9 to 10 hr for 20 templates.

It is possible to split the protocol into 2 days. On day 1, the sequencing reactions are carried out, stop/loading dye is added, and the mixtures are stored overnight at -20°C . The sequencing gels can also be poured and stored overnight (see UNIT 7.6). The next day, the samples are defrosted, heated to 95°C for 2 min, and loaded on the sequencing gels. Samples containing uniform-labeled ^{35}S can be stored up to one week. Samples containing uniform-labeled ^{32}P should be run on the gel the same day; in this case only gels can be prepared on day 1.

The same schedule may be followed for thermal cycle sequencing. Alternatively, the gel may be poured in the afternoon and the cycling reactions set up to be run overnight. The following morning, the gel is run and processed and the procedure from the previous day is repeated as the gel is analyzed.

Dideoxy DNA Sequencing with Chemiluminescent Detection

Standard dideoxy DNA sequencing (UNIT 7.4A) can be performed easily and efficiently with nonisotopic, chemiluminescent detection by utilizing primers labeled with biotin in the sequencing reactions. Reaction products are separated by denaturing gel electrophoresis (UNIT 7.6), transferred to a nylon membrane, and detected by first binding a streptavidin–alkaline phosphatase conjugate, then incubating with a chemiluminescent 1,2-dioxetane substrate. The emitted light signal is imaged on standard X-ray film, producing high-resolution DNA sequencing ladders. This procedure is presented below (see Basic Protocol). Indirect alkaline phosphatase–labeling of biotinylated DNA with free streptavidin and biotinylated alkaline phosphatase is also detailed (see Alternate Protocol 1). Finally, the detection of sequencing reactions labeled with other haptens using specific antibody–alkaline phosphatase conjugates is described (see Alternate Protocol 2).

Most of the information in the Chapter 7 introduction and UNITS 7.1–7.3, and the methods described in UNIT 7.4A, are relevant to chemiluminescent sequencing methods. Primers derivatized with nonisotopic labels such as biotin can be utilized in protocols for DNA sequencing reactions designed for 5′-end-labeled primers. The products generated are subsequently detected by chemiluminescent methods. DNA sequencing reactions performed with Sequenase, Klenow fragment, *Taq* DNA polymerase, as well as thermal cycle reactions using Vent_R(exo[−]) polymerase, are described in UNIT 7.4A; sequencing using 5′-end-labeled primers and *Bst* polymerase is described here. Chemiluminescent DNA sequencing kits incorporating nonisotopically labeled primers and chemiluminescent detection reagents are commercially available (Table 7.4B.1). Biotinylation of oligonucleotide primers is possible using biotinylating phosphoramidites; alternatively, the labeled primers can be acquired from commercial sources at a relatively low cost. With standard cloning vectors, biotinylated versions of universal and many other primers are available and are usually included in nonisotopic DNA sequencing reaction kits.

DNA SEQUENCING USING BIOTINYLATED PRIMERS WITH CHEMILUMINESCENT DETECTION

BASIC PROTOCOL

In this protocol, DNA sequencing reactions are performed using biotinylated primers and *Bst* polymerase. Sequencing products are electrophoresed and DNA is transferred from the gel to a nylon membrane, then UV cross-linked to the membrane. It is incubated first with a streptavidin–alkaline phosphatase conjugate, then with a dioxetane detection solution before being exposed to X-ray film.

Alternatively, the 5′-biotinylated primers can be used in the end-labeled primer protocols of UNIT 7.4A; subsequent electrophoresis, transfer, and chemiluminescent detection is as described here.

Materials

- 1 μg single-stranded DNA (~0.5 pmole) or 1 to 3 μg denatured double-stranded DNA template
- Biotinylated DNA sequencing primer
- 5× *Bst* reaction buffer: 100 mM Tris·Cl, pH 8.5 (APPENDIX 2)/100 mM MgCl₂
- Primer termination mixes (A, C, G, T; see recipe)
- 1 U/μl *Bst* polymerase (Bio-Rad)
- 20× chase solution: 10 mM each of dATP, dCTP, dGTP, dTTP in H₂O

DNA Sequencing

7.4B.1

Supplement 47

Stop solution (see recipe)
0.2- to 0.4-mm-thick sequencing gel containing 8 M urea (*UNIT 7.6*)
1× TBE buffer (*APPENDIX 2*)
Blocking buffer I (see recipe)
Conjugate solution (see recipe)
Wash buffer I (see recipe)
Assay buffer (see recipe)
Dioxetane detection solution (see recipe)
65°, 70°, and 80°C water baths or heating blocks *or* thermal cycler
Filter paper (Whatman 3MM or equivalent)
Nylon membrane (Table 7.4B.1)
UV light source: UV cross-linking apparatus, UV transilluminator, *or* hand-held UV lamp
Large heat-sealable bags (~40 × 53-cm; Table 7.4B.1)
X-ray film (Kodak XAR-5 or equivalent)
Additional materials for DNA sequencing gel electrophoresis (*UNIT 7.6*) and exposure and processing of X-ray films (*APPENDIX 3*)

Perform DNA sequencing reactions

1. Prepare the DNA template mix by combining the following in a microcentrifuge tube:
 - 1 µg single-stranded DNA (~0.5 pmol) *or* 1 to 3 µg denatured double-stranded DNA template
 - 0.5 pmol biotinylated DNA sequencing primer
 - 2 µl 5× *Bst* reaction buffer
 - H₂O to 11 µl.

Heat to 70°C, then cool slowly over 30 min to 30°C.

This step is optional for most single-stranded templates. Sufficient primer annealing occurs at the 65°C reaction temperature (step 4).

2. While the template mix is cooling, aliquot 2 µl each of the A, C, G, and T primer termination mixes into four separate microcentrifuge tubes or microtiter plate wells, and label them A, C, G, and T. Warm the tubes or plate containing termination mixes to 65°C.
3. Add 1 µl *Bst* polymerase to the cooled template mixture from step 1.
4. Add 2.5 µl polymerase/template mixture to each primer termination mix set up in step 2 and incubate 5 min at 65°C.

This is the elongation-termination reaction.
5. Prepare a 1× chase solution by diluting the 20× chase solution stock with water. Add 2 µl of 1× chase solution to each sample tube or well and incubate 5 min at 65°C.

Eight microliters of diluted chase solution are needed per reaction set.
6. Add 4 µl stop solution to each tube or well.

At this point, reactions may be stored at -20°C for future use.

Run the DNA sequencing gel and transfer samples to nylon membrane

7. Set up a standard 0.2- to 0.4-mm-thick sequencing gel containing 8 M urea.

The width of the gel used must be <30 cm to accommodate the average width of commercially available nylon membranes (see step 9). Alternatively, several pieces of membrane

may be placed on the gel or the transfer may be accomplished by direct transfer electrophoresis (DTE; see Critical Parameters).

- Immediately before loading, heat reactions for 2 min at 80°C and place on ice. Load 2 to 3 μ l. Run gels as in UNIT 7.6, monitoring the migration of the marker dyes (see Table 7.6.2).

Do not perform the post-electrophoresis processing described in UNIT 7.6; DNA must be transferred from the gel to nylon membrane to perform the chemiluminescent detection.

- Cut three pieces of Whatman 3MM filter paper to size of gel or slightly larger. Cut a piece of nylon membrane that will cover the desired region of gel.

- Disassemble gel apparatus and separate glass plates.
- Place one piece of dry Whatman 3MM filter paper on the gel, gently rub the paper, and carefully lift the gel up by peeling back the paper. Place the paper with gel attached, gel-side-up, on the glass plate.

The glass plate provides support for the filter paper with the attached gel. It is not necessary to fix the gels or remove the urea.

- Wet nylon membrane thoroughly with 1× TBE buffer, either by immersion or by squirting the membrane with buffer from a squeeze bottle.
- Carefully place wet membrane on gel. Carefully roll a pipet or smooth rod over membrane to remove air bubbles.
- Place two pieces dry Whatman 3MM filter paper on top of membrane. Place another glass plate on top of filter paper and cover with ~2 to 4 kg of weight. Allow transfer to proceed 1 hr.

It is important to assemble the gel/membrane/filter paper/glass plate sandwich immediately after removing the gel from the plate, as the liquid in the gel will cause the filter paper to wrinkle over time. This may lead to uneven contact between the gel and membrane.

- Separate gel/membrane sandwich. Carefully peel membrane back from gel. Mark side of membrane that was in contact with gel with a pencil. Place membrane on filter paper, DNA-side-up, and air dry ~10 min.

Slightly wetting one corner of the membrane with TBE buffer may aid in the separation.

UV-cross-link DNA to membrane

- Using a UV cross-linking apparatus, UV transilluminator, or hand-held UV lamp, achieve a total UV exposure of the membrane of 120 mJ/cm². Proceed with step 17 or store membrane between two pieces of plastic wrap ≤6 months at 4°C.

UV exposure time may be calculated as in the following example: 1.2 mW/cm² × 100 sec = 120 mJ/cm². With most UV sources, irradiation times of 1 to 10 min are adequate. Overexposure to UV light is not deleterious to signal strength because DNA hybridization is not required for detection. Hand-held lamps can be used to expose the whole membrane by clamping the UV source to a support and consecutively exposing individual portions of the membrane. If necessary, the optimum exposure time for a particular UV light source can be calibrated by performing control experiments in which a number of membrane strips containing biotinylated DNA are exposed to varying amounts of irradiation.

Alternatively, baking 1 hr at 80°C may be used to immobilize the DNA with most nylon membranes, according to the manufacturer's recommendations.

Perform chemiluminescent detection

Perform the following steps at room temperature with moderate shaking (120 to 140 rpm). Add each solution either by cutting the bag and resealing with heat or by folding the cut corner of the bag several times and clamping it with binder clips (see Fig. 3.19.2). Reagent volumes given apply to a single 1000- to 1200-cm² membrane. For smaller membranes, add proportionately less of each solution (e.g., 250 ml blocking buffer to a 600-cm² membrane). Only one membrane per bag is recommended. Solutions should not be reused.

- Place the membrane in large heat-sealable bag. Add 500 ml blocking buffer I, carefully remove air bubbles and seal the bag, then incubate 10 min.

A large tray or a roller-bottle machine can be used in place of heat-sealable bags.

- Incubate 20 min in 200 ml conjugate solution.

19. Wash 5 min in 500 ml blocking buffer I.
20. Wash three times, 10 min each time, in 500 ml wash buffer I.
21. Wash two times, 2 min each time, in 500 ml assay buffer.
22. Incubate 5 min in 50 ml dioxetane detection solution.

Manual agitation by rubbing or rocking the bag will facilitate uniform distribution of the solution across the membrane.

23. Drain excess detection solution from bag, smooth out any wrinkles, and reseal.

The membrane must remain wet and extreme care should be taken to avoid any wrinkles during this step, as these will cause distortions in the imaged DNA sequence data. If bag sealing causes wrinkles, the sealed areas should be cut off and excess solution should be pressed out before the membrane is exposed to film. Alternatively, the membrane may be placed between two pieces of plastic wrap or thin Mylar film.

Expose and develop film

24. Place wrapped membranes in direct contact with X-ray film at room temperature.

Exposures are best performed in hard-sided cassettes with a clamping mechanism to ensure even contact of the film with the wrapped membrane.

An initial 60-min exposure is normally adequate. Additional shorter or longer exposures can be performed to optimize signal intensity and resolution. Light output will increase over a period of 6 to 8 hr due to the kinetics of the 1,2-dioxetane light emission on nylon membranes. Incubation of the wrapped membrane at room temperature for several hours before exposure will result in much shorter film exposure times (see Commentary).

TWO-STEP (INDIRECT) DETECTION USING STREPTAVIDIN AND BIOTINYLATED ALKALINE PHOSPHATASE

ALTERNATE PROTOCOL 1

An alternative method for binding alkaline phosphatase to biotinylated DNA takes advantage of the multiple biotin binding sites of streptavidin. Biotinylated primers are used in the sequencing reaction, and the DNA is electrophoresed and transferred to a nylon membrane as described in the basic protocol. Free streptavidin is then bound to the biotin-labeled DNA, followed by incubation with biotinylated alkaline phosphatase, which links the enzyme label to the DNA through a streptavidin bridge. This procedure generates chemiluminescent signal intensities similar to those obtained with streptavidin–alkaline phosphatase conjugates. The following solution volumes apply to one 1000-cm² membrane.

Additional Materials (also see Basic Protocol)

- Two-step blocking solution (see recipe)
- Streptavidin solution (see recipe)
- Two-step wash solution I (see recipe)
- Biotinylated alkaline phosphatase solution (see recipe)
- Two-step wash solution II (see recipe)

1. Carry out DNA sequencing reactions, electrophoresis, DNA transfer, and UV cross-linking (see Basic Protocol, steps 1 to 16).
2. Place membrane in a bag or container. Add 100 ml of two-step blocking solution and incubate 5 min.

Perform all incubations and washes from this step on with moderate shaking (120 to 140 rpm) at room temperature. Solutions should not be reused.

A large tray or a roller bottle machine can be used in place of heat-sealable bags.

DNA Sequencing

7.4B.5

3. Incubate 5 min in 50 ml streptavidin solution.
4. Wash two times, 5 min each time, in 500 ml of two-step wash solution I.
5. Incubate 5 min in 50 ml biotinylated alkaline phosphatase solution.
6. Wash two times, 5 min each time, in 500 ml of two-step wash solution II.
7. Wash 5 min in assay buffer.
8. Incubate 5 min with 50 ml dioxetane detection solution.

Manual agitation by rubbing or rocking the bag will facilitate uniform distribution the solution across the membrane.

9. Drain dioxetane detection solution, process membrane, and expose to X-ray film (see Basic Protocol, steps 23 and 24).

**ALTERNATE
PROTOCOL 2**

**SEQUENCING WITH HAPTEN-LABELED PRIMERS AND DETECTION
WITH ANTIBODY-ALKALINE PHOSPHATASE CONJUGATES**

As an alternative to biotin, other haptens such as digoxigenin, fluorescein, and 2,4-dinitrophenyl (DNP) may be used to label the products of the DNA sequencing reactions by incorporating primers labeled with these haptens. Primers 5'-end-labeled with the appropriate haptens are used in DNA sequencing reactions as described in the basic protocol or in the end-labeled primer protocols of *UNIT 7.4A*. Following gel electrophoresis, DNA transfer, and UV cross-linking, an antibody-alkaline phosphatase conjugate is substituted for the streptavidin conjugate used in the basic protocol; subsequent washing and detection steps are unchanged. Chemiluminescent signal intensity is highly dependent on the conjugate utilized and superior quality conjugates that have been tested for blotting applications are highly recommended (see Table 7.4B.1 for suppliers). Background levels can be higher with antibody detections using certain membranes; several membranes (e.g., Pall Biotodyne A, MSI MagnaCharge, Tropilon-Plus, and Boehringer Mannheim nylon membranes; Table 7.4B.1) are recommended for use with this protocol.

Additional Materials (also see Basic Protocol)

- 5'-haptent-end-labeled primer
- Blocking buffer II (see recipe)
- Wash buffer II (see recipe)
- Antibody-conjugate solution (see recipe)

1. Prepare the DNA template mix (see Basic Protocol, step 1), using a 5'-haptent-end-labeled primer in place of the biotinylated sequencing primer.
2. Perform the DNA sequencing reactions, run the sequencing gel, and transfer the DNA to a nylon membrane (see Basic Protocol, steps 2 through 17).

Sequencing reactions described in UNIT 7.4A may also be carried out.

3. Place the membrane in a bag or container and add 200 ml antibody-conjugate solution. Incubate 30 min.

Perform all incubations and washes from this step on with moderate shaking (120 to 140 rpm) at room temperature.

4. Wash 5 min in 500 ml blocking buffer II.
5. Wash three times, 10 min each time, in 500 ml wash buffer II.
6. Wash two times, 2 min each time, in 500 ml assay buffer.

7. Incubate 5 min in 50 ml dioxetane detection solution.

Manual agitation by rubbing or rocking the bag will facilitate uniform distribution of the solution across the membrane.

8. Drain dioxetane detection solution and expose to X-ray film as described in steps 23 and 24 of the basic protocol.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Antibody-conjugate solution

Prepare antibody-conjugate (e.g., anti-digoxigenin, anti-fluorescein, or anti-DNP alkaline phosphatase; Table 7.4B.1) dilutions in blocking buffer II (see recipe). Follow conjugate manufacturer's recommendations for the appropriate dilutions; these are typically 1/2500 to 1/10,000. Prepare fresh.

Assay buffer

Dissolve DEA (99% purity) in H₂O to 0.1 M (final), adjust pH to 10.0 with concentrated HCl, and add MgCl₂ to 1 mM (final).

Add sodium azide to 0.02% (w/v) to store solution for 2 to 7 days at 4°C.

Biotinylated alkaline phosphatase solution

Dilute biotinylated alkaline phosphatase to 0.5 µg/ml in two-step blocking solution (see recipe). Prepare fresh.

Biotinylated alkaline phosphatase that has been tested for chemiluminescent detection, available as part of kits from Millipore and New England Biolabs, is highly recommended.

Blocking buffer I

1× phosphate-buffered saline (PBS, see recipe)

0.2% (w/v) purified casein or membrane-blocking reagent (Table 7.4B.1)

0.5% (w/v) SDS

Prepare 1× PBS solution from 10× stock. Add casein or membrane-blocking reagent, heat to 70°C with constant stirring, then add SDS. Do not boil.

Add sodium azide to 0.02% (w/v) to store solution for 2 to 7 days at 4°C.

Blocking buffer II

1× phosphate-buffered saline (PBS, see recipe)

0.2% (w/v) purified casein or membrane-blocking reagent (Table 7.4B.1)

0.1% (v/v) Tween 20

Prepare 1× PBS solution from 10× stock. Add casein or membrane-blocking reagent, heat to 70°C with constant stirring, then add Tween 20. Do not boil.

Add sodium azide to 0.02% (w/v) to store solution for 2 to 7 days at 4°C.

Conjugate solution

Prepare streptavidin–alkaline phosphatase (Table 7.4B.1) in blocking buffer I (see recipe). Follow manufacturer's recommendations for appropriate dilution; 1/5000 is typically used. Prepare fresh.

Dioxetane detection solution

Prepare a 1/100 dilution of concentrated (100×) dioxetane (Table 7.4B.1) in assay buffer (see recipe). Make fresh and do not reuse solution.

Phosphate-buffered saline (PBS), 10×82.3 g Na₂HPO₄ (0.58 M)23.5 g NaH₂PO₄ (0.17 M)

40.0 g NaCl (0.69 M)

H₂O to 1 liter

Sterilize and store indefinitely at room temperature

*The pH of a 1× solution should be 7.2.***Primer termination mixes**

Concentrations of dNTPs and ddNTPs in the A, C, G, and T mixes are listed below in mM. Prepare all mixes in highly purified H₂O. Store indefinitely at −20°C.

	A	C	G	T
dATP	4	80	80	80
dCTP	80	4	80	80
dGTP	80	80	4	80
dTTP	80	80	80	4
ddATP	200	—	—	—
ddCTP	—	100	—	—
ddGTP	—	—	60	—
ddTTP	—	—	—	225

Stop solution95% (v/v) deionized formamide (*UNIT 14.3*)

10 mM EDTA

0.1% (w/v) xylene cyanol

0.1% (w/v) bromphenol blue

Store indefinitely at −20°C

Streptavidin solution, pH 7.2

1 mg/ml streptavidin

6.8 mM Na₂HPO₄3.2 mM NaH₂PO₄

150 mM NaCl

0.05% (w/v) sodium azide

Stable ≤6 months at 4°C

Streptavidin that has been tested for chemiluminescent detection, available from Millipore and New England Biolabs, is highly recommended.

Two-step blocking solution, pH 7.2

5% (w/v) SDS

17 mM Na₂HPO₄8 mM NaH₂PO₄

Add sodium azide to 0.02% (w/v) to store solution for 2 to 7 days at 4°C.

Two-step wash solution I

Prepare a 1/10 dilution of two-step blocking solution (see recipe) in water. Make fresh and do not reuse.

Two-step wash solution II

10 mM Tris·Cl, pH 9.5

10 mM NaCl

1 mM MgCl₂

Autoclave to sterilize, then store indefinitely at room temperature.

Wash buffer I

Prepare 0.5% (w/v) SDS in 1× PBS (see recipe). Make fresh if possible and do not reuse.

If necessary, add sodium azide to 0.02% (w/v) to store solution 2 to 7 days at 4°C.

Wash buffer II

Prepare 0.1% (v/v) Tween 20 in 1× PBS (see recipe). Make fresh if possible and do not reuse.

If necessary, add sodium azide to 0.02% (w/v) to store solution 2 to 7 days at 4°C.

COMMENTARY

Background Information

Originally, Maxam-Gilbert and Sanger dideoxy procedures involved the detection of DNA fragments labeled with radioactive isotopes. Recently, however, nonisotopic labeling alternatives have become widely used for DNA sequencing as well as for other applications in molecular biology (UNITS 3.18, 3.19 & 10.8). These nonisotopic methods have proven to be rapid, highly sensitive, and quantitative; furthermore, concerns associated with the use and disposal of radioactivity are eliminated.

Nonisotopic labeling techniques include colorimetric (BCIP and NBT; Richterich et al., 1989), fluorescent (Prober et al., 1987), and 1,2-dioxetane chemiluminescent methods (Beck et al., 1989; Tizard et al., 1990; Creasey et al., 1991; Martin et al., 1991; Hölte et al., 1992; Richterich and Church, 1993; Olesen et al., 1993). In standard isotopic-based sequencing, the label may be attached either to the sequencing primer or incorporated into the extension products as part of a modified nucleotide. For nonisotopic sequencing, the nonisotopic label is usually attached to the 5'-end of the sequencing primer. Although fluorescent detection methods generally require the use of relatively expensive automated equipment, chemiluminescent methods can be performed manually with standard sequencing gel electrophoresis and no specialized equipment.

The basic protocol for DNA sequencing with chemiluminescence described here is based on standard dideoxy methods. Through the incorporation of biotinylated primers, DNA fragments resulting from the sequencing reactions are biotin-labeled; they can then be detected by binding a streptavidin–alkaline phosphatase conjugate and incubating with a 1,2-dioxetane chemiluminescent substrate for alkaline phosphatase. The quality of the DNA sequence data is comparable to results obtained with radioactive isotopes. In fact, the method's high sensitivity has made the use of 1,2-di-

oxetane substrates increasingly popular. In addition to DNA sequencing, chemiluminescent techniques for performing Southern and western hybridization analyses have been developed (UNITS 3.18, 3.19 & 10.8).

Detection is based on the generation of a light signal following dephosphorylation of a 1,2-dioxetane substrate by the enzyme alkaline phosphatase. For example, enzymatic dephosphorylation of the 1,2-dioxetane CSPD (Table 7.4B.1) results in a strongly electron-releasing, destabilized dioxetane anion, which breaks down further, emitting light (Fig. 7.4B.1; Bronstein et al., 1991; Martin et al., 1991). The dephosphorylated dioxetane anion has a half-life of ~40 min on nylon membrane and the emission maximum is 460 nm. The kinetics of light emission of the 1,2-dioxetane substrates AMPPD and CSPD are shown in Figure 7.4B.2 (Martin et al., 1991). The relatively long half-life of the anion on nylon membrane results in the delay before maximum light emission. The presence of a chlorine atom, a remote substituent on the adamantyl group in CSPD, decreases the half-life of the anion, which results in greater intensity light output at early time-points. The shorter half-life, together with the more hydrophobic nature of the chloro-appended adamantyl group, also decreases the rate of diffusion of dephosphorylated anion and limits the loss of imaged band resolution observed in next-day exposures (Martin et al., 1991).

Other luminescent systems have also been used for the detection of nucleic acids (for a survey, see Kricka, 1992). Most of these systems have not been investigated in DNA sequencing applications. The other commonly used luminescent detection method for nucleic acids is based upon the activation of luminol with antibody–horseradish peroxidase conjugates (Matthews et al., 1985; Pollard-Knight et al., 1990). The use of luminol-based detection methods for DNA sequencing was reported by Richterich and Church (1993).

Standard chemiluminescent dideoxy sequencing with biotinylated primers using 1,2-dioxetane-alkaline phosphatase substrates is also described in Beck et al. (1989), Creasey et al. (1991), and Martin et al. (1991). Other sequencing/detection systems include the detection of digoxigenin-labeled DNA sequencing reactions with antibody-alkaline phosphatase conjugates (Höltke et al., 1992; Olesen et al., 1993) and the use of fluorescein- and dinitrophenyl (DNP)-labeled primers with detection by antibody-alkaline phosphatase conjugates (Olesen et al., 1993). DNA sequencing reactions can also be detected on nylon membranes by the hybridization of nonisotopically labeled probes followed by chemiluminescent detection using methods similar to genomic

sequencing procedures originally described for ^{32}P -labeled probes by Church and Gilbert (1984). These probes can either be labeled with biotin (Creasey et al., 1991) or alkaline phosphatase directly (Tizard et al., 1990; Karger et al., 1992, 1993).

Multiplex sequencing (Church and Kieffer-Higgins, 1988), which involves the sequential detection of overlapping sets of DNA reactions on one membrane by the successive hybridization of sequence-specific probes, has been performed with chemiluminescent detection (Creasey et al., 1991; Lakey et al., 1993). A multiplex-labeling procedure can also be used with chemiluminescent detection (Richterich and Church, 1993; Olesen et al., 1993). With this method, overlapping sets of DNA sequenc-

ing reactions, performed with primers labeled with different haptens (e.g., biotin, DNP, digoxigenin, or fluorescein) at the 5'-end, are detected sequentially using hapten-specific alkaline phosphatase conjugates.

The adaptability of the 1,2-dioxetane chemiluminescent detection system is demonstrated by the wide variety of DNA sequencing applications performed with the system. Simple adaptations of the basic protocol described here should be able to be used to perform other techniques requiring high resolution gels, including primer extension experiments and the detection of simple sequence repeat alleles by polymerase chain reaction (PCR) amplification (UNIT 15.1).

Critical Parameters and Troubleshooting

DNA sequencing reactions

Any type of sequencing reaction chemistry can be performed if 5'-end-labeled primers and protocols are utilized. An alternative labeling system based upon the incorporation of biotinylated nucleotides during the extension reactions is available as a kit from U.S. Biochemical (APPENDIX 4). It is important to use high-quality DNA sequencing reactions to give an adequate signal-to-noise ratio. If high backgrounds are seen on long exposures, a sequencing reaction using a control template, provided in many sequencing kits, can be used to distinguish between failure of the sequencing reactions and failure of the chemiluminescent detection procedure.

DNA transfer to membrane

The efficiency of DNA transfer to nylon membrane is highly dependent on the method and the type of membrane used. Capillary transfer seems to be more efficient with positively-charged nylon than with neutral nylon membranes (C.S.M., unpub. observ.). However, the use of neutral nylon normally results in lower background with antibody-based detections. Slightly sharper band resolution is exhibited when the gel is removed from the glass plate prior to setting up the transfer, as compared to placing the membrane directly on the gel without removing it from the plate. A similar membrane/filter paper sandwich is assembled using wet filter paper when the transfer is performed with a large-format electroblotting apparatus (Table 7.4B.1). The efficiency of transfer with an electroblotter is >90%, compared to ~20%

with the capillary method (C.S.M., unpub. observ.), although greater band resolution is achieved with the capillary transfer. This is most likely due to liquid-induced gel expansion during the electrophoretic transfer procedure. For most DNA sequencing experiments, the amount of DNA on the membrane transferred by the capillary method results in a strong chemiluminescent signal, but the more efficient electrophoretic transfer method may be necessary when smaller amounts of DNA are loaded on the gel.

As an alternative to standard gel electrophoresis and horizontal DNA transfer, direct-transfer electrophoresis (DTE) instruments are commercially available (Table 7.4B.1). They are modifications of the original design of Pohl and Beck (1987) and perform simultaneous electrophoretic separation and transfer to nylon membrane. They function by depositing the DNA fragments onto a membrane that is moved slowly along the bottom of the electrophoresis plates. Highly efficient DNA transfer and much better resolution of high-molecular-weight fragments are achieved with this apparatus, resulting in longer sequence readings.

UV cross-linking

Fixing the DNA fragments to nylon membrane prior to chemiluminescent detection is necessary with most membranes. Strongly positively charged nylon membranes such as Biodyne B (Pall) do not require UV cross-linking. However, other positively charged membranes, such as MSI MagnaCharge (Micron Separations, APPENDIX 4), appear to lose slight amounts of DNA during the detection procedures when UV cross-linking has not been performed. Without this cross-linking, neutral nylon membranes consistently lose DNA during the detection procedure. No reduction in the chemiluminescent signal intensity from UV irradiation when using biotinylated primers has been noted (C.S.M., unpub. observ.); therefore, UV cross-linking is recommended if the membrane has not been previously tested for DNA retention. Although overexposure to UV light does not decrease the ability to detect biotinylated DNA, it will interfere with the ability to hybridize probes to bound DNA. Procedures involving multiplex sequencing and detection of DNA sequences with oligonucleotide-alkaline phosphatase conjugates do require DNA hybridization, and it is important to cross-link DNA to the membrane with the optimum UV dose (generally 30–120 mJ/cm²).

Chemiluminescent detection

Chemiluminescent detection steps are easily performed in large plastic bags. Large trays can be used but it is often difficult to find the appropriate size and shape; in addition, larger solution volumes are usually necessary with the trays. Bags should be sealed close to the membrane with enough space at one end to permit resealing or folding. Large (60-cm) bag sealers that facilitate uniform sealing are available commercially (Table 7.4B.1). Folding the membrane can be avoided by adding solutions slowly and not using excessive volumes of solutions. When small volumes of solutions are added, as during the conjugate and substrate incubation steps, manual agitation by rubbing or rocking the bag will facilitate uniform distribution of the solution across the membrane. Membranes and bags should be handled with gloves.

Alternatively, a large format rotating-bottle apparatus (Table 7.4B.1) can be used to perform the chemiluminescent detection steps; in addition, an automated system is available that may be programmed to pump the detection reagents in and out of the rotating bottle (Table 7.4B.1). Both of these instruments utilize large bottles to accommodate full-size sequencing gel blots without overlap. Longer incubation times and washes are necessary with the roller-bottle assemblies (C.S.M., unpub. observ.).

To avoid bacterial alkaline phosphatase contamination, detection solutions should be prepared with ultrapure water. Diluted alkaline phosphatase conjugate solutions should be used immediately, and their reuse is not recommended. Reusing the substrate solution is possible but may result in much lower signal intensity if contamination by alkaline phosphatase occurs. Commercially available chemiluminescent DNA sequencing kits are convenient because they include membrane-blocking agents and enzyme conjugates that have been specifically optimized for use with chemiluminescence. The quality of commercially available enzyme conjugates varies greatly. Using a conjugate not specifically optimized for chemiluminescent detection on nylon membranes may lead to poor results. Casein preparations can be contaminated with biotin or alkaline phosphatase, leading to high background. Therefore, the use of highly purified casein or blocking agents optimized for membrane-based chemiluminescent detection is highly recommended.

Film exposure

The membrane should not be allowed to dry during film exposure. It may be left in the plastic bag and exposed to film after the substrate solution has been removed. However, nonuniform bag sealing may cause wrinkles, which will prevent even contact between the membrane and film and result in blurry regions or dark lines. To avoid this problem, a margin of ~2 cm should be left on all sides of the membrane when sealing the bag. The sealing seams should be trimmed from the bag after performing the chemiluminescent detection steps and excess solution should be squeezed out of the bag, using firm pressure from a paper towel, to avoid leakage during film exposure. Alternatively, the membrane may be placed in a new bag or between two pieces of plastic wrap (thicker wrap will wrinkle less). Two pieces of Mylar film, similar to the material used in report covers, works very well, but may be difficult to find in the right size. Thicker plastic sheets or previously used X-ray film may be used as a membrane support, with a layer of plastic wrap placed over the membrane (this results in fewer wrinkles than found when using two pieces of plastic wrap). It is important to note that the use of any thick transparent material will result in some loss of in-band resolution, because of the diffusion of light through a thicker layer.

Due to the kinetics of light emission of 1,2-dioxetane substrates on nylon membranes, the required exposure time will decrease over a 6- to 8-hr period (see Fig. 7.4B.2). However, delaying exposure to film after substrate addition is unnecessary. Generally, an initial 60-min film exposure will be ~2-fold lighter than a subsequent 60-min exposure performed immediately after this initial one. Film exposures obtained the next day may exhibit more diffuse bands, depending on the specific dioxetane substrate and membrane used. After 2 to 3 days, the signal will disappear from the high-signal areas of the membrane due to substrate depletion.

Table 7.4B.2 lists problems particular to dideoxy sequencing with chemiluminescent detection. General troubleshooting guidelines for dideoxy sequencing can be found in Tables 7.4A.3 to 7.4A.5.

Anticipated Results

Any template DNA can be sequenced using this chemiluminescent detection protocol with biotinylated primers. The technique is sensitive and flexible. The data generated are visualized on X-ray film and are similar to those achieved with radioisotopic detection. In general, band

Table 7.4B.2 Troubleshooting Guide for DNA Sequencing with Chemiluminescent Detection^a

Problem	Possible cause	Solution
High background	Contamination of reagents with alkaline phosphatase	Prepare all buffers daily; use ultrapure deionized water and other reagents free of alkaline phosphatase contamination. Avoid cross-contamination of wash solutions by conjugate solution—i.e., cover solutions during storage; wash funnel used for liquid transfers; clean outside of bag after each solution addition.
	Glove dust	Use powder-free gloves
	Insufficient agitation during incubations	Increase shaker speed; increase volume of liquid; remove air bubbles
	Nonspecific binding of conjugate to membrane	Increase incubation time with blocking buffer or increase number of washes after enzyme/conjugate incubation
Spotchy images	Bacterial or alkaline phosphatase contamination of membrane	Determine that all buffers are free of contamination prior to use and that membrane, blotting paper, and hybridization bags are clean and fingerprint-free
Spots or lines	Mechanical damage to the membrane	Repeat with new membrane
Poor band resolution	Exposure begun too long after substrate removal (depending on specific dioxetane substrate and membrane used)	Perform film exposures soon after substrate addition
	Membrane not in good contact with gel during transfer	Carefully press membrane onto gel with pipet; add heavier weight during capillary transfer procedure
	X-ray film not in good contact with membrane	Reseal membrane with plastic wrap and avoid wrinkles; use exposure cassette with clamps
Low signal	Incorrect assay buffer pH	Adjust assay buffer to pH 10
	Inefficient DNA transfer	Review transfer procedure and repeat experiment. When using capillary transfer method, it is very important to have gel sandwich on an absolutely flat surface. Increase amount of weight to provide more uniform transfer.
Low intensity signal from low-molecular-weight fragments	Low-molecular-weight fragments bind poorly, especially to neutral nylon	Use charged nylon membrane; always cross-link DNA to membrane

^aGeneral troubleshooting information on DNA sequencing reactions and gel electrophoresis is described in Critical Parameters and UNIT 7.4A.

resolution is as good as or better than ³²P detection methods.

Time Considerations

Due to the short film-exposure times, the chemiluminescent DNA sequencing procedure can be performed in a 7- to 10-hr period. The gel pouring and DNA sequencing reactions require 1 hr, and gel electrophoresis takes 3 hr. DNA transfer takes 1 hr, drying and UV cross-linking requires 0.5 hr, detection requires 1.5 hr, and film exposure takes 1 hr. It is advisable to reserve time at the end of the day to perform

any necessary extra film exposures. Alternatively, the procedure may be easily performed over 2 or more days or blocks of time.

Sequencing reactions and gel preparation can be performed in advance. Biotinylated DNA sequencing reactions are stable at -20°C for long periods of time. After electrophoresis and DNA transfer, the nylon membrane can be stored dry between layers of plastic wrap for several weeks at 4°C. UV cross-linking can be performed before or after storage. Any of the chemiluminescent detection steps, except the substrate incubation step, can be increased to

permit an experimental break. Long incubations in excess substrate solution can result in signal "bleeding" from the bands. The length of time suggested for each chemiluminescent detection step may be shortened, generally with satisfactory results. However, if higher background or lower signal occurs, the standard procedure should be followed.

DNA Sequencing by the Chemical Method

This procedure is written for a novice with no chemical sequencing experience. It is assumed, however, that the investigator has experience with DNA fragment isolation (UNIT 2.6) and DNA labeling with [^{32}P]dNTPs (UNITS 3.5 & 3.10). Table 7.5.1 is provided for quick reference during the sequencing reactions. Commercial kits for chemical sequencing are available from Du Pont and E. Merck (APPENDIX 4).

A DNA fragment labeled at only one end with ^{32}P or ^{35}S is divided into four aliquots and subjected to base-specific modification reactions. Piperidine is then added to catalyze strand scission at the modified bases. Finally, the four reactions are subjected to electrophoresis on adjacent lanes of a high-resolution denaturing polyacrylamide gel. The gel is then autoradiographed and the sequence is read from the film.

STRATEGIC PLANNING

The chemical (Maxam-Gilbert) sequencing procedure relies on DNA fragments labeled at *one* end with ^{32}P by a variety of labeling procedures. The DNA fragment can be either double- or single-stranded. Approximately 50,000 Cerenkov cpm are required. End-labeling of DNA at the 5' end can be achieved with T4 polynucleotide kinase and [γ - ^{32}P]ATP (UNIT 3.10). Labeling at the 3' end is achieved with terminal transferase and [α - ^{32}P]ATP followed by alkaline hydrolysis to remove all but the first adenylic acid residue (UNIT 3.6) or by "filling in" the complementary strand of a 5' single-stranded protruding end created by digestion with a restriction endonuclease (UNIT 3.5).

The methods described above always label both ends of the DNA fragment; there are several procedures to obtain a fragment labeled at only one end. In one approach, a restriction fragment labeled at both ends can be digested with a restriction endonuclease that cleaves the fragment asymmetrically. The two labeled fragments are then fractionated by gel electrophoresis and eluted from the gel (UNIT 2.6). In another approach, a fragment labeled at both ends is subjected to electrophoresis under denaturing conditions in which the two complementary single-stranded fragments are resolved. This latter method is no longer widely used and is not treated directly in this manual.

A third way to label only one end of a DNA fragment is to fill in an asymmetric restriction enzyme cleavage site as shown in Figure 7.1.1. Specialized cloning vectors pSP64CS and pSP65CS, described in UNIT 7.1, have been designed for this use. Vectors of this type are particularly convenient for cloning and labeling a set of nested deletions generated by nuclease *Bal* 31 digestion (UNIT 7.2). These vectors are strongly recommended when undertaking large-scale chemical sequencing projects. A support protocol for *Tth*111I digestion and end labeling is included in this unit. A protocol for small-scale plasmid preparation is provided in UNIT 7.3.

In the dideoxy sequencing method, larger oligodeoxynucleotides are much better resolved in the autoradiograms of sequencing gels when ^{35}S is used in place of ^{32}P . There are two reasons, however, why most investigators use ^{32}P for the chemical sequencing method. First, in the chemical method, each oligodeoxynucleotide contains a single radiolabeled nucleotide; because both the specific activity and the energy of decay is higher for ^{32}P than for ^{35}S , considerably shorter exposure times can be obtained with the ^{32}P label. Moreover, it is possible to shorten exposure time with an intensifying screen when using ^{32}P . Second, the oligodeoxynucleotides in the chemical sequencing method are present in approximately equimolar amounts and therefore all bands on an autoradiograph of a chemical sequencing gel have the same intensity. This results in excellent resolution with

³²P. In contrast, in the dideoxy method bands often differ considerably in intensity. If a high-intensity band is adjacent to a low-intensity band at the top of the gel, an exposure that allows the low-intensity band to be seen may overexpose the higher-intensity band, obscuring the lower-intensity band.

Despite the advantages of using ³²P labeling for chemical sequencing, it is sometimes convenient to use ³⁵S labeling. DNA fragments can be labeled at the 3' end using terminal transferase (*UNIT 3.6* and Ornstein and Kashdan, 1985).

CHEMICAL SEQUENCING USING ³²P-LABELED DNA

Materials

- ³²P-labeled DNA (see strategic planning)
- 3 M sodium acetate, pH 5.0
- Isopropanol
- 70% ethanol prepared with sterile H₂O
- Dimethyl sulfate (DMS) reaction buffer
- 5 M NaCl
- DMS
- Formic acid
- Hydrazine
- DMS stop buffer
- Hydrazine stop buffer
- 100% ethanol, prechilled to -20°C
- 5 M NaOH
- 3 M ferric chloride
- 10% piperidine, freshly prepared in sterile H₂O
- Formamide loading buffer

- 1.5-ml snap-top and screw-top (Sarstedt #72.692) microcentrifuge tubes
- 90°C water bath or oven

- Additional reagents and equipment for preparing and running sequencing gels (*UNIT 7.6*) and for autoradiography (*APPENDIX 3*)

Preparation of Salt-Free DNA

1. Precipitate [³²P]DNA by adding 3 M sodium acetate, pH 5.0, to 0.3 M plus 1 vol isopropanol, and place 5 min in a dry ice/ethanol bath (*UNIT 2.1*).
2. Microcentrifuge 5 min at 15,000 × g, room temperature, and discard supernatant.
3. Rinse the pellet twice with 1 ml of 70% ethanol, and dry.
³²P-labeled DNA must be rinsed thoroughly with 70% ethanol prior to sequencing to remove excess salt, which can suppress the reaction of hydrazine with thymine and result in faint T bands in the T + C lane.
4. Resuspend the salt-free DNA pellet in 40 μl sterile water.
5. Count the [³²P]DNA using Cerenkov counting by placing the entire tube in a 20-ml scintillation vial (no scintillation fluid), and counting on the ¹⁴C channel. Multiply the result by 4 to obtain the counts per minute.

If there are too many counts in the tube, 1 μl of the material can be spotted onto a small piece of Whatman 3MM paper, dried, and counted in a scintillation vial without fluid.

It is ideal to have ≥10,000 Cerenkov counts of [³²P]DNA per tube; however, it is possible to obtain a satisfactory sequence with as few as 1000 cpm.

- Distribute 10 μl [^{32}P]DNA into each of four 1.5-ml snap-top microcentrifuge tubes labeled G, G+A, T+C, and C.

If the same amount of DNA is used for each of the four base-specific modification reactions, the intensity of the bands in the G+A and T+C lanes will be approximately half the intensity of the bands in the G and C lanes. If this proves to be a problem, which might be the case if the amount of labeled fragment is limiting, use twice as much DNA in the G+A and T+C lanes.

When sequencing large numbers of samples, it is useful to perform each reaction sequentially. For example, when sequencing 10 samples, number the tubes consecutively from 1 to 40. Tubes 1 to 4 are G, G+A, T+C, and C, respectively, for sample 1; tubes 5 to 8 are G, G+A, T+C, and C, respectively, for sample 2, and so forth. The tubes containing each of the four reactions are color coded (e.g., the G reaction tubes 1, 5, 9, etc. all have the same color code). This allows each set of reactions for each sample to be readily distinguished when adding reagents. The G reactions are performed as a group, followed by the G+A group, etc. While the second group is reacting, the first group can be precipitating, and so on.

Sequencing Reactions

A detailed description of the sequencing protocol is given below and is designed to complement Table 7.5.1, which contains an outline of the sequencing reactions. The outline should be conveniently accessible when doing the sequencing reactions.

Prepare the DNA samples (Table 7.5.1A)

- Prepare the four DNA samples by adding DMS reaction buffer, water, and 5 M NaCl.

NaCl in the C reaction suppresses the reaction of hydrazine with thymine so that only cytosines react and are observed as bands on the gel.

Carry out the base-specific modification reactions (Table 7.5.1B)

CAUTION: Conduct these reactions in a fume hood wearing plastic gloves. DMS is volatile and toxic; it can be inactivated with 5 M NaOH. Hydrazine is toxic and in the anhydrous state, explosive; it can be inactivated with 3 M ferric chloride.

- Add DMS and formic acid to the G and G+A reaction tubes, respectively, and immediately close the tubes and mix.
- Add hydrazine to the T+C and C reaction tubes, and immediately close the tubes and mix.
- Incubate the four tubes at 25°C for the times indicated in Table 7.5.1B—use a stopwatch to time the reactions.

The concentrations of the reagents should not be modified (except for DMS; see commentary) since this may result in unwanted side reactions. The extent of reaction can be controlled by changing the reaction time. The times indicated in Table 7.5.1 are intended as a starting point and will usually allow from 1 to 300 bases to be read, provided adequate counts are used. Shorter reaction times will shift more counts into larger fragments and longer times will result in more counts in shorter fragments.

Stop reactions and collect modified DNA by ethanol precipitation (Table 7.5.1C)

- Add either DMS or hydrazine stop buffer plus 100% ethanol, prechilled to -20°C , and immediately immerse in a dry ice/ethanol bath for 5 min.

The dilution plus the low temperature terminates the reactions.

12. Microcentrifuge 5 min at $15,000 \times g$ and discard the DMS supernatant into 5 M NaOH and the hydrazine supernatant into 3 M ferric chloride.

It is convenient to keep 200 ml of each of these inactivating agents in a dark, 1-liter glass vessel in the hood for the purpose of collecting waste.

13. Rinse the pellets twice with 70% ethanol (to remove excess reagents) and discard the supernatants as in step 12.

Reprecipitate the DNA (Table 7.5.1D)

14. Resuspend each pellet in 200 μ l sterile water, add 20 μ l of 3 M sodium acetate and 500 μ l 100% ethanol, and mix.

15. Immerse 5 min in a dry ice/ethanol bath and repeat steps 12 and 13.

These steps remove residual DMS and hydrazine from the samples, which can complicate the piperidine reaction.

Table 7.5.1 Outline of Chemical Sequencing Reactions

Reaction	Reaction specificity			
	G	G + A	T + C	C
A. Prepare the DNA samples				
DNA, μ l	10	10	10	10
DMS reaction buffer, μ l	200	—	—	—
H ₂ O, μ l	—	—	10	5
5 M NaCl, μ l	—	—	—	5
B. Carry out the base-specific modification reactions				
DMS, μ l	1	—	—	—
Formic acid, μ l	—	25	—	—
Hydrazine, μ l	—	—	30	30
Time (min) at 25°C	4	5	8	8
C. Stop the reactions by diluting with stop buffer and -20°C 100% ethanol and immersing in a bath of dry ice/ethanol for 5 min				
DMS stop buffer, μ l	50	—	—	—
Hydrazine stop buffer, μ l	—	200	200	200
100% ethanol, μ l	750	750	750	750
Collect DNA by centrifuging 5 min at $15,000 \times g$; rinse twice with 70% ethanol; drain				
D. Remove any remaining reagents by reprecipitation				
H ₂ O, μ l	200	200	200	200
3 M sodium acetate, μ l	20	20	20	20
100% ethanol, μ l	500	500	500	500
E. Catalyze the strand scission at modified bases by incubating 30 min at 90°C with 10% piperidine; remove the piperidine by drying under vacuum				
10% piperidine, μ l	70	70	70	70
F. Remove traces of piperidine by evaporating the sample twice from water				
Sterile H ₂ O, μ l (first evaporation)	30	30	30	30
Sterile H ₂ O, μ l (second evaporation)	20	20	20	20

16. Dry the pellets in a Speedvac evaporator.

Catalyze strand-scission reaction with piperidine (Table 7.5.1E)

17. Resuspend pellets in 70 μ l of 10% piperidine.
18. Transfer samples to 1.5-ml screw-top microcentrifuge tubes, tightly cap the tubes, and incubate 30 min at 90°C.

During this reaction, the tubes must be tightly sealed to prevent piperidine loss. If loss occurs, the piperidine reaction with hydrazine-modified nucleosides may not go to completion, resulting in smeared bands in the pyrimidine sequencing lanes. Although snap-top microcentrifuge tubes are most convenient for steps 5 to 11, they do not seal well enough to contain piperidine heated to 90°C. Other materials to seal the tubes, such as Teflon tape, do not provide a dependable seal. Transferring the reactants to Sarstedt screw-top microcentrifuge tubes at this stage provides absolute assurance that these reactions proceed normally.

Remove traces of piperidine from reactions by evaporation (Table 7.5.1F)

19. Microcentrifuge tubes briefly to collect any condensate from the sides of the tubes. Transfer the tubes to a Speedvac evaporator and evaporate the piperidine to dryness.
20. Resuspend dried samples in 30 μ l sterile water, transfer to new tubes, and dry in a Speedvac evaporator.
21. Repeat step 20 using 20 μ l sterile water.

Failure to completely remove piperidine will result in smearing of bands on the sequencing gel. The samples are now ready for gel fractionation.

Denaturing Polyacrylamide Gel Electrophoresis

The following steps are described in full detail in the basic protocol of *UNIT 7.6* (see also commentary of that unit for an extensive discussion of critical parameters).

Prepare the sequencing gels

22. Prepare 6%, 8%, or 12% sequencing gels, preheated with wells rinsed.

To “read” the sequencing gel at the extreme high- and low-molecular-weight regions (1 to 300 bases), it is necessary to run a set of the four sequencing reactions on either two 6% gels run for different lengths of times or on both a 6% and an 8% gel (see annotation to step 26). Running two 6% gels allows the sequence to be read from 20 to 350 bases. To read the first few bases, it is necessary to use an 8% or 12% gel.

Load and run the sequencing gels

23. Resuspend dried samples in 10 μ l formamide loading buffer and vortex to dissolve any material adhering to the tube sides.
24. Heat the samples 2 to 3 min at 90°C.

It is recommended that a burner be used to heat a pan of water to 90°C. This provides a rapid supply of 90°C water and eliminates the need to maintain a water bath at this temperature.

25. Place the samples on ice and immediately layer onto the preheated sequencing gel.

Draw the sample up into a 20- μ l pipettor and place the tip (5 to 200 μ l) down on the surface of the lower (back) plate pointing into the well. The sample can easily be extruded without any special care and will sink to the bottom of the well. The loaded sample will not be a discrete band and will appear to be smeared throughout the well; however, this does not affect the quality of the separation. It is not necessary to change pipet tips between samples. Loading by this method can be accomplished much more quickly than by using a Hamilton syringe.

We suggest layering the samples in the following order: G, A, T, C (grouping purines and pyrimidines). This also facilitates reading the gels, as the lanes will actually contain G, G+A, T+C, C; thus, the related lanes G, G+A and T+C, C are adjacent.

26. Electrophorese the samples 1.5 to 4.5 hr at 40 to 45 V/cm (~70 W for a standard 30 × 40-cm gel.)

If two 6% gels are used, run one for 1.5 to 2 hr and the second one for 4 to 5 hr. This allows the sequence to be read from 20 to 350 bases. To read the first few bases, it is necessary to use an 8% or 12% gel electrophoresed for 1 hr. If a 6% gel and an 8% gel are used, run the 6% gel 3 hr and the 8% gel 1.5 hr.

Process the sequencing gels

27. Dry the gels.
28. Autoradiograph the dried gels on X-ray film with an intensifying screen 1 to 4 days at -70°C.

It is not necessary to fix the gel prior to drying as described in UNIT 7.6; however it will improve the clarity of gels containing ³²P.

29. Read the sequence from the film (see Fig. 7.5.1 and commentary).

Figure 7.5.1 Autoradiogram of a chemical sequencing gel with a portion of the sequence indicated. This example does not contain any compressions.

***Tth*111I DIGESTION AND END LABELING**

This protocol describes end labeling DNA fragments cloned into pSP64CS or pSP65CS in preparation for chemical sequencing (Eckert, 1987). Because the *Tth*111I sites allow labeling one end of a fragment, no gel purification of labeled fragments is necessary, and the DNA can be used directly for chemical sequencing.

Additional Materials

- pSP64CS or pSP65CS recombinant plasmid DNA (prepared as in *UNIT 7.3*)
- Tth*111I restriction endonuclease and 10× buffer (*UNIT 3.1*)
- Klenow fragment labeling mix
- [α -³²P]dNTP (dGTP, dATP, dTTP, or dCTP with specific activity of 600 or 3000 Ci/mmol)
- Klenow fragment of *E. coli* DNA polymerase I (*UNIT 3.5*)
- TE buffer (*APPENDIX 2*)
- 25:24:1 phenol/chloroform/isoamyl alcohol (*UNIT 2.1*)
- Sephadex G-50 slurry, equilibrated in 5 mM Tris·Cl, pH 7
- Additional reagents and equipment to prepare Sephadex G-50 spin column (*UNIT 3.4*)

1. Mix the following in a microcentrifuge tube:

- 5 μ l pSP64CS or pSP65CS recombinant plasmid DNA
- 2 μ l 10× *Tth*111I buffer
- 12 μ l H₂O
- 1 μ l *Tth*111I.

Incubate 20 min at 60°C.

2. Cool tube to 15°C and add the following:

- 20 μ l Klenow fragment labeling mix
- 2 μ l desired [α -³²P]dNTP
- 1 U Klenow fragment.

Incubate 10 min at 15°C.

3. Add 70 μ l TE buffer to terminate reaction.
4. Extract with 50 μ l of 25:24:1 phenol/chloroform/isoamyl alcohol and save the top aqueous phase (*UNIT 2.1*).
5. Prepare two spin columns as follows (see also *UNIT 3.4*):
 - a. Fill two 1-ml syringe barrels (from plastic syringes) with Sephadex G-50 slurry, equilibrated in 5 mM Tris·Cl, pH 7.
 - b. Spin in tabletop centrifuge at 1500 rpm for exactly 4 min.
 - c. Add additional slurry to fill the syringes and centrifuge again at the same speed and time.
6. Apply the sample to one of the columns and centrifuge at 1500 rpm for exactly 4 min.
7. Save the column overflow and pass over the second column as in step 6.
8. Add 1 ml of 100% ethanol to the column overflow and place for 5 min in a dry ice/ethanol bath.
9. Microcentrifuge 5 min at 15,000 × *g* and discard supernatant.
10. Dry the sample and resuspend pellet in 40 μ l water. Use salt-free samples in step 5 of the sequencing (basic) protocol.

REAGENTS AND SOLUTIONS

Dimethyl sulfate (DMS) reaction buffer

50 mM sodium cacodylate, pH 8.0
1 mM EDTA
Store 6 months to 1 year at -20°C

DMS stop buffer

1.5 M sodium acetate, pH 7.0
1.0 M β -mercaptoethanol
Filter sterilize, then add tRNA to 100 $\mu\text{g}/\text{ml}$ final
Store indefinitely at -20°C

Formamide loading buffer

80% formamide
10 mM NaOH
1 mM EDTA
0.1% xylene cyanol
0.1% bromphenol blue
Store at room temperature or 4°C (prepare fresh periodically)

High-quality formamide that does not require deionization is available from Fluka, IBI, and American Bioanalytical.

Hydrazine stop buffer

0.3 M sodium acetate, pH 7.0
0.1 mM EDTA
Filter sterilize, then add tRNA to 25 $\mu\text{g}/\text{ml}$ final
Store indefinitely at -20°C

Klenow fragment labeling mix

40 mM Tris-Cl, pH 7.6
20 mM MgCl_2
20 mM dithiothreitol
Store 6 months to 1 year at -20°C

COMMENTARY

Background Information

Background information and a general discussion of chemical sequencing are provided in the introduction to Chapter 7 and *UNIT 7.1*. Detailed information about pSP64CS pSP65CS can be found in these locations, particularly in *UNIT 7.1*. It is also useful to refer to *UNIT 7.4*, which provides detailed protocols and troubleshooting guides for dideoxy sequencing, because some of this material is also applicable to the chemical sequencing method.

In the original method of Maxam and Gilbert (1980), 1 M piperidine formate was employed in the G+A reaction and the reaction took 60 min at 20°C . In the method presented here, undiluted formic acid is added followed

by a 5-min reaction. In addition, the piperidine strand cleavage of the G+A reaction is carried out later, along with the piperidine cleavage for the G, T+C, and C reactions. These modifications represent a considerable time savings when sequencing a large number of samples. In addition, the use of screw-top tubes for the piperidine reaction is a simple means of guaranteeing that these reactions work well.

Critical Parameters

General guidelines concerning critical aspects of DNA sequencing and the preparation of sequencing gels can be found in Table 7.5.2 and *UNITS 7.4 & 7.6*.

Two critical features unique to the chemical sequencing method are (1) removal of excess

Table 7.5.2 Troubleshooting Guide for Chemical Sequencing

Problem	Possible cause	Solution
Bands fade away at top of gel in one or more lanes	Chemical reactions proceeded too far	Decrease base-specific modification reaction times (do not alter the concentrations of the reagents, except DMS; see critical parameters)
Bands fade away at bottom of gel in one or more lanes	Chemical reactions did not proceed far enough	Increase base-specific modification reaction times (do not alter the concentrations of the reagents, except DMS; see critical parameters)
Shadow bands in all lanes	Incomplete filling-in by Klenow fragment of a 5' overhang created by digestion with a restriction endonuclease (usual cause) Two or more labeled nucleotides have been incorporated at the end of a fragment; decay of the "outer" nucleotide will produce a labeled fragment one base shorter	Repeat end-labeling reaction (<i>UNIT 3.5</i>)
Bands in all 4 lanes	Site-specific nicking of DNA fragment by restriction endonuclease or contaminating nuclease	Increase stringency of restriction endonuclease reaction by altering salt concentration and/or repurify DNA fragment prior to labeling
Bands in all 4 lanes and/or reduced or irregular spacing	Compressions due to secondary structure of oligodeoxynucleotide	Refer to commentary in <i>UNIT 7.6</i> for a discussion of how to recognize and resolve compressions in sequencing gels
Extraneous bands of lower intensity and irregular spacing	Impure DNA fragment. Irregular spacing results from different mobilities of oligos of same length but different base compositions	Repurify DNA fragment prior to labeling
Smearing in pyrimidine (T, T+C lanes)	Incomplete scission by piperidine; residual hydrazine present during piperidine reaction	Ensure that hydrazine is removed before piperidine addition and that piperidine reaction tubes are tightly sealed
Weak T reaction	Residual salt present in DNA sample	Wash DNA fragment thoroughly with 70% ethanol before sequencing
Bands in G, G+A, and T+C lanes	Hydrazine reaction with guanine residues at neutral pH in hydrazine stop mix if sample is not kept chilled	Make sure samples are well-chilled in step 11
Gap in sequence due to missing band	May be due to 5-methyl cytosine modification at <i>Eco</i> RII site [C ^{Me} C(A/T)GG] in DNA from a <i>dcm</i> ⁻ <i>E. coli</i> strain	Verify presence of <i>Eco</i> RII site or prepare DNA from a <i>dcm</i> ⁻ strain of <i>E. coli</i>

salt (steps 1 to 3) before initiating the base-specific modifications and (2) removal of piperidine (steps 19 to 21) following the strand-scission reaction and before loading the samples on the sequencing gels. Failure to remove salt will interfere with the reaction of hydrazine with thymidine residues and will result in weak T bands in the T+C sequencing lane. Failure to remove piperidine following the reactions will result in smearing of the bands in the sequencing gel and inability to read the sequence.

Another critical step is the addition of DMS to the G reaction (step 8). It is important to measure the small 1- μ l aliquot carefully and to be sure that the DMS mixes thoroughly into the reaction. It is sometimes necessary to use shorter reaction times for the DMS reaction than indicated in Table 7.5.1 and if there are many samples, it is difficult to add the 1- μ l DMS aliquots accurately. This problem can be overcome by adding an appropriate amount of DMS to the DMS reaction buffer (the DMS concentration may be lowered if the reaction is proceeding too fast) just before the base-specific modification reactions will be carried out. Then 200 μ l of the DMS reaction buffer containing DMS are added to each sample to start the reaction.

It is very important that the piperidine strand-scission reactions go to completion. This is facilitated by ensuring that the reaction tubes containing piperidine are tightly sealed during the 30-min 90°C incubation (step 18).

Finally, it may be convenient to add additional tRNA to the DMS and hydrazine stop buffers to facilitate recovery of the DNA pellets in the subsequent precipitation steps. Add tRNA to the DMS stop buffer to 600 μ g/ml and to the hydrazine stop buffer to 150 μ g/ml. The tRNA will not interfere with the piperidine reactions.

Troubleshooting

Some of the problems encountered in chemical sequencing are also encountered in the dideoxy method. For example, if the DNA fragment to be sequenced has not been sufficiently purified or is degraded, poor incorporation of label or a high background level in the sequencing gel may occur. When sequencing recombinant pSP64CS or pSP65CS, it is important that the plasmid DNA preparation method efficiently removes the bacterial genomic DNA. Refer to Table 7.5.2 and Kuebbing (1983) for brief troubleshooting guides to

chemical sequencing, and to Maxam and Gilbert (1980) for a more comprehensive discussion of chemical sequencing.

Anticipated Results

Reading a chemical sequencing gel pattern for the first time can be time-consuming; the following is a quick reference guide. As mentioned, it is helpful to layer the samples onto the gel by grouping purines and pyrimidines. Thus, a sample film resulting from the sequence of *G-A-T-C-G-G-A-C-C-T would appear as shown in Figure 7.0.3.

Reading the sequence can be thought of as a problem of subtraction (i.e., G+A minus G is equal to A; T+C minus C is equal to T). The G+A lane will contain all bands resulting from cleavage at Gs and As, while the G lane will contain only G-specific cleavages; therefore, any band in the G+A lane that is not paired with a band in the G lane are As. Likewise, any band in the T+C lane that is not paired with a band in the C lane is a T. In this way, the sequence can be assembled by reading from the bottom of the sequencing gel to the top. The largest fragment will be the uncleaved original fragment. This fragment will frequently be so large (≥ 1 kb) that it will not be resolved on the gel. In most cases, 1 to 100 bases can be comfortably read on a 12% gel, 20 to 200 bases on an 8% gel, and 50 to 400 on a 6% gel. A photograph of a chemical sequencing gel is shown in Figure 7.5.1.

Time Considerations

It is best to try the four reactions (G, G+A, T+C, C) initially with a single DNA practice sample before working with important DNA fragments. After gaining experience, sequencing reactions on as many as ten DNA fragments can be carried out in 4 hr. Generally, sequence reactions are carried out the first day, gels are run the second day, and sequence data are recorded on the third or fourth day.

Denaturing Gel Electrophoresis for Sequencing

The accuracy of DNA sequence determination depends largely upon resolution of the sequencing products in denaturing polyacrylamide gels. This unit provides a detailed description of the setup, electrophoresis, and processing of such gels.

In general, the gels required for DNA sequencing are 40-cm long, of uniform thickness, and contain 4% to 8% acrylamide and 7 M urea (basic protocol). Modifications of the basic protocol increase the length of readable sequence information which can be obtained from a single gel. These include forming the gel with wedge-shaped spacers to create a field gradient (Ansorge and Labeit, 1984; Olsson et al., 1984), or incorporating a buffer gradient (first alternate protocol), an electrolyte gradient (second alternate protocol), or an acrylamide step gradient (Isfort and Ihle, 1988; Williams et al., 1986) into the gel. It is also possible to use longer gels (80 to 100 cm), although these can be technically challenging to pour and handle.

Another modification to the basic protocol—inclusion of formamide in the sequencing gel—is designed to overcome gel compressions arising from secondary structure in the sequencing products during gel electrophoresis (third alternate protocol). Formamide concentration ranges of 25% (Brown, 1984) to 40% (USB, 1990) can be used to alleviate gel compressions. See critical parameters and troubleshooting for a discussion of acrylamide concentrations and electrophoresis conditions.

CAUTION: Acrylamide and bisacrylamide are neurotoxins and should be handled with gloves. Dimethyldichlorosilane should also be handled with gloves and plate treatment with this solution should be carried out in a fume hood (see silanization, *APPENDIX 3*). TEMED and formamide should also be handled with care.

BASIC PROTOCOL

POURING, RUNNING, AND PROCESSING SEQUENCING GELS

This protocol describes preparing the sequencing plates, pouring the sequencing gels, and loading, running, and processing the gels to analyze a set of sequencing reactions (*UNITS 7.4 & 7.5*).

The steps are the same for all acrylamide concentrations; formulations for 4%, 6% and 8% gels are provided in reagents and solutions. Refer to critical parameters for a discussion of choosing the appropriate acrylamide concentration.

Materials

- 70% ethanol *or* isopropanol in squirt bottle
- 5% dimethyldichlorosilane (diluted in CHCl₃; Sigma #D-3879)
- Denaturing acrylamide gel solution
- TEMED
- 10% (w/v) ammonium persulfate (made fresh weekly and stored at 4°C)
- 1× TBE buffer, pH 8.3-8.9 (*APPENDIX 2*)
- Sequencing samples in formamide/dye solution (*UNITS 7.4 or 7.5*)
- 5% acetic acid/5% methanol (vol/vol) fixer solution
- 30 × 40-cm front and back gel plates
- 0.2- to 0.4-mm uniform-thickness spacers
- Large book-binder clamps
- 60-ml syringe
- Pipet tip rack or stopper
- 0.2- to 0.4-mm sharktooth or preformed-well combs
- Sequencing gel electrophoresis apparatus

Denaturing Gel Electrophoresis for Sequencing

7.6.1

Contributed by Barton E. Slatko and Lisa M. Albright

Current Protocols in Molecular Biology (1992) 7.6.1-7.6.13

Copyright © 2000 by John Wiley & Sons, Inc.

Pasteur pipet *or* Beral thin stem
 Power supply with leads
 Sequencing pipet tip
 Gel dryer
 Shallow fixer tray
 46 × 57–cm gel blotting paper (e.g., Whatman 3MM)
 Kodak XAR-5 X-ray film

NOTE: Many companies provide equipment needed for sequencing experiments; a list of suppliers is provided in Table 7.6.1.

Assemble gel sandwiches

1. For each gel, meticulously wash a pair of 30 × 40–cm front and back gel plates with soap and water; rinse well with deionized water and dry.

A thorough washing and rinsing is critical. Soap residue decreases polymerization time, thus risking polymerization while pouring the gel. Dust and other particulates (e.g., residue from previous gels) left on the plates will make it extremely difficult to pour a gel that does not contain bubbles. Particulates in the gel will also distort the banding pattern.

2. Wet plates with 70% ethanol or isopropanol in a squirt bottle and wipe dry with a Kimwipe or other lint-free paper towel.
3. Wearing gloves, apply a film of 5% dimethyldichlorosilane in CHCl₃ to one side of each plate by wetting a Kimwipe with the solution and wiping the whole plate carefully. After the film dries, wipe with 70% ethanol or isopropanol and dry with a Kimwipe. Check plates a final time for dust and other particulates.

Perform this step in a fume hood.

There are two reasons for silanizing the plates: to facilitate pouring a gel without bubbles and to prevent the gel from sticking to the plates during postelectrophoresis processing (see critical parameters for further discussion of silanization strategies).

See APPENDIX 4 for addresses of suppliers.

4. Assemble gel plates according to the manufacturer's instructions with 0.2- to 0.4-mm uniform-thickness spacers and large book-binder clamps, making certain the side and bottom spacers fit tightly together.

A good fit between side and bottom spacers is crucial to prevent leaks. If necessary, use a small amount of acrylamide or 1% agarose to seal the edges and bottom of the gel. Alternatively, before the top gel plate is placed on the spacers and bottom plate, put a very small dab of high-temperature vacuum grease at the point where the bottom spacer meets the side spacers (the grease can be removed later with 70% ethanol).

Gel sandwiches may also be prepared by using two side spacers only (no bottom spacer) and taping the plates together along the sides and bottom using yellow vinyl electrical tape. To prevent leakage, tape the bottom of the sandwich a second time forming "hospital bed corners." It is important that the tape make good tight contact along its length with the sides of the gel plates and that any bubbles are smoothed out.

Prepare gel solution and pour sequencing gel

5. For each gel, prepare 60 ml of the desired denaturing acrylamide gel solution in a 100-ml beaker.

The gel mix can be heated to speed dissolution of the urea; however, to prevent degradation of the acrylamide, do not heat over 55°C. Allow the solution to cool to room temperature ($\leq 25^\circ\text{C}$) to prevent polymerization while pouring the gel.

If particulate matter remains after mixing, filter the solution through Whatman No. 1 filter paper in a funnel.

6. Thoroughly mix 60 μl TEMED, then 0.6 ml of 10% ammonium persulfate, into each acrylamide solution. Add these components immediately before pouring each gel (step 7).

These reagents initiate polymerization and should not be added earlier than this stage. To achieve slower polymerization (an advantage when learning to pour gels), the amounts of TEMED and ammonium persulfate can be reduced to 40 μl and 0.4 ml, respectively.

To check the freshness of the ammonium persulfate solution and TEMED, test the polymerization time. Transfer 0.6 ml of the gel mix to a 1.5-ml microcentrifuge tube and add 0.6 μl TEMED and 6 μl of 10% ammonium persulfate. Mix the solution by inverting the tube several times. Polymerization should occur within 5 min. If it does not, make fresh ammonium persulfate and test another 0.6 ml sample. The amount of TEMED can also be adjusted.

7. Pour the gel immediately. Gently pull the acrylamide solution into a 60-ml syringe, avoiding bubbles. With the short plate on top, raise the top of each gel sandwich to a 45° angle from the benchtop and slowly expel the acrylamide between the plates along one side. Adjust the angle of the plates so that the gel solution flows slowly down one side.

Other methods of delivering the gel solution include using a 25-ml pipet or pouring the solution through the sidearm of a 125-ml sidearm flask. Air bubbles can be prevented by pouring the gel solution at a steady pace while maintaining constant contact between the fluid being poured and the fluid already between the plates. Any air bubbles that form can be removed by tapping the glass plates behind the bubbles or by rocking the plates until the bubbles move to the top of the gel solution.

8. When the gel solution reaches the top of the short plate, lay the gel sandwich down so that the top edge is ~5 cm above the benchtop; place an empty disposable pipet tip rack or stopper underneath the sandwich to maintain the low angle.
9. Insert the flat side of a 0.2- to 0.4-mm sharktooth comb into the gel solution 2 to

3 mm below the top of the short plate, being very careful to avoid bubbles. Use book-binder clamps to pinch the combs between the plates so that no solidified gel forms between the combs and the plates. Layer extra acrylamide gel solution onto the comb to ensure full coverage. Rinse the syringe with water to remove excess acrylamide.

The flat side of the sharktooth comb creates a flat surface at the top of the gel. Be careful not to insert the comb too far into the gel. This will make it difficult to insert the teeth all the way into the gel when the comb is reversed in step 18. Combs with preformed wells are also commercially available. If this type of comb is used, insert the teeth 2 to 3 mm below the top of the short plate after the gel is poured and pinch with book-binder clamps as described above.

If tape was used to seal the gel sandwiches, clamp the sides of the gel together with book-binder clamps in the positions where the gel will be clamped to the electrophoresis apparatus. Place the clamps over the side spacers and not over the gel itself. This minimizes distortion of the gel in the apparatus (see critical parameters).

10. Check for leaks in the gels and slow or stop them by placing book-binder clamps at these spots. Observe polymerization of the gel solution.

Polymerization requires 10 min to 2 hr, depending on the temperature of the room (i.e., cold acrylamide polymerizes more slowly) and the amount of TEMED and ammonium persulfate added. When polymerization is complete, a Schlieren line will be visible at the border of the comb and the surface of the gel.

11. Use immediately or store gels ≤ 48 hr at room temperature.

To store gels, place a paper towel dampened with 1× TBE buffer over the comb. Put entire gel sandwich in a sealed plastic bag or wrap top of the gel tightly with plastic wrap.

Set up the sequencing gel

12. Remove the bottom spacer or the tape at the bottom of each gel sandwich.
13. Remove extraneous polyacrylamide from around the combs with a razor blade. Clean spilled urea and acrylamide solution from plate surfaces with water.

This step helps to remove the comb cleanly and prevents particles of polymerized acrylamide from falling onto the gel surface.

14. Remove sharktooth combs gently from each gel sandwich, avoiding pulling or stretching the top of the gel. Clean combs with water so they will be ready to be reinserted in step 18.

If a preformed-well comb was used, take care to prevent tearing of the polyacrylamide wells. This comb will not be reinserted.

15. Fill the bottom reservoir of each gel apparatus with 1× TBE buffer such that the gel plates will be submerged 2 to 3 cm in the buffer.

16. Place each gel sandwich in a sequencing electrophoresis apparatus and clamp the plates to the support per manufacturer's instructions.

If a bottom spacer was used, a large air bubble will often get trapped at the bottom of the gel. Place the gel sandwich on one bottom corner in the apparatus and slowly lower the sandwich to chase out a large portion of this air bubble. Squirt buffer under the plates using a syringe with a bent 20-G needle to remove any remaining bubbles.

17. Pour 1× TBE buffer into the top reservoir to ~3 cm above the top of the gel. Rinse the top of the gel with 1× TBE buffer using a Pasteur pipet or Beral thin stem to remove fragments of excess polyacrylamide and urea leached from the gel.

Check for leaks from the top buffer tank. Pieces of clay or agarose can be used to seal leaks

from the top buffer tank gasket. To prevent “smiling” (distortion) of the gel bands, check that the buffer level is horizontal and parallel to the bottom of the gel (see critical parameters/troubleshooting).

18. Reinsert the teeth of the cleaned sharktooth combs into the gel sandwich with the points just barely sticking into the gel. Using a Pasteur pipet or Beral thin stem, rinse the wells thoroughly with 1×TBE buffer to remove stray fragments of polyacrylamide.
19. Preheat the gels by turning on the power supplies to 45 V/cm, 1700 V, 70 W constant power ~30 min before loading sequencing samples.

Each commercial gel apparatus will have its own recommendations about voltage and power settings. In general, power settings should be 45 W to 70 W with constant power.

Load and run the gel

20. Rinse wells just prior to loading the gels to remove urea that has leached into them.
21. Cover and heat completed sequencing samples in formamide/dye solution for 2 min at 95°C, then place on ice.
22. Load 2 to 3 µl of each sample per well on each gel to be run. Rinse sequencing pipet tip twice in the lower reservoir after dispensing from each reaction tube.

It is helpful to mark the outside glass plate with individual lanes or sets of four lanes to keep track of the loading order.

Sample loading using ultrathin DNA sequencing pipet tips is recommended (Table 7.6.1). With practice, all samples can easily be loaded in ≤5 min, eliminating the need for electrophoresing one set of samples into the gel before loading the next set.

23. Run gels at 45 to 70 W constant power according to the manufacturer’s recommendations. Maintain a gel temperature of ~65°C.

Temperatures higher than this can result in cracked plates or smeared bands, while too low a temperature can lead to incomplete denaturation of the sequencing products. Monitor the temperature by taping a round-faced gel thermometer with a flat back surface (Table 7.6.1) to the glass plate with paper tape. Dab a spot of vacuum grease between the glass plate and the thermometer to assist in heat conduction.

24. Observe the migration of the marker dyes (Table 7.6.2) to determine the length of the electrophoresis.

If sequencing reactions are loaded on multiple gels, the gels must be coordinated such that sequences in common from the long and short runs will allow overlapping of the sequence, yet still maximize the amount of sequence obtained from the long run (see critical parameters/troubleshooting for examples of electrophoresis times).

Table 7.6.2 Migration of Oligodeoxynucleotides (Bases) in Denaturing Polyacrylamide Gels in Relation to Dye Markers

Polyacrylamide (%)	Bromphenol blue	Xylene cyanol
5	35 b	130 b
6	26 b	106 b
8	19 b	75 b
10	12 b	55 b

Process and dry the gel

Many mishaps occur when processing sequencing gels because they are very thin and fragile and can easily be torn. Minimal handling is essential in the following steps.

25. Fill the dry ice traps attached to the gel dryer (if required) and preheat the dryer to 80°C.
26. After electrophoresis of each gel is complete, drain the buffer from the upper and lower reservoirs of the sequencing apparatus and discard the liquid as radioactive waste.

If two gels are run for a set of sequencing reactions, the difference in electrophoresis times allows processing and drying of each gel as soon as it is finished.

27. Remove the gel sandwich from the electrophoresis apparatus and place under cold running tap water until the surfaces of both glass plates are cool.

This facilitates handling of the gels and prevents the gels from “curling” as they cool.

28. Lay the sandwich flat on paper towels with the notched (short) plate up. Remove excess liquid and remaining clamps or tape.

29. Remove one side spacer and insert a long metal spatula between the glass plates where the spacer had been. Pry the plates apart with a gentle rocking motion of the spatula. The gel should stick to the bottom plate. If it sticks to the top plate, flip the sandwich over. Slowly lift the top plate from the side with the inserted spatula, gradually increasing the angle until the top plate is completely separated from the gel.

If the gel sticks to the top plate in an isolated spot, a stream of water from a squirt bottle can be sprayed at the spot to aid separation. Should gels recurrently stick to both glass plates during processing, more thorough cleaning of the glass plates prior to electrophoresis and/or resilanization of the plates may be necessary.

30. Once the plates are separated, remove the second side spacer and any extraneous bits of polyacrylamide around the gel.

31. If samples contain ³²P, the fixing steps (31 and 32) are optional; proceed to step 33. If samples contain ³⁵S, transfer the gel on the glass plate to a shallow fixer tray and gently cover to a depth of 2 cm with 5% acetic acid/5% methanol fixer solution. Soak the gel 10 to 15 min. Gently rock the tray periodically to gradually loosen the gel from the glass plate.

Urea quenches the ³⁵S signal and must be removed from ³⁵S-containing gels as described here. Although not required, removing the urea will also increase the clarity of ³²P-containing gels.

Occasionally, one or two spots on the gel will stubbornly stick to the glass plate. In this case, free the gel from the plate by moving it gently with a gloved hand. Extreme care must be taken at this stage to avoid stretching or tearing the gel.

A tray with a hole in the bottom through which the fix solution can be drained is useful (Table 7.6.1).

32. Reposition the gel over the plate and remove the fixer solution by aspiration or gravity. Take care to keep the gel centered over the glass plate at this point. Carefully lift the plate with the gel on top from the tray.

33. Place gel on a benchtop. Hold two pieces of dry blotting paper together as one piece. Beginning at one end of the gel and working slowly towards the other, lay the paper on top of the gel. Take care to prevent air bubbles from forming between the paper and the gel.

34. Peel the blotting paper up off the plate—the gel should come with it. Gradually curl the paper and gel away from the plate as it is being pulled away.

Whatman 3MM seems to work best for this procedure.

Optional: this method is more reliable but slightly more tedious. Set another glass plate on top of Schleicher & Schuell #GB002 blotting paper and center it over the gel. Flip the entire sandwich over so that the gel is now resting on top of the blotting paper. Position the sandwich with the glass plates extended ~10 cm past the edge of the benchtop. Slowly slide only the bottom plate back onto the benchtop. Without the support of the bottom plate, the weight of the gel and blotting paper causes them to slowly peel away from the top plate. Reposition the sandwich so that the bottom glass plates extend ~10 cm over the edge of the benchtop (the top glass plate is now extended ~20 cm over the edge) and repeat the process. Lift the top plate from the portion of the gel still in contact with it. If the gel persists in sticking to the top plate, use a stream of water from a squirt bottle to loosen the gel.

35. Place the paper and gel on the preheated gel dryer. Cover with plastic wrap.

Remove any bubbles between the plastic wrap and the gel by gently rubbing the covered surface of the gel from the middle toward the edges with a Kimwipe.

36. Dry the gel thoroughly 20 min to 1 hr at 80°C. Peel the plastic wrap away.

The time required for drying depends on the efficiency of the dryer vacuum. When the gel is completely dry, the plastic will easily peel off without sticking. The plastic wrap will absorb ³⁵S emissions and must be removed prior to autoradiography. Autoradiography without plastic wrap will improve the clarity of sequencing ladders from reactions containing ³²P.

If a gel dryer is not available, place the paper and gel on a glass plate. Clip the paper to the plate to prevent curling. Dry in a forced-air oven or overnight at room temperature.

37. Place each dried gel in a separate X-ray cassette with Kodak XAR-5 film in direct contact with the gel and autoradiograph at room temperature.

Autoradiography is described in APPENDIX 3. No intensifying screen is used. Equivalent films from other manufacturers can be used.

If necessary, several sheets of paper towels or filter paper can be layered in the cassette before enclosing the dried gel and X-ray film. This ensures that the X-ray film and gel are tightly abutted during exposure in the X-ray cassette. Take care not to overpack the cassette which may cause light leaks around the cassette edges.

38. After sufficient exposure time (usually overnight), remove the X-ray film and process according to manufacturer's instructions.

ALTERNATE PROTOCOL

BUFFER-GRADIENT SEQUENCING GELS

Increasing the ionic strength in a sequencing gel decreases the voltage gradient and therefore decreases the rate of migration of DNA fragments (Biggin et al., 1983). In this protocol, the sequencing gel contains a higher concentration of buffer at the bottom of the gel than at the top and as a result, the migration of shorter oligodeoxynucleotides (at the bottom) are slowed down relative to the longer oligodeoxynucleotides (at the top). This allows the gel to be run longer without losing the shorter oligodeoxynucleotides off the bottom and improves the resolution between longer oligodeoxynucleotides.

Additional Materials

Buffer-gradient gel solutions (containing 0.5× and 2.5× TBE; see reagents and solutions)

25-ml pipet equipped with a rubber pipet-filler bulb

1. Assemble one gel plate sandwich as in steps 1 to 4 of basic protocol.
2. In two 100-ml beakers, prepare buffer-gradient gel solutions: 50 ml using 0.5× TBE (clear solution) and 25 ml using 2.5× TBE (blue solution). Heat gently at $\leq 50^{\circ}\text{C}$ while stirring until all the solids have dissolved. Cool the solutions until they are room temperature ($\leq 25^{\circ}\text{C}$).
3. Add 20 μl TEMED and 200 μl of 10% ammonium persulfate to the 0.5× TBE/gel solution and mix gently.
4. Add 10 μl TEMED and 100 μl of 10% ammonium persulfate to the 2.5× TBE/gel solution and mix gently.
5. Using a 25-ml pipet equipped with a rubber pipet-filler bulb, pull up 12.5 ml of the clear 0.5× TBE/gel solution followed gently by 12.5 ml of the blue 2.5× TBE/gel solution.
6. Allow three or four air bubbles to be taken up into the pipet by gently squeezing the suction inlet on the rubber bulb.
This causes the two layers to gently mix at the interface.
7. Release the solution down the glass plate sandwich in a gentle, even manner.
8. Using the same 25-ml pipet, fill the rest of the gel with the 0.5× TBE/gel solution.
9. Insert combs, position clamps, and observe polymerization as in steps 9 and 10 of basic protocol.
10. Run and process the gel as in steps 11 to 38 of basic protocol.

ELECTROLYTE-GRADIENT SEQUENCING GELS

An alternative way to generate an ionic-strength gradient in a gel has been developed by Sheen and Seed (1988). In this protocol, the ionic strength of the bottom of the gel is increased simply by increasing the salt concentration in the bottom buffer chamber. During the run, the salt is electrophoresed into the gel and generates a reproducible and effective gradient.

Additional Materials

0.5× and 1× TBE buffer (*APPENDIX 2*)
3 M sodium acetate unbuffered

1. Pour and prerun the sequencing gel as described in steps 1 to 19 of basic protocol. Use 0.5× TBE buffer in the top and 1× TBE buffer in the bottom reservoir.
2. Prepare and load sequencing samples as in steps 20 to 22 of basic protocol.
- 3a. If ≤ 400 bases of sequence information is needed, add 3 M sodium acetate to the bottom reservoir to a final concentration of 1 M. Proceed to step 4.
- 3b. If ≥ 400 bases of sequence information is desired, proceed to step 4 and wait 2 to 3 hr after beginning the electrophoresis to add 3 M sodium acetate to the bottom reservoir to a final concentration of 1 M.
4. Run gels at 60 W constant power.
It will take about 75% longer than usual for the dye markers to migrate to the same location on the gel.
The temperature of the gel should be monitored carefully. If the gel becomes significantly hotter at the top than the bottom, reduce the power.
5. Process the gel as described in steps 25 to 38 of basic protocol.

**ALTERNATE
PROTOCOL**

DNA Sequencing

7.6.8

FORMAMIDE-CONTAINING SEQUENCING GELS

In this protocol, formamide is added to the acrylamide gel solution (U.S. Biochemical, 1990) to destabilize the secondary structures of sequencing products that can cause the anomalous migration of bands known as compressions (*UNIT 7.4*).

Additional Materials

Formamide gel solution
5% acetic acid/20% methanol (v/v) fixer solution

1. Assemble gel sandwich as in steps 1 to 4 of basic protocol.
2. Prepare formamide gel solution according to the acrylamide concentration desired. Heat gently with stirring until dissolved. Cool solution until it is $\leq 30^{\circ}\text{C}$.

Do not let the temperature of gel solution exceed 55°C .

Filter solution through Whatman No. 1 filter paper if particulate matter is visible.

3. Add 0.15 ml TEMED and 1 ml of 10% ammonium persulfate. Immediately pour the solution into the gel sandwich. Observe polymerization.

The gel solution is viscous. Hold plates at a nearly vertical angle while pouring the solution—this is easiest if the solution is in a beaker.

The gel should polymerize within 30 min.

4. Run the gel 45 to 70 W, constant power.

This requires a higher voltage (60% higher) than nonformamide-containing gels. The DNA migrates about half as fast.

5. Process and dry the gel as described in steps 25 to 38 of basic protocol, except fix the gel 15 min in 5% acetic acid/20% methanol fixer solution in step 31a.

20% methanol prevents the gel from swelling during the fixing step.

REAGENTS AND SOLUTIONS

38% acrylamide/2% bisacrylamide

Mix 38 g of acrylamide (ultrapure) and 2 g *N,N'*-bismethylene acrylamide (ultrapure) in ~60 ml H_2O . Heat if necessary to dissolve, but do not heat above 55°C . Adjust volume to 100 ml. Store in a brown jar for up to several months at 4°C . Discard if an ammonia smell is detected.

CAUTION: Acrylamide is a neurotoxin. Handle with gloves.

Ultrapure acrylamide and bisacrylamide are available from numerous commercial sources. Many of these suppliers also offer premixed acrylamide/bisacrylamide in both solid and liquid form.

Deionization and filtering are usually not needed when using ultrapure reagents. If deionization is desired, add 5 g Amberlite MB-1 (Sigma) or equivalent mixed bed resin and stir 30 min at room temperature. Filter through Whatman No. 1 paper.

Buffer-gradient gel solutions

0.5× TBE (clear solution):

Reagent	Acrylamide concentration (%)		
	4	6	8
Urea (ultrapure) (g)	21	21	21
38% acrylamide/2% bisacrylamide (ml)	5.0	7.5	10.0
10× TBE (APPENDIX 2) (ml)	2.5	2.5	2.5
H ₂ O (ml)	26.5	24	21.5
Total volume (ml)	50.0	50.0	50.0

2.5× TBE (blue solution):

Reagent	Acrylamide concentration (%)		
	4	6	8
Urea (ultrapure) (g)	10.5	10.5	10.5
38% acrylamide/2% bisacrylamide (ml)	2.5	3.75	5.0
10× TBE (APPENDIX 2) (ml)	6.25	6.25	6.25
Sucrose (g)	2.5	2.5	2.5
1% (wt/vol) bromphenol blue (μl)	250	250	250
H ₂ O (ml)	6.25	5.0	3.75
Total volume (ml)	25.0	25.0	25.0

Denaturing acrylamide gel solution

Reagent	Acrylamide concentration (%)		
	4	6	8
Urea (ultrapure) (g)	25.2	25.2	25.2
38% acrylamide/2% bisacrylamide (ml)	6.0	9.0	12.0
10× TBE (APPENDIX 2) (ml)	6.0	6.0	6.0
H ₂ O (ml)	27	24	21
Total volume (ml)	60	60	60

Filter solution through Whatman No. 1 filter paper. Quantities are for a single sequencing gel. If gels are poured daily, make gel solutions in quantity—e.g., make 1 liter of gel solution by multiplying the above quantities by 16.7. Store 2 to 4 weeks at 4°C. Solutions of acrylamide deteriorate quickly, especially when exposed to light or left at room temperature.

Formamide gel solution

Reagent ^a	Acrylamide concentration (%)		
	4	6	8
Urea (ultrapure) (g)	42	42	42
38% acrylamide/2% bisacrylamide (ml)	10	15	20
10× TBE (APPENDIX 2) (ml)	10	10	10
Deionized formamide (ml) ^b	40	40	40
H ₂ O (ml)	10	5	0
Total volume (ml)	100	100	100

^aHeat the ingredients in a beaker while stirring. When dissolved, add H₂O to 100 ml total volume.

^bDeionize formamide by stirring with Amberlite MB-1 (Sigma) or equivalent mixed-bed resin 30 min at 4°C. Filter through Whatman No. 1 filter paper and store at -20°C. Formamide that has been deionized is available from American Bioanalytical.

COMMENTARY

Background Information

Refer to the Chapter 2 introduction for a general discussion of gel electrophoresis of nucleic acids and gels as electric circuits.

Critical Parameters and Troubleshooting

Silanizing the plates

After electrophoresis, the gel is supported by one of the glass plates during processing. As the gel sandwich is disassembled, however, the gel often sticks to both plates because polymerized acrylamide is inherently sticky, especially after being heated during electrophoresis. Silanization helps to prevent this common problem by aiding the release of the gel from one of the plates when the gel sandwich is taken apart; annotations to the steps describing processing of the sequencing gel offer suggestions for coping when the problem does occur. The basic protocol recommends silanizing both gel plates; an alternative strategy is to silanize one plate (usually the short, notched plate) to increase the chance that gel will stick to untreated plate.

An alternate silanizing agent is Sigmacote (Sigma #SL-2), which requires overnight drying or drying at 90°C (see manufacturer's instructions). The advantage of Sigmacote is that it is relatively permanent and only has to be reapplied when the gel starts sticking to the glass plates during subsequent processing. The untreated side of each plate should be marked with a piece of tape to make sure that the silanized side always faces the gel.

Choosing acrylamide gel concentrations

As the percentage of acrylamide in the gel decreases, the pore size increases, allowing resolution of larger oligonucleotides. Thus, lower acrylamide percentages (4% to 6%) allow more sequence to be read from a single gel than does an 8% gel. However, these gels are harder to handle due to increased fragility and softer texture, and the banding pattern may not be quite as sharp as those observed in 8% gels.

We recommend running 6% acrylamide, nongradient gels as a starting point for the novice. Two gels can be run, one for a relatively short time to retain the shorter oligonucleotides, the second for a longer time to maximize separation of the longer oligonucleotides. This two gel procedure, using 6% acrylamide, al-

lows 300 to 350 bases of sequence information to be obtained from a single set of sequencing reactions. If fewer than five sets of sequencing reactions have been performed, one 6% gel can be used for both the short and the long runs (the typical gel format has room for ten sets of sequencing reactions, or 40 samples). An alternative practice is to use an 8% gel for the shorter oligonucleotides and a 6% gel for the longer oligonucleotides (see below for a discussion of electrophoresis times for each of the above examples). As experience is gained with manipulation of gels, modifications of the basic protocol, as described in the introduction, can be incorporated to increase the amount of sequence information gained from each set of reactions.

Precipitating TBE

10× TBE buffer at pH 8.3 to 8.6 (as described in APPENDIX 2) tends to precipitate during long-term storage. Adjusting the pH to 8.9 with NaOH prevents this precipitation without affecting the resolution of the sequencing gel (Mayeda and Krainer, 1991). The TBE buffer in the gel and buffer reservoirs should be prepared from the same 10× stock.

Leaking combs

Sharktooth combs have a smooth edge that forms the top of the gel during polymerization and a "sharktooth" edge containing teeth that form the sample wells when the points of the teeth are inserted into the top of the gel after polymerization. Lanes created by sharktooth combs are spaced more closely together than those made with a preformed-well comb, thus allowing more samples to be loaded on a gel and yielding a sequencing ladder that is easier to read. Care must be taken to preserve the points of the teeth since they will make the wells. Even when all the teeth are intact, sharktooth combs have a tendency to leak between the wells because variations in the comb's thickness can result in a space between the teeth and the glass plates when the combs are reinserted to form wells. Leakage can be tested before loading samples by applying a small amount of loading dye into each well and observing whether the dye flows into adjacent lanes. Those wells that leak can then be omitted from use. This test dye should be run into the gel a short distance before applying the actual samples so that loading can be tracked. Alternatively, for minor leaking, a set of four reactions can be

loaded and run into the gel before the next set is applied. Another trick is to apply a tiny amount of Vaseline on the points of the teeth before reinserting them into the gel. This seals the bottoms of the wells.

“Smiling” gels

Level, “nonsmiling” (nondistorted) bands require even heat dissipation across the gel. To achieve this, both buffer surfaces and the bottom and top of the gel must be aligned parallel to each other. The alignment of the bottom buffer can be a particular problem because it tends to climb up between the back glass plate and the electrophoresis apparatus due to capillary action when the gel sandwich is clamped to it. This can be prevented by inserting a small piece of folded filter paper between the gel sandwich and the electrophoresis apparatus, ~5 cm above the level of the bottom buffer. This forces the bottom of the sandwich away from the apparatus, allowing the bottom buffer to form a level surface.

In addition, deformation of the gel in the apparatus can contribute to uneven heat dissipation. If the gel sandwich is assembled with tape rather than clamps, distortion can be prevented during polymerization by clamping the gel plates with book-binder clamps at the same positions in which they will attach the gel sandwich to the electrophoresis apparatus. This maintains the same pressure points on the gel when it is polymerizing. Some commercially available gel setups allow the gel to be poured in the gel apparatus, avoiding this complication.

To ensure even conduction of the heat generated during electrophoresis, an aluminum plate (0.4 cm thick, 34 × 22 cm) can be clamped onto the front glass plate with the same book-binder clamps used to hold the gel sandwich to the apparatus. The aluminum plate must be positioned so that it does not touch any buffer during electrophoresis. Some commercially available gel setups have this feature, or have a top buffer reservoir that extends down the rear of the apparatus to evenly distribute heat over the gel.

Reading beyond 350 nucleotides

To unambiguously read DNA sequence beyond 350 nucleotides, it is essential to prevent distorted bands as described above. In addition, a concentration of ≥5% glycerol in the gel samples results in distortion of bands in the 450- to 550-nucleotide range (Tabor and

Richardson, 1987); this can be avoided by diluting the sequencing polymerase in diluent without glycerol (UNIT 7.4). The modifications to the basic protocol resulting in various types of gradient gels (see background information) will generally increase the ability to read the sequence in the 350-nucleotide range. A rather infrequently used tactic is to load duplicate sets of each reaction in the order GATCGTAC; this facilitates correct ordering of bands ≥350 nucleotides because each reaction is run on the gel next to each of the other three reactions.

Electrophoresis times and coordinating multiple gels

To decide how long to run the gel that will retain the shortest oligonucleotides (“short” gel), the length of the primer and how far away from the beginning of the target DNA synthesis will be initiated must be known. Add those two numbers together and use Table 7.6.2 as a guideline for bromphenol blue dye migration. Adjust the electrophoresis time so that some polylinker sequences can be retained on the gel and identified. The “long” gel should be run so that the shortest oligonucleotides remaining on this gel overlap by at least ten bases with the longest oligonucleotides on the short gel.

Experience is the best guide in the coordination of the gels. The following examples may serve as initial references.

If two 6% gels and the –40 sequencing primer (a 24-mer that initiates DNA synthesis 40 nucleotides from the M13 polylinker; New England Biolabs) are used, run the first gel 10 to 15 min after the bromphenol blue runs off the bottom of the gel. Run the second gel until the xylene cyanol is almost at the bottom of the gel (~5 hr).

If an 8% gel is used for the shorter oligonucleotides and a 6% gel for the longer oligonucleotides, run the 8% gel until the bromphenol blue runs off and the xylene cyanol has run through ~40% of the gel (~2 hr). Run the 6% gel until the xylene cyanol is at the bottom of the gel (~5 hr).

If the same 6% gel is used for both the short and long runs, load one set of reactions and run the gel until the bromphenol blue is at the bottom. Turn off the power to the gel and load a duplicate set of reactions on the unused part of the gel. Continue running the gel until the duplicate bromphenol blue is at the bottom of the gel. The xylene cyanol dye from the first set of reactions should be at the bottom of the first (long) run.

Time Considerations

Pouring, running, and processing of a sequencing gel is usually interspersed with performing sequencing reactions (UNIT 7.4). The typical gel format has room for ten sets of reactions generating 40 samples. Larger gel formats (up to 78 lanes) are available commercially but we recommend that the novice run and process no more than two 40-sample format gels at one time. This can be accomplished in a single long day, typically 7 to 8 hr for two gels. An experienced sequencer can typically perform the process for four gels in 9 to 10 hr. Sequencing gels can be prepared up to 48 hr in advance of use; assembling and pouring the gel takes ~1 hr.

Computer Manipulation of DNA and Protein Sequences

The ability to determine DNA sequences is now commonplace in many molecular biology laboratories. As the amount of DNA sequence data available to researchers has increased, the use of computers to manipulate, compare, and analyze this data has grown accordingly. Growth rates of DNA databases have entered an exponential phase as determination of DNA sequence becomes more automated and less expensive (see Fig. 19.2.1). The cost of a computer system appropriate for an individual laboratory has also decreased, allowing essentially all researchers Internet access to electronic databases and computerized sequence analysis (see UNIT 19.1).

This unit outlines a variety of methods by which DNA sequences can be manipulated by computers. To begin analysis of a DNA sequence, the information must be in a form that computers can understand. Generally this requires that the DNA sequence information be contained in a file (a file on the computer is simply a collection of information in computer-readable form). Procedures for entering sequence data into the computer and assembling raw sequence data into a contiguous sequence are described first. This is followed by a description of methods of analyzing and manipulating sequences—e.g., verifying sequences, constructing restriction maps, designing oligonucleotides, identifying protein-coding regions, and predicting secondary structures. This unit also provides information on the large amount of software available for sequence analysis.

In addition to the information concerning computer manipulations of DNA sequences in this unit, related units can be found in Chapter 19; these units explain how to use the worldwide Internet computer network to access information from or submit information to the major sequence databases and other electronic resources, and how to conduct DNA and protein homology searches. The chapter also includes general information about electronic information handling.

Many of the electronic resources described in this unit and in Chapter 19 are available at no cost on the Internet. The Appendix to this unit lists some of the commercial software, shareware (whereby the author asks for a donation from satisfied users), and free software

(public domain software as well as copyrighted software that is distributed without charge by the author) related to DNA sequence manipulation. Additional software related to carrying out DNA and protein homology searches is described in Chapter 19.

The discussion of computer-mediated DNA sequence analysis in this unit is intended to be a generalized overview; specific instructions for using particular sequence analysis software packages are beyond the scope of this unit. However, recommendations of software packages for particular tasks have been included wherever possible. Our goal is to serve as a starting point for researchers interested in utilizing the tremendous sequencing resources available to the computer-knowledgeable molecular biology laboratory.

NOTE: The Appendix to this unit, located at the end of the unit but before the references, lists the addresses and phone numbers of all software and hardware vendors discussed below. Additional information about relevant journals and databases is also provided in the Appendix.

SEQUENCE DATA ENTRY

For small sequencing projects, DNA sequence data can easily be entered and manipulated using a word processor or text editor on a microcomputer such as an Apple Macintosh or IBM-compatible. As the size of a project increases, however, a specialized editor for data entry becomes more and more desirable. All software packages for DNA sequence analysis provide some form of sequence editor—a program that acts like a word processor for sequence data. Such an editor may be no more than a small window into which sequence data is entered or it may contain specialized features that aid in proofreading and facilitate input.

Currently there is no standard format for DNA or peptide sequence files. In the early days of sequence analysis, most software programs had their own unique formats for storing sequence information. Although these format differences still exist today (see Fig. 7.7.1), most available software can import several different sequence formats. Thus, a sequence file can be converted into the default format for a particular program by importing (reading) the original sequence file into the program and then

Figure 7.7.1 Commonly used sequence file formats having specific defined elements and defining codes. **(A)** EMBL comment lines begin with two-letter codes: ID, short sequence name; DE, description; and SQ, sequence length. DNA or protein sequence follows; sequence end is denoted by two slashes (//) on a separate line. **(B)** GenBank comments precede the sequence and are separated from it by the code "ORIGIN." Sequence end is denoted by two slashes on a separate line. The actual text of this entry has been abbreviated; see Fig. 19.2.3 for a more complete example of a GenBank file. **(C)** GCG comments precede the sequence and are separated from it by two dots (.). **(D)** Intelligenetics comment lines begin with semicolons (;). A single description line follows, and then the sequence begins on a separate line. Sequence end is denoted by a numeral one (1). **(E)** NBRF (also called PIR format) first line starts with four required characters: a greater-than sign (>); either "D" for DNA or "P" for protein; either "L" for linear or a "C" for circular; and a semicolon. The short sequence name follows on the same line. The next line is a description line. Sequence starts on a new line and its end is denoted by an asterisk (*). **(F)** DNA Strider Text is similar to the Intelligenetics format, but lacks description line. **(G)** FASTA (also called Pearson format) first line begins with a greater-than sign (>), followed by sequence name and a short description. Sequence data starts on a separate line. *Note:* Some formats (including GenBank, GCG, and NBRF) allow numbers to be included within the sequence for ease of reading (the numbers are ignored during sequence analysis).

saving the file in the desired format. However, it is generally simplest to use the sequence editor or entry program provided with the software to be used for subsequent analysis.

Manual Entry Using Word Processors and Sequence Editors

Word processors. A DNA or peptide sequence can be entered into a computer using a word processor or text editor program, simply by creating a new document and then typing in the sequence data. This is sufficient to put sequence data in computer-readable format and is useful if no specialized sequence entry program is available or if the sequence file is to be transferred to a different computer for analysis.

It is imperative that DNA or peptide sequence documents be saved in “text” or ASCII format, because sequence analysis programs cannot translate the default files used by word processor programs; however, most packages provide an easy one-step method of reformatting text files containing DNA or peptide sequences into a format appropriate to the computer at hand. Saving documents as text may require a slightly different Save command or option, as specified in the word processor manual.

Sequence files often contain more information than just the DNA or peptide sequence data. Comments and reference information about the sequence and the history and dates of changes made to the sequence are commonly included. Such comments must be distinguishable by the program from the sequence data in order for the sequence analysis software to function properly. However, it is important to determine what sequence and comment-file formats are allowed by the particular analysis software being used. The most commonly used file formats are shown in Figure 7.7.1. Note that some—e.g., the Intelligenetics and DNA Strider text formats—use specific characters to identify the comments before the sequence file; other formats simply require a string of characters that is used to denote the end of the comments and the beginning of the sequence—e.g., the GenBank flatfile format uses a line beginning with “ORIGIN” and GCG uses “..” (two periods). The NBRF software package (also known as PIR) allows only a single line of comments. Some formats (e.g., NBRF and Intelligenetics) require a specific terminator character for the sequence entry.

It is a good idea to test the file format before investing a large amount of time typing in data with the word processor. This can be done by

creating a small DNA sequence, then experimenting with the comment and sequence formats as well as the word processor’s Save option. The resulting file can then be checked in the analysis program.

Sequence editors. All analysis programs include some form of sequence editor. This is the most effective tool for entering DNA or peptide sequence data because it produces a sequence file in the correct format with the comments separate from the sequence as they should be. There are several free or relatively inexpensive programs available for Macintosh and IBM-compatible computers that simplify the task of entering sequence data. One example for the Macintosh is DNA Strider, which is built around a very easy-to-use sequence editor. It also makes restriction maps, finds open reading frames, and translates DNA sequences into amino acid sequences.

Recently, several programs have become available for microcomputers that “speak” the sequence as it is entered. This may seem like a frivolous feature; however, it is quite useful for entering data by hand from an autoradiogram. The audio feature permits verification of the sequence, thus reducing the need to continually look back and forth between the film and the computer screen. Some of these talking sequence editors use a digitized human voice, but others use synthetically generated speech. The digitized voice, which is generally easier to understand, is more common in programs for Macintosh computers—e.g., SeqSpeak, designed for Macintosh equipped with HyperCard version 2.0 and distributed free of charge (see Table 7.7.2).

Semiautomated Entry Using Digitizing Hardware and Software

Several sequence analysis software packages can accommodate the connection of a relatively inexpensive digitizing pad to the computer; a digitizing pad permits DNA sequences to be read directly from an autoradiogram. Digitizing pads increase both the speed and the accuracy of input. Digitizing devices designed for DNA sequence entry consist of a light box for viewing the autoradiogram and a stylus that resembles a ball-point pen with an attached wire. When the stylus is pressed at the location of a lane or band on the autoradiogram, the digitizing pad detects a signal and converts it to an *x-y* coordinate value that is recorded by the computer. Most digitizing pad entry software requires the basic shape (boundaries) of the autoradiogram lanes to be

entered initially. Subsequently, when the stylus is pressed on an individual band in a lane, the computer utilizes this boundary information to determine which lane was selected, then displays the appropriate nucleotide letter on the computer screen.

The result of the digitized entry process is a file containing the newly determined DNA sequence. In some cases the file must be reformatted before it can be used with an analysis program—this can be determined by comparing the format defined by the entry software with the list of acceptable formats in the sequence analysis software.

DNA sequence entry using a digitizing program can be very quick and accurate when the gel is of good quality. However, if the lanes are irregular due to curving or excessive smiling, the program may incorrectly identify which lane contains a selected band. Commercial gel-reading programs are designed to handle some types of common gel problems. For example, programs avoid smiling errors by requiring the order of the bands to be determined by the user so that the program determines only which lane was selected. The SEQED program of the GCG package for UNIX and VMS and the DNASTar package for IBM-compatibles and Macintosh can both be used with a digitizing pad for semiautomatic DNA sequence determination.

Automated Entry Using Gel Readers and Automated Sequencers

Automated gel readers. Several automated autoradiogram readers are now available that include a scanner and a computer. Automated readers use a high-resolution gray-scale scanner or a digital video camera to digitize an autoradiogram of a sequencing gel produced by conventional methods. The digitized image of the film is then analyzed by the computer using image-analysis techniques. The software is designed to identify first the locations of lanes and then bands within the lanes. This process can be confounded by smudges and random spots on the original film, as well as by gel smiling and curved lanes. Indeed, a major challenge to designers of automatic gel-reading programs is the elimination of such noise in scanned autoradiograms. Automated gel-reader systems (sold by BRL and Milligen, among others) are generally priced for use by large laboratories and core facilities.

When using automated image analysis, it may be advantageous to employ the multiplex method of DNA sequencing (introduction to Chapter 7 and UNIT 15.2; Church and Kieffer-Hig-

gins, 1988), because it is then possible to incorporate a known sequence of DNA into each gel; the resulting sequence can then be analyzed to determine the particular characteristics of the gel. Having this sort of an internal standard greatly simplifies the image analysis required to read more than one unknown sequence from the same gel using the automatic scanner.

Automated DNA sequencers. Automated DNA sequencing machines (discussed in UNIT 7.0) determine the sequence of a DNA fragment and then place the DNA sequence into a file. The most common automated sequencers use special fluorescence-tagged oligonucleotide primers in a dideoxy primer-extension reaction. Reaction products are separated by electrophoresis through a polyacrylamide gel and the fluorescent tag is detected after excitation by a laser at the bottom of the gel. Because each specific nucleotide reaction uses a different fluorescent tag, all four reactions can be loaded in the same lane. The output from the sequencer is a trace of the amount of fluorescence observed as the tagged reaction products pass off the gel. An attached computer analyzes the trace and determines the DNA sequence it represents. Thus, entry of sequence data is completely automated; the user merely has to define or identify the particular sequencing run.

Automated sequencers are quick and currently provide about the same level of accuracy as manual sequencing. Automated and manual sequencing employ similar sequencing technologies—e.g., primer extension and polyacrylamide gel electrophoresis. Although automated sequencing machines are expensive, for large sequencing projects, the automated sequencers may be more economical than manual sequencing because of the reduction in labor costs.

Editing automated sequence data. Because automated autoradiogram scanners are not absolutely accurate, the software packages that accompany them typically permit the user to edit the automatically entered sequence. Generally, the editing process is greatly simplified for projects where overlapping randomly chosen segments or overlapping nested sets of deletions are sequenced because each nucleotide is determined multiple times. A sequence-assembly program can then be used to align the sequences based on overlapping regions. For DNA sequences that have been determined multiple times, inconsistencies between different versions are readily identified by the software, allowing the user to go back to the original data (digitized image or autoradiogram) to assess why the inconsistency occurred.

Automatic sequencing machines (such as those produced by Pharmacia Biotech, Li-Cor, and Applied Biosystems) provide a similar editing feature whereby the user can view the fluorescent trace on a computer screen and override the computer's choice of base if it appears to be incorrect. Some vendors of automated sequencing machines use a statistical means of correcting for discrepancies between regions that have been sequenced multiple times. That is, if a particular region is sequenced several times and the number of differences is low, the machine will automatically adopt the majority consensus sequence.

SEQUENCE DATA VERIFICATION

As with any experimental result, it is important to verify DNA sequence data. This is typically accomplished by sequencing a given region more than once and by sequencing both strands. The computer can be used to compare sequences, find overlapping regions, highlight differences, and provide a graphic overview of the overlapping regions.

Comparison of Multiple Entries

For small projects, the amount and quality of data can be optimized. To identify errors introduced during manual or automated data entry, each gel can be read more than once and the independent readings compared. The comparison can be carried out automatically using an alignment program (see Homology Searching) and any differences can then be investigated. Similarly, several of the digitizing gel readers provide a confirmation option in which each segment of a sequence can be checked automatically, with the machine simply re-entering the band locations. These programs, such as SEQED (included in the GCG package; see Table 7.7.1), alert the user as differences occur. In this way the entry process can be quite fast without sacrificing accuracy.

For large sequencing projects that involve sequencing a number of random clones from a library covering the region of interest, it is usually possible to achieve a sufficient level of redundancy that a majority consensus sequence can be determined.

Comparison to Known Restriction Maps

If a restriction map for the DNA region of interest already exists, a restriction map generated from the DNA sequence (as described below) can serve as a check on the accuracy of the sequence. This is particularly useful for

large regions that have been subcloned for sequencing, where it may not be completely clear how the shorter pieces of DNA that were actually sequenced fit together within the larger region.

Test Translations to Detect Shifts in Reading Frame

One of the most widespread features of sequencing programs is the capacity to translate a DNA sequence into amino acids, thereby generating a putative protein sequence from an open reading frame (ORF); many restriction mapping programs also include a translation feature. When the DNA sequence in question is a prokaryotic coding region or the sequence from a cDNA clone, or when it is believed to be related to a gene from another organism, translating the sequence in this fashion provides a simple check for deletions and insertions. The process will find any stop codons within the sequence; if a stop codon is found within an area that is actually known or thought to be a coding region, the sequence is automatically suspect and should be rechecked. (It is important to remember that in some DNA—such as mitochondrial DNA—the stop codons may be used to specify an amino acid. In yeast mitochondrial DNA, for example, the codon TGA specifies isoleucine. Some software is able to take into account variant genetic codes; for instance, DNA Strider allows the user to select from a list of variant codes, and the GCG package allows the user to reset individual codons.) Although this technique will detect only a subset of possible errors, it can often quickly identify common problems such as simple typing mistakes or miscounting of the number of the same nucleotides in a run of identical nucleotides.

Most DNA sequence packages allow the user to specify a range and reading frame to be used in translating a DNA sequence. DNA Strider (Table 7.7.1) has a useful feature that hunts for ORFs in a DNA sequence and highlights the putative coding sequence, thus doing all the necessary work.

Detecting Overlap with Other Sequenced Fragments

With increasing worldwide interest in genome sequencing projects, sequence assembly packages now provide very effective automatic DNA sequence assembly, connecting shorter pieces of DNA to build the longest continuous sequence possible. Once the sequences to be assembled are identified, they are

compared, overlaps identified, and contiguous sequences (contigs) constructed. Typically, parameters are available to allow adjustment of the alignment process. If the default parameter settings do not result in sequence assembly, the minimum amount of overlap required to identify a match (i.e., the number of base pairs involved) can be reduced or the stringency of the required overlap decreased (i.e., the number of allowable mismatches increased). A good commercial assembly program is LaserGene, available from DNASTar for both Macintosh and IBM-compatible computers (Table 7.7.1). Once a sequence contig has been assembled, the LaserGene program creates a graphic overview of the sequencing project, highlighting regions that need further verification. Another commercial program is Sequencher (Gene Codes). This program provides expanded features for the assembly, processing, and editing of DNA sequences determined with the ABI sequencer; however, it is only available for the Macintosh computer.

If a sophisticated assembly program is not available, contigs can be constructed “by hand” using a comparison program and a multiple sequence editor. First, the comparison program is used to analyze two suspected overlapping sequences; then, if an overlap is found, a consensus sequence is generated that can then be compared with other sequences. In this manner, an overall consensus sequence (contig) can be progressively assembled. A potential pitfall of this process that should be mentioned is that although some DNA sequence analysis programs will consider both the DNA sequence that has actually been entered and its complement sequence (the sequence from the complementary strand of DNA, sometimes called the reverse complement sequence), others analyze only the sequence entered. With these latter programs, unless the DNA sequence of interest contains an inverted repeat (palindromic region), only one of the strands of DNA is likely to be recognizable as being similar to a previously known sequence. It is therefore important to determine which way a particular program operates and, when using a program that does not automatically consider the complement sequence, to conduct a separate search of that sequence.

When conducting sequence comparisons to identify overlaps, it is important to take into account the fact that different programs take slightly different approaches to this process. Some comparison programs that use the Needleman and Wunsch algorithm (e.g., the GCG

GAP program; Needleman and Wunsch, 1970) are designed to find the maximum number of matches between two sequences over the entire length of the two sequences, with the minimum number of gaps. This type of program is best suited for aligning two sequences along their entire lengths. If the two sequences differ greatly in size, however, the result may not satisfactorily represent the similarity between them. For identifying regions of similarity between two pieces of DNA that are largely different in sequence or of significantly different lengths, programs employing algorithms such as those described by Smith and Waterman (1981) or Wilbur and Lipman (1983)—e.g., the GCG BESTFIT program—are more suitable. These algorithms do not try to align the two sequences being compared in their entirety, but instead search for short matches within the sequences.

Editing a Contig and Verifying the Sequence

Generally, software packages that provide sequence assembly programs include multiple sequence editors that display the individual sequences of the aligned contig together one on top of the other, one sequence per line (see Fig. 7.7.2), and can generate the consensus sequence automatically. A multiple sequence editor differs from the sequence editors mentioned earlier in that several sequences can be manipulated at once. However, the most significant feature of a multiple sequence editor is its ability to produce a consensus sequence for an aligned set of sequences. If the consensus sequence is not satisfactory, the alignment can instantly be changed and a new consensus sequence generated.

Another use of a multiple sequence editor is for manually comparing a group of overlapping sequences by aligning common regions vertically on the screen (Fig. 7.7.2), which makes it easy to identify differences in the aligned sequences. It is generally useful to go back to the original gel to determine whether these differences result from misreading, sequence compression, or gel defect. Multiple sequence editors will often have the ability to display the reverse complement of a particular sequence, irrespective of which strand was sequenced.

Some very useful programs are available free of charge; these programs provide automatic multiple sequence alignment functions as well as other types of analysis on a set of sequences. Examples of these are the MACAW software for Microsoft Windows or Macintosh,

Figure 7.7.2 Multiple sequence editor. The GCG program GELASSEMBLE displays the aligned sequences on the top of the screen and a schematic of the sequenced fragments on the bottom. Arrows indicate the direction of sequencing; the asterisk in the lower part of the display indicates the position of the cursor in the sequence alignment as the user edits the sequence.

developed by Greg Schuler of the NCBI (Schuler et al., 1991), and GDE for X-Windows, developed by Steven Smith of the Harvard Genome Laboratory (Table 7.7.2).

RESTRICTION MAPPING

Once a sequence contig is generated, a map of restriction endonuclease cleavage sites can be a useful aid in further analysis of the region. As stated above, construction of a restriction map based on newly determined sequence information allows rapid visual comparison of the sequence with a known restriction map. Restriction maps also identify sites for subcloning or other molecular genetic manipulations and can provide useful summaries of newly determined DNA sequences.

Mapping All Known Commercial Restriction Enzyme Recognition Sites

Programs are available that identify on a strand of DNA the sites of all known restriction enzymes, according to either the first nucleotide of the recognition site or the location of cleavage. Most of these programs produce one list of the sizes of fragments that would be created by cutting with each restriction enzyme and a separate list of the recognition sites identified. They can also display the cleavage sites of specified sets of restriction enzyme of interest, such as those that generate 3'- or 5'-strand overhangs or blunt ends. All restriction mapping programs contain a file or files in which restriction site data are stored; this information can be updated as new restriction enzymes and their cleavage sites are identified. Restriction mapping programs are one of the most common types of molecular biology software; virtually

all commercial software provides excellent restriction mapping features.

An up-to-date list of restriction enzymes is maintained by Richard Roberts (New England Biolabs). It is accessible in the form of a text file called rebase and contains all known type II restriction enzyme recognition sites, sites of cutting, a complete cross-reference of isoschizomers, reference citations, and commercial sources for the restriction enzyme with addresses and phone numbers. The latest version of rebase can be obtained free from a variety of electronic mail (e-mail) and network servers (see UNIT 19.1).

Mapping to Predict Band Sizes

Some software programs can model double digests, predicting the band sizes that would result from cleavage of an entered sequence with a given pair of restriction enzymes. Such double-digest band-size analyses simplify the reading of restriction fragment patterns on gels and can also be useful for planning subsequent cloning strategies. A few programs can also predict the results of partial digests. Software packages that provide restriction fragment pattern analysis features are available from Textco's Gene Construction Kit (for Macintosh only) and Pro-RFLP from DNA ProScan (for Macintosh and IBM-compatible computers).

Graphical Restriction Mapping

Several very elegant programs are available that produce graphical restriction-site maps that are useful for searching for possible sites to be used in further recombinant DNA manipulations. Graphical restriction maps are often represented as collections of horizontal lines,

Figure 7.7.3 One type of graphical restriction map. This figure was produced by the free PlotZ program; GCG MAPPLOT produces similar output.

one for each restriction enzyme, with the recognition sites represented by short vertical marks at the appropriate locations (Fig. 7.7.3). A limited number of programs produce pictures of sequences that look like standard circular plasmid maps, including coding regions and other features of interest within the sequence, as well as the vector DNA and polylinker. These graphical maps can be saved and then manipulated in a graphics editor or drawing program, greatly simplifying the task of preparing figures for presentation; an excellent example of such a program is the Textco Gene Construction Kit. This program reads a variety of sequence-file formats and generates a picture of the DNA sequence in standard restriction map form. The pictures can be edited to include arrows and information boxes that are of publishable quality. In contrast to most graphical mapping programs, the Gene Construction Kit and other commercially available programs such as MacVector and LaserGene use DNA sequence data directly to generate the pictorial maps. Many shareware mapping programs, such as Jingdong Liu's MacPlasMap, do not work with the sequence data directly; rather, recognition site locations must be input by the user. One shareware program that does have the capacity to create graphical maps directly from sequence data, and provides many analysis features as well, is DNA Strider, developed by Christian Marck (Table 7.7.2).

Recent versions of many mapping programs can actually simulate the electrophoretic-gel

banding patterns that will be observed following particular restriction digests. The programs allow the user to specify the type of gel medium being used, making it possible to determine visually whether the banding pattern observed on a gel could be produced by a given sequence. Some programs will even simulate partial digests. The Gene Construction Kit provides the gel simulation feature as does the ACEDB genome database software (see Genetic Sequence Databases); the latter is limited in that it can simulate the gel banding patterns only for sequences already contained within the database being used.

PREDICTION OF NUCLEIC ACID STRUCTURE

Once the DNA sequence of a region has been identified, a number of analyses can be performed to identify interesting features such as repeats, areas of atypical base composition, and RNA secondary structure. These in turn can help to define functional regions within the sequence of interest.

Base Repeats

Direct and inverted repeats are often part of transcriptional or translational control regions. Most sequence analysis software can identify repeats and provide an optional graphic display of their location. The standard "dot matrix" plot is a simple and effective method of identifying repeated regions. The two-dimensional dot matrix represents one sequence on the *x* axis and

the other on the *y* axis. Such programs generate a “dot” at each *x-y* intersection of all GG, AA, TT, and CC pairs; thus, repeats are revealed as diagonal lines. Some dot matrix programs show inverted repeats—which may indicate potential stem-loop structures in the corresponding DNA or RNA—as lines with negative slopes relative to direct repeats. To identify repeats within a single sequence, the same sequence is used for both the *x* and *y* axes.

Analysis packages that do not produce a graphical presentation of the repeated regions usually include a program that lists the repeats and their locations. This involves searching a sequence against itself to find direct repeats or against its complement to detect inverted repeats. The repeats must then be plotted by hand or the distances between them calculated to determine if a periodicity is present. Needless to say, the graphical presentation is preferred because patterns can be readily seen that it would take some time and effort to reveal by the comparison method.

GC and AT Content

The GC/AT content of a sequence may provide some insight into structural features such as Z DNA and bent DNA (see APPENDIX 1). GC/AT content can also serve as a reasonable indicator of a coding region in many invertebrate and plant species. A few sequence-analysis packages contain specialized programs, such as GCG STATPLOT, that show the GC and AT content of a sequence in graphical form—allowing AT- or GC-rich regions to be readily identified. However, many packages provide little more than a tally of nucleotide composition, i.e., the program only lists the number of A, G, C, and T residues in a sequence. A simple method to determine the local GC/AT content of a large sequence is to divide the sequence into several small (e.g., 100-base) segments, then determine the GC/AT content of these small segments individually.

RNA Secondary Structure

Although folding programs are available that predict RNA secondary structure, this type of analysis is still an art. RNA-folding programs help identify possible stable stems in an RNA molecule, but a trial-and-error process is required to determine the biological significance of these results for a given RNA molecule. Even with this limitation, secondary structure predictions can be useful for identifying mRNA control regions as well as possible stable folded regions of an RNA molecule.

The greatest problem with predicting secondary structure is modeling the interactions present in a tertiary structure and then relating those back to the primary sequence for use in a folding program. Indeed, current RNA-folding programs do not take into account possible tertiary structures of a nucleic acid molecule. These programs determine the energetics of a limited number of two-dimensional folded structures. The most stable structure predicted by the program in a two-dimensional world may be far from the most stable structure in three dimensions where loops can interact with loops, helical regions can stack, and various non-Watson-Crick base-pairing structures can occur (see illustrations in APPENDIX 1).

Currently, the most sophisticated RNA-folding program is MFOLD (for Multifold, an extension of an earlier program known as RNA-Fold or FOLD in the GCG package), designed by Michael Zuker of the National Research Council of Canada (Zuker, 1989a,b; Table 7.7.2). In addition to standard analysis of base-pairing energetics, MFOLD takes into account base-pair-stacking energies (Freier et al., 1986; Turner et al., 1987) and single-base-stacking (dangle) enthalpies (Turner et al., 1988). Another major feature of MFOLD is that in addition to predicting a single structure with the lowest predicted free energy, it also depicts many suboptimal structures. The number of suboptimal structures displayed can be varied within a percentage or an absolute value of the best structure's energy. VMS, UNIX, DOS, and Macintosh versions of this program are available from many of the software archives (see Table 7.7.2). Although the output of MFOLD is text-based (Fig. 7.7.4A), several programs are available that generate graphic representations of the predicted structure (e.g., LoopViewer, developed by Don Gilbert; see Fig. 7.7.4B).

OLIGONUCLEOTIDE DESIGN STRATEGY

Increased use of polymerase chain reaction (PCR) methods has stimulated the development of many programs to aid in the design or selection of oligonucleotides used as primers for PCR. Four such programs that are freely available via the Internet (see Table 7.7.2) are: PRIMER by Mark Daly and Steve Lincoln of the Whitehead Institute (UNIX, VMS, DOS, and Macintosh), Oligonucleotide Selection Program (OSP) by Phil Green and LaDeana Hiller of Washington University in St. Louis (UNIX, VMS, DOS, and Macintosh), PGEN by Yoshi (DOS only), and Amplify by Bill Engels

Figure 7.7.4 (A) Text-based output from Zuker's RNA-folding program, available from GCG under the name of FOLD. This type of representation is difficult to visualize, but acceptable when only a quick view of the possible folded structures is desired. (B) Graphic representation of the structure shown in part A, produced by the GCG Squiggles program. The free LoopViewer program (for Macintosh) produces similar representations.

of the University of Wisconsin (Macintosh only). Generally these programs help in the design of PCR primers by searching for bits of known repeated-sequence elements and then optimizing the T_m by analyzing the length and GC content of a putative primer. Commercial software is also available and primer selection procedures are rapidly being included in most general sequence analysis packages.

Sequencing and PCR Primers

Designing oligonucleotides for use as either sequencing or PCR primers requires selection of an appropriate sequence that specifically recognizes the target, and then testing the sequence to eliminate the possibility that the oligonucleotide will have a stable secondary structure. Inverted repeats in the sequence can be identified using a repeat-identification or RNA-folding program such as those described above (see Prediction of Nucleic Acid Structure). If a possible stem structure is observed, the sequence of the primer can be shifted a few nucleotides in either direction to minimize the predicted secondary structure. The sequence of the oligonucleotide should also be compared with the sequences of both strands of the appropriate vector and insert DNA. Obviously, a sequencing primer should only have a single match to the target DNA. It is also advisable to exclude primers that have only a single mismatch with an undesired target DNA sequence. For PCR primers used to amplify genomic DNA, the primer sequence should be compared to the sequences in the GenBank database to determine if any significant matches occur. If the oligonucleotide sequence is present in any known DNA sequence or, more importantly, in any known repetitive elements, the primer sequence should be changed.

Degenerate Probes for Detecting Related Genes

Once a conserved protein sequence has been identified, a degenerate oligonucleotide can be designed for use as a hybridization probe to screen a library to identify additional members of the protein family (see UNIT 6.4). To design this oligonucleotide, the conserved protein sequence must be translated into a degenerate DNA sequence. Most software packages provide this feature; their output is a DNA sequence that is produced using the IUPAC degenerate-nucleotide codes. A degenerate oligonucleotide is then synthesized to correspond to the back-translated protein sequence. Most DNA synthesizers will create an oligonu-

cleotide with more than one nucleotide at any position within the sequence except for the 3' nucleotide.

For efficiency of synthesis and hybridization, the following guidelines, designed to yield oligonucleotides with the lowest possible level of degeneracy, should be followed. First, it is not necessary to incorporate both G and A to match a consensus sequence position containing C and T, because G pairs with both C and T. Second, inosine (I) pairs with G, C, and A. Third, a pyrimidine-pyrimidine mismatch does not disrupt base pairing, but a purine-purine mismatch is destabilizing.

As a general rule, create the minimum sequence that hybridizes to the consensus sequence. For each species (unique sequence) of oligonucleotide in the synthesis, the concentration of oligo used in hybridizations must be increased to achieve an equivalent C_{0t} value.

IDENTIFICATION OF PROTEIN-CODING REGIONS

Identification of potential protein-coding regions, especially in genomic DNA sequences from higher eukaryotes, is still not a completely automated process. It is helpful to simply translate the region in all six reading frames (three on each strand) and then identify all possible exon regions as uninterrupted open reading frames (ORFs). Although identifying the AUG initiation codon is a simple task, determining the location of introns is not as straightforward (unless the sequence is from yeast, where the rules for splicing are simple and seemingly absolute). Although several research groups are working on techniques to identify exon-intron boundaries, the process requires thoughtful consideration of several types of analyses. One useful technique available with some software packages (e.g., GCG TestCode) uses a purely statistical method to determine the nonrandomness of the triplet code characteristic of an ORF (Fickett, 1982). This method works best with large windows (~200 nucleotides), although it may be of limited use for identifying small ORFs. The basic principle is that introns are evolving without any restraint and are thus more random in sequence than exons, which are subject to stabilizing selection.

Prediction of ORFs is a very active research area. The rules used by the cellular machinery to define splice sites for higher eukaryotic sequences are still illusive. Four projects are trying to develop truly automatic gene-identification methods. Although there is some disagreement about the current exact reliability of these

methods, they all claim to locate about 90% of known (i.e., previously well-characterized) exons, and they are continuing to be improved. The first, Gene Recognition and Analysis Internet Link (GRAIL), is available via an electronic mail (e-mail) server and as a UNIX application; it is being developed by a group led by Edward Uberbacher of the Oak Ridge National Laboratory. GRAIL utilizes an artificial intelligence technique called a neural network that learns by example. The GRAIL software was not programmed to recognize a specific set of characteristics of human coding regions. Rather, it is given a set of well-characterized human sequences for which the locations of exons and introns have been experimentally identified. The neural network is programmed to search for particular types of simple features and then to correlate these features with the input set's exon-intron boundaries.

In contrast to GRAIL, the second program, GeneID, developed by Steen Knudsen and Kathleen Klose of Temple Smith's group at Boston University, utilizes many features of coding regions, including exon/intron consensus sequences and codon preferences. Because its rules are generally based on human sequences, GeneID's usefulness with nonmammalian sequences may be limited. GeneID is available from BMERC at Boston University via an e-mail server (see Appendix and *UNIT 19.1*).

The third gene-finding resource, BCM Gene Finder, is provided by the Baylor College of Medicine via e-mail and the World Wide Web (see Appendix and *UNIT 19.1*). A set of analysis programs is available to aid in the identification of genes in human DNA sequences. The analysis method involves predicting all possible internal exons based on the combination of characteristics describing a potential splice site. Then the set of potential exons is analyzed to determine the optimal combination and a model for the putative gene is constructed.

The final service was announced in 1992 and uses a neural network program to identify coding regions. The NetGene service is available through an e-mail server and is provided by the Department of Physical Chemistry at the Technical University of Denmark. This server appears to be changing the slowest, but because no one has yet produced the definitive gene-finding software, it is suggested that all of these servers should be tried to determine which resource is the most useful.

HOMOLOGY SEARCHING

Searching for homology between a newly obtained sequence and a sequence already listed in one of the DNA or protein databases can be very informative. Similarity to a known sequence can suggest the function of the new protein or indicate that no similar sequence has yet been deposited in the database. Because of the size of the databases and the speed with which they are expanding (see Fig. 19.2.1), the task of searching the database is not always easy to accomplish using an isolated laboratory microcomputer. Searching sequence databases for similarities is one of the few sequence-analysis tasks that is still best performed on a larger computer system. To search a single sequence against the entire GenBank, European Molecular Biology Laboratory (EMBL), or DNA Data Bank of Japan (DDBJ) databases requires about an hour on a smaller VAX or microcomputer. For this reason, many laboratories obtain an account on a large computer system or modern workstation that provides access to the large genetic sequence databases (see *UNIT 19.1*). Several sources, including the European Bioinformatics Institute (EBI), the National Center for Biotechnology Information (NCBI), and the University of Houston, provide free databases and homology searches over the Internet to anyone with access to e-mail (see *UNIT 19.1*). Protocols for carrying out these homology searches are described in *UNIT 19.3*.

Comparison of Two Sequences

Many programs are able to align two DNA or protein sequences. Such programs are often used to format an alignment for publication or simply to identify regions of similarity between two input sequences. In addition, these programs also introduce gaps into a sequence to optimize the alignment. Because alignment programs assign numerical penalties to gaps and mismatches, the alignment can be influenced by varying gap and mismatch parameters.

Protein sequences are aligned using a scoring matrix developed by Margaret Dayhoff (Schwartz and Dayhoff, 1978) known as PAM250, which represents the evolutionary change that takes place in a protein sequence over time. A PAM (rearranged acronym for Accepted Point Mutations) is a measure of the number of individual amino acid changes occurring per 100 amino acid residues as a result of evolution. A PAM of 250, therefore, represents 250 mutations occurring within 100 resi-

dues. For two proteins to be separated by 250 PAM requires some amino acids in the sequence to have mutated multiple times. However, as calculated by Dayhoff, two such protein sequences would still have ~20% of their amino acids in common, assuming both a completely random distribution of mutations and lack of selection for conserved functional sequences. The so-called PAM250 log odds matrix, the log of the probability that a given amino acid could mutate in the evolutionary time equal to 250 PAM, was created by analyzing many families of protein sequences that were available in the late 1970s. The PAM250 matrix is used to determine the score of an aligned pair of sequences by summing the matrix values corresponding to each aligned pair of amino acids. These matrices are still commonly used today; however, the PAM matrix table has been recalculated (Gonnet et al., 1992). The Gonnet tables are the first recalculation of the PAM tables since their initial formulation. Subsequently a new amino acid substitution matrix was derived directly from sequence or three-dimensional structural alignments of distantly related proteins. This matrix, called BLOSUM62, is reported to perform better than the previous matrix at detecting distant relationships using either BLAST or FASTA (Henikoff and Henikoff, 1993). The BLAST servers at the NCBI use the BLOSUM62 matrix by default for protein sequence comparisons.

An example of the way information contained within a substitution matrix can be expressed is given here. The standard PAM250 matrix states that a methionine opposite an methionine in an aligned pair of sequences has a score of 6, a methionine opposite a valine has a score of 2, and a methionine opposite a cysteine has a score of -5. These scores reflect the fact that in the data used to generate the matrix, methionine was observed to change frequently to valine (thus, this is considered to be a conservative substitution), whereas methionine very rarely changed to cysteine. Thus, some amino acid changes have positive effects on the alignment score, and others have negative effects. The larger the number, the better the match, and thus a negative value between a pair of amino acids in the matrix means that that combination actually takes away from the alignment.

Comparison of Multiple Sequences

Programs for simultaneously aligning multiple sequences require more computer power and are less common than the alignment pro-

grams discussed above. Three standard multiple-alignment algorithms have been developed for UNIX and VMS-based systems: Des Higgins' Clustal (Higgins and Sharp, 1988, 1989; see Table 7.7.2), the Feng and Doolittle algorithm implemented in the GCG PILEUP program (Feng and Doolittle, 1987; see Table 7.7.1), and PIRAlign from NBRF, which is based on a variation of the Needleman-Wunsch algorithm (Needleman and Wunsch, 1970; see Table 7.7.1). A powerful multiple-alignment tool for Microsoft Windows and Macintosh is the MACAW program created by Greg Schuler (Schuler et al., 1991). These programs identify common regions (or segments) in all the sequences that have been input, and then use the common regions as a starting point for building an overall alignment. They generally work best if the extent of the sequences being aligned is limited to the regions that are conserved among them.

Database Searches

Most researchers currently carry out both DNA and protein database searches over the Internet using the program Basic Local Alignment Search Tool (BLAST), developed by NCBI (Altschul et al., 1990). Detailed protocols for carrying out BLAST searches are given in an upcoming supplement. Here, we simply present a brief overview of the most important features of the BLAST family of programs.

The BLAST family of programs allows rapid similarity searching of nucleic acid or protein databases. The basic BLAST algorithm is used in several different programs that are each specific for a particular database and a particular type of input sequence. BLASTN is used to search a nucleic acid sequence against a nucleic acid database, BLASTP is used to search an amino acid sequence against a protein database, and TBLASTN is used to search an amino acid sequence against a nucleic acid database. In the latter program, the database is translated in all six reading frames prior to the search. The converse analysis is performed by BLASTX, which takes a nucleic acid input sequence and translates it in all six reading frames before searching against a protein-sequence database. Finally, if BLASTP does not identify significant sequence similarities, a more extensive program, BLAST3, is available that also compares an amino acid input sequence against a protein database. Like BLASTP, BLAST3 identifies regions of similarity between the input sequence and sequences present in the database, but the initial search is at lower stringency. This search

produces a collection of pairwise matching sequences that are then compared to each other, resulting in three-way matches where the component two-way matches were not significant. BLAST3 can be useful in identifying divergent members of a common gene family.

If the sequence of interest contains a protein-coding region, it is more informative to search the predicted protein sequence against one of the protein databases than to search the DNA sequence against a nucleic acid database. Because protein sequences evolve at a slower rate than DNA sequences, a distant homology between protein sequences may be missed at the DNA level. If no coding region has been defined, BLASTX can be used to translate the DNA sequences in all six reading frames before searching against a protein database. Because the protein-sequence databases only contain identified proteins, it is also important to check a newly defined amino acid sequence, or translated DNA sequence, against the current GenBank, EMBL, or DDBJ DNA sequence databases using TBLASTN. Such a search may identify a significant similarity to a DNA sequence that was not previously known to encode a protein.

An important feature of BLAST is a statistical significance score of the reported match. This statistical significance score is determined using an implementation of Karlin's significance formula (Karlin and Altschul, 1990), which calculates the Poisson probability that the observed sequence similarity will occur by chance based on the size and composition of the sequence database as well as on the size and quality of the match.

Another frequently used program for searching both protein and DNA sequence databases is FASTA (Pearson and Lipman, 1988), an updated version of the FASTN and FASTP programs. FASTA, which has been included in many commercial analysis packages, uses an initial fast search through the database to identify sequences with a high degree of identity to the test sequence. This fast search is performed by limiting the search to short regions of identity between the test sequence and the database. The word size (or k-tuple) parameter used in the program can be varied; it is the size of the initial match (sequence segment) that is used. The size of the k-tuple parameter indirectly affects the speed and sensitivity of the initial search through the database. Generally, the default value is the most efficient value to use; however, if distant homologies are desired, the

k-tuple value can be decreased (decreasing the k-tuple value causes the search to be more sensitive and take much more computer time).

FASTA builds a list or dictionary of all possible sequences of the size specified by the k-tuple value. The test sequence and all sequences in the database are then processed to find the locations of all segments in the sequence of a length equal to the k-tuple value that are present in the dictionary. For example, if the k-tuple was set to four, the sequence AGTCCTG would only have four entries (AGTC, GTCC, TCCT, and CCTG) in the dictionary of 256 (4^4) different four- (k-tuple value) letter words. The dictionaries of the two sequences can be more quickly compared than the sequences themselves, allowing for efficient identification of regions that contain small similarities. Once a list of the highest-scoring sequences is produced using the initial fast search, a second comparison is performed on just the top-scoring sequences. This secondary alignment uses the algorithm of Needleham and Wunsch (1970) to produce an alignment with gaps and is the output at the conclusion of the analysis. If no good homologies are observed after running FASTA, it is sometimes helpful to repeat the analysis using a smaller k-tuple value or an alternate scoring matrix.

A convenient method of performing a FASTA search on a local computer is to use a free e-mail server (UNIT 19.1). A computerized service provided by several institutions automatically accepts requests for FASTA searches via e-mail, searches the sequence contained within the mail message against a variety of databases, and then returns the results via e-mail. A mail server for FASTA is available from the University of Houston and the European Bioinformatics Institute. A sample mail message is shown in Figure 7.7.5. The FASTA program is currently available for most computers in common use: UNIX, VMS, IBM-compatible, and Macintosh versions of the program are available via the Internet or from Bill Pearson at the University of Virginia. The DOS and Macintosh versions of FASTA can search the CD-ROM version of GenBank or EMBL databases in a few hours.

Both FASTA and TFASTA (which, like T-BLAST, checks an amino acid sequence against DNA sequence databases) produce a score representing the quality of the match. This score is not the same as the significance score determined by one of the BLAST programs. FASTA and TFASTA scores are for each matching pair

Figure 7.7.5 Text of a message sent to the EBI FASTA mail server (e-mail address: fasta@ebi.ac.uk). This message requests that the sequence be searched against the Other Mammalian section of the EMBL database. The answer will include the top 100 matching sequences and alignments of the top 20 matching sequences.

of sequences generated using the PAM250 matrix described earlier (see Comparison of Two Sequences). Thus, the score is a numerical value representing the quality of the observed similarity between two sequences. A high-scoring similarity is generally a significant match; however, FASTA does not give a significance value like that provided by BLAST programs. With FASTA output, it is up to the user to recognize whether a particular observed match is significant or not, and this determination is not always an easy task. Moreover, with either FASTA or BLAST, determining whether a match is biologically significant is up to the investigator. If the BLAST mathematical significance value indicates that a match is not the result of chance, then the biological significance is very likely to be high. However, if the mathematical significance indicates a large probability that the match is just a random event, this does not necessarily mean that the biological significance is also low. Unfortunately, there is no systematic way to determine biological significance of an apparent homology in cases where mathematical similarity is low. In making this determination, the known or presumed function of the protein, the consensus match to known active sites or sequence motifs, and the number of distinct sequences that fit the proposed homologous group must be taken into account.

Because BLAST and FASTA use different algorithms, it is advisable to perform searches on a given sequence using both of these programs. If a significant match is not identified using one of the programs, use the other.

The BLAST programs are available from e-mail servers and as an Internet service (UNIT

19.1) using either a command-line interface or graphical interface (NetBLAST). UNIX and VMS versions are available via network file servers (see Table 7.7.2). A public domain program called MAILFASTA is now available; this program will take a DNA or protein sequence, reformat it, and e-mail it to any or all of the following e-mail servers: BLAST, BLITZ, BLOCKS, FASTA, GeneID, GRAIL, PredictProtein, and Pythia.

GENETIC SEQUENCE DATABASES AND OTHER ELECTRONIC RESOURCES AVAILABLE TO MOLECULAR BIOLOGISTS

Different gene sequence databases can be searched via the Internet or are available to anyone free of charge either via network file transfer protocol (FTP; see UNIT 19.1) or for the price of the distribution media. Some of the larger sequence analysis packages (e.g., GCG) provide tools that reformat the database data files as they are received from the database distributors. Reformatting is generally performed by a computer systems manager. Many users currently access the protein and DNA databases on the Internet. Detailed descriptions of the databases and how to access them via the Internet can be found in UNIT 19.2. UNIT 19.1 is a general guide to the Internet and includes a list of electronic resources available to molecular biologists. Detailed protocols to carry out homology searches using the BLAST family of programs are provided in UNIT 19.3.

APPENDIX

This section lists products and other resources designed for DNA and protein sequence analysis—e.g., databases, software, and journals—and how to obtain them. Some but not all of these products have been described or cross-referenced earlier in this unit.

Commercially Available Software

Table 7.7.1 is a brief description of sequence analysis software packages and some comments concerning their notable features.

Shareware and Free Software

Table 7.7.2 is a brief description of software that is distributed without charge. See also FTP archive and electronic mail listings below.

Electronic Mail Servers

Electronic mail is available at most research institutions, and these servers provide useful information, software, and analysis at no charge. With most servers, sending the simple message “HELP” will cause the latest documentation to be transmitted via e-mail (see *UNIT 19.1*).

FTP Archives Available on Internet

A vast amount of software and databases applicable to molecular biology is available at no charge from anonymous FTP servers as described in *UNIT 19.1*.

Free Databases

A brief description of databases that are available without charge is in *UNIT 19.1*.

International Biotechnologies P.O. Box 9558 New Haven, CT 06535 (203) 786-5600; (800) 243-2555 FAX (203) 786-5694
Pearson Sequence Analysis package FASTA	UNIX, VMS, Macintosh, and DOS-based sequence analysis software and fast database searching; may be stored on either hard disk or CD-ROM.	William R. Pearson Department of Biochemistry Box 440 Jordan Hall University of Virginia Charlottesville, VA 22908
Plasmid Artist	Publication-quality restriction map diagram production program for the Macintosh.	Clontech Laboratory 4030 Fabian Way Palo Alto, CA 94303 (415) 424-8222 FAX (415) 424-1352
Pro-RFLP	Macintosh and DOS gel analysis software for use with a scanner or TV camera; provides a number of features including calibration, database for unknowns, searching for matches to unknowns, complete printer output.	DNA ProScan, Inc. P.O. Box 12185 Nashville, TN 37212 (800) 841-4362
Rodger Staden programs	Several sequence assembly and analysis packages and complete UNIX analysis package; includes features that can analyze the fluorescence trace output files from ABI automatic sequencer machines.	Rodger Staden MRC Lab of Molecular Biology Hills Road Cambridge, England CB2 2QH
Sequencher	Macintosh sequencing support software including vector screening, ORF reports, translations, restriction maps, and a good interface with fluorescent sequencers.	Gene Codes Corporation 2901 Hubbard Road Ann Arbor, MI 48105 (313) 769-7249; (800) 497-4939 FAX (313) 930-0145
XQS ALIGN PSQ NAQ ATLAS	Database management and searching software featuring very fast and flexible keyword searches for VMS.	National Biomedical Research Foundation. Georgetown Univ. Medical Center 3900 Reservoir Road, N.W. Washington, DC 20007 (202) 687-2121 FAX (202) 687-1662

Table 7.7.2 Free Sequence-Analysis Software Programs

Name	Description	Source ^a
Amplify	Utility to aid in designing, analyzing, and even simulating experiments for PCR reactions.	FTP: sumex-aim.stanford.edu
BinHex 4.0	Essential utility required to decode files retrieved from FTP archives or received from mail servers for the Macintosh.	Available from most FTP archives; however, it is generally easiest to ask a colleague for a copy
BLAST	Ultra-fast database searching program for UNIX and VMS C source.	FTP: ncbi.nlm.nih.gov EM: netserv@ebi.ac.uk
BioSCAN	Forms-based search and retrieval resource from the University of North Carolina, Chapel Hill.	WWW URL: http://genome.cs.unc.edu/
BLOCKS Search	Forms-based submission tool via WWW for comparisons to BLOCKS database of highly conserved regions in protein sequences.	WWW URL: http://www.blocks.fcrc.org/
BoxShade	Prepares publication-quality figures of aligned sequences; resulting PostScript output contains shading over regions of similarity.	EM: netserv@ebi.ac.uk
Clustal	Multiple sequence alignment and production of phylogenetic dendrograms; available for DOS, Macintosh, UNIX, and VMS.	FTP: ftp.bio.indiana.edu FTP: ch.embnet.org
Covariation	HyperCard stack to analyze an aligned set of sequences to aid in the identification of covariations (two or more sites in an RNA or DNA molecule that are evolving together).	FTP: ftp.bio.indiana.edu
Disinfectant	Excellent Macintosh virus detection and removal application.	FTP: ftp.acns.nwu.edu FTP: sumex-aim.stanford.edu
Entrez	Application for access to genetics and biomolecular subset of MEDLINE bibliographic database; available for Macintosh, Windows, UNIX, and VMS; computer must be registered with NCBI to obtain access; registration is free.	FTP: ncbi.nlm.nih.gov WWW URL: http://atlas.nlm.nih.gov:5700/Entrez/index.html/
Enzyme Kinetics	HyperCard stack to analyze and plot enzyme kinetic experimental data.	FTP: ftp.bio.indiana.edu
FASTA	Fast sequence database searching program for UNIX, and VMS.	FTP: uvaarpa.virginia.edu
GDE	Superb analysis package for Sun Microsystems SPARCstations; includes multiple sequence alignment, sequencing project management, database searching, and more.	FTP: golgi.harvard.edu
GenBank Search	HyperCard stack that prepares a mail message for the GenBank FASTA and sequence retrieval mail servers; requires MacTCP software on Macintosh computers.	FTP: ftp.bio.indiana.edu

Name	Description	Source ^a
GeneMapper	Full-featured coding region identification and more for Sun Microsystems SPARCstations.	FTP: haywire.nmsu.edu
GenoBase	An experimental WWW resource provided by NIH; provides tables and query capabilities to an object-oriented molecular biology database.	WWW URL: http://specter.dcrn.nig.gov:8004/
GenQuest	Forms-based database searching via WWW from Genome Data Base; provides BLAST, FASTA, and Smith-Waterman searching SWISS-PROT, Genome Sequence Database (GSDB), Protein Databank (PDB), and Prosite.	WWW URL: http://www.gdb.org
Gopher	Client application to the growing number of Internet Gopher servers.	FTP: ftp.bio.indiana.edu FTP: boombox.micro.umn.edu
Linkage	Performs linkage analysis on genetic markers; available for UNIX, DOS, and VMS computers.	FTP: corona.med.utah
LoopViewer	Displays results of Zuker RNA folding programs on a Macintosh; produces output similar to that shown in Figure 7.7.4B.	FTP: ftp.bio.indiana.edu
MACAW	Excellent multiple sequence alignment and editing tool for Microsoft Windows and Macintosh.	FTP: ncbi.nlm.nih.gov
MacMolecule	Displays and rotates molecular structures of nucleic acids and proteins; very useful as a teaching aid.	FTP: ftp.bio.indiana.edu
MacPattern	Macintosh application that searches for patterns in protein sequences utilizing the PROSITE motif database; allows documentation from PROSITE to be directly accessed as well as entry of user-defined patterns.	FTP: ftp.bio.indiana.edu EM: netserv@ebi.ac.uk
MacPlasMap	Plasmid map drawing program for the Macintosh; the cutting sites of restriction enzymes must be entered by the user.	FTP: ftp.bio.indiana.edu EM: netserv@ebi.ac.uk
MandM	Materials and methods HyperCard stack for organizing laboratory protocols.	EM: netserv@ebi.ac.uk
MapMaker	Linkage analysis of F ₂ and CEPH populations; available for Sun Microsystems and VMS.	EM: mapm@genome.wi.mit.edu FTP: genome.wi.mit.edu
Mase	Multiple sequence alignment editor for UNIX.	FTP: mbcr.harvard.edu
MFOLD (or LRNA & CRNA)	VMS version for the prediction of Zuker RNA secondary structures.	FTP: amber.mgh.harvard.edu FTP: ftp.bio.indiana.edu
MulFold	Macintosh version of the MFOLD for prediction of Zuker RNA secondary structures, created by Don Gilbert.	FTP: ftp.bio.indiana.edu

Table 7.7.2 Free Sequence-Analysis Software Programs, continued

Name	Description	Source ^a
NCSA GelReader	Automates the measurement of DNA fragment lengths using a scanned image of an autoradiogram or EtBr-stained gel on a Macintosh; identifies lanes and bands, then exports the predicted band sizes as a text file for use with a spreadsheet.	FTP: ftp.ncsa.uiuc.edu
NCSA Mosaic	First WWW browser for Macintosh, Windows, and UNIX; requires an Internet connection.	FTP: ftp.ncsa.uiuc.edu
Netscape	Commercial WWW browser, available to educational users for free; provides fast displays and inline images in either GIF or JPEG encoding formats; available for Macintosh, Windows, and UNIX.	FTP: ftp.netscape.com
NIH Image	General image-analysis program for biologists that uses scanned images on a Macintosh.	FTP: alw.nih.gov
OSP	Oligonucleotide selection program to create appropriate PCR primers; selects primers using the sequence of the target region determining GC content, possible secondary structure, primer and amplified product length.	FAX: (314) 362-2985 c/o Paula Kassos (Phil Green, Washington University, St. Louis) EM: pg@genome.wustl.edu
PAUP	Phylogenetic analysis software for DOS and Macintosh.	EM: swofford@uxh.cso.uiuc.edu (David Swofford, Illinois Natural History Survey, Champaign, IL)
PGEN	Oligonucleotide design and analysis software for DOS; requires EGA or VGA graphics adaptors; will work from a 360K floppy drive.	FTP: ftp.bio.indiana.edu
Phylip	Phylogenetic analysis software for UNIX.	FTP: ftp.bio.indiana.edu
Plot/A	Protein analysis software with a variety of secondary structure predictions.	FTP: ftp.bio.indiana.edu
PlotZ	Graphical restriction mapping for UNIX and VMS.	FTP: amber.mgh.harvard.edu
PLSearch	Database of primary protein sequence patterns determined by analyzing the SWISS-PROT database, for UNIX.	FTP: mbcr.harvard.edu
Primer	Primer selection software for UNIX, VMS, DOS, and Macintosh; selects primers using the sequence of the target region by determining the GC content, possible secondary structure, primer, and amplified product length.	FTP: genome.wi.mit.edu
SeqApp	Analyzes DNA and protein sequences while also allowing easy access to WAIS and Internet Gopher resources; developed by Don Gilbert; requires a Macintosh and MacTCP.	FTP: ftp.bio.indiana.edu

continued

Polony DNA Sequencing

This unit provides protocols for performing polony DNA sequencing, a nonelectrophoretic sequencing method that eliminates *in vivo* cloning artifacts and affords a lower cost per base than conventional Sanger sequencing (Shendure et al., 2005). The first step in polony DNA sequencing is to construct an *in vitro* paired-tag library from genomic DNA (Basic Protocol 1; Fig. 7.8.1). Next, library molecules are clonally amplified on microbeads by emulsion PCR (Basic Protocol 2; Dressman et al., 2003). This clonal amplification yields polymerase colonies, or polonies, that can be sequenced. A Support Protocol describes a method used to optimize the amount of library DNA used as the ePCR template. Amplicon-bearing beads are then enriched (Basic Protocol 3) and two-dimensionally arrayed within an acrylamide gel matrix on a microscope coverglass (Basic Protocol 4). Finally, millions of short reads are generated in parallel from the microbeads via a cyclic DNA sequencing strategy that utilizes T4 DNA ligase to selectively tag each microbead with fluorescent labels that correlate with the unique nucleotide sequence present on any given bead (Basic Protocol 5).

The combination of protocols can be thought of as a modular platform, with each major step (library construction, emulsion PCR, sequence readout) independent enough to be replaced by an alternate. For example, if paired tags are not necessary to place reads (i.e., to match sequences to a reference genome sequence), single-tag libraries can be constructed (e.g., for barcode sequencing or RNA quantitation). The emulsion PCR protocol presented in this unit is a variation of that published by Dressman et al. (2003), but should not be thought of as the only applicable amplification method. Different sequencing biochemistries can also be used; in fact, during development of the polony sequencing platform, a number of alternate polymerase- and ligase-driven approaches were evaluated.

To implement the protocols presented in this unit, various instruments (e.g., fluorescent microscope, autosampler, and flow cell) and computer hardware and software are required. A discussion of the critical features of the setup is provided (see Critical Parameters and Troubleshooting), but the reader is directed to <http://arep.med.harvard.edu/Polonator> for more detailed information, including full schematics and drawings. Instructions are available there for using the hardware and software, as are binary and source codes for the software. All software is free and open-source, and all hardware is commercially available.

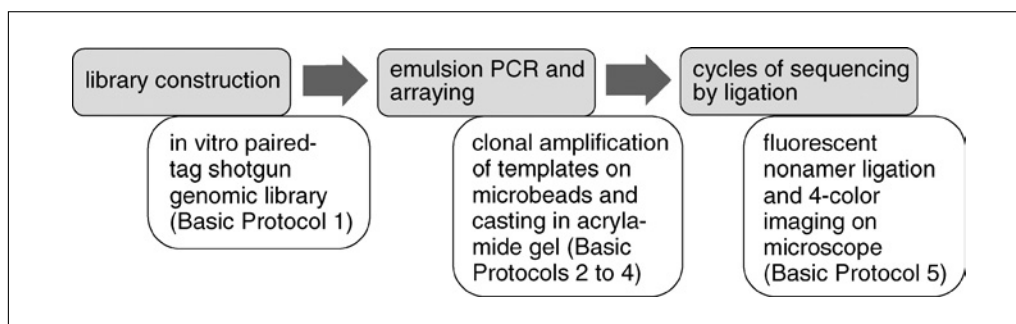

Figure 7.8.1 General procedure for polony sequencing. A paired-tag genomic library is used as template for emulsion PCR on microbeads to generate polymerase colonies (polonies). The beads are cast on a coverslip in a thin layer of polyacrylamide, and put through iterative cycles of single-base sequencing.

CONSTRUCTION OF A SHOTGUN PAIRED-TAG GENOMIC LIBRARY

Polony genomic resequencing is generally performed on a shotgun paired-tag library (Shendure et al., 2005). Each library molecule is 135 bp in length, and has two 17- to 18-bp paired genomic tags separated and flanked by common sequences (Fig. 7.8.2). The key step in this protocol is the circularization of randomly sheared and size-selected genomic DNA around a synthetic insert-linker. This links sequences that are separated on the genome by a defined distance distribution.

Materials

- Genomic DNA
- Buffer EB (Qiagen)
- End-It DNA end repair kit (Epicentre), including:
 - 10× buffer
 - 10× ATP
 - 10× dNTP mix
 - Enzyme mix
- 10× PCR buffer without MgCl₂ (Invitrogen)
- 50 mM MgCl₂
- 100 mM dATP
- 5 U/μl *Taq* DNA polymerase
- 20 mg/ml glycogen
- Oligonucleotides:
 - 100 μM T30-T: 5'-phosphorylated-GTCGGAGGCCAAGGCGGCCGTACGT CCAACT-3' (purified by HPLC)
 - 100 μM T30-B: 5'-phosphorylated-GTTGGACGTACGGCCGCCTTGGCC TCCGACT -3' (purified by HPLC)
 - 1 mM N6 oligonucleotides: 5'-NNNN*N*N-3' (*signifies phosphorothioate linkage; IDT)
 - 100 μM FDV-B: 5'-ATCACCGACTGCCCATAGAGAGGAAAGCGGAGGC GTAGTGGTT-3' (purified by HPLC)
 - 100 μM FDV-T: 5'-AACCACTACGCCTCCGCTTTCCTCTCTATGGGCAGT CGGTGAT-3' (purified by HPLC)
 - 100 μM RDV-B: 5'-AGAGAATGAGGAACCCGGGGCAGTT-3' (purified by HPLC)
 - 100 μM RDV-T: 5'-AACTGCCCCGGGTTTCCTCATTCTCT-3' (purified by HPLC)
- Quick ligation kit (NEB), including:
 - 2× Quick ligation buffer
 - Quick T4 DNA ligase
- 20 U/μl Exonuclease I (NEB)
- 100 U/μl Exonuclease III (NEB)
- TE buffer, pH 8.0 (APPENDIX 2)
- 25 mM dNTP mix (25 mM each nucleotide)
- 10× RepliPhi phi29 reaction buffer (Epicentre Technologies)
- 100 U/μl RepliPhi phi29 polymerase (Epicentre)
- 10× NEBuffer 4 (NEB)
- 1.6 mM *S*-adenosylmethionine (SAM; diluted from 32 mM stock in 1× NEBuffer 4; NEB)
- 2 U/μl *Mme*I (NEB)
- 2000 U/μl T4 DNA ligase and 10× buffer (NEB)
- 40% (w/v) polyethylene glycol 8000 (PEG) in H₂O
- 10× NEBuffer 2 (NEB)
- 10 U/μl *E. coli* DNA polymerase I (NEB)
- 5 U/μl Platinum *Taq* DNA polymerase (Invitrogen)

Qiaquick columns (Qiaquick PCR cleanup kit; Qiagen)
NanoDrop ND-1000 spectrophotometer (NanoDrop Technologies)
Microcon-30 column (Millipore)
Thermal cycler

Additional reagents and equipment for DNA quantitation (*APPENDIX 3D*),
phenol/chloroform extraction and ethanol precipitation (*UNIT 2.1A*), and agarose
and polyacrylamide gel electrophoresis (*UNITS 2.5A & 2.7*)

Prepare genomic DNA for circularization

1. Shear 15 µg genomic DNA to desired size distribution.

The Hydroshear (<http://www.genomicsolutions.com>) is the recommended instrument for this purpose since, when the manufacturer's instructions are followed, it produces a population of fragments having a relatively tight size distribution and ends that can be efficiently blunted. The authors typically shear DNA at a concentration of ~60 ng/µl.

2. Purify DNA on Qiaquick columns (≤ 10 µg per column) as per manufacturer's instructions.

Use as few columns as possible.

3. To repair the DNA ends (i.e., blunt them following shearing), combine the DNA with the components of the End-It DNA end repair kit as follows:

10 µg column-purified, sheared genomic DNA in buffer EB
25 µl 10× buffer
25 µl 10× ATP
25 µl 10× dNTP mix
5 µl enzyme mix
H₂O to a final volume of 250 µl.

Incubate 1 hr at room temperature.

4. Purify DNA on a Qiaquick column per manufacturer's instructions, except elute with 90 µl buffer EB.

5. Quantitate DNA using a NanoDrop ND-1000 spectrophotometer (see *APPENDIX 3D*).

Concentration should be ~100 ng/µl.

6. Incubate 15 min at 70°C to eliminate any residual enzyme activity.

7. Add an adenosine tail by combining the following components:

2.2 µg end-repaired DNA
10 µl 10× PCR buffer without MgCl₂
6 µl 50 mM MgCl₂
0.5 µl 100 mM dATP
0.5 µl 5 U/µl *Taq* DNA polymerase
H₂O to 100 µl.

Incubate 30 min at 70°C then cool to 4°C. Transfer to ice.

*In the A-tailing reaction, *Taq* polymerase adds a single A to the 3' ends of the blunted DNA in a template-independent fashion.*

8. Extract DNA from the reaction mixture with phenol/chloroform and precipitate in ethanol using 20 μg glycogen as carrier (*UNIT 2.1A*). Resuspend pellet in 40 μl buffer EB.

Glycogen should be used as a carrier in all ethanol precipitation steps in this protocol.

9. Separate the sheared, A-tailed DNA on a 6% polyacrylamide gel with TBE buffer (*UNIT 2.7*). Stain with ethidium bromide.

For Invitrogen precast gels, mix 20 μl DNA with 5 μl of 5 \times loading buffer (Novex) and load across two 0.5-cm lanes.

10. Cut out the desired bands and extract DNA using the crush-and-soak method (*UNIT 2.7*). Precipitate in ethanol using glycogen as a carrier, and resuspend in 10 μl buffer EB.

For a paired-tag library with an average intertag distance of 1 kb, excise and pool gel bands centered at 1 kb with a total width of no more than 500 bp. Exposure of the DNA to UV light during visualization should be minimized.

11. Quantitate the size-selected DNA by separating on an agarose or polyacrylamide gel (*UNIT 2.5A or 2.7*) and comparing the brightness of the smear to that of a known amount of a molecular weight standard.

The concentration should be ~ 20 to 40 ng/ μl .

Circularize genomic material around synthetic oligonucleotides

12. Anneal oligonucleotides T30-T and T30-B in a thermal cycler by combining equal amounts and heating to 95°C for 10 min and then slowly cooling to room temperature over the course of 1 hr.

The final concentration of the T30 insert-linker should be 100 μM . T30 has T 3' overhangs designed to be complementary to the A 3' overhangs of the genomic DNA.

13. Ligate genomic DNA fragments in the presence of annealed T30 using the Quick ligation kit as follows:

170 ng size-selected DNA (0.25 pmol at ~ 1 kb)
0.8 μl 1 μM annealed T30 (0.8 pmol)
40 μl 2 \times Quick ligation buffer
4.0 μl Quick T4 DNA ligase
H₂O to a final volume of 80 μl .

Incubate reaction 10 min at room temperature then heat-inactivate 10 min at 65°C. Use the heat-inactivated reaction mixture directly in the next step without further purification.

The ligation should be performed under conditions favoring formation of monomeric recombinant circles (i.e., genomic DNA–T30). To this end, T30 should be present at a three-fold molar excess to genomic fragments.

14. Eliminate all noncircularized material by exonucleolysis as follows:

1.0 μl 20 U/ μl Exonuclease I
0.1 μl 100 U/ μl Exonuclease III
80 μl heat-inactivated reaction mix
TE buffer, pH 8.0, to a final volume of 90 μl .

Incubate 45 min at 37°C, and then heat-inactivate 20 min at 80°C. Use this reaction mixture directly in the next step without further purification.

Amplify circular DNA

15. Prepare the master mix for hyper-branched rolling-circle amplification of the circular DNA:

12 μ l 25 mM dNTP mix
30 μ l 10 \times RepliPhi phi29 reaction buffer
15 μ l 1 mM N6 oligonucleotides
213 μ l H₂O
30 μ l circularized DNA.

Split into 6 tubes of 50 μ l each.

16. Denature material by heating to 95°C for 5 min, then anneal by rapidly cooling to 4°C. Add 2.5 μ l phi29 polymerase to each tube, keeping on ice. Incubate overnight at 30°C.
17. Pool amplified circular DNA into a single tube. Purify DNA using a Microcon-30 column according to the manufacturer's instructions, washing with 1 ml TE buffer, pH 8.0. Wash the membrane several times to maximize recovery.
18. Resuspend the DNA using 750 μ l buffer EB, preheated to 50°C. Quantitate the DNA using a NanoDrop ND-1000 spectrophotometer.

Concentration should be ~230 ng/ μ l.

Release paired tags

19. Digest the amplified DNA with *MmeI* to release the 70-bp T30-linked paired tags:

40 μ g amplified circular DNA
100 μ l 10 \times NEBuffer 4
1.6 μ l of 1.6 mM SAM
60 μ l *MmeI* (2 U/ μ l)
H₂O to 1000 μ l.

Split into eight tubes of 125 μ l each on ice, and then incubate at 37°C for 30 min.

MmeI cuts 18 to 19 bp from its recognition site, which is 1 bp from the start of the genomic fragment. The released fragments contain the common T30 sequence flanked by two 17- to 18-bp tags of genomic DNA.

20. Immediately extract the DNA with phenol/chloroform and precipitate with ethanol using glycogen as a carrier. Resuspend pellet in a total volume of 80 μ l TE buffer, pH 8.0.
21. Purify the 70-bp paired-insert library as in steps 9 and 10, resuspending precipitated DNA in 20 μ l TE buffer, pH 8.0.

The sample should be split across four 0.5-cm lanes of a precast 6% polyacrylamide gel in TBE buffer.

22. Quantitate the gel-purified DNA by electrophoresis (step 11).

DNA concentration should be ~12 ng/ μ l.

Add emulsion PCR adapters

23. To perform the blunting reaction (to remove 2-nt 3' overhangs from the *MmeI* digestion), combine the DNA with components of the End-It DNA end repair kit as follows:

8.5 μ l paired-insert library (~100 ng DNA)
1.25 μ l 10 \times buffer
1.25 μ l 10 \times ATP
1.25 μ l 10 \times dNTP mix
0.25 μ l enzyme mix.

Incubate at room temperature for 45 min.

24. Put on ice and add TE buffer, pH 8.0 to bring volume to 50 μ l. Extract the DNA with phenol/chloroform and precipitate in ethanol using 20 μ g glycogen as carrier. Resuspend DNA in 8 μ l TE, pH 8.0.

25. Prepare emulsion PCR amplification primer sequences by annealing oligonucleotides FDV-T and FDV-B and oligonucleotides RDV-T and RDV-B as in step 12.

The final concentration of each oligonucleotide should be 50 μ M. FDV and RDV are not 5'-phosphorylated, so they will not ligate to one another.

26. Prepare the ligation reaction mixture by mixing the following components on ice:

8.0 μ l blunt-ended library DNA (~100 ng, 2 pmol)
1.0 μ l 50 μ M FDV (50 pmol)
1.0 μ l 50 μ M RDV (50 pmol)
2.5 μ l 10 \times T4 DNA ligase buffer (~0.5 \times)
21.1 μ l 40% PEG
12.3 μ l H₂O.

27. Mix on ice, then add 2.0 μ l of 2000 U/ μ l T4 DNA ligase and incubate overnight at 16°C to ligate primer sequences to the library molecules.

After ligation, several species will be present: FDV-insert-FDV, FDV-insert-RDV, and RDV-insert-RDV.

28. Increase volume to 100 μ l with TE buffer, pH 8.0. Extract the DNA with phenol/chloroform, precipitate in ethanol using glycogen as a carrier, and resuspend in 10 μ l buffer EB.

29. Purify the 135-bp FDV-RDV paired-insert library as in steps 9 and 10, resuspending the precipitated DNA in 10 μ l TE buffer, pH 8.0.

30. Assemble on ice the reaction mixture used to remove nicks in double-stranded library molecules by nick translation:

10.0 μ l library DNA
0.5 μ l 25 mM dNTP mix
2.5 μ l 10 \times NEBuffer 2
1.0 μ l 10 U/ μ l *E. coli* DNA polymerase I
11.0 μ l H₂O.

Incubate 30 min at 16°C.

31. Increase volume to 100 μ l with TE buffer, pH 8.0. Extract the DNA with phenol/chloroform, precipitate in ethanol using glycogen as a carrier, and resuspend in 10 μ l TE buffer, pH 8.0.

Amplify FDV/RDV-adapted library

32. Prepare the master mix for PCR amplification (for eight tubes of 50 μ l each):

50 μ l 10 \times PCR buffer without MgCl₂
4.0 μ l 25 mM dNTP mix
15 μ l 50 mM MgCl₂
426 μ l H₂O
1.0 μ l 100 μ M FDV-T
1.0 μ l 100 μ M RDV-T
2.0 μ l 5 U/ μ l Platinum *Taq* DNA polymerase.

33. Split the master mix into eight tubes of 50 μ l each, and add 0.5 μ l FDV/RDV-adapted library material to each tube.
34. Carry out PCR using the following amplification cycles:

Initial step:	2 min	94°C	(denaturation)
12 cycles:	30 sec	94°C	(denaturation)
	30 sec	55°C	(annealing)
	90 sec	72°C	(extension).

The number of cycles is kept low to minimize PCR amplification bias. Due to suppression PCR effects (Siebert et al., 1995), FDV/FDV- and RDV/RDV-adapted molecules are not amplified.

35. Purify DNA using Qiaquick columns according to the manufacturer's instructions for PCR cleanup.
36. Purify the amplified 135-bp FDV-RDV paired-insert library as in steps 9 and 10, resuspending the precipitated DNA in 10 μ l TE buffer, pH 8.0.

When excising the 135-bp library band, be careful to avoid contamination by marker DNA, if used.

37. Quantitate the final DNA library by electrophoresis (step 11).

The concentration should be \sim 2 ng/ μ l.

EMULSION PCR OF PAIRED-TAG LIBRARY ON MICROBEADS

Emulsion PCR (ePCR) is used to generate clonally amplified DNA fragments suitable for polony sequencing. First, a biotinylated PCR primer is immobilized on streptavidin-coated beads. Next, billions of microreactors are formed by the emulsification of a PCR mix in mineral oil (Dressman et al., 2003). When one bead (bearing an immobilized PCR primer) and one template molecule are trapped in a compartment, amplification will proceed and result in tens of thousands of copies of the template molecule attached to the bead. The result is a complex mixture of clonally amplified templates (polonies) anchored to beads. Each bead bears numerous copies of the same template, but different beads bear different templates.

Materials

MyOne C1 1- μ m paramagnetic, streptavidin-coated beads (Dynal)

Bind and wash (B&W) buffer (see recipe)

Oligonucleotides:

1 mM PR1-F-2BIO: 5'-dual-biotin-CCACTACGCCTCCGCTTTCCTCTCTAT
GGGCAGTCGGTGAT-3'

2 mM PR1-R: 5'-CTGCCCCGGGTTTCCTCATTCTCT-3'

10 μ M PR1-3LF: 5'-CCTCTCTATGGGCAGTCGGTGAT-3'

TE buffer, pH 8.0 (APPENDIX 2)

Light mineral oil (Sigma)

10% Span 80 (see recipe)

Tween 80

Triton X-100

10 \times PCR buffer without MgCl₂ (Invitrogen)

50 mM MgCl₂

25 mM dNTP mix (25 mM each nucleotide)

5 U/ μ l Platinum Taq DNA polymerase (Invitrogen)

Template DNA (library DNA at appropriate concentration; see Basic Protocol 1 and Support Protocol)

BASIC PROTOCOL 2

DNA Sequencing

7.8.7

NXS buffer (see recipe)
0.1 M NaOH
1.5-ml microcentrifuge tubes
Magnetic particle concentrator (MPC; Dynal)
2-ml cryogenic vials (Corning no. 430661)
Stir bar, flea-size (VWR no. 58948-353)
Magnetic stirrer (closed-loop; VWR)
200- μ l eight-tube PCR strips
Thermal cycler

Bind forward PCR primer to microbeads

1. To 30 μ l MyOne beads in a 1.5-ml microcentrifuge tube, add 30 μ l B&W buffer.
2. Mix and then remove all liquid using a magnetic particle concentrator (MPC).
Vortex to mix in all steps except those where enzyme activity is required. In those cases mix gently by flicking or rotating the tube.
3. Wash two times in 60 μ l B&W buffer using an MPC, and resuspend in 60 μ l B&W buffer.
4. Add 1.2 μ l PR1-F-2BIO, mix, and incubate 20 min at room temperature.
Mix periodically by pipetting to prevent settling of beads.
PR1-F-2BIO is synthesized with a dual biotin at the 5' end to tightly bind the streptavidin-coated microbeads. Dual biotin is necessary to ensure the template remains on the bead for the duration of the sequencing run.
5. Remove all liquid using an MPC, and then wash twice in 100 μ l B&W buffer and once in 100 μ l TE buffer, pH 8.0.
6. Remove all liquid using an MPC and resuspend in 60 μ l TE buffer.
Concentration should now be $\sim 5 \times 10^9$ beads/ml.

Perform emulsion PCR reaction

7. Prepare the oil phase by assembling six 1.5-ml microcentrifuge tubes containing the following:
545 μ l light mineral oil
450 μ l 10% Span 80
4.0 μ l Tween 80
0.5 μ l Triton X-100.

Vortex each tube individually for at least 20 sec to thoroughly mix all components.
Watch the pipet tips carefully to ensure that viscous reagents are delivered into the tube. Use reverse pipetting (see http://www.rainin.com/pdf/rainin_classic_manual.pdf) for all oil-phase components.
8. Prepare the aqueous phase by combining the following:
96 μ l 10 \times PCR buffer without MgCl₂
359 μ l 50 mM MgCl₂
135 μ l 25 mM dNTP mix
12.0 μ l 2 mM PR1-R
4.8 μ l 10 μ M PR1-3LF
60 μ l microbeads from step 6
246 μ l H₂O
54 μ l 5 U/ μ l Platinum *Taq* DNA polymerase
1.0 μ l template DNA.

9. Place twelve 2-ml cryogenic vials in the centers of three magnetic stirrers set to 1400 rpm.
10. Place a flea-size stir bar in each vial.
11. Add 400 μ l oil phase to each vial.
12. Add 75 μ l aqueous phase, dropwise over 1 min, to each vial.

Be sure each drop of liquid hits the bottom of the tube, not the walls.

13. Stir for 30 min using a magnetic stirrer.
14. Pipet the contents of each cryogenic vial into a separate eight-tube PCR strip (50 μ l per tube) for a total of twelve strips, or 96 tubes.

Aspirate and dispense slowly to minimize the amount of emulsion that sticks to the walls of the pipet tip.

15. Carry out PCR using the following amplification cycles:

Initial step:	2 min	94°C	(denaturation)
120 cycles:	15 sec	94°C	(denaturation)
	30 sec	57°C	(annealing)
	75 sec	70°C	(extension)
Finish:	2 min	72°C	
Hold:	indefinitely	4°C.	

16. Pool contents of each strip of eight 200- μ l tubes into a separate 1.5-ml microcentrifuge tube (twelve tubes). Immediately proceed with recovery.

Recover beads from emulsion

17. Add 800 μ l NXS buffer to each tube.
 18. Vortex each tube individually at maximum speed for at least 20 sec.
 19. Centrifuge all tubes 90 sec at 16,110 \times g, room temperature.
 20. Aspirate all but 100 μ l supernatant (being sure to remove all of the top oil phase).
 21. Repeat steps 17 to 20 two more times.
 22. Pellet beads in tubes using an MPC, and aspirate all liquid.
 23. Resuspend each pellet in 25 μ l TE buffer, pH 8.0, and transfer all to a single new tube. Mix by pipetting up and down.
- All twelve tubes should be pooled into this one new tube. Try to minimize the amount of oil and detergent carried over into the new tube from the walls of the old tube.*
24. Pellet the beads using an MPC, aspirate all liquid, and add 250 μ l TE buffer, pH 8.0. Vortex briefly, then pulse centrifuge to pull the liquid into the bottom of the tube. Repeat two more times.
 25. Pellet beads using an MPC, and aspirate all liquid.
 26. Remove the nonbiotinylated strand from the beads by incubating in 100 μ l of 0.1 M NaOH for 20 min at room temperature. Periodically mix by pipetting to prevent beads from settling.
 27. Pellet beads using an MPC, and remove all liquid.
 28. Wash once with 100 μ l 0.1 M NaOH and three times with 150 μ l TE buffer. Mix each wash by vortexing to ensure removal of residual NaOH.
 29. Pellet beads using an MPC, aspirate all liquid, and resuspend in 60 μ l TE buffer.

ENRICHMENT FOR AMPLICON-BEARING BEADS

The result of ePCR is a population of beads, most (~80%) of which do not bear an amplified template. In order to maximize the number of amplicon-bearing beads on the sequencing array, an enrichment step is required. Fluorescence-activated cell sorting can be employed to select for these beads by hybridizing a fluorescently labeled probe specific to amplicons. Alternately, the centrifugation technique presented below can be used for more rapid and cost-effective enrichment.

In this protocol, the dense paramagnetic ePCR beads are incubated with low-density polystyrene beads bearing an oligonucleotide complementary to a common amplicon sequence. Amplicon-bearing beads hybridize to these capture beads, while non-amplicon-bearing beads do not. The density differential between captured and uncaptured ePCR beads is exploited for enrichment by centrifugation through a viscous 60% glycerol solution; the former remain in the supernatant while the latter form a pellet.

Materials

Spherotech particles (3- μ m streptavidin-coated polystyrene particles; Spherotech no. SVP-30-5)

Bind and wash (B&W) buffer (see recipe)

1 mM PR1-BIOXL:

5'-biotinTEG-CGTACCCCGCTTGGTCTTTCTCCCGTACCCCGCTTGG
TCTTTCTCCCTGCCCGGGTTCCTCATTCTCT-3'

TE buffer, pH 8.0 (*APPENDIX 2*)

ePCR beads (Basic Protocol 2)

Glycerol

0.1 M NaOH

Magnetic particle concentrator (MPC; Dynal)

1.5-ml microcentrifuge tubes

Bind capture oligonucleotide to capture beads

1. Centrifuge 400 μ l Spherotech particles for 30 sec at $16,110 \times g$, room temperature.
2. Remove all liquid, and wash pellet with 400 μ l B&W buffer.
3. Centrifuge for 30 sec at $16,110 \times g$.
4. Remove all liquid, and resuspend in 400 μ l B&W buffer.
5. Add 8 μ l of 1 mM PR1-BIOXL and incubate at room temperature for 20 min.
6. Wash three times in 800 μ l TE buffer, pH 8.0, pelleting each time by centrifugation. Resuspend final pellet in 80 μ l B&W buffer.

Anneal capture beads to emulsion PCR beads

7. Add 60 μ l ePCR beads to 80 μ l capture beads and incubate at 56°C for 10 min.
8. During the incubation, prepare 1 ml of fresh 60% (v/v) glycerol in H₂O. Vortex to mix thoroughly.
Must be made fresh each day.
9. Add 150 μ l of 60% glycerol to each of four 1.5-ml microcentrifuge tubes.
10. Layer 35 μ l bead mixture from step 7 onto the top of the glycerol solution in each of the four tubes.

Be careful to pipet gently so the bead solution does not mix with glycerol solution.

Separate bead populations by centrifugation

11. Centrifuge tubes for 1 min at $16,110 \times g$.

The amplicon-bearing ePCR beads are hybridized to the complementary sequences carried on the low-density polystyrene capture beads and will remain in the supernatant; the ePCR beads without amplified sequences will form a pellet in the bottom of the tube.

12. Transfer all the supernatant to four new microcentrifuge tubes, being careful not to disturb the pellets.

If necessary, wash the walls of the tubes with the supernatant to collect any beads bound there.

13. To each recovered supernatant tube, add 1 ml H₂O and vortex until thoroughly mixed.

14. Centrifuge for 3 min at $16,110 \times g$, room temperature, to pellet all beads.

15. Aspirate, being careful to not disturb the pellet, and then place tubes on an MPC to hold the pellet firmly in place. Remove any remaining liquid.

16. Separate ePCR beads from capture beads by adding 120 μ l of 0.1 M NaOH and incubating 10 min at room temperature to denature the hybridized DNA strands.

17. Using the MPC, collect the amplicon-bearing ePCR beads into a pellet. Remove and discard all liquid.

The liquid contains the released capture beads.

18. Wash the pellet twice by adding 120 μ l of 0.1 M NaOH, vortexing briefly, centrifuging briefly to pull the liquid to the bottom of the tube, and collecting the pellet using the MPC.

19. Resuspend in 6.5 μ l TE buffer, pH 8.0.

CASTING A POLONY BEAD ARRAY

The amplified, enriched beads are cast in a two-dimensional array to fix their positions during the subsequent sequencing reactions by mixing with acrylamide and pouring into a shallow mold formed by a Teflon-masked microscope slide. The coverslip placed on top of the gel is treated with Bind Silane, which covalently attaches the gel to the glass coverslip. The acrylamide gel mixture is formulated such that it takes 30 min or more to polymerize, during which time the beads settle into a single monolayer before their positions become fixed. This allows efficient imaging of all beads in the gel, since they all reside in the same focal plane of the optics used for imaging.

Once polymerized, the gel is approximately 30 microns thick, while the beads are only 1 micron in diameter. To ensure the DNA-bearing beads are accessible to reagents for enzymatic sequencing reactions, the gel is cast such that the beads will be fixed at the exposed surface (i.e., opposite the side attached to the Bind Silane-treated glass).

Materials

1% Triton X-100 in H₂O

Glacial acetic acid

Bind Silane (Promega)

100% ethanol

Enriched ePCR beads in TE buffer, pH 8.0 (Basic Protocol 3)

40% acrylamide/bisacrylamide (19:1) solution

5% TEMED

0.5% ammonium persulfate (APS)

Wash 1 (see recipe)

BASIC PROTOCOL 4

DNA Sequencing

7.8.11

Round coverslips, 40 mm diameter, no. 1.5 (Bioprotechs no. 40-1313-0319)
1000-ml plastic beaker
Shaker
Vacuum desiccator
Teflon-masked microscope slides (Erie Scientific, no. ER-203W)

Treat coverslips with Bind Silane

1. Wash round coverslips in 1% Triton X-100 for 20 min with gentle shaking.
2. Prepare silane solution in a 1000-ml plastic beaker:
 - 500 ml H₂O
 - 110 μ l glacial acetic acid
 - 2 ml Bind Silane.

Stir for 15 min until Bind Silane droplets have completely disappeared.

3. Immerse coverslip in silane solution and incubate 1 hr at room temperature with gentle shaking.
4. Wash thoroughly with H₂O, then rinse with 100% ethanol.
5. Allow to dry completely in vacuum desiccator. Store coverslips up to 1 month under vacuum.

Cast enriched ePCR beads

6. Prepare bead/acrylamide mixture:
 - 6.5 μ l enriched ePCR beads in TE buffer
 - 1.25 μ l 40% acrylamide/bisacrylamide solution (19:1)
 - 0.5 μ l 5% TEMED
 - 0.5 μ l H₂O.

Mix by pipetting, then add 0.75 μ l of 0.5% APS.

7. Immediately pipet 9.5 μ l onto a Teflon-masked microscope slide and cover with a silane-coated coverslip. Allow to polymerize for 45 min.

The coverslip should spread the liquid across the entire surface of the circular well on the Teflon-masked slide. During polymerization, the beads will settle to the surface of the gel closest to the microscope slide.

8. Invert the slide/coverslip stack and remove microscope slide from gel by gently lifting with a razor blade near the edge of the coverslip.

The gel should remain attached to the coverslip.

9. Immerse the coverslip, with polony bead array attached, in wash 1 until ready for use, up to ~1 month at 4°C.

BASIC PROTOCOL 5

DNA SEQUENCING BY LIGATION WITH DEGENERATE FLUORESCENT NONAMERS

An anchor primer is first hybridized to a known sequence, or priming site, within the single-stranded template. This primer is synthesized with deoxyuridine in place of thymidine. A ligation reaction is then performed with a pool of fully degenerate, fluorescently labeled nonanucleotides. During the ligation reaction, each bead becomes tagged with a fluorophore that indicates the identity of the base present at the position being interrogated. After imaging the array to determine which fluorophore labels each bead, the anchor-primer/fluorescent-nonamer complex is removed from the template by reacting

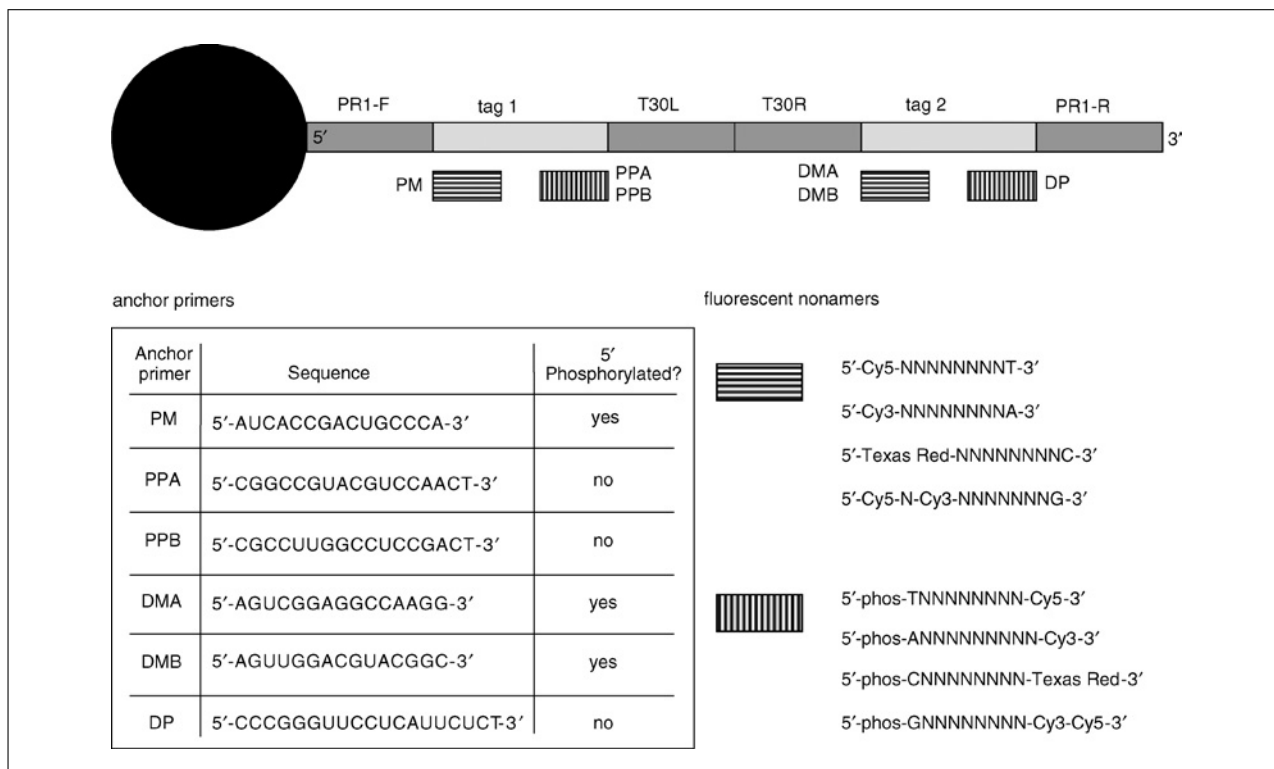

Figure 7.8.2 Schematic of the 135-bp bead-bound template and sequences of oligonucleotides used in sequencing reactions (Basic Protocol 5). For each reaction, the combination of anchor primer(s) and fluorescent nonamers is specified by the position in the tag being sequenced. All anchor primers should be synthesized with deoxyuridine to allow enzymatic removal of the primers. Fluorescent nonamers should be synthesized by Integrated DNA Technologies (IDT) with fully degenerate positions hand mixed to ensure equal ratios of each nucleotide at each position. The T30 sequence is shown as T30L and T30R to emphasize that the sequencing primers do not bind the full length of T30. Abbreviations: DMA and DMB, distal minus A and B strands; DP, distal plus; PM, proximal minus; PPA and PPB, proximal plus A and B strands; PR1-F and PR1-R, forward and reverse PR1 primers.

with the uracil-specific excision reagent (USER) enzyme. The USER enzyme excises all deoxyuridines from the anchor primer, resulting in short fragments that dissociate at moderate temperatures ($<60^{\circ}\text{C}$) due to their low melting points (T_m), and leaving the bead-bound template ready for another position to be interrogated.

The combination of degenerate nonamer pool and anchor primer specifies which position in the template the reaction will interrogate (see Fig. 7.8.2). Whether the anchor primer or the nonanucleotides should be synthesized with a 5' phosphate is dependent on which position in the template is being queried with a given combination of anchor primer and nonamer. When sequencing the 5' side of a tag, the anchor is phosphorylated, and when sequencing the 3' side, the nonamers are phosphorylated.

At the start of a sequencing run, all 3' ends of unextended forward ePCR primers and templates are capped by the addition of dideoxynucleotides using terminal deoxytransferase. This capping reaction is necessary to prevent nonspecific ligation of labeled nonamers to bead-bound ePCR primers and templates.

This protocol describes the ligation and stripping steps required to query the base at a specific position in an iterative fashion. When using the autosampler and flow cell system, multiple solutions can be prepared for one or several cycles and used with a computer program preset with the appropriate times, temperatures, and volumes indicated in the protocol steps. Imaging and analysis procedures are discussed in Critical Parameters and Troubleshooting.

Materials

Bead array with template DNA (Basic Protocol 4)
5× tailing buffer (Invitrogen)
1.25 mM ddNTP mix (1.25 mM each dideoxynucleotide)
15 U/μl terminal deoxytransferase (recombinant; Invitrogen)
Wash 1 (see recipe)
6× SSPE (*APPENDIX 2*)/0.01% Triton X-100
Anchor primer (see Fig. 7.8.2)
2000 U/μl T4 DNA ligase and 10× buffer (NEB)
100 μM degenerate fluorescent nonamer mix (Integrated DNA Technologies)
TE buffer, pH 8.0 (*APPENDIX 2*)
1 U/μl USER enzyme mix (NEB)
Automated fluorescent microscope with flow cell (see Table 7.8.1 for parts list)
Autosampler (see Table 7.8.1)
1-ml disposable syringe
0.45-μm pore size, 4-mm cellulose acetate syringe filter (VWR)

Perform dideoxynucleotide capping reaction

1. Prepare the capping reaction mix:

114 μl H₂O
30 μl 5× tailing buffer
4 μl 1.25 mM ddNTP mix
2 μl 15 U/μl terminal deoxytransferase.

2. Place the bead array with template DNA on a coverslip into the flow cell mounted on the microscope stage. Prime fluid lines with wash 1.
3. Add the reaction mix to the appropriate well of the autosampler. Incubate 60 min at 35°C.

Hybridize anchor primer to array

4. Prepare the hybridization mix by combining:

150 μl 6× SSPE with 0.01% Triton X-100
1.5 μl 1 mM anchor primer.

5. Add hybridization mix to the appropriate well of the autosampler. Incubate 5 min at 56°C, then 2 min at 42°C.

Ligate fluorescent nonamers to visualize complexes

6. Prepare ligation reaction on ice:

15 μl 10× T4 DNA ligase buffer
12.0 μl 100 μM degenerate fluorescent nonamer mix
3.0 μl 2000 U/μl T4 DNA ligase
120 μl H₂O.

When preparing multiple ligation reaction mixtures (for sequential cycles) at once, be sure they are consumed within 6 hr, since T4 DNA ligase is unstable once mixed with reaction buffer. In addition, only one mix containing 5'-phosphorylated nonamers should be prepared, and it should be used in the first sequencing cycle performed.

7. Aspirate the solution into a 1-ml syringe, attach a 0.45- μm filter to the Luer syringe adapter, and pass the contents through the filter into the appropriate well of the autosampler. Incubate 30 min at 32°C.

The nonamer solutions contain large aggregates of fluorescent dye. Filtering is essential to ensure these aggregates are not introduced into the flow cell, since they will gradually accumulate by sticking to the gel, interfere with imaging and data extraction, and poison subsequent reactions.

Incubation temperature and duration can be optimized for variations in signal. If signal is low, a slightly longer time or higher temperature can be used; if signal is very high, cycle time can be decreased by decreasing incubation time appropriately. Although increased concentrations of nonamer may also drive the reaction to completion faster, it should be noted that cost will increase and fidelity may be affected.

8. Image using fluorescence microscopy to determine the nonamer ligated to each bead and a single position of one tag.

The automated microscope used for polony sequencing includes a number of add-on components both for imaging (e.g., motorized stage, piezo objective positioner, illumination wheels) and for fluidics (e.g., flow cell assembly, autosampler, digital I/O modules). Complete details are beyond the scope of this unit. All major components are listed in Table 7.8.1, and a discussion is provided in Critical Parameters and Troubleshooting. More detailed information on assembly (including fittings, tubing, and more) can be found at <http://arep.med.harvard.edu/Polonator>.

Strip fluorescent complexes from the beads

9. Prepare stripping reaction mix by combining:

300 μl TE buffer, pH 8.0
6 μl USER enzyme.

Stripping is performed by reacting the array twice with the stripping solution, hence the volume is double that of a standard reaction. This can be adjusted according to the specific performance observed. If stripping is observed to be complete after one round of reaction and heating, the second stripping can be eliminated.

10. Add wash 1 and the stripping mix to the appropriate wells of the autosampler. Perform stripping protocol as follows:

incubate at 37°C for 5 min
incubate at 56°C for 1 min
wash
incubate at 37°C for 5 min
wash.

The autosampler software for stripping implements this protocol by default.

Query next position

11. Repeat steps 4 to 8 using a different combination of either anchor primer or fluorescent nonamer or both for up to 26 cycles, stripping the fluorescent complexes as in steps 9 and 10 between sequencing cycles.

The read length limit of T4 DNA ligase is 6 or 7 bp from the ligation junction, for a total of 13 bp per tag.

TITRATION OF TEMPLATE FOR CLONAL AMPLIFICATION BY ePCR

Before performing emulsion PCR on a new sample for the first time, the appropriate amount of template must be determined empirically. Since emulsion PCR generates clonally amplified beads by a limiting dilution of template, one can be sure most beads are clonal by finding the template concentration at which approximately 15% to 20% of beads bear an amplicon. Generally, the correct amount of template is somewhere near 1 fmol per reaction. Sample four different concentrations and, if necessary, interpolate to determine the final amount. For example, given that the concentration of the library material is known, amounts of 5 fmol, 1 fmol, 0.2 fmol, and 0.05 fmol per reaction should be tried. Somewhere in this range, a linear increase in amplified beads will be observed with a linear increase in template.

After amplification of the four template samples, bead arrays are cast on microscope slides instead of coverslips (see Basic Protocol 4) for ease of handling. Amplified beads are identified by hybridizing a fluorescently labeled probe complementary to a sequence present in the central (T30) sequence. The percent of amplified beads can then be determined by fluorescence microscopy.

Additional Materials (also see Basic Protocols 2 and 4)

Fluorescently labeled probes:

100 μ M T30-P2-Cy5-A: 5'-Cy5-AGUUGGACGUACGGCC-3'

100 μ M T30-P2-Cy5-B: 5'-Cy5-AGUCGGAGGUCAAGGC-3'

Heat block or slide thermal cycler

Microscope for bright-field and fluorescence microscopy, with CCD camera and filter set for Cy5

Amplify template dilutions

1. Prepare four emulsion PCR reactions as in Basic Protocol 2, using four different amounts of template DNA in the aqueous phase (step 8). Scale down each reaction twelve-fold, so that each template amount is prepared in a single cryogenic vial (step 9) and amplified in a single eight-tube strip (step 14).

This will result in four strips of beads, one per template amount tested. Be sure to scale down the amount of DNA used because each reaction is one-twelfth the size of a standard emulsion PCR reaction.

2. When recovering the beads from the emulsion, be sure to not combine the four strips as in step 23.

The result will be 4 tubes of beads.

3. Resuspend each tube in 6.5 μ l TE buffer, pH 8.0, and proceed to labeling of amplicons without performing enrichment.

Cast bead arrays

4. Cast each sample as a separate bead array on a Teflon-coated microscope slide. Use the same procedure as in Basic Protocol 4, but treat the microscope slide with Bind Silane instead of the coverslip, and invert the stack during polymerization so that the beads are immobilized next to the coverslip instead of the slide.

Hybridize fluorescent probe

5. Prepare the hybridization mixture:

100 μ l of 6 \times SSPE with 0.01% Triton X-100

1.0 μ l of 100 μ M T30-P2-Cy5-A (5'-Cy5-AGUUGGACGUACGGCC-3')

1.0 μ l of 100 μ M T30-P2-Cy5-B (5'-Cy5-AGUCGGAGGUCAAGGC-3')

6. Dry the Teflon surface of the slide with a Kimwipe, being careful to not touch the gel.
7. Pipet the hybridization mixture onto the gel.
The mixture will stay contained on top of the gel if the slide was dried properly.
8. Place the slide face up on a heat block or slide thermal cycler and incubate at 56°C for 5 min.
9. Wash for 5 min in fresh wash 1 to remove free fluorescent probe.

Identify amplified beads

10. Place an array under a fluorescence microscope and acquire an image under transmitted bright-field illumination.

Magnification of 20× is sufficient for the pixel size of most CCD cameras. Long working distance optics with relatively low NA are sufficient when imaging bead arrays at low density (~20,000 beads per field of view). When higher densities are desired (~150,000 to 200,000 per field of view) high-NA dry optics should be used.

Depending on the particular optics used, the beads will appear as black circles or as white points surrounded by dark halos.

11. Acquire a fluorescence image at the same position using appropriate excitation and emission filters for Cy5.
12. Superimpose the two images in false color and determine the percentage of beads that are labeled.
13. Calculate the amount of library material to use in each ePCR based on the percentage of beads that bear labeled amplicons.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Bind and wash buffer

5 mM Tris·Cl, pH 7.5 (APPENDIX 2)
0.5 mM EDTA, pH 8.0 (APPENDIX 2)
1.0 M NaCl
Store up to 6 months at room temperature

NXS buffer

10 mM Tris·Cl, pH 7.5 (APPENDIX 2)
1 mM EDTA, pH 8.0 (APPENDIX 2)
100 mM NaCl
1% Triton X-100
1% (w/v) SDS
Mix ingredients thoroughly
Store up to 6 months at room temperature

Span 80, 10% (v/v)

10% (v/v) Span 80 in light mineral oil

Measure ingredients by positive-displacement syringe or pipet. Vortex to mix thoroughly and incubate under vacuum to remove air bubbles. Store up to 1 week at room temperature.

Wash 1

10 mM Tris-Cl, pH 7.5 (APPENDIX 2)
50 mM KCl
2 mM EDTA, pH 8.0 (APPENDIX 2)
0.01% (v/v) Triton X-100
Mix ingredients thoroughly
Store up to 6 months at room temperature

COMMENTARY

Background Information

Since the dideoxy Sanger method (Sanger et al., 1977) was introduced almost 30 years ago, DNA sequencing has become a standard (albeit expensive) tool in the biologist's repertoire. With the list of reference genome sequences growing, attention is shifting toward the study of how a reference genome differs from derivative experimental genomes of interest (e.g., adaptive evolution of bacterial strains, drug resistance/sensitivity). In many cases, to fully enable these studies, the cost per quality base of DNA sequence must be lower than that obtained with state-of-the-art Sanger sequencing.

Polony sequencing aims to address this need by leveraging highly multiplex processes during both sample preparation and sequencing itself (Shendure et al., 2005). This allows an effective decrease in reagent volumes per reaction from the microliter scale to the femtoliter scale, while also dramatically reducing data acquisition time per base. These reductions in time and materials translate to a lower cost per base and, as an added bonus, higher throughput. As a cyclic array method (for a more thorough discussion, see Shendure et al., 2004), sequence is generated base-by-base through successive cycles of ligation and imaging. Each cycle of ligation and imaging sequences a single base in the template. Each 17- to 18-bp genomic tag in the sequencing template yields 13 bp of sequence when queried by T4 DNA ligase (with the central 4 to 5 bp of the tag remaining unsequenced). The result of a sequencing run is one or more million discontinuous reads of 26 bp each. While each is much shorter than a Sanger read, for many applications this length is sufficient.

Polony sequencing derives its name from the sequencing of DNA molecules that are clonally amplified in or on a solid matrix. Each amplified clone represents a polymerase colony or "polony." Polonies can be amplified from template molecules immobilized in a polyacrylamide matrix (Mitra and Church, 1999) or on beads (Diehl et al., 2006). In this

unit, polonies are generated from a genomic paired-tag library on magnetic beads and are then enriched by hybridization to a common sequence. The enriched beads are cast in an array in a polyacrylamide matrix, where they are sequenced.

The focus of this unit is genomic resequencing. By using a reference genome as a scaffold onto which reads are placed and interrogated for differences, the genome in question can be effectively resequenced using much shorter reads than if a reference did not exist. Additionally, paired tags allow for placement of reads too short to otherwise span repetitive regions. All that is required is that a read-pair be unique enough, given its intertag distance distribution, that it places to only one location on the reference genome. Shendure et al. (2005) demonstrated that 90% coverage of the *E. coli* genome is feasible with paired 13-bp reads having an intertag distance distribution of 1 kb \pm 250 bp. In addition to genomic resequencing, polony technology in general has been used for haplotyping (Mitra et al., 2003; Turner et al., 2006; Zhang et al., 2006) and splicing analysis (Zhu et al., 2003).

Critical Parameters and Troubleshooting

Paired-tag library

The key to successful execution of the library protocol is to achieve yields at each step at least as high as indicated in the protocols. In particular, gel purifications, ethanol precipitations, and column purifications must be reproducibly efficient. DNA quantification should be performed as indicated in the protocol, because NanoDrop readings are not reliable in the authors' hands following ethanol precipitation.

The most critical step in the paired-tag library protocol is the circularization of the genomic fragment around the synthetic linker-insert. Shendure et al. (2005) found this to be the rate-limiting step in terms of the number of unique sequencing templates that were

generated in the library construction. This library protocol is inefficient from a DNA mass standpoint because it represents the product of a number of inefficient individual steps. Additionally, the release of a pair of 18-bp tags from each fragment following circularization results in a nominal mass loss of ~96% for 1000-bp fragments (linearly worse for longer fragments). This loss necessitates the hyperbranched rolling-circle amplification performed after circularization.

Emulsion PCR

When performing emulsion PCR, it is critical not to deviate in any way from the protocol provided until it works to the point of producing clonal, strongly amplified beads from stable emulsions. Once reliable, the method can be used as a control in further optimizations. Inconsistent stability from one batch to the next is usually due to either inconsistent measuring of reagents (especially detergents) or using oil phase components (e.g., 10% Span 80) that were not freshly prepared.

Reverse amplification primer (nonbiotinylated) is present at a very high concentration in the reaction. This primer must be HPLC-purified to prevent formation of primer-dimer product on beads (which may also bear library molecule amplicons). Although primer-dimer formation is also a function of sequence, the PR1 sequences yield especially strong ePCR amplicons relative to several other primer pairs.

The interested reader is directed to excellent papers (Dressman et al., 2003; Diehl et al., 2005, 2006; Li et al., 2006) which cover the technique of emulsion PCR on beads in more detail.

Casting a polony bead array

When preparing Bind Silane-treated slides or coverslips, be sure to use Bind Silane which has not reached its expiration date. Use Erie Teflon-masked slides as the gel molds. Their Teflon coating is unusually hydrophobic and uniform in surface flatness, both of which are necessary to keep the gel from leaking out the top of the circular well before polymerization.

Be certain that no bubbles are present in the gel after it has been spread between the slide and the coverslip. A small bubble noticed in the gel after lowering the coverslip onto the slide can be removed by gently lifting the edge of the coverslip slightly with the edge of a razor blade to move the bubble to the edge of the gel and slowly lowering the coverslip back onto the slide. If this process is performed carefully, the gel will not spread outside the Teflon well.

A jig can be used to hold the coverslip in the correct position relative to the Teflon well of the microscope slide. A 0.5-in.-thick block of polyethylene can be machined with a shallow pocket that will constrain movement of both the slide and the coverslip. This ensures that the array always forms in the center of the coverslip, and thus is always properly placed in the center of the flow cell chamber.

Software, hardware, and sequence analysis

To perform polony sequencing using the protocols presented here, repetitive cycles of sequencing biochemistry and imaging are performed until the desired read length is reached (e.g., 26 cycles for 26 bp). Then, fluorescence data must be extracted from the ~50,000 2-MB images generated by the instrument, normalized, and converted to sequence. In the case of genomic resequencing, these short reads must be placed onto (or matched to) a reference genome to determine which positions differ. The process is summarized below.

The polony sequencing instrument is an inverted epifluorescence microscope which has motorized, encoded *x*, *y*, and *z* axes, as well as motorized fluorescence excitation and emission wavelength selection. The motorized features are controlled by a series of C++ binary files (available with source codes at <http://arep.med.harvard.edu/Polonator>). Attached to the microscope is the fluidics/temperature control system, which performs the biochemistry in the flow cell attached to the automated stage. It is controlled by a series of Matlab scripts, also available at <http://arep.med.harvard.edu/Polonator>.

A list of the major components necessary to build a duplicate of the instrument used by the authors is shown in Table 7.8.1; a full parts list (including fittings, tubing, and details for assembly) is available at <http://arep.med.harvard.edu/Polonator>. In building an instrument, the recommendation is to make no substitutions for parts, even when the particular components seem to have similar performance characteristics. Subtle features present in each component listed are in many cases necessary for the system to function as expected. For example, Nikon is the only microscope manufacturer that manufactures a 20× plan apochromatic objective with both a phase contrast ring (necessary for imaging densely packed bead arrays) and a 1.0-mm working distance (necessary for adequate clearance around the flow cell).

Table 7.8.1 Parts List for Automated Microscope Used in Polony Sequencing

Quantity	Part no.	Manufacturer	Description
1	86022-SPR	Chroma	Cy3/Cy5 polychroic filter w/matched individual exciters/emitters
1	41004*	Chroma	Custom TxRed filter set (S572/23x, Q595LP, S630/60m)
2	CFL	Chroma	Empty filter cube for TE2000
1	91002-02	Hamamatsu	Camera, 1000x1000, electron multiplied, 30 fps readout
1	500-H117E1T4	Prior	Stage, motorized encoded <i>x,y</i> for TE2000; 1-mm screw pitch
1	500-H30XY-E	Prior	Controller for <i>x,y</i> stage w/encoder connectors
1	500-CS152V2	Prior	Joystick for manual <i>x,y</i> control
1	LB-LS/OF30	Sutter	Lambda light source, 300 W xenon
1	LLG	Sutter	Liquid light guide for LS, 2 meters
1	LG-N27	Sutter	Adapter to attach light guide to TE2000 (no epi arm)
1	LB10-3	Sutter	Control unit for 3 wheels and 2 shutters
1	LB10-NW1Q	Sutter	10-position wheel for 25-mm filters with smart shutter
1	LB10-NEW	Sutter	10-position wheel for 25-mm filters - setup for emission
1	10-N27-EM	Sutter	Adapter to attach wheel to side port of TE2000
1	IQ25-SA	Sutter	Smart shutter for transmitted light
1	10-N27-EC	Sutter	Adapter to attach transmitted light shutter to Nikon HMX-II
1	O661301	Sutter	Extra xenon bulb, 300 W
1			Pifoc 400- μ m travel piezo positioner w/controller
1	MEA51001	Nikon	TE2000-E2 inverted microscope
1	MEF55010	Nikon	T-HUBC hub controller
1	MEF55000	Nikon	T-RP remote control pad
1	MPF52061	Nikon	Universal power supply, 110-240V
1	MAE15001	Nikon	Lamphouse HMX2
1	MEE59900	Nikon	T-DH dia-illuminator, 100W
1	MAE15002	Nikon	Collector lens for QH100
1	MBF13240	Nikon	Lamp socket F/HMX 100W QI
1	MXA20425	Nikon	FXA-HMX2 adpt f/halogen
1	84125	Nikon	Microphot-FXA L.L. 12V-100W BU
1	91141-IN	Nikon	T-BP R100 optical path prism
1	MEF42252	Nikon	TE2-PS 100W power supply

Neither of these specifications is advertised as important by most vendors, but for this particular application, both are indeed important.

At the start of the instrument run, a C++ binary file is executed on the computer attached to the microscope to determine the proper focal position for each raster location. In this way, during each subsequent cycle of imaging, the microscope can quickly acquire images from all 500 to 700 raster locations without the need to refocus.

At the conclusion of the sequencing run, images from each cycle must be aligned to each other such that bead pixels from one image correspond to the same bead-pixels in all other images from that same raster location. Bright-field images are then thresholded and used to define the image pixels which coincide with beads. The mean intensity of each bead in each image is computed and saved to disk. These fluorescence values are normalized and converted to four-dimensional unit vectors. When plotted in four-dimensional space, the

data for each cycle will naturally form four clusters corresponding to the four base identities (A, C, G, or T). Bases are called by assigning each bead to the base identity of the cluster to which it is nearest by Euclidean distance. The quality score of each call is the Euclidean distance from the bead to the center of its assigned cluster.

To determine which sequenced bases differ from bases in the reference genome, the polony reads must be placed on the reference sequence while allowing for mismatches. The output of this algorithm is the list of input polony reads annotated with the genomic position to which each places, if any. The critical constraint is that a given read only place to one location on the reference genome, such that bases in the experimental genome can be unambiguously assigned. Once a list of placements has been computed, the experimental genome sequence can be easily derived by sorting the reads by location and reporting the call at each location. When more than one base is called at a given location (e.g., from two different reads), quality scores of each raw base call can be used to resolve the ambiguity.

Anticipated Results

The raw data produced by each sequencing run is ~50,000 2-MB images. These are processed automatically by software available at <http://arep.med.harvard.edu/Polonator> to yield several million 26-bp reads, each annotated with quality scores for each raw base. However, the number of reads produced depends on the number of microbeads arrayed on the coverglass and the fraction of those beads that bear useable amplicons.

Time Considerations

Library construction takes ~1 week if long incubations are performed overnight. The protocol can be stopped, if necessary, after any purification step. Titration of template concentration for emulsion PCR takes 2 days. Emulsion PCR takes part of two days. In experienced hands, two plates of emulsion PCR can be prepared, recovered, and enriched in 2 days by one person. The sequencing run takes 3 hours to set up. Each sequencing cycle takes 1.75 hr, for a total of 49 hours if performed continuously.

CHAPTER 8

Mutagenesis of Cloned DNA

INTRODUCTION

Genes and other genetic elements are frequently characterized by correlating specific changes in DNA sequence with effects on function. The classical approach to this problem has been to obtain mutations by selecting for organisms having new properties. The relevant wild-type and mutant genes can then be cloned and subjected to DNA sequence analysis. Although this approach has been and continues to be useful, it suffers from several disadvantages. First, the methods of mutagenesis severely constrain the kinds of mutations that are obtained. Second, since the entire organism is subjected to mutagenesis, mutations occurring in the gene of interest are relatively rare. Third, since mutations are identified by virtue of their phenotype, it is essentially impossible to obtain “mutants” that behave indistinguishably from the wild-type gene; these are particularly valuable for determining which parts of the gene are not important for function.

The advent of recombinant DNA technology has made it possible to reverse the procedure of classical mutagenesis. Mutations are first generated in cloned segments of DNA by using a variety of chemical and enzymatic methods. These methods can produce mutations at an extremely high frequency (approaching 100% in some cases), and essentially all possible mutations can be generated. Once generated, the mutant DNAs are subjected to DNA sequence analysis and then analyzed for the specific function of interest. In this way, mutations can be obtained in a systematic manner *without* regard to their phenotype. The end result is that the functions of a given region of DNA can be investigated in much more detail.

This chapter describes six basic protocols for altering the nucleotide sequence of cloned DNA segments. The first method, oligonucleotide-directed mutagenesis (*UNIT 8.1*), makes it possible to alter the DNA sequence in a defined way. This is accomplished by synthesizing an oligonucleotide whose sequence contains the mutation of interest, hybridizing the oligonucleotide to a template containing the wild-type sequence, and extending the primer with T4 DNA polymerase. The resulting product is a heteroduplex molecule containing a mismatch due to the mutation in the oligonucleotide. The mutation is “fixed” upon repair of the mismatch in *Escherichia coli* cells. This method is extremely valuable for situations in which it is desired to determine the effects of particular changes in the DNA, and it is also useful for introducing restriction sites at specific positions within a given stretch of DNA. However, it is relatively expensive (one oligonucleotide per mutation) and hence is limited to circumstances where one or a few specific mutations are desired.

The second protocol describes a method for generating a large number of mutations within a small region of DNA (*UNIT 8.2A*). It makes use of synthetically derived mixtures of oligonucleotides that are obtained by adding small, defined amounts of “incorrect” precursors at each step of the DNA synthesis. Each oligonucleotide molecule in the mixture thus has a defined probability of being altered from the wild-type sequence. This degenerate oligonucleotide mixture is converted to double-stranded DNA whereupon individual oligonucleotide molecules are isolated by molecular cloning. In principle, mutations occur at the frequency that was programmed into the DNA synthesis, and they occur at random positions throughout the region of interest. The major limitation of this method is the size of the oligonucleotide; thus, it is valuable for mutagenizing regions of DNA as large as 80 bases in length. However, it should be mentioned that larger regions can be mutagenized by using a set of contiguous or overlapping oligonucleotides that cover the region of interest.

The third procedure makes it possible to synthesize any desired gene segment by combining long oligonucleotides (*UNIT 8.2B*). The region of interest is subdivided into pairs of long single-stranded oligonucleotides that can be annealed at their 3' ends. Using methods similar to those described in *UNIT 8.2A* these pairs of oligonucleotides are converted into double-stranded DNA suitable for cloning. The final product, a custom-designed gene, is obtained by correctly assembling the double-stranded oligonucleotides. It is possible to generate desired sequences up to 400 bp in a single step, and longer regions can be obtained by combining the products of individual steps. The ability to synthesize long regions of any desired sequence is extremely valuable. For example, the introduction of restriction sites throughout a region greatly facilitates further analysis, and extensive modification of codons throughout a protein-coding sequence may result in an increased production of the protein. The only disadvantage of this procedure is its relative expense. It is most useful for solving a particular problem or for creating a modified gene that is more amenable for further study.

The fourth method makes it possible to generate many mutations within larger regions of DNA (up to 1 to 3 kb; *UNIT 8.3*). Here, single-stranded DNA containing the region of interest is treated with a variety of chemicals. By using an appropriate oligonucleotide primer, the mutated region is copied and then cloned. The mutation frequency can be set by the severity of the chemical treatment, and essentially all possible base substitutions can be obtained. This method is particularly valuable when mutagenizing regions of DNA that are larger than can be accommodated in a single or a few oligonucleotides (for shorter regions, the second method is preferred). However, since there are many possible mutations in such relatively large regions, this method is less useful for saturating a region with mutations. Instead, it is best suited for obtaining mutations that confer phenotypes of interest.

The fifth protocol, linker scanning (*UNIT 8.4*), describes a method for creating clustered point mutations in a relatively short region (typically 4 to 10 bp) such that a restriction site is located at the site of mutation. By creating and analyzing a series of linker-scanning mutations throughout a region, it is possible to quickly determine which sequences are functionally important. In addition, the presence of a common restriction site in these mutations allows for the generation of precise deletion or duplication mutations. For an initial functional dissection of a region, linker-scanning mutations have several advantages. Unlike deletion mutations, the changes are highly localized and do not alter any spacing relationships. Compared to point mutations, they are more disruptive and many fewer derivatives are necessary to cover the region; however, they are much less appropriate for analyzing the sequence requirements of a genetic element. Linker-scanning mutations are often used for dissecting transcriptional regulatory signals; they are rarely employed for analyzing protein-coding sequences.

The sixth protocol is a version of oligonucleotide-directed mutagenesis that utilizes the polymerase chain reaction. Oligonucleotides containing the desired changes are used as primers for amplification and the resulting products are cloned by standard methods. The specific procedure differs depending on whether or not the introduced changes generate a restriction site. The major advantages of this PCR-based mutagenesis method are technical simplicity, high frequency of incorporating mutations, and the relative lack of constraints regarding location of restriction sites in the DNA of interest. The method is relatively expensive because it requires two oligonucleotides that are specific for each introduced mutation. In addition, at least two other oligonucleotides are necessary for amplification of PCR, but these can be used for many different experiments if the relevant DNA fragments are cloned into a common vector.

Oligonucleotide-Directed Mutagenesis without Phenotypic Selection

UNIT 8.1

**BASIC
PROTOCOL**

A DNA sequence can be specifically altered by synthesizing the desired sequence change within an oligonucleotide, and then converting this into a biologically active circular DNA strand by using the oligonucleotide to prime *in vitro* synthesis on a single-stranded circular template. This protocol uses a DNA template containing a small number of uracil residues in place of thymine, as shown in Figure 8.1.1 (see further commentary on p. 8.1.5). Use of the uracil-containing template allows rapid and efficient recovery of mutants; in principle this same template can be applied to most of the other mutagenesis protocols in use.

Materials

Single-stranded bacteriophage vector with insert
TY medium containing 0.25 µg/ml uridine (UNIT 1.5)
E. coli CJ236 or alternative *dut⁻ ung⁻ F'* strain (Invitrogen and Table 1.4.5)
5× PEG/NaCl solution
TE buffer (APPENDIX 2)
T4 polynucleotide kinase (UNIT 3.10) and 10× kinase buffer (UNIT 3.4)
10 mM ATP (UNIT 3.4)
Mutagenic oligonucleotide primer
100 and 500 mM EDTA, pH 8.0 (APPENDIX 2)
20× SSC (APPENDIX 2)
5× polymerase mix
T4 OR T7 DNA polymerase (*not* Sequenase; see UNIT 3.5)
T4 DNA ligase (measured in Weiss units; UNIT 3.14)

Additional reagents and equipment for phage titering (UNIT 1.11), phenol extraction (UNIT 2.1), ethanol precipitation (UNIT 2.1), agarose gel electrophoresis (UNIT 2.5), preparation and transfection of competent cells (UNIT 1.8), and DNA sequence analysis (UNIT 7.4)

Preparing uracil-containing DNA template

1. With a sterile Pasteur pipet, remove one plaque produced by single-stranded phage containing the DNA of interest and place in 1 ml sterile TY medium in a 1.5-ml microcentrifuge tube.
2. Incubate 5 min at 60°C to kill cells, vortex vigorously to release phage from the agar, then pellet cells and agar with a 2-min spin in microcentrifuge.
3. Place 100 µl of resulting supernatant into 1-liter flask containing 100 ml TY medium supplemented with uridine to 0.25 µg/ml; add 5 ml of a midlog culture of *E. coli* CJ236 (*dut⁻ ung⁻ F'*) (Kunkel et al., 1987).

*These proportions result in a multiplicity of infection of considerably less than one per cell. Thus, essentially all of the input phage infect cells and are "passaged" through the *dut⁻ ung⁻* strain. Since few uracil-lacking phage remain, a single cycle of growth results in a sufficient survival difference (as measured by titers on *ung⁺* and *ung⁻* hosts) to make the DNA suitable for the *in vitro* mutagenesis protocol. Neither the thymidine nor the adenosine supplementation of medium originally described (Kunkel, 1985) is necessary.*

4. Incubate with vigorous shaking at 37°C for 6 to 18 hr.

Good aeration provided by vigorous shaking is important for high-phage titers.

**Mutagenesis of
Cloned DNA**

8.1.1

5. Pellet the cells by centrifugation at $5000 \times g$ for 30 min. The clear supernatant should contain phage at a titer of $\sim 10^{10}$ to 10^{11} pfu/ml.

*The phage yield may vary, depending on the vector and strain used. For example, experience with *E. coli* RZ1032 for growth of M13 derivatives containing amber mutations suggests that phage titers of 2 to 5×10^{10} pfu/ml are not unusual.*

6. Titer the phage on any *E. coli ung*⁻ (e.g., CJ236) versus *ung*⁺ strain (e.g., JM105, JM107, or JM109). Phage containing uracil in the DNA have normal biological activity in the *ung*⁻ host, but >100,000-fold lower survival in the *ung*⁺ host.
7. Precipitate phage by adding 1 vol of 5× PEG/NaCl solution to 4 vol supernatant. Mix and incubate 1 hr at 0°C.
8. Collect precipitated phage by centrifugation at $5000 \times g$ for 15 min. Drain the pellet well, resuspend in 5 ml TE buffer in a 15-ml Corex tube, and vortex vigorously.
9. Place the resuspended phage solution on ice for 1 hr and then centrifuge as above.

This step removes residual cell debris and has proven useful in reducing the level of endogenous low-molecular-weight DNA, which can nonspecifically prime in subsequent in vitro DNA polymerase reactions.

10. Purify the single-stranded phage DNA by phenol extraction and ethanol precipitation as described in UNIT 2.1. Determine the DNA concentration spectrophotometrically at 260 nm ($1 \text{ OD}_{260} = 36 \mu\text{g/ml}$).

Normally, further purification of the DNA is unnecessary in order to achieve high efficiencies of in vitro mutagenesis. If problems related to template purity are encountered or if mutant production approaching 100% is needed, the DNA can be subjected to any standard purification procedure, since the substitution of a small percentage of thymidine residues by deoxyuridine will not affect the physical properties of the DNA.

*In principle, any cloning vector that can be passaged through an *E. coli dut*⁻ *ung*⁻ strain can be used with the uracil selection technique. Once the uracil-containing DNA is prepared, it can be used as a standard template in a variety of in vitro methodologies for altering DNA sequences (Smith, 1986). Presented below is a typical oligonucleotide-directed mutagenesis experiment.*

Primer extension and product analysis

11. To a 1.5-ml microcentrifuge tube add the following:

2 μl 10× T4 polynucleotide kinase buffer
2 μl 10 mM ATP
Mutagenic oligonucleotide (15 to 50 nucleotides long)
H₂O to 20 μl

The amount of oligonucleotide used depends upon the desired molar ratio of oligonucleotide to single-stranded template. Ratios from 2:1 to 10:1 are routine, but in some instances higher ratios may be useful. For primers that are 15 to 20 bases in length, this corresponds to 4 to 30 ng/ μg single-stranded M13 template.

If the oligonucleotide has already been phosphorylated, proceed directly to step 13.

12. Add 2 U of T4 polynucleotide kinase and incubate 60 min at 37°C. Terminate the reaction by adding 3 μl of 100 mM EDTA, and heat to 70°C to denature the enzyme.

Phosphorylation of the oligonucleotide is required for the subsequent ligation step.

13. To the phosphorylated oligo (20 μ l) add the single-stranded circular uracil-containing DNA template (typically 1 μ g in 1 μ l); add 1.25 μ l of 20 \times SSC.
14. Mix thoroughly, spin 5 sec in microcentrifuge, then place tube in 500-ml beaker of water at 70°C. Allow to cool to room temperature. After another 5-sec spin to collect condensation, place tube on ice.

The precise hybridization conditions depend upon the stability of the heteroduplex formed between the mutagenic oligonucleotide and the template DNA. The ability of the oligonucleotide to prime in vitro DNA synthesis efficiently and at the appropriate position under the chosen hybridization conditions can be determined by DNA sequence analysis.

15. To the hybridization mixture add the following:

20 μ l 5 \times polymerase mix
2.5 U T7 or T4 DNA polymerase
2 U T4 DNA ligase
H₂O to 100 μ l

Since the T4 DNA polymerase activity in commercial preparations can vary with source and age of the enzyme, it may be necessary to add more than 2.5 U.

Enzymes are added last. T7 or T4 DNA polymerase is preferred over Klenow fragment because it will not "strand displace" the mutagenic oligonucleotide after synthesis is completed; this permits efficient ligation and expression of the mutation. T7 DNA polymerase (not Sequenase) is ideal for complete synthesis due to its high processivity. With some oligonucleotide template combinations, this enzyme does not work well, in which case 1 U Klenow fragment can be substituted.

16. Mix thoroughly, then incubate 5 min at 0°C, 5 min at room temperature, and 2 hr at 37°C.

The reaction is begun at lower temperatures to polymerize a small number of bases onto the 3' end of the oligonucleotide, thus stabilizing the initial duplex between the template DNA and the mutagenic oligonucleotide primer. However, since T4 DNA polymerase does not utilize long stretches of single-stranded DNA template well at low temperature, synthesis is then completed at 37°C. The use of a high concentration of dNTPs (500 μ M each) serves to optimize DNA synthesis and to reduce the 3'-exonuclease activity of the T4 DNA polymerase.

17. Add 3 μ l of 500 mM EDTA to terminate the reaction.
18. Analyze 20 μ l of the reaction mixture (200 ng of DNA) by agarose gel electrophoresis in a 0.8% agarose gel. For comparison, adjacent lanes should contain the following standards: single-stranded circular viral DNA; double-stranded, closed circular DNA (RFI); and nicked double-stranded circular DNA (RFII).

A successful reaction should convert essentially all the single-stranded template DNA into RFI and RFII DNA. In the absence of strand displacement (e.g., using T4 DNA polymerase), both RFI and RFII products yield mutations at high efficiency.

Transfection and DNA sequence analysis

19. Based upon an estimate from the gel analysis, use 1 to 100 ng of double-stranded DNA product to transfect any desired *ung*⁺ strain of *E. coli* cells.
20. Resulting clones (as phage plaques or colonies) can be selected or, if no phenotype is known, chosen randomly for isolation of pure genetic stocks. These can be analyzed by sequencing the DNA.

REAGENTS AND SOLUTIONS

5× PEG/NaCl solution

15% (wt/vol) polyethylene glycol 8000
2.5 M NaCl

5× polymerase mix

100 mM Tris·Cl, pH 8.0
10 mM dithiothreitol
50 mM MgCl₂
2.5 mM each of dATP, dTTP, dGTP, dCTP
5 mM ATP

Use of highly purified (e.g., by HPLC) dNTPs is critical.

COMMENTARY

Background Information

The basis of this method is use of a DNA template containing a small number of uracil residues in place of thymine (Fig. 8.1.1). The uracil-containing DNA is produced within an *E. coli dut⁻ ung⁻* strain. *Escherichia coli dut⁻* mutants lack the enzyme dUTPase and therefore contain elevated concentrations of dUTP which effectively competes with TTP for incorporation into DNA. *Escherichia coli ung⁻* mutants lack the enzyme uracil *N*-glycosylase which normally removes uracil from DNA. In the combined *dut⁻ ung⁻* mutant, deoxyuridine is incorporated into DNA in place of thymidine and is not removed. Thus, standard vectors containing the sequence to be changed can be grown in a *dut⁻ ung⁻* host to prepare uracil-containing DNA templates for site-directed mutagenesis.

For the in vitro reactions typical of site-directed mutagenesis protocols, uracil-containing DNA templates are indistinguishable from normal templates. Since dUMP in the template has the same coding potential as TMP, the uracil is not mutagenic, either in vivo or in vitro. Furthermore, the presence of uracil in the template is not inhibitory to in vitro DNA synthesis. Thus, this DNA can be used in vitro as a template for the production of a complementary strand that contains the desired DNA sequence alteration, but contains only TMP and no dUMP residues (Fig. 8.1.1).

After completing the in vitro reactions, uracil can be removed from the template strand by the action of uracil *N*-glycosylase. Glycosylase treatment can be carried out with purified enzyme, but it is most easily achieved by introducing the unfractionated products of the in vitro incorporation reaction into wild-type (i.e., *ung⁺*) *E. coli* cells. Treatment with the glycosylase, either in vitro or in vivo, releases uracil,

producing apyrimidinic (AP) sites in the template strand. These AP sites are lethal lesions, presumably because they block DNA synthesis and are sites for incision by AP endonucleases which produce strand breaks.

Thus, the template strand is rendered biologically inactive and the majority of progeny arise from the infective complementary strand which contains the desired alteration (Fig. 8.1.1). The resulting high efficiency of mutant production (typically >50%) allows one to screen for mutants by DNA sequence analysis, thus identifying mutants and confirming the desired alteration in a single step. This feature is particularly advantageous when no selection for the desired mutants is available.

Literature Review

Several variations of in vitro mutagenesis by primer extension that yield mutants with high efficiency have been developed (for review, see Smith, 1986). The procedure described here is the simplest site-directed mutagenesis protocol, but applied to a special uracil-containing template which allows rapid and efficient recovery of mutants (Kunkel, 1985; Kunkel et al., 1986). In principle, this same template can be applied to most of the other protocols in use.

Critical Parameters

Highly efficient mutagenesis depends upon a good template and a successful DNA polymerase reaction. The template should exhibit a strong difference in survival in *ung⁻* versus *ung⁺* hosts. In addition, it should be relatively free of endogenous low-molecular-weight DNA which could prime in vitro DNA synthesis in the absence of added oligonucleotide; such aberrant priming will yield nonmutant clones. A successful in vitro polymerase reac-

tion should convert the oligonucleotide into a fully double-stranded DNA molecule. In the absence of strand displacement of the oligonucleotide (e.g., using T4 DNA polymerase), high efficiency can even be achieved without ligation (Kunkel et al., 1986).

Finally, the oligonucleotide should be of high quality; i.e., purified away from lower molecular weight contaminants that arise from incomplete DNA synthesis. In some cases, especially for oligonucleotides larger than 40 nucleotides, purification by polyacrylamide gel electrophoresis may be necessary (see UNIT 2.7).

Troubleshooting

Incomplete synthesis can result from several factors, including inefficient hybridization of the oligonucleotide primer, inactive (or excess) DNA polymerase, contaminants in the DNA, the polymerase, or the reagents, or a DNA template that contains structures (e.g., hairpin loops) which block polymerization. Such problems must be dealt with on an individual basis, e.g., by varying hybridization conditions, by ensuring the activity of the DNA polymerase, by repurifying the DNA, or by using alternative incubation temperatures or single-stranded DNA binding protein to assist the polymerase in synthesis on unusually difficult templates.

Low biological activity could also result from dNTP contamination by dUTP (e.g., by deamination of dCTP) which, when incorporated in vitro, provides targets for the production of lethal AP sites in the newly synthesized strand containing the desired mutant. For this reason, high-quality dNTP substrates should be used. This eliminates the need for dUTPase pretreatment of the deoxynucleoside triphosphates (dUTPase is not commercially available).

Anticipated Results

With a high-quality template and polymerase reaction, mutants are recovered at 50 to 80%. Thus, direct sequence analysis of random clones to identify the desired mutant(s) is feasible.

Time Considerations

Starting from a single plaque, it should take 1 day to prepare single-stranded template DNA containing uracil residues. Enzyme reactions can be done in 1 day, and reaction products can be introduced into competent *E. coli* cells at the end of that day. Plaques that arise are purified (1 day) and single-stranded DNA ready for DNA sequence analysis is prepared (1 to 2 additional days). DNA sequencing reactions take 1 day, and the results can be seen on the next day. Thus, the entire procedure can take 5 to 7 days. The procedure can be stopped at essentially any step without significant effect on the mutant frequency.

Mutagenesis with Degenerate Oligonucleotides: Creating Numerous Mutations in a Small DNA Sequence

UNIT 8.2A

**BASIC
PROTOCOL**

A collection of mutagenic oligonucleotides is synthesized by including low concentrations of the three non-wild-type precursors at each step of the synthesis. The frequency of mutation is set by choosing the appropriate amounts of non-wild-type precursors at each step of nucleotide addition. The oligonucleotide also contains an 8-nucleotide palindromic sequence at its 3' end that encompasses a restriction endonuclease site. The palindromic sequence allows nonidentical, but related, mutant DNAs to hybridize at their 3' ends, thereby serving as substrates for DNA polymerase. The resulting molecule is fully double-stranded homoduplex DNA. After digestion with the appropriate restriction endonuclease(s), the double-stranded DNA fragments can be readily cloned to generate a collection of single and multiple point mutants. The protocol is divided into four stages: (1) oligonucleotide design (which includes determination of the mutation frequency, the nucleotides to be mutated, and the structure of the 5' and 3' ends) and subsequent purification after synthesis; (2) mutually primed synthesis to convert the single-stranded oligonucleotide to double-stranded homoduplex form; (3) endonuclease cleavage of the homoduplexes and purification of the final product; and (4) cloning of the double-stranded oligonucleotide into suitable vectors and identification of the mutagenic sequence.

UNIT 8.2B describes related methods for synthesizing long gene segments of any desired sequence.

Materials

- 10× *E. coli* DNA polymerase I buffer (UNIT 3.4)
 - 10 mM dNTP mix of 2.5 mM 4dNTP mix (UNIT 3.4)
 - [α -³²P]dNTP (400 to 800 Ci/mmol; see UNIT 3.4)
 - Klenow fragment of *E. coli* DNA polymerase I (UNIT 3.5)
 - 0.5 M EDTA, pH 8.0 (APPENDIX 2)
 - TE buffer, pH 7.5 (APPENDIX 2)
 - 3 M sodium acetate, pH 5.2
 - Buffered phenol (UNIT 2.1)
 - Ethanol
 - Gel elution buffer: 0.5 M ammonium acetate/1 M EDTA (store protected from light up to several months at room temperature)
 - T4 DNA ligase (measured in cohesive-end units; UNIT 3.14)
- Additional reagents and equipment for restriction endonuclease digestion (UNIT 3.1), denaturing polyacrylamide gel electrophoresis (UNIT 7.4), phenol extraction and ethanol precipitation (UNIT 2.1), nondenaturing polyacrylamide gel electrophoresis (UNIT 2.7), transformation of *E. coli* (UNIT 1.8), and DNA sequence analysis (Chapter 7)

Design and synthesis of the degenerate oligonucleotide (see Fig. 8.2.1)

1. The oligonucleotide is designed such that the 3' end contains an 8-nucleotide palindromic sequence encompassing a restriction endonuclease cleavage site. The site can be one that gives cohesive or blunt ends.

The palindromic sequence is necessary for hybridization of two oligonucleotides to generate substrates for DNA polymerase. See critical parameters.

2. If possible, the 5' end of the oligonucleotide should consist of sequences encompassing a restriction endonuclease site.

A 5' restriction site is not crucial, since the polymerase reaction will generate blunt ends

**Mutagenesis of
Cloned DNA**

8.2.1

Supplement 46

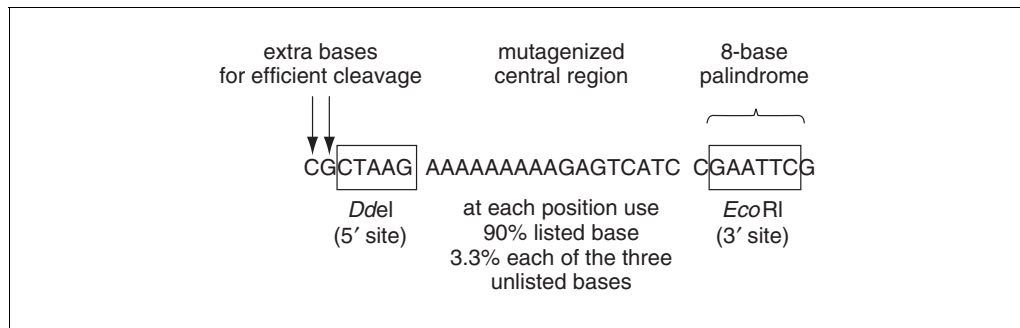

Figure 8.2.1 Design of degenerate oligonucleotide. A 17 base-pair region located between *EcoRI* and *Ddel* sites is mutagenized at a frequency of 10% per position.

suitable for cloning. See critical parameters for further details.

3. The central region contains the mutagenized sequence of interest. Depending on the specific experiment, the length and the mutation frequency of the central region will vary.

The overall limitation on length depends on the efficiency of oligonucleotide synthesis. The phosphite triester method of DNA synthesis as performed by an automated DNA synthesizer can easily produce degenerate oligonucleotides up to at least 100 nucleotides in length.

4. Synthesize the oligonucleotide. At positions where mutations are not desired, such as those comprising the restriction endonuclease cleavage sites, the synthesis is programmed to use homogenous solutions of individual nucleotide precursors. Where mutations are desired, the synthesis is programmed to use defined mixtures of nucleotide precursors.

The frequency of mutation at a given position is determined simply by the relative molarities of the precursors present in the solution. For example, a 10% mutation rate would be achieved with a mixture of 90% wild-type nucleotide and 3.3% each of the three "incorrect" nucleotides. Although newer models of DNA synthesizers are capable of programmed mixing, the most reproducible way to achieve a desired mixture of precursors is to combine appropriate amounts of solid nucleoside phosphoramidites prior to solubilization in anhydrous acetonitrile.

5. Following synthesis, the oligonucleotide is purified by high-performance liquid chromatography and/or electrophoresis in denaturing polyacrylamide gels containing 7 M urea. After purification, the oligonucleotide concentration is adjusted to 1 mg/ml in water (~50 to 100 μ M).

Conversion to double-stranded DNA by mutually primed synthesis (Fig. 8.2.2)

6. Transfer 200 pmol (roughly 1 to 2 μ g) of oligonucleotide to a 500- μ l microcentrifuge tube. Adjust the volume to 7 μ l with water.

The oligonucleotide does not need to be phosphorylated if there will be a restriction site at the 5' end after conversion to double-stranded form. If the 5' end will not contain a restriction site, the oligonucleotide should be phosphorylated by T4 polynucleotide kinase (UNIT 3.10).

7. Incubate the oligonucleotide for 5 min at 70°C; add 1 μ l of 10 \times DNA polymerase I buffer, cool to room temperature, and incubate for at least 60 min.

The second incubation can be done at any temperature that permits hybridization of the 3' end palindromic sequences (typically 23°C).

8. Add 2 μ l of 10 mM 4dNTP mix (2.5 mM each 4dNTP), 5 U Klenow fragment, and 10 μ Ci of any one [α -³²P]dNTP.

A low level of radioactively labeled dNTP is included in the reaction to facilitate purification of the DNA.

Figure 8.2.2 Mutually primed synthesis for cloning degenerate oligonucleotides. A degenerate oligonucleotide (top line; see Fig. 8.2.1.) is self-annealed via the 8-nucleotide palindrome on the 3' end that encompasses the *EcoRI* site, and then treated with the Klenow fragment. The resulting double-stranded DNA contains two oligonucleotide units each derived from an original oligonucleotide molecule (nucleotides that deviate from the "wild-type" sequence are depicted as large letters). Upon cleavage by *EcoRI* and *DdeI*, the double-stranded oligonucleotides are cloned into an appropriate vector.

9. Incubate 1 hr at 23°C. Add 5 more units of Klenow fragment and continue incubation for 2 hr more (or overnight).
10. Stop the reaction with 1 µl of 0.5 M EDTA, adjust the volume to 50 µl with TE buffer, and add sodium acetate to 0.3 M. Extract once with buffered phenol and precipitate the DNA with ethanol. Resuspend the DNA in 20 µl TE buffer.
11. Remove 2 µl for analysis on denaturing polyacrylamide gels (see step 17).
12. In a 30-µl reaction, digest the now double-stranded oligonucleotide with the restriction endonuclease recognizing the outside sites (originally the 5' site of the single-stranded oligonucleotide).

Because of the high concentration of restriction sites, complete digestion will probably require incubation for at least 2 hr with 10 to 40 U of enzyme per original microgram of oligonucleotide. If the oligonucleotide does not contain a 5' restriction site, cleave the DNA with the enzyme recognizing the internal restriction site (originally at the 3' end of the single-stranded oligonucleotide).

13. After digestion, remove 2 µl for analysis on denaturing polyacrylamide gels (see step 17), then extract the remainder of the reaction mixture with buffered phenol, and concentrate the DNA by ethanol precipitation.
14. Purify the double-stranded oligonucleotide mixture by electrophoresis on non-denaturing polyacrylamide gels. To prevent denaturation of the DNA, do not allow the gel to heat up above room temperature.

This step effectively removes the small DNA fragments generated by the restriction digest as well as unreacted, single-stranded oligonucleotides from the desired product. These

contaminants will reduce the ligation efficiency. In general, it is better to perform the gel purification step after cleavage of the outside restriction sites, but prior to cleavage at the internal site (originally the 3' site of the single-stranded oligonucleotide).

15. After electrophoresis, the desired double-stranded molecule is excised as a band from the gel and eluted in gel elution buffer, as described in UNIT 2.7. Resuspend the double-stranded oligonucleotide mixture in 20 μ l TE buffer and store at -20°C .

Since the double-stranded oligonucleotide is a heterogenous mixture of different sequences, the DNAs might not migrate as a sharp band, even though they are of identical length. Electroelution of the double-stranded oligonucleotide is an alternate method of extraction (see UNIT 2.6). Be sure that the molecular weight cutoff of the dialysis bag is below that of the oligonucleotide.

16. Digest the double-stranded oligonucleotide with the enzyme recognizing the internal restriction site (the original 3' site) to produce the final product—a double-stranded, homoduplex version of the oligonucleotide mixture with 5' and 3' ends suitable for ligation into standard vectors. Remove 2 μ l for analysis on denaturing polyacrylamide gels (see step 17). Phenol extract the remainder, ethanol precipitate, and resuspend in 20 μ l TE buffer.

17. Analyze the various 2- μ l aliquots (see steps 11, 13, 16) by electrophoresis on denaturing polyacrylamide gels to confirm that the individual reactions have produced the desired products.

Depending on the initial size of the oligonucleotide, 6 to 12% polyacrylamide gels similar to those used for DNA sequencing are employed. ^{32}P end-labeled oligonucleotides of various lengths are useful as size standards.

Cloning of oligonucleotide

18. Serially dilute the double-stranded oligonucleotide in TE buffer by successive factors of 10 until a 10,000-fold dilution is reached.

It is necessary to empirically determine the optimal oligonucleotide concentration for each cloning experiment. However, the empirical test will often generate a sufficient number of colonies that can be subjected to DNA sequence analysis.

19. Set up a series of ligation reactions, each containing a constant amount of vector and a portion of each dilution of oligonucleotide (UNIT 3.16).

The double-stranded oligonucleotides can be ligated directly into either bacteriophage M13-based vectors (UNIT 1.15) or into plasmid vectors. Due to reliable methods of sequencing double-stranded DNA molecules (UNIT 7.4), it is possible to ligate the oligonucleotide into the vector that will be used to determine directly the phenotypes of the mutants.

20. Introduce the ligation mixtures into an appropriate strain of *E. coli* by standard transformation procedures.

In order to avoid DNAs containing multiple oligonucleotide insertions, it is best to analyze colonies that were generated with the lowest amount of oligonucleotide. If the vector was generated by cleavage with two separate restriction enzymes, the background of colonies without inserted oligonucleotides should be low (UNIT 3.16).

21. Analyze the transformants by restriction enzyme digestion and DNA sequence analysis.

If the background is too high, colonies containing inserted oligonucleotides can be identified by colony filter hybridization using 5'- ^{32}P -labeled oligonucleotide as a probe. The procedure for hybridization using oligonucleotide probes is described in UNIT 6.4.

COMMENTARY

Background Information

The procedure described here is an efficient method for using the products of a single oligonucleotide synthesis to create numerous mutations in a small region of DNA (20 to 80 nucleotides). Mutant oligonucleotides are generated during the organic synthesis reaction by including low concentrations of the three non-wild-type nucleotide precursors with the wild-type precursor at each step of the synthesis (see Fig. 8.2.1). The product of such a DNA synthesis is a degenerate oligonucleotide, i.e., a complex mixture of related molecules, each of which has a defined probability of being altered from the wild-type sequence. The frequencies and types of zero, single, double, and higher order mutations can be set simply by choosing the appropriate amounts of non-wild-type precursors at each step of nucleotide addition during the synthesis.

An important feature of the method is that the single-stranded degenerate oligonucleotide is converted to double-stranded homoduplex molecules that can be cloned directly into standard vectors (see Fig. 8.2.2). The palindromic character of the 3' end of the oligonucleotide allows nonidentical DNAs to hybridize; thus, the oligonucleotides serve as mutual primers for extension by the Klenow fragment of *E. coli* DNA polymerase I. The resulting product is a homoduplex of length $2A + 2N + B$ (where A is the length of the 5' flanking sequence, N is the length of the heterogeneous, mutagenized central region, and B is the length of the 3' palindrome flanking region). By cloning homoduplex DNAs, mismatch repair in vivo is avoided, potential bias against particular mismatched nucleotides is prevented, and mutations located in all possible positions of a sequence can be obtained.

Since the desired rate of mutation is programmed into the oligonucleotide synthesis and hence is predetermined, the expected results from any particular cloning of degenerate oligonucleotides can be calculated simply using the laws of probability. For example, to maximize the number of single and double point mutants within a 15-bp region of DNA, a 10% mutation rate can be employed. This should give, on average, 1.5 nucleotide substitutions per oligonucleotide. Most of the oligonucleotides will have one or two mutations, while some will have none or more than two. The oligonucleotides lacking any mutations

(i.e., the wild-type sequence) provide a necessary control without requiring an extra synthesis.

For many experiments where it is desired to generate a large number of single base pair substitutions within a given region, low mutation rates (1 to 20% per nucleotide) are typically used. For such experiments, eight mixtures of nucleotide precursors are needed during the synthesis. Four of the mixtures are homogeneous solutions of pure nucleotide precursors such as would be used for conventional oligonucleotides. The remaining four mixtures are heterogeneous solutions composed of one major precursor and predetermined amounts of the three "mutagenic" precursors.

Higher mutation frequencies can be used to saturate a particular site with all possible nucleotide changes. In this case, a separate oligonucleotide is synthesized for each single nucleotide that is to be changed to the three possible non-wild-type nucleotides. At the relevant step in the synthesis, an equimolar mixture of the three non-wild-type nucleotide precursors (i.e., 33% each) replaces the wild-type precursor.

Finally, it is sometimes useful to synthesize "custom-designed" degenerate oligonucleotides. For example, when carrying out a low-frequency mutagenesis as described above, it is extremely difficult to obtain all possible mutations. Indeed, although it is relatively easy to obtain about 70% of the possible changes, continued random sequencing will result in many "repeat" mutations before new ones are obtained. In this case, it is better to design a degenerate oligonucleotide that optimizes the chances of obtaining any "missing" mutations of interest. Many, if not all, of the missing mutations can often be obtained with one or a few additional oligonucleotides.

Literature Review

The use of degenerate oligonucleotides for mutagenesis of small regions of DNA was first described by Matteucci and Heyneker (1983). The protocol described here differs from this and alternative procedures basically in the method of cloning the degenerate oligonucleotides. Previous cloning methods have required the synthesis of complementary DNA strands followed by hybridization. Such hybrids necessarily have one or more mismatches which must be repaired in vivo following trans-

formation. The use of mismatch hybrids can reduce overall cloning efficiency and limit the spectrum of single and multiple base changes that occur in a given region of DNA.

The method of mutually primed synthesis described here eliminates cloning bias and positional effects of mismatches because all DNAs are cloned as homoduplex molecules (Hill et al., 1986a,b; Oliphant et al., 1986). In addition, since only a single oligonucleotide synthesis is necessary for obtaining both the wild-type control DNA and a large collection of mutants, significant cost savings can be realized.

Critical Parameters

Since the method relies on efficient organic DNA synthesis, it is essential that the oligonucleotide be synthesized with the freshest possible precursors. This is especially important for the mixed solutions in order to minimize any bias in nucleotide addition. In particular, G residues are sometimes added relatively poorly if the reagents are not fresh. The overall limitation on the length of the region to be mutagenized depends critically on the efficiency of the oligonucleotide synthesis. It is now possible to obtain oligonucleotides that are 100 bases in length, and technological improvements are likely to extend this further. Since 8 to 20 nucleotides at the 5' and 3' ends are constrained by the method, this makes it possible to mutagenize a region as large as 90 bp with a single oligonucleotide. Moreover, larger regions can be mutagenized by using a set of contiguous or overlapping oligonucleotides.

The main critical parameters are the structures at the 5' and 3' ends. The only absolute requirement of the method is that the 3' end be a palindromic sequence that can be cleaved by a restriction endonuclease. The palindrome is necessary for the mutual priming reaction, and the restriction site is necessary for cleavage of the initial product, an oligonucleotide dimer, to oligonucleotide units suitable for cloning. It is preferable if the 5' end also contains a sequence that is recognized by a restriction endonuclease. In the ideal case, cleavage at the 5' site will generate cohesive ends that are different from those generated at the 3' site; this facilitates directional cloning (UNIT 3.16) and makes it possible to perform complex ligation reactions using two different fragments to provide the relevant 5' and 3' joining sites. However, the 5' terminal sequences can be anything; in this

case, the oligonucleotides are cloned via the blunt ends generated by the mutually primed synthesis procedure.

If a restriction site is to be used at both the 5' and 3' end of the oligonucleotide, there is a choice as to which site should be on the different ends. In this case, the restriction site having the highest GC composition should be used at the 3' site in order to facilitate the annealing reaction. For this reason, the palindrome at the 3' end should usually be extended to 8 bases by flanking the site with an additional G or C residue; this has the consequence that the inserted oligonucleotide will contain an extra base between the 3' restriction site and the sequence of interest. Six-base palindromes at the 3' end can suffice for mutually primed synthesis if all residues are GC. However, the reaction is considerably less efficient if other 6-base palindromes are used.

If the 5' end contains a sequence that is to be cleaved with a restriction endonuclease, it is useful to include 1 to 3 extra nucleotides beyond the recognition sequence at the 5' end to facilitate cleavage. In addition, it is advantageous to minimize the length of the palindrome at the 5' end in order to disfavor hybridization that might block complete extension. This can be easily arranged by choosing additional 5'-terminal nucleotides that are not complementary to those immediately flanking the 5' site on the other side.

The choice of vector depends on what is to be done with the mutations once they are obtained. Cloning into standard M13 vectors such as M13mp18 or M13mp19 (UNIT 1.15) has the advantage of easy DNA sequencing; however, the mutated fragments will generally have to be transferred to another molecule for phenotypic analysis. This can be rather cumbersome as it requires preparation of double-stranded M13 DNA (for cloning) in addition to single-stranded DNA (for sequencing). If possible, it is better to clone the degenerate oligonucleotides directly into the molecule that will be used for the phenotypic analysis. By sequencing the double-stranded DNA (UNIT 7.4), only one DNA preparation has to be performed. However, it should be noted that sequencing using the final molecule usually requires a special oligonucleotide primer adjacent to the region of interest.

Anticipated Results

The organic synthesis reaction should easily produce several micrograms of oligonucleo-

tion. After conversion to the double-stranded form, one should have at least 100 ng of DNA. With standard transformation efficiencies, it is possible to generate numerous different mutants and to effectively saturate a small region of DNA with all possible single base changes.

Time Considerations

Typically, oligonucleotides are produced on automated synthesizers that are operated by trained personnel. The actual synthesis and initial purification of the oligonucleotide takes only a few days (waiting for the synthesis facility to make the oligonucleotide can sometimes take a lot longer).

Given the oligonucleotide, conversion to double-stranded form by mutually primed synthesis, the first restriction endonuclease digestion, and nondenaturing gel electrophoresis will require 1 to 2 days. The gel can be run overnight at the end of day 1. Elution of the double-stranded oligonucleotide from the gel, the second restriction digest, and ethanol concentration will require ~1 day. The ligation reaction can be performed overnight at the end of day 2. Transformation and plasmid DNA preparation will require 2 to 3 days. Thus, at the end of 5 days, plasmid or phage DNA can be ready for sequencing to identify the exact

mutation. DNA sequencing will require 1 day with an overnight autoradiographic exposure.

Thus, in 1 week, it is possible to start with a degenerate oligonucleotide and finish with identified mutant DNAs already cloned into vectors suitable for phenotypic analysis.

Gene Synthesis: Assembly of Target Sequences Using Mutually Priming Long Oligonucleotides

BASIC PROTOCOL

The most straightforward way to generate a desired sequence is simply to synthesize it. In the long run, synthesis of appropriately modified versions of a wild-type sequence can also simplify approaches to obtaining many types of mutant versions. This protocol uses pairs of oligonucleotides annealed at a short duplex segment at their 3' ends as both templates and primers (mutually primed synthesis) to generate desired sequences up to 400 bp in a single step (see Fig. 8.2.3).

As with the procedure described in UNIT 8.2A, this protocol is divided into three sections: design of the oligonucleotides, extension by mutually primed synthesis, and cloning of the extension products. The strategy for design of oligonucleotides (steps 1 to 5 in the previous protocol) is discussed in the commentary following this protocol. The procedures for using mutually primed synthesis to extend and clone two partially complementary oligonucleotides are analogous to those described in UNIT 8.2A using a single small oligonucleotide, but have been modified significantly.

Figure 8.2.3 Strategy for constructing a synthetic gene using two pairs of oligonucleotides. Lines represent two pairs of oligonucleotides, corresponding to the four sequences designated by arrows in Figure 8.2.5. Note the region of duplex in each pair which makes mutually primed synthesis possible. A, B, and C represent restriction endonuclease sites needed for cloning the annealed, extended oligonucleotide pairs into the vector. In Figure 8.2.5 sites A, B, and C are *Xba*I, *Hind*III, and *Pst*I, respectively.

Materials

10× T7 DNA polymerase (Sequenase) buffer (UNIT 3.4)
4dNTP mix (2.5 mM each dNTP; UNIT 3.4)
Modified T7 DNA polymerase (Sequenase, U.S. Biochemical; UNIT 3.5)
4 M ammonium acetate
100% and 95% ethanol
TE buffer

Additional reagents and equipment for restriction endonuclease cleavage (UNIT 3.1), phenol extraction and ethanol precipitation (UNIT 2.1), sieving agarose gel electrophoresis (UNIT 2.8), subcloning (UNIT 3.1), and DNA sequencing (UNIT 7.4)

The following steps replace steps 6 to 21 of the basic protocol in UNIT 8.2A.

1. Transfer 1 μg of each of the two oligonucleotides to a microcentrifuge tube, adjust to 17 μl water, and add 2 μl of 10× Sequenase buffer.
2. Heat 5 min at 70°C, followed by 5 min at a temperature appropriate to anneal the oligonucleotides. Remove a 2- μl aliquot for later analysis.

The temperature may be crudely estimated by adding 2°C for each A-T base pair plus 4°C for each G-C base pair in the duplex segment (see UNIT 6.4).

3. Extend the annealed oligonucleotides by adding 2 μl dNTP mix (2.5 mM each dNTP) and 10 U Sequenase. Incubate 30 min at 37°C.

*Because of its processivity, high activity, and relative insensitivity to secondary structure (see UNIT 3.5), Sequenase is particularly appropriate for extensions of longer oligonucleotides, although other DNA polymerases (such as the Klenow fragment of *E. coli* DNA polymerase I) should be adequate. It is not necessary to add ^{32}P -labeled deoxynucleotide triphosphate since there should be enough material to check the single-stranded starting material and the double-stranded product by ethidium bromide staining of a sieving agarose gel (Fig. 8.2.4).*

4. Heat the extended oligonucleotides 10 min to 70°C to inactivate the DNA polymerase. Remove a 2- μl aliquot.
5. Increase the volume to 100 μl with restriction enzyme buffer and 20 to 100 U of restriction enzymes appropriate for cloning. Digest ≥ 2 hr.
6. Phenol extract. Add 100 μl of 4 M ammonium acetate and 400 μl of 100% ethanol, chill to -70°C for 15 min, and spin 5 min in a microcentrifuge. Redissolve pellet in 100 μl TE buffer, add 100 μl of 4 M ammonium acetate and 400 μl of 100% ethanol, chill, and spin again. Rinse pellet with 95% ethanol and dry. Resuspend in 20 μl TE buffer. Remove 2 μl for analysis.

This ammonium acetate differential precipitation is only appropriate if the extended product is larger than approximately 50 bp (see UNIT 2.1). Shorter extended duplexes can be purified by electrophoresis on nondenaturing polyacrylamide gels (UNIT 2.7) or used directly for cloning after recovery using two ethanol precipitations from 0.3 M sodium acetate (UNIT 2.1).

Figure 8.2.4 Sieving agarose gel electrophoresis of starting oligonucleotides and extended, restriction endonuclease-digested product. The oligonucleotides used are 80 nucleotides long, with a 20-bp duplex for self-priming, and the digested product is 135 bp. The sizes of the MW marker (bp) are indicated. **Lanes 1 and 2**, single-stranded oligonucleotides; **lane 3**, annealed oligonucleotides; **lane 4**, extended oligonucleotides; **lane 5**, restriction enzyme-digested extended oligonucleotides; **lane 6**, molecular weight marker.

7. Check the starting material, the extended product, and the digested product by electrophoresis on sieving agarose (see Fig. 8.2.4).

The extended, digested material should give a sharp band of the expected molecular weight.

8. Estimate the amount of extended oligonucleotide present from the analytical gel and subclone using desired vector (see UNIT 3.16 for discussion of subcloning).

Target sequences of 300 to 400 nucleotides are conveniently cloned in three fragment ligations containing two extended, digested target oligonucleotides (see UNIT 3.16, Example 3.16.2). In this case it is important to use equal concentrations of each double-stranded fragment.

9. Sequence several appropriate subclones.

See UNIT 7.4 for a protocol for direct sequencing of minipreps of double-stranded plasmids.

COMMENTARY

Background Information

The strategy for large synthetic projects used here is diagramed in Figure 8.2.3. Overall, this approach is simpler and substantially less expensive than most previous approaches (e.g., Wosnick et al., 1987)—which have relied on annealing relatively large numbers of shorter oligonucleotides—and treatment with DNA ligase to generate the desired fragment. The use of pairs of relatively long oligonucleotides (>100 nucleotides) for mutually primed synthesis minimizes the number of base pairs synthesized chemically, thus minimizing cost. The simple priming reaction is easier to set up and control than the multioligonucleotide annealing reaction. In general, it is also more convenient to synthesize and purify two relatively long oligonucleotides than a larger number of shorter ones. A somewhat similar strategy using single, self-priming long oligonucleotides has recently been described. (Uhlmann, 1988).

It is difficult to describe an average synthesis project, since essentially any sequence could be a target for such an approach. The strategy described here is appropriate for synthesis of *cis*-acting regulatory elements such as enhancers, promoters, and origins of DNA replication. However, it is useful to discuss in some detail the strategy for one relatively common, simple problem: synthesis of the coding region for a protein of modest size. The example described here is the synthesis of a modified version of the coding region for the *E. coli trp* repressor appropriate for further mutagenesis and for expression in mammalian cells. Although this example deals with a wild-type

sequence, any desired amino acid changes could obviously be included, and mutagenesis of a particular region could be carried out using partially degenerate oligonucleotides, as described in the basic protocol.

Generating the target sequence

The synthetic version of the coding region of the wild-type *E. coli trp* repressor is diagramed in Figure 8.2.5. Briefly, two types of changes were incorporated into the synthetic version. (1) A number of changes were introduced to facilitate expression in mammalian cells, including extensive alteration in the area of the initiator AUG to conform to appropriate rules for translation initiation (Kozak, 1987), and alteration of several codons poorly represented in mammalian coding sequences to more commonly used forms (Aota et al., 1988). (2) Restriction endonuclease sites convenient for cloning were placed at the 5' ends of the oligonucleotides, and a number of changes that generated useful new restriction enzyme sites but did not affect amino acid sequence were included. The newly added sites were chosen to facilitate both analysis of primary subclones of the oligonucleotides and future mutagenesis. Since not all cloned oligonucleotides end up with precisely the desired sequence, such additional sites also allow assembly of secondary constructs with the desired sequence from various mutant primary isolates, and are a potentially useful aspect of any large synthesis strategy.

Identification of potential sites for nucleotide sequence changes that generate restric-

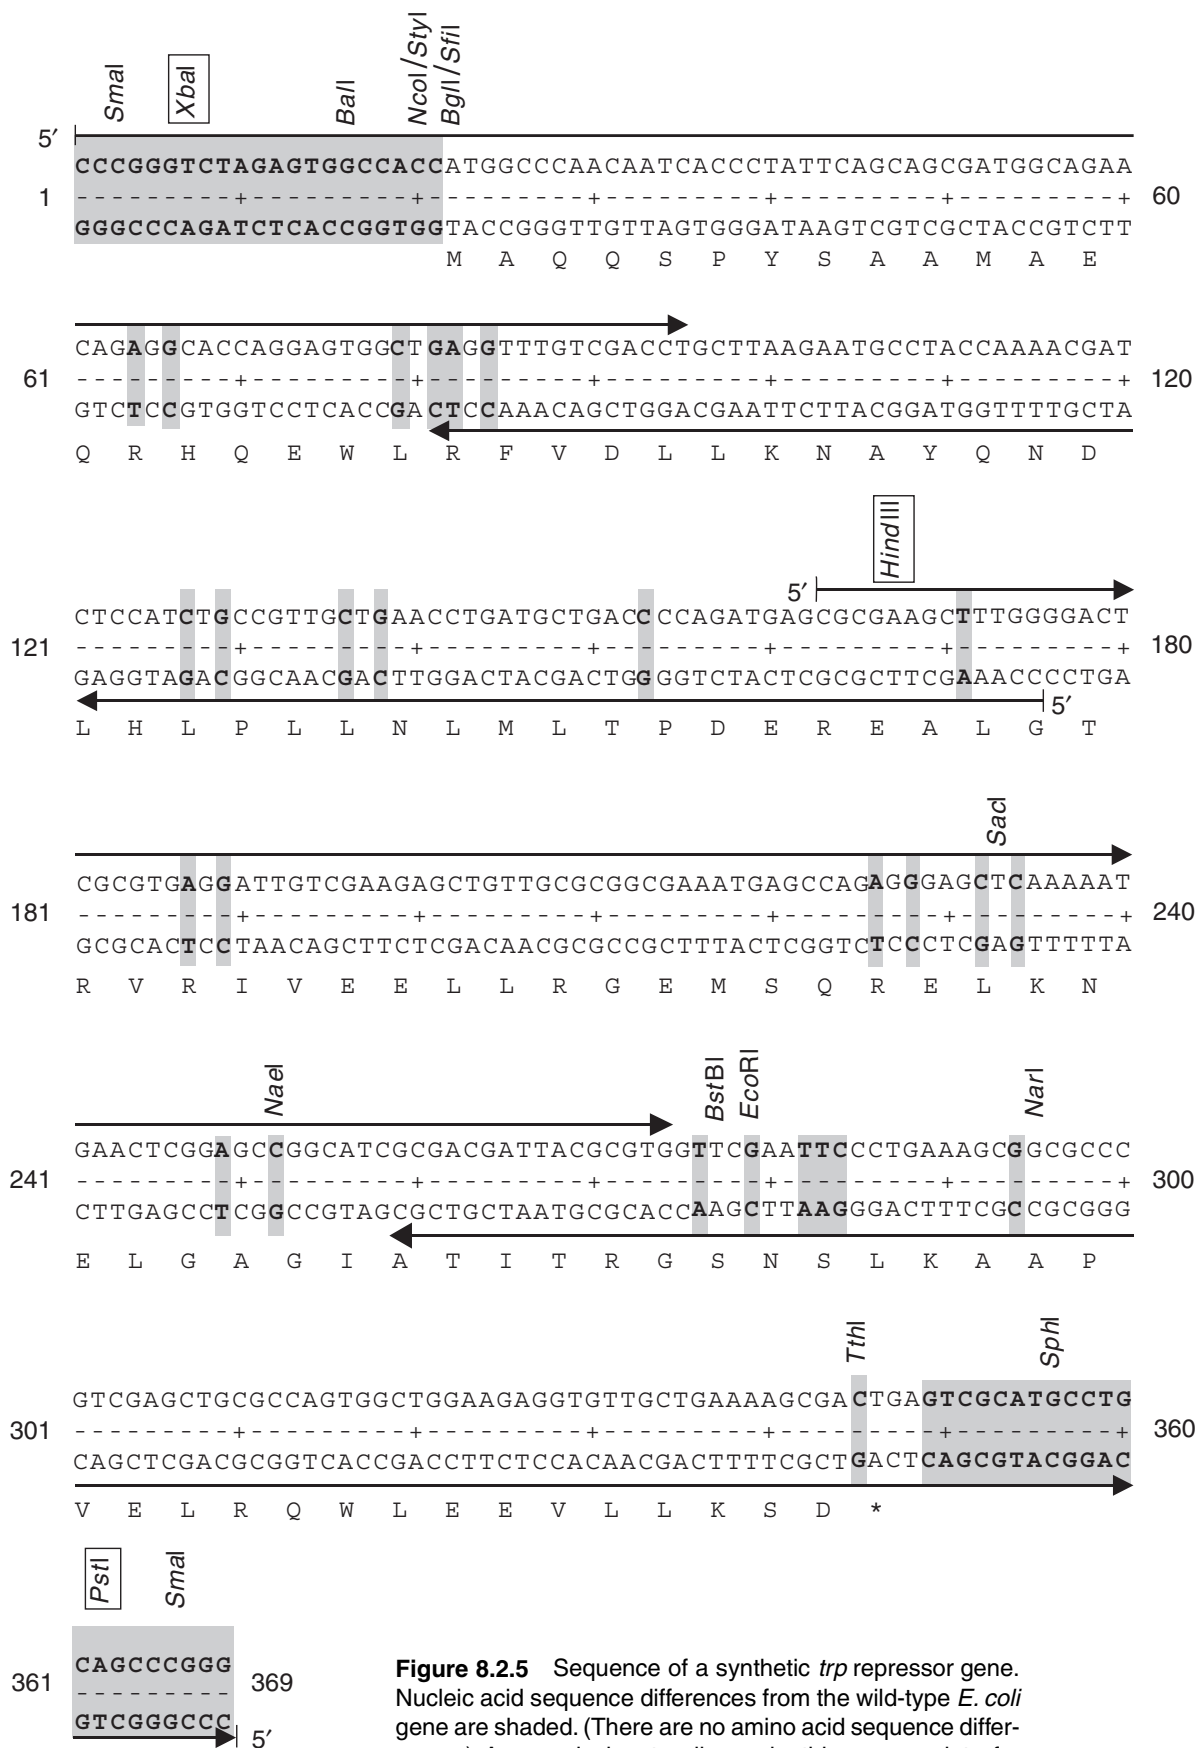

Figure 8.2.5 Sequence of a synthetic *trp* repressor gene. Nucleic acid sequence differences from the wild-type *E. coli* gene are shaded. (There are no amino acid sequence differences.) Arrows designate oligonucleotides appropriate for synthesis. Several newly introduced restriction enzyme sites are indicated; sites used for cloning are boxed.

tion sites but do not alter amino acid sequence is greatly aided by programs specifically designed for this purpose, such as MAP (using the option /SIL) from the University of Wisconsin computer group (see Devereaux et al., 1984). It is worth noting that the opposite strategy—removal of restriction sites without changing coding regions—is quite straightforward and often useful.

Dividing the target sequence into synthetic segments

As indicated by arrows in Figure 8.2.5, two pairs of oligonucleotides (2 of 95 nucleotides and 2 of 111) were chosen, based on the strategy diagrammed in Figure 8.2.3, to cover the 369 bp of the desired fragment. The two pairs include a 15- or 16-bp duplex segment for mutually primed synthesis. This length allows rapid and efficient annealing at convenient temperatures and the resulting duplex is stable during the extension reaction. Additional residues were added beyond sites used for cloning to allow efficient enzyme cleavage.

This example describes a strategy for synthesis of a 369-bp fragment in one step by cloning two pairs of extended oligonucleotides at once. While the use of a three-fragment ligation lowers efficiency of subcloning somewhat, it should not create difficulties if the fragments have heterologous ends (subcloning strategies are discussed in *UNIT 3.16*). For longer target sequences, even more complex ligations could be imagined. However, longer synthetic segments may be substantially less convenient to sequence than several shorter subclones, and are more likely to contain undesired mutations necessitating reconstruction of the desired sequence from individual primary clones. Although other strategies are certainly possible, it may be simpler to divide larger projects into segments of 300 to 400 base pairs, which can then be assembled in secondary ligations. Thus, the 1600-bp coding region of an approximately 50-kD protein might be synthesized as four such segments and assembled by sequentially combining 400- and 800-bp fragments. Of course, careful choice of restriction sites and vectors is particularly important in such projects.

Critical Parameters

Clearly, it is essential to use high-quality oligonucleotides and deoxynucleotide triphos-

phates. The oligonucleotides must be purified away from contaminating shorter chains and unwanted byproducts of synthesis by gel electrophoresis (*UNIT 2.12*) or HPLC (*UNITS 10.12-10.14*).

As described in the example, a ~15-bp duplex is a convenient length for mutual priming. In general, longer sequences are not necessary, and duplexes <10 base pairs should be avoided to ensure stability, particularly if they are A·T rich. A potentially important design problem not encountered in the example described here concerns secondary structures that might interfere with the mutually primed synthesis. In particular, to avoid undesirable extension products, the 3' ends of the oligonucleotides should be designed so they are not self-complementary and do not form stable duplexes with internal sequences. Large, stable internal hairpins could also inhibit extension and, if possible, should be avoided.

Judicious choice of restriction sites can greatly ease analysis of primary clones and their assembly into larger target sequences. Particularly for larger sequences, it may be necessary not only to add desired sites but also to remove undesirable sites by alteration of third positions of codons. Mutations are commonly observed using any synthetic approach, and it is essential to sequence the primary subclones carefully. Including appropriate restriction sites can facilitate reassembly of the desired sequence, from combinations of mutant primary clones.

At various stages of the project, it may be necessary to manually enter rather long sequences into the computer and/or the synthesizer. Thus, there is a realistic possibility of human error in getting the right sequence from design to clone, and sequences must be checked carefully.

Troubleshooting

The main problems likely to be encountered with this strategy are lack of extension of the oligonucleotides and high mutation frequencies. In both cases, low-quality oligonucleotides are the most likely cause. It is essential to purify the oligonucleotides before use, but experience indicates that even gel-purified oligonucleotides produced by syntheses of relatively poor yield do not extend reliably.

Other reasons for failure to extend the oligonucleotides include unanticipated secondary structures or problems with deoxynucleotide triphosphates or DNA polymerase.

As rather large quantities of oligonucleotides are used, one should be sure to include sufficient amounts of triphosphates.

Anticipated Results

The mutually primed synthesis approach should generate a large amount of double-stranded, extended oligonucleotide, and it should be straightforward to use it to generate a large number of primary subclones. Depending on the quality of the oligonucleotides, it should be feasible to obtain desired target sequences of ~400 bp in one step. With judicious choice of restriction sites for cloning, it is possible to start with a number of 400-bp segments at once and assemble larger target sequences rapidly.

Time Considerations

It should take 2 to 3 days to generate primary clones from oligonucleotides and another 2 to 3 days to verify their sequence. (In many cases, of course, one may have to wait much longer for the oligonucleotides to be synthesized and purified.) Starting with a number of 400-bp segments at once, and assuming perfect oligonucleotides and triphosphates, it is theoretically possible for a diligent worker to generate the coding region for a large protein (50 kD) in

<2 weeks. More realistically, one might estimate that assembling 700 to 800 bp of desired sequence in 2 weeks is a fair goal.

Random Mutagenesis by PCR

Error-prone PCR (EP-PCR) is the method of choice for introducing random mutations into a defined segment of DNA that is too long to be chemically synthesized as a degenerate sequence. For shorter (<100 bp) DNA segments, the most powerful method is to chemically synthesize the sequence with a low degree of nucleotide degeneracy (UNIT 8.2A). This method, however, is too expensive and time-consuming to be used for mutagenizing long stretches of DNA. Using EP-PCR, the 5' and 3' boundaries of the mutated region may be defined by the choice of PCR primers. Accordingly, it is possible to mutagenize an entire gene or merely a segment of a gene. The average number of mutations per DNA fragment can be controlled as a function of the number of EP-PCR doublings performed.

The EP-PCR technique described here is based on the protocol of Cadwell and Joyce (1992). The Basic Protocol is for a 400-bp sequence; the Alternate Protocol is for a library. EP-PCR takes advantage of the inherently low fidelity of *Taq* DNA polymerase, which may be further decreased by the addition of Mn^{2+} , increasing the Mg^{2+} concentration, and using unequal dNTP concentrations.

STRATEGIC PLANNING

After choosing a region of DNA to randomly mutagenize, one must decide on the desired level of mutagenesis that is best suited to the project. If the mutation rate is too low, it may not be possible to find the potentially rare variants of interest. If the mutation rate is too high, nearly all of the resulting library molecules will carry multiple mutations and may therefore be inactive. The desired extent of mutation depends on the type of activity one is attempting to generate and the number of library members that can be screened. For example, if one is attempting to generate an activity that may require multiple mutations, such as a novel binding or catalytic activity, then it may be necessary to generate molecules with several mutations per template. In this case it would also be important to have a screening or selection protocol that would allow for the evaluation of a large number of variants. On the other hand, if one is looking for mutations causing loss of protein function or decrease in thermal stability, for example, then 1 to 2 mutations per template may be ideal. In this case it may be sufficient to screen a smaller number of

Table 8.3.1 Average Number of Mutations per DNA Template as a Function of Template Length and Number of EP-PCR Doublings

EP-PCR doublings	Mutations per nucleotide position	Template length				
		100 bp	200 bp	400 bp	800 bp	1600 bp
5	0.0033	0.33	0.66	1.3	2.6	5.3
10	0.0066	0.66	1.3	2.6	5.3	11
20	0.013	1.3	2.6	5.3	11	21
30	0.020	2.0	4.0	7.9	16	32
50	0.033	3.3	6.6	13	26	53

variants. A reasonable approach in many instances is to generate a library such that a few unmutagenized molecules will be present in the collection of screened clones.

The average number of mutations per template increases as a function of the number of doublings in the EP-PCR reaction (Table 8.3.1). It should be noted that it is the number of doublings that is the determining factor, rather than the number of EP-PCR cycles. Each cycle of EP-PCR generally increases the amount of DNA by a factor of 1.7 to 1.9 until the DNA concentration reaches a plateau and then stops increasing altogether. The point at which this plateau occurs depends on the template and primer lengths and sequences, but is generally in the range of 5 to 50 ng/μl. It is not advisable to continue thermal cycles beyond the plateau point.

Prior to performing the actual EP-PCR reaction, it is important to run a pilot reaction to determine the amplification efficiency under the EP-PCR reaction conditions. This should be evaluated for two reasons. First, if the amplification per cycle is too low (<1.7-fold increase in product DNA concentration per cycle), DNA fragments that contain one or both of the primer-binding sites, but are shorter than the desired product, may have a strong selective advantage for amplification. These shorter fragments are produced by mispriming during normal or error-prone PCR. After several cycles, these shorter sequences may “take over” the EP-PCR reaction. This can be an especially severe problem when many cycles (>15) are to be performed. Second, the amplification per cycle must be known in order to calculate the number of EP-PCR cycles necessary to achieve the desired number of doublings.

The amount of DNA amplification per EP-PCR cycle can be determined by diluting a known amount of the unmutagenized PCR product, then amplifying it using the EP-PCR protocol and occasionally removing portions of the reaction for quantitation on an ethidium bromide-stained agarose gel (UNIT 2.7). The amplification per cycle should generally be >1.7. The yield per cycle can be optimized by altering the annealing temperature. Also, the extension time should last for at least 3 min, to ensure complete extension. If this does not bring satisfactory results, longer or shorter primers may have to be used. Primer lengths of 20 to 40 nucleotides usually produce acceptable results. Other parameters may also be optimized to improve the amplification, as described in UNIT 15.1 (the Mg²⁺ concentration should not be reduced, however, as this may lead to increased fidelity of DNA synthesis).

Table 8.3.2 Fraction of Nonmutated DNA Templates as a Function of Template Length and Number of EP-PCR Doublings

EP-PCR doublings	Mutations per nucleotide position	Template length				
		100 bp	200 bp	400 bp	800 bp	1600 bp
5	0.0033	0.72	0.52	0.27	0.071	0.0050
10	0.0066	0.52	0.27	0.071	0.0050	2.5 × 10 ⁻⁵
20	0.013	0.26	0.070	0.0049	2.4 × 10 ⁻⁵	5.8 × 10 ⁻¹⁰
30	0.020	0.14	0.018	0.00033	1.1 × 10 ⁻⁷	1.3 × 10 ⁻¹⁴
50	0.033	0.035	0.0012	1.5 × 10 ⁻⁶	2.2 × 10 ⁻¹²	4.8 × 10 ⁻²⁴

Table 8.3.1 outlines the average number of nucleotide substitutions per template as a function of the number of EP-PCR doublings and the length of the template. Table 8.3.2 shows what fraction of the resulting products will be completely free from mutation.

In most cases, the mutagenized DNA of interest will encode a protein. The fraction of mutated amino acids will be higher than the fraction of mutated nucleotides by a factor of ~2.2. This is because a mutation in any of the three positions of a codon may result in an amino acid substitution. If the initial template is a random open reading frame (i.e., equal probability of each nucleotide at each position in each codon), mutation at the first position of a codon will cause an amino acid change 96% of the time; mutation at the second and third positions will cause amino acid changes 100% and 23% of the time, respectively (as calculated using the mutation frequencies in Table 8.3.6; see Anticipated Results).

MUTAGENESIS OF A DNA SEQUENCE

In this protocol, a 400-bp DNA sequence is mutagenized for ten doublings, to achieve a mutation rate of 0.66% per nucleotide position.

Materials

- 100 mM Tris·Cl, pH 8.3 (*APPENDIX 2*)
- 2 M KCl
- 200 mM MgCl₂
- 25 mM dCTP, pH ~7
- 25 mM dTTP, pH ~7
- 5 mM dATP, pH ~7
- 5 mM dGTP, pH ~7
- 100 μM each 5' and 3' PCR primers
- 200 pg/μl DNA template (400 bp in length)
- 25 mM MnCl₂
- 5 U/μl *Taq* DNA polymerase
- 100-μl PCR tubes (Sarstedt)
- Thermal cycler (see *UNIT 15.1*)
- TOPO T/A cloning kit (Invitrogen)
- QIAprep kit (Qiagen)
- Additional reagents and equipment for PCR amplification (*UNIT 15.1*) and agarose gel electrophoresis (*UNIT 2.7*)

1. Make up the following PCR reaction mixture in a 100-μl PCR tube on ice:

- 51 μl water
- 10 μl 100 mM Tris·Cl, pH 8.3 (10 mM final)
- 2.5 μl 2 M KCl (50 mM final)
- 3.5 μl 200 mM MgCl₂ (7 mM final)
- 4 μl 25 mM dCTP (1 mM final)
- 4 μl 25 mM dTTP (1 mM final)
- 4 μl 5 mM dATP (0.2 mM final)
- 4 μl 5 mM dGTP (0.2 mM final)
- 2 μl 100 μM 5' primer (2 μM final)
- 2 μl 100 μM 3' primer (2 μM final)
- 10 μl 200 pg/μl template DNA (20 pg/μl final)
- 2 μl 25 mM MnCl₂ (0.5 mM final)
- 1 μl 5 U/μl *Taq* DNA polymerase (0.05 U/μl final)
- Total volume, 100 μl.

BASIC PROTOCOL

Mutagenesis of Cloned DNA

8.3.3

The MnCl₂ should be added immediately before the thermal cycling is initiated. The Taq DNA polymerase should be added when the thermal cycling reaction has reached the first annealing step.

2. Place the tube in the thermal cycler and perform ~12 PCR cycles (UNIT 15.1), or enough to obtain a 1000-fold (10 doublings) increase in the amount of PCR product relative to the input template.

The cycling conditions will vary depending on the template and primers, but reasonable starting conditions are: 94°C for 1 min (denaturation), 60°C for 1 min (annealing), and 72°C for 3 min (extension).

The annealing temperature should be kept >50°C, if possible, to avoid mispriming, the frequency of which increases at the high divalent cation concentration used for EP-PCR. The 3-min extension time reduces the selective amplification of shorter, undesirable sequences produced by mispriming.

3. Run an ethidium bromide-containing agarose gel to confirm the amount and correct molecular weight of the product (UNIT 2.7).
4. Clone and sequence a sample of the resulting PCR DNA to determine the frequency of mutations in the product using the TOPO T/A cloning kit and the QIAprep kit.

For information on DNA sequencing, see Chapter 7.

To achieve higher levels of mutagenesis, the template in the initial reaction will need to be diluted to a greater extent, and more EP-PCR cycles will need to be performed. Also, if more than ~15 cycles of EP-PCR are to be performed, a fresh aliquot of Taq polymerase should be added after the 15th cycle.

One problem that often occurs when attempting to achieve a large number of doublings is that PCR products that are smaller than the desired one “take over” the PCR reaction. If this happens, one should first make sure that the EP-PCR conditions are optimized, resulting in an increase in DNA product of at least 1.7-fold per cycle. This may require increasing the extension time to over 3 min, especially when the desired product is >1 kb. Another way to avoid conditions that selectively amplify shorter templates is to increase the denaturing time (up to 75 sec). Also, the annealing temperature should be as high as possible to minimize the occurrence of mispriming events. The highest annealing temperature that gives efficient amplification must be determined empirically. UNIT 15.1 describes other parameters that can be varied to optimize the amplification reaction. If these measures still fail to eliminate the problem, it may be necessary to perform a smaller number of cycles (using a higher starting template concentration), and then gel purify the full-length PCR product before continuing with more thermal cycling. In some cases, it may be necessary to perform this gel purification step periodically (e.g., every 8 cycles). One can use agarose gel purification (UNIT 2.7) which is very easy, sensitive, and convenient. However, polyacrylamide gel electrophoresis (PAGE; UNIT 2.7) can accomplish a higher degree of purification.

MUTAGENIZING A LIBRARY OF SEQUENCES

Sometimes it is desirable to mutagenize an entire collection of sequences simultaneously. The Basic Protocol is appropriate in cases where the starting template is a unique sequence, but the following modifications are recommended when the starting template is itself a library.

The Basic Protocol calls for the EP-PCR reaction to be initiated with a very small amount of template, but this amount may be insufficient to preserve the initial library complexity. To avoid complexity loss before and during the amplification process, one can start with a comparatively large template concentration and perform only four EP-PCR cycles, and then transfer ~10% of the resulting material into a fresh EP-PCR reaction. These “serial transfers” are continued until the desired number of doublings is achieved. One additional advantage of this method is that the progress of the EP-PCR reaction can be monitored throughout the entire procedure, a luxury that is not possible using the Basic Protocol.

This protocol will give ~50 EP-PCR doublings and results in mutations in ~3.5% of the nucleotide positions in the DNA template. However, the actual mutagenic rate may vary with conditions and template.

Additional Materials (also see Basic Protocol)

30 ng/μl DNA template (library)

1. Make up the following EP-PCR reaction mixture on ice:

960 μl water
150 μl 100 mM Tris-Cl, pH 8.3 (10 mM final)
37.5 μl 2 M KCl (50 mM final)
52.5 μl 200 mM MgCl₂ (7 mM final)
60 μl 25 mM dCTP (1 mM final)
60 μl 25 mM dTTP (1 mM final)
60 μl 5 mM dATP (0.2 mM final)
60 μl 5 mM dGTP (0.2 mM final)
30 μl 100 μM 5' primer (2 μM final)
30 μl 100 μM 3' primer (2 μM final)
Total volume, 1500 μl.

2. Divide the EP-PCR reaction mixture into 16 labeled tubes suitable for 100 μl PCR reactions (i.e., into 90-μl aliquots).

These may be stored at 4°C for a few hours.

3. Add 7 μl of the 30 ng/μl DNA library to tube 1 to give ~2 ng/μl. Place tube 1 in the thermal cycler; once it has reached the annealing temperature, add the following and mix:

2 μl 25 mM MnCl₂ (0.5 mM final)
1 μl 5 U/μl *Taq* DNA polymerase (0.05 U/μl final).

ALTERNATE PROTOCOL

4. Perform four cycles of EP-PCR amplification (see Basic Protocol, step 2 annotations, for discussion of conditions). During the final extension at 72°C, place tube 2, containing the fresh EP-PCR, mixture into the same PCR block. Before the final extension is completed on tube 1, but ensuring that tube 2 has reached the extension temperature, transfer 10 µl of EP-PCR reaction mixture from tube 1 into tube 2, and then add the following to tube 2 and mix:

2 µl 25 mM MnCl₂ (0.5 mM final)
1 µl 5 U/µl *Taq* DNA polymerase (0.05 U/µl final).

Remove tube 1 from the block and store at 4°C.

The numbers given here for starting DNA template concentration and transfer volume may need to be modified in accordance with results from pilot EP-PCR reactions, which serve to determine the amplification efficiency.

5. Repeat step 4 for the remaining 14 tubes. Analyze the PCR reaction using agarose gel electrophoresis (UNIT 2.7) after every fourth transfer, and quantitate the bands in successive PCR amplifications.

The DNA amplification per EP-PCR cycle should not decrease to below 1.7, even for the fourth cycle. It is also important that the amount of DNA at the end of the four EP-PCR cycles not increase from transfer to transfer. If this does occur, reduce the transfer volume.

Before the entire EP-PCR protocol is attempted, it is important to pilot the EP-PCR conditions to ensure that low-molecular-weight PCR products are not “taking over” the reaction, and that the amplification per cycle is at least 1.7. The optimal PCR amplification conditions may be different from normal PCR amplification performed upon the same library.

This serial transfer approach yields a succession of samples with increasing levels of mutagenesis. If one is uncertain about the optimal level of mutagenesis for a particular application, the samples from different stages of the EP-PCR procedure can be mixed prior to screening or selection.

COMMENTARY

Background Information

The simplest and most versatile method for introducing random point mutations into a DNA sequence is to take advantage of the inherently low fidelity of *Taq* DNA polymerase. This enzyme can misincorporate with a frequency as high as 0.02% per position (Eckert and Kunkel, 1991). By performing exponential amplification through PCR, these errors will accumulate. Leung et al. (1989) showed that the fidelity of copying by *Taq* polymerase can be further decreased by skewing the relative dNTP concentrations, using a high Mg²⁺ concentration, and including Mn²⁺ in the reaction mixture. Cadwell and Joyce (1992) used a similar strategy to obtain an error rate per nucleotide position of about 0.066% per PCR cycle. This protocol, which forms the basis of that described here, has many useful qualities: (1) it is

extremely simple in that it does not require any unusual reagents such as nucleotide analogs; (2) the EP-PCR efficiency is comparable to that for standard PCR conditions; (3) in many instances the desired level of mutagenesis can be obtained in ~1 hr with a single PCR reaction; and (4) a wide spectrum of nucleotide substitutions is generated. Alternative, more complex procedures also exist that utilize multiple parallel EP-PCR reaction conditions with different dNTP ratios, or use nucleotide analogs (Spee et al., 1993; Fromant et al., 1995; Xu et al., 1999). Vartanian et al. (1996) have described a protocol that can result in very high mutagenic levels.

Critical Parameters

The key to success in this technique is to characterize the amplification efficiency of the

Table 8.2.3 Troubleshooting Guide for Random Mutagenesis by PCR

Problem	Possible cause	Solution
No EP-PCR product	EP-PCR conditions need optimizing	Optimize pilot EP-PCR reaction, especially with regard to annealing temperature. Use long extension times (at least 3 min). If this fails, test primers, template, and other reagents under “normal” PCR conditions to ensure that there has not been a primer design or synthesis error, or a degeneration in reagent quality.
Multiple EP-PCR products of incorrect lengths	EP-PCR conditions need optimizing	Optimize pilot EP-PCR reaction, as above. If this fails to solve the problem, periodically gel purify the product of correct length.
Brown precipitate observed in EP-PCR reaction mixture	Manganese salts are precipitating out of solution	Add manganese to EP-PCR reaction mixture just prior to thermal cycling.
Successive transfers contain decreasing amounts of DNA when visualized on an agarose gel	Transfer volume is too small	Increase transfer volume
Successive transfers contain increasing amounts of DNA when visualized on an agarose gel	Transfer volume is too large, possibly because the efficiency of the PCR reaction is increasing as the most easily amplified sequences begin to dominate the mixture	Decrease transfer volume

EP-PCR reaction and confirm that the DNA concentration is increasing by at least 1.7-fold per cycle. Once the amplification efficiency is known, it will be easy to calculate the number of EP-PCR cycles that must be performed in order to achieve the desired level of mutagenesis. These issues are discussed in detail above (see Strategic Planning).

Troubleshooting

Guidelines for troubleshooting experimental difficulties are presented in Table 8.2.3.

Anticipated Results

The degree of mutagenesis achieved is a function of the number of EP-PCR doublings performed, and therefore can be controlled by the investigator. Anticipated levels of mutagenesis at the DNA, and when applicable, the protein level, are described in Tables 8.3.1, 8.3.2, 8.3.3, 8.3.4, and 8.3.5, and discussed above in Strategic Planning. It is important,

however, to verify that the intended degree of mutagenesis has been achieved by sequencing a few of the resulting, cloned DNA molecules.

The EP-PCR protocol produces all types of substitution mutations, but the distribution is highly nonrandom. The results obtained by the authors in one experiment are shown in Table 8.3.6. It should be noted that in the EP-PCR reaction, both top and bottom DNA strands are equally subject to mutagenesis, so mutations from G to A and from C to T, for example, cannot be distinguished from each other; consequently these are combined together in the table.

Time Considerations

The amount of time required to determine the amplification efficiency of the EP-PCR is 3 hr. If necessary, optimizing the conditions to improve the EP-PCR efficiency requires 1 day. Performing the actual EP-PCR and verifying the total number of doublings achieved takes

Table 8.3.4 Average Number of Amino Acid Mutations per Open Reading Frame (ORF) as a Function of ORF Length and Number of EP-PCR Doublings

EP-PCR doublings	Mutations per codon	ORF length				
		100 bp	200 bp	400 bp	800 bp	1600 bp

50	0.076	0.073	0.0053	2.8×10^{-5}	7.9×10^{-10}	6.3×10^{-19}

Table 8.3.6 Observation of Each Type of Substitution in a Collection of 97 Mutations Generated by EP-PCR

Type of mutation	Number times observed
A→T and T→A	34
G→A and C→T	26
A→G and T→C	24
A→C and T→G	6
G→C and C→G	5
G→T and C→A	2

anywhere between 2 hr and 1 day, depending on the number of EP-PCR cycles performed. It may take one extra day if periodic gel purification of full-length EP-PCR product must be performed. Cloning a sample of the EP-PCR product may be carried out in 1 day. DNA minipreps for sequencing may be prepared in 1 day. Sequencing the DNA to determine the level of mutagenesis may require 1 to 5 days, depending on the sequencing facility. Analyzing the sequencing results and calculating the degree of mutagenesis takes 1 day. If the level of mutagenesis is significantly different from what was desired, one may have to repeat the EP-PCR, then resequence and determine the level of mutagenesis once again.

Linker-Scanning Mutagenesis of DNA

Two protocols are described in which clusters of point mutations are introduced throughout a sequence of interest that has been cloned into a plasmid vector. The first protocol uses complementary oligonucleotides and requires a unique restriction site adjacent to the region that is to be mutagenized. A nested series of deletion mutations is first generated in the region. A pair of complementary oligonucleotides are synthesized to fill in the gap in the sequence of interest between the linker at the deletion endpoint and the nearby restriction site (Fig. 8.4.1). The linker sequence actually provides the desired clusters of point mutations as it is moved or “scanned” across the region by its position at the varied endpoints of the deletion mutation series. An alternate protocol makes use of site-directed mutagenesis procedures (UNIT 8.1) to introduce smaller clusters of point mutations throughout the target region.

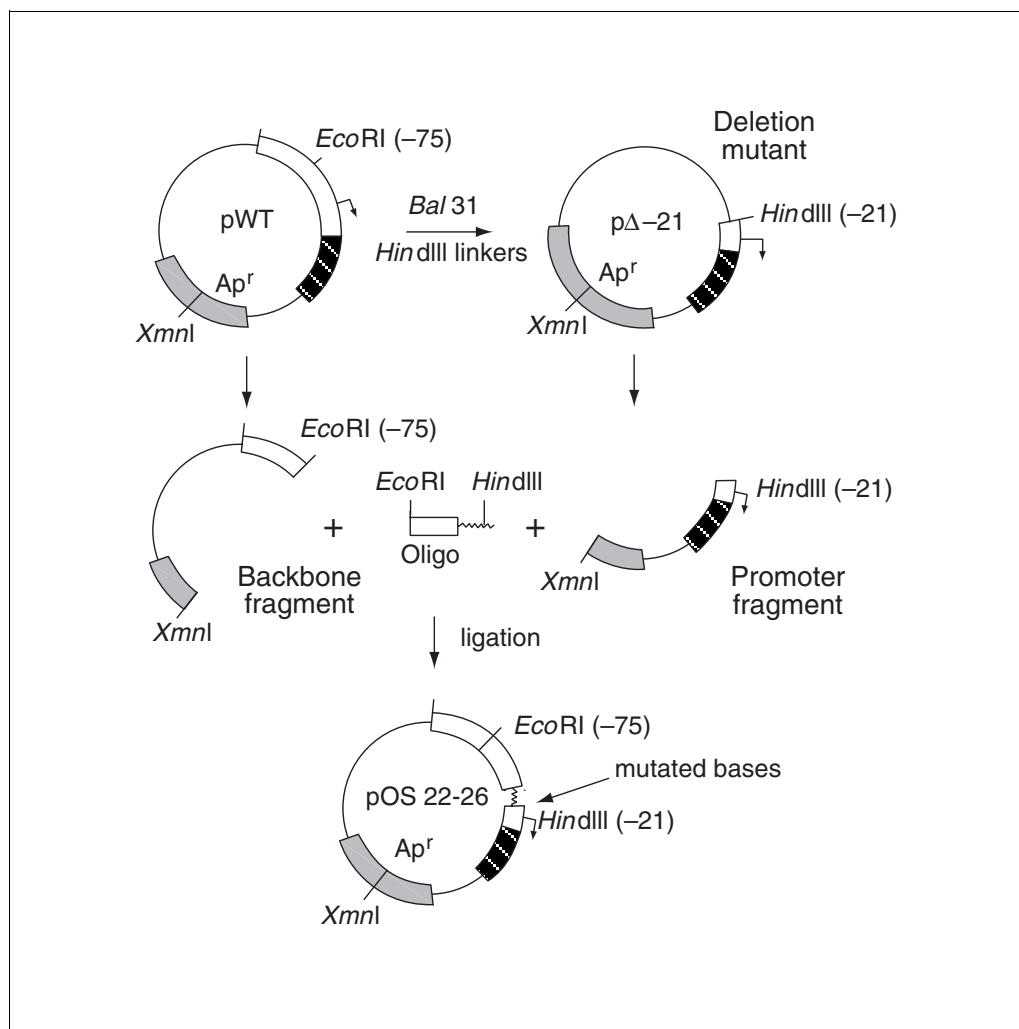

Figure 8.4.1 Assembly of linker-scan mutations using basic protocol. pWT is linearized near the region of interest at a site such as the *Eco*RI site at -75. *Bal* 31 is used to create deletions and *Hind*III linkers are added to the deletion endpoints. The DNA is digested with *Hind*III and *Xmn*I, and then is ligated to the complementary *Xmn*-*Hind*III vector fragment from pWT to form the deletion mutation pΔ -21. The backbone fragment is prepared from pWT by an *Xmn*-*Eco*RI digest and the promoter fragment is prepared from pΔ -21 by a *Hind*III-*Xmn* digest. After isolation, the two fragments are ligated together with the hybridized oligonucleotides to create the linker-scan mutation pOS 22-26. This plasmid is identical to pWT except for the mutated bases at the site of the *Hind*III linker at -21.

LINKER SCANNING USING NESTED DELETIONS AND COMPLEMENTARY OLIGONUCLEOTIDES

This protocol can be used to generate clusters of point mutations throughout a promoter region or throughout any other sequence element involved in replication, splicing, or protein structure. The concept is to make a series of deletion mutations whose nested ends will serve to “move” a linker sequence throughout the region of interest. The deleted sequences are then filled in using synthetic oligonucleotides to regenerate the original sequence at every position except for the bases mutated by the linker (Fig. 8.4.2).

Materials

- High-copy-number plasmid vector (UNIT 1.5)
- Linkers (UNIT 3.16, Example 3.16.6)
- Bal 31 nuclease (UNIT 3.12) or exonuclease III and S1 nuclease (UNITS 3.11 & 3.12, respectively)
- Restriction endonucleases and buffers (UNIT 3.1)
- 0.5 M EDTA, pH 8 (optional; APPENDIX 2)
- 100% ethanol
- Low gelling/melting temperature agarose (UNIT 2.6)
- Competent *E. coli* cells (UNIT 1.8)
- 29:1 acrylamide/bisacrylamide (UNIT 2.7) or sieving agarose (UNIT 2.8)
- Synthetic oligonucleotides for the gene of interest

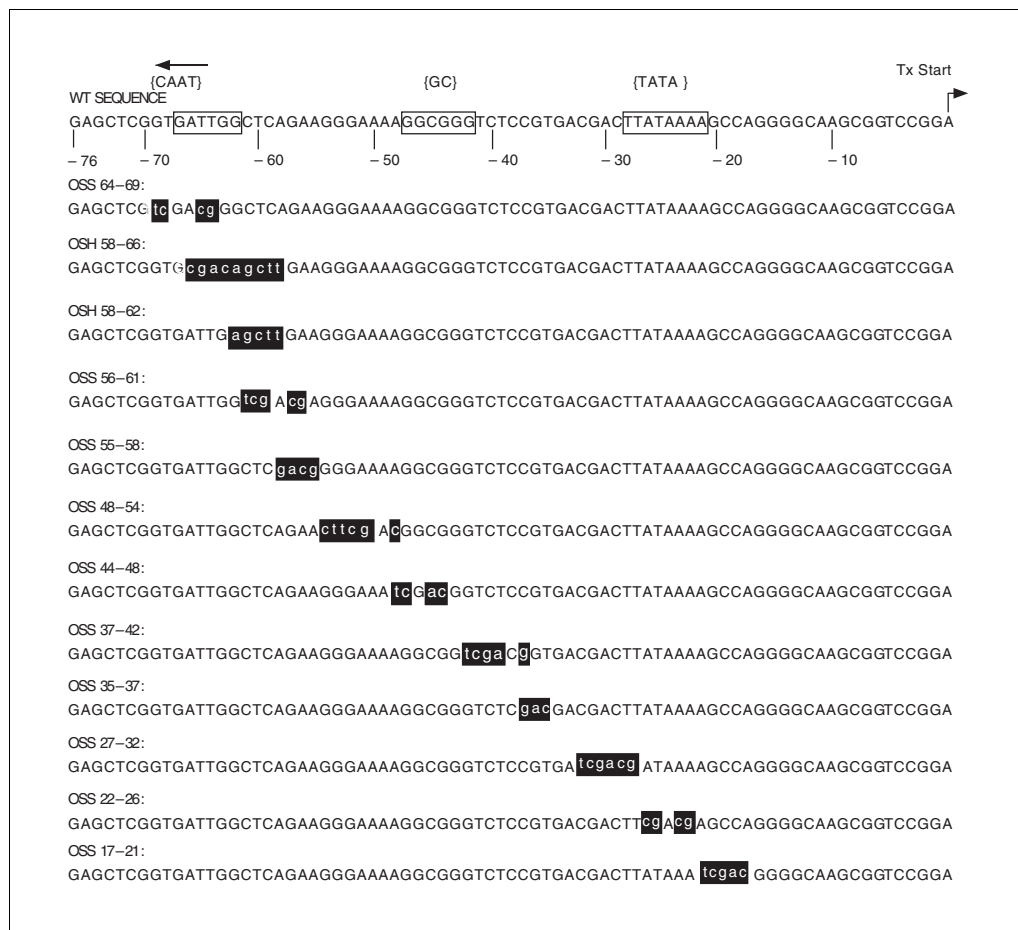

Figure 8.4.2 Linker-scanning mutagenesis of a human *hsp70* gene promoter region (Greene et al., 1987). Wild-type sequence is shown at top. Bases shown in black boxes are those changed by mutagenesis.

TE buffer (*APPENDIX 2*) containing 150 mM NaCl
T4 DNA ligase (measured in cohesive-end units; *UNIT 3.14*)
10× T4 DNA ligase buffer (*UNIT 3.4*)
Selective plates

Additional reagents and equipment for creating nested sets of deletions (*UNIT 7.2*), ethanol precipitation (*UNIT 2.1*), ligating DNA fragments (*UNIT 3.16*), isolating DNA fragments using low gelling/melting temperature agarose (*UNIT 2.6*), preparing and transforming competent *E. coli* cells (*UNIT 1.8*), minipreps of plasmid DNA (*UNIT 1.6*), nondenaturing polyacrylamide gel electrophoresis (*UNIT 2.7*) or sieving agarose gel electrophoresis (*UNIT 2.8*), and DNA sequencing (Chapter 7)

Create a nested set of deletions

1. Generate a nested set of either 5' or 3' deletion mutations in the region of interest in your plasmid. Either *Bal* 31 or *exo* III and S1 nuclease can be used (see *UNIT 7.2*). First, linearize the plasmid with a restriction enzyme for subsequent nuclease digestion; any restriction site that cuts near the sequence of interest (such as the *Eco*RI site at -75 in Fig. 8.4.1) can be used (it is not necessary to use the site defining one end of the insert). For *Bal* 31 digestion, it is necessary to determine the rate of nuclease digestion and adjust conditions (temperature, time of digestion, and amount of nuclease; see *UNIT 3.12*) in trial runs so that the time points taken contain deletion endpoints every six to eight base pairs and span the region to be scanned in order to make a complete set of scan mutations. The extent of nuclease digestion can be monitored by running aliquots of each time point on an agarose gel with appropriate size markers. Stop the digestions by heating to 65°C or by adding EDTA to 50 mM. Precipitate the DNA with 100% ethanol.

You may wish to repair the ends of the DNA as mentioned in UNIT 3.12 to improve subsequent ligation frequencies.

Any vector can be used in cloning the sequence of interest, although a vector such as pUC19 is preferable because of its ease of sequencing and high copy number. See UNIT 7.2 for a full discussion and complete steps for making nested sets of deletions.

2. Ligate a synthetic linker to the ends of the DNA obtained from the appropriate time points (see Example 3.16.6), preferably choosing one denoting a unique restriction site in the sequence of interest but present in the vector. A site in the polylinker is ideal if cloning with pUC19 (*Hind*III in Fig. 8.4.1). Digest with an excess of the restriction enzyme that recognizes the linker in order to leave a cohesive end as well as with another enzyme cutting in the vector sequences—thus yielding fragments with the linker at the deleted end and a vector site at the other.
3. Isolate the desired fragments using low gelling/melting temperature agarose or another method of choice (*UNIT 2.6*), then ligate them to a vector fragment to create intact plasmids containing the deletion mutations (*UNIT 3.16*).
4. Transform competent *E. coli* cells with the ligation mix (*UNIT 1.8*), pick colonies, and prepare minipreps of plasmid DNA (*UNIT 1.6*).
5. Digest the miniprep DNA with appropriate restriction enzymes to yield a small DNA fragment with one terminus at the deletion endpoint. Run the digest on a nondenaturing polyacrylamide gel (*UNIT 2.7*) or sieving agarose gel (*UNIT 2.8*) to determine the fragment size. A small fragment (200 to 300 bp) is necessary to accurately estimate the location of the endpoint of the deletion for each individual mutation.

6. When a satisfactory set of deletions has been obtained that spans the region of interest, sequence each deletion mutation to determine the exact deletion endpoint (Chapter 7).

This is most easily done if the deletion is adjacent to a vector sequence for which an oligonucleotide primer is available for dideoxy sequencing (e.g., the polylinker of pUC19).

Design complementary oligonucleotides

7. Design complementary oligonucleotides to restore the wild-type sequence between the linker present at each deletion endpoint and a nearby restriction site (again, preferably unique to the plasmid) upstream of the region for a 5' deletion series or downstream of the region for a 3' deletion series (*EcoRI* was chosen in Fig. 8.4.1).

*The site must be located so that the oligonucleotides are of a reasonable length, i.e., <100 bases. Remember to include the cohesive ends for both sites in the oligos (*EcoRI* and *HindIII* in Fig. 8.4.1).*

Synthesis of all of the oligonucleotides required to make a complete set of linker-scan mutations can be very expensive. This cost can be reduced almost in half by using mutually primed synthesis (UNIT 8.2; Fig. 8.2.2) to produce the oligonucleotides.

Isolate DNA fragments

8. Make the following fragments for ligation to the oligonucleotides: (a) a fragment spanning the linker site and a convenient site in the plasmid's drug marker ("promoter" fragment; *Hind-Xmn* in Fig. 8.4.1), cut from each deletion mutation; and (b) a fragment spanning the site in the drug marker and the restriction site near the region to be scanned ("backbone" fragment; *Xmn-Eco* in Fig. 8.4.1), cut from the wild-type parental plasmid. Isolate the necessary fragments by one of the methods in UNIT 2.6.

A site in the drug marker is preferred because it provides "forced cloning"—i.e., the site must be regenerated to allow expression of the selective marker.

Hybridize complementary oligonucleotides

9. Resuspend each oligonucleotide strand at ~100 µg/ml in TE buffer containing 150 mM NaCl. Mix equimolar amounts of each strand and heat 10 min at 65°C.
10. Cool slowly to room temperature by placing the tubes at room temperature for 20 min. Check the OD₂₆₀ to determine final concentration. Also, check to be sure that the oligonucleotides have completely hybridized by running aliquots of each complementary strand as well as the hybrid on a 4% sieving agarose gel.

Assemble linker-scan mutations

11. Set up the three-part ligation (Fig. 8.4.1), as exemplified by the following: Mix equimolar amounts of the promoter and backbone fragments with a 50-fold molar excess of the hybridized oligonucleotides relative to the plasmid fragments (UNIT 3.16); use ~400 ng total DNA in 10 µl, for a final DNA concentration of 40 µg/ml. Add 0.4 µl (160 cohesive-end units) T4 DNA ligase and incubate 2 hr at 15°C. If a blunt site is being used at the promoter-backbone fragment junction (as *Xmn* is used in Fig. 8.4.1), add 1 µl (400 U) ligase and incubate an additional 2 hr at 30°C. Dilute 40-fold with TE buffer to a DNA concentration of 1 µg/ml to promote intramolecular ligation in the next step.

Note that during the ligation the only 5' terminal phosphate groups present are on the backbone and promoter fragments. These phosphate groups are essential for covalent linkage of each DNA strand by ligase (see UNIT 3.14).

- The hybridized oligos do not have 5' terminal phosphates. Therefore, each end of the backbone and promoter fragment will be covalently attached to one strand of a double-stranded oligonucleotide. It is necessary to melt the noncovalently bound strand of each oligonucleotide away from the ligated fragments to allow circularization of the plasmid. To do this, heat the diluted ligation reaction to 65°C for 10 min, then cool to room temperature slowly.

This step should result in the hybridization of the two complementary strands that are covalently bound to the plasmid fragments. The net effect is to incorporate one copy of the hybridized oligos into the ligation product, with one nick on each strand. Tandem repeats of the oligo sequence are thus prevented as all noncovalently bound oligos melt away.

- Transform competent *E. coli* cells with 20 to 25 µl of the diluted ligation reaction (UNIT 1.8) and plate on selective media. Pick colonies and prepare minipreps of plasmid DNA to be checked by restriction digests and by DNA sequencing to be sure the final sequence is as desired—i.e., a restoration of the wild-type sequence except for the six bases changed by the linker sequence at the deletion endpoint.

ALTERNATE PROTOCOL

LINKER SCANNING USING OLIGONUCLEOTIDE-DIRECTED MUTAGENESIS

It is also possible to construct a set of linker-scan mutations using the methods of Kunkel (see UNIT 8.1). In this protocol, mutations are introduced into a sequence by annealing a synthetic oligonucleotide containing one or more mismatches to the sequence of interest cloned into a single-stranded M13 vector. This template is grown in an *E. coli dut⁻ ung⁻* strain, which allows the incorporation of uracil into the template strand. The oligo is annealed to the template and extended with T4 DNA polymerase to create a double-stranded heteroduplex. Finally, the heteroduplex is introduced into a wild-type *E. coli* strain which will prevent replication of the template strand due to the presence of apurinic sites (generated where uracil is incorporated), thereby resulting in plaques containing only mutated DNA.

Additional Materials

- M13 template (UNIT 1.15)
- E. coli dut⁻ ung⁻* strain (UNIT 8.1 and Table 1.4.5)
- T4 DNA polymerase (UNIT 3.5)

Additional reagents and equipment for oligonucleotide-directed mutagenesis without phenotypic selection (UNIT 8.1)

- Design a set of oligonucleotides, each of which has several adjacent bases mutated as a group flanked by wild-type sequences that will allow hybridization to the appropriate region of the gene. As the group of adjacent mismatches are “scanned” through the oligo sequences, they will result in a set of exact linker-scan mutations.

This protocol has the major advantage that it does not require an adjacent restriction site or the construction of a nested set of deletion mutations. One difficulty with using this approach to create linker scans is that it is unclear how many adjacent bases can be stably mismatched at one time. Linker scans have been made via this approach with mismatched bases in groups of three (T. Kadesch, personal communication).

A critical issue in designing the oligonucleotides is the length of the mismatched region. Long mismatches (e.g., 8 to 10 bases) will necessitate fewer constructions to fully mutate a given stretch of DNA. However, these mismatches may form less stable hybrids with the template, and thus may be more difficult to construct. In addition, the longer the mismatched region, the greater the possibility of having

one linker-scan mutation disrupting more than one element. In order to identify all of the functional elements of a region, it is necessary to have null mutations interdigitated between mutations that disrupt function. This allows detection of individual functional elements. The larger the mismatched, or linker-scanned, region is, the lower the probability that this result will be obtained.

2. Hybridize the oligonucleotides to the M13 template, extend with T4 DNA polymerase, and transform wild-type *E. coli* as described by Kunkel (UNIT 8.1). Plate and isolate the double-stranded RF DNA from colonies of each transformation.
3. Sequence the DNA purified from the transformants to verify that the desired mutations have been correctly introduced.

COMMENTARY

Background Information

In mapping sequences important for any function, the first step is usually to make deletion mutations to try to find critical sequences. For more detailed analysis, however, this approach suffers from the drawback that the deletion often removes elements important for function and thus can obscure the individual contribution of each sequence element. By putting in clusters of point mutations, elements outside of the clustered mutations are left intact. Use of clustered mutations minimizes potential artifacts caused by creating new sequences at the junction between vector and the deletion endpoint. In addition, linker-scan mutations do not alter the spatial relationships between sequence elements in the region of interest. Although advanced methods are now available to saturate a region with point mutations (see UNIT 8.3), such protocols require a large amount of time and effort, including DNA sequencing. In many cases it may be preferable to locate and analyze important sequence elements by linker scanning before resorting to point mutagenesis of such elements.

Literature Review

The basic protocol is an adaptation of the original linker scanning protocol developed by McKnight and Kingsbury (1982) to locate sequence elements important for transcription of the HSV *tk* gene. Their procedure uses two sets of nested 5' and 3' deletion mutations with linkers at the endpoints. "Matching" deletions are then combined at the linker to create the scan mutations. The problem with their approach is that it is very hard to get perfectly matching deletions, resulting in the insertion or deletion of one or more bases.

The basic protocol presented here uses only one such set of deletions. Oligos are then used to fill in the gap between the nearby restriction

site and the linker at the deletion endpoint, resulting in exact scan mutations—no bases are inserted or deleted. Exact substitutions are also made by the procedure described in the alternate protocol.

The alternate protocol, based on the procedure by Kunkel (UNIT 8.1), has two major advantages. Fewer oligonucleotides are needed, since it is not necessary to synthesize two complementary oligos as with the basic protocol. Also, it is not necessary to have a restriction site adjacent to the region to be mutagenized. It is not yet clear, however, how many adjacent mismatched bases can be tolerated in the Kunkel procedure. Once this parameter has been optimized, the alternate protocol will most probably be more rapid and less expensive than the basic protocol. Finally, the alternate protocol requires special *E. coli* strains, fine-tuning of hybridization and elongation steps, and—because the procedure is only 50% to 80% efficient—somewhat more screening for correctly introduced mutations than is required for the basic protocol.

Critical Parameters

The main requirement for the use of the basic protocol is to have a restriction site in the sequence nearby the region of interest. The site should leave cohesive ends upon digestion and should preferably be unique. However, as long as the site is not duplicated within any one fragment needed for the construction, this does not present a problem because the fragments are prepared in separate digests. In Figure 8.4.1, the *EcoRI* site used to define one end of the backbone fragment is not unique—two other *EcoRI* sites are also present further downstream. Fortunately, these sites are contained in the promoter fragment, which is prepared by an *Xmn-HindIII* digest, and thus do not present a problem in the construction.

Although Figure 8.4.1 depicts a linker-scan mutation with a 5' deletion used in the construction, there is no reason why a 3' deletion cannot be used as well. All that is required is a restriction site nearby but downstream of the region of interest, instead of upstream as for the 5' deletion.

Selection of the linker or of the mismatched bases in the two protocols must be made very carefully. It is possible for a linker sequence to mimic a functional sequence element upon fusion to certain sequences at the deletion endpoint, which could introduce artifacts into an entire set of constructs. A linker should be chosen that does not resemble any known functional element. See also the discussion in the annotation to step 1 of alternate protocol.

The amount of sequence that can be scanned using the basic protocol is limited by the length of oligos that can be synthesized. Very little oligo is required for this protocol, but yields of oligos greater than 100 bases in length are very low and the expense of synthesizing these oligos is very high. Conversely, if an oligo is too short (<6 bases) it will not stably hybridize to its complementary oligo. As long as one strand can "bridge" the two restriction sites on either side of the gap to be filled, the resulting single-stranded gap can be filled in after the ligation reaction with the Klenow fragment of *E. coli* DNA polymerase I (*UNIT 3.5*). The alternate protocol has no such limit, as all the required oligonucleotides differ in sequence but not in length.

Most of the problems that occur in making linker scans with either protocol can be traced to incorrect oligonucleotides. It is best to have the oligos gel-purified and as clean as possible for optimal ligations. Accurate sequencing of both the deletion endpoints and of the final constructs is critical to obtain accurate data.

Anticipated Results

The three-part ligation reaction usually results in 20 to 30 colonies after transforming and plating 5% of the ligation reaction. Even if the resulting linker-scan mutation appears correct

upon restriction digest, it is best to sequence the constructs to be sure the structure is completely accurate. With a well spaced set of deletion mutations, it is possible to change every base of a region in 4- to 6-base groups.

As noted above, the alternate protocol is only 50% to 80% efficient in introducing the desired mutations into the construct. In contrast, virtually all colonies obtained using the basic protocol have the correct structure.

Time Considerations

Generation of a deletion series and sequencing the endpoints can be accomplished in ~2 weeks using the procedures cross-referenced in this manual. The time required to synthesize all of the necessary oligonucleotides is usually the rate-limiting step for either protocol. Once all of the oligonucleotides are obtained and hybridized, the ligations, minipreps, and final sequencing require only 3 to 4 days.

The alternate protocol will require approximately the same amount of time as the basic protocol, depending on the size of the region to be scanned and on the actual efficiency of the procedure. Both of these factors contribute to the number of colonies that must be screened by DNA sequencing.

Directed Mutagenesis Using the Polymerase Chain Reaction

UNIT 8.5

The polymerase chain reaction (PCR) is most often used for the enzymatic amplification and direct sequencing of small quantities of nucleic acids (see Chapter 15). This technology can also be used as a quick and efficient method for introducing any desired sequence change into the DNA of interest.

This unit contains two basic protocols for introducing base changes into specific DNA sequences. Basic Protocol 1 describes the incorporation of a restriction site and Basic Protocol 2 details the generation of specific point mutations. An alternate protocol describes generating point mutations by sequential PCR steps. Although the general procedure is the same in all three protocols, there are differences in the design of the synthetic oligonucleotide primers and in the subsequent cloning and analyses of the amplified fragments.

INTRODUCTION OF RESTRICTION ENDONUCLEASE SITES BY PCR

**BASIC
PROTOCOL 1**

In this protocol, synthetic oligonucleotides incorporating the desired restriction site are used in conjunction with the appropriate flanking sequence primers to amplify two fragments of DNA. Each of these amplified fragments will contain the new restriction site at one end. Following enzymatic digestion at both the new and flanking restriction sites, the amplified fragments are ligated and subcloned into a vector to facilitate sequence analysis. The procedure is summarized in Figure 8.5.1.

Materials

- DNA sample to be mutagenized
- pUC19 plasmid vector (Figure 1.5.2) or similar high-copy-number plasmid having M13 flanking primer sequences
- TE buffer (*APPENDIX 2*)
- 10× MgCl₂-free PCR amplification buffer (*UNIT 15.1*) supplemented with MgCl₂ as appropriate (see step 5)
- 2 mM 4dNTP mix (*UNIT 15.1*)
- 500 ng/μl (100 pmol/μl) M13 forward and reverse flanking sequence primers (New England Biolabs)
- 5 U/μl *Taq* DNA polymerase (*UNITS 15.1 & 3.5*)
- Mineral oil
- Chloroform (*UNIT 2.1*)
- Buffered phenol (*UNIT 2.1*)
- 100% ethanol
- Appropriate restriction endonucleases (Table 8.5.1)
- 500-μl microcentrifuge tube
- Automated thermal cycler
- Additional reagents and equipment for subcloning DNA (*UNIT 3.16*), plasmid DNA miniprep (*UNIT 1.6*), synthesis and purification of oligonucleotides (*UNITS 2.11 & 2.12*), PCR amplification (*UNIT 15.1*), DNA extraction and precipitation (*UNIT 2.1*), quantitation of DNA by absorbance spectrometry (*APPENDIX 3D*), restriction endonuclease digestion (*UNIT 3.1*), agarose and polyacrylamide gel electrophoresis of DNA (*UNITS 2.5 & 2.7*), purification of DNA from low gelling/melting agarose gels (*UNIT 2.6*), ligation of DNA fragments (*UNIT 3.16*), transformation of *E. coli* (*UNIT 1.8*), and DNA sequence analysis (*UNIT 7.4*)

Supplement 37

Figure 8.5.1 Introduction of a restriction site into a specific DNA fragment. **(A)** The fragment of interest is cloned into a high-copy-number vector. Sites for two oligonucleotide primers, such as the M13 forward and reverse primers (F and R), flank the cloning site. In two separate reactions, fragments upstream (A—E) and downstream (E—C) of the introduced site are PCR-amplified using the flanking primers and oligonucleotides containing the site to be introduced (primers F and 1, R and 2). The amplified fragments are digested with the appropriate restriction endonucleases, then ligated and subcloned into an appropriately cut vector and transformed into *E. coli*. The resultant plasmid contains an inserted fragment identical to the original DNA except for the introduced restriction site. **(B)** The oligonucleotides needed to change the primary sequence to an *EcoRI* restriction site are indicated. Note the four-base “clamp” sequence at the 5' end of the primers.

^aReprinted with permission from New England Biolabs.***Prepare the template DNA and oligonucleotide primers***

1. Subclone the DNA to be mutagenized into pUC19 or similar high-copy-number vector, using restriction sites flanking the area to be mutated (see *UNIT 3.16*).

A different restriction site should be used for each end of the fragment to facilitate cloning at various steps in the procedure.

2. Prepare template DNA by plasmid miniprep (*UNIT 1.6*). Resuspend 100 ng of the DNA in TE buffer at a final concentration of 1 ng/μl.

3. Synthesize oligonucleotide primers (primers 1 and 2 in Fig. 8.5.1B; also see *UNIT 2.11*).

The 5' end of each primer consists of the restriction site to be introduced, preceded by three or four extra nucleotides (a "clamp" sequence). The restriction site sequences are followed by ≥ 15 bases that are homologous to the template DNA.

4. Purify synthesized oligonucleotides by denaturing polyacrylamide gel electrophoresis (*UNIT 2.12*). Recover the oligonucleotides (*UNIT 2.1*) and resuspend in 500 μl TE buffer. Determine absorbance at A_{260} (*APPENDIX 3D*) and adjust concentration to 500 ng/ μl (100 pmol/ μl), if necessary.

Because the purity of the oligonucleotides does not seem to affect the PCR reaction significantly, primers may also be used in a reaction immediately after synthesis.

Amplify by PCR

5. Combine the following in each of two 500- μl microcentrifuge tubes, adding oligonucleotides 1 and 2 to separate tubes:

10 μl (10 ng) template DNA
10 μl 10 \times amplification buffer
10 μl 2 mM 4dNTP mix
1 μl (500 ng) oligonucleotide 1 or 2 (1 μM final)
1 μl (500 ng) appropriate M13 flanking sequence primer, forward or reverse (1 μM final)
H₂O to 99.5 μl
0.5 μl *Taq* DNA polymerase (5 U/ μl).

Overlay reaction with 100 μl mineral oil.

The first tube will contain oligonucleotide 1 and its appropriate flanking sequence primer. The second tube will contain oligonucleotide 2 and its appropriate sequence primer (see Fig. 8.5.1A). If the oligonucleotides are not purified, add $1/500$ to $1/2000$ of the oligonucleotide preparation (from step 3) to the reaction. This should represent 500 to 1000 ng (100 to 200 pmol) full-length oligonucleotide.

*A 15-mM concentration of MgCl_2 in the amplification buffer works for many primers; the optimal concentration for a given sequence and primer can be determined as outlined in *UNIT 15.1*. It should be kept in mind, however, that the fidelity of *Taq* DNA polymerase decreases with increasing Mg^{2+} concentration.*

6. Carry out PCR (*UNIT 15.1*) in an automated thermal cycler under the following conditions:

20 to 25 cycles:	45 sec	93°C (denaturation)
	2 min	50°C (annealing)
	2 min	72°C (extension)
1 cycle:	10 min	72°C (extension)

7. Analyze 4 μl of the reaction mix by nondenaturing agarose (*UNIT 2.5A*) or acrylamide gel electrophoresis (*UNIT 2.7*) to verify that the amplification has yielded the predicted product.

*See *UNITS 2.5 & 2.7* to choose the type of gel best suited for the size of the predicted amplification product.*

8. Pipet most of the mineral oil from the reaction mix and extract once with chloroform to remove remaining oil. Extract with buffered phenol and concentrate by precipitation with 100% ethanol (*UNIT 2.1*).

Subclone fragments and check the restriction-site mutation

9. Digest half the amplified DNA with the restriction endonucleases for the flanking and introduced sites. Purify digested fragments on a low gelling/melting agarose gel (UNIT 2.6).
10. Ligate and subclone (UNIT 3.16) both fragments into an appropriately digested vector to obtain a recombinant plasmid containing a single DNA fragment incorporating the new restriction site.

Alternatively, subclone them individually to facilitate the next step.

11. Transform plasmid into *E. coli* (UNIT 1.8). Prepare DNA by plasmid miniprep (UNIT 1.6).
12. Analyze the amplified fragment portion of the plasmid DNA by DNA sequencing (UNIT 7.4) to confirm the addition of the restriction-site mutation.

This is critical because the Taq DNA polymerase can introduce additional mutations into the fragment (see Critical Parameters).

INTRODUCTION OF POINT MUTATIONS BY PCR

In this protocol, synthetic oligonucleotides are designed to incorporate a point mutation at one end of an amplified fragment. Following PCR, the amplified fragments are made blunt-ended by treatment with Klenow fragment. These fragments are then ligated and subcloned into a vector to facilitate sequence analysis. This procedure is summarized in Figure 8.5.2.

Materials

DNA sample to be mutagenized
Klenow fragment of *E. coli* DNA polymerase I (UNIT 3.5)
Appropriate restriction endonuclease (Table 8.5.1)

Additional reagents and equipment for synthesis and purification of oligonucleotides (UNITS 2.11 & 2.12), phosphorylation of oligonucleotides (UNIT 3.10), electrophoresis of DNA on nondenaturing agarose and low gelling/melting agarose gels (UNITS 2.5A & 2.6), restriction endonuclease digestion (UNIT 3.1), ligation of DNA fragments (UNIT 3.16), transformation of *E. coli* (UNIT 1.8), plasmid DNA miniprep (UNIT 1.6), and DNA sequence analysis (UNIT 7.4)

Prepare the template DNA and oligonucleotide primers

1. Prepare template DNA (see Basic Protocol 1, steps 1 and 2).
2. Synthesize (UNIT 2.11) and purify (UNIT 2.12) the oligonucleotide primers (primers 3 and 4 in Fig. 8.5.2B).

The oligonucleotide primers must be homologous to the template DNA for ≥ 15 bases. No four-base "clamp" sequence is added to these primers.

3. Phosphorylate the 5' end of the oligonucleotides (UNIT 3.10).

This step is necessary because the 5' end of the oligonucleotide will be used directly in cloning.

Amplify DNA and prepare blunt-end fragments

4. Amplify the template DNA (see Basic Protocol 1, steps 5 and 6).
5. After the final extension step, add 5 U Klenow fragment to the reaction mix and incubate 15 min at 30°C.

**BASIC
PROTOCOL 2**

**Mutagenesis of
Cloned DNA**

8.5.5

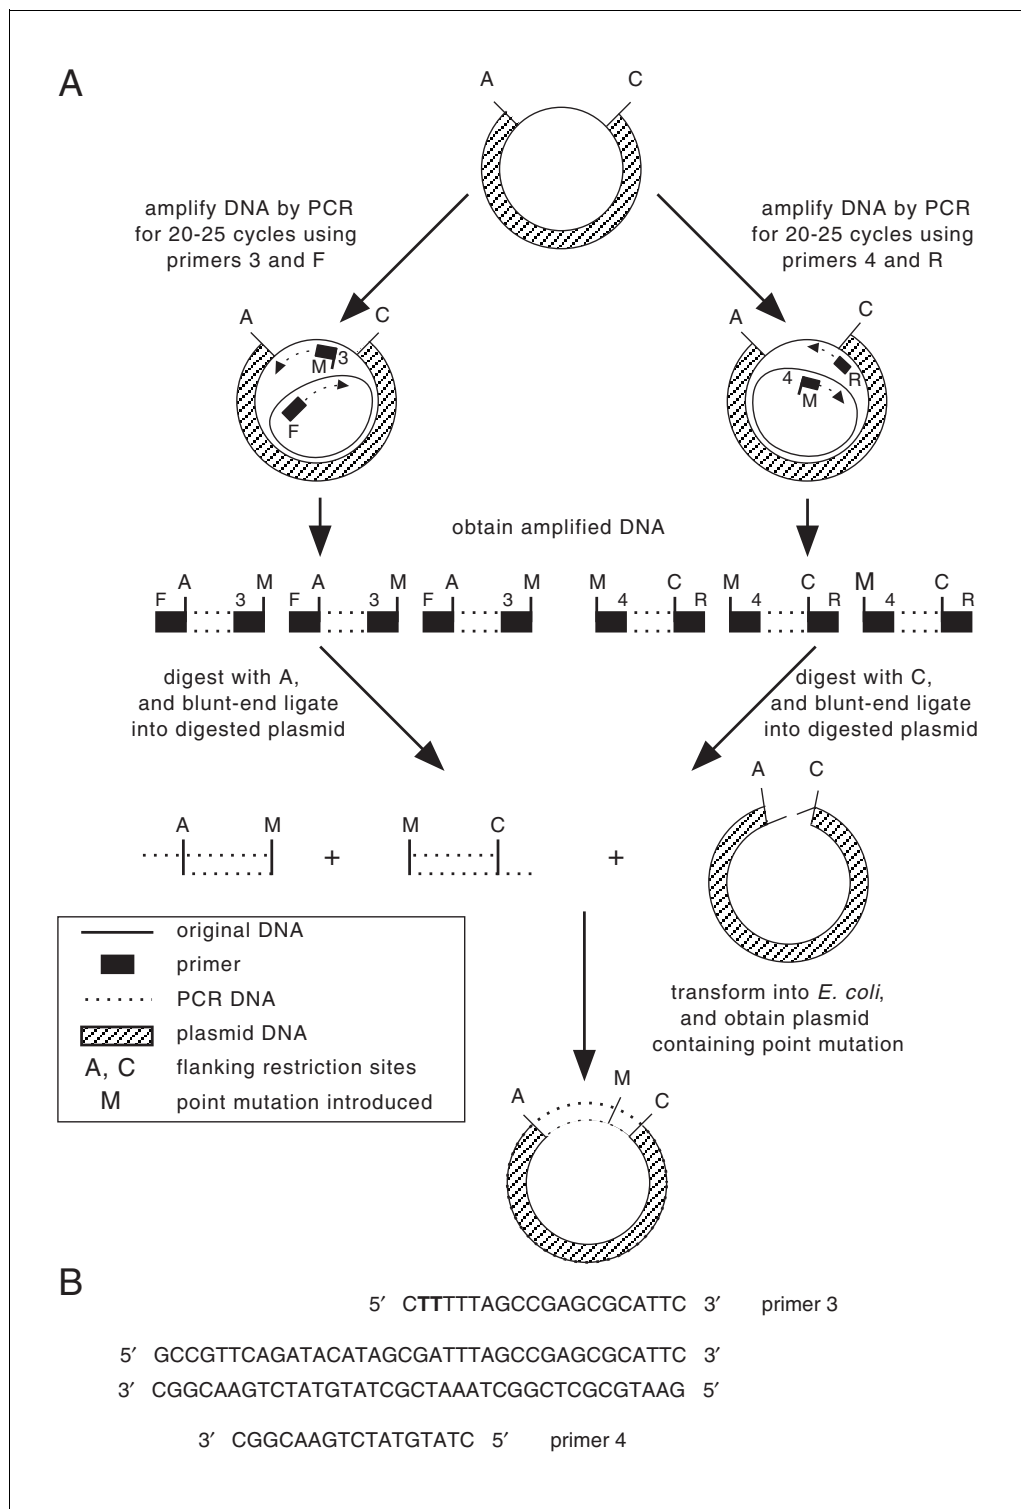

Figure 8.5.2 Introduction of a point mutation into a specific DNA fragment. **(A)** The fragment of interest is cloned into a high-copy-number plasmid vector. Sites for two oligonucleotide primers, such as the M13 forward and reverse primers (F and R), flank the cloning site. In two separate reactions, fragments upstream (A—M) and downstream (M—C) of the point mutation are PCR-amplified using the flanking primers and oligonucleotides containing the point mutation to be introduced (primers F and 3, R and 4). The fragments are digested with the appropriate restriction endonucleases and made blunt-ended. These fragments are ligated and subcloned into an appropriately cut vector and transformed into *E. coli*. The resultant plasmid contains an inserted fragment identical to the original DNA except for the introduced point mutation. **(B)** The oligonucleotides needed to generate a point mutation in the primary sequence are shown. Note that there are no “clamp” sequences at the 5′ ends of the primers.

During PCR, the Taq polymerase adds an extra nontemplated nucleotide to the 3' end of the fragment. The 3' → 5' exonuclease activity of the Klenow fragment is required to make the ends flush and suitable for blunt-end cloning (UNIT 3.5).

6. Analyze and process the reaction mix (see Basic Protocol 1, steps 7 and 8).
7. Digest half the amplified fragments with the restriction endonucleases for the flanking sequences (UNIT 3.1). Purify digested fragments on a low gelling/melting agarose gel (UNIT 2.6).

Subclone fragments and check the point mutation

8. Subclone the two amplified fragments into an appropriately digested vector by blunt-end ligation (UNIT 3.16).
9. Transform recombinant plasmid into *E. coli* (UNIT 1.8). Prepare DNA by plasmid miniprep (UNIT 1.6).
10. Analyze the amplified fragment portion of the plasmid DNA by DNA sequencing to confirm the point mutation (UNIT 7.4).

This is critical because the Taq DNA polymerase can introduce additional mutations into the fragment (see Critical Parameters).

INTRODUCTION OF A POINT MUTATION BY SEQUENTIAL PCR STEPS

ALTERNATE PROTOCOL

In this procedure, the two fragments encompassing the mutation are annealed with each other and extended by mutually primed synthesis; this fragment is then amplified by a second PCR step, thereby avoiding the blunt-end ligation required in Basic Protocol 2. This strategy is outlined in Figure 8.5.3. For materials, see Basic Protocols 1 and 2.

Prepare template DNA and oligonucleotide primers

1. Prepare template DNA (see Basic Protocol 1, steps 1 and 2).
2. Synthesize (UNIT 2.11) and purify (UNIT 2.12) the oligonucleotide primers (primers 5 and 6 in Fig. 8.5.3B).

The oligonucleotides must be homologous to the template for 15 to 20 bases and must overlap with one another by ≥10 bases. The 5' end does not have a "clamp" sequence.

Carry out first PCR amplification

3. Amplify the template DNA and generate blunt-end fragments (see Basic Protocol 2, steps 4 and 5).
4. Purify the fragments by nondenaturing agarose gel electrophoresis (UNIT 2.5A). Resuspend in TE buffer at 1 ng/μl.

Carry out second PCR amplification

5. Combine the following in a 500-μl microcentrifuge tube:
 - 10 μl (10 ng) each amplified fragment
 - 1 μl (500 ng) each flanking sequence primer (each 1 μM final)
 - 10 μl 10× amplification buffer
 - 10 μl 2 mM 4dNTP mix
 - H₂O to 99.5 μl
 - 0.5 μl *Taq* DNA polymerase (5 U/μl).

Overlay with 100 μl mineral oil.

Mutagenesis of Cloned DNA

8.5.7

Figure 8.5.3 Introduction of a point mutation by sequential PCR steps. **(A)** The first steps of this protocol are as described in Figure 8.5.2A except primers 5 and 6 are used. The amplified fragments are then placed in the same tube and amplified in a second PCR step (using primers F and R only). This second PCR step obviates the need for the blunt-end ligation. The full-length fragment generated here is digested with the appropriate restriction endonucleases, subcloned into an appropriately cut vector, and transformed into *E. coli*. The resultant plasmid contains an inserted fragment identical to the original DNA except for the point mutation. **(B)** The oligonucleotide primers needed to generate a point mutation in this procedure are shown. Note that there are 12 bases of overlap between the two primers.

6. Carry out PCR for 20 to 25 cycles, using the conditions for introduction of restriction endonuclease sites by PCR (see Basic Protocol 1, step 6).
7. Analyze and process the reaction mix (see Basic Protocol 1, steps 7 and 8).

Subclone fragments and check the mutation

8. Digest the DNA fragment with the appropriate restriction endonuclease for the flanking sites (*UNIT 3.1*). Purify the digested fragment on a low gelling/melting agarose gel (*UNIT 2.6*). Subclone into an appropriately digested vector.
9. Transform recombinant plasmid into *E. coli* (*UNIT 1.8*). Prepare DNA by plasmid miniprep (*UNIT 1.6*).
10. Analyze the amplified fragment portion of the plasmid DNA by DNA sequencing (*UNIT 7.4*) to confirm the point mutation.

This is critical because the Taq DNA polymerase can introduce additional mutations into the fragment (see Critical Parameters).

COMMENTARY

Background Information

The PCR procedure described here will rapidly, efficiently, and reproducibly introduce any desired change into a DNA fragment. It is similar to the oligonucleotide-directed mutagenesis method described in *UNIT 8.1*, but does not require the preparation of a uracil-substituted DNA template.

The main disadvantage of PCR-generated mutagenesis is related to the fidelity of the *Taq* DNA polymerase. The mutation frequency for *Taq* DNA polymerase was initially estimated to be as high as $1/5000$ per cycle (Saiki et al., 1988). This means that the entire amplified fragment must be sequenced to be sure that there are no *Taq*-derived mutations. To reduce the amount of sequencing required, it is best to introduce the mutation by amplifying as small a fragment as possible. With rapid and reproducible methods of double-stranded DNA sequencing (*UNIT 7.4*), the entire amplified fragment can usually be sequenced from a single primer. If the fragment is somewhat longer, it is best to subclone the fragment into an M13-derived vector, so that both forward and reverse primers can be used to sequence the amplified fragment.

If there are no convenient restriction sites flanking the fragment of interest, the utility of this method is somewhat reduced. Many researchers prefer the mutagenesis procedure in *UNIT 8.1* to avoid excessive sequencing.

Critical Parameters

The most important requirement for this protocol is that the melting temperature of the oligonucleotide be sufficiently high to allow

efficient annealing and amplification. The T_m can be estimated according to the equation:

$$T_m = nGC(4^\circ\text{C}) + mAT(2^\circ\text{C})$$

where n is the number of G and C residues and m is the number of A and T residues in the oligonucleotide.

For a 15-mer of 50% GC content, the calculated T_m will be 42°C. However, after a single round of extension, there are six to ten additional bases of homology, and the T_m increases to between 60° and 72°C. Generally, primers with 15 bases of homology to the template are sufficient for amplification. It may be necessary, however (especially in the case of AT-rich sequences), to increase the length of homology or to lower the hybridization temperature accordingly. This must be determined empirically.

If a mismatch is present in the oligonucleotide, it is better that it be as close as possible to the 5' end of the oligonucleotide. There, the mismatch has relatively little effect on the T_m . By contrast, a point mutation in the middle of an oligonucleotide will have a large effect on the T_m . When designing oligonucleotides, it is desirable to have the longest uninterrupted stretch of homology possible.

An additional problem is that not all restriction endonucleases are capable of efficiently digesting sites at the end of a fragment; this problem is mitigated to some extent by the inclusion of the extra four bases as a "clamp." But even with this precaution, it will be difficult to clone with certain enzymes. Table 8.5.1 is a partial list of enzymes and their relative abilities

to cleave sites on short oligonucleotides, which should be used as a guide when choosing between potential restriction enzymes. An alternative is to blunt-end clone the amplified fragment and subsequently subclone from that cloned insert using the enzyme of interest.

A full discussion of critical parameters for PCR amplification can be found in *UNIT 15.1*.

Anticipated Results

Each of the procedures presented here has a 100% efficiency rate. All cloned, amplified fragments will contain the mutation corresponding to the synthesized oligonucleotide.

Time Considerations

Once the oligonucleotides are synthesized, the relevant fragments can be amplified and

subcloned within a single day. Thus, in 2 to 3 days it is possible to proceed from oligonucleotides to a fully sequenced fragment with the incorporated mutation.

CHAPTER 9

Introduction of DNA into Mammalian Cells

INTRODUCTION

After cloning a gene, many researchers wish to analyze its characteristics by reintroducing normal and mutant variants into various cell types. There are many reasons to do this. The genetic elements responsible for regulation of expression can be determined by mutating regulatory sequences and subsequently examining activity under a variety of physiological conditions. The effects that the gene has on cellular growth can be ascertained by characterizing the phenotypes of cell lines that either overexpress the gene, or that express mutant forms of the gene. Overexpressing cell lines can also be used for purification of the product for biochemical characterization, or large-scale production of a product for use as a drug. All these goals require the ability to introduce DNA into a cell efficiently. The protocols in this chapter cover methods that are used to introduce genes into mammalian cells, as well as techniques used to investigate their regulation, to express the gene products, and to delete the endogenous form of the gene.

Many researchers must transfect DNA into a cell line that is chosen not for ease of transfection but for its biological properties. A frequent reason for introducing DNA into mammalian cells is to analyze gene expression. It is critical that an appropriate cell line be used in these studies. For example, in HeLa cells the β -globin gene is expressed at a low level that is not inducible, but it is inducible upon differentiation of MEL cells. Clearly, MEL cells should be used to investigate the mechanism of the induction. Many researchers must therefore transfect DNA into a cell line that is chosen not for ease of transfection but for its biological properties. Analysis of phenotypes of overexpression or deletion usually must also be done in appropriate cell lines.

The first section of the chapter presents four techniques for introducing DNA into mammalian cells: calcium phosphate transfection (*UNIT 9.1*), DEAE-dextran transfection (*UNIT 9.2*), electroporation (*UNIT 9.3*), and liposome-mediated transfection (*UNIT 9.4*). The first two procedures produce a chemical environment that results in DNA attaching to the cell surface; the DNA is then endocytosed by as yet uncharacterized pathways. The parameters for transfecting cells by these techniques vary for each different cell type and therefore need to be carefully optimized; these issues are discussed in the introduction to this first section.

Electroporation uses an electric field to open up pores in the cell. The DNA presumably diffuses into the cell through the pores. This technique therefore is not dependent upon special characteristics of the cell and can be used with virtually any cell type. The optimal amplitude and length of pulse will vary for each cell type, so this procedure too requires fine-tuning.

In liposome-mediated transfection, the mechanism by which liposomes containing cationic and neutral lipids mediate transfection of DNA into animal cells is not well understood. Negatively charged phosphate groups on DNA bind to the positively charged surface of the liposome, and the residual positive charge then presumably mediates binding to negatively charged sialic acid residues on the cell surfaces.

**Introduction
of DNA into
Mammalian Cells**

9.0.1

Supplement 64

The simplest way to optimize parameters for transfection is to use an easily assayed reporter gene as the transfected DNA during the optimization. Reporter systems are covered in the second section of this chapter (*UNITS 9.6 & 9.7*), with descriptions of how these genes can be used to optimize transfection efficiency and to analyze promoter function. Reporter genes allow indirect measurement of promoter activity, so the researcher will need to analyze RNA levels and the structure of the RNA produced from the transfected gene. Strategies for using the techniques of RNA isolation and analysis (Chapter 4) in conjunction with transfection procedures to analyze directly the regulation of a gene are described in *UNIT 9.8*.

Reporter genes are used not only to measure the activity of a gene, but also to visualize the location of the protein that is expressed. *UNIT 9.7C* describes the use of the Green Fluorescent Protein (GFP) to directly visualize proteins in living cells. This reporter can provide a simple method for evaluating the percentage of cells that have been transfected and can serve as a marker for cells within a population that have received transfected DNA. GFP is also used to examine the dynamics of protein movement and expression within a cell over time by creating a fusion protein between GFP and a protein of research interest.

CHOICE OF TRANSFECTION METHOD

There are two types of transfections that are routinely done in mammalian systems—*transient* and *stable* or *permanent*. In a transient transfection, transcription or replication of the transfected gene can be analyzed between 1 and 4 days after introduction of the DNA, generally by harvesting the transfected cell. Alternatively, many experiments require formation of cell lines that contain gene(s) that are integrated into chromosomal DNA resulting in a stable or permanent transfection; *UNIT 9.5* describes selectable markers that are used in this type of transfection.

All four methods described above can be used for transient transfections. Three of these—calcium phosphate transfection, electroporation, and liposome-mediated transfection—can be used to efficiently produce cell lines containing stably integrated DNA. Electroporation is most easily done using suspension cultures, as cells must be transferred into cuvettes, whereas calcium phosphate- and liposome-mediated transfections are most easily done using adherent cells. Two methods for calcium phosphate-mediated transfection are presented in the first unit. The HEPES-buffered system can be used for producing either transiently or stably transformed lines. The second method, based on a BES buffer system, is now widely used for the stable transformation of most common fibroblast and epithelial cells, and for these applications is at least 10-fold more efficient than other methods. DEAE-dextran transfection does not work well when producing stable cell lines, but is more reproducible than calcium phosphate transfection when used in transient protocols. Electroporation is also very reproducible, but requires more cells than either of the chemical procedures do. Although these considerations are important in choosing a transfection protocol, the most critical parameter may be the efficiency with which DNA is introduced into the recipient cell, and this may have to be determined experimentally.

There are numerous techniques used in mammalian cell culture that are not discussed in this chapter. In particular, it is assumed that the conditions needed for optimal growth and passage of the cell lines used in a specific research project will already have been determined. In order for transfection to work efficiently, it is necessary that the recipient cells be healthy. A brief discussion at the end of this introduction describes the reagents used in mammalian cell culture.

VIRAL VECTORS

DNA can also be introduced into eukaryotic cells by using viral vectors. Viral vectors can allow introduction of DNA into virtually all cells in a given experiment. Certain viral systems will result in overexpression of proteins (e.g., baculovirus and vaccinia virus; see Chapter 16) or will allow single-copy stable integrants of expressed genes (e.g., retroviral vectors, *UNITS 9.9-9.14*). Viral systems therefore can be much more powerful than transfection systems—however, constructing a recombinant virus and packaging that virus involves a significant effort. It is therefore prudent to plan experiments unusually carefully when using viral vectors to ensure that a recombinant virus is really needed and that the optimal virus is constructed.

Retroviruses are not generally used for overproducing a protein, but are instead used to introduce a gene in a stable fashion into a cell line or into cells in an animal. These vectors can therefore be used either to express a gene product in a set of cells or to express a marker gene that will allow identification of an infected cell and its progeny. An overview of the retroviral life cycle and of retroviral vectors is provided in *UNIT 9.9*. Standard cloning procedures are used to create a retroviral vector, after which a packaging line must be made to produce infectious particles (*UNIT 9.10*). An alternative approach for the transient transfection and production of retroviral supernatants is presented in *UNIT 9.11*. These cell lines can then be used to produce large amounts of recombinant retroviruses (*UNIT 9.12*). The resultant retrovirus stocks may then be used in a variety of experiments; however, it is critical to ensure that they are free of wild-type “helper” retroviruses that may arise from the packaging cell lines. These helper viruses are replication-competent, and therefore can create serious complications in certain experiments. Assays that can be used to detect helper virus in a preparation are described in *UNIT 9.13*. Detailed protocols for introducing recombinant retroviruses into animals are beyond the scope of this chapter, although *UNIT 9.14* provides a beginning point for these *in vivo* experiments.

Until recently, the introduction of mutations into mammalian systems relied upon random mutagenesis followed by selection for a particular phenotypic change. This approach works only with genes whose loss of or change in function results in a selectable phenotype. In contrast, gene targeting in somatic cells by homologous recombination (*UNIT 9.15*) allows mutation of any desired gene, regardless of phenotype. Mutating the gene in somatic cells that have defined behavioral characteristics allows the researcher to assess the impact of the mutation in a defined and clonal cellular background. Mutant cells can be examined in culture, or can be examined after injection into animals. While this protocol can only work with cells that are diploid and efficiently transfectable, it has proven to be very useful in a variety of situations.

REAGENTS AND SOLUTIONS

Unlike *Escherichia coli*, mammalian cells are extremely sensitive to growth conditions. In addition, because their doubling time is usually 12 to 48 hr, mammalian cultures are susceptible to contamination by bacteria and fungi, and the necessity to maintain sterile conditions during experimental procedures involving cell growth cannot be overemphasized. The four transfection protocols described in this chapter are stressful to the cell and thus can cause extensive cell death if the transfected cells are not healthy prior to transfection. This means that cell culture conditions that are marginal for normal growth and passage of cells will probably not suffice for transfection purposes. The following precautions and ingredients are crucial to success in culturing mammalian cells:

1. **Glassware.** Numerous solutions commonly used in the laboratory are cytotoxic when present even in trace amounts. Many laboratories therefore keep separate glassware for tissue culture purposes. This glassware is never mixed with glassware used in the laboratory. Tissue culture glassware should be left soaking in water after use in order to prevent drying of residual chemicals onto the glass. For these reasons, plasticware is frequently used for pipets and for storage of reagents used in tissue culture.
2. **Water.** Only distilled and deionized water should be used for preparation of solutions used in tissue culture. Some laboratories use a glass still to produce this water, whereas in some newer facilities, house purification systems are sufficient.
3. **Media.** It is possible to purchase sterile media in solution. Alternatively, packaged, premixed powders can be purchased. These can be made in 10- to 20-liter batches in the laboratory. The resulting solutions must then be filter sterilized. This is most conveniently done using a high-capacity pump (500 ml/min) and filter apparatus.

Media are supplemented shortly before use with serum. Frequently, fetal bovine serum (FBS; also known as fetal calf serum) is used, but for some uses, less expensive sera may be employed (see below). Other supplements can include glutamine, nonessential amino acids, 2-mercaptoethanol (2-ME), penicillin, and streptomycin sulfate to formulate “complete” media; however, the exact formulation will vary with different cell types. Nomenclature of media employed in this manual indicates the base medium as well as the percentage of serum. For example, “complete DMEM-10” means that DMEM is supplemented with 10% serum plus the other ingredients noted above (see recipe, *UNIT 9.4*).

4. **Serum.** Horse, calf, and fetal bovine serum can be purchased. In using serum, it is accepted that a partially undefined material is being used, which may show considerable variation in the ability to support growth of particular cells. Thus, for every culture application, serum should be “screened” to determine if, in fact, it supports the growth of the cells of interest. Such screening can also be done to determine if the serum is unduly stimulatory to the cells of interest, thereby leading to high background responses. There is no easy way to screen lots of serum because the suitability of a given lot can only be determined in the application at hand. It is recommended that for extensive studies of a given cell population, small amounts of different lots of serum be obtained from one or more suppliers with the proviso that the supplier put aside a much larger amount of the lot(s) for possible delivery. The various lots are then tested in an assay of interest (a proliferation assay, a transient transfection assay, etc.) to determine which lot provides the most vigorous response and the least background response (response in the absence of specific stimulus). The lot with this characteristic is then bought in large amounts and the other lots are “released” (allowed to be sold to other purchasers). Reliable suppliers of serum are Armour and Hyclone.

Generally, heat-inactivated (1 hr at 56°C) serum is required to support long-term cultures. The heat treatment is thought by some labs to reduce the number of viral and other adventitious contaminants and by others to be required to inactivate complement. It therefore has developed into a standard procedure before the use of a particular batch of serum, despite alleged disadvantages (i.e., inactivation of certain growth factors and production of heat-labile serum components that are toxic to cells). If desired, test whether the growth-supporting function of a certain lot of serum can be improved by not heating it, particularly when culturing fastidious cells.

Given the high cost of serum, a lower percentage (5%) can be used for short-term procedures such as washing cells. In addition, bovine serum, which is about ten times

less expensive than fetal bovine serum, can sometimes be substituted in short-term procedures. Store all serum at -20°C .

5. **Supplements.** Many researchers use antibiotics in mammalian culture media to prevent contamination. The most effective addition is gentamicin sulfate, which is purchased as a 50 mg/ml solution and used at 20 to 50 $\mu\text{g/ml}$. A somewhat less expensive (and less stable) antibiotic combination that is also somewhat less effective is a cocktail of penicillin (50 to 100 U/ml) and streptomycin sulfate (100 $\mu\text{g/ml}$). Note that use of antibiotics in the media can mask sloppy tissue culture technique. Sloppy technique can result in contamination of a culture by agents that are not susceptible to the antibiotics, such as mycoplasma. Some laboratories therefore do not use antibiotics in order to ensure that strict sterility is being maintained. Some experiments will require other additions to the media, such as nucleosides or drugs. These solutions should be made up using tissue culture glassware or plasticware, and care should be taken to avoid the use of stir bars or other items that might have trace amounts of laboratory chemicals on them. The solutions should be filter sterilized through Nalgene filters.

2-mercaptoethanol is often included in media but the precise mode(s) of action of 2-ME has not been defined. The presence of 2-ME during growth of established cell lines appears not to be required, but it has proven to be a critical ingredient in primary cultures. 2-mercaptoethanol must be added to media immediately before use because its activity rapidly declines in diluted form. Thus, concentrated 2-ME (14.3 M) is diluted to 50 mM in HBSS or PBS and this solution is added to media at a final concentration of 50 μM . The 50 mM stock solution is stored at 4°C and should be replaced after ~ 4 months.

Other reagents are added to media immediately before use; these are typically made in large batches at 100 \times or 200 \times concentrations and stored in aliquots of convenient size until use. Stock solutions containing L-glutamine, nonessential amino acids, and antibiotics are stored at -20°C . Stock solutions containing HEPES are stored at room temperature.

6. **Trypsin/EDTA.** A buffered salt solution containing 0.5% (w/v) trypsin and 0.2% (w/v) EDTA is used to dissociate adherent cells from tissue culture dishes. This solution can be prepared in the laboratory or purchased.

A more complete description of the preparation of culture media and techniques for mammalian cell tissue culture can be found in *APPENDIX 3F*.

Robert E. Kingston

TRANSFECTION OF DNA INTO EUKARYOTIC CELLS

OPTIMIZATION OF TRANSFECTION

When embarking upon any transfection procedure, a critical first step is to optimize conditions. Every mammalian cell type has a characteristic set of requirements for optimal introduction of foreign DNA; there is a tremendous degree of variability in the transfection conditions that work, even among cell types that are very similar to one another. Often, an experimenter must screen a wide variety of cell types for a desired regulatory trait, such as an appropriate response to a particular effector molecule. It is thus helpful to have a straightforward, systematic approach to optimizing transfection efficiency. Transient assay systems are particularly useful for this purpose. A fusion gene that is known to function in mammalian cells can be transfected into cells under a variety of conditions, and transfection efficiency can be easily monitored by assaying for the fusion gene product. The human growth hormone (hGH; see *UNIT 9.7A*) assay system is particularly useful for this purpose because both harvest and assay take very little time. However, any reporter system can be used to optimize transfection efficiency.

The single most important factor in optimizing transfection efficiency is selecting the proper transfection protocol. This usually comes down to a choice among calcium phosphate-mediated gene transfer (*UNIT 9.1*), DEAE-dextran-mediated gene transfer (*UNITS 9.2 & 16.12*), electroporation (*UNIT 9.3*), and liposome-mediated transfection (*UNIT 9.4*). Fusion techniques such as protoplast fusion and microinjection may also be considered. Cells are variable with respect to which transfection protocol is most efficient. It is recommended that any adherent cell line under investigation be tested for transfection ability with DEAE-dextran, calcium phosphate, and liposome-mediated transfection. Nonadherent cell lines can be transfected by electroporation and liposome-mediated transfection. Generally, if a cell can be grown in culture, it can be transfected.

Calcium Phosphate Transfection

The primary factors that influence efficiency of calcium phosphate transfection (*UNIT 9.1*) are the amount of DNA in the precipitate, the length of time the precipitate is left on the cell, and the use and duration of glycerol or DMSO shock. A calcium phosphate optimization is shown in Table 9.1.1. Generally, higher concentrations of DNA (10 to 50 μg) are used in calcium phosphate transfection. Total DNA concentration in the

precipitate can have a dramatic effect on efficiency of uptake of DNA with calcium phosphate-mediated transfection. With some cell lines, more than 10 to 15 μg of DNA added to a 10-cm dish results in excessive cell death and very little uptake of DNA. With other cell types, such as primary cells, a high concentration of DNA in the precipitate is necessary to get any DNA at all into the cell on a routine basis. For example, with human foreskin fibroblasts, transfection of 5 μg of a reporter plasmid with 5 μg of carrier DNA (e.g., pUC13) gives significantly less expression than does transfection of 5 μg of reporter plasmid with 35 μg of carrier DNA. Presumably, this is because the amount of DNA affects the nature of the precipitate and thus alters the fraction of the applied DNA that is taken up into cells.

The optimal length of time that the precipitate is left on cells varies with cell type. Some cell types, such as HeLa or BALB/c 3T3, are efficiently transfected by leaving the precipitate on for 16 hr. Other cell types cannot survive this length of exposure to the precipitate. Transfection efficiency of some cell types, such as CHO DUKX BII, is dramatically increased by glycerol or DMSO shock (*UNIT 9.1*). The pilot experiment listed will indicate whether the cell type is tolerant to long exposure to a calcium phosphate precipitate and whether glycerol shock should be used. Once the results of this experiment are in hand, finer experiments can be done to further optimize conditions. For example, if shocking with 10% glycerol for 3 min enhances transfection efficiency, an experiment varying the time of glycerol shock or also trying 10% and 20% DMSO shock might be done.

Once optimal conditions for transfection are found, extensive DNA curves varying the amount of reporter plasmid should be prepared. The total amount of DNA should be kept constant at the optimal level determined in the first experiment. The amount of reporter plasmid DNA (e.g., pXGH5) should be varied, and carrier DNA (e.g., pUC13) should be used to make up the difference. This is to ensure that transfections are performed under conditions where the amount of reporter plasmid in the cell is not saturating the cellular transcription and translation machinery.

DEAE-Dextran Transfection

There are several factors that can be varied in DEAE-dextran transfection (*UNIT 9.2*). The number of cells, concentration of DNA, and concentration of DEAE-dextran added to the dish are the most important to optimize. To a first approximation, most cell types that can be transfected using DEAE-dextran will have a preference for 1 to 10 μg DNA/10-cm dish and for 100 to 400 μg DEAE-dextran/ml of medium. Table 9.1.2 shows how the

Table 9.1.2 Optimization of DEAE-Dextran Transfection

5×10^5 cells/10-cm dish:			2×10^6 cells/10-cm dish:		
Dish	pXGH5 (μg)	DEAE-dextran ($\mu\text{g}/\text{ml}$)	Dish	pXGH5 (μg)	DEAE-dextran ($\mu\text{g}/\text{ml}$)
1	1	400	11	1	400

9	10	100	19	10	100
10	0	200	20	0	200

dishes in an optimization might be chosen. The 20-dish experiment consists of two sets of 10 dishes; one set is plated at 5×10^5 cells/dish, the other is plated at 2×10^6 cells/dish. Each set contains dishes that will be transfected with 1 to 10 μg of a reporter plasmid and 100 to 400 $\mu\text{g}/\text{ml}$ DEAE-dextran. If an hGH expression vector such as pXGH5 is used, a time course of expression under each condition can be determined by removing 100- μl aliquots of the medium 2, 4, and 7 days posttransfection (with a medium change after the day 4 aliquot is removed).

With the results of this pilot experiment in hand, a second experiment using a narrower range of DEAE-dextran concentrations and a wider range of DNA doses should be undertaken. For example, if the cells appear to express more hGH at 100 $\mu\text{g}/\text{ml}$ DEAE-dextran than at higher concentrations in the pilot experiment, the second experiment should cover from 25 to 150 $\mu\text{g}/\text{ml}$ DEAE-dextran. Because DEAE-dextran is toxic to some cells, a brief exposure to small concentrations may be optimal. The wide range of added DNA in this experiment is crucial in two respects. First, it is valuable to know the smallest amount of the transfected reporter gene that can give a readily detectable signal. Second, the linearity of the dose of DNA with the amount of reporter gene expression generally decays for large amounts of input DNA. When excessive (i.e., nonlinear) amounts of DNA are used in transfection experiments, it is possible that the effects observed are dose-response effects rather than the phenomenon intended for study. This serious and common problem can be eliminated by doing a careful DNA dose-response curve as above.

Electroporation

Perhaps because it is not a chemically based protocol, electroporation (*UNIT 9.3*) tends to be less affected by DNA concentration than either DEAE-dextran- or calcium phosphate-mediated gene transfer. Generally, DNA amounts in the range of 10 to 40 $\mu\text{g}/10^7$ cells work well, and there is a good linear correlation between the amount of DNA present and the amount taken up. The parameter that can be varied to optimize electroporation is the amplitude and length of the electric pulse, the latter being determined by the capacitance of the power source. The extent to which this can be varied is determined by the electronics of the power supply used to supply the pulse. The objective is to find a pulse that kills between 20% and 60% of the cells. This generally is in the range of 1.5 kV at 25 μF . If excessive cell death occurs, the length of the pulse can be lowered by lowering the capacitance. Settings between 3 and 25 μF can be tried.

Liposome-Mediated Transfection

Three primary parameters—the concentrations of lipid and DNA and incubation time of the liposome-DNA complex—affect the success of DNA transfection by cationic liposomes (*UNIT 9.4*). These should be systematically examined to obtain optimal transfection frequencies.

Concentration of lipid. In general, increasing the concentrations of lipid improves transfection of four cell lines examined (CV-1 and COS-7 with Lipofectin, and HeLa and BHK-21 with TransfectACE; see *UNIT 9.4*). However, at high levels ($>100 \mu\text{g}$), the lipid can be toxic. For each particular liposome mixture tested, it is important to vary the amount as indicated in Table 9.1.3.

Concentration of DNA. In many of the cell types tested, relatively small amounts of DNA are effectively taken up and expressed. In fact, higher levels of DNA can be inhibitory in some cell types with certain liposome preparations. In the optimization protocol outlined in Table 9.1.3, the standard reporter vector pSV2CAT is used; however, any plasmid DNA whose expression can be easily monitored would be suitable.

Table 9.1.3 Optimization of Liposome-Mediated Transfection

Dish (35-mm)	pSV2CAT (μg)	Liposomes (μl)	Dish (35-mm)	pSV2CAT (μg)	Liposomes (μl)
1	0.1	1	11	5	5
2	0.1	2	12	5	10
3	0.1	4	13	5	15
4	0.1	8	14	5	20
5	0.1	12	15	5	30
6	0.5	1	16	10	5
7	0.5	2	17	10	10
8	0.5	4	18	10	15
9	0.5	8	19	10	20
10	0.5	12	20	10	30

Time of incubation. When the optimal amounts of lipid and DNA have been established, it is desirable to determine the length of time required for exposure of the liposome-DNA complex to the cells. In general, transfection efficiency increases with time of exposure to the liposome-DNA complex, although after 8 hr, toxic conditions can develop. HeLa or BHK-21 cells typically require ~3 hr incubation with the liposome-DNA complex for optimal transfection, while CV-1 and COS-7 cells require 5 hr of exposure.

UNIT 9.1

Calcium Phosphate Transfection

This unit presents two methods of calcium phosphate-based eukaryotic cell transfection that can be used for both transient and stable (UNIT 9.5) transfections. In these protocols, plasmid DNA is introduced to monolayer cell cultures via a precipitate that adheres to the cell surface. A HEPES-buffered solution is used to form a calcium phosphate precipitate that is directly layered onto the cells (see Basic Protocol). For some cells, shocking the cells with glycerol or DMSO (see Support Protocol) improves transfection efficiency. In the alternate high-efficiency method, a BES-buffered system is used that allows the precipitate to form gradually in the medium and then drop onto the cells (see Alternate Protocol). The alternate method is particularly efficient for stable transformation of cells with circular plasmid DNA. For transformation with linear plasmid or genomic DNA, or for transient expression, however, the Alternate Protocol is comparable to the Basic Protocol. Both methods of transfection require very high-quality plasmid DNA. Factors that can be optimized for calcium phosphate transfections are presented in the introduction to Section I, and protein expression strategies are discussed in Chapter 16. Additional details of mammalian cell culture are given in APPENDIX 3F.

BASIC PROTOCOL

TRANSFECTION USING CALCIUM PHOSPHATE-DNA PRECIPITATE FORMED IN HEPES

A precipitate containing calcium phosphate and DNA is formed by slowly mixing a HEPES-buffered saline solution with a solution containing calcium chloride and DNA. This precipitate adheres to the surface of cells and should be visible in the phase contrast microscope the day after transfection. Depending on the cell type, up to 10% of the cells on a dish will take up the DNA precipitate through an as yet undetermined mechanism. Glycerol or dimethyl sulfoxide shock increases the amount of DNA absorbed in some cell types (see Support Protocol).

Calcium Phosphate Transfection

9.1.4

Materials

- Exponentially growing eukaryotic cells (e.g., HeLa, BALB/c 3T3, NIH 3T3, CHO, or rat embryo fibroblasts)
- Complete medium (depending on cell line used)
- CsCl-purified plasmid DNA (10 to 50 μg per transfection)
- 2.5 M CaCl_2 (see recipe)
- 2 \times HEPES-buffered saline (HeBS; see recipe)
- PBS (APPENDIX 2)
- 10-cm tissue culture dishes
- 15-ml conical tube
- Additional reagents and equipment for ethanol precipitation (UNIT 2.1A) and mammalian cell tissue culture (APPENDIX 3F)

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly.

NOTE: All culture incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

1. Split exponentially growing eukaryotic cells into 10-cm tissue culture dishes the day before transfection. Feed cells with 9.0 ml complete medium 2 to 4 hr prior to precipitation.

When transfecting adherent cells that double every 18 to 24 hr, a 1:15 split from a confluent dish generally works well. On the day of the transfection, it is important that cells are thoroughly separated on the dish, as the ability to take up DNA is related to the surface area of the cell exposed to the medium. Cells should be split in a manner that accomplishes this.

The desired density of cells on dishes to be transfected will vary with cell type and the reason for doing the transfection. The optimal density is that which produces a near confluent dish when the cells are harvested or split into selective medium.

2. Ethanol precipitate the DNA to be transfected and air dry the pellet by inverting the microcentrifuge tube on a fresh Kimwipe inside a tissue culture hood. Resuspend the pellet in 450 μl sterile water and add 50 μl of 2.5 M CaCl_2 .

The amount of DNA that is optimal for transfection varies from 10 to 50 μg per 10-cm plate, depending on the cell line to be transfected.

DNA to be transfected should be purified twice by CsCl gradient centrifugation (UNIT 1.7). DNA can also be prepared using column procedures (UNIT 2.1B). Some column procedures produce DNA that does not transfect well, so column-purified DNA should be tested and compared to CsCl-purified DNA for transfection efficiency. Supercoiled DNA works well in transfections. Impurities in the DNA preparation can be deleterious to transfection efficiency. A description of how to optimize the amount of DNA to transfect and other parameters of calcium phosphate-mediated transfection is provided in the discussion of Optimization of Transfection.

Ethanol precipitation sterilizes the DNA to be transfected. For transfections that will be harvested within 3 to 4 days (transient analysis), this is not necessary. For transient experiments, many researchers make a 450- μl aqueous solution containing the DNA directly, without ethanol precipitation. If this is done, care should be taken to keep the amount of Tris in the solution to a minimum, as Tris may alter the pH of the precipitate and therefore reduce transfection efficiency.

3. Place 500 μl of 2 \times HeBS in a sterile 15-ml conical tube. Use a mechanical pipettor attached to a plugged 1- or 2-ml pipet to bubble the 2 \times HeBS and add the DNA/ CaCl_2

Figure 9.1.1 Formation of calcium phosphate precipitate.

solution dropwise with a Pasteur pipet (see Fig. 9.1.1). Immediately vortex the solution for 5 sec.

If no mechanical pipettor is available, the solution can be bubbled by blowing through rubber tubing that is attached to a pipet via a filter. The filter is necessary to maintain sterility. This does not give as reproducible results as the mechanical pipettor.

4. Allow precipitate to sit 20 min at room temperature.
5. Use a Pasteur pipet to distribute the precipitate evenly over a 10-cm plate of cells and gently agitate to mix precipitate and medium.
6. Incubate the cells 4 to 16 hr under standard growth conditions. Remove the medium. Wash cells twice with 5 ml PBS and feed cells with 10 ml complete medium.

The amount of time that the precipitate should be left on the cells will vary with cell type. For hardy cells such as HeLa, NIH 3T3, and BALB/c 3T3, the precipitate can be left on for 16 hr. Other cell types will not survive this amount of exposure to the precipitate. See discussion of Optimization of Transfection for optimization of this step as well as for a discussion of how to determine whether glycerol shock is useful.

7. For transient analysis, harvest the cells at the desired time point (UNITS 9.6-9.8 & 14.6). For stable transformation, allow the cells to double twice before plating in selective medium (UNIT 9.5).

GLYCEROL/DMSO SHOCK OF MAMMALIAN CELLS

The Basic Protocol works well for cell lines such as HeLa, BALB/c 3T3, NIH 3T3, and rat embryo fibroblasts. Transfection efficiency in some cell lines, such as CHO DUKX, is dramatically increased by “shocking” the cells with either glycerol or DMSO. Precipitates are left on the cell for only 4 to 6 hr, and the cells are shocked immediately after removal of the precipitate.

Additional Materials (also see *Basic Protocol*)

10% (v/v) glycerol solution or DMSO in complete medium, sterile
PBS (*APPENDIX 2*), sterile

Replace step 6 of the Basic Protocol with the following:

- 6a. Incubate the cells 4 to 6 hr and remove the medium. Add 2.0 ml of a sterile 10% glycerol solution. Let the cells sit 3 min at room temperature.

Alternatively, 10% or 20% DMSO can be used. DMSO tends to be somewhat less harmful to the cells, but also may not work as well.

- 6b. Add 5 ml of PBS to the glycerol solution on the cells, agitate to mix, and remove the solution. Wash twice with 5 ml of PBS. Feed the cells with complete medium.

It is important to dilute the glycerol solution on the cells with PBS before removing the glycerol solution so the cells do not stay in glycerol too long. Excessive exposure to glycerol will kill cells.

HIGH-EFFICIENCY TRANSFECTION USING CALCIUM PHOSPHATE–DNA PRECIPITATE FORMED IN BES

A solution of calcium chloride, plasmid DNA, and *N,N*-bis(2-hydroxyethyl)-2-aminoethanesulfonic acid (BES) buffer, pH 6.95, is added to a plate of cells containing culture medium. The plates are incubated overnight while a calcium phosphate–DNA complex forms gradually in the medium under an atmosphere of 3% CO₂. With this method, 10% to 50% of the cells on a plate stably integrate and express the transfected DNA. Transient expression under these conditions is comparable to that obtained with the Basic Protocol. Glycerol or DMSO shock does not increase the number of cells transformed.

Materials

Exponentially growing mammalian cells (see *Critical Parameters*)
Complete medium: Dulbecco modified Eagle medium containing 10% (v/v) fetal bovine serum (FBS)
CsCl-purified plasmid DNA
TE buffer, pH 7.4 (*APPENDIX 2*)
2.5 M CaCl₂ (see recipe)
2× BES-buffered solution (BBS; see recipe)
PBS (*APPENDIX 2*)
Selection medium (*UNIT 9.5*; optional)
10-cm tissue culture dishes
35°C, 3% CO₂ humidified incubator
35° to 37°C, 5% CO₂ humidified incubator
Fyrite gas analyzer (optional; Fisher Scientific or Curtin Matheson)

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly.

1. Seed exponentially growing mammalian cells at 5×10^5 cells/10-cm tissue culture dish in 10 ml complete medium the day prior to transfection.

There should be $<10^6$ cells/dish just prior to infection. Enough surface area should remain on the plate for at least two more doublings.

2. Dilute CsCl-purified plasmid DNA with TE buffer to $1 \mu\text{g}/\mu\text{l}$. Store the DNA solution at 4°C .

Purity of the plasmid DNA is critical.

The optimum amount of plasmid to use can be determined by transfecting three dishes of cells with 10, 20, and $30 \mu\text{g}$ of plasmid DNA and incubating overnight. The dishes should then be examined with a microscope at $100\times$. A coarse, clumpy precipitate will form at DNA concentrations that are too low, a fine (almost invisible) precipitate will form at concentrations that are higher than optimal, and an even, granular precipitate will form with optimal DNA concentrations.

3. Prepare 0.25 M CaCl_2 from 2.5 M stock. Mix 20 to $30 \mu\text{g}$ plasmid DNA with $500 \mu\text{l}$ of 0.25 M CaCl_2 . Add $500 \mu\text{l}$ of $2\times$ BBS, mix well, and incubate 10 to 20 min at room temperature.

4. Add the calcium phosphate–DNA solution dropwise onto the medium-containing plate while swirling the plate. Incubate 15 to 24 hr in a 35°C , 3% CO_2 incubator.

Level of carbon dioxide is critical. Use a Fyrite gas analyzer to measure percent CO_2 prior to incubation.

5. Wash the cells twice with 5 ml PBS, and add 10 ml complete medium. For stable transformation, incubate overnight in a 35° to 37°C , 5% CO_2 incubator. For studies involving transient expression (UNITS 9.6-9.8 & 14.6), incubate the cells for 48 to 72 hr after adding the DNA.

6. Split the cells 1:10 to 1:30, depending on the growth rate of the host cell, before beginning to select stable transformants. Incubate overnight in a 35° to 37°C , 5% CO_2 incubator.

7. Start selection by changing the medium to selection medium or by incubating cells under appropriate selection conditions (UNIT 9.5).

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

BES-buffered solution (BBS), $2\times$

50 mM *N,N*-bis(2-hydroxyethyl)-2-aminoethanesulfonic acid (BES;

Calbiochem-Novabiochem)

280 mM NaCl

1.5 mM Na_2HPO_4 , pH 6.95

800 ml H_2O

Adjust to pH 6.95 with 1 N NaOH, room temperature

Add H_2O to 1 liter

Filter sterilize through a $0.45\text{-}\mu\text{m}$ nitrocellulose filter (Nalgene)

Store in aliquots at -20°C

As discussed in the Commentary, the pH of this solution is critical (pH 6.95 to 6.98). When a new batch of $2\times$ BES buffer is prepared, its pH should be checked against a reference stock prepared (and tested) earlier.

This solution can be frozen and thawed repeatedly.

CaCl₂, 2.5 M

183.7 g CaCl₂·2H₂O (Sigma; tissue culture grade)

H₂O to 500 ml

Filter sterilize through a 0.45-μm nitrocellulose filter (Nalgene)

Store at -20°C in 10-ml aliquots

This solution can be frozen and thawed repeatedly.

HEPES-buffered saline (HeBS) solution, 2×

16.4 g NaCl (0.28 M final)

11.9 g HEPES (*N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid; 0.05 M final)

0.21 g Na₂HPO₄ (1.5 mM final)

800 ml H₂O

Titrate to pH 7.05 with 5 N NaOH

Add H₂O to 1 liter

Filter sterilize through a 0.45-μm nitrocellulose filter

Test for transfection efficiency

Store at -20°C in 50-ml aliquots

An exact pH is extremely important for efficient transfection. The optimal pH range is 7.05 to 7.12.

There can be wide variability in the efficiency of transfection obtained between batches of 2× HeBS. Efficiency should be checked with each new batch. The 2× HeBS solution can be rapidly tested by mixing 0.5 ml of 2× HeBS with 0.5 ml of 250 mM CaCl₂ and vortexing. A fine precipitate should develop that is readily visible in the microscope. Transfection efficiency must still be confirmed, but if the solution does not form a precipitate in this test, there is something wrong.

COMMENTARY

Background Information

Calcium phosphate transfection was first used to introduce adenovirus DNA into mammalian cells by Graham and van der Eb (1973). It was later found to be possible to integrate exogenous DNA into mammalian chromosomes using this technique (Wigler et al., 1978). The protocol described here has evolved from these methods; in particular, the order of addition of the HEPES-buffered saline solutions (HeBS) to calcium chloride is different. In addition, many investigators have found that it is not necessary to add chromosomal DNA as carrier when doing a transfection. Transfections work well if only plasmid DNA, such as pUC vectors, is used.

This HEPES-based approach has been used to analyze replication and promoter function using “transient” protocols, in which cells are harvested 48 to 60 hr after the transfection is started. It also is presently the most widely used technique for producing cell lines in which transfected DNA is stably integrated into the chromosome, although the BES-based technique (see Alternate Protocol) is gaining widespread use for production of stable transfor-

ants (UNIT 9.5). Calcium phosphate-mediated transfection tends to work much better than DEAE-dextran-mediated transfection (UNIT 9.2) in formation of stable cell lines. It is believed that this is because cells in a calcium phosphate transfection pick up more DNA than DEAE-dextran-transfected cells. Electroporation (UNIT 9.3) and liposome-mediated transfection (UNIT 9.4) can also be successfully used to produce stable cell lines.

Another major strength of calcium phosphate transfection is that transfected cells generally contain a representative sampling of the various plasmids in the precipitate. Hence, one can prepare a 10:1 ratio of two plasmids and expect that the plasmids will be present in that ratio in the transfected cells.

The BES-based high-efficiency calcium phosphate transfection (see Alternate Protocol) is a modification of the standard calcium phosphate method that employs a buffer system originally developed for phage particle-mediated gene transfer (Ishiura et al., 1982). With this buffer system the calcium phosphate-DNA precipitate forms gradually in the culture medium, dropping gently onto the cells over a 15-

to 24-hr period. This method can stably transform most common mammalian fibroblast and epithelial cell lines 10- to 100-fold more efficiently than other methods. For transient expression, it is no better than the standard method.

Critical Parameters and Troubleshooting

Calcium phosphate transfections are finicky—they are not difficult to do, they just do not always work—even in the hands of people who routinely do them. In the Basic Protocol, the most common reason for failure is a 2× HeBS solution that is no longer at the appropriate pH. The optimum pH range for transfection is extremely narrow (between 7.05 and 7.12; Graham and van der Eb, 1973). The pH of the solution can change during storage and an old 2× HeBS solution may not work well. Some investigators also have noticed that the 2.5 M CaCl₂ solution can go bad over time. Both solutions should be made fresh if transfections have stopped working well.

A second problem is that the pH of the medium can turn acidic while the transfection is in progress. This results in an extremely heavy precipitate (making the medium resemble orange juice) and generally results in cell death. Care should be taken to maintain a pH of 7.2 to 7.4 and CO₂ concentrations in the incubator as listed in the protocols. Incubator and medium conditions that are fine for routinely growing cells may not suffice for calcium phosphate transfection.

Many factors can influence the efficiency of HEPES-buffered calcium phosphate-mediated transfection. A description of experiments that can be done to optimize transfection efficiency using both this procedure and the BES procedure can be found in the discussion of Optimization of Transfection.

Several parameters are crucial to achieve high efficiency with the Alternate Protocol: pH of the 2× BES-buffered saline (BBS), percentage of carbon dioxide in the incubator during formation of precipitate, and form and amount of DNA used.

A pH curve of the 2× BBS buffer should be made because minor variations in pH can have substantial effects on transfection efficiency. Perform pilot experiments with buffers of varying pH. The optimal pH is within a very narrow range (6.95 to 6.98). Once the optimal buffer is found, use it as a reference to prepare buffer stocks. If no precipitate forms, the concentration of calcium chloride or 2× BES solution

(BBS) may be wrong. Be sure to mix reagents thoroughly before adding them to the DNA. Crystal formation upon the addition of calcium chloride indicates incorrect calcium chloride concentration, and the transfection must be repeated.

The first overnight incubation should be at 3% CO₂, but a variation of 0.5% may be acceptable. After overnight incubation at 3% CO₂ the culture medium should be alkaline (pH 7.6). Measure the CO₂ levels of the incubator before using. A Fyrite device is recommended for this.

Only plasmid DNA gives high efficiencies of gene transfer with the Alternate Protocol. Efficiency is also dependent on the purity and concentration of the DNA. Toxicity that often occurs with common fibroblasts and epithelial cell lines is usually caused by impure DNA, not calcium phosphate. DNA prepared by cesium chloride gradient centrifugation is rarely toxic to cells. The optimal DNA concentration varies among plasmid preparations as well as with different cells and media. Each new plasmid preparation and each new cell line being transfected should be tested for optimum DNA concentration.

If it is suspected that a particular plasmid preparation is toxic, use a control plasmid—one known not to be toxic to these cells—to test for toxicity. If the plasmid DNA is toxic, prepare new DNA.

Cotransfection efficiency is 10- to 20-fold better with the BES method (see Alternate Protocol) than with the Basic Protocol, although efficiencies vary with the plasmid and marker gene used. A 1:10 ratio of selectable marker to nonselected gene is recommended, but the efficiency of transfection will depend on optimum DNA dose. Glycerol shock or DMSO treatment will not increase the number of cells transfected with this method.

The BES protocol (see Alternate Protocol) has been optimized for use with cells that grow in Dulbecco modified Eagle medium containing 10% (v/v) fetal bovine serum (FBS). RPMI and minimal essential medium (MEM α) have also been demonstrated to give good results under the stated conditions. The FBS must be tested before use by examining the growth, plating efficiency, and transformation efficiency of at least two cell lines. (Serum is tested without heat inactivation.) Because FBS is very costly, 10% (v/v) newborn calf serum and 5% (v/v) FBS can be added to the medium (a total of 75 ml serum/500 ml medium) instead of 10% FBS. This gives equivalent efficien-

cies of stable transformation. The lots of newborn calf serum also must be tested for growth and plating efficiencies, as these have been found to vary. If horse or other serum or medium is required, optimum conditions may need to be rechecked.

The Alternate Protocol works well for most established cell lines that grow as monolayers, including mouse, rat, hamster, monkey, and human. It does not seem to work well for neuronal lines. This may be due to the deleterious effect of the calcium on these cells. Cells that grow in suspension are transfected rather poorly by this method, but their stable transformation frequencies seem to be better than those obtained by the Basic Protocol and almost comparable to those obtained by electroporation.

Anticipated Results

The efficiency that can be obtained with calcium phosphate-mediated transfection varies with cell type and other parameters as described. Methods for optimizing these parameters are presented in the discussion of Optimization of Transfection. Up to 10^3 colonies can be obtained by transfecting 1 μg of a plasmid containing a dominant selectable marker (*UNT 9.5*) into 10^6 cells by the HEPES-based protocol. Efficiencies for stable transformants are generally >10- to 100-fold higher when the BES-based protocol is used, with 10% to 50% of the cells on a plate stably transformed (Chen and Okayama, 1987). Transient expression is comparable in the Basic and Alternate Protocols (Chen and Okayama, 1988).

Time Considerations

For the Basic Protocol, preparation of twelve DNA precipitates and addition of the precipitates to the cells takes 1 to 2 hr. Without the ethanol precipitation step, the procedure can be done in 1 hr. With practice, the actual mixing of the CaCl_2 and $2\times$ HeBS solutions will take ~ 1 min. This means that up to eighteen precipitates can be made before the first precipitate is ready to apply to the cells.

For the Alternate Protocol, no ethanol precipitation step has been necessary for either transient or stable transfections. It takes slightly less time than the Basic Protocol because the $2\times$ BBS does not need to be added dropwise to the calcium chloride–DNA solution.

Transfection Using DEAE-Dextran

Transfection of cultured mammalian cells using diethylaminoethyl (DEAE)-dextran/DNA can be an attractive alternative to other transfection methods in many circumstances. The major advantages of the technique are its relative simplicity and speed, limited expense, and remarkably reproducible interexperimental and intraexperimental transfection efficiency. Disadvantages include inhibition of cell growth and induction of heterogeneous morphological changes in cells. Furthermore, the concentration of serum in the culture medium must be transiently reduced during the transfection. Any of these factors may adversely affect or be incompatible with some bioassays or experimental goals. In addition, for nonstandard cell types there may be a requirement for extensive preliminary investigation of optimal transfection conditions. Together, these factors influence the suitability of this technique to specific purposes. In general, DEAE-dextran DNA transfection is ideal for transient transfections with promoter/reporter plasmids in analyses of promoter and enhancer functions, and is suitable for overexpression of recombinant protein in transient transfections or for generation of stable cell lines using vectors designed to exist in the cell as episomes. The procedure may also be used for expression cloning (Aruffo and Seed, 1987; Kluxen and Lubbert, 1993; Levesque et al., 1991), although electroporation is usually preferred for this purpose (Puchalski and Fahl, 1992).

This unit presents a general description of DEAE-dextran transfection (see Basic Protocol) as well as two more specific protocols for typical experimental applications (see Alternate Protocols 1 and 2).

The Basic Protocol is suitable for transfection of anchorage-dependent (attached) cells. For cells that grow in suspension, electroporation (UNIT 9.3) or lipofection (UNIT 9.4) is usually preferred, although DEAE-dextran-mediated transfection can be used (Fregeau and Bleackley, 1991). For suspension cells, the transfection step should be performed on collected cells that have been resuspended at 10^7 cells/ml in transfection medium, using reagents and conditions that are otherwise similar to those of the Basic Protocol.

NOTE: All reagents and equipment coming into contact with live cells must be sterile, and proper sterile technique should be followed accordingly.

NOTE: All culture incubations are performed in a 37°C, 5% CO₂ incubator unless otherwise specified.

GENERAL PROCEDURE FOR DEAE-DEXTRAN TRANSFECTION

Cultured cells are incubated in medium containing plasmid DNA and DEAE-dextran, which form complexes that are taken up by cells via endocytosis. Chloroquine can be included to inhibit degradation of plasmid DNA. Cells are exposed transiently to DMSO or another permeabilizing agent to increase DNA uptake (DMSO “shock”). Important variables include the concentration of DEAE-dextran, the ratio of DNA to DEAE-dextran, the duration of transfection, and the presence and timing of chloroquine exposure (see Critical Parameters). This protocol is suitable for transfection of COS and CV1 cells; Alternate Protocols 1 and 2 describe two examples of transfection experiments.

Materials

- Cells to be transfected and appropriate culture medium (e.g., complete DMEM; APPENDIX 3F) with and without 10% FBS
- 100 mM (1000×) chloroquine diphosphate in PBS, filter-sterilized (store at 4°C)
- Plasmid DNA(s), prepared by CsCl density-gradient centrifugation or affinity chromatography (UNIT 1.7)

BASIC PROTOCOL

Introduction of DNA into Mammalian Cells

9.2.1

Contributed by Tod Gulick

Current Protocols in Molecular Biology (1997) 9.2.1-9.2.10

Copyright © 1997 by John Wiley & Sons, Inc.

TE buffer (*APPENDIX 2*)
 10 mg/ml DEAE-dextran stock solution (see recipe)
 10% (v/v) dimethyl sulfoxide (DMSO) in PBS, filter-sterilized (store up to 1 month at room temperature)
 Phosphate-buffered saline (PBS; *APPENDIX 2*)
 Appropriate-sized tissue culture vessels (Table 9.2.1)
 Inverted microscope
 Additional reagents and equipment for mammalian cell culture (*APPENDIX 3F*)

1. Plate cells at a density to achieve 50% to 75% confluence on the target day for transfection. For COS or CV1 cells, perform a 1:10 split 2 days prior to transfection.

The surface area of various cell culture vessels given in Table 9.2.1 can be used to determine how to split cells to the desired density.

Some cell types including many primary cells show particular sensitivity to the toxicity of DEAE-dextran. These cells should be plated at higher density or transfected after reaching near-confluence.

2. Determine the total volume of medium to be used in the transfection based on the number of culture vessels containing cells to be transfected and the volume per vessel shown in Table 9.2.1. Make up this amount of medium (plus some excess) to contain 2.5% FBS by combining 1 part medium containing 10% FBS with 3 parts serum-free medium.

DEAE-dextran can precipitate in the presence of high medium protein, necessitating use of a low FCS concentration. Alternatively, NuSerum (Collaborative Research), which contains only ~30% serum, can be used at a final concentration of 10%.

3. Add 100 mM (1000×) chloroquine diphosphate stock solution to the 2.5%-FBS-containing transfection medium prepared in step 2 to achieve a final concentration of 100 μM. Warm transfection medium to 37°C.

Table 9.2.1 Surface Areas of Commonly Used Tissue Culture Vessels and Corresponding Appropriate DEAE-Dextran Transfection Medium Volumes

Vessel	Area (cm ²)	Appropriate vol. DEAE-dextran medium ^a (ml)
T175 flask	175	
T150 flask	150	
T75 flask	75	
T25 flask	25	
150-mm dish	148 ^b	10
100-mm dish	55 ^b	4
60-mm dish	21 ^b	2
35-mm dish	8 ^b	1
6-well plate (35-mm wells)	9.4 ^b	1
12-well plate (22-mm wells)	3.8 ^b	0.5
24-well plate (15.5-mm wells)	1.9 ^b	0.25

^aThese volumes are roughly a linear function of vessel surface area. To ensure that cells are completely covered by medium during the transfection, small wells require proportionately larger volumes due to annular sequestration of medium because of surface tension at the periphery.

^bCostar; other manufacturer products may deviate slightly.

Chloroquine is toxic to all cells, so exposure time should be limited to <4 hr. If longer transfection times are required for optimal transfection of a particular cell type, chloroquine should be added during the final hours of the transfection.

4. Dilute plasmid DNA in TE buffer or distilled water to between 1.0 and 0.1 $\mu\text{g}/\mu\text{l}$, depending on the quantity to be transfected. Add the DNA solution directly to the warmed transfection medium to a final concentration of 1.0 $\mu\text{g}/\text{ml}$.

DNA solution(s) should comprise <1% of the total volume of transfection medium, so that the concentration of medium components is not significantly altered. Optimal DNA concentration in the transfection medium may have to be determined experimentally.

Maintaining dilute stock DNA solutions for dedicated use in transfections reduces interexperimental variation as well as the time required to set up transfection experiments.

5. Warm the 10 mg/ml DEAE-dextran stock solution to 37°C and mix thoroughly by inversion. Add to the DNA-supplemented transfection medium to a final concentration of 100 $\mu\text{g}/\text{ml}$ DEAE-dextran and mix by inversion.

The order of addition to the transfection medium is critical. Adding plasmid DNA to medium that has already been supplemented with DEAE-dextran can result in precipitation, seen as a rosy white glob. Optimal DEAE-dextran concentration in the transfection may have to be determined experimentally.

6. Aspirate medium from the 50% to 70% confluent cell cultures (see step 1) and replace with the appropriate volume of 37°C DEAE-dextran/DNA-supplemented transfection medium (see Table 9.2.1). Incubate 4 hr.

Uniformity of transfection efficiency may be improved by placing culture vessels on a rocker platform within the incubator during the transfection to ensure even exposure of cells to DEAE-dextran/DNA in the medium and to avoid desiccation of cells in the center of the vessel. Optimal transfection time may have to be determined experimentally.

7. Examine cells with an inverted microscope.

Cells may appear granular, some cell nuclei may appear pyknotic, and some cell borders may be somewhat ragged. An efficient DEAE-dextran transfection is usually associated with 25% to 75% cell death.

8. Warm the 10% DMSO/PBS to 37°C. Aspirate the transfection medium, note the volume, and replace with 2 to 3 volumes of 37°C DMSO/PBS. Incubate at room temperature for >2 but <10 min. Aspirate the DMSO/PBS and wash the cell layer with a volume of PBS equal to the amount of DMSO/PBS removed. Aspirate and replace with a standard amount of complete medium containing 10% FBS.

Loss of firm cellular anchorage to the culture vessel may occur. Medium exchange and cell washing should therefore involve careful aspiration and pipetting, perhaps by holding the tip of the pipet against a wall of the culture dish or well. It is sometimes advisable to omit the PBS wash (as in the experiment described in Alternate Protocol 1, step 8) and simply add the complete medium, then change the medium a second time several hours after the DMSO shock when cells have recovered and are more firmly adherent.

9. Continue incubating the cells and analyze at times appropriate to the bioassay or intended purpose of the experiment.

The onset and duration of expression of the transfected gene varies from one cell type to another, and especially with the expression vector used. It is advisable to perform a parallel transfection with a readily assayable reporter gene in the identical vector to assess the temporal features of expression. A reporter that is secreted by the cell into the culture medium, such as human growth hormone or secreted alkaline phosphatase, is ideal for this purpose, since aliquots of medium from a single transfection sample can be collected at serial time points. This parallel transfection can also be used in preliminary experiments to optimize transfection conditions.

SAMPLE EXPERIMENT: TRANSFECTION TO TEST PROMOTER FUNCTION

In this protocol for a typical application of DEAE-dextran transfection, a thyroid hormone–response element in a hormone-responsive gene promoter will be mapped. Thyroid hormone (T_3) modulates transcription by activating the thyroid hormone receptor (TR), a transcription factor that binds to specific response elements in target-gene promoters as a heterodimer with the retinoid X receptor (RXR). Expression of TR, but not RXR, is minimal and limiting in fibroblasts, such that overexpression of TR using an expression vector significantly increases transcriptional response to T_3 in these cells. In this example, four promoter/reporter constructs will be tested, representing a promoter 5' deletion series. The hormones, retinoids, and fatty acids in fetal bovine serum (FBS) can interfere with or cause high background in transcription assays in transfected cells. These moieties can be removed from FBS by charcoal treatment (see Reagents and Solutions).

This protocol corresponds step-for-step with Basic Protocol; variations from the original procedure and reagents specific to this particular experiment are noted.

Additional Materials (also see Basic Protocol)

- CV-1 cells (ATCC #CCL 70) growing in 100-mm dish
- Complete DMEM medium (APPENDIX 3F) with and without 10% FBS
- Complete DMEM medium (APPENDIX 3F) with 10% charcoal-treated FBS (see Support Protocol)
- Plasmid DNAs:
 - Control reporter plasmid (e.g., β -galactosidase, secreted alkaline phosphatase, or growth hormone, driven by a viral promoter)
 - Four test promoter constructs (promoter/CAT or promoter/luciferase; UNIT 9.6)
 - Expression plasmid with TR gene insert (pTR)
 - No-insert expression plasmid (p[–])
- Complete DMEM medium (APPENDIX 3F) with 10% charcoal-treated FBS (see Support Protocol), supplemented with 10 nm thyroid hormone (T_3)
- 12-well tissue culture plates
- 100-ml tissue culture dishes
- Additional reagents and equipment for trypsinizing and subculturing monolayer cells (APPENDIX 3F) and analyzing reporter gene activity (UNITS 9.6 & 9.7)

1. Two days prior to the transfection, trypsinize and suspend CV1 cells from a confluent 100-mm dish in 36 ml complete DMEM medium/10% FBS. Place 1 ml complete DMEM/10% FBS in each well of four 12-well plates, then add 250 μ l of the cell suspension to each of these wells. Plate the residual cells in 100-mm dishes for later use, or discard. 12 to 24 hr before the transfection, change medium to complete DMEM/10% charcoal-treated FBS.

The sensitivity of most reporter assays permits use of many fewer cells/transfection conditions than are generally used, with consequent cost savings. CV1 cells in a well of a 12-well plate will provide sufficient reporter-gene activity for most promoter/reporters. In this protocol, triplicate wells for each condition will be analyzed. Four promoter/CAT or promoter/luciferase reporters (UNITS 9.6 & 9.7) will be tested. Cells will include or exclude pTR cotransfection. Transfected cells will be incubated in the presence or absence of T_3 . Thus, four 12-well plates are required for the experiment—i.e., 3 wells (triplicates) \times 4 wells (four reporters) \times 2 wells (with and without pTR cotransfection) \times 2 wells (with and without T_3) = 48 wells. These 48 wells include \sim 180 cm^2 (see Table 9.2.1) such that approximately one-third of the cells on one 100-mm (55 cm^2) dish will be used in order to achieve a 1:10 split.

Addition of suspended cells to empty tissue culture plates or wells results in an uneven distribution of adherent cells, which can introduce undesirable intersample variability; hence medium is added to the wells first.

Preincubation in medium supplemented with charcoal-stripped FBS (see Support Protocol) ensures that any hormones of interest are absent from medium bathing the control cells during subsequent experiments.

2. Add 7 ml DMEM/10% charcoal-treated FBS to 21 ml serum-free DMEM to make 28 ml of DMEM/2.5 % FBS.

In this experiment, the FBS in the DMEM/10 has been stripped of low molecular weight hydrophobic moieties, including T_3 , using charcoal.

The amount here was calculated as 48 wells multiplied by 0.5 ml/well, and a small excess was added. In experiments in which the transfection medium will be divided into multiple aliquots carrying different plasmids or plasmid combinations, it is useful to carry a volume excess throughout the preparation of the separate transfection media to adjust for pipet-calibration errors.

3. Add 28 μ l 100 mM chloroquine diphosphate to the medium and place the tube in a 37°C water bath.
4. Dilute the reporter plasmids (control and test promoter constructs) in TE buffer to 1 μ g/ μ l; dilute the TR (pTR) and no-insert (p[-]) expression plasmids in TE buffer to 0.2 μ g/ μ l. Add 14 μ l of the diluted reporter plasmid to the transfection medium (final concentration, 0.5 μ g/ml). Divide this medium into four equal 6.6-ml aliquots and add 6.6 μ l of a test promoter construct to each separate tube (final concentration, 1 μ g/ml). Divide each of these into two tubes, each containing 3.2 ml. Add 8 μ l pTR to one set of four tubes and 8 μ l p[-] to the other set of four tubes (final concentration, 0.5 μ g/ μ l). Use each of these eight transfection medium samples to transfect cells within six wells in step 6, below.

All cells will be transfected with a control reporter—e.g., β -galactosidase, secreted alkaline phosphatase, or growth hormone—driven by a viral promoter. Each of the four test promoter/reporters will be transfected into cells within 12 wells. A TR expression vector will be transfected into 6 of each of these sets of 12 wells. Cells in triplicate wells in each of these conditions will be cultured in medium supplemented with T_3 , while those in the other triplicate wells will be cultured in medium devoid of T_3 .

Plasmids that are included in more than one transfection condition are added prior to division of medium into separate aliquots to ensure that these samples receive equivalent amounts of plasmid DNA. The final concentration of DNA in each transfection medium sample should be equivalent. For this and other reasons, an “empty vector” should be used as described for p[-] above.

5. Warm the stock DEAE-dextran to 37°C, mix by inversion, and add 32 μ l to each of the eight tubes containing DNA-supplemented transfection medium (final DEAE-dextran concentration, 100 μ g/ml). Mix by gentle inversion.
6. Aspirate medium from six wells on one plate, and replace with one of the eight transfection-medium samples prepared in step 4 at 500 μ l per well. Repeat for each of the different transfection-medium samples. Incubate 4 hr.
7. Examine cells with inverted microscope.
8. Aspirate medium from wells in one plate and add 1 ml DMSO/PBS per well. Repeat for each plate. Return to the first plate, aspirate the DMSO/PBS and replace with 1 ml/well complete DMEM/10% charcoal-treated FBS. Incubate cells for 4 to 12 hr. Aspirate medium from wells and replace the medium from one set of triplicate wells for each transfection condition with 1 ml/well T_3 -supplemented DMEM/10% char-

coal-treated FBS and the other set of triplicate wells for each transfection condition with (T_3 -unsupplemented) DMEM/10% charcoal-treated FBS.

9. Incubate cells 24 to 48 hr. Aspirate 500 μ l of medium from each separate well and save for control reporter activity determinations in order to normalize test reporter activities. Wash wells with PBS and harvest cells for CAT or luciferase activity measurements (UNITS 9.6 & 9.7).

Reporter activity is used to confirm and quantitate promoter T_3 responsiveness ($+T_3/-T_3$), to verify a direct transcriptional response mediated by the TR (augmentation of response to T_3 in pTR-cotransfected cells), and to map the T_3 -responsive region of the promoter (region present in a T_3 -responsive promoter/reporter and absent in an unresponsive one).

The use of a control reporter permits normalization for transfection efficiency, and for nonspecific-stimulus effects on gene expression. In many cases, when using this transfection technique, adequate and informative preliminary experiments can be conducted without this control (since transfection efficiency is so uniform), thereby saving time and expense. This is seldom possible when using other transient-transfection techniques, especially calcium phosphate coprecipitation (UNIT 9.1), where transfection efficiency varies markedly within an experiment. Of course, initial experiments should be performed to exclude nonspecific stimulus effects.

ALTERNATE PROTOCOL 2

SAMPLE EXPERIMENT: TRANSFECTION TO TEST ENZYME STRUCTURE/ACTIVITY RELATIONSHIPS

In this experimental application of DEAE-dextran transfection, an enzyme and several enzyme mutants are overexpressed in COS cells to provide material for kinetic analyses in a structure/activity analysis. A vector designed for high-level expression that replicates in SV40-transformed cells (e.g., CDM8) will be used.

This protocol corresponds step-for-step with Basic Protocol; variations from the original procedure and reagents specific to this particular experiment are noted.

Additional Materials (also see Basic Protocol)

- COS cells (ATCC #1650) growing in 100-mm dish
- Complete DMEM medium (APPENDIX 3F) with and without 10% FBS
- Control plasmid containing reporter gene (e.g., luciferase, CAT, or secreted alkaline phosphatase)
- CDM8 vectors containing gene for wild-type enzyme and genes for four mutant enzymes
- 100-ml tissue culture dishes

Additional reagents and equipment for analyzing reporter gene activity (UNITS 9.6 & 9.7) and analysis of recombinant proteins (Chapter 10)

1. Two days prior to the transfection, split five 100-mm dishes of confluent COS cells into 50 100-mm dishes.

Ten 100-mm dishes of COS cells will provide sufficient recombinant enzyme activity for kinetic analyses. Recombinant wild-type enzyme and four mutant enzymes will be overexpressed. Thus, 50 dishes are required for this experiment.

2. Add 50 ml DMEM/10% FBS to 150 ml serum-free DMEM to make 200 ml DMEM/2.5% FBS.

This was calculated as 50 dishes at 4 ml/100-mm dish (see Table 9.2.1).

3. Warm the transfection medium in a 37°C water bath. Do not add chloroquine diphosphate.

Chloroquine treatment increases DEAE-dextran transfection efficiency, but may reduce the amount of recombinant protein produced by the transfected cells. It is advisable to test this in early pilot experiments.

4. Dilute the reporter gene plasmid and each of the CDM8/enzyme expression vectors to 1 µg/µl in TE buffer. Add 20 µl reporter plasmid to the transfection medium and mix (final concentration, 0.1 µg/ml). Divide the medium into five aliquots of 40 ml. Add 160 µl of one CDM8/enzyme expression plasmid to one aliquot (final concentration, 4 µg/ml) and repeat this for each of the CDM8/enzyme expression plasmids.

All cells will be transfected with a control plasmid containing a reporter gene such as luciferase, CAT, or secreted alkaline phosphatase to evaluate transfection efficiency. Each of the five enzyme expression vectors will be used to transfect cells in ten dishes.

If the COS cells have an endogenous activity identical or similar to the activity of the recombinant protein to be overexpressed, it may be prudent to include cells that are transfected with “empty vector” in experiments of this type to permit parallel assays of endogenous COS cell activities for “background” subtraction.

Plasmids may compete for replication and/or transcription factors. The control reporter plasmid can be included at low concentration because the reporter has a very sensitive assay.

5. Warm the stock DEAE-dextran to 37°C, mix by inversion, and add 800 µl to each of the tubes containing DNA-supplemented transfection medium (final DEAE-dextran concentration, 200 µg/ml). Mix by gentle inversion.
6. Aspirate medium from ten dishes and replace with 4 ml of the appropriate DEAE-dextran/DNA-supplemented transfection medium. Repeat for each set of ten dishes. Incubate 3 hr.
7. Examine cells with inverted microscope. Continue the transfection until some cells appear slightly granular.
8. Aspirate transfection medium from one of the sets of ten dishes and replace with 10 ml/dish DMSO/PBS. After 2 min, aspirate the DMSO/PBS and wash gently with 10 ml PBS. Aspirate PBS and add 10 ml DMEM/10 FBS. Repeat for each set of ten dishes.
9. Incubate cells 48 to 96 hr. Harvest cells as appropriate for recombinant protein assays. Save aliquots of culture medium (for secreted control reporter) or cell extract (intracellular reporter) to determined transfection efficiency.

Normalization for transfection efficiency may not be necessary, particularly in circumstances where an independent assay for recombinant protein production is available, as might be provided by a specific antibody.

CHARCOAL STRIPPING OF FETAL BOVINE SERUM

Activated charcoal is used to remove low-molecular-weight lipophilic compounds from serum including hormones, retinoids, and fatty acid ligands of nuclear receptor transcription factors.

Materials

Fetal bovine serum (FBS), heat-inactivated (*APPENDIX 3F*)

Activated charcoal, acid-washed (Sigma)

Ultracentrifuge with Beckman SW 28, JA-20.1, or equivalent swinging-bucket rotor

SUPPORT PROTOCOL

Introduction of DNA into Mammalian Cells

9.2.7

1. Add 2 g activated charcoal per 100 ml heat-inactivated FBS. Add a stir-bar and place on a stir plate in a 4°C cold room or refrigerator. Stir for 2 hr.

Although it is difficult to maintain sterile conditions during charcoal stripping, care should be taken to avoid flagrant contamination and to keep the serum at 4°C.

2. Collect serum in centrifuge tubes and centrifuge 30 min at $72,000 \times g$ (20,000 rpm in SW 28 rotor) or 60 min at $51,500 \times g$ (20,000 rpm in JA-20.1), 4°C.

3. Gently pour off serum from each centrifuge tube into a sterile beaker, divide into aliquots in sterile conical tubes, and store frozen at -20°C .

Some residual charcoal may be present but the serum should be only lightly peppered with charcoal after centrifugation.

4. Prior to use, thaw a tube of charcoal-stripped medium and use immediately to supplement complete medium. Filter sterilize the medium using a 0.22- μm bottle-top filter and collect in a sterile bottle. Store at 4°C.

The serum is filtered after it is added to the medium because the undiluted serum is too viscous to filter readily.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

DEAE-dextran stock solution, 10 mg/ml (100 \times)

Make a 10 mg/ml stock solution of diethylaminoethyl (DEAE)-dextran (mol. wt. $\sim 500,000$ Da; Sigma) in tissue culture-quality PBS (APPENDIX 2). Mix well, filter sterilize using an 0.22- μm filter, mix again, divide into aliquots, and store up to 3 months at 4°C.

Warm to 37°C and mix well by inversion immediately before each use.

COMMENTARY

Background Information

The mechanism by which cells take up DNA in DEAE-dextran-mediated transfection appears to involve endocytosis after adsorption of DNA/DEAE-dextran complexes onto cells. The advantages of the technique relate largely to the relative simplicity, limited expense, and lack of interexperimental and intraexperiment variability in transfection efficiency.

Critical Parameters

There are several crucial parameters in the transfection procedure, and the weight of importance of each differs for different cell types. Furthermore, maximizing efficiency of a transfection (percent of cells transfected) does not necessarily correspond with optimizing the desired goal of the transfection, such as production of recombinant protein (Kluxen and Lubbert, 1993) or maintenance of colony-forming potential of cells containing transfected DNA (Puchalski and Fahl, 1992). Systematic analyses of variables in DEAE-dextran/DNA trans-

fection for particular cell types have been reported (Fregeau and Bleackley, 1991; Puchalski and Fahl, 1992; Kluxen and Lubbert, 1993; Yang and Yang, 1997), and these studies provide useful information. However, the existence of numerous variables and their mutual codependence makes interpolation, extrapolation, or guessing transfection conditions toward any specific end for any particular cell type difficult to extract from literature reports. Thus, the investigator should carry out a modest set of pilot experiments to optimize conditions.

The major variables that influence DEAE-dextran/DNA transfection include: (1) DEAE-dextran concentration; (2) DNA concentration and the ratio of DNA concentration to DEAE-dextran concentration; (3) duration of transfection; (4) use of chloroquine; (5) use of permeabilizing agents; and (6) serum concentration. The influence of each of these factors on the various goals of DNA transfection will be addressed.

The concentration of DEAE-dextran used in transfections varies from 50 to 500 $\mu\text{g/ml}$. There is an inverse relationship between the concentration used and the duration of exposure prior to onset of cytotoxicity for all cell types. In initial experiments, it may be best to use a low concentration (100 or 200 $\mu\text{g/ml}$) to provide an adequate temporal window to evaluate cytotoxicity microscopically. Lethal cytotoxicity can precede microscopic evidence of the same, such that transfections with high concentrations of DEAE-dextran can result in near-complete cell loss even when most cells appear healthy at the end of the transfection period.

The DNA concentration used depends in part on the vector, cell type, and the purpose of the transfection. For maximal cell adsorption of complexes and maximal transfection efficiency, the ratio of transfection-medium DEAE-dextran concentration to DNA concentration should be 40:1 to 50:1, perhaps because of the existence of an optimal electrostatic cell membrane/DEAE-dextran/DNA-complex interaction (Yang and Yang, 1997). Thus, at a DEAE-dextran concentration of 200 $\mu\text{g/ml}$, plasmid DNA should be included at 4 to 5 $\mu\text{g/ml}$. Since this ratio influences transfection efficiency, "empty vector" should be included in controls at the same concentration as test vectors. This ideal [DEAE-dextran]/[DNA] ratio may depend on transfection-medium serum concentration.

The amounts of DNA to be used in cotransfection experiments again depend on the intended purpose of each component transfection. When a control reporter plasmid is used to simply normalize for transfection efficiency, it is often possible and desirable to include a low concentration of the plasmid, since reporter enzyme assays are generally exquisitely sensitive. In experiments in which simultaneous cotransfection of single cells with two plasmids is a goal, it is appropriate to add the plasmids at the same or similar concentrations. Furthermore, transfection efficiency is of paramount importance in this circumstance, since the percentage of cells that take up both plasmids is a fraction of those that take up each alone. This is particularly important in a case like that presented in Alternate Protocol 1, where coexistence of the transcription-factor expression vector and the promoter/reporter plasmid in a single cell is important.

DEAE-dextran-mediated cytotoxicity is a function of exposure time. In general, efficient transfections can be achieved with a 4-hr incu-

bation if other parameters are adjusted appropriately. This is a convenient transfection duration since it corresponds to the maximal allowable period of cell exposure to chloroquine. Shorter transfection times may be appropriate for some cell types.

The utility of chloroquine in increasing the efficiency of DEAE-dextran transfection is well documented. However, there may be an attenuation in the amount of transfected gene expression (Kluxen and Lubbert, 1993) and increased cell loss and disruption of cellular morphology (Puchalski and Fahl, 1992) when this reagent is included. Thus, use of chloroquine is appropriate for purposes where transfection efficiency is a dominant priority. In other cases, preliminary experiments should evaluate the impact of this agent on the bioactivity desired. While some investigators add chloroquine in the final stage of (or after) a longer transfection, it is generally easier to increase the DEAE-dextran concentration in this circumstance to permit a single 4-hr transfection in medium containing all components.

Using a final cell "shock" with a permeabilizing agent markedly increases DEAE-dextran transfection efficiency without additional cytotoxicity (Lopata, et al, 1984) and should be used universally, unless this manipulation somehow interferes with the desired bioactivity. DMSO at a concentration of 10% is generally used, although 15% glycerol may be more effective for some cell types. Enhancement of transfection efficiency increases as a function of permeabilizing-agent exposure time up to 2 min, after which there is no additional impact (Sussman and Milman, 1984). Since longer exposure, up to 5 to 10 min, produces no negative effect, the "shock" should be for >2 min, but need not be rigorously timed or reproduced, even between transfected samples within an experiment.

Use of transfection medium supplemented with 10% FBS results in formation of macroscopic protein/DEAE-dextran/DNA complexes that are not compatible with efficient transfection. Serum-free medium can be used during the transfection, as can medium supplemented with either 2.5% FBS or 10% NuSerum. The concentration of serum in the transfection medium affects the extent of DEAE-dextran-mediated and chloroquine-mediated cytotoxicity, with a protective effect provided by the serum. FBS concentration may also influence the optimal ratio of [DEAE-dextran]/[DNA].

Anticipated Results

The efficiency of DEAE-dextran-mediated transfection varies considerably among cell types. One can expect to achieve 20% to 60% transfection efficiency with many cells using this procedure if proper attention is paid to optimization of transfection conditions. Following transfection using this technique, there are generally significant morphological changes in cells, and some of these may weigh against the use of this technique for certain purposes.

Time Considerations

Splitting cells into the required number of plates several days prior to the transfection may take ~30 min. Depending on the complexity of the transfection, preparing transfection media may take 5 min to 1 hr. If stock solutions of DNA, DEAE-dextran, chloroquine, and DMSO/PBS are prepared in advance, 30 min should be adequate for this phase, even in a moderately complex transfection experiment like that presented in Alternate Protocol 1. During the subsequent transfection, cells should be monitored using a microscope periodically after 3 hr. The DMSO or glycerol shock, cell wash, and medium replacement requires only ~10 min. Thus, with minimal but careful planning of experimental design, a transfection can readily be completed in 5 hr.

Transfection by Electroporation

UNIT 9.3

Electroporation—the use of high-voltage electric shocks to introduce DNA into cells—is a procedure that is gaining in popularity. It can be used with most cell types, yields a high frequency of both stable transformation and transient gene expression, and, because it requires fewer steps, can be easier than alternate techniques (UNITS 9.1, 9.2, 9.4 and introduction to Section I).

The basic protocol describes the electroporation of mammalian cells. The alternate protocol outlines modifications for preparation and transfection of plant protoplasts.

ELECTROPORATION INTO MAMMALIAN CELLS

**BASIC
PROTOCOL**

Electroporation can be used for both transient and stable (UNIT 9.5) transfection of mammalian cells. Cells are placed in suspension in an appropriate electroporation buffer and put into an electroporation cuvette. DNA is added, the cuvette is connected to a power supply, and the cells are subjected to a high-voltage electrical pulse of defined magnitude and length. The cells are then allowed to recover briefly before they are placed in normal growth medium. Factors that can be varied to optimize electroporation effectiveness are discussed in introduction to Section I, and protein expression strategies are discussed in Chapter 16.

Materials

Mammalian cells to be transfected

Complete medium (APPENDIX 3F) without and with appropriate selective agents (UNIT 9.5)

Electroporation buffer, ice-cold

Linear or supercoiled, purified DNA preparation (see step 7)

Beckman JS-4.2 rotor or equivalent

Electroporation cuvettes (Bio-Rad #165-2088) and power source

Additional reagents and equipment for stable transformation in selective medium (UNIT 9.5) and for harvesting transfected cells (UNITS 9.6-9.8 & 14.6)

Prepare the cells for electroporation

1. Grow cells to be transfected to late-log phase in complete medium. Each permanent transfection will usually require 5×10^6 cells to yield a reasonable number of transfectants. Each transient expression may require $1-4 \times 10^7$ cells, depending on the promoter.
2. Harvest cells by centrifuging 5 min at $640 \times g$ (1500 rpm in a JS-4.2 rotor), 4°C.
Adherent cells are first trypsinized (introduction to Chapter 9) and the trypsin inactivated with serum.
3. Resuspend cell pellet in half its original volume of ice-cold electroporation buffer.
The choice of electroporation buffer may depend on the cell line used. See critical parameters for a complete discussion.
4. Harvest cells by centrifuging 5 min as in step 2.
5. Resuspend cells at 1×10^7 /ml in electroporation buffer at 0°C for permanent transfection. Higher concentrations of cells (up to 8×10^7) may be used for transient expression.

Supplement 62

6. Transfer 0.5-ml aliquots of the cell suspension into desired number of electroporation cuvettes set on ice.

Add DNA and electroporate the cells

7. Add DNA to cell suspension in the cuvettes on ice.

For stable transformation, DNA should be linearized by cleavage with a restriction enzyme (UNIT 3.1) that cuts in a nonessential region and purified by phenol extraction and ethanol precipitation (UNIT 2.1). For transient expression, the DNA may be left supercoiled. In either case, the DNA should have been purified through two preparative CsCl/ethidium bromide equilibrium gradients (UNIT 1.7) followed by phenol extraction and ethanol precipitation. The DNA stock may be sterilized by one ether extraction (UNIT 2.1); the (top) ether phase is removed and the DNA solution allowed to dry for a few minutes to evaporate any remaining ether.

For transient expression, 10 to 40 μg is optimal. For stable transformation, 1 to 10 μg is sufficient. Cotransfection (UNIT 9.5), although not recommended because of the work required to select and test transformants, can be done with 1 μg of a selectable marker containing DNA and 10 μg of the DNA containing the gene of interest.

8. Mix DNA/cell suspension by holding the cuvette on the two “window sides” and flicking the bottom. Incubate 5 min on ice.
9. Place cuvette in the holder in the electroporation apparatus (at room temperature) and shock one or more times at the desired voltage and capacitance settings.

The number of shocks and the voltage and capacitance settings will vary depending on the cell type and should be optimized (critical parameters; see also introduction to Section I).

10. After electroporation, return cuvette containing cells and DNA to ice for 10 min.

Culture and harvest the transfected cells

11. Dilute transfected cells 20-fold in nonselective complete medium and rinse cuvette with this same medium to remove all transfected cells.
- 12a. For stable transformation: Grow cells 48 hr (about two generations) in nonselective medium, then transfer to antibiotic-containing medium.

Selection conditions will vary with cell type. For example, neo selection generally requires ~400 $\mu\text{g}/\text{ml}$ G418 in the medium. XGPRT selection requires 1 $\mu\text{g}/\text{ml}$ mycophenolic acid, 250 $\mu\text{g}/\text{ml}$ xanthine, and 15 $\mu\text{g}/\text{ml}$ hypoxanthine in the medium (see UNIT 9.5).

It is often convenient to plate adherent cells at limiting dilution (see UNIT 11.8) immediately following the shock, or suspension cells at the time of antibiotic addition.

- 12b. For transient expression: Incubate cells 50 to 60 hr, then harvest cells for transient expression assays.

Transfected cells can be visualized by standard transient expression assays (UNITS 9.6A-9.7).

ALTERNATE PROTOCOL

ELECTROPORATION INTO PLANT PROTOPLASTS

This is a modification of the basic protocol that is intended for use with plant cells. Plant cells are stripped of their cell walls and DNA is introduced into the resulting protoplasts.

Additional Materials

- 5-mm strips (1 g dry weight) sterile plant material
- Protoplast solution
- Plant electroporation buffer
- 80- μm -mesh nylon screen
- Sterile 15-ml conical centrifuge tube

Additional reagents and equipment for plant RNA preparation (UNIT 4.3)

1. Obtain protoplasts from carefully sliced 5-mm strips of sterile plant material by incubating in 8 ml protoplast solution for 3 to 6 hr at 30°C on a rotary shaker.
2. Remove debris by filtration through an 80- μ m-mesh nylon screen.
3. Rinse screen with 4 ml plant electroporation buffer. Combine protoplasts in a sterile 15-ml conical centrifuge tube.
4. Centrifuge 5 min at $300 \times g$ (1000 rpm in a JS-4.2 rotor). Discard supernatant, add 5 ml plant electroporation buffer, and repeat wash step. Resuspend in plant electroporation buffer at $1.5\text{--}2 \times 10^6$ protoplasts/ml.

Protoplasts can be counted with a hemacytometer (UNIT 1.2).

5. Carry out electroporation as described for mammalian cells (steps 6 to 11 of the basic protocol). Use one or several shocks at 1 to 2 kV with a 3- to 25- μ F capacitance as a starting point for optimizing the system.

Alternatively, use 200 to 300 V with 500 to 1000 μ F capacitance if the phosphate in the electroporation buffer is reduced to 10 mM final.

6. Harvest cells after 48 hr growth and isolate RNA, assay for transient gene expression, or select for stable transformants.

Protoplasts can also be selected and grown into full transgenic plants (Rhodes et al., 1988).

REAGENTS AND SOLUTIONS

Electroporation buffers

Choice of electroporation buffer depends on the cells being used in the experiment (see critical parameters). The following buffers (stored at 4°C) can be used:

1. PBS (APPENDIX 2) without Ca^{++} or Mg^{++}
2. HEPES-buffered saline (HeBS; UNIT 9.1)
3. Tissue culture medium without FCS (introduction to Chapter 9)
4. Phosphate-buffered sucrose: 272 mM sucrose/7 mM K_2HPO_4 (adjusted to pH 7.4 with phosphoric acid)/1 mM MgCl_2

Plant electroporation buffer

Prepare in PBS (APPENDIX 2):

0.4 M mannitol
5 mM CaCl_2
Store at 4°C

Protoplast solution

2% (w/v) cellulase (Yakult Honsha)
1% (w/v) macerozyme (Yakult Honsha)
0.01% (w/v) pectylase
0.4 M mannitol
40 mM CaCl_2
10 mM 2-[*N*-morpholino]ethanesulfonic acid (MES), pH 5.5
Prepare fresh before use

COMMENTARY

Background Information

DNA transfection by electroporation is a technique that is applicable to perhaps all cell types. It yields a high frequency of stable transformants and has a high efficiency of transient gene expression. Electroporation makes use of the fact that the cell membrane acts as an electrical capacitor that is unable to pass current (except through ion channels). Subjecting membranes to a high-voltage electric field results in their temporary breakdown and the formation of pores that are large enough to allow macromolecules (as well as smaller molecules such as ATP) to enter or leave the cell. The reclosing of the membrane pores is a natural decay process that is delayed at 0°C.

During the time that the pores are open, nucleic acid can enter the cell and ultimately the nucleus. Linear DNA with free ends is more recombinogenic and more likely to be integrated into the host chromosome to yield stable transformants. Supercoiled DNA is more easily packaged into chromatin and is generally more effective for transient gene expression.

The use of high-voltage electric shocks to introduce DNA into cells was first performed by Wong and Neumann using fibroblasts (Wong and Neumann, 1982; Neumann et al., 1982). The technique was then generalized (Potter et al., 1984) to all cell types—even those such as lymphocytes that, unlike fibroblasts, cannot be transfected with other procedures (e.g., calcium phosphate or DEAE-dextran DNA coprecipitates). Although whole plants or leaf tissue have been reported to be transfectable by electroporation, plant cells must generally be made into protoplasts before DNA can be easily introduced into them (alternate protocol; Fromm et al., 1985; Ou-Lee et al., 1986). Like mammalian cells, plant protoplasts may be electroporated under a variety of electrical conditions (critical parameters). Both high voltage with low capacitance (short pulse duration) or low voltage with high capacitance (long pulse duration) have been used to achieve successful gene transfer (Chu et al., 1991).

The wide use of electroporation has been made possible in large part by the availability of commercial apparatuses that are safe and easy to use and that give extremely reproducible results. Designs of these machines vary substantially, but fall into two basic categories that use different means of controlling pulse duration and voltage (the two electrical parameters that govern pore formation). One kind

uses a capacitor discharge system to generate an exponentially decaying current pulse, and the other generates a true square wave (or an approximation thereof). The capacitor discharge instruments charge their internal capacitor to a certain voltage and then discharge it through the cell-DNA suspension. Both the size of the capacitor and the voltage can be varied. Because the current pulse is an exponentially decaying function of (1) the initial voltage, (2) the capacitance setting of the instrument, and (3) the resistance of the circuit (including the sample), changing the capacitor size to allow more (or less) charge to be stored at the voltage will result in longer (or shorter) decay times and hence a different effective pulse duration. In contrast, square wave generators control both the voltage and pulse duration with solid-state switching devices. They also can produce rapidly repeating pulses.

Most of our electroporation experiments have used the Bio-Rad Gene Pulser, a capacitor discharge device, but are directly applicable to other capacitor discharge devices, and with some adjustment to square wave generators. Capacitor discharge devices are also available from GIBCO/BRL, BTX, Hoefer Scientific, and International Biotechnologies (see *APPENDIX 4* for suppliers' addresses). These machines, either in a single unit or through add-on components, can deliver a variety of electroporation conditions suitable for most applications. Square wave generators are available from BTX or Baekon and offer great control over pulse width, allow multiple, rapid pulses, and can be more effective for cells that are very sensitive or otherwise difficult to transfect. These machines are generally more expensive. It has become apparent that alternating current pulses at ~100 kHz may be the most effective wave form for electroporation and possibly electrofusion (Chang, 1989). However, dedicated electroporation devices utilizing such waves are not yet commercially available and must be constructed from components. For a complete discussion of electroporation instruments, see Potter (1988).

Electroporation can be easier to carry out than alternative techniques, which is why it is becoming popular. Its drawback for use with transient analysis is that almost five-fold more cells and DNA are needed than with either calcium phosphate- or DEAE-dextran-mediated transfection (*UNITS 9.1, 9.2, & 16.12*). The main difference between electroporation and

calcium phosphate coprecipitation procedures is the state of the integrated DNA after selection in appropriate antibiotic media. In the case of calcium phosphate, the amount of DNA taken up and integrated into the genome of each transfected cell is in the range of 3×10^6 bp. As a result, the transfected DNA often integrates as large tandem arrays containing many copies of the transfected DNA. This would be an advantage when transfection of genomic DNA into recipient cells and selection for some phenotypic change such as malignant transformation is desired; here a large amount of DNA integrated per recipient cell is essential. In contrast, electroporation can be adjusted to result in one to many copies of inserted DNA per recipient cell. This would be an advantage for gene expression studies, as the identity of the particular copy responsible for the gene expression can be controlled.

Critical Parameters

As discussed above, the two parameters that are critical for successful electroporation are the maximum voltage of the shock and the duration of the current pulse (see also introduction to Section I). The voltage and capacitance settings must be optimized for each cell type, with the resistance of the electroporation buffer being critical for choosing the initial instrument settings. The guidelines presented in this unit are meant to be adapted according to the manufacturers' instructions and the individual investigator's needs. Optimal stable and transient transformation occur at about the same instrument settings, so transient expression can be used to optimize conditions for a new cell type.

For low-resistance (high-salt) buffers such as PBS, HeBS, or tissue culture medium, start with a capacitor setting of 25 μ F and a voltage of 1200 V for 0.4-cm cuvettes, then increase or decrease the voltage until optimal transfection is obtained (usually at ~40% to 70% cell viability as detected by trypan blue exclusion; *UNIT 9.6A*). For many cell types, the choice between PBS, HeBS, and tissue culture medium is arbitrary. However, some cells (especially primary cells) are very easily killed and thus electroporate poorly at the high voltages needed for PBS or HeBS electroporation buffers. Particularly sensitive cells seem to prefer tissue culture medium, though it has been shown that the calcium and magnesium ions in the medium lower the electroporation efficiency (Neumann et al., 1982). Phosphate-buffered sucrose has the advantage that it can be optimized at voltages several hundred volts below those used

with PBS or HeBS. Alternatively, Chu et al. (1991) found many sensitive cells were electroporated more effectively in HeBS with a low voltage/high capacitance setting that resulted in at least 10-fold longer pulse duration. For these conditions, start at 250 V/960 μ F and change the voltage up to 350 V or down to 100 V in steps to determine optimal settings.

Keeping cells on ice (at 0°C) often improves cell viability and thus results in higher effective transfection frequency, especially at high power which can lead to heating (Potter et al., 1984). However, Chu et al. (1991) found that under low voltage/high capacitance conditions, some cell lines electroporate with higher efficiency at room temperature. Therefore, steps 6 to 10 of the basic protocol should be carried out separately at both temperatures to determine the optimum conditions for a new cell line.

Another factor contributing to cell death appears to be the pH change that results from electrolysis at the electrodes. This problem can be reduced by replacing some of the ionic strength of the PBS with extra buffer (e.g., 20 mM HEPES, pH 7.5).

Optimal parameters for plant electroporation differ depending on whether tissue culture cells or various parts of the whole plant are used as a source of protoplasts. In particular, the high salt in PBS can be damaging to protoplasts freshly produced from plant tissue. Replacing the NaCl in PBS with 135 mM LiCl may increase CAT transient gene expression (*UNIT 9.6A*) in electroporated plant protoplasts 4- to 70-fold (Saunders et al., 1989). Alternatively, an electroporation buffer of 0.6 M mannitol/25 mM KCl for leaf cells, or 0.7 M mannitol/40 mM KCl/4 mM MES (pH 5.7)/1 mM 2-ME added for root and stem cells, is recommended (Sheen, 1990). In addition, 0.1% BSA/15 mM 2-ME/1 mM MgCl₂ can be added to either protoplast isolation buffer and the CaCl₂ reduced to 1 mM final. A low salt concentration in the electroporation buffer reduces the optimal capacitance setting to 200 μ F.

Anticipated Results

The efficiency of transfection by electroporation is dependent upon cell type. For fibroblasts, which are easily transfected by calcium phosphate or DEAE-dextran coprecipitation (*UNITS 9.1 & 9.2*), electroporation gives a stable transformation frequency of 1 in $\sim 10^3$ to 10^4 live cells—approximately that obtainable by the above traditional procedures. For cells refractory to traditional methods, electroporation gives a stable transformation frequency be-

tween 1 in 10^4 to 10^5 for most cell types. Occasionally a cell line (e.g., some T lymphocytes) will transfect poorly under our standard conditions (1 in 10^6), and even this frequency is sufficient to obtain significant numbers of transfectants. In general, cells that transfect efficiently for stable transformants also do so for transient gene expression. Increasing the number of cells and the amount of DNA used in the electroporation for studying transient gene expression can circumvent problems of low transfection efficiency and low promoter/enhancer efficiency.

For plant protoplast electroporation, the frequency of stable transformants is between 1 in 10^2 and 1 in 10^3 dividing cells.

Time Considerations

The entire process of electroporation of mammalian cells will take <1 hr. Electroporation of plant cells requires ≤ 6 hr to prepare the protoplasts and <1 hr for the actual electroporation process. As with other transfection procedures, the experiment should be planned to allow for harvest or splitting of the cells 1 to 2 days after transfection.

Transfection of Cultured Eukaryotic Cells Using Cationic Lipid Reagents

The development of high-efficiency methods for the introduction of functional genetic material into eukaryotic cells using cationic lipid-based transfection reagents has accelerated biology research in the studies of gene expression, control of cell growth, and cell lineage. Cationic lipid-mediated transfection techniques are commonly used in industrial protein production as well as in some clinical gene therapy protocols.

Most natural lipids are either neutral or negatively charged (anionic). Positively charged (cationic) lipids were first introduced in 1987 (Felgner et al., 1987). The cationic lipids function by spontaneous electrostatic interaction of their positive charges with the negative charges in the backbone of DNA, RNA, or oligonucleotides, condensing the extended macromolecules to a compact structure. The cationic charges and the lipophilic nature of the cationic lipids then allow the condensed aggregates to interact with and cross the negatively charged and hydrophobic cell membrane and enter the target cells. It is also possible to deliver some proteins into cells using cationic lipids (Sells et al., 1995). Most (but not all) cationic lipid reagents used for transfection consist of mixtures of cationic and neutral lipids (e.g., DOPE, cholesterol) that are formulated in water to yield noncovalent structures called liposomes—hollow spheres with aqueous cores and a diameter of 100 to 400 nm (Felgner et al., 1987). Some are dissolved in ethanol and form micelles (Behr et al., 1989). There are many cationic lipid reagents available (see Background Information and Table 9.4.1). They perform with various efficiencies in different applications and target cells.

This unit describes cationic lipid-mediated transfection of a variety of cell types. DNA transfection is presented for adherent mammalian cells (cell lines as well as primary cultures; see Basic Protocol 1), along with a modified protocol for enhanced transfection (see Alternate Protocol). DNA transfection of suspension mammalian cells (lymphoid, myeloid, and leukemic-derived cells) is also presented (see Basic Protocol 2). For adherent mammalian cells, RNA transfection is also covered (see Basic Protocol 3). Finally, DNA transfection is presented for insect cells (see Basic Protocol 4). To determine

the best transfection conditions for a particular reagent, use the optimization/fine-tuning procedure (see Support Protocol).

NOTE: There are minor differences among the recommended protocols for the various commercially available cationic lipid reagents. The appropriate product profile sheets should be consulted before beginning an experiment.

NOTE: All culture incubations for mammalian cells should be performed in a humidified 37°C, 5% CO₂ incubator. Some media may require altered levels of CO₂ (e.g., for growth of CHO cells in suspension, 8% CO₂ is preferable) to maintain pH 7.4. Insect cells are cultured at 27°C.

BASIC PROTOCOL 1

CATIONIC LIPID-MEDIATED TRANSFECTION OF ADHERENT MAMMALIAN CELLS WITH DNA

This protocol describes the procedure for transfection of DNA into most adherent mammalian cell lines or cultures of primary cells grown attached to culture vessels (Fig. 9.4.1). DNA and lipid reagent are diluted into separate aliquots of serum-free medium, and are then mixed together and allowed to form complexes. Complexes and transfection medium (which may contain serum) are added to the cells in one of two ways. Either the complexes are diluted with transfection medium and this mixture is added to cells that have been rinsed and aspirated (as shown in Fig. 9.4.1), or complexes are added directly to transfection medium that has already been added to the cells (with or without washing). The cells and complexes are incubated together for several hours. After transfection, the volume of the medium is increased if necessary to prevent drying, serum is added if the transfection was serum free, and cells are incubated an additional day or two to allow expression of the transgene.

It is advisable to optimize the conditions for transfection using the Support Protocol. Suggested starting ranges for optimizing the various components of these mixtures are given in Table 9.4.2 for six different popular culture vessel sizes. Transfections can be scaled up to other vessel sizes by increasing the amounts of lipid, DNA, and medium in

Figure 9.4.1 Diagram of cationic lipid-mediated transfection procedure.

proportion to the difference in surface area. Table 9.4.3 shows the surface areas of several popular culture vessels.

Adherent cells

Cell culture medium with serum (e.g., complete DMEM, *APPENDIX 3F*)

Dilution medium: serum-free cell culture medium or specialized medium for lipid-mediated transfection (e.g., Opti-MEM I, Life Technologies)

Plasmid DNA, purified by anion-exchange chromatography (e.g., Concert High Purity columns, Life Technologies; or see *UNIT 2.1B* or Goldsborough et al., 1998), cesium chloride density gradient (*UNIT 1.7*), or alkaline lysis (*UNIT 1.6*)

Cationic lipid reagent (see Table 9.4.1)

Polystyrene or polypropylene tubes

Additional reagents and equipment for trypsinization and counting of cells (*APPENDIX 3F*), Xgal staining (*UNIT 9.11*), and selection of stable transformants (*UNIT 9.5*)

1. The day before transfection, trypsinize and count adherent cells (*APPENDIX 3F*). Plate cells in cell culture medium with serum so that they are 50% to 95% confluent on the day of transfection. Avoid antibiotics at the time of plating and during transfection.

The single most important factor in reproducible, high-efficiency transfection is a consistent number of healthy, proliferating cells. Transfection is most efficient when the cells are

Table 9.4.2 Suggested Starting Ranges of Reagents for Lipid-Mediated Transfection^a

Culture vessel	DNA (μg)	Dilution medium (μl)	Cationic lipid reagent (μl)	Transfection medium (ml)	Transfection volume (ml)
	Step 2	Steps 2 & 3	Step 3	Step 5	Step 6
96-well	0.05-0.4	10-25	0.075-1.5	0.08-0.1	0.1-0.15
24-well	0.2-1.6	25-50	0.5-10	0.2-0.5	0.25-0.6
12-well	0.4-3.2	50-100	1-20	0.4-1	0.5-1.2
6-well	1-8	100-250	2.5-50	0.8-2.5	1-3
60-mm	2-16	250-500	5-100	2-5	2.5-6
100-mm	6-48	750-1500	15-300	5-15	6.5-18

^aStep numbers are indicated from Basic Protocol 1. Volumes have been optimized for LipofectAmine 2000. See Support Protocol for additional optimization strategies.

Table 9.4.3 Surface Areas of Commonly Used Culture Vessels

Culture vessel	Surface area (cm ²)
96-well	0.3
24-well	2
12-well	4
6-well	10
35-mm	8
60-mm	20
100-mm	60
150-mm	140
T25	25
T75	75
T150	150

maintained in mid-log growth. Because transfection efficiency is sensitive to culture confluency, cultures should be maintained carefully and passaged frequently, and a standard seeding protocol should be followed from one experiment to the next. Antibiotics may cause some toxicity if present during transfection. For some transfection reagents, the higher cell density is recommended (90% to 95%).

Multiwell cell culture dishes are the easiest to use. Some cells are weakly adherent. If necessary, increase adherence by plating cells on polylysine-coated wells (0.1 mg/ml poly-L-lysine, Sigma; poly-D-lysine-precoated plates, Becton Dickinson).

This protocol is written without specific amounts of reagents. Table 9.4.2 gives the recommended starting amounts for several popular vessels. See Support Protocol for fine tuning the reagent volumes for highest transfection efficiency.

2. On the day of transfection, dilute plasmid DNA into dilution medium in a polystyrene or polypropylene tube and mix. Prepare in bulk for multiple transfections.

Although DNA prepared by anion-exchange chromatography (UNIT 2.1B) or CsCl gradients (UNIT 1.7) yield the best results, DNA prepared by alkaline lysis (miniprep; UNIT 1.6) will work with lower efficiency.

Commercial medium that is specialized for lipid-mediated transfection (e.g., Opti-MEM I) yields the highest efficiency, but other serum-free media may be used.

Polystyrene or polypropylene tubes work well for dilutions. For small-scale transfections, round-bottom 96-well plates with covers are suitable.

3. Dilute cationic lipid reagent into dilution medium in a second tube and mix. Prepare in bulk for multiple transfections.

See Table 9.4.1 for a partial listing of commercially available reagents. A preparation of the cationic lipid DDAB with the neutral lipid DOPE can be made in the laboratory (Rose et al., 1991), although efficiency may be lower than with some commercial preparations.

If using Lipofectin, dilute into Opti-MEM I and allow to incubate at room temperature for 30 to 45 min (Ciccarone and Hawley-Nelson, 1995). If using LipofectAmine 2000, dilute into Opti-MEM I and allow to incubate no more than 30 min (Ciccarone et al., 1999).

4. Combine diluted DNA and diluted cationic lipid reagent, mix, and incubate for 15 min at room temperature.

Incubation times >15 min (up to 6 hr for some reagents) work just as well.

5. While complexes are forming, replace medium on the cells with the appropriate volume of fresh transfection medium.

This step is not necessary if the complexes are diluted with transfection medium or if using LipofectAmine 2000 (see step 6).

This medium can be the same as the dilution medium. It is possible to use serum in the transfection medium at this step.

6. Add DNA-lipid complexes to each well containing cells. Mix complexes into the medium gently, holding the plate at a slant. Incubate 5 hr at 37°C in 5% CO₂.

Adding transfection medium directly to the cells (as described in the steps) helps prevent cells in multiwell plates from drying out, as transfection medium can be added to multiple wells rapidly. Alternatively, complexes can be diluted with the appropriate volume of fresh transfection medium and added to cells from which the cell culture medium has been aspirated (with or without washing, see Fig. 9.4.1). If using LipofectAmine 2000, fresh transfection medium is not required. Undiluted complexes can be added directly to the cell culture medium.

The exposure time may be >5 hr (up to overnight). Be sure that there is sufficient medium to prevent the cells from drying out (it is not necessary to increase other components if this

is done). If necessary to maximize cell growth, replace the medium containing complexes with fresh complete medium after 5 hr incubation.

7. After 5 hr incubation, add cell culture medium to reach normal volume and add serum to bring the final concentration to that of normal cell culture medium.

This step is omitted in some protocols, especially when serum is present during transfection and volumes are adequate to prevent drying.

- 8a. *For transient expression analysis:* Assay cell extracts or stain cells (UNIT 9.11) in situ 24 to 48 hr after the start of transfection, depending on cell type and promoter activity.
- 8b. *For stable expression analysis:* Passage cells into fresh culture medium 1 day after the start of transfection. At 2 days posttransfection, add the appropriate antibiotic to select for expression of the transfected antibiotic-resistance gene (UNIT 9.5).

Several days or weeks of selection are required for stable expression.

ENHANCED CATIONIC LIPID-MEDIATED TRANSFECTION OF ADHERENT MAMMALIAN CELLS WITH DNA

**ALTERNATE
PROTOCOL**

This is an efficient and reproducible protocol for transfection of DNA into most adherent mammalian cell lines or cultures of primary cells grown attached to culture vessels (Dube, 1997; Shih et al., 1997; Fig. 9.4.2). The procedure is essentially as described in Basic Protocol 1, except that DNA is diluted into serum-free medium along with a proprietary enhancing reagent and incubated for 15 min, allowing the formation of precomplexed DNA before addition to the diluted cationic lipid reagent.

Figure 9.4.2 Diagram of enhanced cationic lipid-mediated transfection procedure.

**Introduction of
DNA into
Mammalian Cells**

9.4.5

Table 9.4.4 Suggested Starting Amounts of Reagents for Transfection with LipofectAmine Plus^a

Culture vessel	DNA (μg)	Plus reagent (μl)	Dilution medium (μl)	LipofectAmine (μl)	Transfection medium (ml)	Transfection volume (ml)
	Step 2	Step 2	Steps 2 & 3	Step 3	Step 5	Step 6
96-well	0.1	1	10	0.5	0.08	0.1
24-well	0.4	4	25	1	0.2	0.250
12-well	0.7	5	50	2	0.4	0.5
6-well	1	6	100	4	0.8	1.0
60-mm	2	8	250	12	2	2.5
100-mm	4	20	750	30	5	6.5

^aStep numbers indicated from Alternate Protocol. It is possible to fine tune transfections by testing a range of lipid and DNA concentrations to obtain optimal efficiency; however, the peak activity is usually a broad plateau with this reagent.

The protocol that follows was developed for LipofectAmine Plus, which is composed of two reagents: LipofectAmine (the cationic lipid reagent) and Plus reagent (the enhancer). One of the main advantages of the Plus enhancer is a high plateau of transfection activity across a broad range of lipid and DNA concentrations. This decreases the necessity for optimization and allows the recommendation of specific starting conditions (Table 9.4.4). Transfections can be scaled up to other vessel sizes by increasing the amounts of lipid, DNA, enhancer, and medium in proportion to the difference in surface area (see Table 9.4.3).

The other commercially available enhanced cationic lipid reagent is Effectene (Qiagen, see Table 9.4.1). If using this product, consult the appropriate product profile sheets before beginning the experiment.

NOTE: Consult annotations of the standard transfection procedure (see Basic Protocol 1) for additional details, which also apply to this protocol.

Additional Materials (also see Basic Protocol 1)

Cationic lipid reagent and enhancer (e.g., LipofectAmine Plus, including LipofectAmine and Plus reagents; Life Technologies)

1. The day before transfection, trypsinize and count adherent cells (*APPENDIX 3F*). Plate cells in cell culture medium with serum so that they are 50% to 80% confluent on the day of transfection. Avoid antibiotics at the time of plating and during transfection.

For this protocol, refer to Table 9.4.4 for recommended amounts of reagents in different vessels.

2. On the day of transfection, dilute plasmid DNA into dilution medium in a polystyrene or polypropylene tube and mix well. Add enhancer, mix, and incubate 15 min at room temperature.

DMEM is preferred over Opti-MEM 1 in this protocol. It is important to add the DNA first and mix well before adding the Plus reagent to avoid precipitation of the DNA. Incubation times >15 min (up to an hour) work just as well.

3. Dilute cationic lipid reagent into dilution medium in a second tube and mix.
4. Combine precomplexed DNA and diluted cationic lipid reagent, mix, and incubate for 15 min at room temperature.

Incubation times >15 min (up to an hour) work just as well when LipofectAmine is the cationic lipid and Plus reagent is the enhancer.

5. While complexes are forming, replace medium on the cells with the appropriate volume of fresh transfection medium.

The medium can be the same as the dilution medium. It is possible to use serum in the transfection medium at this step. In some cells (e.g., HeLa and NIH 3T3), transfection in medium containing serum is as efficient or more efficient than in medium without serum.

6. Add DNA-enhancer-lipid complexes to each well containing cells. Mix complexes into the medium gently, holding the plate at a slant. Incubate at 37°C in 5% CO₂ for several hours.

The exposure time with LipofectAmine Plus may be as short as 3 hr or up to overnight. Be sure there is sufficient medium to prevent the cells from drying out (it is not necessary to increase other components if this is done).

7. After incubation, add cell culture medium to reach normal volume and add serum to bring the final concentration to that of normal cell culture medium.

8. Perform transient or stable expression analysis (see Basic Protocol 1, steps 8a and 8b).

CATIONIC LIPID-MEDIATED TRANSFECTION OF SUSPENSION CELLS WITH DNA

BASIC PROTOCOL 2

This protocol is essentially the same as for adherent cells (see Basic Protocol 1) in that lipid and DNA are diluted separately into dilution medium, mixed, and allowed to form complexes before exposing to cells. However, complexes are formed in the wells of multiwell culture plates, and cells are then distributed into the wells containing complexes and allowed to transfect.

Materials

Dilution medium: cell culture medium without serum or specialized medium for transfection (e.g., Opti-MEM I, Life Technologies)

Cationic liposome reagent (e.g., DMRIE-C or LipofectAmine 2000, Life Technologies; also see Table 9.4.1)

Plasmid DNA, purified by anion-exchange chromatography (UNIT 2.14 or Goldsborough et al., 1998), cesium chloride density gradient (UNIT 1.7), or alkaline lysis (UNIT 1.6)

Cell suspension: 1 × 10⁷ cells/ml in normal cell culture medium without serum or antibiotics

Cell culture medium (e.g., complete DMEM; APPENDIX 3F)

Serum

6-well tissue culture plates

1. To each well of a 6-well tissue culture plate add 0.5 ml dilution medium.

Commercial medium that is specialized for lipid-mediated transfection (e.g., Opti-MEM I), without serum or antibiotics, gives the best results. However, other serum-free media may also be used.

When transfecting in different-sized culture plates, change the amounts of DNA, cationic lipid reagent, and medium in proportion to the difference in surface area (see Table 9.4.3).

2. Add 0, 2, 4, 6, 8, or 12 μl cationic lipid reagent to each well and mix gently by swirling the plate.

DMRIE-C was found to give high efficiency transfection of DNA in Jurkat (human T cell lymphoma), K562 and KG-1 (human myelogenous leukemia), and MOLT-4 (human lymphoblastic leukemia) cell lines. It is a lipid suspension that may settle with time. To ensure that a homogenous sample is taken, mix thoroughly by inverting the tube 5 to 10 times before removing a sample for transfection.

Introduction of DNA into Mammalian Cells

9.4.7

3. Add 0.5 ml dilution medium containing 4 μg plasmid DNA to each well. Mix by swirling plate.

The amount of DNA should be optimized for each cell line.

4. Incubate at room temperature for 15 to 45 min to allow formation of lipid-DNA complexes.

5. Add 0.2 ml cell suspension (2×10^6 cells) to each well and mix gently.

The single most important factor in reproducible, high-efficiency transfection is a consistent number of healthy, proliferating cells. Transfection is most efficient when the cells are maintained in mid-log growth.

6. Incubate several hours at 37°C in a 5% CO₂ incubator.

A 4-hr incubation is adequate for DMRIE-C transfections.

7. To each well add 2 ml cell culture medium containing 1.5 \times the usual amount of serum.

For Jurkat and MOLT-4 cells, addition of 1 $\mu\text{g}/\text{ml}$ phytohemagglutinin (PHA) and 50 ng/ml phorbol myristate acetate (PMA) enhances promoter activity and gene expression. For K562 and KG-1 cells, PMA alone enhances promoter activity.

8. Assay the cells at 24 or 48 hr posttransfection for transient or stable expression (see Basic Protocol 1, step 8a or 8b).

BASIC PROTOCOL 3

CATIONIC LIPID-MEDIATED TRANSFECTION OF ADHERENT CELLS WITH RNA

In this protocol, lipid is first diluted into dilution medium and mixed. RNA is then mixed directly into the diluted lipid and immediately added to cells (which have been rinsed with serum-free medium), and cells are incubated for transfection.

Materials

Adherent cells

Cell culture medium with serum (e.g., complete DMEM; *APPENDIX 3F*)

Dilution medium: serum-free cell culture medium or specialized medium for transfection (e.g., Opti-MEM I, Life Technologies)

Cationic lipid reagent (e.g., DMRIE-C, Life Technologies; also see Table 9.4.1)
mRNA (*UNIT 4.5*)

6-well or 35-mm tissue culture plate

12 \times 75-mm polystyrene tubes

Additional reagents and equipment for trypsinizing, counting, and plating cells

(*APPENDIX 3F*)

1. The day before transfection, trypsinize and count adherent cells (*APPENDIX 3F*). In each well of a 6-well tissue culture plate, or in six 35-mm tissue culture plates, seed $\sim 2\text{--}3 \times 10^5$ cells in 2 ml of the appropriate cell culture medium supplemented with serum.

Transfection is most efficient when the cells are growing rapidly. Cultures should be maintained carefully and passaged frequently. As transfection efficiency may be sensitive to culture confluency, it is important to maintain a standard seeding protocol from experiment to experiment.

2. Incubate at 37°C in a 5% CO₂ incubator until the cells are $\sim 80\%$ confluent.

This will usually take 18 to 24 hr, but the time will vary among cell types.

3. On the day of transfection, wash the cells in each well with 2 ml dilution medium at room temperature.

Commercial medium that is specialized for lipid-mediated transfection (e.g., Opti-MEM I), without serum or antibiotics, gives the best results. However, other serum-free media may also be used.

4. Add 1.0 ml dilution medium to each of six 12 × 75–mm polystyrene tubes.
5. Add 0, 2, 4, 6, 8, or 12 µl cationic lipid reagent to each tube and mix or vortex briefly.

DMRIE-C was found to give high-efficiency transfection of RNA in adherent cell lines (Ciccarone et al., 1995). It is a lipid suspension that may settle with time. To ensure that a homogenous sample is taken, mix thoroughly by inverting the tube 5 to 10 times before removing a sample for transfection.

6. Add 2.5 to 5.0 µg RNA to each tube and vortex briefly.

mRNA that is capped and polyadenylated is translated more efficiently and is more stable within the cell.

7. Immediately add lipid-RNA complexes to washed cells and incubate 4 hr at 37°C in a 5% CO₂ incubator.

The time of exposure of cells to lipid-RNA complexes, as well as the amount of RNA added to the cells, should be adjusted for each cell type.

8. Replace transfection medium with cell culture medium containing serum.
9. Allow cells to express the RNA for 16 to 24 hr and analyze them for expression of the transfected RNA as appropriate for the transgene used.

CATIONIC LIPID–MEDIATED TRANSFECTION OF ADHERENT Sf9 AND Sf21 INSECT CELLS WITH BACULOVIRUS DNA

BASIC PROTOCOL 4

As for transfecting mammalian cells (see Basic Protocol 1), cationic lipid reagent and nucleic acid are diluted separately into serum-free medium and then mixed and allowed to form complexes. Complexes are then diluted with fresh transfection medium and added to the cells for transfection. After the cells are fed and incubated, budded virus can be isolated from the medium.

Materials

Insect cells: Sf9 or Sf21 cells (UNIT 16.9)

Insect medium (UNIT 16.9; e.g., Sf-900 II SFM, Life Technologies) with and without serum and antibiotics

Baculovirus DNA: purified DNA or bacmid DNA miniprep (UNITS 16.9 & 16.10; Anderson et al., 1995)

Cationic lipid reagent (Table 9.4.1)

6-well tissue culture plate

27°C incubator

12 × 75–mm polystyrene tubes, sterile

Additional reagents and equipment for culturing insect cells and harvesting baculovirus from cell supernatants (UNIT 16.10)

1. In each well of a 6-well tissue culture plate, seed $\sim 9 \times 10^5$ insect cells in 2 ml insect medium without serum or antibiotics (UNIT 16.10).

Insect cells must be plated when they are in mid-log growth phase. Cells that have reached stationary phase transfect and infect at very low efficiency. Therefore, it is advisable to

Introduction of DNA into Mammalian Cells

9.4.9

maintain a standard cell passage protocol that keeps the cells in log growth. For Sf9 or Sf21 cells adapted in Sf-900 II SFM, cells are passaged twice weekly to a density of 3×10^5 cells/ml in suspension, and plated for transfection on the third day postseeding, when they are in mid-log phase. For other cell culture media and growth conditions, adjust conditions to maintain similar growth characteristics.

For culture of insect cells, use 50 units/ml penicillin and 50 μ g/ml streptomycin (half the usual final concentration). For transfection, it is preferable to omit antibiotics from the medium to avoid toxicity.

2. Allow cells to attach at 27°C for ≥ 1 hr.
3. For each transfection, dilute 1 to 2 μ g baculovirus DNA into 100 μ l insect medium without serum or antibiotics in a 12 \times 75-mm polystyrene tube.
4. For each transfection, dilute 1.5 to 9 μ l cationic lipid reagent into 100 μ l insect medium without serum or antibiotics in a separate 12 \times 75-mm polystyrene tube.

The suggested amount is 6 μ l, but this should be optimized for each system.

CellFectin gives high-efficiency transfection of DNA in insect cell lines (Anderson et al., 1995). It is a lipid suspension that may settle with time. To ensure that a homogenous sample is taken, mix thoroughly by inverting the tube 5 to 10 times before removing a sample for transfection.

5. Combine the two solutions, mix gently, and incubate at room temperature for 15 to 45 min to form lipid-DNA complexes.
6. For each transfection, add 0.8 ml insect medium without serum or antibiotics to each tube containing lipid-DNA complexes and mix gently.
7. Aspirate medium from cells and overlay diluted lipid-DNA complexes onto the washed cells.

Alternatively, the medium on the cells can be replaced with 0.8 ml fresh insect medium and the undiluted complexes can be added directly to the fresh medium on the cells.
8. Incubate cells for 5 hr in a 27°C incubator. Protect plates from evaporation by putting them in a humidified container.
9. Remove transfection mixture and add 2 ml insect medium containing antibiotics and serum, if desired. Incubate cells in a 27°C incubator for 72 hr.
10. Harvest baculovirus from cell supernatants (UNIT 16.10).

Gene expression may also be evaluated in the cells after removal of virus-containing medium.

SUPPORT PROTOCOL

FINE TUNING OR OPTIMIZING CONDITIONS FOR CATIONIC LIPID REAGENT TRANSFECTIONS

This protocol provides an example of a simple one-step procedure for determining conditions conducive to high-efficiency transfections using cationic lipid reagents in any target cell type. A matrix of DNA and lipid reagent concentrations is used on transfections performed in a multiwell plate (Fig. 9.4.3). Once the best conditions have been determined, the transfections may be scaled up to larger vessels using the relative surface area (see Table 9.4.3) to increase the amounts of all reagents proportionately. This protocol can be modified for use with any transfection protocol.

Additional Materials (also see *Basic Protocol 1* and *Alternate Protocol*)

- 24-well tissue culture plates
- 96-well round-bottom plates (sterile, with lid)

1. The day before transfection, trypsinize and count cells (*APPENDIX 3F*). Plate cells in each well of a 24-well tissue culture plate using normal cell culture medium with serum, so that they are 50% to 95% confluent on the day of transfection. Avoid antibiotics at the time of plating and during transfection.

The single most important factor in high-efficiency transfection is healthy, proliferating cell cultures. Antibiotics may cause some toxicity if present during transfection.

In a 24-well plate, seeding 4×10^4 to 2×10^5 cells per well will usually give good plating density. Any type of plate may be used by scaling the reagent and cell amounts in proportion to the relative surface area (see Table 9.4.3).

2. Dilute DNA into dilution medium (appropriate for the lipid being optimized) without serum or antibiotics in four microcentrifuge tubes. Use a range of DNA concentrations, and use a volume of dilution medium that is 7× the appropriate protocol volume (see *Basic Protocol 1*, step 2, and Table 9.4.1). Mix gently after each addition.

This makes enough DNA per tube for seven wells on a 24-well plate. Good ranges include 0.2 to 1.6 μg DNA per well.

If the Plus enhancer is being used, include it in the diluted DNA tubes, using 10 μl Plus reagent per μg DNA. Add the Plus reagent to the diluted DNA after mixing well. If the Plus reagent is added first, precipitation may occur.

3. Dilute cationic lipid reagent into dilution medium without serum or antibiotics in six microcentrifuge tubes. Use a range of DNA concentrations, and use a volume of dilution medium that is 5× the appropriate protocol volume (see *Basic Protocol 1*, step 3, and Table 9.4.1). Mix gently after each addition.

Be sure to observe timing that works best for the cationic lipid reagent being used.

This makes enough diluted lipid per tube for five wells on a 24-well plate. Good ranges include 0.5 to 5 μl lipid reagent per well.

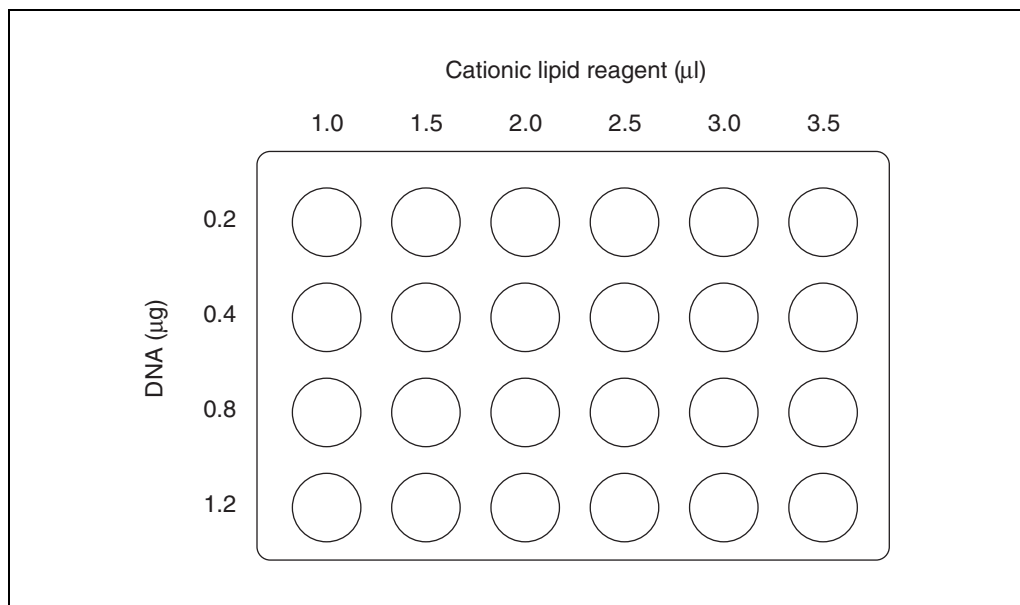

Figure 9.4.3 A sample matrix for fine tuning (optimizing) transfection reagent efficiencies using cationic lipid reagents.

4. Pipet equal per-well volumes of diluted DNA and diluted cationic lipid reagent into the wells of a 96-well plate in a matrix corresponding to the wells on the 24-well plate (Fig. 9.4.3). Mix the complexes with the pipet tip by triturating. Cover the plate and incubate for 15 min at room temperature.

Incubation times >15 min (up to an hour) work just as well, but be sure the complexes do not dry by covering them well.

5. While complexes are forming, replace medium on the cells with fresh transfection medium.

See Basic Protocol 1, steps 5 and 6, for alternate procedures for combining complexes, medium, and cells. The medium can be the same as the serum-free dilution medium. It is possible to use serum in the transfection medium at this step. It is also possible to omit this step when using LipofectAmine 2000.

6. Add aliquots of DNA-lipid complexes (total volume from wells in step 4) to each well containing cells with fresh transfection medium. Mix complexes into the medium gently, holding the plate at a slant. Incubate at 37°C in 5% CO₂ for 5 hr.

The exposure time may be >5 hr (up to overnight). Be sure there is sufficient medium to prevent the cells from drying out (it is not necessary to increase other components if this is done). If using the Plus enhancer, a 3-hr exposure is sufficient.

7. After 5 hr incubation, add cell culture medium to reach normal volume and add serum to bring the final concentration to that of normal cell culture medium.

If necessary to maximize cell growth, replace the medium containing the complexes with fresh complete medium after 5 hr incubation. This step may be omitted entirely for some protocols.

8. Check expression as described (see Basic Protocol 1, steps 8a and 8b).

If peak activity is found to occur on the edge of the matrix of concentrations tested, adjust the concentrations to include the observed peak at the center of a new matrix and repeat the transfection.

COMMENTARY

Background Information

There are currently at least eight companies that market cationic lipid-based transfection reagents. A partial listing of companies and products may be seen in Table 9.4.1. Many companies offer more than one type of reagent. Among the more popular ones are LipofectAmine 2000 and LipofectAmine Plus (Life Technologies), DOTAP and FuGENE 6 (Roche), and Effectene (Qiagen). Some of the structures are proprietary. The structures that are published can be classified into two general categories based on the number of positive charges in the lipid headgroup. The first cationic lipid (DOTMA) has a single positive charge per molecule and is used in Lipofectin (Life Technologies; Felgner et al., 1987). Several other cationic lipid-based transfection reagents such as DOTAP liposomal transfection reagent (Roche) and DMRIE-C (Life Technologies) also make use of singly charged cationic lipid mole-

cules. Increasing the number of positive charges per cationic lipid molecule to as many as five improved transfection efficiency dramatically in most cell types. This can be seen in the examples of DOGS, the cationic lipid in Transfectam (Promega; Behr et al., 1989); DOSPA in LipofectAmine (Life Technologies; Hawley-Nelson et al., 1993); and TMTPS in CellFectin (Life Technologies; Anderson et al., 1995). Further increase in transfection efficiency can sometimes be achieved by precomplexing DNA with a proprietary enhancer. Two commercially available transfection kits with enhancers are LipofectAmine Plus (Life Technologies; Shih et al., 1997) and Effectene (Qiagen).

Life Technologies has designed cationic lipid reagents with specialized applications such as high-efficiency transfection of insect cells (see Basic Protocol 4) or delivery of RNA (see Basic Protocol 3). Lipofectin has high

activity for endothelial cell transfection (Tilkens et al., 1994).

Basic Protocol 1 and the Alternate Protocol described in this unit are the procedures with the highest potential for efficient DNA transfection of adherent mammalian cells (Shih et al., 1997; Ciccarone et al., 1999). LipofectAmine 2000 has a simple protocol that yields the highest transfection efficiencies in many cell types. Using the enhancer reagent results in more reproducible transfections without extensive optimization because of the overall high activity. Prior to the availability of enhanced cationic liposome transfections (e.g., using LipofectAmine 2000 and Effectene), the most effective procedure for transfection of adherent mammalian cells with DNA was with other polycationic reagents (e.g., LipofectAmine; Hawley-Nelson et al., 1993) following Basic Protocol 1. In order to achieve high-efficiency transfections with Basic Protocol 1, it is necessary to optimize lipid and DNA concentrations with the target cells at the desired plating density using a procedure similar to that described in the Support Protocol. Many cationic lipid reagents, as well as transfection reagents based on other chemistries, are available that can be used in Basic Protocol 1 for adherent mammalian cell DNA transfection, but they may yield lower efficiencies than the Alternate Protocol with the enhancer. Optimization using the Support Protocol is highly recommended when not using the enhancer, and the protocol can be modified for use with any cationic lipid reagent.

Critical Parameters

The most critical parameter for successful transfection is cell health. Cells should be proliferating as rapidly as possible at the time they are plated for transfection. On the day of transfection, mitoses should be abundant in healthy cultures. Fresh cultures with a finite life span should be used at the earliest possible passage.

For reproducible transfection results, it is critical to plate the same number of healthy cells for each transfection. Cells should always be counted, preferably using a hemacytometer and trypan blue (APPENDIX 3F).

Although optimization is not required for high-efficiency transfection when using an enhancer (see Alternate Protocol), it is essential for success without the enhancer, and may improve efficiency even with the enhanced method.

The medium used to dilute and form complexes between the cationic liposomes and the DNA must not contain serum. Serum contains

sulfated proteoglycans and other proteins, which compete with the DNA for binding to the cationic lipids. The medium should also not contain antibiotics. There is toxicity to the cells when cationic lipid reagents are used in the presence of antibiotics.

The dilution medium/plating medium for the cells may have some influence on transfection efficiency. Some proprietary serum-free media contain components that inhibit transfection and should be replaced with Opti-MEM I, DMEM, or other media without serum during transfection (Hawley-Nelson and Ciccarone, 1996).

Serum may be present in the medium on the cells during transfection. For most cationic lipid reagents, on most cell types, transfection activity is not inhibited in the presence of serum provided the complexes were formed in serum-free medium (Brunette et al., 1992; Ciccarone et al., 1993, 1999; Shih et al., 1997).

The specific serum-free medium used to dilute the lipid and DNA can have a slight effect on the efficiency of transfection. For the enhanced protocol (Alternate Protocol), normal culture medium such as DMEM is recommended. For the standard procedure (Basic Protocol 1, 2, and 3), Opti-MEM I medium works best. The improvements resulting from using the recommended media are less than two fold. When using Lipofectin, dilution in Opti-MEM I followed by a 30- to 45-min incubation is recommended (Ciccarone and Hawley-Nelson, 1995). With LipofectAmine 2000, the reverse is true: extended incubation (>30 min) of LipofectAmine 2000 in Opti-MEM prior to addition of DNA results in lower transfection activity (Ciccarone et al., 1999).

High-purity DNA will increase transfection efficiency. Miniprep DNA does work, however, when efficiency is not critical. A wide range of sizes of polynucleotides may be transfected, from 18-mer single-stranded oligonucleotides (Chiang et al., 1991; Bennett et al., 1992; Yeoman et al., 1992; Wagner et al., 1993) to 400-kb YAC DNAs (Lamb et al., 1993). Excess vortexing of complexes or DNA solutions may result in some shearing, especially with larger molecules. The concentration of EDTA in the diluted DNA should not exceed 0.3 mM.

Transgene expression may be increased in some cell types by inducing the promoter. This is observed in Jurkat cells when phytohemagglutinin and phorbol myristate acetate are added following transfection to activate the cytomegalovirus promoter (Schifferli and Ciccarone, 1996).

Troubleshooting

The most common complaints surrounding transfections include decreased transfection efficiency and low cell yield. Decreases in efficiency often result from changes in the target cell line. Cultured cell lines are usually aneuploid and often consist of a mixture of genotypes and phenotypes that can be subject to selection in the laboratory environment. Primary cultures, although usually genotypically uniform, often consist of a mixture of phenotypes from different tissues and can change their population characteristics in response to their environment. Whenever a decrease in transfection efficiency is observed, the first

thing to try is to work with a freshly thawed culture or isolate (Hawley-Nelson and Shih, 1995). Be sure the same number of cells is plated in each experiment, since plating density affects efficiency and peak position (Hawley-Nelson et al., 1993).

Low cell yield often results from the use of too much DNA or cationic lipid reagent. Use lower concentrations of these two components and examine the results for transfection efficiency as well as cell yield. Acceptable efficiency can usually be obtained with higher cell yield by using lower concentrations of lipid and DNA (Hawley-Nelson et al., 1993; Life Technologies, 1999).

Figure 9.4.4 Results of fine-tuning or optimizing conditions for transfection. Before transfection, 293 H cells were plated at 2×10^5 /well in a 24-well plate precoated with poly-D-lysine. The following day, cells were transfected with pCMV-SPORT β gal DNA using LipofectAmine 2000 as described (see Support Protocol). One day posttransfection, cells were fixed and stained with Xgal. **(A)** Amounts of DNA and lipid reagent used. **(B)** Results of Xgal staining.

Table 9.4.5 Activity for a Scaled-up Transfection Using LipofectAmine Plus in BHK-21 Cells

Plate	Surface area ratio to 24-well plate	Cells/well ($\times 10^4$)	DNA/well (μg)	Plus reagent (μl)	LipofectAmine reagent (μl)	β -gal (ng/cm^2) ^a
24-well	1	4	0.4	2	2	188 \pm 5
12-well	2	8	0.8	4	4	193 \pm 12
6-well	5	20	2	10	10	179 \pm 27
60-mm	10	40	4	20	20	171 \pm 16
100-mm	28	112	11.2	560	56	157

^aResults are the mean of three transfections \pm the standard deviation.

Cell yield can also be improved in several other ways. (1) Increasing the plating density. This usually requires adjustment of lipid and DNA amounts, but often the transfection efficiency as well as the cell yield increases with higher plating input (Life Technologies, 1999). (2) Decreasing time of exposure of the cells to cationic lipid–DNA complexes. This can be done by increasing volume and adding back serum at earlier times or by removing the complexes from the cells at the end of transfection. (3) Performing the transfection in the presence of serum. Most cationic lipid reagents work well in transfection medium containing serum (Brunette et al., 1992; Ciccarone et al., 1993, 1999; Shih et al., 1997). One exception is LipofectAmine without the Plus enhancer.

Some cationic lipid solutions are naturally cloudy. Sometimes cloudiness is observed when complexes are made with DNA. Usually this does not interfere with transfection efficiency. Most cationic liposome solutions (especially DMRIE-C and CellFectin) should be mixed gently by inversion just before use to produce a uniform suspension. With Plus reagent, it is possible to precipitate the DNA when the Plus reagent is diluted first into the DMEM and DNA is added second. Always dilute the DNA into DMEM and mix well before adding Plus reagent.

Anticipated Results

Transfection should be observed for most adherent mammalian cells transfected with DNA using Basic Protocol 1. Efficiencies vary with cell type. For example, 293, COS-7, and CHO-K1 cells yield 95% or more blue cells following Xgal staining of cells transfected with pCMVSPORT β gal plasmid DNA using LipofectAmine 2000. The authors have noted efficiencies of other cell types as high as 49% for SK-BR3 breast cancer cell lines, 77% for BE(2)C human neuroblastoma cells, and 43% for MDCK canine kidney cells (Ciccarone et

al., 1999). Efficiencies also vary for suspension cells. The authors note that while LipofectAmine Plus is relatively inefficient for transfecting Jurkat cells, DMRIE-C can yield up to 85% blue cells following pCMV·SPORT β gal plasmid DNA transfection, gene activation with phytohemagglutinin and phorbol myristate acetate, and Xgal staining (Ciccarone et al., 1995, Schifferli and Ciccarone, 1996).

The result of a typical fine-tuning/optimization protocol is shown in Figure 9.4.4. The transfection reagent was LipofectAmine 2000, the DNA was pCMV·SPORT β gal, the cells were 293 H. Cells were stained the day following transfection and were allowed to stain overnight at 37°C. A selection of transfection conditions can be made.

Conditions found to be advantageous for transfection in small wells may be scaled up, the results of a typical scale-up are given in Table 9.4.5.

The results of a stable transfection of NIH 3T3 cells with pSV2*neo* DNA using an enhancer reagent (LipofectAmine Plus) are shown in Figure 9.4.5. The transfection was done on 24-well plates, the cells were passaged onto 6-well plates the following day, and selection with geneticin was done for 10 days. The figure shows optimization of conditions and the generally high efficiency that can be achieved using this method.

Time Considerations

Counting and plating the cells should be done the day before transfection and will usually require <1 hour. Transfection is usually done in the morning. Depending on the number of conditions being evaluated, it may require all morning plus a short period in the afternoon to increase medium volume or feed the cells. The total time required is <1 day.

Figure 9.4.5 Stable transfection of NIH 3T3 cells. Cells were plated at 6×10^4 cells/well in 24-well plates. The day after plating, cells were transfected with LipofectAmine Plus complexed with pSV2neo DNA. The following day, cells were passaged at a total dilution of 1/150. Cells were exposed to 0.6 mg/ml Geneticin antibiotic from day 3 to day 13, and were then washed once with PBS and stained with 0.2% toluidine blue in PBS with 10% formalin.

Selection of Transfected Mammalian Cells

Analysis of gene function frequently requires the formation of mammalian cell lines that contain the studied gene in a stably integrated form (Chapter 16). Approximately one in 10^4 cells in a transfection will stably integrate DNA (the efficiency can vary depending on the cell type). Therefore, a dominant, selectable marker is used to permit isolation of stable transfectants. In the first part of this unit, the procedure for determining selection conditions and the resulting stable transfection is presented (see Basic Protocol 1) and the most commonly used selectable markers are discussed (see Basic Protocol 2). Basic Protocol 2 includes conditions for thirteen markers commonly used for selection of mammalian cells.

In order to study the function of a particular gene, it is often necessary to work with a homogeneous population of cells overexpressing either wild-type or mutant variants of the corresponding protein. Two points must be considered, however, when designing such experiments. First, if the gene product of interest has a negative or toxic effect on cell growth, selection of cells stably expressing that gene cannot be achieved using a dominant selection marker. Cells carrying an antibiotic-resistance marker lose their growth advantage when expressing a toxic gene. Second, isolation of a homogeneous pool of cells stably expressing a gene by antibiotic selection often takes a month or more. By the time a stably transfected pool of cells is isolated, many important, temporally dependent biochemical events may have already occurred. One solution to both of these problems is to select transfected cells from the total population soon after transfection (see Basic Protocol 3). To do so, cells are cotransfected with a plasmid (pHook-1 from Invitrogen) that expresses a membrane-anchored selection tag, along with a second plasmid expressing the gene of interest. Alternatively, cells can be transfected with pHook-2 or pHook-3, plasmids that express both the gene of interest and the selection tag. To isolate a homogeneous pool of transfected cells, the total cell population is harvested and incubated with magnetic beads that bind to the selection tag displayed on the transfected cells. After exposure to a magnet, bead-bound transfected cells are centrifuged down into a pellet while unbound cells remain in the supernatant and can be discarded. Optimization of transfection conditions can be facilitated by a simple staining assay (see Support Protocol).

STRATEGIC PLANNING

There are several aspects of the vector to be considered for use in stable transfection. The following parameters should be considered when designing vectors to express either the marker gene or a gene of interest that is introduced with the marker gene.

Construct Design

A typical construct is depicted in Figure 9.5.1.

Promoters

The choice of promoter can be critical for efficient expression, as it is the promoter and accompanying enhancers that drive the expression of the coding regions of the gene of interest and the selectable marker. Promoters are usually short DNA sequences (<1 kb) that bind endogenous transcription factors. They may or may not have a TATA box. Cytomegalovirus and simian virus 40 (SV40) promoters have been favorite general mammalian promoters for years, and many derivatives have been made and are commercially available. More recently, other promoters such as pMC1 and PGK (promoter from phosphoglycerate kinase) have been popular because of the high levels of expression obtainable. It is also possible to use a promoter that is specific for the cell type.

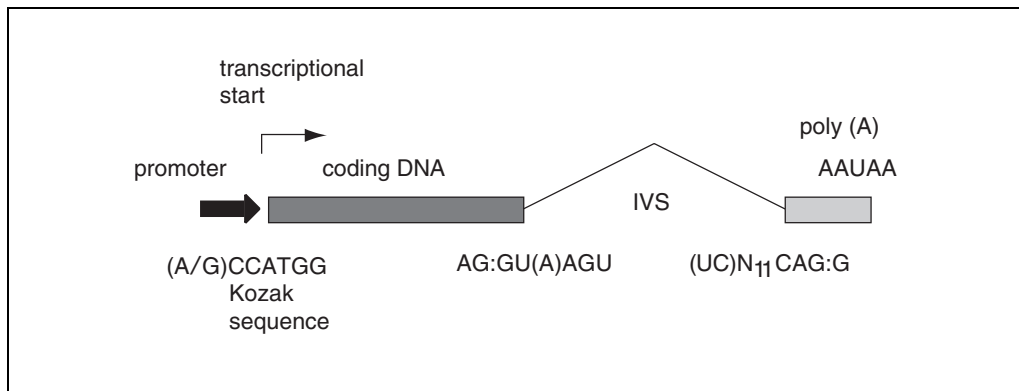

Figure 9.5.1 Generalized construct for expression of genes in mammalian cells. Each integrated construct must contain a promoter region with a transcriptional start site and a coding sequence. Features that increase expression include translational start sites according to Kozak's rules, intervening sequences with splice donor and acceptor sites, and polyadenylation signals. Abbreviation: IVS; intervening sequence.

Conditional-expression promoters have also been introduced recently, increasing the utility and flexibility of stably transfected lines. These promoters require the introduction of a specific transactivator, which is sensitive to an administered compound. Two transcription factors have been developed based on the tet operon which use tetracycline to turn expression off (tet-off) or on (tet-on). For details of tetracycline-regulated systems, see *UNIT 16.14*, Gossen and Bujard (1992), and Gossen et al. (1995). In addition, the insect hormone ecdysone has been used to activate expression based on the ecdysone receptor and responsive element (No et al., 1996).

Translational start site

The translational start site can dramatically affect expression and should be considered both in designing the expression construct for the gene of interest and in choosing the specific version of a selectable marker. Most selectable markers are based on a bacterial resistance gene, and in their native state may give low levels of expression. One major reason for this is the differences in translational start sites. Whereas bacterial systems translate polycistronic messages well, translation of most mammalian mRNA is greatly decreased (~10-fold) by upstream ATG start sites. In addition, the mammalian start site is most efficient if it follows "Kozak's rules" (Kozak, 1989). Many commonly used selectable markers have been modified to give good mammalian translation.

Polyadenylation site

A sequence in the 3' end of the expression vector that signals the addition of a poly(A) tail often stabilizes the mRNA and leads to better expression. The polyadenylation signal consists of a conserved sequence (AAUAA) 11 to 30 nucleotides upstream of the polyadenylation site, and a GU- or U-rich region downstream. Many different sources of polyadenylation signals are used. A common one is derived from the SV40 virus, but constructs using the PGK promoter often use the phosphoglycerate kinase polyadenylation signal as well.

Intervening sequence and splice sites

Addition of an intervening sequence (intron) that is spliced out in the final mRNA can also increase expression. A 5' and 3' splice site flanking the intron are necessary for splicing out of the intron. The mechanism by which addition of an intron might increase expression is not well understood.

Introduction of DNA into Cells

For the creation of stable lines, the results can vary depending on the method of DNA introduction used. Calcium phosphate (*UNIT 9.1*) and dextran (*UNIT 9.2*), as well as liposome-mediated and positively charged liposome-mediated (*UNIT 9.4*) transfection methods, all tend to introduce multiple copies of transfected genes, usually at a single site. These methods aggregate the DNA and are suitable for cotransfection of separate plasmids, typically in the ratios of 5 to 10 parts DNA of interest to one part DNA of selectable marker. These multiple copies can integrate as head-to-head, head-to-tail, or a combination of the two orientations. Because of the tandem array of similar sequences, intrachromosomal rearrangement can occur, leading to loss of copies and a decrease in the level of expression.

Electroporation (*UNIT 9.3*) will usually introduce DNA in a single copy in a single site, depending on the DNA concentration (i.e., high DNA concentrations will introduce multiple copies at a single site in ~25% of cells, although 75% will still contain single copies). If a single copy is desired (as for removal of selection markers as described below) electroporation of colinear constructs is required.

Separate plasmids for the gene of interest and the selectable marker can be used if multiple copies of genes are desired. Both aggregation methods and electroporation will yield resistant colonies with multiple copies of the gene. If only a single copy is desired, then electroporation should be used with a single plasmid that contains both the gene of interest and the selectable marker.

Removal of Selectable Markers

The selectable marker can be removed using recombinases (Fig. 9.5.2). This is desirable if more than one sequential genetic manipulation is planned. Because tandem repeats would be eliminated by the recombinase expression, single-copy integration is desirable; therefore the preferred method of transfection is electroporation. Removal of the selectable marker is accomplished by transiently expressing the Cre recombinase, which removes the sequence between the identical recognition sequences (*lox* sites).

Amplification of Expressed Gene

Some selectable markers (most notably DHFR) can be used to amplify the expression of the integrated DNA. Amplification is accomplished by gradually increasing the selection pressure with higher concentrations of selection medium. This results in tandem duplication of the integrated DNA (see *UNIT 23.5*).

Figure 9.5.2 Using the Cre-*lox* system to remove a selectable marker after integration at a unique site. Transient expression of Cre recombinase causes the excision of sequences between the *lox* sites.

Figure 9.5.3 Using the Cre-lox system to integrate an expression construct at a specific reproducible site. The target site is a previous integrated defective form of a selectable marker (lacking a promoter and ATG start codon). Transfection with a plasmid containing the gene of interest leads to integration at the *lox* site and adds a promoter and translational start site, restoring expression of the selectable marker.

Introduction of DNA at Specific Sites

One of the problems with production of stable lines is that the transfected DNA integrates at a random site. Many of the integrations will not give adequate expression. To address this problem, two different approaches can be taken.

It is possible to use homologous recombination to introduce DNA at a specific site. While this approach has largely been applied to transgenic animals, the same principles can be applied to a cell line. It is possible then to create a cell line where the gene of interest is expressed by an endogenous promoter in its normal genomic location.

Sauer and coworkers developed the Cre recombinase system to introduce DNA at a selected site, shown in Figure 9.5.3 (Fukushige and Sauer, 1992). Initially an inactive modified *neo* is integrated into the DNA which contains an in-frame *loxP* site at the 5' end of *neo* without an ATG initiation codon or a promoter. This cell line can then be transfected with a plasmid containing the gene of interest and a promoter in front of a modified *lox* site. When electroporated into the previously established cell line with a Cre expression vector, recombination is targeted to the *loxP* site in the genome and can be selected in G418 because of the reconstituted *neo* activity. This constant-site integration gives consistent expression of the gene of interest in different clones.

STABLE TRANSFER OF GENES INTO MAMMALIAN CELLS

In this protocol, appropriate selection conditions for the parental cell line are first determined. The gene to be studied is then cotransfected into that cell line with a gene that expresses a selectable marker. The cells are allowed to grow under selection for approximately ten doublings before individual colonies are picked and expanded into cell lines.

Materials

- Complete medium (APPENDIX 3F)
- Selective medium (see Basic Protocol 2)
- Cloning cylinders (UNIT 16.23 and Fig. 16.23.2)

Additional reagents and equipment for mammalian cell culture and counting cells (APPENDIX 3F) and transfection (UNITS 9.1, 9.3 & 9.4)

NOTE: All reagents and equipment coming into contact with live cells must be sterile, and proper sterile technique should be followed accordingly.

NOTE: All culture incubations are performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

1. Ensure that the cell line to be transfected can grow as an isolated colony. For adherent cells, plate ~100 cells on a 10-cm tissue culture dish and feed every 4 days for 10 to 12 days. Count the number of viable colonies (see APPENDIX 3F for basic cell culture techniques).

Selection of stably transfected colonies requires that cells be grown essentially in isolation. A cell line that does not grow as an isolated cell will not be able to be stably transfected. The simplest way to determine how many colonies are present on a tissue culture dish is to stain with methylene blue. Aspirate off the medium, then place ~2 ml of 2% methylene blue (made up in 50% ethanol) on the dish. Wait 2 min, pour off methylene blue, and wash residual dye off in a bucket of cold water.

Cell lines that survive poorly as single cells may be selected by using a feeder layer—i.e., a monolayer of cells treated to prevent cell division (Robertson, 1987).

2. Determine the selection conditions for the parental cell line. For example, if hygromycin-B selection is to be used, determine the minimum level of hygromycin-B that must be added to the medium to prevent cell growth. Split a confluent dish of cells 1:15 into medium containing various levels of the drug. Incubate the cells for 10 days, feeding with the appropriate selective medium every 4 days, and examine the dishes for viable cells.

Mammalian cells can divide once or twice under selective conditions that will eventually kill them. For example, DHFR-deficient cells will divide in selective medium until they deplete their endogenous reserve of nucleotides. For this reason, it is essential to split cells at least 1:15 when testing selection conditions, or the cells may reach confluence before the selection can take effect. Several selection markers commonly used in mammalian cell culture are described below. The choice of a marker is determined both by the cell type to be transfected and the reason for doing the transfection (see Basic Protocol 2).

3. Determine the most efficient means of transfecting the parental cell type (introduction to Section I).

Calcium phosphate- and liposome-mediated transfection (UNITS 9.1 & 9.4) and electroporation (UNIT 9.3) are the methods of choice for producing stable transfectants, as both techniques introduce a large amount of DNA into cells that pick up DNA. The presence of a large amount of DNA increases the probability that some of it will become stably integrated. Transfection mediated by DEAE-dextran does not work well for production of stable cell lines.

4. If calcium phosphate transfection is used, split the parental cell line 1:15 into complete medium the day before the DNA is applied to the cell. If electroporation is used, refer to UNIT 9.3, Basic Protocol, step 7. If liposome-mediated transfection is used, see UNIT 9.4.
5. Cotransfect desired gene and marker gene into parental cell line. Use a molar ratio 5:1 of the plasmid containing the gene of interest to the plasmid containing the selective marker. Include a control where carrier DNA (e.g., pUC13) is used instead of the plasmid containing the gene to be studied. Do several separate transfections containing the gene of interest in case one of the transfections fails.

It is not necessary to physically link the selective marker to the gene of interest prior to transfection if a 5:1 ratio is used. If selection requires transfection of a large amount of the selection plasmid, then a 5:1 ratio will not be achievable in some cases, and a single plasmid should be constructed that contains both the selective marker and the gene of interest. If no colonies result from the transfection containing the gene of interest, but colonies do appear in the control containing pUC13, then the gene of interest may be cytotoxic.

Efficient transfection by electroporation requires linearization of the construct.

6. Allow the cells to double twice under nonselective conditions. Split the cells 1:15 into selective medium.
7. Place at least five dishes into selective medium from each transfected dish to maximize the number of colonies that can be picked and expanded into cell lines. Feed the cells with selective medium every 4 days (or as needed). After 10 to 12 days, inspect the plates for colonies by holding the plates up to a light at an angle.

One of the plates can be stained (see annotation to step 1) to facilitate counting the colonies. Note that staining kills the cells.

8. Pick large, healthy colonies.

Colonies should contain ~500 to 1000 cells when they are picked.

In some cases, it may be wise to continue selection after picking. Some large colonies can "protect" nonresistant cells.

BASIC PROTOCOL 2

SELECTABLE MARKERS FOR MAMMALIAN CELLS

For many of the selection conditions outlined below, the desired concentration of one or more of the drugs used for selection will vary depending on susceptibility of a particular cell line to the drug. For these drugs, approximate ranges needed for selection are given. Precise ranges for the parental cell line to be used can be determined by characterizing cell viability across a range of concentrations of the drug (see Basic Protocol 1, step 2).

Positive Selection

Adenosine deaminase (ADA)

Selection conditions. Medium supplemented with 10 µg/ml thymidine, 15 µg/ml hypoxanthine, 4 µM 9-β-D-xylofuranosyl adenine (Xyl-A), and 0.01 to 0.3 µM 2'-deoxycoformycin (dCF). Fetal bovine serum (FBS) contains low levels of ADA which will detoxify the medium, so serum should be added immediately prior to use.

Basis for selection. Xyl-A can be converted to Xyl-ATP and incorporated into nucleic acids, resulting in cell death. Xyl-A is detoxified to its inosine derivative by ADA. dCF is a transition state analog inhibitor of ADA, and is needed to inactivate ADA endogenous to the parental cell type. As the level of endogenous ADA varies with cell type, the appropriate concentration of dCF for selection will vary as well.

Comments. High levels of expression of the transfected ADA gene will be necessary to achieve selection in cells with high endogenous ADA levels. ADA-deficient CHO cells are available. ADA can be used in amplification systems (Kaufman et al., 1986), as increasing the level of dCF selects for cells that have amplified the ADA gene.

Reference. Kaufman et al. (1986).

Aminoglycoside phosphotransferase (neo, G418, APH)

Selection conditions. 100 to 800 µg/ml G418 in complete medium. G418 should be prepared in a highly buffered solution (e.g., 100 mM HEPES, pH 7.3) so that addition of the drug does not alter the pH of the medium.

Basis for selection. G418 blocks protein synthesis in mammalian cells by interfering with ribosomal function. It is an aminoglycoside, similar in structure to neomycin, gentamycin, and kanamycin. Expression of the bacterial *APH* gene (derived from *tn5*) in mammalian cells therefore results in detoxification of G418.

Comments. Varying concentrations of G418 should be tested, as cells differ in their susceptibility to killing by G418. Different lots of G418 can have different potencies, causing many investigators to buy a large amount of one lot to standardize selection conditions. Cells will divide once or twice in the presence of lethal doses of G418, so the effects of the drug take several days to become apparent.

Reference. Southern and Berg (1982).

Bleomycin (phleo, bleo, zeocin)

Selection conditions. Complete medium supplemented with 0.1 to 50 µg/ml phleomycin.

Basis for selection. This gene encodes a 13,000-Da protein that stoichiometrically binds the drug (bleomycin, phleomycin, or zeocin) and inactivates it.

Comments. Three homologous genes that confer bleomycin resistance have been isolated from the gram-positive bacterial plasmid pUB110, from the central region of the gram-negative transposon Tn5, and from resistant strains of *Actinomyces*.

References. Mulsant et al. (1988); Sugiyama et al. (1994).

Cytosine deaminase (CDA, CD)

Selection conditions. Medium containing 1 mM *N*-(phosphonacetyl)-L-aspartate, 1 mg/ml inosine, and 1 mM cytosine.

Basis for selection. Cytosine deaminase converts cytosine to uracil. *N*-(Phosphonacetyl)-L-aspartate blocks the de novo synthesis pathway of pyrimidines and forces the cells to rely on a cytosine deaminase scavenger pathway.

Comment. Originally defined as a negative selectable marker.

Reference. Wei and Huber (1996).

Dihydrofolate reductase (DHFR)

Selection conditions. α - medium supplemented with 0.01 to 300 µM methotrexate (MTX) and dialyzed fetal bovine serum (FBS).

Basis for selection. DHFR is necessary for purine biosynthesis. In the absence of exogenous purines this enzyme is required for growth. Dialysis of serum to remove endogenous nucleosides and use of media devoid of nucleosides is therefore necessary for selection. MTX is a potent competitive inhibitor of DHFR, so increasing MTX concentration selects for cells that express increased levels of DHFR.

Comments. Extremely high levels of expression of the transfected normal *DHFR* gene are needed for selection in cell lines with high endogenous DHFR levels. A mutant *DHFR* gene is available that encodes an enzyme resistant to MTX (Simonsen and Levinson, 1983). This gene can be used for dominant selection in most cell types. DHFR can be used to amplify transfected genes. This is most efficiently accomplished using a DHFR-deficient CHO cell line and a normal *DHFR* gene for selection.

Reference. Simonsen and Levinson (1983).

Histidinol dehydrogenase (hisD)

Selection conditions. Complete medium supplemented with 2.5 mM histidinol or medium lacking histidine and containing 0.125 mM histidinol.

Basis for selection. This gene encodes an enzyme that catalyzes the oxidation of L-histidinol to L-histidine. Thus, medium deficient in histidine but containing histidinol will not support cell growth. In addition, histidinol is toxic in the presence of histidine because of inhibition of histidyl-tRNA synthase, so *hisD*-containing cells can be selected by their ability to detoxify histidinol.

Comment. Histidinol in complete medium usually works well.

Reference. Hartman and Mulligan (1988).

Hygromycin-B-phosphotransferase (HPH)

Selection conditions. Complete medium supplemented with 10 to 400 µg/ml hygromycin-B.

Basis for selection. Hygromycin-B is an aminocyclitol that inhibits protein synthesis by disrupting translocation and promoting mistranslation. The *HPH* gene (isolated from *E. coli* plasmid pJR225; Gritz and Davies, 1983) detoxifies hygromycin-B by phosphorylation.

Comments. While the level of hygromycin-B needed for selection can vary from 10 to 400 µg/ml, many cell lines require 200 µg/ml.

References. Gritz and Davies (1983); Palmer et al. (1987).

Puromycin-N-acetyl transferase (PAC, puro)

Selection conditions. Complete medium supplemented with 0.5 to 10 µg/ml puromycin.

Basis for selection. Puromycin inhibits protein synthesis. The gene encodes an enzyme for the inactivation of puromycin by acetylation.

Comment. This selectable marker is comparable to *neo* in selection efficiency. Many cell types select well at 2.0 µg/ml.

Reference. de la Luna et al. (1988).

Thymidine kinase (TK)

Selection conditions. Forward (TK⁻ to TK⁺): Complete medium supplemented with 100 µM hypoxanthine, 0.4 µM aminopterin, 16 µM thymidine, and 3 µM glycine (HAT medium).

Basis for selection. Under normal growth conditions, cells do not need thymidine kinase, as the usual means for synthesizing dTTP is through dCDP. Selection of TK⁺ cells in HAT medium is primarily due to the presence of aminopterin, which blocks the formation of dTDP from dCDP. Cells therefore need to synthesize dTTP from thymidine, a pathway that requires TK.

Comments. Thymidine kinase is widely used in mammalian cell culture because both forward and reverse selection conditions exist. Unlike markers such as ADA and DHFR, however, it is not possible to select for variable levels of TK, so the gene cannot be used for amplification. Like ADA and DHFR, most mammalian cell lines express TK, removing the possibility of using the marker in those lines unless BUdr is used to select a TK⁻ mutant.

Reference. Littlefield (1964).

Xanthine-guanine phosphoribosyltransferase (XGPRT, gpt)

Selection conditions. Medium containing dialyzed fetal bovine serum, 250 µg/ml xanthine, 15 µg/ml hypoxanthine, 10 µg/ml thymidine, 2 µg/ml aminopterin, 25 µg/ml mycophenolic acid, and 150 µg/ml L-glutamine.

Basis for selection. Aminopterin and mycophenolic acid both block the de novo pathway for synthesis of GMP. Expression of XGPRT allows cells to produce GMP from xanthine, allowing growth on medium that contains xanthine but not guanine. It is therefore necessary for selection to use dialyzed fetal calf serum and a medium that does not contain guanine.

Comments. XGPRT is a bacterial enzyme that does not have a mammalian homolog, allowing XGPRT to function as a dominant selectable marker in mammalian cells. The amount of mycophenolic acid necessary for selection varies with cell type and can be determined by titration in the absence and presence of guanine.

Reference. Mulligan and Berg (1981).

Negative Selection

Cytosine deaminase (CDA, CD)

Selection conditions. Complete medium supplemented with 50 to 250 µg/ml 5-fluorocytosine.

Basis for selection. Cytosine deaminase converts the 5-fluorocytosine to 5-fluorouracil, resulting in inhibition of proliferation.

Comment. If the CD-positive cells are a minority (<1%), there is no detectable bystander killing; however, if the majority of cells contain CD then CD-negative cells survive only at higher dilutions (≤ 10,000 plated cells per 100-mm plate).

Reference. Mullen et al. (1992).

Diphtheria toxin (DT)

Selection conditions. The expression of the diphtheria toxin gene is itself toxic.

Basis for selection. Diphtheria toxin inhibits protein synthesis by the NAD-dependent ADP-ribosylation of elongation factor 2.

Comment. Since this selection is not conditional, this marker is only useful for elimination of cells expressing DT. Therefore, stable cell lines expressing DT can not be isolated. It has been used as a substitution for HSV-TK for homologous recombination or for the elimination of tissues in transgenic animals.

Reference. Yagi et al. (1990).

Herpes simplex virus thymidine kinase (HSV-TK), + to –

Selection conditions. Complete medium supplemented with 2 µM ganciclovir {9-[(1,3-dihydroxy-2-propoxy)methyl]guanine; DHPG} or 0.2 µM FIAU [1-(2'-deoxy-2'-fluoro-1-β-D-arabinofuranosyl-5-iodo)uracil].

Basis for selection. The selection drugs (ganciclovir or FIAU) are nucleoside analogs and are phosphorylated by the HSV-TK gene product. This phosphorylation leads to incorporation of the drug into the growing DNA chain during S phase, and subsequent cell death. Although the related compound 9-[(2-hydroxyethoxy)methyl]guanine (acyclovir) causes chain termination, ganciclovir does not. These drugs are ~1000-fold poorer substrates for mammalian TK and are thus not harmful to non-HSV-TK containing cells at these concentrations.

Comment. This system has been widely used for increasing the selection of homologous recombinants by including the *HSV-TK* gene outside the regions of homology (see *UNIT 23.1*). It can be used for selection of recombination after Cre recombinase expression if the *TK* is placed between the *lox* sites.

References. Cheng et al. (1983); Staschke et al. (1994).

RAPID SELECTION OF TRANSFECTED MAMMALIAN CELLS

This protocol is for mammalian cells that have been transfected in one of two ways. Either they have been cotransfected with pHook-1 and a preexisting expression plasmid, or transfected with pHook-2 (or pHook-3) with the gene of interest subcloned into the multicloning site. Cells are incubated to allow for expression of the gene of interest and the selection tag, then they are harvested. Transfected cells are subsequently selected from culture by incubation with Capture-Tec magnetic beads (Invitrogen).

Materials

Gene of interest
Cell line for transfection and appropriate complete medium (*APPENDIX 3F*)
Capture-Tec system (Invitrogen) consisting of pHook-1, pHook-2, or pHook-3 plasmid (three different kits are sold) and Capture-Tec magnetic beads
3 mM EDTA in PBS
Phosphate-buffered saline (PBS; *APPENDIX 2*)

Cell scraper
60-mm tissue culture plates
Magnetic stand (e.g., Invitrogen; other models may be used) or strong magnet
End-over-end rotating mixer

Additional reagents and equipment for mammalian cell culture and counting cells (*APPENDIX 3F*), transfection (*UNITS 9.1-9.4*), and subcloning genes (*UNIT 3.16*)

NOTE: All reagents and equipment coming into contact with live cells must be sterile, and proper sterile technique should be followed accordingly.

NOTE: All culture incubations are performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

Choose vector system and transfect cells

1a. *If an expression construct containing the gene of interest already exists:* Cotransfect cells with construct containing gene of interest and pHook-1 (*UNITS 9.1-9.4* and Strategic Planning in this unit). Mock transfect several plates without added DNA to determine the amount of background selection (if any).

Also cotransfect with pHook-1 and control plasmid pcDNA3.1/His/lacZ (provided with the pHook-1 version of the Capture-Tec kit) in place of the construct containing the gene of interest, to assess cotransfection efficiency (see Support Protocol). Carry these control cells through all subsequent steps.

Transfection conditions for each cell line should be optimized to ensure the highest efficiency (see UNITS 9.1-9.4).

1b. *If it is desirable to link expression of the gene of interest with the sFv hook (see Commentary):* Subclone gene of interest into the multicloning site of either pHook-2 or pHook-3 (*UNIT 3.16*), then transfect cells with the plasmid (*UNITS 9.1-9.4* and Strategic Planning in this unit). Mock transfect several plates without added DNA to determine the amount of background selection (if any).

Also transfect cells with pHook-2/lacZ or pHook-3/lacZ control plasmids (provided, respectively, with the pHook-2 and pHook-3 versions of the Capture-Tec kit) to assess transfection efficiency (see Support Protocol). Carry these control cells through all subsequent steps.

Transfection conditions for each cell line should be optimized to ensure the highest efficiency (see UNITS 9.1-9.4).

2. After transfection (or mock transfection), return cells to incubator for 2 to 48 hr.

Harvest the transfected cell population

3. After incubation, replace medium with 3 mM EDTA in PBS. Harvest cells, using a cell scraper if necessary, and transfer to a centrifuge tube.

If the cell line being used tends to form aggregates while in culture, low levels of trypsin (0.05%) can be added to disperse them at this point. Keep in mind, however, that under these conditions the sFv membrane tag (see Background Information) may be cleaved, thereby lowering the number of cells selected overall.

4. Centrifuge cells 5 to 10 min at 800 to 1000 × g, room temperature. Decant supernatant.
5. Resuspend cells in 1 ml complete medium per 60-mm plate (~1 × 10⁶ cells). Transfer each sample to a single 1.5-ml microcentrifuge tube.

It is important to achieve a single-cell suspension to ensure efficient selection. For many cell lines this can be done by pipetting the sample up and down in a small-bore pipet. A Pasteur pipet with a flame-polished tip works well for this purpose.

Select transfected cells with magnetic beads

6. Resuspend the Capture-Tec magnetic bead slurry by vortexing, then place 10 μl (1.5 × 10⁶ beads) into each of a series of microcentrifuge tubes.

Prepare sufficient beads for the three magnetic separations described below.

7. Wash beads in each tube by resuspending in 1 ml complete medium, then separating them out into a pellet with a magnetic stand or strong magnet and removing the medium.
8. Add each of the cell suspensions from step 5 to one of the microcentrifuge tubes containing washed Capture-Tec beads. Incubate 30 min at 37°C on an end-over-end rotator at 5 to 10 rpm.
9. Place the tubes containing the bead/cell mixture in a magnetic stand and mix for 30 sec to 1 min with gentle rocking. Remove supernatant containing unbound cells.

If working with pHook-1, retain the supernatants with the unselected cells from the pcDNA3.1/His/lacZ-transfected controls for use in the Support Protocol. If working with pHook-2 or -3, retain the supernatants from the pHook-2/lacZ or pHook-3/lacZ controls.

10. Remove the tubes from the magnetic stand and resuspend the beads and cells in 1 ml complete medium. Vortex gently to resuspend cells.

It is important to resuspend cells thoroughly to disperse any aggregates that may have formed during the selection procedure. Cell aggregates can trap beads and be selected nonspecifically.

11. Repeat magnetic separation on the cells (steps 8 to 10) twice more.
12. Resuspend selected cells in a small volume (50 to 100 μl) of complete medium or PBS and count cells (APPENDIX 3F).

If the cells are to be lysed, the beads may be removed after lysis by using a magnet to pellet the beads. The supernatant may then be transferred to a new tube.

When observing cells microscopically after selection, the magnetic beads can be easily seen. Unbound beads should be visible, indicating that the beads are in excess over the number of transfected cells. If unbound beads are not visible, it may indicate that not all the transfected cells were selected. Increasing the number of beads to 20 μ l (3×10^6 beads) the next time cells are selected will ensure that all of the transfected cells have an ample chance to interact with the beads and be selected.

OPTIMIZATION OF COTRANSFECTION CONDITIONS

The positive control plasmid pcDNA3.1/His/lacZ, provided with pHook-1, results in the expression of β -galactosidase when successfully cotransfected into cells along with pHook-1. Similarly, the plasmids pHook-1/lacZ and pHook-2/lacZ result in expression of β -galactosidase when successfully transfected. Hence, these plasmids can be used to check for cotransfection in selected cells and to assess transfection efficiencies. To do so, cells transfected with one of the above plasmids are magnetically selected (see Basic Protocol 3) then selected cells, nonselected cells, and mock-transfected cells are stained with 5-bromo-4-chloro-3-indolyl- β -D-galactopyranoside (Xgal) and counted. Cells expressing β -galactosidase will turn blue in the presence of Xgal. Comparison of the number of blue nonselected cells versus blue selected cells will allow the investigator to determine the selection efficiency. Untransfected cells (mock transfected) should not stain blue with Xgal. Optimal cotransfection conditions are defined as the pHook-1 to pcDNA3.1/His/lacZ ratio that gives the greatest enrichment of blue-stained cells in the selected population. For pHook-2/lacZ and pHook-3/lacZ controls, optimum transfection conditions are defined as the DNA concentrations that yield the highest number of blue cells selected.

Materials

- Magnetically selected and unselected (supernatant) control cells (see Basic Protocol 3) transfected with:
 - pHook-1 and control plasmid pcDNA3.1/His/lacZ (if using pHook-1)
 - pHook-2/lacZ (if using pHook-2)
 - pHook-3/lacZ (if using pHook-3)
- Magnetically selected and unselected (supernatant) mock transfected cells
- Phosphate-buffered saline (PBS; APPENDIX 2)
- Xgal staining solution (see recipe)
- Tissue culture dishes
- Inverted microscope

NOTE: All reagents and equipment coming into contact with live cells must be sterile, and proper sterile technique should be followed accordingly.

NOTE: All culture incubations are performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

1. Centrifuge the suspensions of cells 5 min at 800 to 1000 \times g, room temperature. Decant supernatants.
2. Wash by resuspending each pellet in 1 ml PBS, centrifuging again as in step 1, then decanting the supernatants.
3. Resuspend each pellet of selected and unselected cells in 100 μ l Xgal staining solution. Transfer to tissue culture dishes.
 - Depending on cell type, cells may be incubated in tubes, then counted on a hemacytometer.*
4. Incubate cells 2 to 24 hr at 37°C.

5. Examine dishes under an inverted microscope for development of blue color. Count total cells and blue-stained cells.

Remember to normalize to total cell number.

In pHook-1 cotransfections, nearly all selected cells should express β -galactosidase. If there are a large number of nonselected cells that are blue, increasing the amount of pHook-1 relative to pcDNA3.1/His/lacZ could increase the number of cells selected, but may lower the percentage of selected cells that express β -galactosidase. By design, selected cells expressing pHook-2 and pHook-3 should all express the gene of interest.

REAGENTS AND SOLUTIONS

Xgal staining solution

Inorganic salt mix

PBS, pH 7.4 (APPENDIX 2) containing:

4 mM $K_3Fe(CN)_6$

4 mM $K_4Fe(CN)_6 \cdot 3H_2O$

2 mM $MgCl_2 \cdot 6H_2O$

Prepare fresh

Working solution: Immediately before use, add 20 mg/ml Xgal stock solution in dimethylformamide (store at $-20^\circ C$) to a final concentration of 1 mg/ml.

The authors prepare the inorganic salt mix fresh for each experiment by adding 400 mM $K_3Fe(CN)_6$ stock, 400 mM $K_4Fe(CN)_6$ stock, and 200 mM $MgCl_2 \cdot 6H_2O$ stock (all of which may be stored frozen at $-20^\circ C$) to 10 \times PBS (APPENDIX 2) at ten times the final concentrations listed above, then diluting this 10 \times mix to 1 \times with water. 20 mg/ml Xgal stock solution is then added immediately before use to a concentration of 1 mg/ml, as described above.

For further description of Xgal, see Table 1.4.2.

COMMENTARY

Background Information

Isolation of a cell line stably transfected with DNA encoding a particular gene is dependent on a selection strategy that affords the transfected cell a growth advantage in culture. To implement this approach, an antibiotic-resistance marker is transfected into cells along with the gene of interest. The antibiotic-resistance genes allow the transfected cells to survive in a culture containing the corresponding antibiotic, while cells that do not have that marker stably integrated into their genome perish after several weeks in culture.

Thymidine kinase (*TK*) was the first gene to be extensively used for selection in mammalian cells. The use of 5-bromodeoxyuridine (BrdU) to provide an easy selection for TK^- cells resulted in establishment of several such lines, one of which was used to demonstrate that calcium phosphate-mediated transfection of a viral *TK* gene could lead to establishment of TK^+ cells that contained a stably integrated copy of the viral gene (Wigler et al., 1977). This advance made it possible to introduce foreign genes into mammalian cells by transfecting

them with a *TK*-expressing plasmid (cotransfection; Perucho et al., 1980; Robins et al., 1981).

The difficulty with using *TK* as a selectable marker is that mammalian cells are TK^+ and only a very low level of *TK* expression is needed for cells to survive in HAT medium, necessitating the use of a TK^- parental cell type. This motivated the development of vectors that express bacterial drug resistance genes in mammalian cells. These genes can act as dominant selectable markers in virtually every mammalian cell type, as no endogenous mammalian gene can confer resistance. Four commonly used genes of this sort are *APH* (commonly referred to as *neo*), *XGPRT* (*gpt*), *HPH*, and *puro* (see Basic Protocol 2). These genes allow introduction of exogenous DNA into any cell that can be transfected.

While bacterial-derived markers allow facile introduction of genes into mammalian cells, they do not allow selection over a wide range of selective conditions. The ability to select for expression over a greater than thousand-fold range in drug concentration provides the ability

to overexpress newly introduced genes. Mammalian cells that achieve increased resistance to a drug generally have increased the copy number of the gene conferring drug resistance, a process termed amplification. Any gene that is cotransfected with the marker gene will integrate near that gene, and will thus also become amplified. Amplification of the *DHFR* gene through use of increasing amounts of the drug methotrexate has been widely used to overexpress exogenous genes. The adenosine deaminase (*ADA*) gene can also be amplified by using increasing concentrations of 2'-deoxycoformycin (dCF; Kaufman et al., 1986).

The antibiotic-resistance marker method works well when the gene of interest has either a neutral or a stimulatory effect upon cell growth. However, if a gene has a negative or toxic effect on cells, any growth advantage afforded transfected cells by an antibiotic-resistance marker may be negated. The magnetic-bead selection method (see Basic Protocol 3) helps overcome this problem. By using the magnetic-bead system, a homogeneous population of transfected cells can be isolated from culture within hours of introduction of DNA rather than weeks or months later as is the case with standard antibiotic-selection technologies. The system described in Basic Protocol 3 employs a single-chain antibody (sFv) directed against a hapten (phenyloxazalone; phOx) to isolate transiently transfected cells from total populations in culture. Three plasmids can be used: pHook-1, pHook-2, and pHook-3 (Fig. 9.5.4). Each of these encodes a fusion protein between the anti-phOx sFv (NQ10/12.5; Griffiths et al., 1984; Hoogenboom et al., 1991), and the transmembrane domain of the platelet derived growth factor receptor (PDGFR; Gronwald et al., 1988). When expressed in transfected cells, the fusion protein anchors to the membrane via the transmembrane domain of the PDGFR, and the functional phOx sFv (sFv hook) is displayed on the cell surface. Cells transiently transfected with the pHook vectors can then be selected from culture using antigen-coated magnetic beads (Fig. 9.5.5). This system bypasses the need for creating stably transfected cell lines in order to generate homogeneous populations of cells expressing an exogenous gene.

pHook-2 and pHook-3 are designed to constitutively express both the sFv hook (driven by the RSV promoter) for cell selection and a second gene (driven by the CMV promoter) from a single plasmid. These vectors can be used to enrich for populations in which 100%

of selected cells express the exogenous gene (Chesnut et al., 1996). pHook-2 and pHook-3 both have the same promoters driving expression of the sFv hook and the multicloning site. The differences between pHook-1 and pHook-2 lie in the antibiotic resistance system employed, plasmid size, and unique restriction sites in the multicloning site. pHook-2 expresses the ampicillin-resistance gene (β -lactamase) for selection in bacteria and a gene encoding neomycin resistance (aminoglycoside phosphotransferase) for stable selection in mammalian cells. pHook-3 which is significantly smaller, contains the resistance gene for Zeocin (the *Sh ble* gene product; see Basic Protocol 2 and Drocourt et al., 1990), which acts as a selectable marker in both bacteria and mammalian cells.

The systems described above are useful in studying a wide variety of molecules and their effect on cellular biochemistry. Transiently transfected cells expressing novel proteins or RNA molecules, even those that exert a negative or toxic effect on cell growth, can be selected from culture as homogeneous populations at specific time points and subjected to biochemical characterization. In addition to measuring the effect of gene expression on cell morphology or the modification of specific cellular proteins, the temporally dependent activation and inactivation of downstream genes can be determined by techniques such as differential-display PCR (*UNIT 25B.3*; Liang et al., 1993).

Critical Parameters

General considerations

The efficiency with which the parental cell line can be transfected and the degree of expression of the selective marker determine the success of an attempt to produce stable cell lines. As well, it is important to carefully consider whether the parental cell line is appropriate to the final goal of the research. At least 1 month is required to prepare stable cell lines, and many researchers have reached the end of that time realizing that the resultant line would be much more useful if the initial transfection had been planned more carefully. For example, if stable cell lines are being produced to analyze how a promoter is induced during differentiation, a parental line should be used that differentiates well and an internal reference promoter might be included in the initial transfection.

In order to produce stable cell lines, it is obviously necessary that the selective marker

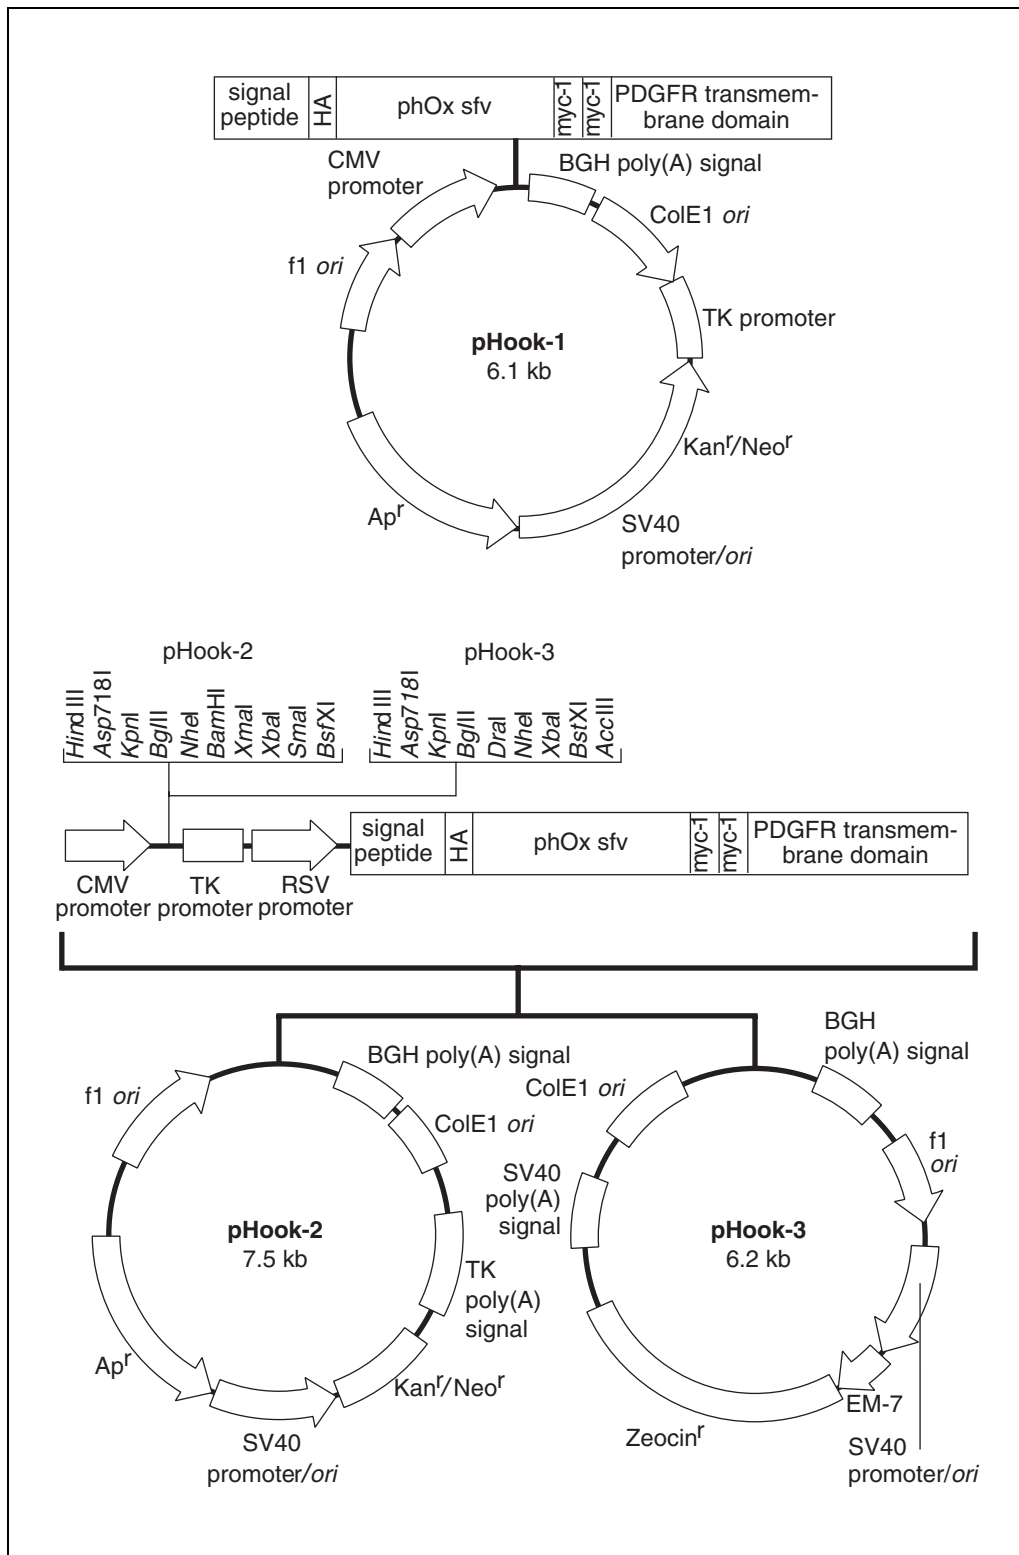

Figure 9.5.4 Plasmid maps of pHook-1, pHook-2, and pHook-3. pHook-1 expresses a fusion protein consisting of the signal peptide from Ig κ V-J2-C region fused with the anti-phOx sFv and the transmembrane domain from the PDGF receptor. pHook-2 and pHook-3 express the same fusion protein but also contain a separate expression cassette consisting of the CMV promoter, a multiple cloning site, and a polyadenylation signal. Definitions: EM-7, synthetic bacterial promoter; HA, hemagglutinin epitope tag; myc-1, myc epitope tag (see text for additional definitions).

Figure 9.5.5 Magnetic cell-selection protocol. **(A)** Cells are transfected with one of the pHook vectors and returned to culture for 2 to 24 hr. **(B)** The cell population, including transfected cells displaying the sFv hook (dark circles) and untransfected cells (open circles), is then harvested and incubated with antigen-coated magnetic beads (small dots) for 30 min. **(C)** Selection of transfected cells is achieved by exposing the cell/bead mixture to a magnet and discarding cells that are not retained by the magnet.

be expressed at a level adequate to detoxify the selective drug. This is most easily accomplished using *TK* as a marker when transfecting TK^- cells, or when using any bacterial gene (*APH*, *XGPRT*, *HPH*, or *puro*) as a dominant selectable marker. This is because the recipient cells contain no endogenous gene that detoxifies the selective drugs, so a small level of synthesis from the transfected gene will give the transfected cells a significant advantage over the parental cells. This is much harder to accomplish when using DHFR or ADA to transfect a normal cell type. Mammalian cells can have fairly high endogenous levels of ADA and DHFR, and therefore extremely high levels of expression from the transfected gene may be necessary to enable the recipient cells to grow under selective conditions. While it has proven possible to select stable transfectants of normal cells using both ADA and DHFR, it is difficult. If these markers are used, a parental line that is ADA- or DHFR-deficient greatly increases the

yield of transfectants, as a much lower level of selection can be used. If amplification of the transfected genes is desired, use of the deficient lines is recommended as there is no risk of amplifying the endogenous gene when the selective pressure is applied.

If a cell line cannot be efficiently transfected, it can prove extremely difficult to select stable cell lines using any selective marker. It is essential, then, to have a protocol that provides efficient transfection of the parental cell type. Optimization of transfection conditions for transient expression (see introduction to Section I) usually produces conditions that work well for production of stable cell lines. The exception to this is DEAE-dextran-mediated transfection, which generally works less efficiently for production of stable cell lines than either calcium phosphate transfection or electroporation even with a cell type that is transfected efficiently by DEAE-dextran as judged at transient times after transfection.

Finally, when setting up a transfection to produce stable lines, it is important to remember that the results of the transfection will not be known for two weeks. Having one dish of a transfection fail can therefore be extremely frustrating if a duplicate dish was not done. Many investigators therefore do transfections in duplicate or triplicate to ensure at least one set of successful transfections when trying to produce a particular stable cell line.

Magnetic bead selection

To ensure the highest number of selected cells in a particular experiment, it is important to optimize the transfection conditions for that cell line. Once the transfection conditions are optimized, the choice of pHook vector must be made. If the gene of interest is already cloned into an expression vector, pHook-1 may be the best choice. This vector is designed as a cotransfection plasmid, and since the sFv hook is expressed from the strong CMV promoter, it offers the highest efficiency selection of the pHook vectors. Cells cotransfected with pHook-1 and a reporter vector have been selected at high efficiency where 95% of the selected cells express the gene of interest (Chesnut et al., 1996). If the analysis of gene activity requires very low or no untransfected cell background, then one may wish to subclone the gene of interest into either pHook-2 or pHook-3. These vectors are designed to express both the sFv membrane tag and the gene of interest from the same construct. While these vectors allow the isolation of cells which all express the cloned gene, the overall selection efficiency is lower than with cells transfected with pHook-1. This is most likely due to the fact that the sFv-hook expression is driven by the weaker RSV promoter in these vectors.

One of the major obstacles to efficient selection is aggregation of cells in culture. The efficiency of selection decreases in cases where cells aggregate in such a way that untransfected cells are brought down into the pellet along with those that are transfected. The severity of aggregation varies from cell line to cell line. In some cases, however, limited trypsinization prior to the selection step can increase efficiency. This treatment should be undertaken only as a last resort since the exposed sFv fusion protein contains several exposed lysines and arginines that may be cleaved by trypsin, thereby reducing cell selection.

Anticipated Results

Approximately 10^3 colonies can be produced by transfecting 1 μg of a plasmid expressing a selective marker into 10^6 cells from a highly transfectable cell line (e.g., HeLa, CHO DUKX, NIH 3T3). Approximately 10% of these will be large, vigorously growing colonies that can readily be expanded into cell lines. The precise number of stable transfectants to be expected can vary dramatically depending on the cell type and the efficiency with which the marker gene is expressed.

In the magnetic-bead selection system, the number of cells that are selected in a particular experiment will vary with the transfection efficiency and the ability of the cells to secrete and display the sFv membrane tag. In general, selection efficiencies range from 2% to 25% in most adherent human cell lines. The overall number of cells selected using pHook-1 is usually higher than with pHook-2 or pHook-3. In many cases, selection is up to 50% higher with pHook-1. As mentioned above, this decrease in selection with pHook-2 and pHook-3 is accompanied by an increase of the percentage of selected cells expressing the gene of interest, from ~95% to 100%.

Time Considerations

It takes 1 day to set up the DNA and perform the initial transfections. The transfected cells should double twice before being split into selective medium, and after being placed in selective medium generally take 10 to 12 days to form colonies. Another week or so is required to expand the colonies into cell lines. The entire procedure takes ~1 month.

The overall time investment required for the magnetic bead selection procedures comprises mostly the incubations required for tissue culture. Once the cells have been transfected and allowed to express the gene of interest and the sFv hook, the actual selection procedure can be completed in <1.5 hr.

USES OF FUSION GENES IN MAMMALIAN TRANSFECTION

USING FUSION GENES TO MEASURE PROMOTER ACTIVITY

Transfection is the most commonly used procedure for analyzing mammalian gene expression *in vivo* (introduction to Section I, *UNITS 9.1-9.4, 16.12 & 16.13*). Early studies of gene expression relied on the creation of clonal cell lines that contained the promoter of interest. Creation of such lines is extremely time-consuming, however, and it was found that chromosomal location can have significant effects on gene expression. Alternatively, expression can be measured by simply introducing the intact gene of interest into cells and measuring the level of RNA produced from this gene (*UNIT 9.8*). This method of analysis is direct, difficult, not very sensitive, and time-consuming.

Many experimenters therefore use transient assay systems that are based on the use of fusion genes and assess gene expression within 48 hr after introduction of the DNA. The fusion gene usually consists of the promoter activator binding site or enhancer sequence under study attached to a gene directing the synthesis of a reporter molecule; the amount of reporter protein synthesized under various conditions is presumed to reflect the ability of the inserted sequence to direct and/or promote transcription. It follows that a useful transient expression system should be based on the synthesis of an easily assayed reporter protein that has minimal or no effects on the physiology of the transfected cell. Ideally, the assay for this reporter molecule would be extremely sensitive. This section presents a general overview of reporter systems (*UNIT 9.6*), followed by specific protocols that describe the use of selected reporter systems that fulfill all of the above requirements. These examples include two isotopic assays using chloramphenicol acetyltransferase (CAT) and human growth hormone (hGH) expression plasmids (*UNIT 9.7A*), two chemiluminescent assays using firefly luciferase and β -galactosidase expression plasmids (*UNIT 9.7B*), and fluorescent assays using expression plasmids carrying green fluorescent protein (*UNIT 9.7C*).

CAT has been the most frequently used reporter enzyme, and thus a major advantage of this system is that it is an extensively validated and widely accepted measure of promoter activity. Another advantage is that the enzyme assays are relatively easy and quite reliable but can be time-consuming. A disadvantage of this system is that, for reasons that are not completely clear, CAT mRNA accumulates to only very low levels. This can make it difficult to demonstrate that the promoter of interest is initiating transcription at the appropriate position.

Unlike the enzymatic assays for CAT, β -galactosidase, and luciferase, the hGH reporter assay is immunologically based, employing commercially available radioimmunoassay kits that are relatively quick and convenient to use. Moreover, unlike the enzymatic or mRNA assays, hGH is assayed in the medium, rather than in cell extracts. This makes it possible to monitor expression directed by a single population of transfected cells over time and also makes hGH useful as an internal control for any of the enzymatic assays. Such internal controls can be very helpful in comparing expression levels between different test plasmids. Based on ease of detecting expression from various comparable plasmids, the hGH assay seems to be a slightly more sensitive than the CAT assay. This is at least partly a consequence of the substantially greater accumulation of hGH mRNA.

Luciferase is another widely used reporter enzyme. The luciferase assay is much faster and more sensitive than the CAT assay and does not use radioactivity. The increased

sensitivity is particularly useful if the cell line of interest is hard to transfect, or if the promoter of interest is very weak. A disadvantage of the luciferase assay is that it requires a rather expensive piece of equipment, the luminometer, to measure enzyme activity.

The use of β -galactosidase coupled with a chemiluminescent detection system provides a quick and sensitive alternative nonisotopic reporter system. In this assay (see *UNIT 9.7B*), the 1,2-dioxetane-substituted AMPGD (Galacton, Tropix) is used as a substrate for the β -galactosidase assay. Following a short incubation of cell extract with enzyme, light emission is measured using either a luminometer or a scintillation counter. The sensitivity of the chemiluminescent β -galactosidase assay is comparable to that of the luciferase assay.

The green fluorescent protein (GFP), cloned from the jellyfish *Aequorea victoria*, serves as an easily detected fluorescent tag requiring no substrates or associated cofactors. GFP—along with its variously engineered versions—has increasingly become widely used as a reporter of gene expression and for studies of protein localization in vivo (see *UNIT 9.7C*). A number of GFP expression systems are now available, and have been used successfully to introduce GFP into a wide variety of organisms and cell types, and into virtually any subcellular region.

A potentially serious problem with using reporter genes to analyze promoters is that sequences within a gene can play a significant role in regulation of its promoter. Thus, subcloning a promoter into a vector that expresses a reporter gene may separate the promoter from sequences necessary for the transcriptional response under study. Similarly, the reporter gene may contain sequences that affect the ability of particular promoter sequences to function normally. It is therefore important to verify that any regulatory event observed with a fusion gene also affects expression of the gene in vivo, both in terms of kinetics and magnitude of the response. It is also a good idea to assess the mRNA by S1 analysis (*UNIT 4.6*) to make sure that the subcloned promoter still initiates transcription at the correct start site.

Vectors are available that contain a reporter gene and mammalian processing signals adjacent to restriction sites into which a promoter of interest can be inserted (see Figs. 9.7.1 and 9.7.2). When fusing a promoter to a reporter gene, it is essential to ensure that there are no ATG codons between the transcriptional start site and the ATG of the reporter gene. In particular, it is important to check that no ATG is created when the fusion is engineered.

CHARACTERIZATION OF TRANSFECTION EFFICIENCY THROUGH USE OF FUSION GENES

Fusion genes that express an easily assayed protein are critical in establishing optimal transfection conditions. The use of such genes allows rapid and simple assessment of the efficient introduction of DNA into cells under a variety of conditions (introduction to Section I). The ability to monitor transfection efficiency easily is extremely useful in establishing transfection conditions and in ensuring that a transfection has worked prior to extensive workup of the transfected cells, e.g., when doing S1 analysis (*UNIT 4.6*).

Overview of Genetic Reporter Systems

A central question in molecular and cell biology is how *cis*-acting DNA sequences and *trans*-acting factors act in unison to control eukaryotic gene expression. These interactions are mediated by specific binding of a transcription factor or a complex of factors to enhancer and promoter elements generally found upstream of the transcription start site. Direct quantitation of changes in gene expression requires the measurement of specific mRNAs using techniques such as northern blot hybridizations (UNIT 4.9) or nuclease protection assays (UNIT 4.7). These procedures can be time-consuming and are not always practical for analysis of many different gene constructs. Furthermore, such techniques require that the analyzed gene be modified in some manner to distinguish it from the native gene in transfected cells.

An alternate approach to gauge changes in transcription is to link the presumed *cis*-acting sequence(s) from the gene of interest to the

coding sequence for an unrelated reporter gene (Alam and Cook, 1990). To test for complete promoters, the DNA fragment is placed directly upstream of the reporter gene in a vector lacking endogenous promoter activity (Fig. 9.6.1). Similarly, for activator binding sites, the heterologous sequence is placed in a vector proximal to a basal promoter that contains sequences required for recognition by the basic transcription machinery (e.g., RNA polymerase II). Following introduction of the chimeric reporter construct into an appropriate cell type or animal, measurement of reporter-gene product provides an indirect estimate of the induction in gene expression directed by the regulatory sequences. It is important to recognize that these assays use reporter constructs to measure protein level or activity and not RNA level. The two levels are frequently, but not always, correlated with one another. Any treatment of the cells or extracts that may affect message translation will alter the accuracy of measurements

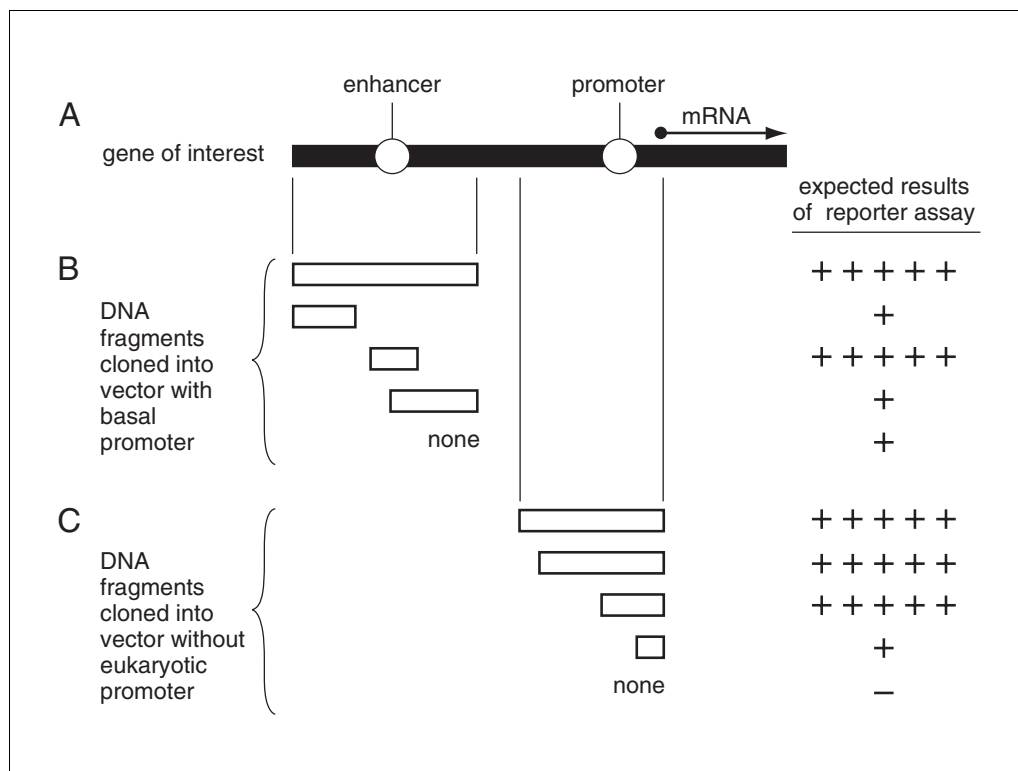

Figure 9.6.1 Schematic of promoter and enhancer definition studies. (A) A hypothetical eukaryotic gene with promoter and enhancer elements indicated by open circles. (B) A series of DNA fragments that could be cloned into the MCS of a reporter vector containing a basal promoter for the purpose of identifying the position of an enhancer. (C) Cloning of DNA into a promoterless reporter vector to define the minimal functional promoter. The expected results of the subsequent reporter assays for these constructs are shown to the right of the corresponding DNA fragments. + and +++++ indicate lesser and greater expression, and - indicates no expression.

of the reporter construct. Furthermore, when dealing with an inducible system, the stability of the reporter must be taken into account. For example, if the reporter-gene product is very stable, high levels of protein can build up in the cell prior to induction. Upon induction following addition of the effector, the protein level may well increase, but the observed fold increase may be less dramatic because of the high basal level of reporter protein that has already accumulated in the cell.

With these considerations, the reporter can be used to characterize the cellular, tissue, or temporal specificity of the *cis*-acting element or its responsiveness to external stimuli such as hormones. Furthermore, *cis*-regulatory elements can be functionally characterized by constructing successive deletion mutants (Fig. 9.6.1), by altering sequence orientations, or by site-directed mutagenesis. Moreover, the requirements for *trans*-acting factor(s) can be investigated by expression of the reporter construct in different cell types and organisms or by biochemical manipulation of the source of the factors. For example, involvement of specific signaling pathways in the response to external stimuli can be investigated by treating cells with inhibitors and/or activators of protein phosphorylation, glycosylation, or fatty acylation. Kinetic studies with protein synthesis inhibitors may be employed to correlate the requirement for new protein synthesis with induction of the reporter gene.

There are several criteria for selection of a transcription reporter gene. (1) The reporter protein should be absent from the host, or easily distinguished from endogenous versions. (2) A simple, rapid, sensitive, and cost-effective assay should be available to detect the reporter protein. (3) The assay for the reporter protein should have a broad linear range to facilitate analysis of both large and small changes in promoter activity. (4) Expression of the gene must not alter the physiology of the recipient cells or organism. These criteria are met to varying degrees by the reporter systems outlined in Table 9.6.1. Each of these reporter genes and the corresponding assay systems have specific features and limitations that must be considered in choosing a system tailored to the particular question being studied. For example, the reporter protein may be expressed intracellularly or secreted from the cell and assayed in the culture medium. There may be limitations in the cell types suitable for a particular reporter system due to low expression levels or the presence of endogenous activities

that contribute to high background. The reporter proteins that are commonly used vary widely in their relative stabilities, which is an important consideration in the study of inducible reporter constructs. Finally, the reporter protein may be measured by an *in vitro* activity or immunological assay or detected *in vivo* via histochemical procedures. These and other issues will be addressed for each reporter gene in the sections that follow.

DESIGN OF REPORTER VECTORS

The general design of a reporter vector referred to as “pGENERIC,” is shown in Figure 9.6.2. The vector backbone typically contains a bacteriophage origin of replication (*f1 ori*) for single-stranded DNA production to facilitate sequencing and mutagenesis studies, and a bacterial origin of replication (often from pBR322 or pUC-derived plasmids) for propagation of the vector in *Escherichia coli*. Additional origins of replication are often added to permit stable propagation in other host species. Production of the vector in bacteria is also facilitated by an antibiotic resistance gene, in most cases coding for β -lactamase, which imparts ampicillin resistance to *E. coli* cells transformed with the vector. A polyadenylation signal downstream of the reporter gene ensures proper and efficient processing of the reporter transcript in eukaryotic cells. A second polyadenylation site may be placed upstream of the reporter to prevent background transcription from cryptic promoters located in the flanking DNA (Araki et al., 1988). Lastly, a multiple cloning site (MCS) upstream of the reporter gene allows for the insertion of foreign DNA containing putative promoter and/or enhancer elements. For cloning purposes, the MCS typically contains five to seven closely aligned unique restriction endonuclease sites. In addition to the MCS, reporter vectors often contain one or more unique restriction sites downstream of the reporter gene for testing putative enhancer elements or for excision of the reporter gene.

Some vectors already contain a basal promoter immediately upstream of the reporter gene. Such promoters are frequently of viral origin (Wenger et al., 1994), and ideally provide a constitutive level of transcription in a broad range of cell types. These reporter vectors are used to identify and characterize activator binding sites and enhancer sequences, and also to study the process of transcription activation. A reporter vector containing a basal promoter, and possibly an upstream enhancer,

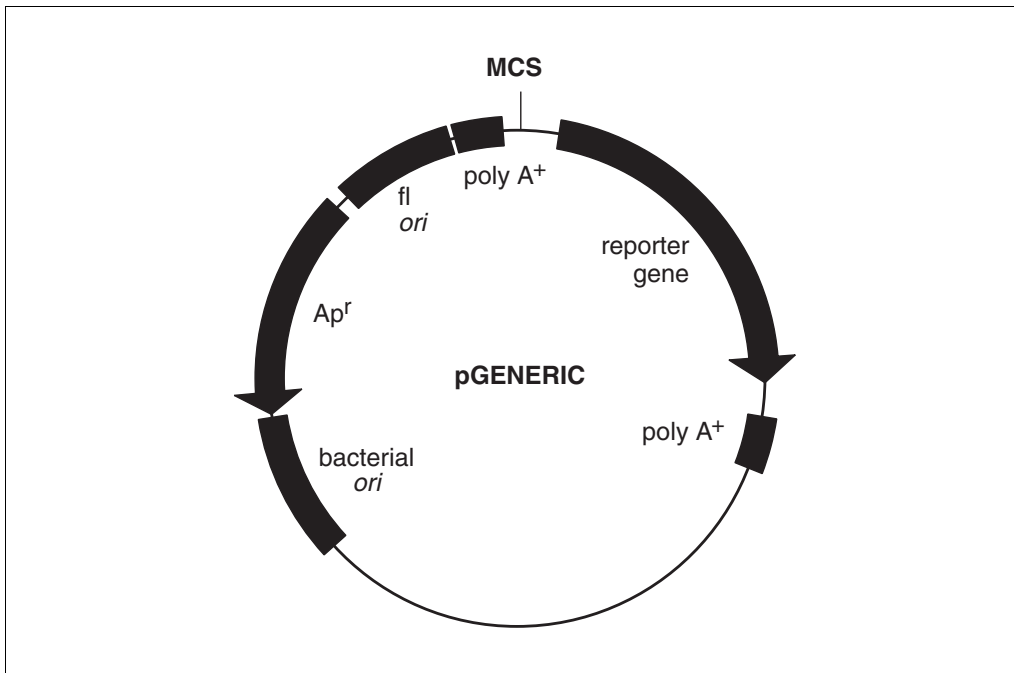

Figure 9.6.2 Plasmid map of a representative reporter vector. MCS denotes the multiple cloning site used for insertion of foreign DNA into the reporter vector. Poly A⁺ indicates the positions of polyadenylation signals. *Ori* refers to the bacteriophage (f1) and bacterial plasmid origins of replication. Arrows indicate the direction of transcription for the reporter gene and an antibiotic resistance gene (Ap^r).

may also be used as a positive control to normalize transfection efficiencies of experimental reporter constructs.

IN VITRO REPORTER ASSAYS

In vitro reporter assays refer to procedures in which the reporter protein is quantified using either cell or tissue lysates containing the reporter, or (for secreted reporter proteins) the culture medium from transfected cells. These assays utilize direct quantitation of the reporter protein by enzymatic or immunological means to provide an indirect estimate of the transcriptional activity of the reporter vector encoding the protein. Such assays are distinguished from the in vivo reporter systems described below in that numerical data suitable for comparative studies of different promoters, enhancers, and cell-type requirements are more readily obtained.

Chloramphenicol Acetyltransferase (CAT)

Many of the above criteria for genetic reporters are satisfied by the enzyme chloramphenicol acetyltransferase (CAT; *UNIT 9.7A*; Gorman, 1982). This enzyme catalyzes the transfer of acetyl groups from acetyl-coenzyme A to chloramphenicol. Because CAT is a prokaryotic enzyme, there are minimal competing ac-

tivities in most eukaryotic cells, resulting in high signal-to-background ratios in these reporter assays. However, most formats of the CAT assay require a relatively expensive radioactive substrate, the assays are very time-consuming to perform, and the sensitivity of CAT assays is inferior to that of recently developed nonisotopic reporter systems. CAT is quite stable (half-life 50 hr in mammalian cells; Thompson et al., 1993), making it well-suited as a reporter in transient transfection experiments, but less desirable for stable expression studies. Moreover, the stability exhibited by CAT can be a disadvantage in inducible systems (e.g., inducible enhancers), where accumulation of the reporter protein may mask the induction brought about by addition of the effector. For applications of this type, a reporter protein with a relatively short half-life, such as firefly luciferase, is more desirable.

The most common CAT assay is based on incubation of cell lysates prepared from transfected cells with ¹⁴C-labeled chloramphenicol. Acetylated and unacetylated forms of this compound are separated by thin-layer chromatography on siliconized glass plates. The plates are exposed to X-ray film for a qualitative estimate of CAT activity. For more quantitative data, the spots corresponding to the positions of the mono- and diacetylated forms of chloram-

phenicol can be scraped from the plate and counted in a liquid scintillation counter. This assay can be particularly tedious with several samples and is difficult to interpret due to the presence of two reaction products. Differential extraction techniques have been developed for the quantitative separation of chloramphenicol from its acetylated derivatives, eliminating the need for time-consuming chromatography (UNIT 9.7A). In this format, the radiolabel resides on acetyl-coenzyme A, and ^3H can be substituted for ^{14}C , making the assay somewhat less hazardous and less expensive. Use of an alternate solvent system results in enhanced sensitivity by improving the signal-to-background ratio (Cassinotti and Weitz, 1994).

There are two nonisotopic detection methods for quantifying CAT. A CAT ELISA procedure performed in 96-well microtiter plates is available to directly quantify CAT using an anti-CAT antibody (from Boehringer Mannheim). This assay has the advantage of directly measuring CAT protein levels rather than CAT activity. A nonisotopic CAT activity assay has also been developed; this uses a fluorescent derivative of chloramphenicol (from Molecular Probes) that undergoes a single acetylation reaction. Because only a single reaction product is produced from this substrate, quantitative analysis of CAT activity is more reliable than with chloramphenicol. Moreover, this assay is more sensitive than those employing a radioactive substrate and has a broader linear range.

Firefly Luciferase

Cloning of the *luc* gene from the firefly *Photinus pyralis* (de Wet et al., 1987) provided the first nonisotopic genetic reporter system with widespread utility in mammalian cells. The bioluminescent reaction catalyzed by luciferase requires luciferin (the substrate), ATP, Mg^{2+} , and molecular O_2 . Mixing these reagents with cell lysates containing luciferase results in a flash of light that decays rapidly (in <1 sec). The light signals are detected using a luminometer equipped with an autoinjection device to facilitate rapid mixing of reaction components. Alternatively, the light signal can be recorded using a liquid scintillation counter (Nguyen et al., 1988). The total light emission is proportional to the luciferase activity of the sample, which in turn provides an indirect estimate of the transcription of the luciferase reporter gene. Luciferase is sensitive to degradation by proteases, and therefore has a half-life of ~ 3 hr in transfected mammalian cells

(Thompson et al., 1993). The rapid turnover of luciferase protein makes this reporter a good candidate for studying inducible systems where the increase above basal expression levels needs to be maximized.

The original luciferase assay provides good sensitivity (10 to 1000 times as sensitive as the radioactive CAT assay), but is somewhat intricate to perform and lacks reproducibility between samples, largely due to the rapid “flash” kinetics of the photon emission. An improved assay for luciferase that includes coenzyme A in the reaction mixture produces a more sustained light signal because of the favorable reaction of luciferase with luciferyl-CoA (luciferyl-coenzyme A; Bronstein et al., 1994). Moreover, the longer duration of the light signal increases luminescence intensity by tenfold, thereby making the luciferase assay more sensitive. Future prospects for improving the assay further include the production of modified luciferase enzymes with shifted emission wavelengths which would permit simultaneous analysis of two or more genetic reporters in the same population of cells via detection of different colors of light.

β -Galactosidase

The *lacZ* gene from *E. coli*, which encodes the enzyme β -galactosidase, is among the most versatile genetic reporters, having both in vitro and in vivo assay formats employing a variety of different substrates. The enzyme catalyzes the hydrolysis of various β -galactosides, including several specialized substrates tailored to different assay formats. In addition to its use as a reporter for uncharacterized *cis*-regulatory sequences, expression of β -galactosidase under the control of a constitutive promoter is frequently used as an internal control to normalize the variability of other reporter assays. β -galactosidase is particularly useful for normalizing CAT and firefly luciferase, as cell lysates prepared for these reporter assays are also suitable for measurement of β -galactosidase activity (Alam and Cook, 1990). Both a colorimetric assay using *o*-nitrophenyl- β -D-galactopyranoside (ONPG) and a fluorometric assay using 4-methylumbelliferyl- β -D-galactoside (MUG) have been developed for β -galactosidase (UNIT 16.20 and Young et al., 1993, respectively), but these have received limited use, due primarily to their poor sensitivity. The development of chemiluminescent 1,2-dioxetane substrates for β -galactosidase has greatly improved the utility of *lacZ* as a transcriptional reporter by increasing the sen-

sitivity of the assay and extending the linear dynamic range of detection (*UNIT 9.7B*; Bronstein et al., 1994). When a luminometer is used to detect the chemiluminescent signal, the assay is 50,000-fold more sensitive than the colorimetric assay. Sensitivity can also be enhanced by using assay conditions that minimize endogenous enzyme activity contributed by eukaryotic β -galactosidase (Young et al., 1993).

Secreted Alkaline Phosphatase (SEAP)

Secreted alkaline phosphatase (SEAP; Berger et al., 1988) differs from the abovementioned reporter proteins in that SEAP is secreted from transfected cells and can thus be assayed using a small aliquot of the culture medium. The SEAP gene encodes a truncated form of human placental alkaline phosphatase (PLAP), which lacks a critical membrane-anchoring domain, thereby allowing the protein to be efficiently secreted from transfected cells. Levels of SEAP activity detected in culture medium are directly proportional to changes in intracellular concentrations of SEAP mRNA and protein (Cullen and Malim, 1992). SEAP has the unusual properties of being extremely heat-stable and resistant to the phosphatase inhibitor L-homoarginine. Therefore, endogenous alkaline phosphatase activity can be eliminated by pretreatment of samples at 65°C and incubation with the inhibitor. The secreted nature of SEAP provides several advantages for its use as a genetic reporter: (1) preparation of cell lysates is not required; (2) the kinetics of gene expression can be easily studied by repeated collection of medium from the same cultures; (3) transfected cells are not disturbed during measurement of SEAP activity and remain intact for further investigations; (4) background from endogenous alkaline phosphatase activity in the culture medium is almost absent; and (5) sample collection and assay can be automated using 96-well microtiter plates.

The original SEAP assay was a colorimetric procedure using the alkaline phosphatase substrate *p*-nitrophenyl phosphate (Cullen and Malim, 1992). This procedure is fast, simple to perform, and very inexpensive. However, the assay's sensitivity is poor, and it has a narrow linear dynamic range. Sensitivity can be improved by using a two-step bioluminescent assay for SEAP based on hydrolysis of D-luciferin-*O*-phosphate (Berger et al., 1988). The dephosphorylation reaction catalyzed by SEAP yields free luciferin, which in turn serves as the substrate for firefly luciferase. The sensitivity

of this assay is roughly equivalent to that of the conventional bioluminescent assay for luciferase. The most sensitive SEAP assays use chemiluminescent alkaline phosphatase substrates such as 1,2-dioxetane CSPD (Bronstein et al., 1994; see Table 10.8.1). Dephosphorylation of CSPD results in a sustained "glow"-type luminescence that remains constant up to 60 minutes and is readily detected using a luminometer or scintillation counter. In addition to enhancing sensitivity, the chemiluminescence assay for SEAP greatly increases the linear dynamic range of detection.

Human Growth Hormone (hGH)

Human growth hormone (hGH) is normally secreted exclusively from the somatotrophic cells of the anterior pituitary gland. The restricted pattern of hGH expression makes this protein an attractive choice as a genetic reporter for most mammalian cell types. hGH reporter assays have many of the same advantages as SEAP (*UNIT 9.7A*; Selden et al., 1986), but are less desirable due to the relatively low sensitivity of the procedure and the need for a hazardous radioimmunoassay to quantitate hGH. Measurement of hGH has been used as an internal control to normalize transfection efficiency and is well suited in this regard to normalize expression from experimental SEAP reporter constructs.

β -Glucuronidase (GUS)

The bacterial β -glucuronidase (GUS) gene is the predominant reporter used to study gene expression in plants (Gallagher, 1992). GUS is used as a reporter in both plant and mammalian cells, but is particularly useful in higher plants due to the absence of endogenous GUS activity in most species. Higher plants transformed with GUS are healthy, develop normally, and are fertile. As with β -galactosidase, one of the principle advantages of GUS as a reporter is the wide diversity of assays available for the enzyme. Several different colorimetric assays for GUS have been developed using a variety of β -glucuronides as substrates. The most popular of these uses X-Gluc (Jefferson et al., 1987), a substrate that can also be used for histochemical staining of tissues and cells expressing GUS activity. A more sensitive fluorescence assay for GUS uses the substrate 4-MUG (Jefferson et al., 1987). A chemiluminescent assay for GUS has also been developed; this is very similar to the procedure used to quantify β -galactosidase, and employs an adamantyl 1,2-dioxetane aryl glucuronide sub-

Table 9.6.1 Genetic Reporter Systems

Reporter gene	In vitro assay	In vivo assay	Strengths	Weaknesses	Limit of detection (molecules) ^a	Cost/assay (U.S. dollars) ^b	Available reporter vectors ^c
Chloramphenicol acetyltransferase (CAT)	Chromatography, differential extraction, fluorescence, or immunoassay	None commonly available	Minimal endogenous activity in mammalian cells; stable protein; various assay formats available	Assays are time-consuming and laborious; most formats require expensive radioactive substrate; relatively low sensitivity and narrow linear range (2 orders of magnitude); fluorescent assays offer better sensitivity, but require a fluorometer for quantitation; short half-life of CAT mRNA	$5-10 \times 10^7$	2.00-7.00	pSV0CAT and pSV2CAT (Gorman et al., 1982); pA ₁₀ CAT2 (Laiminis et al., 1984); pCAT-Basic, pCAT-Enhancer, pCAT-Promoter, and pCAT-Control (Promega)
Firefly luciferase	Bioluminescence (luminometer or scintillation counter)	Bioluminescence assay in live cells with luciferin esters as substrate	Nonisotopic; good sensitivity and broad linear range (4 orders of magnitude); minimal endogenous activity in mammalian cells; relatively inexpensive	Short half-life of protein; assay requires a luminometer or scintillation counter; conventional assay lacks reproducibility	$1-2.5 \times 10^5$	0.10-0.25	pT8luc, pSluc2, pXP1/pXP2, and pOLUC (Nordeen, 1988) pMAMneo-LUC (Clontech) pGL2-Basic, pGL2-Enhancer, pGL2-Promoter, and pGL2-Control (Promega)
β -galactosidase	Colorimetric, fluorescence, chemiluminescence (luminometer or scintillation counter)	Histochemical staining with X-gal substrate; bioluminescence assay in live cells with fluorescein di- β -D-galactopyranoside (FDG)	Nonisotopic; various assay formats available for different applications; chemiluminescent assay is very sensitive, and has an extremely broad linear range (5-6 orders of magnitude); well suited as internal control for normalizing other reporters	Many cell types have high endogenous β -galactosidase activity; assays require fluorometer or luminometer	10^4-10^5 (chemiluminescence assay)	0.01-0.02	p β gal-Basic, p β gal-Enhancer, p β gal-Promoter, and p β gal-Control (Clontech) pSV- β -gal (Promega)
Secreted alkaline phosphatase (SEAP)	Colorimetric, bioluminescence, or chemiluminescence (luminometer or scintillation counter)	None commonly available	Nonisotopic; secreted reporter protein; various assay formats available; chemiluminescent assay is very sensitive, and has a broad linear range (4 orders of magnitude); useful for high throughput assays performed in 96-well microtiter plates	May not be suitable for cells expressing low levels of placental-type alkaline phosphatase (lung, testes, and cervix); may not be suitable if experimental design affects secretory capacity of target cells	10^4-10^5 (chemiluminescence assay)	0.01-0.04	pSEAP-Basic, pSEAP-Enhancer, pSEAP-Promoter, and pSEAP-Control; (Clontech) pBC12/RSV/SEAP and pBC12/HIV/SEAP (Berger et al., 1988)

continued

Table 9.6.1 Genetic Reporter Systems, continued

Reporter gene	In vitro assay	In vivo assay	Strengths	Weaknesses	Limit of detection (molecules) ^a	Cost/assay (U.S. dollars) ^b	Available reporter vectors ^c
Human growth hormone (hGH)	Radioimmunoassay	None commonly available	Secreted reporter protein; direct detection of protein levels; simple assay, easy to perform; high-throughput assay performed in 96-well microtiter plates; useful as internal control for normalizing other reporters (e.g., SEAP)	Radioactive assay requiring ¹²⁵ I-labeled antibody; no signal amplification as with activity assays; relatively low sensitivity and narrow linear range; expensive	3 × 10 ⁸	1.00-2.00	pXGH, pOGH, and pTKGH (Selden et al., 1986)
β-glucuronidase (GUS)	Colorimetric, fluorescence, or chemiluminescence (luminometer or scintillation counter)	Histochemical staining with X-Gluc substrate	Nonisotopic; various assay formats available for different applications; GUS protein is stable; chemiluminescent assay is very sensitive, and has an extremely broad linear range (6 orders of magnitude); predominant reporter used in plant genetic research	Assays with best sensitivity require fluorometer or luminometer (scintillation counter can substitute)	N/A	N/A	pBI101, pBI101.2, pBI101.3, pBI121, pBI221, and pGUSN358-S (Clontech)
Green fluorescent protein (GFP)	Fluorescence (UV light box or fluorescence imaging device)	Fluorescence (UV light box, fluorescence microscopy, or FACS analysis)	Reporter of gene expression and protein localization in live cells; fluorescence occurs in a species-independent fashion; fluorescence is an intrinsic property of the protein and does not require additional gene products, substrates, or cofactors; fluorescent signal is highly resistant to photobleaching; no apparent toxic effects of GFP expression in bacteria or eukaryotes	Signal intensity may be too weak for some applications; this limitation is largely overcome by brighter GFP mutants such as EGFP	N/A	Essentially free, no additional reagents necessary	pEGFP, pEGFP1, pEGFP-N1,2,3, and pEGFP-C1,2,3 (Clontech)

^{a,b,c}Much of this information was taken from Alam and Cook, 1990. The lists of available reporter vectors may not be complete. N/A: information not available.

strate (Bronstein et al., 1994). This assay is approximately 100-fold more sensitive than the fluorometric assay using 4-MUG, and has a wider linear dynamic range. In addition to the uses of GUS as a genetic reporter, GUS fusion proteins have been used extensively to study protein localization and transport in both plant and animal species (Gallagher, 1992).

IN VIVO REPORTER ASSAYS

In vivo reporter assays may be defined as those in which the reporter protein is detected in either live cells or tissues (e.g., of transgenic animals), or in cells or tissues that have been fixed for histochemical staining. The data provided by this approach is less quantitative than in vitro reporter systems, but provides important information regarding the cell-type specificity of promoter/enhancers and the tissue distribution of specific transcription factors. Because this method focuses on localization of reporter proteins to the site of their production, it is well suited to reporter assays that employ either precipitating substrates or substrates that generate a luminescent or fluorescent signal. Conversely, secreted proteins such as SEAP and hGH are of less use as in vivo reporter genes.

Green Fluorescent Protein (GFP)

Light is produced in several bioluminescent jellyfish as a result of energy transfer to green fluorescent proteins (GFPs). One such GFP, from *Aequorea victoria*, fluoresces in vivo after receiving energy from the Ca²⁺-activated photoprotein aequorin (Inouye and Tsuji, 1994). This process occurs without requirement for a substrate or cofactor and proceeds via direct transfer of energy between the two proteins. Purified GFP has similar spectral properties to the protein expressed in vivo, absorbing blue light and emitting green light that is detectable using a fluorescence microscope or a UV light box or by fluorescence-activated cell sorting (FACS). The absorption and emission wavelengths of GFP are similar to those of fluorescein, and conditions used for visualizing fluorescein are also suitable for GFP. Full-length GFP appears to be required for fluorescence; however, the minimal chromophore responsible for light emission can be assigned to a hexapeptide within the protein (Cody et al., 1993). This region of the protein contains a Ser-dehydroTyr-Gly trimer, which cyclizes to yield a chromophore that emits light by an as yet unknown mechanism.

Cloning and sequencing of the *A. victoria* GFP gene (Prasher et al., 1992) allowed expression of the protein in heterologous systems. GFP expressed in either prokaryotic or eukaryotic cells yields a bright green fluorescence when the cells are excited by blue or UV light. GFP fluorescence does not require additional gene products from *A. victoria* and occurs in a species-independent fashion. Recent studies using the nematode *Caenorhabditis elegans*, an organism often used for developmental studies, have demonstrated the utility of GFP as a reporter of gene expression in vivo (Chalfie et al., 1994). These researchers expressed GFP in *C. elegans* under the control of a neuron-specific promoter and used GFP fluorescence to monitor the formation of neuronal processes in real time as the worms developed. GFP has also been expressed in yeast, mammalian cells, and *Drosophila*. Moreover, both N- and C-terminal protein fusions with GFP have been constructed and shown to maintain the fluorescence properties of native GFP (Wang and Hazelrigg, 1994).

A critical aspect of GFP-based reporter systems is the ability to monitor transcriptional changes in real time. Future directions for improvement of GFP as a genetic reporter include efforts to increase the intensity of the fluorescent signal and thereby enhance detection sensitivity, and to reduce the variability of the signal between replicate samples. As with firefly luciferase, variant GFPs with shifted emission wavelengths may allow the use of this reporter to study two or more transcriptional events in the same cell population. The availability of multiple fluorescent proteins derived from wild-type GFP will not only facilitate the simultaneous detection of several transcription reporters, but also permit a similar analysis of protein trafficking events using GFP fusion proteins.

Firefly Luciferase

Recent studies have shown that firefly luciferase activity can be detected in live cells by means of soluble luciferase substrates capable of crossing the plasma membrane (Bronstein et al., 1994). These compounds are generally uncharged luciferin esters that readily penetrate and cross lipid bilayers. Once inside the cell, these substrates are converted by endogenous esterases into firefly luciferin, which in turn serves as the substrate for the firefly luciferase encoded by the reporter gene. A photolyzable "caged" luciferin compound has been described that appears to enter cells more efficiently. This

compound can be hydrolyzed to yield free luciferin either by endogenous esterases or by visible light (Yang and Thomason, 1993). In its present form, the *in vivo* luciferase assay is somewhat insensitive and lacks the capability for real time analysis provided by GFP. Through the development of alternate luciferase substrates having a higher quantum yield and more sophisticated detection instruments, it is possible that luciferase may develop into a useful reporter system for *in vivo* analyses.

β -Galactosidase

In vivo levels of the β -galactosidase reporter protein can be determined in prokaryotic and eukaryotic cells, tissue sections, and intact embryos using the precipitating substrate X-Gal (Alam and Cook, 1990). The reaction with X-Gal produces a rich blue color that can easily be scored against background in most applications. Histochemical staining with X-Gal requires fixation of the cells or tissue prior to the enzymatic assay. Detection of *lacZ* expression in whole embryos has been particularly useful for characterizing tissue-specific gene expression during early development. Detection of β -galactosidase activity in live cultured cells is achieved with the substrate fluorescein di- β -D-galactopyranoside (FDG; Bronstein, 1994). FDG is delivered into live cells by hypotonic loading, and after cleavage by β -galactosidase is trapped inside the cell due to the hydrophobic structure of the reaction product. Cells expressing the reporter protein are detected via fluorescence from the fluorescein moiety of the metabolized substrate.

Another important application of *in vivo* expression of β -galactosidase are so called "enhancer trap" studies, in which positional effects of reporter integration into the chromosomes of transgenic organisms is used as a means of locating enhancer sequences (Alam and Cook, 1990). In one approach, a vector containing a weak basal promoter cloned directly upstream of the *lacZ* gene is introduced into mouse eggs and integrates into the mouse genome. Stable transgenic animals are bred from the progeny of the resulting adult animals. A sufficiently weak promoter is chosen such that expression of β -galactosidase occurs only when the promoter is proximal to an enhancer sequence near the site of integration. The expression pattern of β -galactosidase in transgenic lines indirectly reflects both the tissue specificity and strength of nearby enhancer(s). Experiments of this type utilize expression of a reporter to identify novel genes and regulatory flanking sequences that

have potentially interesting patterns of expression during early development.

Isotopic Assays for Reporter Gene Activity

UNIT 9.7A

This unit describes two widely used reporter systems that are based on radioactive detection assays. The first assay uses chloramphenicol acetyltransferase (CAT) activity as a measure of the level of expression of a transfected gene. This bacterial enzyme catalyzes the transfer of an acyl group from acetyl CoA (or any of several other acyl CoA cofactors) to chloramphenicol. In the assays described here, transfected cells are harvested and lysed by freeze-thaw steps (first basic protocol) or simply lysed in the tissue culture plates using Triton X-100 (first alternate protocol). Acyl CoA and radioactively labeled chloramphenicol are added to cell lysate, and modified derivatives of the antibiotic are separated from the starting material using either thin-layer chromatography (TLC; basic protocol) or phase-extraction (second alternate protocol). The chromatographic approach, which uses ^{14}C -labeled chloramphenicol, is the most frequently encountered. The phase-extraction assay, which uses ^3H -labeled chloramphenicol, is substantially cheaper and easier. The second reporter system (second basic protocol) uses a kit to perform a simple two-site radioimmunoassay to quantitate the amount of human growth hormone (hGH) secreted into culture medium by transfected cells. Medium is incubated with ^{125}I -labeled antibody specific for hGH, and immune complexes are collected by an avidin-coated bead. The quantity of hormone is determined based on comparison with a standard curve. *UNIT 9.6* provides an overview of reporter gene systems.

CHROMATOGRAPHIC ASSAY FOR CAT ACTIVITY

Cells are harvested 48 to 72 hr after transfection with chloramphenicol acetyltransferase (CAT) expression plasmids (Fig. 9.7.1), and a lysate is prepared by freeze-thaw cycles. A cytoplasmic extract of the lysate is incubated with radioactive chloramphenicol and acetyl CoA. Acetylated chloramphenicol is separated from the nonacetylated form by thin-layer chromatography (TLC) and autoradiographed.

Materials

Cells transfected with CAT expression plasmid (*UNITS 9.1-9.4 & UNIT 16.12*; Fig. 9.7.1), in 100-mm petri plates

Phosphate-buffered saline (PBS; *APPENDIX 2*)

TEN solution (see recipe)

1 M and ice-cold 0.25 M Tris·Cl, pH 7.5 (*APPENDIX 2*)

200 $\mu\text{Ci/ml}$ [^{14}C]chloramphenicol (35 to 55 mCi/mmol)

4 mM acetyl CoA (store ≤ 2 weeks at -20°C)

Ethyl acetate

19:1 (v/v) chloroform/methanol

Rubber policeman or equivalent

Thin-layer chromatography (TLC) tank

Whatman 3MM filter paper

Thin-layer chromatography (TLC) sheets (plastic-backed, silica gel 1B; J.T. Baker)

Pen or marker with radioactive ink

Additional reagents and equipment for autoradiography (*APPENDIX 3*)

Prepare extracts by freeze-thaw lysis

1. Wash 100-mm plate of cells transfected with CAT expression plasmid twice with 5 ml PBS per wash. Add 1 ml TEN solution to each plate. Let cells sit 5 min on ice.

TEN solution helps adherent cells lift off the plate. If cells in suspension are used, simply wash the cells once with PBS and once with TEN solution, collecting each time by centrifugation, and proceed to step 3.

Figure 9.7.1 Expression vector p300-CAT. This vector is designed for insertion of the desired control elements. It was constructed by cutting the CAT cassette out of pUC-CAT (Gilman et al., 1986) and blunt-end coning it into the *EcoRI* site of pBluescript M13⁻. Every restriction endonuclease site in the polylinker, which is pUC-like, is unique and therefore available for cloning. The vector is a phagemid that produces the strand that permits sequencing of promoter inserts in the 5' to 3' direction using the reverse primer. In addition, the design of mutagenic oligonucleotides is facilitated by use of the sequence of the top strand of a double-stranded sequence.

2. Scrape the cells off the plate with a rubber policeman. Transfer them to a 1.5-ml microcentrifuge tube on ice.
3. Microcentrifuge cells 1 min at maximum speed, 4°C.

Do not centrifuge cells too long or they will form a pellet that is difficult to resuspend.

4. Resuspend cell pellet in 100 µl ice-cold 0.25 M Tris·Cl, pH 7.5.

One hundred microliters of solution is sufficient for ~10⁷ cells.

5. Freeze cells 5 min in dry ice/ethanol. Transfer to 37°C and thaw 5 min. Repeat this freeze-thaw process twice more, for a total of three freeze-thaw cycles.

Successive freezing and thawing lyses the cells.

6. Cool cell lysate on ice, then microcentrifuge 5 min at maximum speed, 4°C. Remove and save the supernatant.

The supernatant is a cytoplasmic extract and contains the CAT enzyme. The supernatant can be stored by freezing in dry ice/ethanol and storing at -20°C. It is important to freeze the supernatant rapidly to maintain full activity.

Assay the extract

7. To assay 20 μl of cell extract, make the following cocktail (130 μl per reaction):

2 μl 200 $\mu\text{Ci/ml}$ [^{14}C]chloramphenicol (35 to 55 mCi/mmol)
20 μl 4 mM acetyl CoA
32.5 μl 1 M Tris·Cl, pH 7.5
75.5 μl H₂O.

One to fifty microliters of extract can be assayed. When assaying different amounts of extract, adjust the cocktail so that the final concentration of Tris·Cl is 0.25 M and the final volume of each reaction is 150 μl .

8. For each assay, add 130 μl cocktail and 20 μl extract to a microcentrifuge tube and mix gently. Incubate 1 hr at 37°C.

Assay time can be extended to several hours if very little activity is present. If a long assay is performed, replace the 4 mM acetyl CoA with 40 mM acetyl CoA because acetyl CoA is not stable under the assay conditions. It is critical that the assay be done in the linear time range. This can be verified by setting up a 600- μl reaction, removing 145- μl aliquots at various time points, and analyzing conversion to acetylated chloramphenicol, as in steps 9 to 14. A plot of activity versus time must be linear through the time point chosen for routine assay for the assay to be valid.

9. Add 1 ml ethyl acetate to the reaction and vortex. Microcentrifuge 1 min and remove the top (ethyl acetate) layer.

The chloramphenicol and acetylated chloramphenicol are extracted into the ethyl acetate.

10. Dry the ethyl acetate 45 min in a Speedvac evaporator.

Alternatively, the ethyl acetate can be allowed to evaporate overnight in a fume hood. This sometimes leads to extra spots on the final TLC because of breakdown products.

Perform thin-layer chromatography

11. Equilibrate the thin-layer chromatography tank: add 190 ml chloroform, 10 ml methanol, and a piece of Whatmann 3MM filter paper approximately the size of the TLC sheet to the tank and let stand 2 hr.

The ratio of methanol to chloroform has a major effect on the separation. Methanol can be lost quickly by evaporation, so it is best to use the solvent mixture for only 24 hr or less.

12. Resuspend each sample in 30 μl ethyl acetate.
13. Spot sample, 5 μl at a time, 2 cm above the edge of a plastic-backed TLC sheet.
14. Develop the chromatogram in an equilibrated chromatography tank containing 200 ml of 19:1 chloroform/methanol.
15. Allow the chromatography to run 2 hr or until the solvent front is close to the top of the sheet. Remove the TLC sheet and air dry. Mark the TLC sheet with radioactive ink, cover with plastic wrap, and place on film for autoradiography.

The final autoradiogram will have up to five spots for each sample. They are, in ascending order, a weak spot at the origin, nonacetylated chloramphenicol, the two forms of acetylated chloramphenicol, and diacetylated chloramphenicol (Fig. 9.7.2). If the diacetylated spot is present, the assay is out of the linear range (conversion to acetyl chloramphenicol $\geq 20\%$ to 30%). If this occurs, dilute sample or reduce assay time.

Figure 9.7.2 Schematic depiction of results of a CAT assay.

16. Calculate the activity of the extract by first determining the percentage of counts that are in the monoacetylated chloramphenicol species. To determine the amount of label in each spot, align the chromatogram and the autoradiogram using a light box and the marks made with radioactive ink. Outline the area of each spot on the chromatogram with a pencil, cut out each spot, add to scintillation fluid in a scintillation vial, and count in a scintillation counter. Calculate CAT activity as follows:

$$\% \text{ acetylated} = \frac{\text{counts in acetylated species}}{\text{counts in acetylated species} + \text{counts in nonacetylated chloramphenicol}}$$

ALTERNATE PROTOCOL 1

IN SITU LYSIS OF CELLS FOR CAT ASSAY

This protocol—in situ lysis of cells transfected with CAT expression plasmid, based on an approach developed by Brian Seed of Massachusetts General Hospital—is faster and easier than the freeze-and-thaw lysis in the basic protocol, but it may lead to somewhat more variable results.

Additional Materials (also see *Basic Protocol 1*)

Cells transfected with CAT expression plasmid (*UNITS 9.1-9.4 & 16.13*), in 60-mm petri plates
 Hypotonic buffer (see recipe)
 Triton lysis buffer (see recipe)

1. Wash 60-mm plate of cells transfected with CAT expression plasmid once with 2 ml PBS.
2. Add 2 ml hypotonic buffer per plate. Incubate at room temperature 2 to 5 min.
During this incubation the cells will swell noticeably.
3. Aspirate hypotonic buffer and add 400 μ l Triton lysis buffer.
Cells will lyse almost immediately after they come in contact with Triton lysis buffer.
4. Scrape the plate with a rubber policeman and transfer lysate to a 1.5-ml microcentrifuge tube using a 1000- μ l pipettor.
5. Microcentrifuge 1 min to remove nuclei and insoluble proteins.
6. Transfer supernatant to a clean microcentrifuge tube and proceed with the assay for CAT activity (first basic protocol, step 7 or second alternate protocol, step 5).

PHASE-EXTRACTION ASSAY FOR CAT ACTIVITY

ALTERNATE
PROTOCOL 2

Extracts of cells transfected with CAT expression plasmid are incubated with ^3H - or ^{14}C -labeled chloramphenicol and unlabeled butyryl CoA. Butyrylated chloramphenicol is separated from the unmodified form by a simple phase extraction. The assay is simple, fast (hours versus days), and inexpensive (50 cents versus 7 to 8 dollars per sample with ^3H -labeled chloramphenicol).

Additional Materials (also see Basic Protocol 1)

- Mammalian cells transfected with CAT expression plasmid (UNITS 9.1-9.4 & 16.13) or protoplasts transfected with CAT expression plasmid (UNIT 9.3)
- 0.01 $\mu\text{Ci}/\mu\text{l}$ [^3H]chloramphenicol solution (see recipe)
- 5 mg/ml butyryl CoA (store ≤ 4 months at -20°C)
- 100 mg/ml unlabeled chloramphenicol
- 2 M Tris-Cl, pH 8.0 (APPENDIX 2)
- 2:1 (v/v) tetramethylpentadecane (TMPD)/xylenes

Prepare cell extracts

From mammalian cells:

- 1a. To prepare cell extracts from mammalian cells, follow either the freeze-thaw method in steps 1 to 6 of the first basic protocol or the in situ lysis method in the first alternate protocol. If cells are harvested using trypsin or by scraping, replace steps 1 to 4 of the in situ lysis method with steps 2a to 4a below.
- 2a. Spin cells in a clinical centrifuge 5 min at $300 \times g$, room temperature, and discard supernatant.
- 3a. Add 2 ml hypotonic buffer per 10^7 cells and repeat step 2a.
- 4a. Add 200 μl Triton lysis buffer per 10^7 cells.

From plant protoplasts:

- 1b. Harvest plant protoplasts (10^5 cells) in 1.5-ml microcentrifuge tubes by microcentrifuging 5 min at 2000 to 4000 rpm, room temperature. Discard supernatant.
- 2b. Add 50 μl hypotonic buffer to the pellet and vortex vigorously.
- 3b. Freeze the sample by incubating the tube ≥ 15 min at -70°C or 5 min in a dry ice/ethanol bath.
- 4b. Thaw and microcentrifuge 2 min at 13,000 rpm, room temperature. Transfer supernatant (containing the CAT extract) to a clean tube.

It is sometimes necessary to heat the sample 10 min at 65°C to inactivate potential inhibitors (see Critical Parameters).

Assay cell extract

5. To assay 50 μl cell extract, make the following CAT assay mix (50 μl per reaction):
 - 20 μl 0.01 $\mu\text{Ci}/\mu\text{l}$ [^3H]chloramphenicol solution
 - 5 μl 5 mg/ml butyryl CoA
 - 5 μl 2 M Tris-Cl, pH 8.0
 - 20 μl H_2O .

For each reaction, use 0.2 μCi [^3H]chloramphenicol. If [^{14}C]chloramphenicol is used as substrate, also use 0.2 μCi /reaction.

Introduction of
DNA into
Mammalian Cells

9.7.5

6. For each assay, add 50 μ l CAT assay mix to 50 μ l cell extract. Incubate 30 to 90 min at 37°C.

The range of linearity is between 0.01% and 50% conversion, making this an excellent assay for measuring the activity of very weak promoters. For measuring the activity of strong promoters that give 30% to 100% conversion, incubate <90 min to obtain data in the linear range, or add additional substrates (unlabeled chloramphenicol and butyryl CoA) to the CAT assay mix.

7. Extract acylated chloramphenicol with 200 μ l of 2:1 TMPD/xylenes by vigorous shaking. Centrifuge and remove the top (organic) phase to a scintillation vial.

A 2:1 mixture of TMPD/xylenes provides both efficient extraction and a low background (see Critical Parameters). Alternatively, samples may be extracted with 200 μ l of 100% xylenes. If xylenes are used, it is necessary to back extract twice to reduce the extremely high background before transferring the organic phase to a scintillation vial. Back-extract the sample by adding 100 μ l water or TE buffer to 200 μ l of xylenes that contain acylated chloramphenicol and shaking vigorously. Centrifuge, remove the top xylenes phase to a new tube, and repeat.

8. Add 3 to 5 ml scintillation fluid to the sample and count to determine CAT activity.

BASIC PROTOCOL 2

RADIOIMMUNOASSAY FOR HUMAN GROWTH HORMONE

Growth hormone secreted into culture medium by transfected cells is measured by a simple two-site radioimmunoassay using a kit.

Materials

Cells transfected with hGH expression plasmid (*UNITS 9.1-9.4 & UNIT 16.12*; see Fig. 9.7.3)

Human Growth Hormone Radioimmunoassay Kit (Allegro Human Growth Hormone, Nichols Institute Diagnostics) containing:

¹²⁵I-labeled antibody solution

Wash solution

Human growth hormone (hGH) standards

Avidin-coated beads

12 \times 75-mm round-bottom test tube

γ counter

1. Remove 100 to 500 μ l medium from mammalian cells transfected with hGH expression plasmid (Fig. 9.7.3).

hGH is secreted by virtually all mammalian cells after transfection with the appropriate vector. In medium, hGH is stable several months at -20°C and several days at 4°C. Avoid repeated thawing and freezing of samples.

2. Pipet 100 μ l medium or standards into a 12 \times 75-mm round-bottom test tube.
3. Add 100 μ l of ¹²⁵I-labeled antibody solution to the tube and mix.
4. Add one avidin-coated bead and cap the tube or cover it with Parafilm. Incubate 90 min at room temperature on a horizontal rotating shaker set at ~170 rpm.

Alternatively, the assay can be done in a stationary tube with a 4-hr incubation.

Figure 9.7.3 Expression vectors for human growth hormone (hGH; Selden et al., 1986).

5. Wash the bead twice by adding 2 ml wash solution and aspirating completely.

The wash solution should be added rapidly so that the bead is raised from the bottom of the tube.

6. Count the tube in a γ counter 1 min.
7. Plot a standard curve with the data from the hGH standards supplied with growth hormone assay kit. Calculate the values of the unknowns using this standard curve.

The assay is not linear for values >50 ng/ml. Samples with values >50 ng/ml should be diluted and reassayed.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

[³H]chloramphenicol solution

Prepare a 0.2 μCi/μl [³H]chloramphenicol stock by adding 960 μl of 100% ethanol and 40 μl of 100 mg/ml unlabeled chloramphenicol to 250 μl of [³H]chloramphenicol (250 μCi/250 μl in ethanol; 42.0 to 58.2 Ci/mmol).

Preextract the 0.2 μCi/μl [³H]chloramphenicol stock by first diluting it 20-fold in water, and then extracting this mixture with an equal volume of xylenes. Shake vigorously. Microcentrifuge 2 min at 13,000 rpm, at room temperature in a clinical centrifuge or microcentrifuge at maximum speed to separate the phases, and discard the top xylenes phase. Extract the aqueous phase one more time, centrifuge, and discard the top xylenes phase. This creates a working solution of 0.01 μCi/μl [³H]chloramphenicol.

When using ³H-labeled instead of ¹⁴C-labeled chloramphenicol, preextraction with xylenes is necessary to reduce the background. Preextraction of [¹⁴C]chloramphenicol reduces background, but not to the same extent as with [³H]chloramphenicol.

Hypotonic buffer

25 mM Tris·Cl, pH 7.5 (APPENDIX 2)

2 mM MgCl₂

Store up to 6 months at room temperature

TEN (Tris/EDTA/NaCl) solution

40 mM Tris·Cl, pH 7.5 (APPENDIX 2)

1 mM EDTA, pH 8.0 (APPENDIX 2)

150 mM NaCl

Store up to 6 months at room temperature

Triton lysis buffer

0.25 M Tris·Cl, pH 7.8 (APPENDIX 2)

0.5% (v/v) Triton X-100

Store up to 6 months at 4°C

COMMENTARY

Background Information

CAT reporter gene assay

Chloramphenicol acetyltransferase (CAT) is a bacterial drug-resistance gene that inactivates chloramphenicol by acetylating the drug at one or both of its two hydroxyl groups. This gene is not found in eukaryotes; thus, there is no background activity in a normal mammalian cell. This characteristic, along with the ease and sensitivity of the assay for CAT activity, has made the CAT gene the most widely used reporter gene for studies of mammalian gene expression. Another commonly encountered reporter system uses firefly luciferase. That assay, which is more sensitive than the CAT assay, is described in UNIT 9.7B.

The CAT gene was first adapted for use in mammalian systems by Gorman et al. (1982).

The bacterial gene was fused to SV40 splice and polyadenylation signals to create a form of the gene that is expressed in mammalian cells. The original vectors contained either a *Hind*III or *Sma*I site for insertion of the promoter. Modified vectors, such as pUC-CAT, have been made that contain a polylinker for promoter insertion (Fig. 9.7.1; Gilman et al., 1986; Prost and Moore, 1986).

The chief advantage of using the CAT gene as a reporter in mammalian cells is that it can be very easily and sensitively detected. It is possible to detect CAT activity driven by a promoter whose expression is several orders of magnitude too weak to be detected directly by RNA analysis. This can create a problem in interpretation for the investigator, as it is possible that the level of CAT expression from a fusion gene reflects the level of a message that

is not originating at the promoter under study but is instead originating from an upstream promoter. Thus, without being able to analyze directly the structure of the CAT message, it is not possible to state unequivocally that the level of CAT enzyme reflects appropriately initiated message from the promoter under study.

There is a wide body of anecdotal evidence to suggest that the CAT mRNA is present at low levels and thus is unusually difficult to analyze directly. It is clearly possible, however, to detect appropriately initiated transcription from mammalian promoters fused to CAT genes by S1 analysis as early as 30 hr after introducing a nonreplicating plasmid into cells by transfection procedures. It remains possible, if not likely, that fusion of a test promoter to a mammalian fusion gene, such as human growth hormone (hGH), may create a more easily analyzed fusion RNA. As the ability to determine whether the level of the reporter gene actually reflects the amount of appropriately initiated message is crucial to the long-term success of most projects, it is worthwhile to characterize the RNA made from any fusion gene early on.

The first basic protocol uses an assay that requires [¹⁴C]chloramphenicol and thin-layer chromatography, making this a costly assay. The phase-extraction assay (Seed and Sheen, 1988) presented in the second alternate protocol is much less expensive, and exploits the relatively low specificity of CAT for the acyl donor, allowing butyryl CoA to be substituted for acetyl CoA. The greater hydrophobicity of butyrylated chloramphenicol allows an effective discrimination between free and acylated chloramphenicol by a simple phase extraction. The assay permits [³H]chloramphenicol to be substituted for the 10-fold more expensive [¹⁴C]chloramphenicol and affords substantial savings compared to alternatives currently available. Preextraction of the radiolabeled chloramphenicol before the reaction and either the use of TMPD/xylenes or back-extraction of the xylenes phase after the reaction allow a significant increase in sensitivity (25-fold) by reducing the background. The assay is linear with enzyme concentration over two to three orders of magnitude, without dilution of the enzyme or adjustment of the duration of incubation.

Human growth hormone reporter gene assay

The human growth hormone (hGH) transient assay system (Selden et al., 1986) is based on a simple immunological detection of hGH

secreted by the transfected cells. Human growth hormone is a 191-amino acid protein synthesized and secreted by the somatotroph cells of the anterior pituitary. The hGH gene (Fig. 9.7.3; DeNoto et al., 1981) contains five exons and is the best characterized of the five members of the hGH gene family.

Secretion of hGH into the medium begins ~24 hr posttransfection, but the time of onset varies somewhat depending on the cell type. In several cell lines, levels of secreted hGH have been shown to be proportional to levels of cytoplasmic hGH mRNA. Thus, secretion does not appear to be the rate-limiting step for appearance of hGH in the medium. Several characteristics of hGH make it useful as a reporter protein.

First, the medium of transfected cells is assayed for secreted hGH. The transfected cells are not destroyed, so this allows continuous monitoring of transient expression from the same cell population.

Second, hGH messenger RNA is quite stable in most mammalian cells. Changes in level of the reporter protein can therefore be correlated with changes in the level of hGH mRNA.

Third, the hGH assay is rapid, sensitive, and easy to perform. All cell types tested so far (including AtT-20, CV-1, HeLa, BALB/c 3T3, REF-52, rat embryo fibroblasts, human foreskin fibroblasts, GC, GH⁴, H35, JEG, L, and primary pituitary cells) were able to secrete hGH into the medium.

These properties suggest several related applications for the hGH transient systems:

1. Use of hGH as a reporter gene to analyze gene expression, analogous to the use of the CAT assay system. Vectors are available that contain a polylinker immediately adjacent to the hGH gene for insertion of eukaryotic promoters (pØGH; Fig. 9.7.3; Selden et al., 1986).
2. Use of a well-characterized hGH fusion gene, such as pXGH5 (Fig. 9.7.3; Selden et al., 1986), to characterize or optimize transfection efficiency (introduction to Section I).
3. Use of a well-characterized hGH fusion gene as an internal control for normalizing the efficiency of expression between different transfections. Transfection efficiency can vary dramatically between dishes in an individual experiment. Thus, it is valuable to transfect a constant amount of an internal standard plasmid in each transfection and use the level of expression from that plasmid to normalize for transfection efficiency. For example, an hGH fusion gene can be used for normalization when

analyzing a set of mutant promoters that have been fused to CAT.

A fundamental difference between the hGH transient assay system and other systems such as CAT or β -galactosidase is that hGH is a mammalian gene. This may contribute to the apparent stability of the hGH message, a valuable characteristic in analyzing promoter expression. It should be noted, however, that the sequences encoding the gene may not be entirely "silent" in terms of regulatory signals. In particular, the hGH gene encodes sequences that can allow response to glucocorticoids in certain fusion genes (Selden et al., 1986).

Critical Parameters

It is essential that the assay for CAT activity be within the linear range both for time (step 8 of the first basic protocol and step 6 of the second alternate protocol) and for activity. When conversion of chloramphenicol to acetyl chloramphenicol is >20% to 30%, the assay ceases to be linear. For example, a sample giving 90% conversion contains greater than nine times more activity than a sample giving 10% conversion. Thus, the sample giving 90% conversion must be diluted or assayed for a shorter time period to give an accurate measure of CAT activity.

Preparation of plant protoplasts using the second alternate protocol varies for the type of plant used. Some investigators have found that certain plant extracts (e.g., *Arabidopsis*) contain inhibitors of the CAT enzyme. A comparison of CAT activities from matched extracts that have been either heated 10 min at 65°C or not heated will indicate whether this heat inactivation step is needed.

Xylenes efficiently extract the acylated chloramphenicol (second alternate protocol) but also extract some of the nonacylated chloramphenicol, leading to a high background. While tetramethylpentadecane (TMPD) does not extract the nonacylated chloramphenicol, it does not efficiently extract the acylated form either. When xylenes alone are used to extract the acylated chloramphenicol, back-extraction of the xylenes phase can be performed to reduce the background before counting. The combination of preextraction and back-extraction (when xylenes alone are used) can increase the sensitivity of the assay ~25-fold, as compared to a single extraction with TMPD/xylenes.

As with any assay, results for the hGH radioimmunoassay must fall within the linear

range of the assay to be meaningful. The standards supplied with the growth hormone kit used in this protocol range from 0.5 to 50 ng/ml growth hormone. Usually the assay is linear within this range. The standards should be used in every growth hormone assay to ensure that the values obtained experimentally fall within the linear range.

Troubleshooting

There are three possible reasons why an extract might give no CAT activity. First, the fusion construct may simply be inactive in the cell type being transfected. Plasmids such as pSV2-CAT (Gorman et al., 1982), which are known to efficiently produce CAT, can be used as controls. Second, a bad reagent may affect the assay, although this rarely happens. This problem can be assessed by using an extract previously known to have good activity, or by using a commercial CAT preparation (e.g., Promega) as a positive control. Finally, the most common reason for a lack of CAT activity is poor transfection efficiency. Transfection solutions can be remade, or transfection efficiency can be tested using an expression vector known to be functional.

There are reports that extracts from some cell lines contain uncharacterized inhibitors of CAT that can be inactivated by heating 20 min at 70°C. This will generate a substantial amount of precipitated denatured protein that should be removed by microcentrifuging 1 min. The fully active CAT enzyme remains in the supernatant.

Anticipated Results

The amount of CAT enzyme produced in a transfection varies widely with transfection efficiency and the particular fusion construct. It is necessary to empirically establish standard conditions for various combinations of promoters and cell types. The chromatographic and phase-extraction assays should be approximately equal in sensitivity. The lower limit of this assay is 0.2 to 1.0×10^{-6} U; there is no upper limit because cell extracts with higher activity can be diluted and reassayed. 50% conversion of [3 H]chloramphenicol should yield 100,000 to 124,000 cpm.

The amount of hGH produced after a transfection will vary according to the fusion construct used and the cell type transfected. Transfection of pXGH5 into HeLa or BALB/c 3T3 cells by CaPO₄ transfection should produce levels near 50 ng/ml in the medium 48 hr after transfection.

Time Considerations

Harvest and preparation of extracts from twelve samples for the CAT assay with the basic freeze-thaw procedure takes 1 to 2 hr. In situ lysis takes ~30 min. With most transfection systems, a 1-hr incubation time is sufficient to detect CAT activity. If a longer incubation time is used, the amount of acetyl CoA in the reaction mix should be increased 10-fold. Thin-layer chromatography takes 2 hr to set up and after completing the incubation, 3 to 4 hr to run the chromatogram. A signal should be detectable on a 24-hr autoradiogram. Starting from the termination of the CAT reaction, the phase-extraction alternate protocol takes ≤30 min to obtain quantitative results from twelve samples.

The hGH radioimmunoassay is rapid and requires very little hands-on time. Harvest is accomplished by removing an aliquot of medium, so it takes only a few minutes. Assay of twenty-four samples takes no more than 30 min hands-on time and 2 hr running time.

Nonisotopic Assays for Reporter Gene Activity

This unit describes two nonisotopic systems for reporter gene activity in cells transfected with the firefly luciferase expression plasmid (first basic protocol and alternate protocol) or the β -galactosidase expression plasmid (second basic protocol). Both of these chemiluminescent assays have the advantages of high sensitivity and broad linear range. In the chemiluminescent detection procedures given in this unit, both luciferase activity and β -galactosidase activity can be measured with either a luminometer or a scintillation counter. Additional discussion and comparison of nonisotopic systems can be found in *UNIT 9.6*.

BASIC PROTOCOL 1

FIREFLY LUCIFERASE REPORTER GENE ASSAY

This protocol describes a reporter system in which firefly luciferase activity is measured to determine the level of expression of a transfected gene. This nonradioactive system has become popular because it is more sensitive than the chloramphenicol acetyltransferase (CAT) system (*UNIT 9.7A*), and individual assays are much quicker and easier to carry out. Cells transfected with luciferase expression plasmids (Fig. 9.7.4) are lysed using either Triton X-100 or freezing and thawing (alternate protocol) to release the reporter protein luciferase. Both ATP and the substrate luciferin are added to the lysate in a luminometer. The enzyme catalyzes a rapid, ATP-dependent oxidation of the substrate, which then emits light. Total light output is measured and is proportional to the amount of luciferase present over a wide range of enzyme concentrations.

Materials

- Cells transfected with luciferase expression plasmid (*UNITS 9.1-9.4 & 16.13*; Fig. 9.7.4), in 60-mm petri plates
- PBS (*APPENDIX 2*), ice-cold
- Triton/glycylglycine lysis buffer (see recipe)
- Luciferase assay buffer (see recipe)
- Luciferin stock solution (see recipe)
- 25 mM glycylglycine, pH 7.8 (free base, crystalline; Sigma)
- Firefly luciferase of known activity (Sigma) for use as standard
- Rubber policeman or equivalent
- Luminometer (manual or automated) with printer or chart recorder and cuvettes

1. Wash three 60-mm plates of cells transfected with luciferase expression plasmid three times with 4 ml ice-cold PBS per wash, aspirating medium between each wash.

The luciferase enzymatic reaction is inhibited by traces of calcium; therefore, calcium-containing medium must be washed out of the plate thoroughly before cell harvest. Triplicate plates are needed for statistical manipulations.

2. Add 350 μ l Triton/glycylglycine lysis buffer to each plate. Scrape with a rubber policeman.
3. Transfer solubilized cells to a 1.5-ml microcentrifuge tube. Microcentrifuge 5 min at maximum speed, 4°C. Transfer supernatant (cell lysate) to a clean microcentrifuge tube and store on ice for assay.

Reporter luciferase activity is efficiently extracted by Triton; <10% of reporter activity should remain in the insoluble pellet after centrifugation.

4. Gently vortex cell lysate and place 100 μ l in a luminometer cuvette. Add 360 μ l luciferase assay buffer. Place cuvette in luminometer chamber.

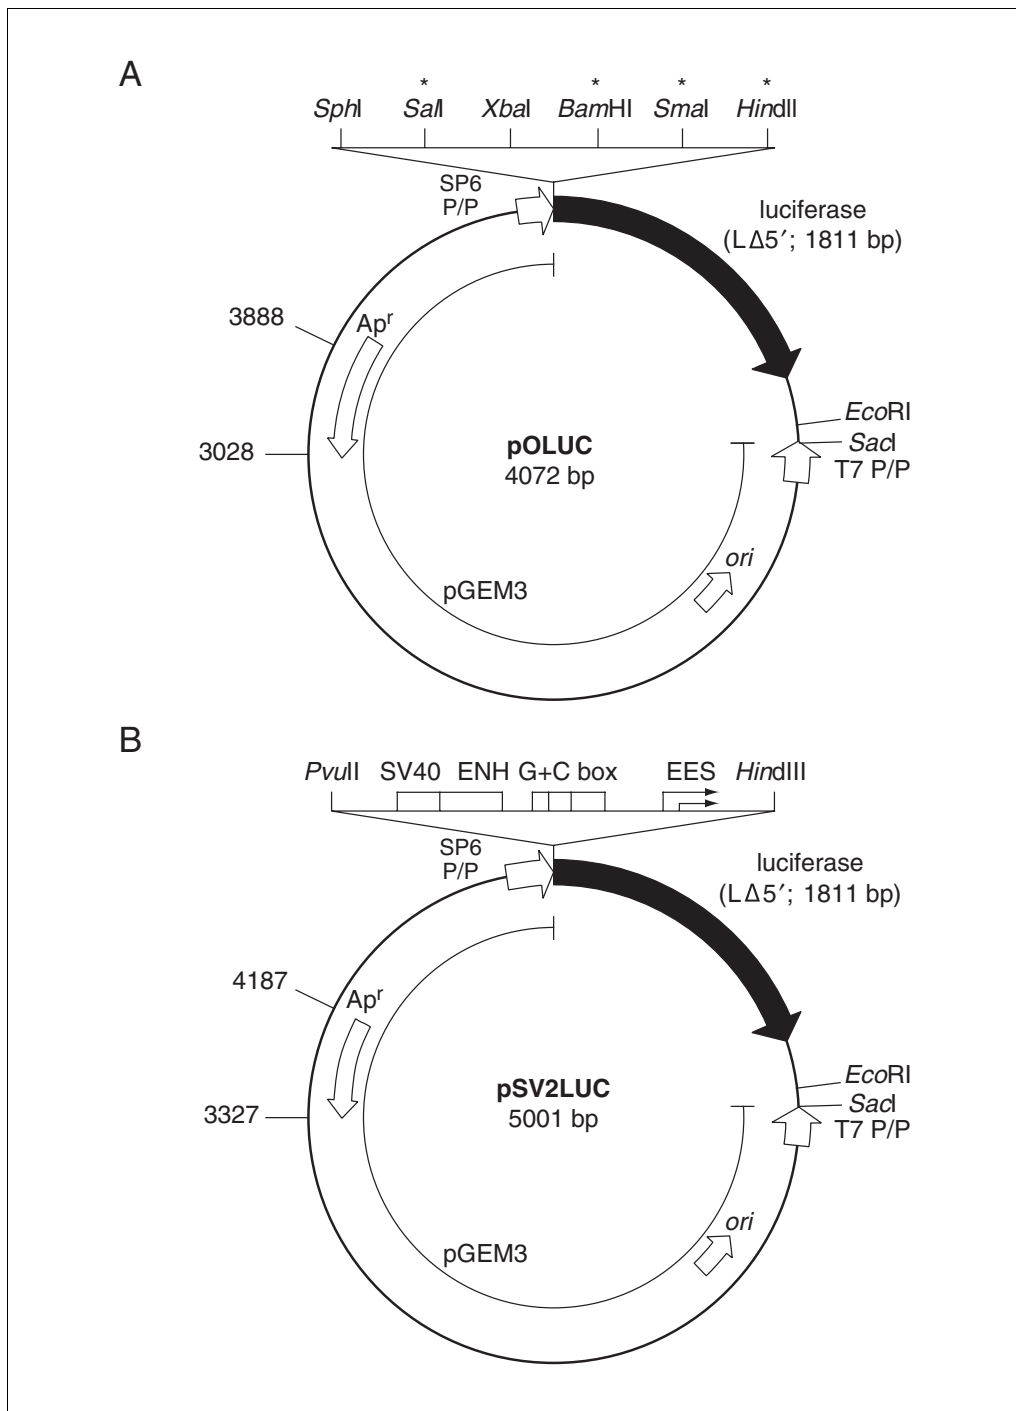

Figure 9.7.4 Luciferase expression vectors. **(A)** pOLUC is a promoterless vector containing a luciferase gene. It is derived from pGEM3, a high-copy ampicillin-resistance plasmid whose multiple cloning sites are flanked by SP6 promoter/primer sequences (SP6 P/P) and T7 promoter/primer sequences (T7 P/P). Unique restriction sites for insertion of sequences of interest are indicated by asterisks (*). **(B)** pSV2LUC contains the strong eukaryotic simian virus-40 (SV40) promoter/enhancer sequences inserted into pOLUC for use as a positive control for luciferase expression or as a standard for normalization between transfections. SV40 ENH designates the 72-base-pair repeats of the SV40 enhancer, G+C box(es) are the SP1-binding sites of the SV40 promoter, and EES designates the early-early transcription start sites.

5. Dilute luciferin stock solution to 200 μ M in 25 mM glycylglycine, pH 7.8.

Luciferin is rapidly oxidized by exposure to light; discard unused diluted solution.

6. Inject 200 μ l diluted luciferin solution into the sample in the luminometer and measure light output for 20 sec at 25°C. Quantitate by subtracting machine background (determined by measuring light output in a cuvette that has no cellular lysate) and by comparing bioluminescence of each sample with luciferase standards obtained commercially.

Enzymatic activity is proportional to light activity over three orders of magnitude. Because the luciferase reaction is complete in 20 sec, samples containing reporter activity that exceeds the linear range of the photomultiplier tube can be immediately reassayed after appropriate dilution in glycylglycine buffer.

ALTERNATE PROTOCOL

LUCIFERASE ASSAY IN FREEZE-THAW-LYSED CELLS

This protocol uses cycles of freezing and thawing transfected cells in a potassium phosphate buffer to produce a cell lysate. Although this method of extraction takes longer than Triton X-100 lysis, the lysates give more CAT enzymatic activity for experiments using cotransfected CAT reporter vectors and are stable for prolonged periods at 4°C.

Additional Materials (also see *Basic Protocol 1*)

Extraction buffer (see recipe)

Additional reagents and equipment for freeze-thaw lysis of cells as for chromatographic CAT assay (*UNIT 9.7A*)

1. Wash three 60-mm plates of cells transfected with luciferase plasmid in PBS as described in step 1 of the first basic protocol.
2. Add 1 ml extraction buffer to each plate. Scrape cells immediately with a rubber policeman.
3. Transfer cells to a 1.5-ml microcentrifuge tube. Microcentrifuge 15 to 30 sec.
4. Remove and discard supernatant. Add 100 μ l extraction buffer to the cell pellet.
5. Lyse cell membranes by three cycles of freeze-thaw.
6. Microcentrifuge lysed cells 5 min at maximum speed, 4°C. Remove and assay the supernatant as in the luciferase assay basic protocol (steps 4 to 6).

CHEMILUMINESCENT β -GALACTOSIDASE REPORTER GENE ASSAY

This protocol describes a chemiluminescence detection procedure for measuring β -galactosidase activity in extracts of cells transfected with a β -galactosidase expression plasmid (Fig. 9.7.5). The assay requires <30 min and has a sensitivity equivalent to or greater than the luciferase assay. Cells are lysed with a lysis solution containing Triton X-100. After a short incubation with substrate, a light-emission accelerator is added to enhance light production and detection. Light emission is measured with a luminometer or a scintillation counter. When the detection is performed in a luminometer, the dynamic range of the assay is approximately six orders of magnitude (20 fg to 20 ng of β -galactosidase). Lysates of cells cotransfected with luciferase reporter plasmids can also be assayed for luciferase activity (first basic protocol).

**BASIC
PROTOCOL 2**

Figure 9.7.5 β -galactosidase expression vector. p β -gal-Basic lacks eukaryotic promoter and enhancer sequences and allows insertion of promoter-containing DNA fragments into the polylinker upstream of the *lacZ* gene. Enhancer sequences can be cloned into the polylinker or into unique sites downstream of *lacZ*. All four vectors in this series contain an SV40 intron and SV40 polyadenylation signal downstream of *lacZ* to ensure proper and efficient processing of the transcript. The vector backbone contains a f1 origin for single-stranded DNA production and a pUC-19 origin of replication and ampicillin-resistance gene for propagation in *Escherichia coli*. The multiple cloning site (polylinker) region is identical in all four vectors in the series; in p β -gal-Promoter and in p β -gal-Control a 202-bp promoter-containing fragment has been inserted between *BglII* and *HindIII*. The sequence of p β -gal-Basic has been deposited in GenBank (Accession #U13184).

**Introduction of
DNA into
Mammalian Cells**

9.7.15

Materials

Cells transfected with a β -galactosidase expression plasmid (*UNITS 9.1-9.4 & 16.13*; Fig. 9.7.5), in 60-mm petri plates
Mock-transfected control cells, in 60-mm petri plates
PBS (*APPENDIX 2*)
Triton lysis solution (see recipe)
 β -galactosidase reaction buffer (see recipe)
Light-emission accelerator solution (see recipe)
Rubber policeman (or equivalent)
Luminometer with chart recorder and tubes *or* scintillation counter

1. Rinse one 60-mm plate of cells transfected with β -galactosidase expression plasmid and one 60-mm plate of mock-transfected cells twice with PBS.

Mock-transfected cells are processed in parallel with transfected cells and the resulting lysate is used for positive and negative controls.

2. Add 250 μ l Triton lysis solution.
3. Detach cells from plate using a rubber policeman. Transfer cell extract to a 1.5-ml microcentrifuge tube and microcentrifuge 2 min at maximum speed, 4°C.
4. Transfer supernatant to a clean microcentrifuge tube.

As a negative control, assay a volume of mock transfected cell extract equivalent to the volume of experimental cell extract used. As a positive control, add 1 μ l β -galactosidase (Sigma Grade VIII, 10 U/ml stock) to a volume equivalent to that of experimental cell extract.

Cell extracts may be used immediately or frozen several months at -70°C before continuing with the procedure.

5. Place 2 to 20 μ l cell extract into a luminometer tube.

Assays should be performed in triplicate.

The amount of cell extract required may vary depending on the level of enzyme expression. For accurate comparisons, the signal should remain within the linear range of the assay. Use 5 μ l extract if β -galactosidase is an internal control and 10 to 20 μ l extract for experiments where low levels of enzyme expression are expected. Smaller volumes of extract may increase the coefficient of variation as a result of increased pipetting errors.

6. Add 200 μ l β -galactosidase reaction buffer to the luminometer tube and incubate 60 min at room temperature.

Incubation time may be decreased to 15 min; however, sensitivity may decrease slightly as a result.

Chemiluminescent signal intensity varies with time. The incubation time with β -galactosidase reaction buffer should be identical for each sample. For example, if it takes 10 sec to complete each measurement, the reaction buffer should be added to consecutive tubes at 10-sec intervals.

7. Place tube into luminometer and inject 300 μ l light-emission accelerator solution. Wait 2 to 5 sec after injection and take the measurement for 5 sec.

Injections may be performed manually if the accelerator is added in the same time interval as the reaction buffer. See Background Information for a discussion of how to use a scintillation counter to measure activity.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see *APPENDIX 2*; for suppliers, see *APPENDIX 4*.

β-galactosidase reaction buffer

100 mM sodium phosphate, pH 8.0

1 mM magnesium chloride

1× 3-(4-methoxyspiro[1,2-dioxetane-3,2'-(5'-chloro)-tricyclo[3.3.3.1^{3,7}]decan]-4-yl)phenyl β-D-galactopyranoside (Galacton) chemiluminescent substrate (Tropix)

Store up to one month at 4°C

This solution is available as part of the Galacto-Light assay kit (Tropix).

Extraction buffer

100 mM potassium phosphate, pH 7.8

1 mM DTT (add just before use)

Store at room temperature; stable several months without DTT

Light-emission accelerator solution

10% (v/v) Emerald luminescence amplifier (Tropix)

0.2 N sodium hydroxide

Store up to 1 year at 4°C

A modified version of this solution that produces lower, nonenzymatic background is available as part of the Galacto-Light assay kit (Tropix).

Luciferase assay buffer

25 mM glycylglycine, pH 7.8

15 mM potassium phosphate, pH 7.8

15 mM MgSO₄

4 mM EGTA

2 mM ATP (Sigma)

1 mM DTT (add just before use)

Store at 4°C; stable several months without DTT

Luciferin stock solution

1 mM D-luciferin, synthetic crystalline (Sigma)

25 mM glycylglycine, pH 7.8

10 mM DTT (add just before use)

Divide into 1-ml aliquots and place in a light-tight box

Store at -70°C; stable several months without DTT

Triton/glycylglycine lysis buffer

1% (v/v) Triton X-100

25 mM glycylglycine, pH 7.8

15 mM MgSO₄

4 mM EGTA

1 mM DTT (add just before each use)

Store at 4°C; stable several months without DTT

Triton lysis solution

100 mM potassium phosphate, pH 7.8

0.2% (v/v) Triton X-100

1 mM DTT (add fresh immediately prior to use)

Store at 4°C; stable several months without DTT

This solution is available as part of the Galacto-Light assay kit (Tropix).

COMMENTARY

Background Information

Firefly luciferase assay

Firefly luciferase is an enzyme that produces light by ATP-dependent oxidation of the substrate luciferin in a two-step process. The heterocyclic luciferin is first adenylated and then undergoes oxidative decarboxylation, producing AMP, CO₂, and light from an activated luciferin intermediate. Light emission is maximal at 562 nm; the time course consists of an initial flash within seconds of adding luciferin, followed by a plateau of light output. When the assay is performed in the presence of excess substrates, light output is proportional to enzyme concentration. The luciferase reporter assay offers a sensitive, rapid, nonradioactive assay for measurement of promoter activity (Gould and Subramani, 1988; Brasier et al., 1989; Williams et al., 1989). A discussion of this and other widely used reporter systems is presented in the introduction to Section II and *UNIT 9.6* of this chapter.

With the cloning and expression of the luciferase gene from the firefly *Photinus pyralis* by de Wet et al. (1987), luciferase cDNA was cloned into derivatives of the pSV2 vector. The pSVOALA5' plasmid is a promoterless vector that contains both a 5' deleted cDNA missing an upstream ATG initiation codon and tandem polyadenylation signals between the pBR322 portion of the vector and the luciferase 5' untranslated tract.

Because of the limited number of unique restriction sites available for cloning test promoters, several investigators have engineered multiple cloning sites into the same or distinct vectors. Nordeen et al. (1988) generated the PXP-(1,2) series of vectors that contain multiple cloning sites in a modified pSV2 vector. Brasier et al. (1989) generated a promoterless luciferase reporter vector, pOLUC, containing LA5' sequences in a pGEM3-derived plasmid (Fig. 9.7.4). The pGEM3-derived vectors have the advantage of being high-copy-number plasmids, which allows production of larger amounts of plasmid DNA for transfection studies. Because of the potential problem with luciferase activation of cryptic promoters within reporter vectors, it is always wise to map the mRNA start site of any new promoter. With the pGEM3-derived luciferase vectors, no transcripts were detected originating upstream of a minimal promoter from the gene encoding angiotensinogen when it was transfected into HepG2 cells (Ron et al., 1990).

Chemiluminescent β -galactosidase assay

β -galactosidase is one of the most widely used reporter genes. It is commonly quantitated using the colorimetric substrate *o*-nitrophenyl- β -D-galactopyranoside (ONPG), but this assay has poor sensitivity with a detection limit of ~100 pg. It has been reported that as little as 2 fg of β -galactosidase can be detected with a chemiluminescent assay incorporating a 1,2-dioxetane chemiluminescent substrate for β -galactosidase (Galacton substrate; Jain and Magrath, 1991). Therefore, the chemiluminescent β -galactosidase assay is over three orders of magnitude more sensitive than the chloramphenicol acetyltransferase (CAT) assay and two orders of magnitude more sensitive than the fluorometric assay utilizing 4-methylumbelliferyl- β -D-galactopyranoside (MUG; Alam and Cook, 1990; Jain and Magrath, 1991). Upon cleavage with β -galactosidase, Galacton substrate breaks down and light is generated at a maximum wavelength of 470 nm (Bronstein et al., 1989). The signal-to-noise ratio of the reaction is further increased by the addition of a quaternary ammonium polymer formulation such as the Emerald luminescence amplifier (Tropix). These polymers increase the emission efficiency of the reaction by reducing aqueous quenching of the excited-state emitter in the polymer's hydrophobic domains. This increases the radiative decay of the excited state, thus producing a higher-intensity signal. Energy transfer to fluorescein, which possesses a higher quantum yield of fluorescence, provides further signal enhancement and a shift in emission maximum to 530 nm.

Higher sensitivity is achieved by performing the enzyme reaction at a different pH than is present during the measurement of the light signal. Bacterial β -galactosidase operates at a pH optimum between 6.5 and 8.0. In contrast, light production is increased at a pH > 9.5. Therefore, purified enzyme or cell extract containing β -galactosidase is incubated 15 min to 1 hr with the chemiluminescent substrate at pH 8 to allow the enzymatic reaction to occur. A light-emission accelerator containing alkali is added and light emission is measured immediately.

This chemiluminescent β -galactosidase assay has also been used successfully to measure β -galactosidase levels in bacteria (Nelis and Van Poucke, 1993) and yeast (D. Nathan and S. Linqvist, personal communication).

Critical Parameters

Measurements for luminescent reporter assays require specialized equipment—either a luminometer or a scintillation counter. Choice of equipment to quantitate bioluminescence must include consideration of several variables. Luciferase activity is proportional either to peak light output or integrated light output between 1 and 16 sec. The intra-assay variation is lower with integrated values, but some manual luminometers are equipped with chart recorders that only register peak luminescence. Although automated equipment is generally more expensive than manual, automation can be cost-effective for laboratories that rely heavily on data generated by cell transfection. Sensitivity is a vexing problem in measurement of bioluminescence as no standards exist for comparisons among different equipment. In practice, most available luminometers are adequately sensitive for assaying reporter gene activity; however, before investing in an expensive piece of equipment, it is wise to test a transfection on a demonstration model. More extensive discussion of luminometers and suppliers is found in VanDyke (1985) and Stanley (1992). A luminometer with a low-noise photomultiplier tube is recommended to achieve maximum sensitivity and dynamic range in the chemiluminescent β -galactosidase assay and the bioluminescent luciferase assay. Alternatively, a scintillation counter may be used for each of these assays (Fulton and Van Ness, 1993), but lower sensitivity may result. In the chemiluminescent β -galactosidase assay, the light emission maximum occurs ~2 sec after the addition of accelerator and decays with a half-life of approximately 4.5 min. Alternatively, Galacton-Plus chemiluminescent substrate exhibits a half-life of greater than 180 minutes and is better suited for use with luminometers without injectors or with scintillation counters. In contrast, the luciferase assay can be formatted in two ways that yield different kinetics: an unenhanced assay characterized by a flash of light followed by a rapid decay in light emission, and an enhanced assay that exhibits greater light output and slower signal decay. Nguyen describes the use of a scintillation counter to measure an unenhanced luciferase assay (Nguyen et al., 1988). Enhanced luciferase assays, available from Analytical Luminescence Laboratory and Promega, allow easier measurement in luminometers without injectors and in scintillation counters because light emission half-lives for these assays are 5 and 10 min, respectively.

Many luminometers are equipped with automatic injection devices. Such devices are optional with the β -galactosidase and the enhanced luciferase assays. The volumes recommended in the β -galactosidase detection protocol for both the reaction buffer and the light-emission accelerator may be proportionally reduced to use the smaller-volume injectors often recommended in luciferase protocols or microtiter plates, with only a slight reduction in sensitivity.

Some scintillation counters can measure chemiluminescence directly if the coincidence circuit is turned off. If chemiluminescence is measured without turning off the coincidence circuit, a linear relationship can be established by calculating the square root of the cpm minus background (Nguyen et al., 1988). The usefulness of a scintillation counter for measuring luminescence assays depends on the instrument background noise and ease with which the sample may be introduced into the counting chamber.

Firefly luciferase assay

Cell type. Luciferase enzyme in transfected mammalian cells is targeted to membrane-bound peroxisomes, apparently by information encoded by carboxy terminal amino acids (Gould and Subramani, 1988). This targeting may confound application of the assay to all cell types—e.g., it may affect the optimal time of harvest for transfected cell lines. In HepG2 cells transiently transfected with SV40 enhancer/promoter-driven luciferase plasmids, stable luciferase enzymatic activity was seen after 48 hr. In striking contrast, with rat hepatoma (H4 II E) and rat islet (RIN 1056A) cells, peak expression of luciferase reporter activity was seen 12 to 24 hr after transfection. Thus, this reporter system may not be ideal for use in these particular cell lines. Cell lines that have been successfully transfected include HepG2, JEG, HeLa, BHK, COS, mouse L cells, CV-1, and Jurkat. Clearly, a time course for assay of luciferase is an important parameter to examine when transfecting cell types other than these.

Cell lysis. Luciferase is commercially available for use as a positive control for assay reagents. ATP concentration is one important parameter to optimize in cellular lysates because ATP levels may vary within biological samples. In HepG2 cells, a concentration of 1 to 2 mM ATP gives optimal luminescence; concentrations >2 mM inhibit the activity of the transfected enzyme (Nguyen, 1988; Brasier et al., 1989).

Extracts prepared by Triton lysis are more unstable than extracts prepared by freeze-thaw lysis (alternate protocol), and must be assayed immediately or stored at -70°C to maintain full activity (Brasier et al., 1989).

Hormonal manipulation. The luciferase system has successfully been used to analyze the regulatory effects of several hormones, including glucocorticoids and thyroid hormone, on various promoters. However, an artifactual 2- to 5-fold induction of luciferase activity by dibutyryl cyclic AMP in pOLUC-transfected HepG2 cells has been observed (A.B., unpub. observ.). Thus, this vector is probably not appropriate for studies of cyclic AMP response elements.

Cotransfection with control plasmid. Changes in transfection efficiency can be evaluated by transfecting with both a luciferase test plasmid and an internal control plasmid such as the chloramphenicol acetyltransferase (CAT) expression plasmid. Normalizing data for transfection efficiency lowers scatter within triplicate plates and makes measurement of weak promoters reproducible. The inclusion of a cotransfected reporter may influence the choice of a lysis strategy. CAT enzymatic activity is detectable with the Triton lysis protocol, but the sensitivity of the CAT assay can be reduced 10-fold by the concentration of detergent used in the luciferase lysis procedure. Lower concentrations of detergent (e.g., 0.5%) are adequate to lyse cells, but freeze-thaw lysis should be considered if the activity of the cotransfected CAT reporter is weak. The CAT assay is compatible with the potassium phosphate lysis buffer, and both enzymes exhibit the same pH optimum. Alkaline phosphatase expressed by a cotransfected control plasmid can also be extracted with the luciferase Triton lysis procedure. In the spectrophotometric assay of Triton X-100 extracts, alkaline phosphatase activity is linear, but the blank and alkaline phosphatase standards must have the same final concentration of Triton as the cellular lysates. Use of the hGH reporter system (UNIT 9.7A) or the chemiluminescent secreted alkaline phosphatase assay (Bronstein et al., 1994) avoids the problem of matching lysis strategies.

Chemiluminescent β -galactosidase assay

Cotransfection. The chemiluminescent β -galactosidase substrate is ideal for cotransfection with the luciferase reporter gene because both assays are rapid, exhibit high sensitivity, and can be performed in the same cell extracts

(Fulton and Van Ness, 1993). Luciferase assay measurements can be performed during the β -galactosidase assay steps. Detection of the β -galactosidase samples follows the luciferase measurements.

Controls. Purified β -galactosidase should be added to mock-transfected cell extracts and used as a positive control. Mock-transfected cell extracts are important as a negative control to establish an assay baseline by measuring the endogenous enzyme background.

Cell lysis. Cell extracts may be prepared using a Triton X-100 lysis buffer such as that listed in the protocol. Alternatively, the cell culture lysis reagent recommended by Promega for use with luciferase can be used in cotransfections of the luciferase and β -galactosidase reporter genes.

Endogenous enzyme activity. It has been shown that endogenous β -galactosidase activity can be reduced by increasing the pH of the reaction buffer from pH 7 to pH 8 (Jain and Magrath, 1991). Inhibition of the endogenous enzyme enables greater discrimination between the transfected bacterial enzyme and endogenous activity. Heating extracts at 50°C for one hour has been shown to significantly reduce endogenous enzyme activity (Young et al., 1993). A modified version of this procedure has been used with the luminescent detection assay to detect β -galactosidase in tissue (Shaper et al., 1994).

Anticipated Results

Luciferase activity is linear up to 200 μg protein in cell extracts; using integrated light output between 1 and 16 sec, the intra-assay variation should be $\leq 5\%$. In a representative experiment from transfected HepG2 cells with assays of triplicate plates under the conditions described in the basic protocol, activity from pOLUC-transfected cells was 1572 ± 60 integrated light units (ILU) and activity from pSV2LUC-transfected cells was $83,040 \pm 1400$ ILU, where the luminometer background was 100 ILU. The sensitivity of the luciferase reporter system is estimated to be 10 to 1000 times that of the CAT reporter system (de Wet et al., 1987; Williams et al., 1989).

The sensitivity of the chemiluminescent β -galactosidase assay varies widely and is highly dependent on the level of endogenous β -galactosidase. Background attributed to the chemiluminescent reagents alone is generally very low; however, the range may vary somewhat depending upon the circumstances and instrument used. For example, background measured

using a Berthold Luminometer Model LB952T is usually 400 to 800 relative light units measured in a 5-sec interval. In cells with relatively high levels of endogenous enzyme activity, this assay can still be quite useful as an internal control for transfection efficiency.

Time Considerations

Harvesting twelve samples and preparing extracts for the luciferase assay should take 30 min. Each assay point is finished within 20 sec of injecting luciferin solution. With an automated luminometer, a 24-point assay is completed within 12 min. Data manipulation requires ~1 hr.

Extract preparation for 12 samples for the chemiluminescent β -galactosidase assay may be accomplished in <30 min. A 15-min to 1-hr substrate incubation is followed by accelerator addition and measurement in a luminometer, which requires ~15 sec per sample. When this assay is used as an internal control for luciferase, both assays can be performed concurrently.

Use of the *A. Victoria* Green Fluorescent Protein to Study Protein Dynamics in Vivo

Fluorescent molecules serve as valuable tools for the detection of a variety of biochemical phenomena. Such reagents have been employed for protein localization, quantitation of gene expression, detection of nucleic acids, cell sorting, and determination of chemical concentrations. However, the use of such techniques generally requires significant nonphysiological perturbations to the biological system being studied. For example, cells being processed for immunofluorescence must be fixed and permeabilized. Therefore, although this method is relatively simple and efficacious, it is not appropriate for the observation of dynamic phenomena.

A variety of fluorescent compounds exist that can efficiently localize within living cells. For instance, the karyophilic dye Hoechst 33258 is often used to detect the nuclei of living cells in culture, whereas the lipophilic dye DiI (1, 1'-dioctadecyl-3, 3, 3', 3'-tetramethylindocarbocyanine perchlorate) is commonly used to label cell membranes within living tissues. However, such compounds cannot be used to localize specific proteins, and the range of cellular constituents that can be labeled is somewhat limited.

Methods for transiently permeabilizing cells to allow uptake of fluorescent macromolecules have been successfully employed in conjunction with in vivo detection. For instance, microinjection of fluorophore-labeled antibodies can be used to track the dynamics of cellular antigens. However, such techniques are restricted to a limited variety of cell types, and permeabilization may perturb the cells' behavior. Furthermore, such procedures are technically difficult and may require specialized equipment.

In sum, although fluorescence is a useful tool for detecting molecules within cells, its application in vivo has heretofore been limited. The ideal vital fluorescent tag should (1) be detectable without causing cytological damage, (2) be able to label a wide variety of cell types readily, and (3) be able to be targeted to virtually any subcellular region. The recently cloned (Prasher et al., 1992) *Aequorea victoria* green fluorescent protein (GFP) is potentially such a molecule. The object of this section is to describe the use of this proteinaceous fluorophore for in vivo observation of cellular phenomena.

OVERVIEW OF GFP FLUORESCENCE

In the jellyfish *A. victoria*, the chemiluminescent protein aequorin emits blue light upon binding calcium ions. In vivo, however, the jellyfish glows green. This is because a second protein, GFP, absorbs the (short-wavelength) blue light and concomitantly emits (longer-wavelength) green light (Morin and Hastings, 1971). Although the 28-kDa protein was isolated over twenty years ago, its sequence has only recently been determined (Prasher et al., 1992). The utility of this protein as a molecular probe was first demonstrated by Chalfie et al. (1994), who expressed GFP in both *Escherichia coli* and *Caenorhabditis elegans*. In both cases, upon excitation with long-wave ultraviolet or blue light, the organism glowed green, indicating that *A. victoria*-specific factors were not required for GFP fluorescence. Furthermore, the spectral properties of GFP produced in *E. coli* are essentially indistinguishable from those of the protein isolated directly from the jellyfish (Morise et al., 1974; Chalfie et al., 1994; Inouye and Tsuji, 1994a).

UTILIZATION OF GFP

Because the cDNA sequence of GFP is known, it can in principle be expressed in any organism for which a gene delivery system is available. To date, GFP has been expressed and detected in a wide variety of organisms, including bacteria (Chalfie et al., 1994), fungi (Flach et al., 1994), plants (Haseloff and Amos, 1995), cultured mammalian cells (Olson et al., 1995; Pines, 1995), nematodes (Chalfie et al., 1994), and fruit flies (Wang and Hazelrigg, 1994). It has been expressed and detected both in intact form and as fusions to other proteins. In at least one reported case, both N- and C-terminal fusions localized properly and retained their function in vivo (Wang and Hazelrigg, 1994).

The fluorescence properties of GFP have been extensively studied (see Ward, 1981). The fluorophore is excited maximally at a wavelength of 395 nm with a secondary peak (of lower absorption) at 475 nm. The emission spectrum has a single peak at 509 nm. Thus, GFP can be detected (suboptimally) using a microscope equipped for fluorescence with filters for the commonly used fluorophore fluorescein isothiocyanate (FITC). Figure 9.7.6A illustrates the GFP excitation and emission

spectra along with the spectra of a typical FITC filter set. Notice that a typical FITC filter set fails to excite the major peak of GFP and excludes much of the light emitted by the protein. Two filter sets more suited to the excitation and emission spectra of GFP have recently become commercially available (Figs. 9.7.6B and C).

Isolated GFP is extremely stable; it retains its native fluorescence characteristics even when incubated with 6 M guanidinium hydrochloride, 8 M urea, or 1% SDS (Ward et al., 1980). Fluorescence is observed over a pH range of 7 to 12.2 and at temperatures $>65^{\circ}\text{C}$ (Ward, 1981). The protein can be denatured using a combination of chaotropic salt with strong acid (pH <4), strong base (pH >11), or high temperature. However, the protein will almost fully renature when such conditions are alleviated (Ward and Bokman, 1982). Thus, the

protein should retain its fluorescence under most physiological conditions.

Nascent GFP does not fluoresce immediately after translation; an intramolecular oxidation reaction that forms the chromophore must first occur. This chromophore is believed to be derived from the sequence Ser-Tyr-Gly at amino acid positions 65 to 67 (Cody et al., 1993). When GFP is expressed in bacteria under anoxic conditions, fluorescence is not observed. However, when the protein is exposed to atmospheric oxygen at room temperature, half-maximal fluorescence is observed after 1.5 to 2 hr (Heim et al., 1995). When purified protein is exposed to strong reducing agents such as sodium dithionite, fluorescence is completely lost. However, this state is reversible upon removal of reducing agent in the presence of atmospheric oxygen (Inouye and Tsuji, 1994b).

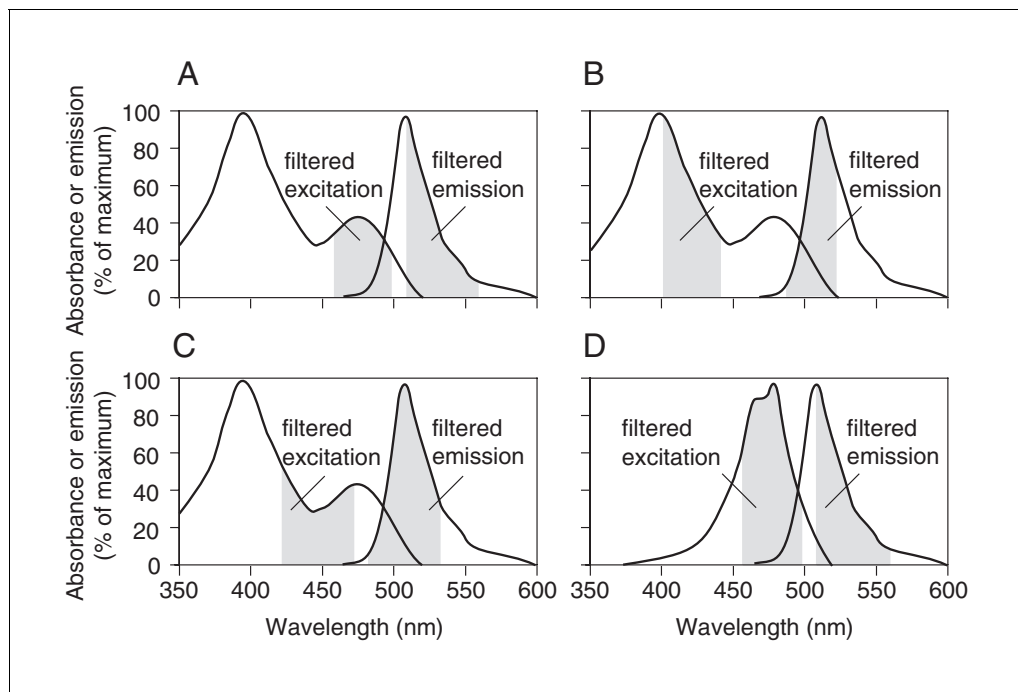

Figure 9.7.6 Selected spectra of wild-type and mutant GFPs juxtaposed with the spectra of several GFP epifluorescence filter sets (all from Chroma Technology). The left curve in each part is the excitation spectrum and the right is the emission spectrum. The grayed areas indicate the regions of the GFP spectra that are excited (“filtered excitation”) and passed (“filtered emission”) by the filter set. Note, however, that some excitation sources (e.g., mercury arc lamps) do not provide appreciable amounts of light over the entire filtered excitation region. **(A)** Spectra of wild-type GFP with the “Hi-Q FITC” filter set. **(B)** Wild-type GFP with the “Standard GFP” filter set, which takes advantage of the strong light output of a mercury lamp at 405 and 436 nm as well as the excitation and emission characteristics of GFP. **(C)** Wild-type GFP with the “Hi-Q GFP” filter set, which takes advantage of the strong light output of the mercury lamp at 436 nm as well as the high-amplitude ($\lambda_{\text{max}} = 509 \text{ nm}$) emission peak of GFP. **(D)** A spectrally shifted mutant [S65T, V163A] with the “Hi-Q FITC” filter set. Although the spectra of this mutant coincide well with those of the FITC filter set, a mercury arc lamp lacks strong excitation peaks over the 450 to 500 nm range. Thus, when using this mutant, a xenon arc lamp may be a more appropriate excitation source.

A number of GFP expression systems are currently available. The authors have developed a series of C-terminal fusion vectors that promote GFP expression in the budding yeast *Saccharomyces cerevisiae* (Fig. 9.7.7). Vectors designed to drive GFP expression in mammalian cells are commercially available (Clontech). Bacterial expression vectors have been described by Chalfie et al. (1994) and Heim et al. (1994). In these cases, high-level GFP expression is driven by a strong transcriptional promoter. For accurate expression (and localization) of fusion proteins, it may be advantageous to use the fusion gene-specific promoter if it provides a sufficient level of protein. For instance, a fusion of a yeast centrosomal protein, Nuf2p, to GFP was produced using the

NUF2 promoter to drive its expression (Kahana et al., 1995).

PROBLEMS WITH GFP

A frequent complaint about GFP is that it does not fluoresce brightly enough to be detected when expressed at low to moderate levels. However, high-level expression of GFP fusion proteins may result in mislocalization or cellular damage. In this section, three potential causes of this apparent “dimness” are identified: low “capacity,” “delayed” chromophore formation, and poor expression.

Low fluorescence capacity

Molecule for molecule, GFP is “dimmer” than most commonly used chemical fluoro-

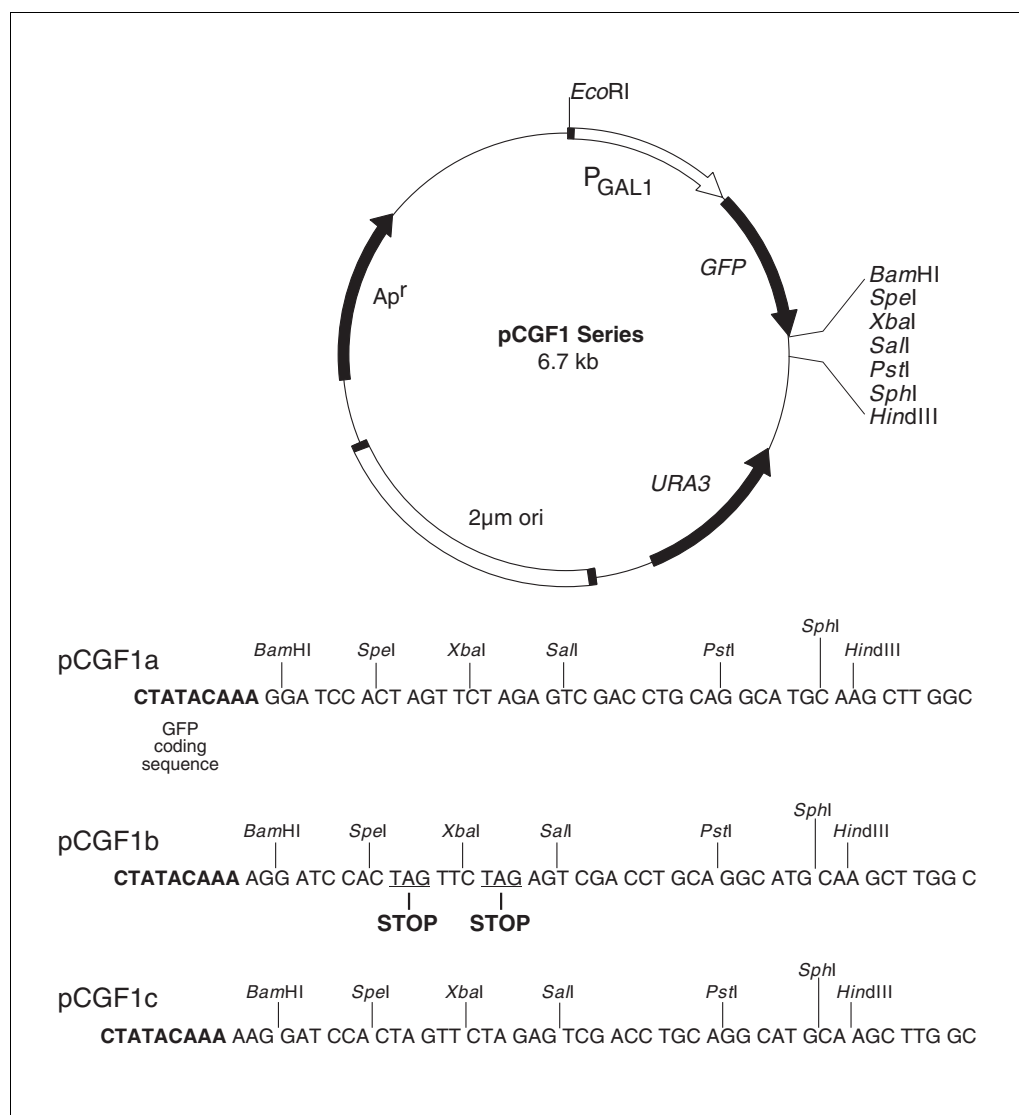

Figure 9.7.7 pCGF (C-terminal GFP Fusion) vectors for use in the yeast *S. cerevisiae*. The galactose-inducible *GAL 1* promoter (Yocum et al., 1984) is used to drive expression of a GFP fusion protein. A protein may be fused in any of three frames to the C-terminus of GFP. All restriction sites shown are unique.

phores. This is generally because GFP has a lower capacity to absorb excitation light than most commonly used chemical fluorophores. Basically, the phenomenon of fluorescence involves two activities: the absorption of light of one wavelength and emission of light of a longer wavelength. The ability of a material to fluoresce can therefore be expressed in terms of these two activities. Two quantities that describe them can be defined: extinction coefficient (ϵ) and quantum yield (QY). Extinction coefficient is a measure of the ability of a material to absorb radiation of a certain wavelength. Quantum yield reflects the ratio of (longer-wavelength) photons emitted to (shorter-wavelength) photons absorbed. In layman's terms, ϵ describes the "capacity" of the fluorophore, whereas QY represents its "efficiency." Thus, fluorescence "intensity" may be described (to a first approximation) as the product of ϵ and QY.

For wild-type GFP at a wavelength of 395 nm (the major excitation peak), ϵ is $24,000 \text{ M}^{-1} \text{ cm}^{-1}$ and QY is ~ 0.77 —that is, 77 photons are emitted per 100 photons absorbed (Ward, 1981; Heim et al., 1995). If a standard FITC filter set is used, this peak is not excited (see Fig. 9.7.6A). At the longer-wavelength excitation peak of 475 nm (which is excited using a FITC set), ϵ is diminished to $7150 \text{ M}^{-1} \text{ cm}^{-1}$. In contrast, FITC exhibits a similar QY but an ϵ of $76,000 \text{ M}^{-1} \text{ cm}^{-1}$ at its optimal excitation wavelength of 495 nm. Hence, a protein observed by immunofluorescence with a FITC-conjugated secondary antibody (assuming one FITC molecule per protein molecule) will appear roughly ten times brighter than a GFP fusion protein when viewed through a FITC filter set. In theory, GFP being detected with a GFP-specific filter set (see Fig. 9.7.6B) should fluoresce about one-third to one-fourth as brightly as FITC observed with a FITC filter set. In conclusion, GFP is an inherently dimmer fluorophore than the spectrally similar FITC.

"Delayed" fluorescence

Because GFP must undergo a posttranslational oxidation step to form its chromophore, it may not be detectable in certain situations. As mentioned, half-maximal fluorescence is observed in bacteria ~ 1.5 hr after exposure to atmospheric oxygen at room temperature. Similar measurements have not been made for GFP expressed in eukaryotic cells, but the reducing potential of cytoplasm may inhibit chromophore formation. When a GFP-cyclin fusion is expressed in COS-7 cells, there is a 3-hr lag

between the time it can be detected by immunofluorescence and the time it can be detected by *in vivo* fluorescence (Pines, 1995). Thus, if a fusion protein were to exhibit a rapid turnover rate *in vivo*, it would never exist in a fluorescent form. Based upon these observations, the use of GFP for a marker of transient gene expression may be infeasible, because the protein is not detectable immediately after translation.

Poor expression

A variety of GFP expression systems are now available. If fluorescence is not observed, however, it may be difficult to determine if a protein is being expressed efficiently. Because GFP cDNA is derived from jellyfish mRNA, it is not clear if the codons used are efficiently translated in other cell types. Furthermore, it is clear that the *A. victoria*-derived mRNA is not stable in all organisms. For instance, it has been shown that GFP mRNA is aberrantly spliced in *Arabidopsis thaliana* (Haseloff and Amos, 1995). Thus, the only reliable way to assay expression is by immunoblotting (UNIT 10.8). If a fusion protein is being expressed, antibodies raised against the fused protein (i.e., the original protein of interest) should recognize a band shifted by ~ 28 kDa. The authors have found that commercially available anti-GFP antibodies (Clontech) recognize fusion proteins in both immunoblotting and immunoprecipitation experiments. Thus, it should be possible to determine whether an observed lack of fluorescence is due to an actual lack of expression.

MUTANTS OF GFP

To ameliorate some of the problems discussed here, a variety of mutant forms of GFP have been synthesized. These mutants offer increased fluorescence intensity, shifted spectra, and more rapid posttranslational chromophore formation. Heim et al. (1995) and Delagrave et al. (1995) have found that a variety of mutations in and around the chromophore sequence can cause changes in the spectral characteristics of the protein. A mutation of Tyr⁶⁶ to histidine causes the protein to absorb long-wave ultraviolet light and emit blue light. However, the intensity is diminished by $\sim 50\%$ compared to that of the wild-type GFP (Heim et al., 1994). Mutation of Ser⁶⁵ to tyrosine (S65T) results in a protein that absorbs light maximally at 490 nm but continues to emit maximally at 509 nm, making it more suited to the spectra of a standard FITC filter set. Furthermore, the extinction coefficient of the S65T mutant is increased to $39,200 \text{ M}^{-1} \text{ cm}^{-1}$ at 490 nm exci-

tation (QY = 0.68) and the half-time of chromophore formation is reduced by ~66% (Heim et al., 1995). Such a mutant should be extremely useful, especially when a standard FITC filter set is used. The authors have determined that mutation of Val¹⁶³ to alanine (V163A) results in a GFP that is significantly more soluble in bacteria and seems to form its chromophore up to 25% faster than does wild-type GFP, but has the same spectral characteristics as the wild-type protein. A double mutant of S65T and V163A (which has the characteristic spectral shift of S65T) has been expressed in yeast and found to provide a signal that is significantly more detectable than that of wild-type GFP when a FITC filter set is used (see Fig. 9.7.6D).

MICROSCOPY SETUP

The authors routinely observe GFP fusion proteins in yeast using a standard microscope equipped for epifluorescence. Several aspects of the experimental setup have been optimized for detection of the GFP signal.

Objective lenses

Light intensity observed through a lens system may be described by the following relation (Hecht, 1987):

$$\text{intensity} \propto \frac{(\text{numerical aperture})^4}{(\text{magnification})^2}$$

Thus, for optimal signal, high-numerical-aperture (high-NA) objectives and the lowest possible magnification should be used. For example, using a 1.4-NA lens instead of a 1.3-NA lens of the same magnification results in nearly a 35% increase in intensity. Reduction in magnification from 100× to 60× (at constant NA) results in a roughly two-fold increase in intensity. For yeast, the authors have found that a 60× to 63× 1.4-NA lens with 10× eyepieces gives optimal signal and resolution for most applications. For mammalian cells (which are considerably larger), a 40×, 1.3-NA lens may be more appropriate.

Excitation sources

Most fluorescence microscopes are equipped with mercury arc lamps. In general, such lamps are available in 50-, 100-, and 200-W versions. However, there is not necessarily a direct correlation between power and intensity. Although a 200-W mercury lamp gives off more total light energy than a 100-W lamp, this is distributed over a much wider area than that emitted by the lower-power lamp. In practice, the overall intensity (total light output per unit

area) of a 100-W lamp is greater than that of a 200-W lamp. Furthermore, mercury arc lamps do not produce equal amounts of light over the entire spectrum; they tend to emit in strong “peaks” of high output at specific wavelengths. For instance, a mercury lamp provides most of its light in strong peaks at 337, 365, 405, 435, 546, and 577 nm (see Reichman, 1994). However, due to its high overall intensity, a 100-W mercury lamp is suitable for most routine epifluorescence applications.

Xenon arc lamps are also used as light sources for fluorescence microscopes. Overall, they produce much less light than mercury arc lamps at similar power levels. However, their light output is more spectrally uniform than that of the mercury sources. In practice, a 75-W xenon arc lamp will produce roughly as much (GFP-exciting) blue light as a 100-W mercury lamp (see Reichman, 1994). One benefit of the xenon lamp is that it produces less short-wavelength light than does a mercury lamp, which may minimize photodamage to the sample by stray light that passes fluorescence filters. The authors have found that a 75-W xenon arc lamp works extremely well for observing GFP fusions in yeast cells.

Often, lasers are utilized as light sources for microscopy (i.e., in confocal scanning microscopes). It has been reported that the 488-nm line of a krypton/argon laser is suitable for exciting GFP (Wang and Hazelrigg, 1994; Olson et al., 1995).

Fluorescence filters

Several types of filter sets are currently available that are appropriate for observing GFP. Before discussing these, it is important to delineate the three commonly used types of optical filters: band-pass, short-pass, and long-pass. Band-pass filters allow a finite range of light to pass through while excluding both longer and shorter wavelengths; short-pass filters exclude only light longer than a particular wavelength; and long-pass filters exclude only light shorter than a certain wavelength. Band-pass filters are typically used to specify excitation illumination, whereas both band-pass and long-pass filters are commonly used to specify emission spectra. Short-pass filters are sometimes used as excitation filters, but generally not for routine epifluorescence experiments.

Band-pass emission filters are generally more useful for observing a particular fluorophore when others are present or when nonspecific background fluorescence is present in the sample. Long-pass (LP) filters are typically

more useful when signal strength is low and maximal signal must be detected. The authors have used both standard FITC long-pass (excitation 450 to 490 nm, emission 520 LP) and FITC band-pass filters (excitation 460 to 500, emission 510 to 560; see Figs. 9.7.6A and D) for detecting GFP fluorescence in yeast. The authors have also used the GFP-specific (band-pass) filter set (excitation 400 to 440 nm, emission 480 to 520 nm; see Fig. 9.7.6C), but have observed that photobleaching of GFP is greatly accelerated when excitation is with this shorter-wavelength light. When a digital camera is used to record multiple images over extended periods of time, a FITC long-pass filter gives the most usable signal in terms of maximizing detectability and minimizing photobleaching.

Placed in between the excitation and emission filters is the third moiety of the filter set, known as the dichroic mirror (or beam splitter). This mirror serves to direct excitation (short-wavelength) light from the lamp to the sample and emission (long-wavelength) light from the sample to the eyepieces (or detector). Typically, the dichroic mirror is defined by a single wavelength: all light below this wavelength is reflected (to the sample), while all longer-wavelength light passes through the mirror (to the detector). Thus, the wavelength of a dichroic mirror is chosen to be between the longest excitation-filter wavelength and the shortest emission-filter wavelength. For example, when using the standard FITC long-pass filter set (excitation 450 to 490 nm, emission 520 LP), a dichroic mirror defined at a wavelength of 510 nm is used.

CONCLUSIONS

The existence of a completely proteinaceous fluorophore gives researchers a unique opportunity to observe dynamic cellular phenomena under physiological conditions. Because it requires no exogenous factors for fluorescence, the *A. victoria* green fluorescent protein has made such observations more feasible in a number of biological systems. The fact that GFP has been expressed and detected in a wide variety of organisms in both intact and (recombinantly) fused forms illustrates its versatility as a reporter molecule. Although difficulties have been reported in detecting GFP in some systems, advances in technology will certainly improve the situation. As spectrally enhanced mutants, expression vectors, antibodies, and GFP-specific filters become more widely available, the use of this unique in vivo fluorophore should become more common among a wide

variety of researchers. As GFP technology becomes more accessible, the end result should be a greater understanding of a variety of dynamic biological phenomena.

It is possible to transfect mammalian cells with a gene of interest and directly detect the RNA made from that gene 24 to 48 hr later (UNITS 9.1-9.4, 16.12, & 16.13; see Treisman, 1986, and Kingston et al., 1986, for examples). This type of analysis circumvents the need for fusion genes, but takes many more hours to do than an experiment done using fusion genes. The ability to analyze the RNA directly allows mutation and functional analysis of an intact gene, as the promoter does not have to be subcloned. This technique is also essential when fusion genes are used. In order to be sure that the level of the reporter protein produced by a fusion gene provides an accurate measure of appropriately initiated RNA from the promoter under study, it is necessary to determine the amount and 5' end of the fusion message. An investigator who verifies this using direct RNA analysis can proceed with some confidence that the level of the reporter protein is a measure of promoter activity.

The difficulty in directly analyzing RNA is that the sensitivity of detection is at the limits of present technology. Consequently, the transfection protocol, RNA preparation, and RNA analysis techniques all have to be working near optimum in order for an experiment to work. The cell type used must be readily transfectable, and the promoter being studied must be relatively efficiently expressed or the amount of RNA produced will be below the limits of detection. Direct analysis of RNA is several orders of magnitude less sensitive than the commonly used reporter gene systems. These difficulties make it clear why fusion genes containing a readily assayed reporter protein are presently so popular.

The following parameters should be considered when directly analyzing RNA after a transfection.

TRANSFECTION EFFICIENCY

It is imperative that the cell type and transfection protocol used result in efficient transfection. The efficiencies that result from CaPO₄-mediated transfection of HeLa, BALB/c 3T3, or NIH 3T3 cells are sufficient to do direct analysis of RNA expression after transient transfection. Optimization of transfection efficiency in the cell type used (introduction to Section I) should be done prior to attempting to analyze RNA from transfected genes.

Even after optimization, transfection efficiencies vary from day to day. One way to avoid the extensive workup of an experiment that is doomed to failure due to inefficient transfection is to include an easily assayed reporter gene in the transfection as an indicator of transfection efficiency. For example, an hGH expression plasmid can be included in each dish, and the level of secreted hGH can be rapidly measured at the time of harvest. The experiment can be aborted if the transfection efficiency is too low (we expect hGH levels of greater than 50 ng/ml 48 hr after transfecting 1 μg of pXGH5 into a 10-cm dish of BALB/c 3T3 cells). Alternatively, a reporter gene such as a CAT construct can be transfected into one or two plates and that activity determined, although use of a non-secreted reporter protein is more cumbersome due to the necessity of making a cell lysate.

RNA PREPARATION

RNA must be efficiently made in an intact form. The total cytoplasmic (UNIT 4.1) and guanadinitium isothiocyanate (UNIT 4.2) protocols are both well suited to this purpose. Two 10-cm dishes of adherent cells should produce 100 μg of total RNA (this number will be lower for particularly flat cell types). Expression from a transfected gene can be detected by analyzing 40 μg of total RNA. Sensitivity will be increased by using poly(A)-selected RNA (UNIT 4.5), but this is time-consuming. In addition, numerous dishes would have to be transfected to produce the amount of RNA required for the poly(A) selection.

ANALYSIS OF RNA

Both S1 analysis using single-stranded probes (UNIT 4.6) and ribonuclease protection analysis (UNIT 4.7) have the sensitivity necessary to detect gene expression at transient times after transfection. S1 analysis tends to have a lower background, allowing longer exposure times to be used. Ribonuclease protection analysis uses a probe of higher specific activity and thus should be significantly more sensitive if optimized. It can be more difficult to optimize the ribonuclease protection protocol, but it is worthwhile if the added sensitivity results in routine ability to detect expression from a transfected gene.

PROMOTER STRENGTH

Clearly, it is difficult to detect expression of RNA from an extremely weak promoter. If the promoter strength is more than an order of magnitude below that of, for example, the SV40 early promoter in HeLa cells, heroic efforts may be necessary in order to analyze the RNA. In such cases, poly(A) selection may be necessary as well as the use of body-labeled probes.

TRANSDUCTION OF GENES USING RETROVIRUS VECTORS

Overview of the Retrovirus Transduction System

A retrovirus vector is an infectious virus used to introduce a nonviral gene into mitotic cells *in vivo* or *in vitro*. Originating from replication-competent viruses isolated from rodents or chickens, the vectors are modified in various ways to serve in the transduction process. The efficient and precise integration machinery of naturally occurring retroviruses is utilized to produce either a single copy or a few copies of the viral genome stably integrated into a host chromosome.

Retroviral vectors are useful in achieving stable and efficient transduction of a gene or genes into cells that are not easily transfected, such as primary cells of various types and cells *in vivo* (which are usually not susceptible to transfection at all). Transfection refers to gene transfer (usually for expression) by processes that make a cell transiently permeable to DNA. Transfection methods include calcium phosphate- and DEAE-dextran-mediated transfection, and electroporation (*UNITS 9.1-9.3*). Not all cells can be transfected (especially primary cells), and the optimal transfection procedure varies for different cell types. Transfection methods may result in stable integration, in which the introduced DNA is integrated into the host chromosomal DNA, or transient transfection, in which there is no selection for integration and most of the introduced DNA has not integrated into the host chromosomes. In contrast to transfection, retroviral infection is dependent on binding to specific receptors on the cell surface. Some of these receptors, such as ecotropic and amphotropic receptors, are expressed on many cell types, including most primary cells, and as a result, it is possible to infect most cells with retroviruses. For the purposes of these units, transduction refers to the ability of a retroviral vector to insert itself into the host DNA as a provirus. Because most commonly used retroviral vectors are replication-defective, transduction usually refers to the ability of a replication-defective retroviral vector to undergo one round of infection before stable integration.

Retroviral transduction may not be the method of choice when working with cells that

can be efficiently transfected or in experiments in which high plasmid copy number is desirable (for transient expression protocols, see *UNITS 9.1-9.4* and *UNITS 16.13 & 16.15-16.18*). Because the size of retroviral RNA that can be efficiently packaged is limited, retroviral gene transfer is unable to transduce large (>11 kb) DNA fragments. Another limitation to retroviral transduction is that postmitotic cells cannot be transduced because mitosis is required for entry of the viral integration complex into the nucleus (Miller et al., 1990; Roe et al., 1993). New technologies that may circumvent some of these limitations are being developed—e.g., visna virus-based retroviral vectors (Naldini et al., 1996).

This unit presents an overview of the retrovirus life cycle and a description of vector designs and packaging cell lines (reviewed in Boris-Lawrie and Temin, 1993; Riviere and Sadelain, 1996; Miller, 1996). Production of retroviral stocks by either transient transfection (*UNIT 9.11*) or stable transduction (*UNIT 9.10*) is then detailed, with protocols for titering and assaying the resultant virus stock. For various applications, it is desirable to produce large quantities of the virus, to concentrate the virus stock (*UNIT 9.12*), and/or to check the stock for contamination by helper viruses (particularly when animals are to be infected; *UNIT 9.13*). Finally, outlines for infection of cells *in vivo* and *in vitro* are suggested (*UNIT 9.14*).

RETROVIRUS LIFE CYCLE

Although retroviral genomes are made of RNA, retroviruses produce a DNA copy of their genome immediately after infection of the host cell through a series of steps involving both retroviral and host factors (Fig. 9.9.1). The viral DNA then integrates (mediated by the viral *int* gene product) into the host genome where it is referred to as a provirus (Fig. 9.9.2). Most experimental retrovirus vectors were originally derived from cloned proviral sequences.

Infectious retroviral stocks are made by transfecting a retroviral vector plasmid into cell lines called packaging lines for replication-incompetent vectors (Fig. 9.9.3), or into host lines

Figure 9.9.1 Generation of a double-stranded DNA copy of the RNA genome of a retrovirus. The genomic RNA is packaged in the virion with a retrovirus-specific cellular tRNA hybridized to a complementary sequence near its 5' end called the primer-binding site (PBS). The retroviral RNA has a short direct-repeat terminal sequence (R) at each end. The overall reaction is catalyzed by reverse transcriptase, which has both deoxynucleotide-polymerizing and RNase H activities and which digests the RNA strand in a DNA-RNA hybrid. The entire process yields a double-stranded DNA molecule that is longer than the template RNA and has a long terminal repeat (LTR) at each end. Note that the 5' LTR in the double-stranded DNA is derived from the 3' LTR. This has important implications for vector design and control of retroviral expression from transfected plasmids. (Adapted from *Molecular Cell Biology* by Darnell, Lodish, and Baltimore. Copyright 1986 by Scientific American Books, Inc. Used with permission of W.H. Freeman and Company.)

that support replication for replication-competent vectors (see discussion of Replication-Competent Vectors). Once in a cell line, transcription proceeds from the viral long terminal repeat (LTR) promoter encoded by the plasmid, generating an RNA viral genome. The viral genome is then encapsidated by viral structural

proteins, and infectious viral particles are produced by budding from the surface of cells (Fig. 9.9.3). The supernatant produced by such cells comprises a virus stock. The number of infectious viral particles per ml in a stock, referred to as colony forming units/ml (CFU/ml), is determined by a bioassay (UNITS 9.10 & 9.11). The

Figure 9.9.2 Life cycle of replication-competent retrovirus. All retroviruses infect host cells through an interaction with a specific viral receptor on the host-cell surface. They thereby enter the host cell and initiate reverse transcription of the RNA viral genome using reverse transcriptase contained within the viral particle. After synthesis of a linear duplex DNA copy of the viral genome, the viral DNA integrates into the host genome. Integration is mediated by the viral *int* gene product (encoded at the 3' end of the *pol* region) and usually occurs at the ends of the viral genome. Within the host genome, integration can occur at a very large number of chromosomal locations with little or no apparent specificity. One infectious virion produces one integrated copy of the viral genome. This “provirus” is subsequently replicated with the host DNA and is passed on to all progeny cells. After integration, the viral LTR promoter at the 5' end of the genome is usually active and directs synthesis of a full-length (i.e., unspliced) copy of the viral genome, which terminates in the 3' LTR.

In replication-competent viruses, the viral genome encodes the viral proteins *gag*, *pol*, and *env* required to make viral particles. The full-length viral transcript serves several functions. It is the mRNA for the *gag* proteins (which comprise the bulk of the viral particle), reverse transcriptase, and the *int* gene product, and it is the precursor RNA that is used to generate a spliced mRNA for the *env* protein, found on the surface of the viral particle. Finally, in its unspliced form, it is also the RNA that encodes Ψ, the recognition sequence for encapsidation. Because it contains the Ψ sequence, it can be recognized by the packaging proteins and become packaged into a viral particle. Due to this role, the unspliced full-length transcript is also referred to as the “genomic RNA.” Infection by a replication-competent virus thus leads to production of infectious retroviral particles identical to the original infecting particle. These particles are budded from the host cell and can go on to initiate more rounds of infection in other host cells.

bioassay, or “titration,” is carried out on a convenient target cell line that is easy to grow and is very susceptible to infection by a particular virus, such as NIH 3T3 cells for viruses with an ecotropic, amphotropic, or polytropic host range. The titered stock is then used to infect cells *in vivo* or *in vitro*. Once integrated into the host cell the vector provirus makes mRNA(s) for the gene(s) of interest (Fig. 9.9.3).

REPLICATION-INCOMPETENT VECTORS

Replication-incompetent retrovirus vectors were derived from proviruses that were cloned from cells infected with a naturally occurring retrovirus. Deletion of some or all of the genes encoding virion structural proteins was carried out to create room for inserted genes and to cripple the virus (see Fig. 9.9.4). Although extensively deleted, the vectors retain the *cis*-

Figure 9.9.3 Production of an infectious retroviral particle from a bacterial plasmid that encodes a retroviral genome requires the introduction of the bacterial plasmid into mammalian or avian cells. This is true for both replication-competent and replication-incompetent vectors. In the example shown here, a replication-incompetent vector encoding *neo* and a gene of interest (*x*) are introduced, via CaPO_4 -mediated transfection, into a packaging line. The packaging line is a mouse or quail cell line (see Table 9.9.1) that encodes the proteins necessary for production of viral particles (i.e., gag, pol, and env). The bacterial plasmid can be transcribed either transiently (for a few days after transfection) from nonintegrated plasmid molecules or stably from integrated plasmid molecules. The viral transcript is initiated in the 5' LTR and terminated in the 3' LTR, and is thus a full-length viral transcript. It contains the packaging sequence Ψ , which is recognized by the capsid proteins and allows it to be packaged into viral particles. A fully infectious viral particle containing the vector genome is thus budded from the packaging cell. The culture supernatant is removed from cells and used as the source of virus for future experiments (e.g., see Fig. 9.9.4).

Also shown in this figure is the production of another transcript, initiated at an internal promoter (*pro*) and encoding the *neo* gene. The *neo* transcript produced by the internal promoter does not contain Ψ and thus does not become encapsidated. It will, however, serve as an mRNA for *neo*, thereby allowing for growth of these cells in the selective drug G418. As described in *UNIT 9.10*, this drug-resistance feature can be exploited to select cells that have been stably transfected with the retroviral plasmid.

acting viral sequences necessary for transmission. These sequences include the Ψ packaging sequence (necessary for recognition of the viral RNA for encapsidation into the virus particle), reverse transcription signals, integration signals, and viral promoter, enhancer, and polyadenylation sequences (Fig. 9.9.4). The viral promoter, enhancer, and polyadenylation signals are contained in the retroviral LTR. The former two elements, together with the retroviral envelope, determine the cell-type specificity of the virus. For example, Moloney murine leukemia virus (MoMuLV), whose LTR is the most common one used for retroviral vectors, is expressed in most cell types. Murine stem cell virus (MSCV), a derivative of murine embryonic stem cell virus (MESV; Hawley et al., 1994), is reported to give better expression in stem cells, whereas spleen focus-forming virus

(SFFV) gives better expression in erythroid cells (Boris-Lawrie and Temin, 1993).

Using the transcription regulatory sequences provided by the virus, any cDNA can be expressed in the vector. Alternate constructs that lack the viral promoter and/or enhancer have also been made. These constructs are used for applications such as studies of alternative promoter regulation, or when trying to avoid the repression of transcription that sometimes can occur when using the viral LTR. Recently, retroviral vectors have been described that replace the viral promoter/enhancer with inducible elements (Hofmann et al., 1996; Paulus et al., 1996), such as the tetracycline-responsive elements (Gossen and Bujard, 1992; reviewed in Shockett and Schatz, 1996). These vectors may circumvent some of the difficulties in expressing toxic genes, as well as providing the

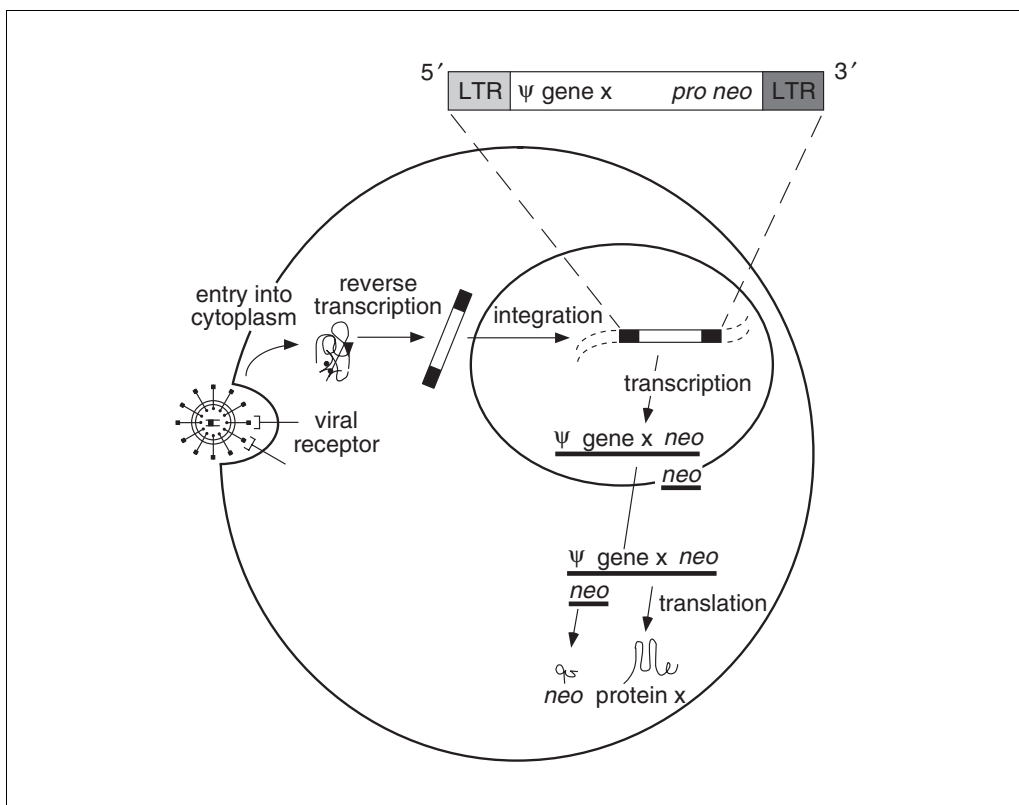

Figure 9.9.4 Infection of a target cell and expression by a replication-incompetent retrovirus vector occurs through interaction with a host-cell receptor. The virus then reverse transcribes and integrates, just like a replication-competent virus, as described in Figure 9.9.2. A full-length viral transcript can also be initiated in the 5' LTR and end in the 3' LTR, exactly as in the case of the replication-competent virus. However, the viral transcript typically does not encode any of the proteins required to make a viral capsid. It usually encodes a gene of interest (x). In addition, many replication-incompetent vectors encode another promoter (pro) within the viral genome for synthesis of an mRNA for another gene (e.g., neo). Because such a vector does not encode viral capsid proteins, cells infected with a replication-incompetent vector cannot make more viral particles. Thus, there is no spread of the viral genome from an infected cell to other cells. However, the viral genome does pass to all progeny cells through the normal processes used by the host to pass on all host genes.

ability to regulate gene expression from retroviral vectors. One drawback of using retroviral vectors that lack the viral promoter and/or enhancer is that retroviral titers drop by several orders of magnitude (Yu et al., 1986).

Vector designs are continually evolving, and it is best to obtain vectors from a laboratory that has experience with several different designs and that will advise on their use. There are many more murine replication-incompetent vectors available than avian ones. (Perhaps because more effort has gone into the design and use of murine replication-incompetent vectors, murine versions are also in general more successful than their avian counterparts.) In many instances, a vector will have to be modified by cloning a gene(s) of interest into an appropriate site, and subsequently introducing the recombinant vector into an appropriate packaging line (UNITS 9.10 & 9.11). Other vectors will be ready for use without any additional cloning or transfection steps. Examples of several different types of retroviral vectors that have been successfully used for gene transfer are shown in Figures 9.9.5 and 9.9.6. A large number of retroviral vectors have been developed and a review of all of these is beyond the scope of this chapter. For a more detailed explanation of individual retroviral vectors, the reader should consult the specific references.

REPLICATION-COMPETENT VECTORS

Vectors that retain all of the genes encoding the virion structural proteins, as well as all of the cis-acting viral elements necessary for transmission, are "replication-competent." Vectors of this type have been designed to carry and express additional, nonviral sequences. This frequently has been successful for genes ≤ 2 kb using avian replication-competent vectors (Hughes et al., 1987), but few successes have been reported for the murine replication-competent vectors. Replication-competent vectors have not been as popular as replication-incompetent vectors due to the greater popularity of mammals as experimental organisms. However, when working with avian species, they are very useful when it is desirable to transduce nearly all of the cells in an animal or in a tissue culture dish.

PACKAGING LINES AND VIRUS PRODUCTION

Replication-incompetent retrovirus vectors do not encode the structural genes whose products comprise the viral particle (see Fig. 9.9.4). To produce infectious viral particles from a

retrovirus plasmid, the viral structural proteins encoded by *gag*, *pol*, and *env* are supplied in *trans* by packaging cell lines (Fig. 9.9.3 and Table 9.9.1). These cells may be derived from a variety of cell lines that contain the viral *gag*, *pol*, and *env* genes as a result of introduction by transfection. The most commonly used cells are human 293 cells, primate COS cells, mouse NIH 3T3 fibroblasts, and quail QT6 cells. In contrast to retroviral vectors, the viral RNA that encodes the structural proteins does not contain the retroviral packaging sequence Ψ . Thus, the packaging lines do not efficiently package the RNA that encodes the genes *gag*, *pol*, or *env*. Prior to the introduction of vector DNA into these lines, cellular RNAs are randomly encapsidated and budded as normal viral particles. To produce viral particles that contain the vector genome, the vector DNA is introduced into the packaging cell line. The vector RNA is preferentially packaged because it contains the packaging sequence Ψ (Fig. 9.9.3).

Until recently, most packaging cell lines were developed using NIH 3T3 cells and used for the creation of stable retroviral producer cell lines. Stable retroviral producer cell lines contain a single (or few) integrated provirus and are capable of long-term production of retroviral supernatants. Although stable retroviral producer cell lines are able to produce high-titer retroviral supernatants expressing some cDNAs, with many retroviral constructs it has proven difficult to obtain high-titer retroviral supernatants. This is thought to result from outgrowth of clones that express low levels of retrovirus during the prolonged selection process necessary for creation of stable cell lines (see Fig 9.9.7). To overcome this problem, several groups have developed strategies based on transient retroviral production (Landau and Littman, 1992; Pear et al., 1993; Finer et al., 1994; Soneoka et al., 1995; Naviaux et al., 1996; see Fig. 9.9.7 and UNIT 9.11). These strategies, based on the use of either COS cells or 293 cells, have proven very successful for the production of high-titer retroviral supernatants from a large number of cDNAs, including some that were unable to produce high viral titers in NIH 3T3-based packaging lines.

As with naturally occurring retroviruses, packaged retrovirus vectors enter the host cell via interaction of a viral envelope glycoprotein (a product of the viral *env* gene) with a host-cell receptor (Table 9.9.2). The murine and avian viruses have several classes of envelope glycoprotein that interact with different host-cell receptors. Packaging lines that express various

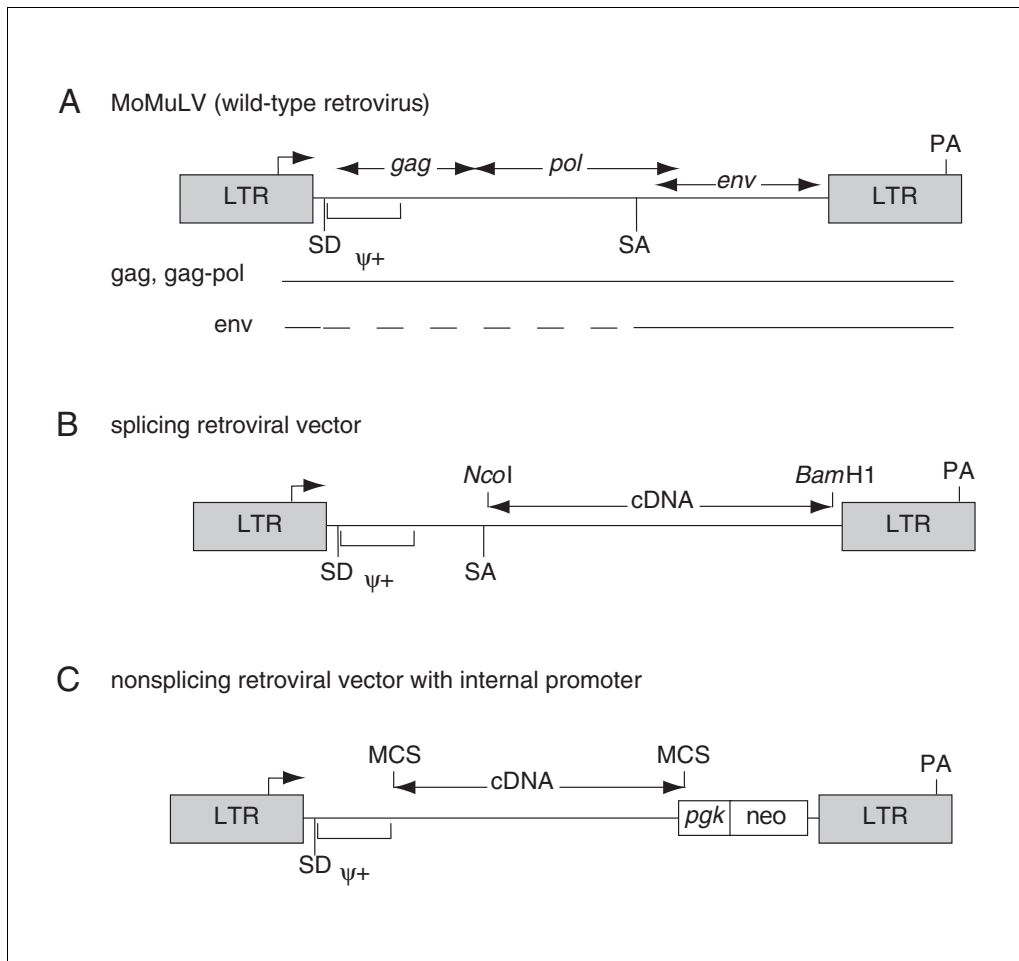

Figure 9.9.5 Overview of some recent developments in retroviral vector design. **(A)** Structure of wild-type Moloney murine leukemia virus (MoMuLV). Shown are the retroviral long terminal repeat (LTR), consisting of U3, R, and U5 regions (transcription initiation begins in the R region); splice donor (SD) and splice acceptor (SA) sites; extended retroviral packaging site (Ψ^+); and retroviral structural genes *gag*, *pol*, and *env*. Because Ψ^+ extends into *gag* (Bender et al., 1987), to prevent translation of *gag* product most retroviral vectors that use Ψ^+ contain mutations in the *gag* start codon. The *gag* and *pol* messages are expressed from an unspliced transcript, whereas the *env* message is spliced as shown below the vector. **(B)** Structure of a splicing retroviral vector. These vectors express the cloned DNA from a spliced message, as though it were the *env* gene. The example shows MFG, a vector that tries to closely emulate *env* expression for the cloned cDNA by expressing it from a spliced transcript and cloning it into an *Nco*I restriction site so that the translation initiation site is identical to *env* (Dranoff et al., 1993). **(C)** Structure of a nonsplicing retroviral vector that also contains an internal promoter. These vectors express the cloned cDNA as an unspliced message. There is also an internal promoter that expresses a marker for antibiotic resistance, which may be expressed as either an unspliced or a spliced message. One potential drawback to this strategy is competition between the internal promoter and the retroviral LTR. Because selection is frequently based on the marker and not the gene of interest, it is not uncommon to obtain drug-resistant colonies that do not express the gene of interest. This particular example shows murine stem cell virus (MSCV), which in addition to the above features contains a multiple cloning site (MCS) to facilitate insertion of the cDNA, an LTR from murine stem-cell virus to enhance expression in stem cells, and other modifications to enhance viral titer and gene expression (Hawley et al., 1994).

These markers cannot be used for subsequent selection. *gpt*, xanthine-guanine phosphoribosyltransferase; *tk*, herpes simplex virus thymidine kinase; *lpph*, hygromycin phosphotransferase; *diffr*, a mutant dihydrofolate reductase gene; *ble*, a bacterial gene that confers resistance to bleomycin and phleomycin in mammalian cells; *pac*, puromycin *N*-acetyl phosphotransferase; *bsr*, a bacterial gene that confers resistance to blasticidin S; and *neo*, neomycin phosphotransferase.

^cExcept where noted, all lines are capable of titers >10⁶ CFU/ml.

^dUnless otherwise noted, contact the authors of the specified reference.

^eThese are not packaging cell lines. Rather than being stably introduced into the 293 cells, the retroviral structural genes are cotransfected with the retroviral vector.

^fTo receive these cell lines, obtain a Material Transfer Agreement from and return it to: Office of the General Counsel, Attn: Teresa L. Solomon, Esq., The Rockefeller University, 1230 York Ave., New York, NY 10021-6399, (212) 327-7598, Fax (212) 327-7688.

^gBecause of its cytotoxicity, VSV G protein is not stably integrated into the gag-pol-producing cell line.

^hIn the original report, the retroviruses were pseudotyped with both MLV-amphotropic envelope and VSV G protein.

viral envelope proteins are listed in Table 9.9.1, along with a summary of some of their properties. The abilities of these viruses to transduce mouse and/or human cells is listed in Table 9.9.2. It should be noted that a given murine vector can be encapsidated by packaging proteins produced by ecotropic, amphotropic, or polytropic cell lines. The gag and pol proteins encoded by the ecotropic and amphotropic packaging lines are virtually identical. The only significant differences among the proteins encoded by the various lines are in the env protein.

MURINE RETROVIRUSES

Ecotropic Receptors

The most commonly used type of murine viral glycoprotein is the ecotropic type, which binds to the *ecotropic receptor* found only on

rat and mouse cells. The ecotropic receptor has been cloned (MCAT-1; Albritton et al., 1989) and is a cationic transporter (Kim et al., 1991; Wang et al., 1991). The ecotropic glycoprotein, gp70, does not allow infection of human cells, and thus viruses bearing ecotropic receptors are considered relatively safe for gene-transfer experiments. The Ψ 2 line (Mann et al., 1983) was one of the most commonly used packaging cell lines of this class. Although capable of high-titer retrovirus production, this cell line can also produce helper virus (*UNIT 9.13*), a replication-competent virus (RCV) that can promote the horizontal spread of marker viruses. Two more recently developed ecotropic packaging lines— Ψ CRE (Danos and Mulligan, 1988) and GP+E-86 (Markowitz et al., 1988a)—have not shown helper-virus production to date and have been widely used for the creation of retro-

Figure 9.9.6 Expression elements in retroviral design. **(A)** Structure of MSCV IRES-NEO, a retroviral vector that uses an internal ribosomal entry site (IRES) from murine stem cell virus (MSCV) to express a second gene. An alternative to expressing a second gene from an internal promoter is to use an IRES. An IRES provides *cis*-acting sequences that allow for cap-independent translation initiation at internal initiation codons (reviewed in Boris-Lawrie and Temin, 1993). When used in a retroviral vector, this may alleviate some of the problems associated with promoter competition (Ghattas et al., 1991). Use of an IRES results in a polycistronic message that is translated independently. It is possible to use multiple IRES constructs to express more than two genes; compared to the gene closest to the LTR, all subsequent genes are expressed at 50% of this level (Zitvogel et al., 1994). IRES constructs that have been successfully used in retroviral vector have been cloned from poliovirus or encephalomyocarditis virus (EMCV). **(B)** Structure of a retroviral vector that contains a hybrid 5' LTR and is also a self-inactivating vector. Because the 5' LTR drives expression of the retroviral RNA destined to become encapsidated but does not become the 5' LTR in the provirus (see Fig. 9.9.1), it is possible to replace nonessential U3 sequences in the 5' LTR with heterologous sequences. For example, vectors that fuse the cytomegalovirus (CMV) promoter to the R-U5 region of the MoMuLV LTR are associated with higher titers in 293 cells (Finer et al., 1994; Soneoka et al., 1995; Naviaux et al., 1996). It is also possible to insert genes into the 3' U3 region outside the retroviral transcription unit. Following reverse transcription this region will be copied in both LTRs, allowing for expression of the cloned DNA from a cloned promoter. Although this strategy is associated with lower retroviral titers, it has recently been successfully used for the creation of tetracycline-regulatable retroviruses (Hofmann et al., 1996; Paulus et al., 1996).

Table 9.9.2 Host Range of Retroviral Vectors^a

Vector pseudotype	Cells that can be transduced	
	Mouse	Human
Ecotropic	Yes	No
Amphotropic	Yes	Yes
GALV	No	Yes
VSV	Yes	Yes
RD114	No	Yes
10A1	Yes	Yes

Figure 9.9.7 Comparison of methods used for production of retroviral supernatants by stable (left) and transient (right) producer cell lines. In both methods, the first step is introduction of the retroviral plasmid DNA into the packaging cell line. Because packaging cell lines used for stable production are derived from NIH 3T3 cells, very few cells in the population release high-titer retroviral supernatants (see *UNIT 9.11*); it is therefore necessary to identify these cells. This is usually accomplished in two steps. First, those cells that have been successfully transfected are identified and subsequently tested for high-titer retroviral production. Under optimal circumstances, stable retroviral producer lines can be isolated after 2 to 3 weeks of selection and screening. In the transient methods, it is possible to harvest high-titer retroviral supernatants 48 hr after transfection. The high efficiency of 293-based packaging cell lines is thought to be due to both their high transfection efficiency and their ability to express transfected DNA at high levels.

viral producer cell lines. Several alternative transient transfection approaches give equivalent results for production of high-titer, helper-free viruses with ecotropic host range by transient transfection. Either the retroviral vector is introduced into the 293-derived packaging cell line, Bosc23 (Pear et al., 1993), which contains stably integrated cDNAs expressing the retroviral structural genes; or the vector is transiently introduced, together with the packaging constructs, into 293 cells (Soneoka et al., 1995; Naviaux et al., 1996).

Amphotropic Receptors

The *env* genes of the amphotropic class of viral glycoproteins endow a murine virus with a very broad host range, including rodent, mouse, human, chicken, dog, cat, and mink. The gene for the amphotropic virus receptor, Ram1, which localizes to human chromosome 8, has been cloned and encodes a sodium-dependent phosphate symporter (Kavanaugh et al., 1994; Miller et al., 1994; van Zeijl et al., 1994). Packaging cell lines, similar to those developed for production of retroviruses with an ecotropic host range, have been created for both stable and transient production of amphotropic retroviruses. Commonly used NIH 3T3-based packaging lines for the stable production of viruses with an amphotropic host range include PA317 (Miller and Buttimore, 1986), Ψ CRIP (Danos and Mulligan, 1988), and GP+Am (Markowitz et al., 1988b). Production of low levels of replication-competent virus has been reported for PA317 cells, whereas helper virus production has not been reported for either the Ψ CRIP or GP+Am cell lines. Strategies for producing high titer by transient transfection have also been described utilizing either a 293-packaging cell line, Bing (Pear et al., 1996), or cotransfection of the retroviral vector and structural proteins into 293 cells (Finer et al., 1994; Naviaux et al., 1996). Although neither of the transient strategies releases helper virus, the Bing cells release 100 infectious units/ml of a retrovirus that encodes hygromycin phosphotransferase resistance (Pear et al., 1996). An amphotropic packaging cell line similar to Bing, ϕ NX-A does not release hygromycin-resistant retrovirus (P. Achacoso & G. Nolan, pers. comm.).

A receptor that shares close homology with the receptor for murine amphotropic retroviruses is the receptor for gibbon ape leukemia virus (GALV; Miller et al., 1994; van Zeijl et al., 1994). The GALV receptor

(GLVR1) is located on human chromosome 2 and, similar to the amphotropic receptor, is a sodium-dependent phosphate symporter (Miller et al., 1994; van Zeijl et al., 1994). GLVR1 is also the receptor for simian sarcoma-associated virus (SSAV) and feline leukemia virus subgroup B (Takeuchi et al., 1992). Closely related to the amphotropic and GALV envelopes is the 10A1 envelope. Viruses that contain the 10A1 envelope can enter cells by both the amphotropic and GALV receptors (Miller and Miller, 1994a).

Although these vector systems work well in vitro, their potential in vivo use for human gene therapy is limited by their rapid inactivation by human serum. Packaging cell lines derived from the human fibrosarcoma cell line HT1080 (Cosset et al., 1995) produce retroviruses that are resistant to human complement (especially when pseudotyped with the feline virus RD114 envelope).

The expression of a specific receptor differs among both species and cell types. For optimal infection efficiency, it is important that the retrovirus express the appropriate envelope protein.

Polytropic and Other Receptors

Receptors other than the ecotropic and amphotropic receptors can be utilized for retroviral entry. Pseudotyping the retroviral envelope with the vesicular stomatitis virus (VSV) G protein (Burns et al., 1993; reviewed in Yee et al., 1994) endows viruses of one class with characteristics of another class. VSV G protein-pseudotyped viruses enter cells by interacting with widely expressed cell membrane components and thus are able to infect a wide variety of cell types, including insects, fish, frogs, and humans. Although VSV G protein is toxic to cells, it is possible to transiently express this protein in 293 cells with a retroviral vector and obtain high-titer retroviral supernatants that use VSV G protein for cell entry (Burns et al., 1993).

Retroviral pseudotyping can also be done using cell-surface molecules (Kasahara et al., 1994; Han et al., 1995) or antibodies against cell-surface molecules (Somia et al., 1995; Marin et al., 1996). To date, retroviral titers obtained using these approaches have been low; however, they offer the hope that it will be possible to target retroviral entry. Also in development are packaging lines based on lentiviruses, which offer the prospect of transducing nonmitotic cells (Naldini et al., 1996).

AVIAN RETROVIRUSES

Avian retroviruses can use six different subgroups of *env*: A, B, C, D, E, and F. Initially it was thought that each *env* subgroup used a different receptor on avian cells. However, definition of the relationship between each avian *env* subgroup and its receptor is presently not clear. Two avian leukemia virus packaging lines—Q2bn (Stoker and Bissell, 1988) and Isolde (Cosset et al., 1990)—are used for production of avian replication-incompetent vectors. They were made using the same strategies employed in constructing Ψ 2 and Ψ CRE (see Ecotropic Receptors), respectively. These avian lines employ the avian subgroup A envelope, which does not allow infection of mammalian cells; viruses produced by these lines are therefore considered relatively free of hazard to the investigator.

SAFETY ISSUES

There are important biological safety issues that should be carefully considered when working with retrovirus vectors. These issues will vary with a given experiment, so detailed protocols should be discussed with the appropriate biological safety committee at the experimenter's company or institution. In particular, extreme precautions and containment levels may be necessary when working with amphotropic and polytropic viruses.

Preparation of a Specific Retrovirus Producer Cell Line

UNIT 9.10

Establishing a cell line that produces high levels of a specific retrovirus construct is a lengthy process that involves several steps. First, the retroviral construct must be stably introduced into an appropriate packaging cell line. This can be accomplished either directly by transfection or by transfection to produce a transient virus stock followed by cross-infection of this stock into a separate packaging line (see Basic Protocol 1 for descriptions of both of these methods). After stable lines are produced, they must be characterized to identify lines that produce high titers of virus with an appropriate structure. The most common method for determining virus titer is using a drug selection protocol (see Basic Protocol 2); a sample calculation of BAG virus titer is also presented (see Support Protocol 1). Sometimes, a short and direct method of estimating virus titer is available when the virus encodes a histochemically detectable gene such as *lacZ*. In such a case, infected cells can be stained with Xgal (see Support Protocol 2). Similarly, it is possible (regardless of the genes encoded by the vector) to estimate rapidly the levels of virus being produced by a given cell line by quantitating any specific product of the virus (e.g., RNA) present within the producer line (see Alternate Protocol).

Although the protocols described in this unit for generating stable retroviral producer cell lines allow expression at high titer for some constructs, their creation can be laborious and may not be effective for all constructs (e.g., due to a gene that is toxic to producer cells). Alternatively, the generation of high-titer retrovirus by transient production, described in *UNIT 9.11*, has facilitated the production of high-titer retroviral supernatants from cDNAs that have proved problematic with stable producer lines.

INTRODUCTION OF A RETROVIRUS VECTOR INTO A PACKAGING CELL LINE

BASIC
PROTOCOL 1

Producing an infectious virus from a bacterial plasmid involves introduction of the plasmid into a packaging line. The transfection protocol most commonly used, which is quite reliable and easy to perform, is from Parker and Stark (1979) and is a modification of the CaPO_4 transfection protocol of Graham and van der Eb (1973; also see *UNIT 9.1*). This protocol has been successfully used with every packaging line we have tried ($\Psi 2$, ΨCRE , ΨCRIP , PA317, Q2bn, and Isolde; see Table 9.9.1). Stable producers can be selected among the stably transfected cells, or by cross-infection using transiently produced virus from one class of packaging line to infect a packaging line bearing a different class of envelope (Fig. 9.10.1). Protocols for production of replication-competent avian vectors are also given in Morgan and Fekete (1996).

Materials

- Appropriate packaging cell line(s) (*UNIT 9.9*) with appropriate medium
- Retrovirus plasmid DNA
- HEPES-buffered saline (HeBS; see recipe)
- 2 M CaCl_2
- Medium, without and with serum
- HeBS containing 15% (v/v) glycerol (HeBS/glycerol)
- 800 $\mu\text{g}/\text{ml}$ (100 \times) polybrene in distilled H_2O , filter sterilized (store at -20°C)
- 10% to 15% (v/v) dimethylsulfoxide (DMSO)
- 10-cm or 6-cm dishes
- 24-well or 6-well tissue culture dishes
- Cloning cylinders (*UNIT 16.23*)

Introduction
of DNA into
Mammalian Cells

9.10.1

Supplement 63

Figure 9.10.1 Production of a stable producer line for a replication-incompetent vector. To have a continual source of high-titer virus stocks, a stable producer line is made by stable transduction of the viral genome into packaging cells. One of two basic methods for transduction is used. The starting point for both methods is to introduce a bacterial plasmid encoding the vector into packaging cells as shown in Figure 9.9.3. The virus produced transiently by the transfected cells is then harvested and used to infect a packaging line bearing a different *env* protein (see text) as shown in **A**. Alternatively, selection of the transfected packaging cells in which integration of the bacterial plasmid has occurred can be carried out as shown in **B**. In either method, drugs (e.g., G418 for the virus shown here) are used to select those cells that have stably integrated the viral sequences. Drug-resistant colonies can then be screened for production of high-titer virus stocks.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly.

NOTE: All incubations involving tissue culture cells should be performed in a humidified 37°C, 5% CO₂ incubator unless otherwise noted.

Transfecting Cells and Obtaining Viral Supernatant

1. Plate packaging cells to ~10% to 20% the density of confluent cells (referred to hereafter as a 1:10 or a 1:5 split) in a 10-cm dish the day before transfection.

A 10-cm dish is typically used but a 6-cm dish can also be used, in which case all volumes given here and the amount of DNA should be scaled down by a factor of 3.

2. Place 10 μg of retrovirus plasmid DNA into 0.5 ml HeBS.

The DNA need not be sterile. Falcon tubes (5-ml; #2054) provide for good visibility of the precipitate. A selectable drug-resistance gene must be used if the purpose of this procedure is to make a stable packaging line. The drug marker can be encoded by the vector, or by an independent, nonretroviral plasmid that can be cotransfected. If cotransfection is being performed, use a molar ratio of viral to nonviral (or drug marker) plasmid of 10:1 and mix them together in the HeBS (see UNIT 9.5 for discussion of selectable markers).

3. Add 32 μl of 2 M CaCl_2 to DNA while gently shaking the tube. Tap the tube for ~30 sec and incubate 45 min at room temperature.

A fine, hazy blue precipitate should develop. Large, clumpy precipitates do not work well.

4. Remove medium from packaging cells and gently pipet the HeBS-DNA precipitate onto the center of the dish. Expose cells to DNA 20 min in a tissue culture hood; after ~10 min, gently rock the dish to redistribute the solution from the edges of the dish to the entire surface of the dish.

5. Add 10 ml medium and incubate cells 4 hr at 37°C.

6. Aspirate the medium completely, and gently add 2.5 ml room temperature HeBS/glycerol. Return dish to incubator for 3.5 min, 90 sec, or a time that has been determined to be optimal for the cells.

An incubation time of 3.5 min in HeBS/glycerol is suitable for several lines, including $\Psi 2$, ΨCRE , ΨCRIP , and PA317. However, only 90 sec was optimal for some avian lines, including Q2bn. If problems are encountered with glycerol overexposure, such as cells lifting off the dish during the rinse, titrate the amount of time in the HeBS/glycerol solution.

7. Quickly remove HeBS/glycerol and gently rinse with 10 ml medium. Repeat medium rinse and add 5 ml medium with serum (use medium and serum recommended for the particular packaging line). Incubate 18 to 24 hr.

8. Remove the medium and filter through a 0.45- μm filter (the type that easily fits onto a syringe) to obtain supernatant containing the transiently produced virus.

This “transient” harvest can be stored at -70° or -80°C or used immediately for an infection of another packaging line bearing a different env class in order to make an infected producer line (steps 10 to 12 below). If the goal is to produce virus transiently for some other purpose, the experiment will end at step 8 and the original transfected cells can be discarded.

Generating Stable Producer Lines

If the purpose of the transfection is to make stable producer lines, there are two options at this point. The first option (step 9 followed by steps 13 to 18) is to select among the transfected cells for those that have stably integrated the vector plasmid. They can be placed under drug selection and the resulting drug-resistant cells screened for virus production (see Support Protocol 2). The second option is to use “cross-infected” packaging cells. The transiently produced virus harvested in step 8 above can be used to infect another packaging line, as outlined in steps 10 to 12. The *infected* packaging cells can then be placed under drug selection (steps 13 to 19). Obviously, only viruses that encode drug resistance genes can be used for this latter protocol. Regardless of the method used, the goal is to isolate packaging cells that have stably integrated the viral genome and that make the highest possible titer.

Prepare transfected cells for selection

9. After harvesting the transiently produced virus, add 10 ml medium to the transfected cells. Incubate 2 to 3 days, then proceed to step 13.

Prepare infected cells for selection

This route can only be used if the virus carries a selectable marker. This method may be preferable over using transfected cells, as the provirus that results from infection is usually stably associated with the host genome and does not rearrange or delete after integration. Transfection often leads to rearrangements, including deletion, of integrated plasmids. Moreover, for some retroviruses it has been observed that single-copy integrated proviruses can lead to a more uniform level of transcription among individual colonies, whereas transfection leads to widely varied levels of gene products among different colonies. To use this method, two packaging lines expressing different classes of viral glycoproteins must be used. When a packaging line produces a particular *env* glycoprotein (e.g., murine amphotropic *env*), the receptors on the surface of the packaging cells become blocked by the binding of that viral glycoprotein. Thus, if one tries to infect such a line with a virion bearing the same *env* type (e.g., amphotropic *env*), there are no free receptors on the cell surface and the added virion cannot gain entry to the cell and thus a packaging line bearing a different *env* type must be “cross-infected.” When using cross-infection, the two packaging lines must be homologous (i.e., both must be murine or both must be avian).

10. Split a packaging line 1:10 to 1:20 the day before the infection (i.e., the day of the transfection). Use a packaging line with a different envelope class than the cell line used in step 1.
11. Remove the medium from packaging line to be infected. Add virus (from step 8) as follows: for a 10-cm dish, dilute 0.1 to 1 ml virus stock to 3 to 5 ml final volume and add 800 $\mu\text{g/ml}$ polybrene to 8 $\mu\text{g/ml}$; for a 6-cm dish, dilute 0.1 to 1 ml virus stock to 2 ml final and add 800 $\mu\text{g/ml}$ polybrene to 8 $\mu\text{g/ml}$ final. Incubate ≥ 1 hr.

The amount of virus stock to use is difficult to predict if the vector is a novel construct. Use several amounts to infect several dishes to ensure that at least one dish will yield enough producer colonies after the selection process. If working with a published vector, use an amount of virus suggested by prior experience.

Include polybrene for murine viruses and all avian subgroups other than A. Longer incubation times do not hurt the cells if they are insensitive to polybrene (as most packaging cells are).

12. Add medium to 10 ml final volume for a 10-cm dish, and to 4 ml for a 6-cm dish. Incubate 2 to 3 days.

If the cells are insensitive to polybrene, as well as to the medium and serum that are present in the viral inoculum, leave the virus on the cells and simply add medium to the cells to increase the volume as indicated above. However, when this is not the case, discard the viral inoculum and replace it with the appropriate volume of the normal medium and serum used for growth of the cells.

Select stable producers

13. Prepare 1:10 or 1:20 splits of the transfected (step 9) or infected (step 12) cells 2 to 3 days after transfection or infection and plate in selective medium. Incubate 3 days.
14. Replace the medium with fresh selective medium. Incubate an additional 4 to 7 days (7 to 10 days after cells have been placed under selection) until colonies are visible.

15. Pick well-isolated colonies using cloning cylinders and transfer into two wells for each clone in 24-well or 6-well tissue culture dishes. Grow until 50% to 90% confluent.

A population of colonies can be pooled, rather than carried as individual lines. Pooling producers can be satisfactory if high titer is not required. However, when transfection is being used to generate stable producers, the way to isolate the highest-titer virus is to pick colonies and screen them individually. When cross-infection is being used, quite often pooled producers make as high a titer as individual colonies (see Commentary).

Cultivate producer clones and harvest virus stocks

16. Remove the medium and replace it with one-half the normal volume. Incubate 2 to 3 days.

The incubation time depends on the packaging line. The authors determine the time empirically and use 2 to 3 days for Ψ 2 and 1 to 2 days for Isolde or Ψ CRIP. One can also remove the medium every 24 hr for 2 to 3 days and pool the individual harvests.

17. Remove the medium and either titer it immediately (see Basic Protocol 2) or store at -70° or -80°C for future titration (see Support Protocol 2) and use.

18. Continue to passage the producer clones until they can be frozen, and/or until the best producers are identified.

Use the same passaging protocol that is suggested by the originators of the particular packaging line.

19. When a good producer clone is identified, store many vials (20 to 25) of these cells in 10% to 15% DMSO in liquid nitrogen, using aliquots of 1 to 2 ml.

Freezing many vials is done to guard against the typical cell culture hazards, as well as the problem of recombination that can generate helper virus, and to allow for a backup supply of cells in the event that there is loss of titer (some clones reduce their virus output over time, for unknown reasons).

DETERMINATION OF VIRAL TITER: IDENTIFICATION OF PRODUCER CLONES MAKING HIGH-TITER VIRUS

After isolating clones of virus producers or after generating pools of producers, those making high titers need to be identified. In addition, it is necessary to determine the amount of virus in a given stock for use in experiments. The usual method is to perform a bioassay using the virus to infect target cells as described here, although rough quantitative analyses can alternatively be performed on the producer cells to quantitate the presence of vector RNA or protein (see Alternate Protocol and Support Protocol 2).

It should be noted that if the protocol described here for determining viral titer is used, one is simply measuring the amount of virus that produces either a selectable marker or a histochemical marker. Therefore, it is also necessary to ensure that the titered virus has not rearranged or deleted—i.e., that it still expresses the gene of interest as well as the markers that are being scored in the titration assay. The final step of this protocol addresses the issue of subsequent functional and/or structural assays that should be carried out.

Additional Materials (also see Basic Protocol 1)

Target cell line (e.g., NIH 3T3 fibroblasts)

Virus stock (see Basic Protocol 1; e.g., Ψ 2 BAG supernatant)

Xgal (see Support Protocol 2), or G418 or other selection drug (e.g., UNIT 9.5)

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly.

BASIC PROTOCOL 2

Introduction of DNA into Mammalian Cells

9.10.5

NOTE: All incubations involving tissue culture cells should be performed in a humidified 37°C, 5% CO₂ incubator unless otherwise noted.

1. Split NIH 3T3 target cells 1:10 to 1:20 into 6-cm dishes the day before infection.

NIH 3T3 cells are mouse fibroblasts that are frequently used for murine retrovirus infections (see Table 9.9.1). If using avian viruses, substitute chicken embryo fibroblasts split 1:4 or 1:5, or use quail cell line QT6 split 1:6 for subgroups A or E (but not subgroup B).

When titering on CEFs, make sure that the genotype of the CEFs will allow infection of the avian env subgroup that is being titered (see Morgan and Fekete, 1996).

2. On the day of infection, remove medium from the target cells and add medium containing virus stock. Use 1 to 2 ml medium containing from 0.01 µl to 0.1 ml of virus stock, depending upon the expected titer, to infect a 6-cm dish of cells, or 3 to 5 ml for a 10-cm dish; add 800 µg/ml polybrene to 8 µg/ml final for murine or avian subgroups other than A. Incubate cells (in 8 µg/ml polybrene concentration) 1 to 3 hr at 37°C.

It is best to titer at least two dilutions that differ by 10-fold to obtain a countable number of colonies (20 to 100). Some cells can stay overnight in the high (8 µg/ml) polybrene whereas other cells are bothered by this. Because the murine virus only has a half-life of 4 hr, longer incubations do not usually result in much more infection. Virus absorption takes place fairly rapidly, within ~1 hr.

If the cells are insensitive to polybrene, as well as to the medium and serum present in the virus stock, the medium containing virus can remain on the cells and more medium can simply be added to the cells to bring the volume to the level required to dilute the polybrene to 2 µg/ml. However, when this is not the case, discard the medium containing the polybrene and virus and replace it with the appropriate volume of the normal medium and serum that are used for growth of the cells.

3. Add medium to dilute polybrene to 2 µg/ml. Incubate infected cells at least 2 or 3 times the length of a cell cycle.

This period allows for integration and expression of the viral genes and is 2 to 3 days for NIH 3T3 and QT6 cells. For primary CEF cells, it may be shorter (e.g., 1.5 to 2 days).

- 4a. *If the virus carries a histochemical marker gene such as lacZ:* Stain the infected cells with Xgal (see Support Protocol 2) or using other marker-appropriate method; no drug selection is needed. Proceed to step 7 to calculate titer by counting the number of blue colonies.

- 4b. *If the virus carries a drug resistance gene:* Split infected cells into selection conditions. If the resistance gene is *neo*, split the cells 1:10 to 1:20 and set up two 10-cm dishes containing G418 for each. Incubate 3 days.

The amount of G418 to use depends upon the cells being selected. For murine fibroblasts (e.g., NIH 3T3) use 1 mg/ml G418 (i.e., 1 mg/ml as weighed out from the bottle, not corrected for percent of active compound).

5. Change the medium, including appropriate selection drug(s). Incubate a total of 7 to 10 days (for NIH 3T3 under G418 selection) after which time colonies should be obvious.
6. Count colonies before they spread (usually before 12 days under selection).
7. Calculate the titer as follows:

$$\text{G418-R CFU/ml} = \frac{\text{no. of colonies}}{\text{virus volume (ml)} \times \text{replication factor} \times \text{fraction of infected cells plated}}$$

or, if the virus carries *lacZ*,

$$\text{Xgal CFU/ml} = \frac{\text{no. of Xgal}^+ \text{ colonies}}{\text{virus volume (ml)}}$$

As with most bioassays where there are several steps, perfect reproducibility in this assay should not be expected. A rule of thumb is that titers varying >3-fold are significantly different; titers within a factor of 3 are for most intents and purposes about the same. If greater accuracy is necessary, perform the assay several times and average the results. When it is important to compare two stocks, titer them side by side in the same experiment.

Calculation of titer is done differently in different labs, partly because it is difficult to account for the number of cell divisions that occurred after viral integration and before plating the cells into selective medium. For example, if there are two to three cell divisions after integration and before G418 selection, a single viral particle could result in two to four G418-resistant colonies. Recently, with the advent of screenable markers, such as *lacZ*, it is possible to titer the CFU using a direct measure of the number of Xgal⁺ colonies present 2 days after inoculation of NIH 3T3 cells. A direct method such as this does not require a subcultivation after infection and before assessment of the number of colonies. There is thus no ambiguity due to the number of cell divisions, as each colony is scored as 1, regardless of the number of cells in the colony.

The BAG virus (Fig. 9.10.2) encodes both *neo* and *lacZ* and has allowed direct comparison of two methods of scoring positive cells—i.e., resistance to G418 and Xgal staining. This comparison has been made with several BAG stocks, infecting with the same stock at the same time in parallel dishes. In this case, the number of G418-resistance (R) CFU/ml can be corrected for the number of cell divisions by determining the average

Figure 9.10.2 The BAG retrovirus (Price et al., 1987) was created from the Moloney murine leukemia virus–derived vector, DO-L of Korman et al. (1987). The *lacZ* gene of *E. coli* was fused to the start codon for Moloney virus pr65 *gag*. The *neo* gene of Tn5 is used to provide for selection in G418. Transcription occurs from two promoters: the viral 5' LTR promoter for *lacZ* mRNA, and the SV40 early promoter for *neo* mRNA. Polyadenylation for both mRNAs is provided by sequences in the 3' LTR.

number of cells per Xgal⁺ colony and using that factor as the replication factor (shown above) in the calculation of G418-R titer. When such corrections have been made, the Xgal CFU/ml and the G418-R CFU/ml are in agreement usually within a factor of 2 (see Support Protocol 1). When the vector under titration does not have a histochemical marker gene, then a guess should be made for the replication factor. Usually, 2 to 4 are reasonable estimates of the replication factor if two to three cell cycle times were allowed after infection and prior to selection.

8. Run an assay to determine that the producer clone is making a virus that is not rearranged or deleted—i.e., a virus that has the intended structure.

Because the titration is usually performed using a drug marker such as neo, or a histochemical marker such as lacZ, the titration assay does not prove that the virus is transducing and expressing any gene other than neo or lacZ. Presumably, for many vectors, there is an additional gene of interest that one hopes to express. Thus, some assay capable of determining whether the protein of interest is being expressed must be carried out. If such an assay is not straightforward (e.g., the function of the gene of interest has not been ascertained), at least the structure of the viral genome, and the presence of viral RNAs, should be investigated. A Southern blot analysis (UNITS 2.9 & 2.10) can be performed on cells infected with virus from the producer clone. Alternatively, or additionally, the proviral genome can be cloned directly from infected cells into bacteria using one of several rescue schemes (Cepko et al., 1984). The cloned provirus can then be examined in great detail. In addition, it is important to analyze RNA structure using northern blot (UNIT 4.9) or RNase protection assays (UNIT 4.7) when the mRNA for the gene of interest is a subgenomic RNA.

SUPPORT PROTOCOL 1

SAMPLE CALCULATION OF TITER FOR BAG VIRUS

Experimental setup

Each of two 10-cm dishes of NIH 3T3 cells were infected with 1 µl of BAG virus (which encodes both *neo* and *lacZ*) diluted into 3 ml medium for the initial step of the infection protocol. Following a 2-day incubation, the two parallel dishes were treated two different ways to assess *neo* and *lacZ* expression:

1. Expression of *neo* was assessed by splitting one dish of infected cells 1:20 onto two 10-cm G418 selection dishes (thus, fraction of infected cells plated = 0.05) and incubating 10 days (see Support Protocol 2, steps 4b, 5, and 6).
2. Expression of *lacZ* was assessed by staining the other dish of infected cells with Xgal (see Support Protocol 2, step 4a). The number of Xgal⁺ colonies was determined that same day.

Experimental results

Ten days post-initiation of G418 selection, an average of twenty G418-resistant (G418-R) colonies/dish were observed in the G418 selection dishes. On the dish stained with Xgal, there were 200 Xgal⁺ colonies. [The average number of cells per colony after Xgal staining was four (i.e., replication factor = 4).]

Calculation of titer (see Basic Protocol 2, step 7)

$$\text{G418-R CFU/ml} = \frac{20}{0.001 \times 4 \times 0.05} = 10^5$$

$$\text{Xgal CFU/ml} = \frac{200}{0.001} = 2 \times 10^5$$

RAPID EVALUATION OF PRODUCER COLONIES

Rather than titrate the virus stock for vector activity, one can quantitatively analyze the producer cells for the presence of vector RNA or protein. There is often (though not always) a correlation between amount of viral product within the packaging cell and the titer of virus vector in the supernatant. For example, the amount of β -galactosidase protein present in a producer line that carries a *lacZ* vector is usually directly correlated with the amount of *lacZ* virus in the supernatant. Thus, each clone can be screened by ONPG hydrolysis (Table 1.4.2) or by Xgal staining (see Support Protocol 2). Alternatively, RNA dot blots (UNIT 4.9) can be used to quickly assess the amount of vector RNA and this has also been correlated with titer. Because Xgal staining, as well as RNA analysis methods, are invasive and lethal, duplicate wells containing the colonies picked from the drug-selection dishes (see Basic Protocol 2, step 5) are made so that a dish of live cells is available after the analysis. Direct titration of the culture supernatants (see Basic Protocol 2) is the more typical method to screen producer clones, but requires a longer period of time and thus more subcultivations of the producers while awaiting the results.

XGAL STAINING OF CULTURED CELLS

This protocol can be used to stain infected cells to obtain a direct measure of titer. It can also be used to stain producer lines themselves (see Alternate Protocol) to discover which producer clones make high levels of β -galactosidase as an indication of those that may make high titers of *lacZ*-bearing viruses. Cultured cells are stained with Xgal using either of two fixatives. The choice of fixatives is based primarily on convenience as both work quite well, although the glutaraldehyde fixative gives slightly bluer cells.

Materials

- Cells infected or transfected with a *lacZ*-encoding virus (see Basic Protocol 1)
- PBS (APPENDIX 2)
- Fixative solution: 0.05% glutaraldehyde *or* 2% paraformaldehyde solution (see recipes)
- Xgal solution (see recipe)

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly.

NOTE: All incubations involving tissue culture cells should be performed in a humidified 37°C, 5% CO₂ incubator unless otherwise noted.

1. Discard medium and add fixative solution (2 ml for 6-cm dish and 5 ml for 10-cm dish). Incubate at room temperature with 2% paraformaldehyde for 60 min, or with 0.05% glutaraldehyde for 5 to 15 min.

It is best to perform all steps involving fixatives in a fume hood. Longer incubation times may inhibit enzyme activity in subsequent steps.

2. Discard fixative solution using proper chemical disposal protocol for your institution and rinse cells thoroughly three times in PBS at room temperature. Leave the second rinse on for ~10 min and perform first and third washes quickly.

Residual fix will inhibit the enzyme reaction.

3. Add Xgal solution.

Use a minimal volume to cover the cells because Xgal is very expensive.

4. Incubate 1 hr to overnight at 37°C. Positive cells will stain blue.

The dish can be stored indefinitely at 4°C.

of DNA into
Mammalian Cells**

9.10.9

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Glutaraldehyde fixative (0.05%)

Glutaraldehyde (obtained from Sigma) is typically supplied as a 25% solution and can be stored frozen at -20°C in aliquots. Aliquots of the 25% solution can be frozen and thawed many times. Immediately before use, thaw an aliquot and dilute 500-fold in PBS to 0.05%.

CAUTION: *Glutaraldehyde is a carcinogen and may cause an allergic reaction. Use in a fume hood and discard waste as directed by your institution.*

HEPES-buffered saline (HeBS)

137 mM NaCl

5 mM KCl

0.7 mM Na_2HPO_4

6 mM dextrose

21 mM HEPES

Adjust pH to 7.05; check carefully, as this is a critical parameter

Store indefinitely at room temperature

Paraformaldehyde fixative (2%)

Dissolve 2 g paraformaldehyde (e.g., from BDH) in 100 ml of 0.1 M PIPES, pH 6.9 [30.24 g piperazine-*N,N'*-bis(2-ethanesulfonic acid) per liter] containing 2 mM MgCl_2 (200 μl of a 1 M solution) and 1.25 mM EGTA (250 μl of a 0.5 M solution, pH 8.0). Heat in the fume hood with stirring 5 to 10 min (do not boil). Cool to 4°C . Always use a paraformaldehyde solution that is well buffered and <1 week old.

CAUTION: *Formaldehyde is a carcinogen and may cause an allergic reaction. Use in a fume hood and discard waste as directed by your institution.*

Xgal solution

Prepare in PBS:

5 to 35 mM $\text{K}_3\text{Fe}(\text{CN})_6$ (potassium ferricyanide)

5 to 35 mM $\text{K}_4\text{Fe}(\text{CN})_6 \cdot 3\text{H}_2\text{O}$ (potassium ferrocyanide)

1 to 2 mM MgCl_2 or MgSO_4

Just before use, add 40 \times Xgal in *N,N*-dimethyl formamide (Table 1.4.2) to 1 mg/ml final

CAUTION: *Avoid contact and inhalation of cyanide. Discard waste as directed by your institution.*

The amount of ferric and ferrous cyanide to use is a matter of preference. The higher amount causes precipitation of indole to occur more quickly and thus reduces diffusion. However, it may cause a greenish background upon prolonged incubation (overnight or longer) in some tissues, although not usually on cell lines.

The first three ingredients (i.e., excluding Xgal) can be stored at least a few months at room temperature. 40 \times Xgal can be stored in a glass container covered with foil for months at -20°C .

COMMENTARY

Background Information and Critical Parameters

Introduction of a vector into a packaging line can be accomplished by transfecting a vector plasmid or by using virus produced by one line to infect a different packaging line (“cross-infection”; Fig. 9.10.1). Transfection is a nonspecific entry technique that allows one to introduce any DNA into some types of cells (UNITS 9.1-9.5). Transfected DNA can be transcribed transiently in ~10% to 50% of the packaging cells, within a period of a few hours to a few days after transfection. However, only ~1 in 5000 cells will stably integrate the DNA. Although the transfected DNA bears the retroviral sequences necessary for the precise integration that is the hallmark of the retroviral lifecycle, transfected retroviral DNA does not undergo precise or efficient integration. Transfected retroviral DNA integrates as nonspecifically and with as poor an efficiency as any other plasmid DNA. Key features of the viral structure and enzymatic activities are present only following infection and are absent from transfected plasmid DNA.

Transiently or stably produced vector RNA (which contains Ψ) is efficiently packaged and budded from the surface of packaging cells (Fig. 9.9.3). Thus, the infectious retrovirus vector can be harvested by removal of the supernatant of the packaging line. A given line that has stably integrated the virus may produce high amounts of virus indefinitely. Cells that have stably integrated the viral genome are usually selected by application of a drug that selects for a gene encoded by the virus. If no such dominant, selectable gene (UNIT 9.5) is encoded by the virus, the transfected cells can be cotransfected with a nonviral plasmid that does encode such a gene. By using a 10:1 molar ratio of viral to nonviral plasmid, cells can be selected that have integrated both plasmids. If instead a producer is generated by cross-infection, a very small amount of virus should be used for the infection. If a high multiplicity of infection (MOI) is used, there is a risk of transferring defective genomes or wild-type helper recombinants (see UNIT 9.13). In some instances, with some vectors, it appears that cross-infection results in producer clones that have a high probability of producing the maximal titer for a given vector. Producer clones isolated following transfection produce quite variable titers, presumably because transfection results in varied configurations of the transfected DNA. Infec-

tion, on the other hand, results in a single-copy provirus quite reliably.

Infection of a packaging line by virus produced by the same packaging line is very low in efficiency (although it is not blocked entirely). The viral glycoprotein produced by a packaging line apparently binds the host-cell receptor for that *env*-encoded glycoprotein class. A virion bearing that same *env* class thus cannot easily enter. However, because the different classes of viral glycoproteins use different cellular receptors, virions produced by transfections of one class of packaging line can be used to “cross-infect” another (e.g., Ψ CRE-produced virus can infect Ψ CRIP quite effectively). There is also an alternative method that allows infection of a packaging line with virions produced by that packaging line class (Rein et al., 1982). An inhibitor of glycosylation, such as tunicamycin, can be used to transiently block the production of the *env* glycoprotein. During the application of this drug block, the cells can be infected with virions bearing the same class of *env* glycoprotein. The drug is then washed out. This method requires careful titration of the drug parameters (e.g., time and dose) as these drugs can be toxic to the cells. As it is quite easy to introduce viral genomes using standard transfection methods, these methods have been outlined in this unit.

Troubleshooting

The titer (concentration, expressed as colony forming units per ml, CFU/ml) of virus varies widely and depends on a combination of factors. The vector, the insert(s), the packaging line, and the method of harvesting all contribute to the final titer. Although titers from stable producers can be as high as 10^8 CFU/ml, 10^6 CFU/ml is considered to be a good titer for a murine ecotropic stock, and 10^5 CFU/ml for an avian replication-incompetent stock. Titers of transiently produced stocks (i.e., those stocks harvested from packaging cells 18 to 24 hr posttransfection) are generally lower, from 10^4 to 10^5 CFU/ml.

If no high-titer producers are identified among at least 20 individual producer clones, it may be due to poor transfection, poor production of virions by the packaging line, poor infectibility of the cells upon which the virus is titered, or problems with transmission or expression of the virus. All but the latter can be controlled for by transfecting and titering a control vector that is known to produce a high

titer. If the control vector works well, but the new vector does not, the problem is in the design of the new vector and can be difficult to resolve. Try using different vectors to express the gene of interest. Variables relating to the vector that can be important include the viral sequences present within the vector (e.g., the more *gag*, the better; Bender et al., 1987), the promoter used for expression of the gene of interest and/or the marker gene whose activity is being followed in the titration assay, and the position of the gene of interest within the vector. Within the sequence of the gene of interest, the presence of splice or polyadenylation sites can cause problems in virus transcription and transmission. The inserted gene can be trimmed to encode only the protein-coding region to alleviate some problems. Trying different vector designs can sometimes improve the situation, but there are some genes which, for obscure reasons, do not express and/or transmit at a high level within any existing retrovirus vector.

When attempting to isolate stable producer lines for a particular construct, difficulties can also be encountered when large numbers of colonies are being handled at once, prior to identification of the few colonies that are producing a high titer. It is definitely an advantage if either RNA or some other vector gene product can be scored using a short-term assay (see Alternate Protocol) in order to minimize the number of subcultivations prior to discarding the poor producers. The other problems that can be encountered in making stable producers are loss of titer from a clone that previously had demonstrated high titer, and helper-virus contamination (the latter is covered in UNIT 9.13).

For loss of titer, two explanations seem most likely. The first is loss of capsid production by the packaging cells. There sometimes is a loss of virion production with some producer lines (Isolde, PA317, and possibly others). In these cases, it is suggested that the packaging lines and producer clones be carried under conditions of drug selection for maintenance of the *gag*, *pol*, and *env* genes (Cosset et al., 1990; Miller and Buttimore, 1986). The other problem that leads to loss of titer is loss of vector RNA production, presumably due to some modulation of the LTR promoter activity (C. Cepko, unpub. observ.). Clones that were originally 100% blue when stained with Xgal became a mixture of blue and white, and even 100% white, upon subcultivation over a short period of time (weeks). When *lacZ* RNA levels were checked on a northern blot, it was found

that white clones, or subclones of previously mixed clones, had low levels of *lacZ* RNA. This phenomenon has been seen with many different promoters and with nonretroviral constructs. Unfortunately, there is no known method of making the promoter turn back on. Even if one can select for a linked drug-resistance gene, this does not always select for the LTR activity. Of course, producer clones with a large percentage of white cells do not make high viral titer. The same phenomenon probably occurs with other vectors that do not encode *lacZ*, as other producers prepared in the author's laboratory have lost titer as well. When such clones were checked for production of virions using a reverse transcriptase assay (UNIT 9.13), there did not appear to be any loss of virion production, and thus loss of vector RNA production is the likely problem.

Anticipated Results

Using a good murine vector, the titer of transiently produced stocks from $\Psi 2$ or Ψ CRIP should be 10^3 to 10^4 CFU/ml. A lower titer—e.g., 10 to 100 CFU/ml—usually indicates that the stable titers will also be low. For transient titers from Q2bn, a good titer is 10^4 CFU/ml; in the author's experience Isolde does not yield good transient titers—only ~10 to 100 CFU/ml.

When selecting stable colonies, most packaging lines transfect well. Expect ~30 to 100 colonies per 10-cm dish under selection with a 1:20 split into drug selection. Good stable titers are $\sim 10^6$ CFU/ml for $\Psi 2$ stocks. For all other packaging lines (with the exception of Bosc, as discussed in UNIT 9.11), the author has not achieved stable titers as high as those made by $\Psi 2$. However, other groups report that for some vectors, they have made producers with titers as high as those made by $\Psi 2$. If stable transfection is used to make the producers, expect ~25% of the producer clones to have the optimal titer for that vector. If cross-infection is used, 25% to 100% of the clones might have the optimal titer for that vector. If pooled producers from cross-infected cells are made, the optimal titer from the pool may be achieved. For Isolde, stable titers can be 10^5 CFU/ml; Q2bn seems to give ~10-fold-lower stable titers. Replication-competent avian vectors have stable titers of $>10^6$ CFU/ml (Hughes et al., 1987; and see Morgan and Fekete, 1996).

Time Considerations

During the first 2 weeks following transfection, there is minimal work. However, during

the period of isolating colonies, titering supernatants, and freezing producer clones, there can be nearly constant tissue culture work. The amount of work will depend on how many colonies are isolated.

Transient Transfection Methods for Preparation of High-Titer Retroviral Supernatants

Although stable retroviral producer cell lines are useful for expressing some genes at high titer and the creation of such lines is the method of choice for producing large quantities of retroviral supernatant, this is a lengthy and laborious process, and for many genes it has failed to yield high retroviral titers. As a result of these deficiencies, transient production of retroviral supernatants has become the preferred method of producing retrovirus for most laboratory uses. In comparison to the production of stable retroviral producer cell lines, generation of high-titer retrovirus by transient production not only is less laborious, but also has allowed the production of high-titer retroviral supernatants from cDNAs that cannot be produced by stable producer cell lines. Transient transfection has also increased the versatility of retrovirus-mediated gene transfer to include the rapid testing of different constructs, viral pseudotyping, and construction of retroviral cDNA libraries.

The most significant change allowing the use of transient transfection is the choice of packaging cell lines. NIH 3T3 cells, which are the choice for stable production (UNIT 9.10), produce relatively low titers (10^3 to 10^4 infectious U/ml) following transient transfection. Development of packaging cell lines derived from either primate (COS) or human (293) cells made it possible to obtain transient titers from one (COS) to several logs (293) higher than NIH 3T3 cells. The increase in titer with these latter cell lines is thought to be due to several properties of these cell lines—high transfectability, few endogenous proviruses, high-level expression from a number of promoters, and expression of additional proteins (such as adenoviral E1A or polyoma large T antigen) that may enhance gene expression and retroviral titer.

Although transient retroviral production has been described in COS cells (Landau and Littman, 1992), systems based on human 293 cells, an adenovirus-transformed human embryonic kidney cell line (Graham et al., 1977), have produced the highest retroviral titers and are the most widely used. Two approaches have been taken for producing high-titer retroviral supernatants in 293 cells (Pear et al., 1993; Finer et al., 1994; Soneoka et al., 1995; Naviaux et al., 1996). One approach (Pear et al., 1993) has created a stable retroviral packaging cell line in 293 cells by sequentially introducing constructs encoding the retroviral structural genes. Using this strategy, a cell line with an ecotropic host range, Bosc23, and a cell line with an amphotropic host range, Bing, have been developed. To create retroviral supernatants, only the retroviral vector needs to be introduced into the cell lines. In the approach of Finer et al. (1994), Soneoka et al. (1995), and Naviaux et al. (1996), plasmids encoding the retroviral vector and retroviral structural genes are coin-troduced into 293 or 293T cells. Both approaches have consistently yielded retroviral titers of $>10^6$ for a wide variety of genes, and neither produces replication-competent retrovirus.

Although retroviruses have been most widely used for infecting cells through the ecotropic or amphotropic receptors, methods have recently been described for expanding the host range of retroviral vectors. To date, this has been best exploited for vesicular stomatitis virus (VSV) G protein, which confers a polytropic host range capable of infecting mammalian, fish, and insect cells (Burns et al., 1993; reviewed in Yee et al., 1994). VSV G protein is thought to mediate cell entry by interacting with phosphatidyl serine and possibly other components of lipid bilayers present in the cell membranes of most mammalian and nonmammalian eukaryotic cells (Schlegel et al., 1983). In addition to their wide host range, retroviruses pseudotyped with VSV G protein can be concen-

Current Protocols in Molecular Biology (1996) 9.11.1-9.11.18

Copyright © 2004 by John Wiley & Sons, Inc.

trated to achieve titers $>10^9$ infectious U/ml. An important breakthrough for VSV G pseudotyping was the use of transient transfection in 293 cells for expressing VSV G protein. This is because VSV G protein is fusogenic and leads to syncytium formation and cell death. By expressing VSV G protein by transient transfection in 293 cells, it is possible to successfully pseudotype retroviral virions during a window between the onset of protein expression and massive cell death.

This unit describes methods for optimizing retroviral production from the 293-based systems (see Basic Protocol 1) and for growing and freezing 293 cells (see Support Protocol). Methods are included for pseudotyping the virus with VSV G protein by sequential transfection (see Basic Protocol 2) or cotransfection (see Alternate Protocol 1). Virus produced by transiently transfected cells can be used to infect cells. Adherent cells can be infected directly with retroviral supernatant (see Basic Protocol 3) or by spin infection (see Alternate Protocol 2). Nonadherent cells can be infected by addition of retrovirus supernatant (see Basic Protocol 4), cocultivation with producer cells (see Alternate Protocol 3), or spin infection (see Alternate Protocol 4). These infection methods are also applicable to retrovirus produced by any of the stable producer cell lines (*UNIT 9.10*).

CAUTION: The viral supernatants produced by these methods may contain potentially hazardous recombinant constructs. The user must exercise due caution in the production, use, and storage of recombinant retroviral virions, especially those with amphotropic and polytropic host ranges, for all genes expressed by the retroviral vectors. Appropriate NIH and regional guidelines should be followed in the use of these recombinant retrovirus production systems.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly.

NOTE: All culture incubations are performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

BASIC PROTOCOL 1

TRANSIENT TRANSFECTION OF A RETROVIRUS VECTOR INTO 293 CELLS

The first step in producing infectious virus from a bacterial plasmid involves introduction of the plasmid into the retroviral packaging cells. Transfection is the method of choice for this step because it causes many copies of the retroviral vector plasmid DNA to be taken up by each cell. This results in a high level of expression with consequent high retroviral titer. Although other equally efficacious methods exist (see Critical Parameters), the least expensive and simplest method is a modification of the calcium phosphate-mediated transfection protocol of Graham and van der Eb (1973; see *UNIT 9.1* and discussion of Optimization of Transfection).

Although it is possible to scale up, highest retroviral titers are obtained using 60-mm dishes. This protocol can be used to cotransfect retroviral structural genes together with the retroviral vector into 293 cells or to transfect retroviral vector into 293-derived packaging cell lines.

Materials

- 293 cells *or* appropriate packaging cell line (see Table 9.9.1)
- 293 cell growth medium (see recipe)
- 25 mM chloroquine in PBS (1000×; store at -20°C; optional)
- Retroviral plasmid DNA
- 2 M CaCl₂
- 2× HEPES-buffered saline (HeBS), pH 7.05 (see recipe)

Transient Production of Retroviral Supernatants

9.11.2

500 mM sodium butyrate, pH 7.0 (50×; optional)

60-mm tissue culture dishes

0.45- μ m filter Sorvall RT-3000B centrifuge and rotor (or equivalent)

Additional reagents and equipment for culture of mammalian cells (APPENDIX 3F) and calcium phosphate transfection (UNIT 9.1)

NOTE: All solutions should be filtered through a 0.2- μ m filter or autoclaved.

1. Twenty-four hours prior to transfection, plate 2.5×10^6 293 cells in 4 ml of 293 cell growth medium (6.25×10^5 cells/ml) in a 60-mm tissue culture dish (see Critical Parameters).

The culture should be ~80% confluent prior to transfection and cell clumping should be minimized.

2. Just prior to transfection, remove the medium and gently add fresh 293 cell growth medium.

Addition of 25 μ M chloroquine to the medium before transfection may boost the retroviral titer by 2-fold. If chloroquine is used, it is important that it not be left on the cells for >12 hr (see Critical Parameters).

3. Prepare a transfection cocktail by adding 6 to 10 μ g retroviral vector plasmid DNA to water and diluting to 438 μ l final volume. Add 62 μ l of 2 M CaCl_2 to the DNA solution.

Plasmid DNA prepared by cesium chloride gradients or by using a commercial kit appears to work equally well. It is unnecessary to perform additional phenol extraction or precipitation steps prior to using the DNA, and the DNA may be stored in either water or TE buffer.

When cotransfecting retroviral vector with retroviral structural genes on multiple plasmids, the total amount of transfected DNA should be 10 to 15 μ g and the plasmids should be introduced in approximately equimolar ratios. These amounts and ratios may have to be altered to optimize retroviral titers (see Critical Parameters).

4. Add 500 μ l of 2× HeBS and mix by shaking the tube or pipetting. Within 1 to 2 min, add this solution to the cells and gently swirl the plate to ensure uniform mixing. Incubate until transfected cells are close to 100% confluent (24 to 48 hr post transfection). Remove the medium and add fresh medium at ~24 hr post transfection (see step 5).

HeBS may also be added to the DNA/ CaCl_2 solution by bubbling. Transfection efficiency is highest if DNA/ CaCl_2 /HeBS mix is added immediately to cells rather than waiting for a visible precipitate to form (30 to 60 min). Although a precipitate is usually visible on the plate within 1 to 2 hr after transfection, the quantity of precipitate appears to be related to the amount of input DNA (W. Pear; unpub. observ.), and the amount of precipitate is usually an unreliable indicator of transfection efficiency.

If chloroquine is included in the medium, remove medium ~10 hr after transfection and gently replace with fresh 293 cell growth medium.

Addition of 10 mM sodium butyrate to the cells may enhance retroviral titers by several-fold (Soneoka et al., 1995). It should be added to the 293 growth medium 12 to 24 hr after transfection at a final concentration of 10 mM. Cells should be treated for 12 to 14 hr with sodium butyrate and washed with PBS prior to proceeding to step 5.

5. Approximately 16 to 24 hr prior to harvesting the retroviral supernatant, remove the medium and gently replace with 4 ml of 293 cell growth medium.

The transfected cells should be close to 100% confluent at this time. The relative retroviral titer may be increased by adding 3 ml rather than 4 ml of medium. If the cells that will be infected require special medium (e.g., RPMI medium, growth factors), the special medium,

rather than 293 cell growth medium, should be added to the cells. Except for the presence of fetal bovine serum, 293 cells appear to tolerate a wide variety of culture conditions.

6. Harvest retroviral supernatant ~48 hr following transfection by gently removing the supernatant from the cells. Either filter the supernatant through a 0.45- μ m filter or centrifuge it 5 min at $500 \times g$ (1000 rpm in Sorvall RT-3000B rotor), 4°C, to remove live cells.

At harvest, the supernatant will be yellow. Acidity does not appear to affect retroviral titer. Once retroviral supernatant is harvested, the transfected cells may be assayed for transfection efficiency by staining for a histochemical marker (such as lacZ, UNIT 9.10) or cell surface marker, by preparing DNA from the cells and assaying by Southern hybridization (UNIT 2.9A), or by lysing cells for protein immunoblot analysis (UNIT 10.8). Optimal transfection efficiencies should range from 30% to 60%. If the supernatant is to be tested for the presence of replication-competent (helper) virus, see UNIT 9.13.

It is necessary to wait at least 36 hr post transfection to obtain high-titer retroviral supernatants. At this point, it may be possible to serially, harvest and replenish supernatant every 12 hr up to 72 hr post transfection without a significant drop in retroviral titer. If the cells are sparse at 24 hr post infection, it may be necessary to wait until 72 hr to obtain high-titer supernatant.

7. If the retroviral supernatant is to be used within 1 to 2 hr, store it on ice. For longer intervals, freeze the supernatant on dry ice and transfer it to -80°C.

Retroviral half-life is 3 to 6 hr at 37°C (Sanes et al., 1986). To maintain high titers, supernatants should be left on ice or frozen following harvest. Freezing does not appear to cause >2-fold drop in titer, as long as the supernatant does not undergo more than one freeze/thaw cycle; exposure to more than one such cycle causes a marked drop in retroviral titer. For this reason, supernatant should be aliquoted in appropriate volumes for subsequent infection. To thaw frozen supernatants, warm for a minimal period at 37°C and use immediately.

SUPPORT PROTOCOL

GROWTH AND STORAGE OF 293 CELLS

The two most important variables in determining the success of retroviral production are the state of the packaging cells and the quality of the transfection reagents. This protocol discusses methods for optimizing growth of 293 cells, passaging the cells, and freezing stocks. Further details for the culture, freezing, and storage of mammalian cell lines can be found in APPENDIX 3F.

Materials

293 cells or packaging cell lines (e.g., Bosc23; see Table 9.9.1) derived from 293 cells

293 cell growth medium (see recipe)

Freezing medium: 90% (v/v) heat-inactivated FBS/10% (v/v) DMSO

Trypsin solution: 0.05% (v/v) trypsin/0.53 mM EDTA

PBS without Ca²⁺ or Mg²⁺ (APPENDIX 2)

10-cm tissue culture dishes

Sorvall RT-3000B centrifuge and rotor (or equivalent)

2-ml cryogenic vials

Culture and passage 293 cells

1. Passage and grow 293 cells or the packaging cell lines derived from them in 10 ml of 293 cell growth medium in 10-cm tissue culture dishes.

Cells are typically grown in 10-cm dishes; however, other sizes can be used and the protocols scaled appropriately. It is recommended that cells be maintained at relatively high density and passaged at a split ratio $\leq 1:5$ to maintain uniformity of the cells in culture. This is especially true for packaging cell lines. It is also recommended that when cells are first received they be expanded to prepare 50 to 100 vials of frozen cells to provide a uniform source of cells for virus production.

Cells should not be allowed to become overconfluent, as this leads to formation of cell clumps that can cause uneven cell distribution after replating and result in less efficient transfection. Cells should be split when they reach 90% confluence and the medium is acidic. If clumping occurs, growing cells for 1 to 2 passages at high density (1:3 split) should remove the clumps.

293 cells and packaging lines derived from those cells appear to tolerate a wide variety of growth conditions and addition of factors without drop in retroviral titer. One variable that is important for maximal retroviral titers is to use heat-inactivated fetal bovine serum (FBS) in the tissue culture medium, rather than horse serum (HS) or newborn calf serum (NCS). To date, both DMEM and RPMI have given good results, and the addition of IL-2, IL-3, IL-6, and stem cell factor (SCF) has not caused the retroviral titers to decrease (W. Pear, unpub. observ.).

2. When the cells are confluent, remove the medium and gently rinse once with PBS without Ca^{2+} and Mg^{2+} .

293 cells are much less adherent than murine fibroblasts. As a result, washes must be performed very gently to avoid removing cells.

3. Add 1 ml trypsin solution and incubate 2 to 3 min at 37°C.

Although cells may be detached by tapping the plate after 30 sec, a more efficacious method to obtain a single-cell suspensions is to return the cells to the incubator for 2 to 3 min. The cells should then detach by themselves.

4. Quench trypsin with 4 ml of 293 growth medium and transfer the cell suspension to a conical centrifuge tube. Centrifuge 3 min at $500 \times g$ (1000 rpm in Sorval RT-3000B rotor), 4°C or room temperature.

To obtain single-cell suspensions, it is recommended that cells be vigorously pipetted in a conical tube rather than on the tissue culture dish.

5. Resuspend pellet vigorously in 5 ml of 293 cell growth medium. Let the suspension stand 1 min to allow the largest clumps to settle. Aliquot the cells without using the last 200 μl of cell suspension (clumps).

Freeze 293 cells

6. Incubate a 10-cm dish of 293 cells in 293 growth medium until the cells are 80% confluent.

Maximal viability is achieved if cells are frozen prior to confluence. One 10-cm dish that is 80% confluent will provide enough cells for 2 to 3 vials of frozen cells.

7. Using trypsin solution, remove the cells from the dish (see steps 2 to 4). Centrifuge the cells 3 min at $500 \times g$, 4°C or room temperature.
8. Remove the medium and resuspend the cells in 2 to 3 ml freezing medium per 10-cm dish.

9. Add 1 ml cell suspension to each 2-ml cryogenic vial and store overnight at -80°C . On the following day, transfer the vials to liquid nitrogen.

Thaw 293 cells

10. Remove a vial of cells from liquid nitrogen and thaw rapidly, warming by hand or at 37°C .
11. Add 1 ml 293 growth medium to the cryogenic vial and add the cell suspension to a tube containing 10 ml growth medium. Centrifuge 3 min at $500 \times g$, 4°C or room temperature.
12. Remove the supernatant and resuspend the cell pellet in 10 ml growth medium. Transfer the cells to a 10-cm tissue culture dish. Incubate.

BASIC PROTOCOL 2

PSEUDOTYPING A STABLE CELL LINE SEQUENTIALLY WITH VSV G PROTEIN

Pseudotyping retroviruses with the vesicular stomatitis virus (VSV) G protein creates virus with a polytropic host range and makes it possible to concentrate the virus by centrifugation. Calcium phosphate-mediated transfection yields retroviral titers in the range of 10^5 to 10^6 CFU/ml; however, concentration of the viruses can increase the titer by several log factors. Because concentration requires larger initial volumes of retroviral supernatants, best results are obtained if a stable cell line that expresses gag-pol and the gene of interest is prepared first. A VSV G protein expression vector is then transiently expressed in this cell line for production of retroviral supernatants. This method is adapted from Burns et al. (1993) and Matsubara et al. (1996). An alternative method is to introduce retroviral vector and VSV G protein-expressing plasmids by cotransfection (see Alternate Protocol 1); it should be possible to introduce *gag-pol* construct at the same time. Although the latter approach may be laborious for obtaining large quantities of retroviral supernatants for concentration, it may yield higher titers for proteins that are detrimental to the long-term growth of 293 cells.

Materials

- Retroviral packaging cell line with amphoteric host range (e.g., PA317, Ψ CRIP, GP+Am12, or Bing; see Table 9.9.1) and appropriate culture medium
- Retroviral vector DNA
- gag-pol-expressing cell line (e.g., Anjou65, ATCC CRL 11268; see Table 9.9.1) and appropriate culture medium
- 293 cell growth medium (see recipe)
- VSV G protein expression plasmid: e.g., pHCMV-VSV-G (Matsubara et al., 1996)
- TNE buffer (see recipe) or 1% (v/v) Hanks basic salt solution (HBSS; APPENDIX 2)
- 60-mm tissue culture dishes
- Sorvall RT-3000B centrifuge and rotor (or equivalent)
- Beckman L3-50 centrifuge and SW 41 rotor (or equivalent)
- Additional reagents and equipment for culturing of mammalian cells (APPENDIX 3F), transfecting cells and harvesting virus (see Basic Protocol 1), infecting cells (see Basic Protocols 3 or 4 or Alternate Protocols 2, 3, or 4), selecting clones with drugs (UNIT 9.5), assaying clones for the gene of interest (e.g., UNITS 9.6-9.8 & 9.10), and freezing cells (see Support Protocol)

Create a stable cell line

1. Transfect a retroviral packaging cell line with an amphotropic host range with 6 to 20 μg retroviral vector DNA (see Basic Protocol 1). Incubate 48 hr.

2. Twenty-four hours before harvesting retroviral supernatant, plate 2.5×10^6 gag-pol-expressing cells into the appropriate culture medium in 60-mm tissue culture dish.
3. Collect retroviral supernatant at 48 hr post transfection. Filter through a 0.45- μ m filter or centrifuge 5 min at $500 \times g$ (1000 rpm in Sorvall RT-3000B rotor), 4°C, to remove cells.
4. Use 1 ml retroviral supernatant to infect the gag-pol-expressing cell line.

For production of stable producer cell lines, infection is preferred to transfection because there is a reduced risk of rearrangement.

5. Select individual clones of stable producer cell lines—i.e., by drug selection (UNIT 9.5), FACS sorting, or other method.
6. Identify clones that express the gene of interest (e.g., UNITS 9.6-9.8 & 9.10).

These are the stable producer cell line(s) that will be used for subsequent experiments.

7. Aliquot and prepare frozen stocks of the stable producer cell line (see Support Protocol).

Pseudotype the producer cell line

8. Twenty-four hours prior to transfection, plate 2.5×10^6 stable producer cells in appropriate culture medium in a 60-mm dish.

If desired, the procedure can be scaled up for larger volumes. It is even possible to transfect spinner cultures (J.C. Burns, pers. comm.).

9. Transfect stable producer cells with 3 to 6 μ g VSV G protein expression plasmid by modified calcium phosphate-mediated transfection (see Basic Protocol 1). Incubate 24 hr.

Adjust the volumes proportionally if larger volumes are used in step 8.

10. Replace the medium with fresh 293 cell growth medium and continue incubation 24 to 48 hr.
11. Harvest retroviral supernatants between 48 and 72 hr by collecting the medium from the culture. Concentrate supernatant immediately (proceed to step 12) or store at -80°C .

Syncytium formation is evident ~36 hr following transfection. Syncytia are identified by the formation of multinucleated giant cells which are the result of membrane fusion caused by VSV G protein.

Concentrate VSV G protein-pseudotyped viral supernatant

12. Concentrate retroviral supernatant by centrifuging 90 min at $50,000 \times g$ (17,000 rpm in an SW 41 rotor), 4°C.
13. Resuspend the pellet overnight at 4°C in 20 μ l of TNE buffer or 0.1% HBSS.

Pellet is resuspended in 1/200 of viral culture volume.

14. Use concentrated retroviruses immediately for infection, store them frozen at -80°C , or concentrate the stock by another round of centrifugation (steps 12 and 13).

PSEUDOTYPING COTRANSFECTIONALLY WITH VSV G PROTEIN

It is also possible to produce a retrovirus pseudotyped with vesicular stomatitis virus (VSV) G protein by transient cotransfection. This method is adapted from J. Burns (pers. comm.) and Pear et al. (1996).

Materials

293 cells or 293-derived cells expressing retroviral gag-pol: e.g., Anjou65 (ATCC CRL 11269)
293 cell growth medium (see recipe)
Retrovirus vector DNA
VSV G protein expression plasmid: e.g., pHCMV-VSV-G (Matsubara et al., 1996)
60-mm tissue culture dishes

Additional reagents and equipment for culture of mammalian cells (*APPENDIX 3F*), modified calcium phosphate–mediated transient transfection of cells (see Basic Protocol 1), and concentrating pseudotyped viral supernatants (see Basic Protocol 2)

1. Twenty-four hours prior to transfection, plate 2.5×10^6 293 cells, or cells of a 293 derivative stably expressing the retroviral gag-pol genes, into 293 cell growth medium in a 60-mm dish.
2. Cotransfect 3 to 5 μg retroviral vector DNA and 3 to 5 μg of a VSV G protein expression plasmid by modified calcium phosphate–mediated transfection (see Basic Protocol 1). Incubate.

If 293 cells were plated in step 1, also cotransfect a gag-pol expression plasmid.

3. On the following day, replace the medium with 4 ml fresh 293 growth medium.
4. Harvest retroviral supernatants between 48 and 72 hr by collecting the culture medium. Concentrate the virus immediately (see Basic Protocol 2) or store at -80°C .

Syncytium formation is evident ~36 hr following transfection.

INFECTION OF ADHERENT CELLS WITH RETROVIRAL SUPERNATANT

This protocol gives methods for infecting adherent cells with retroviral supernatant. This is the most common method for determining the retroviral titer (*UNIT 9.10*) and testing for the presence of helper virus (*UNIT 9.13*). Infectious titer can be quantitated based on marker staining—e.g., using *lacZ* (*UNIT 9.10*), or green fluorescent protein (GFP; *UNIT 9.7C*)—or drug resistance (*UNIT 9.5*). Recent reports suggest that viral transduction by centrifugation (spin infection; see Alternate Protocol 2) will increase infectious titers 2- to 4-fold (Kotani et al., 1994). These methods are written for cells of the commonly used murine fibroblast line NIH 3T3; however, they should be adaptable to other adherent cell lines with minor modifications.

Materials

Retroviral supernatant, fresh or frozen (see Basic Protocols 1 or 2)
Target cells: e.g., NIH 3T3 cells
4 mg/ml polybrene in PBS (*APPENDIX 2*), filtered and stored at 4° or -20°C
Fibroblast growth medium
Antibiotic for drug selection (*UNIT 9.5*; optional)
10-cm tissue culture dishes

Additional reagents and equipment for culture of mammalian cells (*APPENDIX 3F*) and for assaying of reporter gene expression (e.g., *UNITS 9.6-9.8 & 9.10*) or drug selection (*UNIT 9.5*).

1. Twelve to eighteen hours prior to transfection, plate 5×10^5 NIH 3T3 cells into appropriate tissue culture medium in a 10-cm tissue culture dish.

Infection protocols can be scaled up or down. For a 60-mm plate, plate 2×10^5 cells and infect in a volume of 1 ml.

2. Prepare a 3-ml infection cocktail containing:

Retroviral supernatant: ≤ 1.5 ml

4 $\mu\text{g/ml}$ polybrene

Fibroblast growth medium to a final volume of 3 ml.

The retroviral supernatant should be $\leq \frac{1}{2}$ the final volume of the infection cocktail. 293 supernatants appear to contain a cytostatic factor that can be diluted out by changing the transfection medium 18 to 24 hr before retroviral harvest and by avoiding infectious stocks that contain viral supernatant at ratios $>1:1$ (Naviaux et. al., 1996).

3. Remove the medium from the dish of cells and add the infection cocktail. Incubate ≥ 3 hr.

If infection continues >6 hr, a 5-ml infection cocktail is recommended to prevent dehydration.

4. After the infection incubation, add 7 ml fibroblast growth medium to the dish. Incubate 36 to 48 hr.

*Drug selection (e.g., G418, puromycin) can begin 24 hr post infection (*UNIT 9.5*). If the cells are not over-confluent (i.e., if they are $<50\%$ confluent) at this time, it is unnecessary to split the cells prior to adding drug. If the cells are $>50\%$ confluent, it is necessary to split the cells as described in *UNIT 9.5*.*

5. Assay the cells for reporter gene expression (*UNITS 9.6-9.8 & 9.10*).

INFECTION OF ADHERENT CELLS BY SPIN INFECTION

Adherent cells can also be infected by centrifuging the cells in the presence of the infection cocktail (spin infection). This protocol is modified from the methods of Kotani et al. (1994).

Materials

Target cells: e.g., NIH 3T3 cells

Fibroblast growth medium

Retroviral supernatant

4 mg/ml polybrene in PBS (*APPENDIX 2*), filtered and stored at 4° or -20°C

6-well tissue culture plates

Beckman GS-6KR or Sorvall RT-3000B centrifuge with microplate carriers (or equivalent)

Additional reagents and equipment for culture of mammalian cells (*APPENDIX 3F*) and for assaying of reporter gene expression (e.g., *UNITS 9.6-9.8 & 9.10*) or drug selection (*UNIT 9.5*)

ALTERNATE PROTOCOL 2

1. Twelve to eighteen hours prior to infection, plate 1×10^5 target cells per well into fibroblast growth medium in a 6-well tissue culture plate.
2. For each well to be transfected, prepare a 4-ml infection cocktail containing:
 - Retroviral supernatant: ≤ 2 ml
 - 4 $\mu\text{g/ml}$ polybrene
 - Fibroblast growth medium up to 4 ml.

An infection cocktail of ≥ 4 ml is necessary to prevent dehydration of the cells.

The retroviral supernatant should be $\leq 1/2$ the final volume of the infection cocktail. 293 supernatants appear to contain a cytostatic factor that can be diluted out by changing the transfection medium 18 to 24 hr before retroviral harvest and by avoiding infectious stocks that contain viral supernatant at ratios $>1:1$ (Naviaux et. al., 1996).
3. Remove the medium from the cells and add the infection cocktail.
4. Centrifuge the cells 1.5 to 2 hr at $1000 \times g$ (2500 rpm in Beckman GS-6KR or Sorvall RT-3000B rotor), room temperature.
5. Return the cells to the incubator.
6. Change medium the next day and incubate until 48 hr post infection.
7. Assay for reporter gene expression (e.g., *UNITS 9.6-9.8 & 9.10*), add antibiotic for drug selection (*UNIT 9.5*), or test for effect of the gene of interest.

**BASIC
PROTOCOL 4**

**INFECTION OF NONADHERENT CELLS BY RETROVIRAL
SUPERNATANT**

Nonadherent cells can be infected by direct addition of retroviral supernatant or by cocultivation of nonadherent cells with retroviral producer cells (see Alternate Protocol 3). The advantage of cocultivation is that there is continuous retroviral production; however, this must be weighed against the disadvantage of harvesting producer cells together with target cells. This effect may be minimized by irradiating producer cells prior to cocultivation. Alternatively, nonadherent cells can be infected by spin infection (see Alternate Protocol 4). In general, infection by cocultivation is equivalent to spin infection.

Materials

- Retroviral supernatant
- 4 mg/ml polybrene in PBS (*APPENDIX 2*), filtered and stored at 4° or -20°C
- Target cell growth medium
- Exponentially growing nonadherent target cells
- 15-ml centrifuge tube
- 60-mm tissue culture dishes
- Sorvall RT-3000B centrifuge and rotor (or equivalent)
- Additional reagents and equipment for culture of mammalian cells (*APPENDIX 3F*) and for assaying of reporter gene expression (*UNITS 9.6-9.8 & 9.10*) or drug selection (*UNIT 9.5*)

1. Prepare a 3-ml infection cocktail containing:
 - Retroviral supernatant: ≤ 1.5 ml
 - 2 $\mu\text{g/ml}$ polybrene
 - Target cell growth medium up to 3 ml.

The retroviral supernatant should be $\leq 1/2$ the final volume of the infection cocktail. 293 supernatants appear to contain a cytostatic factor that can be diluted out by changing

the transfection medium 18 to 24 hr before retroviral harvest and by avoiding infectious stocks that contain viral supernatant at ratios >1:1 (Naviaux et. al., 1996).

Many nonadherent cells are more stringent in their growth requirements than fibroblasts. For this reason, it may be necessary to use a medium other than 293 cell growth medium during the 24 hr prior to viral harvest and/or add growth factors or cytokines to the medium. It is essential, however, that heat-inactivated fetal bovine serum (FBS) be used as the serum source.

2. Centrifuge 3×10^5 to 3×10^6 exponentially growing target cells 5 min at $500 \times g$ (1000 rpm in Sorvall RT-3000B rotor), 4°C or room temperature.
3. Remove supernatant and resuspend the cells in the infection cocktail at a final density of 10^5 to 10^6 cells/ml.
4. Add the cell suspension to a 60-mm dish and incubate 24 hr.
5. Twenty-four hours post transfection, centrifuge the cells 5 min at $500 \times g$, 4°C or room temperature, and resuspend the pellet in target cell growth medium. Incubate cells another 24 hr.
6. Assay for reporter gene expression (e.g., *UNITS 9.6-9.8 & 9.10*), add antibiotic for drug selection (*UNIT 9.5*), or determine infectious titer (*UNIT 9.10*).

INFECTION OF NONADHERENT CELLS BY COCULTIVATION

Nonadherent cells can also be infected by cocultivating them with retroviral producer cells for 48 hr.

Materials

Transfected packaging cells (see Basic Protocol 1) in 60-mm tissue culture dishes

Retroviral supernatant

4 mg/ml polybrene in PBS (*APPENDIX 2*), filtered and stored at 4° or -20°C

10^5 to 10^6 cells/ml nonadherent target cells

Target cell growth medium

15-ml conical centrifuge tubes

60-mm tissue culture dishes

Sorvall RT-3000B centrifuge (or equivalent)

Additional reagents and equipment for culture of mammalian cells (*APPENDIX 3F*) and for assaying of reporter gene expression (e.g., *UNITS 9.6-9.8 & 9.10*) or drug selection (*UNIT 9.5*)

1. Twenty-four hours after packaging cells have been transfected, prepare a 3-ml infection cocktail containing:
 - Retroviral supernatant: ≤ 1.5 ml
 - 2 $\mu\text{g/ml}$ polybrene
 - 3×10^5 to 3×10^6 nonadherent target cells
 - Target cell growth medium to 3 ml.

Replication of transfected retroviral packaging cells without loss of retroviral production can be achieved by irradiating them with 1500 rads (C. Zent, Univ. of Chicago, unpub. observ.) prior to addition of infection cocktail.

2. Aspirate the medium from the transfected packaging cells and gently add the infection cocktail to the cells. Incubate 24 hr.

To prevent detachment of adherent transfected packaging cells, add cocktail to the side of the dish rather than directly onto the cells.

**ALTERNATE
PROTOCOL 3**

**Introduction
of DNA into
Mammalian Cells**

9.11.11

3. Twenty-four hours after the infection cocktail is added (48 hr post transfection), gently remove 2 ml medium (which will contain many nonadherent cells) and transfer to a conical tube. Centrifuge 5 min at $500 \times g$, 4°C or room temperature.

It is not necessary to remove all of the nonadherent cells from the dish because the purpose of this step is to replenish the medium (which is acidic). Sufficient residual medium should remain on the dish to prevent dehydration during the short centrifugation step.

4. Prepare a fresh infection cocktail containing:

Retroviral supernatant: ≤ 1.5 ml (optional)
2 $\mu\text{g/ml}$ polybrene
Target cell growth medium to 3 ml.

Adding virus in this step is optional, but it may increase infection efficiency.

5. Remove the supernatant and gently resuspend the cell pellet in freshly prepared infection cocktail.
6. Using extreme care to avoid disruption of the adherent cell layer, add the fresh infection cocktail to the wall of the plate. Incubate 24 hr.
7. At 72 hr post transfection, collect nonadherent cells from the dish by gentle pipetting.

It is necessary to sufficiently wash the plate with FBS or medium to remove most nonadherent cells while minimizing contamination with adherent cells. Typically, there is about 10% contamination of nonadherent cells. Because adherent cells detach in sheets, rather than as individual cells, many of the cells can be removed by allowing the large clumps of cells to settle out and removing the others (see Support Protocol, step 5). Alternatively, cells can be transferred to a new 60-mm dish and given sufficient time for the adherent cells to reattach (~ 3 hr), after which the nonadherent cells can be removed.

8. Centrifuge the suspension of nonadherent cells 5 min at $500 \times g$, 4°C or room temperature. Resuspend the cells in target cell growth medium. Plate the target cells in 60-mm tissue culture dishes. Incubate an additional 24 to 48 hr.
9. Assay for reporter gene expression (e.g., *UNITS 9.6-9.8 & 9.10*) or add antibiotics for drug selection (*UNIT 9.5*), or assay for the gene of interest.

ALTERNATE PROTOCOL 4

INFECTION OF NONADHERENT CELLS BY SPIN INFECTION

Alternatively, nonadherent target cells can be infected by centrifuging the cells in the presence of infection cocktail, a method modified from Kotani et al. (1994).

Materials

Retroviral supernatant
4 mg/ml polybrene in PBS (*APPENDIX 2*), filtered and stored at 4° or -20°C
Target cell growth medium
Exponentially growing nonadherent target cells
24-well tissue culture plates
Sorvall RT-3000B centrifuge with microplate carrier (or equivalent)
10-cm tissue culture dishes

Additional reagents and equipment for culture of mammalian cells (*APPENDIX 3F*)
and for assaying of reporter gene expression (e.g., *UNITS 9.6-9.8 & 9.10*) or drug
selection (*UNIT 9.5*)

- For each well to be transfected, prepare a 2-ml infection cocktail containing:
 - Retroviral supernatant: ≤ 1 ml
 - 4 $\mu\text{g/ml}$ polybrene
 - Target cell growth medium to 2 ml.
- Add $1\text{--}2 \times 10^6$ exponentially growing nonadherent target cells per well of a 24-well tissue culture plate. Centrifuge 5 min at $500 \times g$ (1000 rpm in Sorvall RT-3000B rotor), 4°C or room temperature.

The cell number should be adjusted so that cells completely cover the surface of the well and form a monolayer following centrifugation.
- Remove the supernatant and add infection cocktail. Centrifuge the cells 1.5 to 2 hr at $1000 \times g$ (2500 rpm in Sorvall RT-3000B rotor), room temperature.
- Either immediately after centrifugation or after ≤ 6 hr of incubation, transfer the cells in the infection medium to a 10-cm dish. Dilute to 10 ml final volume with target cell growth medium. Incubate to 48 hr post infection.

If the cells are left overnight in only 1 to 2 ml of infection cocktail, the medium will be very acidic by the following morning.
- Assay cells for reporter gene expression (e.g., *UNITS 9.6-9.8 & 9.10*) or add antibiotic for drug selection (*UNIT 9.5*).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see *APPENDIX 2*; for suppliers, see *APPENDIX 4*.

293 cell growth medium

Dulbecco's modified Eagle medium (high glucose) containing:

- 10% (v/v) heat-inactivated fetal bovine serum (FBS)
- 100 U/ml penicillin
- 100 U/ml streptomycin
- 2 mM L-glutamine
- Store at 4°C

This medium should be stable for at least 3 months except that L-glutamine has a half-life of 1 month.

HEPES-buffered saline (HeBS), 2 \times

- 50 mM *N*-2-hydroxyethylpiperazine-*N'*-ethanesulfonic acid (HEPES)
- 10 mM KCl
- 12 mM dextrose
- 280 mM NaCl
- 1.5 mM Na_2HPO_4
- Adjust pH to 7.05 ± 0.05
- Filter through 0.2- μm filter
- Store in 50- μl aliquots at -20°C

Avoid multiple freeze/thaw cycles. To thaw, warm to room temperature and invert or vortex the tube to achieve uniform mixing.

Although it is unclear why, the ability of the 2 \times HeBS solution to produce working calcium phosphate precipitates deteriorates after 6 months to 1 year, even when the solution is stored at -20°C . Fresh 2 \times HeBS should therefore be prepared every 6 months.

TNE buffer

50 mM Tris-Cl, pH 7.8

130 mM NaCl

1 mM EDTA

Store at room temperature indefinitely

COMMENTARY

Background Information

Creation of high-titer retroviral supernatants by transient transfection offers several advantages over the creation of stable cell lines, especially for experimental purposes. The transient methods described in this unit take advantage of the high transfectability and high protein expression in 293 cells. When retroviral vectors (e.g., see Figs. 9.9.5 & 9.9.6) are expressed with the retroviral packaging constructs in these cells, the vector RNA (containing the Ψ site) is efficiently packaged and budded from the surface of the packaging cells. The infectious retrovirus vector may be harvested by removing the packaging cell supernatant. Because the transient methods are not dependent on stable integration of the introduced plasmid(s), high-titer viral supernatant may be harvested from the packaging cells from 36 to 96 hr following transfection. Two different approaches, both utilizing 293 cells, have successfully produced helper-free high-titer retroviral supernatants expressing a wide variety of genes. In the method of Pear et al. (1993), three cell lines (Anjou, Bosc23, and Bing) were made by stably transfecting plasmids expressing gag-pol (Anjou), gag-pol and ecotropic envelope (Bosc23), or gag-pol and amphotropic envelope (Bing) into 293T cells. 293T cells are a derivative of 293 cells that express the SV40 large T antigen (DuBridge et al., 1987). These cell lines were selected for high levels of expression of reverse transcriptase and the appropriate envelope protein. All of the retroviral structural genes are expressed from the Moloney murine leukemia virus (MoMuLV) long terminal repeat (LTR). High-titer retroviral supernatants may be made from these cell lines by introducing either a retroviral vector alone (Bosc and Bing) or a retroviral vector and a plasmid-expressing envelope (Anjou). Because the retroviral structural genes are expressed from two different stably integrated plasmids that contain multiple mutations (Danos and Mulligan, 1988), more than two recombination events are necessary for the creation of replication-competent retrovirus. To date, generation of helper virus by these cell lines has not been reported.

A second generation retroviral packaging cell line, termed ϕ NX, has recently been developed for high-titer, transient production (P. Achacoso and G.P. Nolan, pers. comm.). The major addition is that the *gag-pol* construct has an IRES-CD8 surface marker, so it is possible to follow gag-pol expression in living cells on a cell-by-cell basis. This facilitates checking the line for continued high-level gag-pol expression using CD8 as proxy. Additionally, non-MoMuLV-based promoters are used to express *gag-pol* (and *env*) genes, further minimizing the potential for recombination with vector LTRs. Otherwise, the construction of these cell lines is similar to Bosc23. Amphotropic and ecotropic versions of these have been prepared, and they stably express gag-pol and env proteins over several months. These lines are helper-free and produce retroviral supernatants that have titers similar to Bosc23 and Bing. The methods described in this unit work well with the ϕ NX cell line.

In the strategies of Finer et al. (1994), Soneoka et al. (1995) and Naviaux et al. (1996), both the retroviral vector and the retroviral packaging constructs are cotransfected into 293 cells and retroviral supernatants are harvested 48 hr later. These groups found that titers were highest when the packaging constructs were expressed from a cytomegalovirus (CMV) promoter and a retroviral vector in which the 5' LTR was a hybrid between CMV and MoMuLV sequences. Although previous reports suggested that cotransfection of retroviral vector and packaging constructs could lead to replication-competent retrovirus (Danos and Mulligan, 1988; Pear et al., 1993), these groups have engineered their constructs to minimize regions of homology that might lead to helper virus formation. In particular, deletion of 3' LTR sequences appears important for preventing the formation of replication-competent retrovirus (Soneoka et al., 1995).

Critical Parameters

Several parameters are important to optimize for high-titer retroviral production. Cells should be at optimal density (usually ~80% confluent) with minimal clumping at the time

of transfection. In addition to cell density, production of high-titer retroviral supernatants also requires that the cells continue to grow for ≥ 24 hr following transfection. A rough indicator is that the plate should be nearly 100% confluent ~ 24 hr after transfection. Several factors that may account for failure to obtain this degree of confluence are the nature of the protein expressed by the retroviral vector, the quantity of input DNA, and the length of chloroquine and/or sodium butyrate treatment. Expression of some proteins (such as P210bcr/abl) appears detrimental to 293 cell growth. High-titer retroviral supernatants can be obtained with vectors expressing such genes by increasing the number of cells plated prior to transfection and/or decreasing the quantity of transfected retroviral plasmid DNA. For expression of some genes, 293 cells may need to be nearly 100% confluent at the time of transfection. In addition to the protein product, it appears that the quantity of transfected DNA may have a toxic effect upon the cells. For up to 10 to 15 μg transfected DNA per 60-mm plate, increasing the amount of input DNA increases retroviral titer; however, as more DNA is added beyond that point, the quantity of DNA has a toxic effect on the cells. As discussed in the protocols, to prevent toxicity from chloroquine or sodium butyrate, cells should not be exposed to either of these reagents for ≥ 12 to 14 hr. When trying to optimize titers from a new retroviral construct, it is recommended that cell density, input DNA, and length of chloroquine and/or sodium butyrate treatment all be optimized. If the cells are not confluent at 24 hr post transfection, but reach confluence by 48 hr post transfection, it may be possible to obtain high-titer supernatants between 48 and 72 hr post transfection. Supernatants harvested >96 hr post transfection do not produce high retroviral titers.

Another variable that must be optimized is the transfection reaction. Of particular importance is the pH of the $2\times$ HEPES-buffered saline (HeBS), which should be 7.05 ± 0.05 . For reasons that are not clear, $2\times$ HeBS loses its effectiveness between 6 months and 1.5 years. Unfortunately, there is no way to detect this except for a bad experimental result. For this reason, it is recommended that fresh stocks of $2\times$ HeBS be prepared every 6 months.

Although the modified calcium phosphate-mediated transfection method is inexpensive and gives consistently good results, other methods of gene transfer, including lipid-mediated

transfection (*UNIT 9.4*), work equally well. A recent report suggests that receptor-mediated, adenovirus-augmented transfection is superior to calcium phosphate-mediated transfection for some cell types (von Ruden et al., 1995). It has not yet been determined if this method is superior for gene transfer into 293 cells.

There are several techniques that may increase retroviral titer—adding factors to the transfection or cell growth medium, amplifying the plasmid DNA, decreasing the incubation temperature, and infecting by centrifugation. Addition of $25 \mu\text{M}$ chloroquine during transfection may increase titers 2-fold; presumably this is due to the lysosomal neutralizing activity of the chloroquine. Sodium butyrate has been reported to increase retroviral titers from several-fold to 1 log by acting as a transcriptional activator of the MoMuLV LTR, as well as other promoters including CMV (Soneoka et al., 1995). Increasing the extracellular concentration of dNTPs may increase retroviral titers up to 10-fold by enhancing endogenous reverse transcription (Zhang et al., 1995). 293T cells, a 293 cell derivative, contain a temperature-sensitive large T antigen, whose permissive temperature is 32°C (DuBridge et al., 1987). Thus, incubation at this temperature in conjunction with the use of constructs that contain the SV40 origin of replication may result in plasmid replication and higher retroviral titers. This may come at a cost, however, as large T-induced replication is associated with higher recombination rates (St.-Onge et al., 1993). Shifting the cells to lower incubation temperatures (32° to 34°C) following transfection has been reported to increase retroviral titers by 5- to 15-fold (Kotani et al., 1994). This is hypothesized to result from both improved retroviral survival and increased production. Similarly, infecting by centrifugation may increase retroviral infection by 4- to 10-fold (Kotani et al., 1994). It is important to note that all of the above methods have given variable results in different investigators' hands, and each should be optimized (see Troubleshooting).

Unlike retroviruses expressing the amphotropic and ecotropic envelopes, VSV G protein-pseudotyped retroviruses can be efficiently concentrated 100- to 1000-fold because they can better withstand shearing forces during centrifugation. This attribute together with their polytropic host range makes them a very useful laboratory tool, especially for stable gene transfer into nonmammalian cells.

Troubleshooting

To maximize retroviral production, it is recommended that conditions be optimized using a nontoxic reporter protein such as lacZ (*UNIT 9.10*), green fluorescent protein (GFP; *UNIT 9.7C*), placental alkaline phosphatase (PLAP), or a cell-surface marker. During optimization, both transfection frequency of the producer cells and infection rate of the target cells should be measured. A number of variables that can affect retroviral production have been previously discussed (see Critical Parameters).

To avoid drift of the packaging cell lines or highly transfectable 293 cells, it is recommended that they be maintained for ~20 passages (2 months) before establishing a fresh stock by thawing a frozen vial of cells. It may be possible to carry the cells for longer periods without loss of efficacy, and it is recommended that the cells be assayed at various times to check the ability to produce high-titer supernatants. Bosc and Bing cells were made using 293T cells that contain selectable markers for neomycin (1 mg/ml), hygromycin (400 µg/ml), and mycophenolic acid (50 µg/ml). There does not appear to be any advantage in growing the cells in selection medium. If retroviral titers drop when using these cells, their growth may be tested by growing in hygromycin- and xanthine-guanine phosphoribosyltransferase-containing selection medium. If a majority of the cells are not resistant to these antibiotics, a fresh vial of earlier-passage cells should be thawed rather than attempting to reselect the cells. Similarly, when cells are initially received, aliquots should be tested for resistance to these antibiotics. 293 cells do not contain a selectable marker.

It should be noted that the amphotropic envelope-expressing Bing cells release ~100 units of infectious retrovirus per ml of retroviral supernatant expressing hygromycin resistance which results from the introduction of the gene for hygromycin resistance into these cells by a retroviral vector (W. Pear, unpub. observ.). Replication-competent retrovirus has not been detected in this cell line. The φNX-A cells do not produce a hygromycin-resistant retrovirus (G.P. Nolan, pers. comm.).

For efficient infection, addition of a polycation increases infection efficiency by >100-fold (reviewed in Burns et al., 1993). Polybrene gives the best results at concentrations between 2 and 8 µg/ml. Polybrene may, however, be toxic to some cell types. For example, NIH 3T3 cells tolerate 4 µg/ml polybrene for at least 18

hr; however, treatment of these cells with 8 µg/ml for this period is detrimental. If high polybrene concentrations are chosen, the medium should be changed after 3 to 5 hr. For nonadherent cells, including primary bone marrow cultures, 1 to 2 µg/ml polybrene is well tolerated for ≤48 hr. It is possible to use other cations, such as protamine sulfate or poly-L-lysine; however, infectious titers are diminished by 2- to 4-fold with these agents (Burns et al., 1993).

Efficient infection of nonadherent cells has been cumbersome due to the need to cocultivate the retroviral producer cells with the target cells. It is difficult to separate the producer cells from target cells. An additional difficulty is imposed by 293 cells which, because of their high density, tend to rapidly acidify medium. For this reason, it is important to replenish medium daily when performing cocultivations. An alternative to cocultivation is spin infection. This technique appears to produce equivalent results as cocultivation for several nonadherent cell lines (W. Pear, unpub. observ.). Although the original protocols of Kotani et al. (1994) indicate that infections should be performed at 32°C, many centrifuges are unable to maintain that temperature; equivalent results are obtained by spin infecting at room temperature (W. Pear, unpub. observ.).

One major problem with retroviral gene transfer is that, despite producing high-titer retroviruses, it is difficult to maintain gene expression following infection. Although there are a number of potential mechanisms at the transcriptional and posttranscriptional levels, a teleologic explanation is that the retrovirally expressed protein is detrimental to cell growth resulting in outgrowth of clones that express lower levels of the protein. This is a particular problem with vectors that contain an internal promoter expressing a selectable marker, because even though the marker is selected there is no selective pressure to express the gene of interest. One method to increase the likelihood that the gene of interest will be expressed (although there may still be posttranscriptional mechanisms that affect the level of expression) is to use a polycistronic retroviral vector (see *UNIT 9.10*). Other methods of overcoming gene toxicity are being developed. Particularly promising are the tetracycline-inducible promoters originally described by Gossen and Bujard (1992); these promoters have shown some degree of success when incorporated into retro-

viral vectors (Hoffman et al., 1996; Paulus et al., 1996).

Anticipated Results

Transfection efficiencies of 293 cells should be in the range of 30% to 60%. Infectious titers of 10^6 to 10^7 infectious U/ml should be expected from most retroviral vectors when titered on murine NIH 3T3 cells. Titers may be slightly reduced with large cDNA inserts (>4 kb). Titers may be lower on other cell types, particularly cells expressing only the amphotropic envelope receptor. For VSV G protein pseudotyping followed by concentration by centrifugation, titers of 10^9 infectious U/ml should be expected.

Time Considerations

Plating cells, transfections, infections, and medium changes may take from <1 hr/day to several hours per day depending on the number of dishes and transfections/infections. Production of viral supernatant and infection of target cells each require 3 to 4 consecutive days.

Large-Scale Preparation and Concentration of Retrovirus Stocks

UNIT 9.12

For some applications, such as infection of cells *in vivo*, it is necessary to concentrate retrovirus stocks in order to increase their titer. This is typically due to a limitation in the volume that can be injected at any one site. In addition, if one wishes to infect a population of cells uniformly with a virus that does not encode a selectable marker, high-titered stocks are necessary. This is because the initial infection must be relied upon, without selection, to generate as many infected cells as possible. In order to prepare the highest-titered stock for multiple experiments, several hundred milliliters to a few liters of producer cell supernatant can be prepared, titered, and concentrated (and tested for helper-virus contamination if this is required for the application at hand).

Because viruses are macromolecular structures, they can be concentrated fairly easily by a relatively short centrifugation step. The viral particles can either be pelleted (see Basic Protocol) or centrifuged onto a sucrose density step gradient. Alternatively, virions can be precipitated using polyethylene glycol or ammonium sulfate, and the resulting precipitate collected by centrifugation (see Alternate Protocol 1). After resuspension of the precipitates, the virions can be used directly, or further purified either by sedimentation onto sucrose density gradients, or by column filtration as described here. Perhaps most simply of all, small volumes of virus stock can be concentrated by centrifugation through a filter that allows only small molecules to pass (see Alternate Protocol 2).

NOTE: Retroviral particles are fragile, with short half-lives even under optimum conditions. When handled too roughly, they lose infectivity. Thus, resuspension of pellets and other procedures must be carried out gently, and materials should be kept cold.

PREPARATION OF VIRUS STOCK AND CONCENTRATION BY CENTRIFUGATION

**BASIC
PROTOCOL**

In this procedure, the virus stock is harvested after producer cells are split from newly confluent cultures and grown for 2 to 3 days. The stock is titered and then concentrated by centrifugation. Upon suspension of the pellet, the concentrated virus is again titered and frozen in small aliquots. The example given below is for a murine replication-incompetent Ψ 2 stock.

Materials

- Identified high-titer Ψ 2 producer cells, 50% to 90% confluent (UNIT 9.10)
- Complete DMEM containing 10% calf serum (DMEM-10, APPENDIX 3F, prepared with calf serum instead of FBS)
- NIH 3T3 cells
- 800 μ g/ml polybrene
- 0.45- μ m filters for large volumes (e.g., Nalgene 115-ml or 500-ml filters)
- Beckman JA-14 rotor with 250-ml centrifuge bottles (or equivalent) if concentrating large volumes *or* Beckman SW-27 or SW-41Ti rotor (or equivalent) if concentrating small volumes

NOTE: All incubations involving tissue culture cells should be performed in a humidified incubator 37°C, 5% CO₂ unless otherwise noted.

9.12.1

Supplement 37

Prepare virus stock

1. Split producer cells 1:10 or 1:20 from newly confluent cultures into twenty to fifty 10-cm dishes. Incubate cells until they are 50% to 90% confluent.
2. Discard medium and add half the normal volume of medium (e.g., add 5 ml for a 10-cm dish). Make sure that the medium is not alkaline and add the medium gently as the entire monolayer may peel off if stressed. Incubate 2 to 3 days.

The degree of confluence suggested here is based upon both theoretical and empirical considerations. The greater the number of producer cells, the greater the virus production; however, if cells are past confluence for too long, they may reduce their production of virus and, in some cases, the monolayer of cells will peel off the dish. In our experience with Ψ2 producers, the best titers are obtained as described here. However, for different packaging lines, optimum conditions may vary—e.g., the supernatant may need to be harvested just as the cells reach confluency, or the medium may need to be changed to half volume the day before confluency and harvested the following day.

3. Harvest the supernatant, filter through a 0.45- μ m filter, and store at -70° or -80° C, or titer and concentrate immediately (steps 4 to 8).

The cells will be extremely densely packed when the harvest is made and the medium will be yellow. Nonetheless, this method of harvest seems to work well for several producers (e.g., Isolde and Ψ2).

4. Titer the virus stock as described in UNIT 9.10.

It is customary to titer before concentration. If the titer is sufficiently high, it can be aliquoted and used without concentration. However, if the highest possible titer is desirable, stocks should be concentrated. Stocks can be concentrated before being titered, although sometimes this is wasted effort as the stock may be very low in titer before concentration and thus not worth concentrating.

Concentrate virus stock

5. For large volumes, centrifuge the virus stock 20 min at $25,000 \times g$ (e.g., 14,000 rpm in a JA-14 rotor), 4° C, in 250-ml bottles that have been sterilized by autoclaving. For smaller volumes, centrifuge 10 min in an SW-27 or SW-41Ti rotor at 20,000 rpm using tubes that have been rinsed with 70% ethanol (to reduce contamination with bacteria).

This step serves to pellet nonviral, cellular debris.

6. Pour the supernatant directly into sterile bottles and centrifuge 5 to 16 hr at 14,000 rpm, 4° C, if using a JA-14 rotor or 2 hr at 20,000 rpm if using an SW-27 or SW-41Ti rotor.

The longer the spin, the harder the pellet, and the easier it is to pour off the supernatant (step 7) without dislodging the pellet. However, it is harder to resuspend the pellet after the longer spins. With centrifugation of large-volume stocks (e.g., >200 ml), we recommend the longer spins and the use of a Beckman JA-14 rotor or its equivalent. With smaller volumes, we recommend the SW-27 or SW-41Ti swinging bucket rotors with shorter spins (2 hr at 20,000 rpm, 4° C). Swinging-bucket rotors make a firm pellet at the bottom of the tube, so that it is easy to pour off the supernatant without dislodging the pellet; in addition, it is easier to see the pellet in tubes spun in swinging-bucket rotors.

7. Discard supernatant while carefully avoiding discarding the pellet, which sometimes dislodges when using the large volumes.

If using the JA-14 rotor, when removing the bottles from the rotor, mark the side of the bottle that should contain the pellet. The pellet will be smeared down the side of the bottle and will be difficult to see. Although normally the supernatant is discarded, a

small volume of the supernatant may be saved to titer to determine whether the virus was indeed pelleted.

8. Gently resuspend the pellet in DMEM-10 using 0.1% to 1% of the original volume.

Resuspension may take 2 hr if the pellet is fairly sticky. It is convenient to leave the centrifuge bottle in an ice bucket in the tissue culture hood and pipet the suspension approximately every 15 min. A 1- or 2-ml pipet can be used if large volumes were concentrated. If so, leave the original pipet in the bucket and use this pipet for the complete resuspension. This is because the virus pellet often sticks to the first pipet that touches it. Sometimes the pellet can be seen as an almost translucent, gooey yellow pellet. If the JA-14 rotor was used, be sure to wash down the sides of the bottle, as this is where much of the stock will be located. To resuspend pellets made in the SW-27 or SW-41 rotors, use a pipettor suitable for small volumes. In either case, avoid making bubbles, as this can denature the viral proteins.

Alternatively, an easier way to resuspend pellets made in the swinging-bucket rotors is to pour off almost all of the supernatant, e.g., leaving only 0.10 to 0.15 ml in an SW-27 large bucket; this may require keeping a Pasteur pipet handy to remove the last few drips of supernatant from the mouth of the tube as one pours it off. Return the tube to the bucket and replace the bucket cap. Place the buckets on a shaker at low speed in a 4°C cold room, or place them in an ice bucket and slowly shake 1 to 2 hr on the benchtop. After shaking, gently pipet up and down several times and transfer to a smaller tube.

Titer and freeze concentrated virus

9. Store the virus at -70° or -80°C in small aliquots (typically 5 to 50 µl).

Systematic tests in our laboratory have indicated that, in general, stocks can be frozen and thawed several times with no loss of titer. However, we have occasionally observed loss of titer over time in the freezer, or upon freeze-thaw. Thus, the most conservative approach is to make small aliquots and to minimize the number of times they are thawed and refrozen.

We have also found that small volumes can desiccate over long-term storage. To combat this, we place a drop of the oil used to cover PCR reactions onto each small aliquot before freezing.

10. Titer an aliquot of concentrated and unconcentrated virus as described in UNIT 9.10.

The titer can also be determined using an aliquot before freezing the stock.

CONCENTRATION BY PEG PRECIPITATION AND CHROMATOGRAPHY

A method that is rapid and easy is to precipitate virus with polyethylene glycol, with an optional step of chromatography on Sepharose (Aboud et al., 1982).

Additional Materials

- 5 M NaCl, filter sterilized
- Polyethylene glycol (PEG) 6000, filter sterilized
- NTE buffer (see recipe)
- Sepharose CL-4B or CL-2B (Pharmacia)
- Savant high-speed centrifuge *or* Beckman SW-41Ti rotor
- Additional equipment for preparation of Sepharose column (UNIT 5.6)

Precipitate virus with PEG

1. Prepare a virus stock (see Basic Protocol, steps 1 to 4)
2. Add 5 M NaCl to the virus stock to 0.4 M final while stirring at 4°C.

ALTERNATE PROTOCOL 1

Introduction of DNA into Mammalian Cells

9.12.3

3. Slowly add PEG 6000 to 8.5% final (w/v) and continue stirring 1 to 1.5 hr at 4°C.

For reasons that are not clear, some batches of PEG do not work well as they lead to problems in resuspending the pellet.

4. Collect the precipitate by centrifuging 10 min at 7000 × g (e.g., at 7500 rpm in a SW-41Ti rotor or 10,000 rpm in a Savant high-speed centrifuge.)
5. Dissolve the pellet in NTE buffer in 1% of the original volume. If necessary, proceed to step 6 for column chromatography.

The stock can be used directly after this step or stored at -70° or -80°C. It can also be further purified on a Sepharose CL-4B column to remove PEG.

Carry out Sepharose chromatography

6. Prepare a column of Sepharose CL-4B or CL-2B as described in UNIT 5.6 (Support Protocol), equilibrating in NTE buffer.

Column size will depend upon the amount of virus pellet; 10-ml Econo-Columns from Bio-Rad work well for pellets prepared from 100 ml of virus stock.

7. Apply the virus to the top and chromatograph at 1 ml/min with NTE buffer.
8. Collect 0.3- to 0.5-ml fractions.
9. Assay fractions for virus by measuring absorbance at 280 or 260 nm (see Aboud et al., 1982) or by reverse transcriptase (RT) assay (UNIT 9.13).
10. Pool appropriate fractions and titer as in UNIT 9.10.

For examples of virus recovery as determined by both Xgal CFU bioassay and RT assay, see Figure 9.12.1.

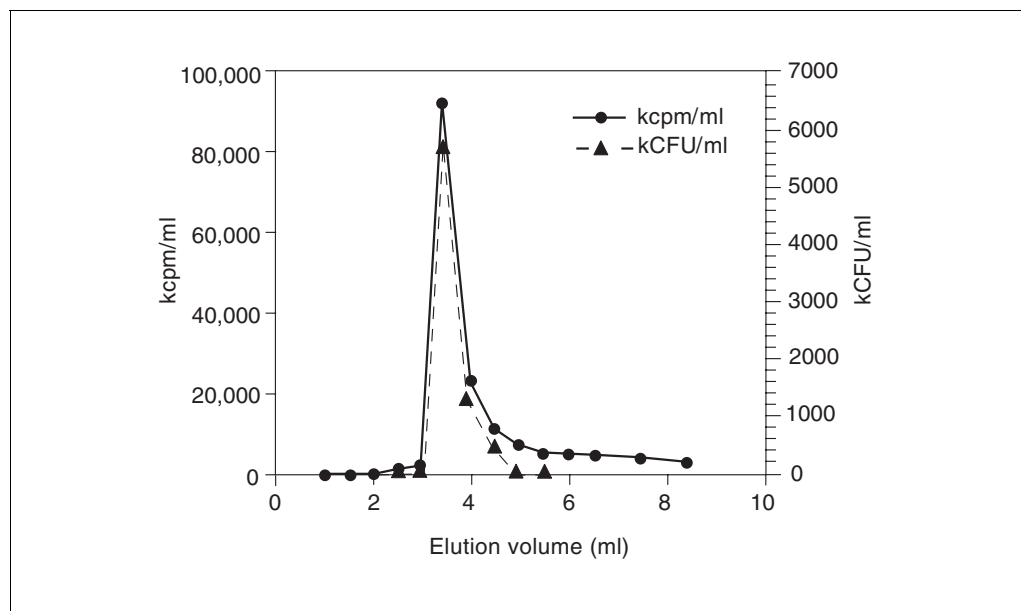

Figure 9.12.1 Ψ2 BAG supernatant (8 ml) was concentrated 100-fold by PEG precipitation. The resulting 80 μl was loaded onto 10 ml of Sepharose CL-2B in a Bio-Rad Econo-Column. Fractions of 0.5 ml were collected and tested for both reverse transcriptase activity and Xgal CFU.

CONCENTRATION USING MOLECULAR-WEIGHT-CUTOFF FILTERS

This method is the simplest means of concentrating small to medium volumes of retrovirus stocks. Supernatants prepared as in steps 1 to 4 of the Basic Protocol are centrifuged through filters, either the Centricon-30 microconcentrator from Amicon or the CentriCell 60 from Polysciences, essentially following the manufacturers' instructions. These filters allow passage of molecules that are much smaller than the virus (e.g., Centricon-30 filters allow passage of molecules of <30 kDa). For example, supernatants can be centrifuged at $5000 \times g$ in a Sorvall SS-34 centrifuge (Stoker et al., 1990); the material that does not flow through the filter is removed and used as the concentrated stock. The amount of time that the stock is centrifuged is chosen according to the degree that one wishes to concentrate the stock. The longer the centrifugation, the more concentrated the stock.

NTE buffer

100 mM NaCl
10 mM Tris·Cl, pH 7.4 (APPENDIX 2)
1 mM EDTA
Filter sterilize

COMMENTARY

Troubleshooting

When resuspending the pellet that results from centrifugation alone or from PEG precipitation followed by centrifugation, complete dissolution may not be possible; there are some stocks that have small clumps remaining, even after much effort is spent in resuspending them. (The clumps are most likely composed of viral particles and perhaps cellular debris.) Do not overdo the pipetting, as the solution has a very high protein concentration and will degenerate into a foamy mess with inactivated virus. The virus is not very hardy and can lose infectivity rapidly if mishandled. If the resuspended pellet is very clumpy, spin out the clumps at a low speed (e.g., 1000 rpm for 5 min in a tabletop centrifuge, or 1 min in a microcentrifuge). Store the supernatant at -70° or -80°C and then continue to attempt resuspension of the remaining clumps in pellet if more recovery is necessary.

The PEG protocol can work well with murine viruses; it has not been attempted with avian viruses in this laboratory. However, as indicated above, lots of PEG can apparently vary, causing problems in resuspension of the pellet. Changing the PEG lot and reducing the amount of serum in the virus stock may solve the resuspension problem. Producer cells can be grown in the usual 10% serum until they reach confluency, and then can be changed to reduced protein—either 2% serum or 10% NuSerum (Col-

laborative Biomedical Products) until the supernatant is harvested 2 to 3 days later.

If a concentrated virus is used to infect cells *in vitro*, a toxicity problem may be encountered, which is quite obvious within 12 hr of infection. Apparently, some cells fuse and form multinucleated syncytia when incubated with high concentrations of virions. This is probably due to virions causing membrane fusion between the plasma membranes of two or more cells, presumably via the virion, which has its own membrane and may fuse with the cellular membranes after binding to the viral receptor. To minimize this problem, it may be necessary to dilute the virus somewhat, reduce the time of cells' exposure to the inoculum, and/or plate the target cells such that very few are touching each other.

Anticipated Results

The recovery of virus using the centrifugation protocol is usually not 100%, although it may be this high on rare occasions. Usually, it is 10% to 30%. If the reduction in volume is $100\times$, and the recovery is 10%, then the titer increases $10\times$, which is useful for many experiments. If greater increases in titer are needed, when resuspending the pellet from the centrifugation protocol, use a volume for resuspension that is $\geq 200\times$ less than the original volume of the virus stock. One can also attempt to centrifuge the first concentrated stock and resuspend in $0.1\times$ the volume. However, the stock that

results is extremely viscous and clumpy and difficult to use for most experiments.

When the PEG protocol works (i.e., there is no problem in resuspending the pellet), it works easily and well, yielding highly infectious stocks of 100× concentration. This is a rapid method that can be easier than the centrifugation method. It can yield virus stocks that are less clumpy than the centrifugation method, especially when column chromatography is used.

Time Considerations

The pelleting/centrifugation protocol can be completed in 3 to 4 hr, including labeling tubes, aliquoting, etc. The PEG protocol, from the time of precipitating the stock to resuspending the pellet, takes ~2 hr. Column chromatography takes ~1 hr to set up and run the column.

Assaying column fractions can take 2 hr if using the RT assay, and 2 to 14 days if performing a bioassay such as Xgal or G418-R CFU determination.

Helper virus is a replication-competent virus that is sometimes present in stocks of replication-incompetent virus. There are several types of applications in which the presence of helper virus can be problematic. If animal infections are being done, helper virus can lead to leukemia, particularly if the infection is carried out pre- or neonatally. If retroviruses are being used for lineage analysis, helper virus may cause horizontal spread of the marker virus, creating false lineage relationships.

This unit describes protocols for the detection of helper virus by a selectable marker assay (see Basic Protocol), by rescue of an integrated provirus (see Alternate Protocol 1), or by measuring reverse transcriptase activity (see Alternate Protocol 2).

DETECTION OF HELPER VIRUS THROUGH HORIZONTAL SPREAD OF DRUG RESISTANCE

BASIC PROTOCOL

The following is a very sensitive method of examining the ability of a virus supernatant to promote the horizontal spread of a viral genome from an infected cell to neighboring nonsibling cells. Target cells, such as NIH 3T3 or CEF cells, are infected with the test virus stock, and after several generations of growth the supernatant is harvested. This supernatant is then assayed for the presence of virus carrying the marker of the initial stock—e.g., neomycin resistance (*neo*). The presence of virus that can transmit this marker indicates that the original stock contained helper virus. The assay is easy to perform for a variety of vectors and also allows the host range of the helper virus to be tested (see Background Information). The example below is for a murine virus. An alternative, equally sensitive assay to detect helper virus is rescue of an integrated provirus that expresses an easily assayable marker, such as lacZ (see Alternate Protocol 1).

For controls in this assay, a helper virus-free stock and a helper-containing stock are used. The former has usually been verified in previous experiments as helper-free. A helper-containing stock (wild-type or replication-competent) is usually obtained from a retrovirologist. Alternatively, a helper-containing stock can be made by obtaining a plasmid encoding a wild-type replication-competent provirus and transfecting it (UNIT 9.10) into NIH 3T3 cells (for murine virus) or CEF cells (for avian virus). After transfection, the cells are passaged for 1 to 2 weeks (with 2 µg/ml polybrene for the murine virus and avian subgroup E virus) to allow for spread. The supernatant is then harvested and stored at -70° or -80°C. Titration of a wild-type stock can be accomplished by the XC plaque assay for murine viruses (Rowe, 1970), by the RT assay (see Alternate Protocol 2), or by immunohistochemical staining of *gag* for avian viruses (Stoker and Bissell, 1987). If the RT assay is used, a stock of a known titer is needed for comparison.

Materials

NIH 3T3 cells (used only with murine viruses)

Three titered virus stocks: test virus containing *neo* marker, helper virus-free control containing *neo* marker (negative control), and wild-type helper virus
800 µg/ml polybrene, filter sterilized (stored at -20°C)

Complete DMEM containing 10% calf serum (DMEM-10, APPENDIX 3F; prepared with calf serum instead of FBS)

6-cm dishes

0.45-µm filter

Additional reagents and equipment for determination of viral titer (UNIT 9.10)

Introduction of DNA into Mammalian Cells

9.13.1

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly.

NOTE: All incubations involving tissue culture cells should be performed in a humidified 37°C, 5% CO₂ incubator unless otherwise noted.

1. The day before the assay is initiated, split NIH 3T3 cells 1:50 into three 6-cm dishes. Label one dish as a positive control, one dish as a negative control, and one dish for the stock to be tested.

A 1:50 split is used instead of the standard 1:10 or 1:20 split to allow time for the virus to spread before the cells become confluent. Viruses can only integrate into mitotic cells.

2. Prepare test virus stock: Add 0.01 ml of 800 µg/ml polybrene (8 µg/ml final) to 1 ml of test virus supernatant. Filter this solution through a 0.45-µm filter.

The test virus stock carries the neo or other selective marker.

If a concentrated virus stock is used (UNIT 9.12), 1 to 30 µl of the concentrated stock is diluted in 1 ml medium, and 0.01 ml polybrene (8 µg/ml final) is added. This solution is passed through a 0.45-µm filter immediately before use.

The volume of test virus to be used for the infection depends on the degree to which the stock must be scrutinized, although typically 1 ml of an unconcentrated stock is used.

3. Prepare a positive control stock: Prepare a mixture of 1 ml helper-free stock and 10 to 100 CFU of helper stock. Add 0.01 ml of 800 µg/ml polybrene (8 µg/ml final) and filter through a 0.45-µm filter.

The helper-free virus stock carries the neo or other selective marker. It is used for detection purposes. The helper stock is used to allow horizontal spread of the neo genome of the helper-free stock.

The volumes of helper-free and helper stocks to be used depends on the titers of these stocks and the titer of the test stock. The amount (CFU) of helper-free virus should equal the amount (CFU) of the test virus. Only a small amount (10 to 100 CFU) of helper virus is required so that one can monitor the sensitivity of the assay for small amounts of helper-virus contamination.

4. Prepare a negative control stock: Prepare 1 ml of helper-free stock alone by adding 0.01 ml of 800 µg/ml polybrene (8 µg/ml final) and filtering through a 0.45-µm filter.

5. Infect one dish (step 1) with each virus stock.

6. Place all three infected dishes 1 to 3 hr in a CO₂ incubator at 37°C to permit absorption. Add 4 ml DMEM-10 and continue incubation until cells reach confluency (~3 to 4 days).

Polybrene concentration must be maintained at 2 µg/ml for the length of the assay to allow spread of both helper and marker-containing viruses.

7. Split cells 1:50 into new 6-cm dishes. Set up only one new dish for each of the three dishes, and discard the unused portion of originally infected cells. Include polybrene at 2 µg/ml (final). Incubate until cells reach 50 to 90% confluency.

Although not necessary, it is advisable to save some of the initial supernatants (e.g., remove ~2 ml supernatant and store at -80°C) prior to splitting in this step. If there is a helper virus present, the relative titers of these initial supernatants and the final supernatants (step 9) may be informative concerning the amount of helper present in the stock.

8. Discard medium and replace with half the volume of fresh DMEM-10. Incubate an additional 2 to 3 days.

At this point, the supernatant of the dish inoculated with the test virus stock will contain virus only if the original test stock contained helper virus.

9. Harvest the final supernatant from the confluent cells, filter through a 0.45- μ m filter, and add polybrene to 8 μ g/ml final. Store at -70° or -80° C or use immediately to titer and assay the virus for G418 resistance (*neo* marker).
10. Split fresh, uninfected NIH 3T3 cells 1:10 or 1:20 into three 6-cm dishes the day before titering the supernatants.
11. Use 1 ml of each supernatant (from step 9) to infect NIH 3T3 cells and carry out the remaining titration steps as described in *UNIT 9.10* (Basic Protocol 2, steps 1 to 6).

If the test stock is an avian replication-incompetent virus stock, use CEF cells instead of NIH 3T3 cells. In steps 1 and 7 split them 1:10 (they do not grow well if split more dilute than 1:10). The helper-free and helper-containing negative and positive control stocks must also be avian. Polybrene is required for avian viruses of subgroups other than A. Make sure that the CEF cells are from a strain that can support infection with the subgroup under study (Morgan and Fekete, 1996).

PROVIRAL RESCUE TO DETECT REPLICATION-COMPETENT RETROVIRUS

ALTERNATE PROTOCOL 1

This alternate protocol describes another assay, equal in sensitivity to the drug resistance assay presented in the Basic Protocol, for examining the ability of a virus supernatant to promote the horizontal spread of a viral genome from an infected cell to neighboring nonsibling cells. This assay uses rescue of an integrated provirus containing a marker gene to detect the presence of replication-competent retrovirus. In the example below, an indicator cell line that contains a single integrated copy per cell of a retroviral vector expressing β -galactosidase (*lacZ*) is infected with a retroviral stock. If the stock contains the retroviral packaging genes, the integrated provirus will be packaged and it will thereby be possible to transfer this genome to sibling cells. The presence of helper virus can be easily detected by assaying for *lacZ* activity by histochemical staining (*UNIT 9.10*). In order to obtain sufficient retroviral titers to detect the rescued virus, it is necessary to passage the secondarily infected cells for several weeks in the presence of polybrene. In this example, the *lacZ*-bearing indicator provirus is integrated into NIH 3T3 cells, and thus only retroviruses capable of infecting these cells can be assayed for helper activity. Similar indicator cells can be constructed for retroviruses with other host ranges by using cell lines appropriate for this host range and selecting a clone that contains only a single integrated provirus.

Additional Materials (also see *Basic Protocol*)

BAG-3T3 indicator cells: NIH 3T3 cells containing a single copy per cell of an integrated BAG provirus (Fig. 9.10.2)

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly.

NOTE: All incubations involving tissue culture cells should be performed in a humidified 37°C, 5% CO₂ incubator unless otherwise noted.

1. The day before the assay is initiated, split BAG-3T3 cells 1:50 into three 6-cm dishes. Label one dish as a positive control, one dish as a negative control, and one dish for the stock to be tested.

A 1:50 split is used instead of the standard 1:10 or 1:20 split to allow time for the virus to spread before the cells become confluent. Viruses can only integrate into mitotic cells.

2. **Prepare test virus stock:** Add 0.01 ml of 800 µg/ml polybrene (8 µg/ml final) to 1 ml of test virus supernatant. Filter this solution through a 0.45-µm filter.

Unlike in the Basic Protocol, the test virus stock does not need to carry a selectable marker.

If a concentrated virus stock is used (UNIT 9.12), 1 to 30 µl of the concentrated stock is diluted in 1 ml medium, and 0.01 ml polybrene (8 µg/ml final) is added. This solution is passed through a 0.45-µm filter immediately before use.

The volume of test virus to be used for the infection depends on the degree to which the stock must be scrutinized, although typically 1 ml of an unconcentrated stock is used.

3. **Prepare a positive control stock:** Prepare a stock that contains 10 to 100 CFU of helper virus in 1 ml. Add 0.01 ml of 800 µg/ml polybrene (8 µg/ml final) and filter through a 0.45-µm filter.

The helper stock is used to allow horizontal spread of the integrated lacZ-expressing provirus. It may be desirable to assay several dilutions of the helper stock to determine the sensitivity of the marker rescue assay.

4. **Prepare a negative control stock:** Prepare 1 ml of helper-free stock alone by adding 0.01 ml of 800 µg/ml polybrene (8 µg/ml final) and filtering through a 0.45-µm filter.

5. Infect one dish (step 1) with each virus stock.

6. Place all three infected dishes 1 to 3 hr in a CO₂ incubator at 37°C to permit absorption. Add 4 ml DMEM-10 and continue incubation until cells reach confluency (~3 to 4 days).

Polybrene concentration must be maintained at 2 µg/ml for the length of the assay to allow spread of both helper and marker-containing viruses.

7. Split cells 1:50 into fresh 6-cm dishes. Set up only one new dish for each of the three dishes, and discard the unused portion of originally infected cells. Include polybrene at 2 µg/ml final. Incubate until cells reach 50% to 90% confluency.

Although not necessary, it is advisable to save some of the initial supernatants (e.g., remove ~2 ml supernatant and store at -80°C) prior to splitting in this step. If there is a helper virus present, the relative titers of these initial supernatants and the final supernatants (step 9) may be informative concerning the amount of helper present in the stock.

8. Discard medium and replace with ½ vol fresh DMEM-10. Incubate an additional 2 to 3 days.

At this point, the supernatant of the dish inoculated with the test virus stock will contain virus only if the original test stock contained helper virus.

It may be necessary to maintain the cells for 1 to 2 additional passages (i.e., repeat step 7) in order to detect helper virus.

9. Harvest the final supernatant from the confluent cells, filter through a 0.45- μm filter, and add polybrene to 8 $\mu\text{g}/\text{ml}$ final. Store at -70° or -80°C or use immediately to titer and assay the virus for β -galactosidase (*UNIT 9.10*, Support Protocol 2).
10. Split fresh, uninfected NIH 3T3 cells 1:10 or 1:20 into three 6-cm dishes the day before titering the supernatants.
11. Use 1 ml of each supernatant (from step 9) to infect NIH 3T3 cells and carry out the remaining titration steps as described in *UNIT 9.10* (Basic Protocol 2, steps 1 to 6).

REVERSE TRANSCRIPTASE ASSAY TO DETECT HELPER VIRUS

Virus supernatants generated in the Basic Protocol (step 9) can be monitored for the incorporation of radioactive dTTP. This serves as an assay for reverse transcriptase activity that will only be observed when helper virus is in the original stock. This assay also can be used for other purposes—e.g., to test packaging lines for maintenance of virus production.

Additional Materials (also see *Basic Protocol*)

- Reverse transcriptase (RT) reaction cocktail (see recipe)
- Virus supernatants: test and control samples (see Basic Protocol, step 9)
- 2 \times SSC (*APPENDIX 2*)
- 95% ethanol
- 96-well microtiter dish
- Whatman DE52 or DE81 paper, precut to 2.5-cm circles or sheets cut to accommodate the number of samples

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly.

NOTE: All incubations involving tissue culture cells should be performed in a humidified 37 $^\circ\text{C}$, 5% CO_2 incubator unless otherwise noted.

1. Add 50 μl RT reaction cocktail to separate wells of a 96-well microtiter dish. Set up one well for each test or control sample.
2. Add 10 μl of each virus supernatant to its designated well.
3. Cover microtiter dish and place 1 to 2 hr in a CO_2 incubator at 37 $^\circ\text{C}$.
4. Spot 10 μl of each reaction onto a 2.5-cm circle of DE52 or DE81 paper, set up on a piece of plastic wrap. Label the paper with a soft (no. 2) lead pencil.

Samples can also be spotted on a large sheet of paper, which is then cut into individual sample pieces after the washing process.

5. Place paper in a tray and cover with 2 \times SSC. Wash 20 min with gentle shaking on a shaker at room temperature. Discard SSC and repeat wash step twice.
6. Soak 1 min in 95% ethanol.
7. Air dry \sim 10 min.
8. Count in scintillation counter or expose to film.

The higher the level of helper virus the more virions in the supernatant—and thus the higher the level of reverse transcriptase activity (see Background Information).

**ALTERNATE
PROTOCOL 2**

**Introduction
of DNA into
Mammalian Cells**

9.13.5

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Reverse transcriptase (RT) reaction cocktail

Prepare an appropriate quantity of RT reaction cocktail as indicated by Table 9.13.1.

Table 9.13.1 Preparation of RT Reaction Cocktail

Reagent ^a	Number of assays			
	20	40	80	100
1 M Tris·Cl, pH 8.3, μ l	50	100	200	250
0.2 M DTT, μ l	100	200	400	500
0.02 M MnCl ₂ , μ l	30	60	120	150
3 M NaCl, μ l	20	40	80	100
100 μ g/ml oligo(dT), μ l	50	100	200	250
100 μ g/ml poly(rA), μ l	100	200	400	500
0.2 mM dTTP, μ l	50	100	200	250
1% NP-40, μ l	50	100	200	250
[α - ³² P]dTTP, μ Ci ^b	100	200	400	500
Final volume (add dH ₂ O), ml	1	2	4	5

^aCocktail components are for assay of murine RT (from Goff et al., 1981). For avian RT, substitute 1% 2-mercaptoethanol (final) for DTT; 10 mM MgCl₂ (final) for MnCl₂; and 100 μ M dTTP (final) for 10 μ M dTTP (Omer and Faras, 1982).

^bSpecific activity >500 Ci/mmol. Because volume will vary with different lots, the volume of distilled H₂O to add should be varied to compensate.

COMMENTARY

Background Information

The production of wild-type, replication-competent helper virus by packaging cell lines can be an issue of concern when using replication-incompetent vectors. If the vectors are being used for lineage analysis, the virus stock must be free of helper virus. Similarly, for most infections of young animals, where the wild-type viruses are leukemogenic, helper viruses must not be present.

The genome that supplies the *gag*, *pol*, and *env* genes in the Ψ 2, Ψ am, PA12, PA317, and Q2bn packaging cell lines (UNIT 9.9) does not encode the Ψ sequence, but can still become packaged—although at a low frequency. If the helper genome is coencapsidated with the vector genome, recombination in the next cycle of reverse transcription can occur. If recombination allows the helper genome to acquire the Ψ sequence from the vector genome, a recombinant that is capable of autonomous replication will result. This recombinant can spread through an entire culture (although slowly due to envelope

interference). Once this occurs, it is best to discard the producer clone, as there is no convenient way to eliminate the wild-type virus.

As would be expected, helper virus contamination happens with a greater frequency in stocks with high titer. The PA317 packaging line has a safer design than Ψ 2, Ψ am, PA12, and Q2bn, while the Ψ CRE, GP + E-86, Ω E, Ψ CRIP, and Isolde lines probably have the best design for not producing helper virus. Recombination leading to helper virus creation has not yet been observed in Ψ CRE, GP + E-86, Ω E, Ψ CRIP, or Isolde, but one must be cautious and assay stocks produced by these lines (for a review of lines, see Table 9.9.1).

These protocols can also be used to determine the host range of the helper virus. This can be tested by infection of cells of different species [e.g., dog (D17) or human (HeLa) cells cannot be infected with ecotropic virus, only with amphotropic virus].

Alternative methods to detect helper virus include the XC plaque assay (Rowe et al.,

1970) and S+L⁻ assay (Eckner and Hettrick, 1977; Miller and Buttimore, 1986). These assays require additional cell lines. The assay listed here for horizontal spread is quite sensitive but very time-consuming. The RT assay is sensitive, but does not always detect crippled helper (virus that can replicate, but is mutant and does not replicate as well as wild-type).

Troubleshooting

If supernatants are assayed by titration of selectable markers and many (e.g., greater than several thousand) marker-resistant colonies are observed, the original test stock contained wild-type helper virus. Once this occurs, it is best to discard the producer clone, as there is no convenient way to eliminate the helper virus. If a smaller number of colonies result than expected (see Anticipated Results), there are several possible explanations. There may be “crippled” helper in the original test stock generated by an imperfect recombination event. For many applications, crippled helper is not a confounding influence. Alternatively, some of the Ψ^- genome (e.g., the genome carrying *gag*, *pol*, and *env*) can transfer to the first set of infected NIH 3T3 cells and lead to a low titer, without true helper virus contamination (e.g., see Danos and Mulligan, 1988).

Anticipated Results

Virus stock that contains wild-type helper virus should produce more than several thousand colonies carrying the *neo* marker (G418-resistant) colonies on the assay dishes generated by step 9 of the Basic Protocol or several thousand *lacZ*⁺ colonies generated by step 11 of Alternate Protocol 1. If the reverse transcriptase assay is used, the RT activity from the test supernatants should be compared to that in the control supernatants (cells infected with a known helper-free virus stock, and cells infected with a stock of known wild-type helper virus). Stocks contaminated with helper virus should show a >1000-fold enhancement of RT activity when compared to helper-free controls. A truly helper-free stock will be equal in RT activity to that generated by the helper-free control.

Time Considerations

Virus supernatant generation (Basic Protocol) requires 10 days. To titer the stocks for presence of viruses carrying the selectable marker or *lacZ*, another 10 to 13 days are needed (see UNIT 9.11). To test supernatants for reverse transcriptase activity (Alternate Protocol 2), 50 samples can be processed in 2 to 3 hr.

Retrovirus Infection of Cells In Vitro and In Vivo

UNIT 9.14

There are many applications in which retrovirus vectors are used as transduction agents. In some cases, the vector carries a gene that one wishes to express in a target cell in order to study the function of that gene. In other cases, the virus is used to introduce a histochemical marker gene into cells in order to follow their fate. Retrovirus vectors can also be used in a variety of cells type to investigate regulatory sequences in which a reporter gene and regulatory sequences are carried by the vector and to immortalize or transform primary cells by transduction of oncogenes.

For each application, the infection protocol may vary and must often be optimized. Guidelines for infection of cells in some typical *in vivo* and *in vitro* experiments are presented here. In addition to these guidelines, the cited literature contains protocols that have been used successfully to infect cells under specific circumstances and may provide a good starting point for similar cells. To optimize infection of a particular type of cell, it is often advantageous to use vectors that are easy to score. These include vectors carrying selectable or screenable markers (such as BAG; Figs. 9.10.1 and 9.10.2).

CAUTION: When working with human blood, cells, or infecting agents, strict biosafety practices must be followed (see UNIT 16.15).

INFECTION OF CELLS IN VITRO

Infection of target cells *in vitro* is accomplished by simply incubating the virus with the cells (e.g., UNIT 9.10, Basic Protocol 2). For most *in vitro* applications using a murine virus, a polycation such as polybrene is used to aid viral infection. These polycations apparently promote virus binding to the host cell surface by reducing electrostatic repulsion between the negatively charged surfaces of the cell and virion. When incubating target cells with virus *in vitro*, problems may occur if undiluted, high-titer virus is used directly on some cell types—i.e., fusion of target cells can occur with subsequent death of most fused cells within a few days. This is presumably due to the virus serving as a fusogen (i.e., binding to the surface of more than one cell and promoting membrane fusion).

Alternatively, cells to be infected *in vitro* can be incubated with the packaging line that produces the desired vector (cocultivation

method). This method is used to infect hematopoietic cells and appears to greatly increase the infection efficiency (Williams et al., 1984; Lemischka et al., 1986). In some cases, it may be desirable to prevent cell division of the producer cells during or after cocultivation. This can be achieved by using protocols that allow virus production, but that prevent further cell division of the producer cells. For example, prior to cocultivation, confluent or nearly confluent producer cells can be killed by irradiation (2800 rad for NIH 3T3 cells, 1500 rad for 293 cells) or a 3-hr treatment with mitomycin C (10 μ g/ml in medium) followed by several rinses with medium. After this treatment, the cells to be infected are plated onto producer cells. Target cells should continue to grow, but producer cells will die as they can no longer divide. If the target cells are nonadherent, they can be removed by simply washing the producer monolayer gently after ~48 hr of cocultivation. An alternative to cocultivation is spin infection (UNIT 9.11; Kotani et al., 1994), which achieves similar infectious titers without the difficulties caused by the presence of producer cells.

It is difficult to generalize about the efficiency of infection, although it can approach 100%. For the most part, the variables that influence infectability of a given cell are unknown. However, it is clear that for optimal results, the cells should be as mitotically active as possible. Although virus will enter cells and undergo partial reverse transcription in nonmitotic cells, there will be no integration or expression of the viral genes. If virus is applied to cells that are not dividing, it may remain competent to finish reverse transcription and integration for 1 to 2 days, although this has not been carefully determined for most cell types. One approach that may overcome the difficulties in transducing non-dividing cells is the use of retroviral packaging cell lines and vectors based on human immunodeficiency virus (HIV; Naldini et al., 1996). This approach has successfully produced high-titer, helper-free viruses that are able to infect cell lines arrested at various phases of the cell cycle at frequencies that far exceed those attainable using Moloney-based packaging systems. In addition, these vectors are able to infect adult rat neurons at low frequency.

Expression of viral gene products is usually

**Introduction
of DNA into
Mammalian Cells**

9.14.1

assayed two or three cell cycles after infection. When assaying *lacZ* expression in NIH 3T3 cells via Xgal staining (UNIT 9.10), we have found that the number of clones peaks at ~48 hr postinfection (three cell cycles). However, Xgal staining is visible within 24 hr in a subset of the infected cells.

Infections of tissue explants or cultured embryos can also be performed essentially as described above. A tissue explant can be bathed in as much virus stock as is desired for a few hours (when using murine viruses or avian viruses of any subgroup other than A, include polybrene at 8 µg/ml), or it can be cultured over a monolayer of producer cells (as above in the cocultivation method).

Creation of Retroviral cDNA Libraries

Expression cloning has been extremely useful for isolating a wide variety of genes, including cell surface markers, cytokines, and multiple receptors (see UNIT 6.11). This methodology relies on high levels of gene expression in the transfected cell line and the ability to recover the appropriate cDNA by plasmid rescue. To accomplish the former, COS cells are frequently used for expression cloning, as the expression of SV40 large T antigen causes high levels of protein expression from vectors that contain the SV40 origin of replication.

Although expression cloning in COS cells has been extremely useful for the expression cloning of a number of cDNAs, this approach is limited to cell lines that are efficiently transfected and to phenotypic assays with a short readout period. These limitations have made it difficult to use expression cloning strategies in primary hematopoietic cells due to their poor transfectability and the long-term culture required for phenotypic selection. In contrast to expression cloning in COS cells, retroviral cDNA libraries offer the possibility of introducing cDNAs into a wide variety of cell types, including primary cells. As a result, it is possible to devise novel assays to select cDNAs that are based on specific properties of the cells themselves, such as transformation, growth factor dependence, or in vitro differentiation.

Retroviral expression cloning has been successfully used to clone cDNAs using NIH 3T3-based packaging lines. These strategies have been useful for identifying genes involved in factor-dependent growth (Rayner and Gonda, 1994; Wong et al., 1994) and transformation (Whitehead et al., 1995), as well as for the selection of peptides and antisense messages that induce etoposide resistance (Gudkov et al.,

1993, 1994). Although overcoming some of the limitations of COS-based expression cloning, use of NIH 3T3-based packaging lines has two major disadvantages for expression cloning. These are that (1) it is difficult to obtain high titers by transient transfection, limiting the complexity of the library, and (2) the frequency of each cDNA may change during selection of the transfected population and the resulting retroviral stock may not represent the original cDNA library. An advance in the ability to prepare cDNA expression libraries has been the methodology to prepare high titer retroviral supernatants by transient transfection (UNIT 9.11; reviewed in Onishi et al., 1996). These approaches overcome the major disadvantages of the NIH 3T3-based packaging cells—i.e., it is possible to obtain high transient transfection efficiencies and it is unnecessary to select the cells prior to harvest of the retroviral stock. An application of the use of transient retroviral production for expression cloning has been described for cloning cDNAs from factor-dependent cell lines (Kitamura et al., 1995). In this report, the authors were able to develop expression libraries with complexities of $>10^6$ and detect cDNAs at a frequency of 1 in 10^7 (Kitamura et al., 1995).

The technology for retroviral expression cloning is presently evolving, and the reader should consult the most recent literature for the best choice of packaging cell line and retroviral vector. With the methods for transient retroviral production, the basic strategy is to clone a cDNA library into a retroviral vector, transfect the library into the packaging cells, harvest the retroviral stock between 48 and 72 hr post-transfection, and infect the target cells. These methods are described in UNIT 9.11. The target cells are subsequently assayed for the phenotype of interest. Some considerations in the choice of retroviral vectors are the presence of multiple cloning sites for efficient cloning of the cDNAs into the vector, the presence of the extended packaging signal for improved titer (Bender et al., 1987), the use of IRES (internal ribosome entry site) elements rather than internal promoters to increase the likelihood that the cloned cDNA will be expressed, and the presence of primers that surround the multiple cloning site so that the cDNA can be amplified by PCR following phenotypic selection. Another consideration is the infection efficiency of the target cells. For example, in the studies of Onishi et al. (1996), the authors were able to infect Ba/F3 and BW5147 cells with $>50\%$ efficiency but infection of LG3 myeloid cells

resulted in an infection efficiency of only 8.3%. To obtain adequate infection efficiencies, it may be necessary to pseudotype the retroviruses (UNIT 9.11) or introduce a retroviral receptor into the cell line to be assayed (UNIT 9.9). One drawback to high infection efficiencies, however, is that with higher infection efficiency, the infected cells are more likely to contain multiple integrated proviruses (Onishi et al., 1996). This may increase the difficulty in identifying the cDNA that confers the phenotype of interest. Another consideration in the generation of retroviral cDNA libraries is whether the library should be normalized prior to screening. An advantage of normalization is that there will be an “enrichment” of rare messages; however, the cost is that the resulting cDNA library is no longer representative of initial population of cDNAs.

INFECTION OF RODENTS AND CHICKS IN VIVO

Transduction of genes via retrovirus vectors can be performed *in vivo*. The following paragraphs describe *in vivo* infection of rodents, the laboratory animal most often used in experimental procedures; however, the techniques apply to other species (e.g., avian) as well. For more detailed information on infection of chick embryos, see Fekete and Cepko (1993a,b), Homburger and Fekete (1996), and Morgan and Fekete (1996).

NOTE: Detailed protocols for the care and handling of laboratory animals are beyond the scope of this unit. The reader is referred to *Current Protocols in Immunology*, Chapter 1 (Donovan and Brown, 1995) for instructions on proper animal restraint, anesthesia, injections, and euthanasia techniques that are essential to the infection methods described.

Infection of Postnatal Animals In Situ

Volume and titer of virus stock. The volume that can safely be delivered to a tissue *in vivo* is generally quite small—0.1 to 1 μ l. It is therefore important to prepare high-titer (usually concentrated) virus stock (UNIT 9.12). In general, virus titer should range from 10^6 to 10^8 CFU/ml. Because of these limitations, it is quite important to deliver the virus directly to the area containing the highest percentage of mitotic target cells. It is unclear if there are factors in tissue fluids (e.g., ventricular fluids or cerebral spinal fluids) that inhibit or destroy viral infectivity.

Delivery of virus. Virus delivery to postnatal animals is fairly straightforward. It is possible

to use a hand-held Hamilton syringe with a 33-G needle or use a drawn-out glass pipet. If glass pipets are used, the size of the needle tip should be determined empirically for the tissue under study. The skin, and even the skull, are soft enough on the first few days after birth for direct injection into the tissue. For tougher injection sites on older animals, it may be necessary to first make a hole using a stronger needle, such as one made of steel, prior to inserting a more delicate needle at a specific site. Coinjection with a dye such as 0.05% (w/v) trypan blue or 0.025% fast green aids in detecting the accuracy of injections and does not impair viral infectivity. Rodents ≤ 7 days old can be anesthetized by simply cooling on ice for a few minutes. Landmarks (e.g., sutures or blood vessels) near the area to be injected can be visualized using a fiber-optics light source. The injection is made directly into the desired area using a hand-held pipet. It is best to practice a series of injections with dye alone and then immediately dissect the animal for examination of the injection site. After the injection method is perfected, virus can be injected. Animals can then be examined for evidence of viral infection at any time, depending upon the experimental design.

Setup of pilot experiments to optimize injection and expression efficiency. When performing infections of tissue for the first time, or when infection and expression efficiency of the target cells is unknown, it is useful to perform pilot experiments using a retrovirus vector carrying a histochemical marker gene such as *lacZ*. Infection with a *lacZ*-coding virus allows for examination of the injected animal a few days after infection to determine if the target cells have been infected and are capable of expressing the viral genes. For such experiments, it is necessary to optimize conditions of the Xgal staining reaction (UNIT 9.10) for the particular tissue under study.

An excellent way to simultaneously determine the accuracy of injection, and whether the Xgal histochemistry is working, is to inject cells that contain the *lacZ* gene, such as the $\Psi 2$ BAG producer cells (obtainable from ATCC, #CRL 9560; UNIT 9.10). The cells can be pre-labeled with a fluorescent dye such as carboxy-fluorescein diacetate succinimyl ester (CFSE, Molecular Probes; prepare 10 mM stock in DMSO and store in foil at 4°C). As detailed by Bronner-Fraser (1985), cells suspended in PBS are exposed to 0.3 mM CFSE solution at 37°C for 30 min just before trypsin treatment. After dissociation, the cells are pelleted and washed

twice with medium or PBS, and resuspended to a concentration of 10^8 cells/ml. A few minutes after injection of the CFSE-labeled cells, the animal should be killed, the tissue fixed, then stained with Xgal (UNIT 9.10). The injected cells can then be monitored independently from the Xgal staining by viewing the CFSE fluorescence under UV illumination. If the Xgal histochemistry is working properly, no fluorescent cells should be visible because Xgal-stained cells are usually so full of indigo dye that all fluorescence is absorbed. Once the injection method and Xgal histochemistry have been optimized, BAG virus is injected into the site and the tissue is examined for viral infection several days later.

If the Xgal histochemistry is *not* working well, fluorescent cells will be visible, indicating the site of the injection and the failure of the Xgal histochemistry. In this case, one should vary fixation and tissue preparation methods until good Xgal staining is achieved (Cepko, 1989). Alternatively, the DAP retrovirus vector (Fields-Berry et al., 1992) encoding human placental alkaline phosphatase can be used. A stable $\Psi 2$ line that makes DAP at titers of $1-2 \times 10^6$ CFU/ml (more reliably than $\Psi 2$ BAG) can be obtained from ATCC (CRL #1949). Histochemical detection of the alkaline phosphatase enzyme is as simple as Xgal histochemistry (Fields-Berry et al., 1992). For further discussion of both Xgal and alkaline phosphatase assays, see Cepko et al. (in press).

Infection of Prenatal Rodents In Utero

Injections made in utero (through uterine wall) are performed with drawn-out glass pipets (e.g., see Austin and Cepko, 1990). The actual diameter and shape of the tip should be determined empirically (e.g., for injections of the lateral ventricle through the uterine wall of rats at embryonic day 15—E15—the outside diameter of the tip is ~ 50 μm and the inside diameter is ~ 15 μm). Animals are anesthetized with a mixture of ketamine (20 to 40 mg/kg) and xylazine (3 to 5 mg/kg) and are opened via an incision along the midline. The orientation of an embryo can be determined by visualizing the head with fiber optics. Injections of 0.1 to 1.0 μl are made through the uterine wall into the area of interest. When the target of the injection is the lateral ventricle, the inoculum can be seen filling the lateral ventricle when properly delivered to this area. Other areas may not be as visible and practice injections followed by immediate dissection and examination are again recommended. The mother is

then closed with suture. The injected animals can be delivered prenatally, or allowed to finish gestation and be born normally, to be sacrificed at a postnatal age, depending upon the design of the experiment.

Infection of Prenatal Rodents Exo Utero

It is difficult to make precisely directed injections into many of the mitotic zones of prenatal mammals through the uterine wall. The exo utero surgical procedure developed by Muneoka et al. (1986) at least partially circumvents this problem. In this procedure, mouse embryos at embryonic days 11 to 19 (E11 to E19) are released from the uterus by cutting the uterine wall, but remain attached to the uterus via the placenta. The abdominal cavity of the mother is filled with a buffered saline solution to protect the embryos. An incision can be made in the extra-embryonic membranes that surround the embryo so that embryo can be directly manipulated or injected. Subsequently, the extra-embryonic membranes are closed with fine sutures. The embryos can be brought to term in the abdominal cavity and delivered by Caesarean section.

Injections can be made through an incision in the extra-embryonic membranes that are subsequently closed with 10-0 suture. However, in our hands (Turner et al., 1990), embryonic and neonatal survival was improved by injecting directly through the extra-embryonic membranes without an incision or suture. Although injections made by this approach were more difficult to target, 25% of the embryos injected at E13 survived to adulthood and all injected animals contained clones of retrovirally infected cells. Additional factors that influence the success of this method are choice of mouse strain and health of the mouse colony. Outbred mouse strains such as CD-1 or Swiss Webster appear to be best, but even these strains may have different embryo survival rates when obtained from different suppliers or colonies. Apparently healthy mouse colonies can harbor subclinical infections that do not affect unoperated embryos but that can stress operated embryos beyond their ability to survive.

Ex Vivo Infection of Murine Bone Marrow Cells and Bone Marrow Transplant

Ex vivo retroviral infection of murine bone marrow has been used for in vitro experiments as well as for subsequent transfer and rescue of

lethally irradiated animals. The goal of many of these experiments is to transduce hematopoietic stem cells; however, the methods discussed below can be altered to optimize infection of a particular hematopoietic cell type. As discussed below, the conditions for infecting hematopoietic stem cells are still being developed, and the reader should consult the most recent literature to ascertain the best conditions. Optimal conditions for irradiating mice need to be established for each irradiator and are also dependent on weight, age, and mouse strain.

Donor mice (age 5 to 8 weeks) are treated with 250 μg per gram (mouse weight) 5-fluorouracil (5-FU) by tail vein injection in a volume of $\leq 200 \mu\text{l}$. 5-FU treatment kills dividing cells, and in doing so, enriches for hematopoietic progenitor cells (van Zandt, 1984; Bodine et al., 1991). Five days later, donor mice are sacrificed and the tibia and fibias are removed. These bones are flushed with 2 to 3 ml per bone of PBS or DMEM using a 25- to 27-G needle attached to a syringe. The flushed marrow cells (including red blood cells) are pooled, centrifuged 10 min at $500 \times g$, 4°C , and resuspended in 10^6 cells/ml of a prestimulation cocktail consisting of DMEM, 15% fetal bovine serum, antibiotics (penicillin and streptomycin), 6 ng/ml IL-3, 10 ng/ml IL-6, and 100 ng/ml stem cell factor. The bone marrow cells are incubated in the prestimulation cocktail for 24 to 48 hr prior to infection. A number of other cytokines have been tried, including IL-1 α , and the concentrations of the cytokines used vary widely from lab to lab (Bodine et al., 1989, 1994; Daley et al., 1990; Fraser et al., 1992; Pear et al., 1996).

The cells are infected by either spin infection or cocultivation (UNIT 9.11) in the above infection cocktail with 4 $\mu\text{g}/\text{ml}$ polybrene added. In addition, viral supernatant may replace one-third of the volume of DMEM. Following infection, nonadherent cells are removed and injected into the tail vein of lethally irradiated 4- to 8-week-old recipient mice in a volume of $\leq 200 \mu\text{l}/\text{mouse}$. Approximately $2\text{--}5 \times 10^5$ unfractionated bone marrow cells per mouse are necessary to ensure long-term reconstitution of most mouse strains. The animals are subsequently monitored for bone marrow reconstitution.

INACTIVATION OF GENES IN MAMMALIAN CELLS

Human Somatic Cell Gene Targeting

Human somatic cell gene targeting provides a powerful tool to scientists studying gene function in cultured human cells. This technology allows scientists to knock out genes in human somatic cells in a fashion analogous to the creation of knockout mice. Human somatic cell gene targeting brings the power of genetics to the study of human genes in human cells by making it possible to compare cells or individuals that are genetically identical except for a single, well-defined mutation in an endogenous gene. A partial list of genes successfully targeted in human somatic cells is presented in Table 9.15.1.

Once this “molecular scalpel” has been employed, a researcher has at his or her disposal a set of cultured human cells that are genetically identical except for a specific, targeted change—the presence (in the parental cells) or absence (in the knockout cells) of a functional human gene. Since the cells are otherwise genetically the same, any biological or biochemical difference between the cells sheds light on the function of the targeted gene. This type of classical genetic analysis—the study of gene function by comparing cells or organisms that are genetically identical except for a single, well-defined genetic change in an endogenous gene—has been a mainstay of genetics in model systems for decades and has yielded innumerable critical discoveries. Until relatively recently, however, this capability has been restricted to model organisms and was not applicable to human cells.

The biological and biochemical characteristics of such isogenic sets of human cells can be analyzed in many different ways. For example, the growth properties of the cells can be studied *in vitro* to assess differences in their morphology and other growth characteristics (Shirasawa et al., 1993). The cells can be analyzed using flow cytometry to assess their cell-cycle profile during exponential growth or cell-cycle arrest, or after treatment with growth factors, small-molecule therapeutics, and lead compounds (Waldman et al.,

1995). The propensity of the cells to undergo apoptosis in vitro can be assessed using a variety of assays (Waldman et al., 1996). Microarrays can be employed to identify novel putative effectors of the targeted gene (Kim et al., 2002a).

The cells can also be studied in vivo. Since the cell lines commonly used for gene targeting are derived from human cancers, they will form tumors when injected subcutaneously into immunodeficient mice. By creating and comparing so-called “isogenic tumors,” it is possible to examine the role of the targeted gene in a wide variety of processes—e.g., one can study the effects of oncogenes and tumor-suppressor genes in tumor formation and on the sensitivity of tumors to anticancer agents (Shirasawa et al., 1993; Waldman et al., 1997).

This unit presents protocols for human somatic cell gene targeting. The Strategic Planning section presents a number of considerations that must be made when planning such an experiment. Basic Protocol 1 provides details for vector construction. Basic Protocol 2 describes the transfection procedures. Basic Protocol 3 is a method for excising the antibiotic-resistance gene from a heterozygous knockout to make it possible to target the remaining allele; the Alternate Protocol describes how to switch selectable markers for the same purpose. Basic Protocol 4 describes how to target the remaining allele, converting a heterozygous knockout cell line to a homozygous knockout cell line.

STRATEGIC PLANNING

Selection of a Parental Cell Line

To date, six different human cell lines have been successfully used for human somatic cell gene targeting (listed in Table 9.15.2). The list is short because suitable cell lines must possess each of three distinct characteristics. The first of these, which is very important, is that suitable cell lines should be diploid (or near-diploid), such that there are two (and only two) copies of the gene to be targeted. Second, the cells should transfect with high efficiency, since the promoterless enrichment built into human gene targeting vectors leads to the formation of relatively few colonies (since randomly integrated promoterless targeting vectors generally fail to express *neo^r* and therefore do not form drug-resistant colonies). Third, the cells should grow quickly and clonally, since one will need to grow individual clones in 96-well plates, preferably in 2 to 3 weeks. Of the cell lines listed in Table 9.15.1, HCT116 cells have proven to be the most robust and therefore have been used in the majority of human somatic cell gene targeting projects. As such, the authors of this unit tend to focus initial targeting efforts on HCT116 cells, since it is preferable to test new targeting vectors in a cell line that has been well established as suitable for human somatic cell gene targeting. Once the efficacy of targeting in HCT116 cells has been demonstrated, only then is the attempt made to target the gene in other cell lines as well.

Table 9.15.2 Human Cell Lines for Gene Targeting

Cell line	Reference
HCT116	Shirasawa et al., 1993
DLD1	Shirasawa et al., 1993
HT1080	Porter and Itzhaki, 1993
SW48	Kim et al., 2002b
HaCaT	Zawel et al., 2002
Human fibroblasts	Brown et al., 1997

In addition to meeting these three requirements, it is important for both experimental and technical reasons that the chosen cell line express the gene to be targeted. Experimentally, there is not much point in deleting a gene in somatic cells that is not expressed. Technically, homologous integration of a promoterless targeting vector into a transcriptionally silent locus will lead to the absence of *neo^r* expression and the failure to form a drug-resistant colony. Thus, the authors recommend first confirming that the gene of interest is expressed in candidate cell lines prior to initiating a targeting project (via immunoblotting, northern blotting, or RT-PCR).

Architecture of a Promoterless Targeting Vector

Promoterless targeting vectors require that the selectable marker gene be inserted in-frame into the gene being targeted. Homologous integration of such a targeting vector into the human genome then leads to the expression of a functionally active drug-resistance protein. There are several general factors to consider when planning to construct such a targeting vector.

One early concern was that targeting vectors for human somatic cell gene targeting would need to be composed of isogenic DNA—i.e., DNA derived from the actual cell line in which the gene would be targeted. These concerns were based on early gene-targeting studies performed in mouse embryonic stem cells, which indicated that the polymorphisms present in genomic DNAs derived from different strains of mice could affect the targeting frequency in a dramatically adverse fashion (Deng and Capecchi, 1992; van Deursen and Wieringa, 1992). If this were true for gene targeting in human cells, it would be difficult to target a gene in multiple cell lines using the same targeting vector. Furthermore, since humans (unlike mice) are not inbred, the targeting vector for each allele of a gene would need to be composed of different genomic DNA. As such, the need for isogenic DNA would substantially increase the technical complexity of human somatic cell gene targeting. Fortunately, experience has shown that targeting vectors composed of nonisogenic genomic DNA are able to create knockouts in a wide variety of genetically unrelated human cell lines (Sedivy et al., 1999).

In the authors' experience, the *neo^r* protein is frequently unable to tolerate the fusion of unrelated amino acids onto its amino terminus (C. Lee., J.S. Kim., and T. Waldman, unpub. observ.). This being the case, it is inadvisable to design a targeting strategy which leads to the formation of a *neo^r* fusion protein. There are two effective strategies that circumvent this limitation. First, one can design the targeting vector such that the initiating methionine of the gene being targeted is replaced precisely with the initiating methionine of *neo^r* gene. Second, one can replace internal exon(s) with an IRES-*neo^r* gene.

Finally, it is not possible to design a true promoterless targeting vector for deleting the first exon of a gene, since the left arm of such a targeting vector would contain promoter elements of the gene being targeted. If the initiating methionine of a gene is, in fact, in the first exon, the authors recommend designing the targeting vector to delete internal exon(s) using an IRES-*neo^r* strategy.

Building a Targeting Vector

Building promoterless targeting vectors is a nontrivial exercise in recombinant DNA technology. There are two factors that complicate construction of these vectors. First, there is virtually no sequence flexibility in the junction between the left arm of the targeting vector and the selectable marker cassette, making the use of standard restriction enzyme-based recombinant DNA strategies problematic. Second, it is frequently necessary to add several sequence features between the end of the selectable marker gene and

the right homology arm of the targeting vector, such as restriction sites and a PCR priming site.

The authors have found that the most straightforward way to circumvent these difficulties is to build the targeting vectors in two steps, exploiting the high efficiency of homologous recombination in *S. cerevisiae* (Storck et al., 1996; Oldenburg et al., 1997). First, a 5- to 10-kb fragment containing the genomic region of interest is cloned (generally from a bacterial artificial chromosome, or BAC; *UNIT 5.9*) into a yeast shuttle vector, which contains selectable markers and origins of replication for propagation in both *E. coli* and *S. cerevisiae*. Next, the selectable marker gene (generally either *neo^r* or IRES-*neo^r*) is PCR-amplified from a plasmid using long primers that add both the needed sequence features, along with 30 to 50 nucleotides of homology to the cloned genomic region for directing the desired recombination event. This PCR product is then cotransformed into *S. cerevisiae* together with linearized recombinant shuttle vector, and recombinants are identified and used as the final targeting vector. This strategy makes it possible to design any junction and to add desired sequence features all in one step, and does not rely on the serendipitous presence of needed restriction sites.

It should be noted that it is also theoretically possible to exploit homologous recombination in *E. coli* to accomplish the same goals (Zhang et al., 2000b). However, unlike in yeast, in *E. coli* it is generally necessary to *select* for homologous recombination between the vector and the PCR product. Therefore, the PCR-amplified *neo^r* cassette would need to contain a selectable marker for growth in bacteria as well.

Screening for Knockouts in Human Cells

The simplest approach for identifying gene-targeted cell lines is to conduct an initial PCR-based screen, then confirm the putative knockouts with a Southern blot. There are two general factors to consider when planning the details of such a screening strategy.

Historically, PCR screening for knockouts has relied on one primer in the selectable marker gene (generally *neo^r*), and another primer located in the genomic region just outside one of the homology arms of the targeting vector. Homologous integration of the targeting vector creates a template for PCR, whereas random integration does not. As such, diagnostic PCR products are produced only from gene-targeted clones. The fundamental difficulty with this classic PCR-based screening strategy is the lack of a positive control for PCR—i.e., by definition there exists no template for PCR unless a knockout is created. As such, it is virtually impossible to optimize the PCR reaction prior to screening for knockouts, and therefore difficult to definitively interpret a negative result. If none of the clones are PCR-positive, the question remains—were there truly no knockouts, or did the PCR not work?

Recently, a strategy has been devised to overcome this limitation, providing an internal positive control for PCR in each reaction (Chan et al., 1999; for a schematic of this approach, see Fig. 9.15.1). This approach is very similar to the classic approach, except that the PCR primer generally located in the *neo^r* gene is substituted by a PCR primer located in the genomic region being *deleted by the targeting vector*. Importantly, this PCR priming site is built into the targeting vector such that homologous integration of the targeting vector simultaneously *deletes the endogenous priming site, and reintroduces it in a slightly different location*. As such, clones in which the targeting vector has integrated randomly create a PCR product of a certain size, and clones in which the PCR product has integrated via homologous recombination create a PCR product of a different size. Therefore, it is no longer the presence or absence of a PCR product that determines a knockout; instead, a PCR product is produced in all the PCR reactions and its size

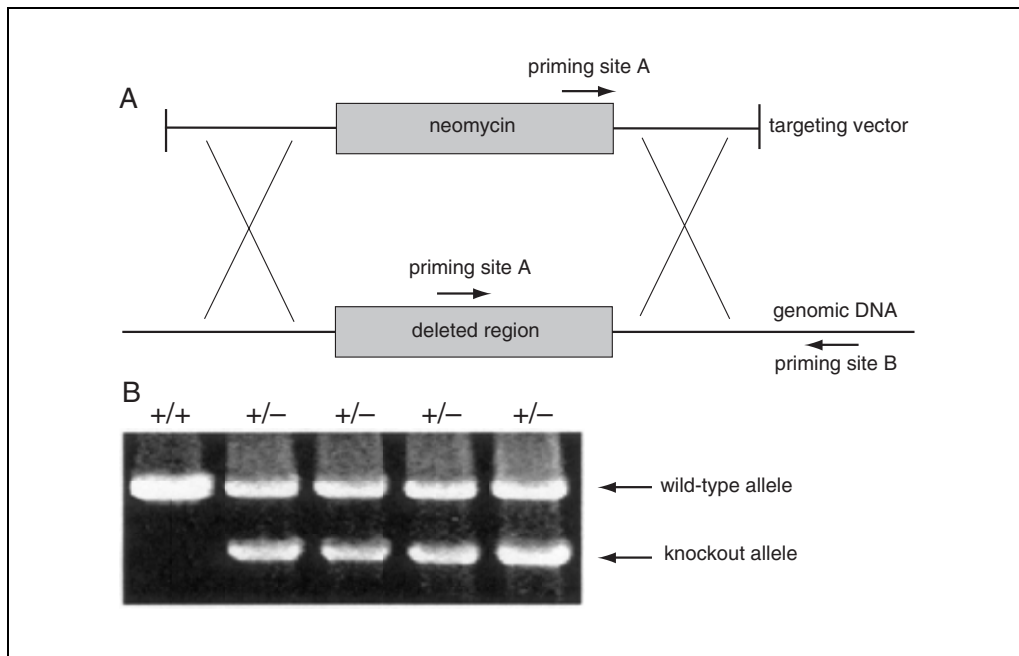

Figure 9.15.1 PCR screening for knockouts.

determines whether a knockout is present. This elegant modification of the classic PCR screening approach has significant implications for interpreting PCR screening data. The other practical implication is that the diagnostic PCR must be optimized prior to completion of the targeting vector, since the PCR priming site must be built into the targeting vector itself.

In addition to altering the size of a PCR product, homologous integration of the targeting vector invariably modifies the restriction map of the local genomic region. By using a Southern blot–based approach, it is possible to discriminate between wild-type alleles and targeted alleles. The details of choosing restriction sites and probes are described in Basic Protocol 1.

Targeting the Second Allele

One particularly challenging aspect of human somatic cell gene targeting is the creation of homozygous knockouts by disruption of the second, remaining allele. Since heterozygous knockout cells are already drug-resistant, it is necessary to modify the targeting vector to change the selectable marker gene. While swapping selectable markers is not technically demanding (especially if homologous recombination in *S. cerevisiae* was employed to create the targeting vector), experience has demonstrated that selectable markers other than *neo^r* (e.g., *hyg^r* and *puro^r*, among others) are suboptimal for somatic cell gene targeting. In particular, targeting vectors relying on these selectable markers are frequently either unable to generate drug-resistant colonies at all or require such low concentrations of drug that it is difficult to kill the background cells (Hanson and Sedivy, 1995; J.S. Kim, C. Lee, and T. Waldman, unpub. observ.). While the reasons for these difficulties are unknown, some have speculated that endogenous promoters are unable to generate a high enough level of gene expression to confer resistance to these specific drugs.

The most straightforward way to circumvent difficulties with selectable markers other than *neo^r* is to build a Cre-*loxP* recyclable *neo^r* targeting vector and use it to target each allele sequentially. In such a targeting vector, the *neo^r* gene is flanked by *loxP* sites. After

creation of heterozygous knockout cells, Cre is added to the cells (generally via infection with a recombinant Cre-containing adenovirus), and drug-sensitive derivatives are identified. These cells are then retransfected with the same targeting vector for deletion of the remaining allele.

The second inherent difficulty in targeting the second allele is that the frequency of homologous integration is exactly half that of the first allele. This is because half the second allele homologous integration events will disrupt the already targeted allele.

BUILDING A TARGETING VECTOR

The first step in the creation of a human promoterless targeting vector is to obtain human genomic DNA that will form the basis of the homology arms of the targeting vector. To do this, the authors generally identify BAC clone(s) that contain the needed genomic region (UNIT 5.9).

Once BACs have been identified and prepped, the next step is to subclone a smaller fragment (generally 5 to 10 kb) into a yeast shuttle vector. This subclone will be used as raw material for final assembly of the targeting vector via homologous recombination in *S. cerevisiae* (Storck et al., 1996; Oldenburg et al., 1997). Alternatively, it is possible to consecutively subclone each homology arm into a vector. However, subcloning a single larger piece that will ultimately form *both* homology arms saves a subcloning step.

The final step in construction of the targeting vector is to use homologous recombination in *S. cerevisiae* to replace critical exon(s) in the cloned genomic region with an in-frame *neo^r* or IRES-*neo^r* gene. The decision whether to use *neo^r* or IRES-*neo^r* is made according to the guidelines in step 6, below, and Critical Parameters and Troubleshooting. There are two feasible alternative approaches. First, it is possible to add the promoterless *neo^r* gene via conventional restriction enzyme–based cloning. However, the authors find that such an approach often requires complex multistep strategies because of the lack of convenient restriction sites. Second, it is possible to conduct similar homologous recombination reactions in strains of *E. coli* that overexpress recombinase proteins (Zhang et al., 2000b). In this case the disadvantage is that such an approach generally requires that the insert include an *E. coli* selectable marker gene.

Before beginning the homologous recombination, it is necessary to identify a unique restriction site in the cloned genomic region for linearization of the recombinant shuttle vector prior to transformation of *S. cerevisiae*. The recombination junctions will need to flank this restriction site.

Once such a restriction site is identified, the *neo^r* gene (or IRES-*neo^r* gene) is PCR-amplified with long primers designed to add needed sequence features to the ends (e.g., a priming site for PCR-based diagnosis of knockouts, restriction site or sites for Southern blot-based diagnosis of knockouts, and sequence homologies for recombination in *S. cerevisiae*). This PCR product is then cotransformed into *S. cerevisiae* with the linearized recombinant yeast shuttle vector. After plating the transformation mix on the appropriate selective medium, individual yeast colonies are screened via whole-cell PCR to identify those harboring the desired recombinant plasmid. PCR products derived from recombinant plasmids are then sequenced to exclude plasmids harboring mutations in the recombination junctions. These plasmids are then transferred into *E. coli* and prepped. Finally, the integrity of the finished targeting vector is confirmed by restriction analysis and sequencing of critical junctions.

Materials

Genomic DNA (UNIT 2.2) derived from the parental cell line (e.g., HCT116; ATCC #CCL 247)

BAC DNA purification kit: e.g., Nucleobond Plasmid Maxi kit (Clontech) or similar kit from Qiagen (also see UNIT 2.1B)

Yeast shuttle vectors (e.g., YEp24, pRS423, pRS424, pRS425, or pRS426, available from ATCC)

E. coli cells (DH10B)

pMC1neopolyA (Stratagene) or an IRES-*neo*^r plasmid (available from John Sedivy at Brown University upon request)

EXPAND High Fidelity PCR System (Roche)

QIAX Gel Extraction Kit (Qiagen) or equivalent

Appropriate selective yeast media (Qbiogene)

Yeast PCR kit (Qbiogene)

Yeast RPM kit (Qbiogene)

Facility for BAC library screening (e.g., Research Genetics)

30°C incubator

Additional reagents and equipment for primer design (UNIT 7.7), synthesis of oligonucleotides (UNIT 2.11), PCR (UNIT 15.1), gel purification of DNA fragments (UNIT 2.7), preparation and screening of a BAC library (<http://www.chori.org/bacpac/home.htm>), plating bacteria (UNIT 1.3), single-cell PCR (UNIT 25A.3), restriction digestion (UNIT 3.1), agarose gel electrophoresis (UNIT 2.5A), restriction mapping (UNITS 3.2, 3.3, & 7.7), finding sequence information on the Web (UNITS 19.2 & 19.3), dephosphorylation of DNA by calf intestinal phosphatase (UNIT 3.10), DNA subcloning and ligation (UNIT 3.16), introduction of plasmid DNA into *E. coli* (UNIT 1.8), colony hybridizations (UNIT 6.3), preparation of plasmid DNA (UNIT 1.7), DNA sequencing (Chapter 7), phenol extraction and ethanol precipitation of DNA (UNIT 2.1A), gel purification of DNA fragments (UNITS 2.5A, 2.7, or 2.8), introduction of DNA into *S. cerevisiae* (UNIT 13.7), growth of *S. cerevisiae* (UNIT 13.2), and DNA preparation from *S. cerevisiae* (UNIT 13.11)

Identify and isolate BAC clones

1. Design (UNIT 7.7) and synthesize (as described in UNIT 2.11; or order from synthesis facility) a PCR primer pair for amplification of the genomic region of interest from human genomic DNA derived from the parental cell line. Optimize and perform PCR amplification (UNIT 15.1; the PCR product should be 500 to 1000 nucleotides in length) to produce a probe for BAC library screening (step 2). Gel purify the DNA fragment obtained from PCR (UNIT 2.7).

The primer pair will be used both to create a probe for library screening and to confirm that the BACs identified harbor the correct insert. Ideally, the probe will be derived from intronic sequence, since probes derived entirely from exons can hybridize to pseudogenes.

2. Perform a hybridization-based BAC library screening using the probe for the region of interest created in step 1. For protocol details, see the laboratory Web page of Pieter De Jong at the Children's Hospital Oakland Research Institute (<http://www.chori.org/bacpac/home.htm>).

Since the physical map and sequence of the human genome is by now largely completed, it is often possible to search GenBank (UNIT 19.2) and identify the needed BAC, then order it from a BAC repository. However, if such information is unavailable, or if the BAC or BACs ordered from the repository do not contain the correct insert, it is necessary to screen a library to identify the needed BACs. In fact, the authors often screen a library even if a single correct BAC is available, since it is generally advantageous to have several different BAC clones with the needed insert, each with different boundaries and junctions.

Although the materials are available to screen BAC libraries in academic laboratories), the authors generally contract out the screening to Research Genetics, which performs this procedure routinely. Screening BAC libraries involves hybridization of radiolabeled probes to very large commercially available membranes that contain hundreds of thousands of gridded BAC clones. Performing the actual hybridizations is tricky because of the size of the membranes. Furthermore, identification of the correct clones on the huge filters takes practice.

If sending the probe to a commercial facility (e.g., Research Genetics), it generally takes 2 to 6 weeks to receive the final product, which will be stabs inoculated with bacteria harboring the desired BACs.

Alternatively, it is possible to skip this BAC step by generating the needed genomic DNA via PCR amplification of the needed homology arms from a genomic DNA template. However, the authors prefer to use BACs as the source of genomic DNA for building targeting vectors, since it can be difficult to create large homology arms using PCR. Also, PCR can introduce mutations into the homology arms and therefore reduce the targeting efficiency of the completed targeting vector.

3. Once the BACs are received, confirm that they contain the correct insert as follows.
 - a. Streak out bacteria from the stabs onto the appropriate selective medium to generate single colonies (UNIT 1.3).
 - b. Grid individual colonies (generally ten or so) to a grid plate (UNIT 1.3).
 - c. Using the PCR primer pair optimized in step 1 above, test each of the grid positions with whole-cell PCR (UNIT 25A.3) to identify bacteria harboring the desired insert.

Confirming the BAC clone is important since the bacterial stabs are created by directly inoculating bacteria stored as glycerol stocks in 384-well plates. It is possible (and in the authors' experience not uncommon) for the bacteria in a particular well to be a mixed population caused by spillage from adjacent wells, or the wrong clone entirely.

4. Prepare BAC DNA from positive clones using the Nucleobond Plasmid Maxi or similar DNA purification kit.

The authors generally use Nucleobond columns from Clontech, though kits available from other manufacturers (e.g., Qiagen; UNIT 2.1B) will undoubtedly also work well.

5. Digest the various BACs with several different restriction enzymes (UNIT 3.1) and compare the restriction digestion patterns by agarose gel electrophoresis (UNIT 2.5A).

This step confirms the large size of the purified DNAs. Furthermore, it is generally expected that different BACs share some bands but differ in others, reflecting the fact that they are derived from the same genomic region but have different boundaries.

Subclone genomic DNA from the BAC into the yeast shuttle vector

To choose a restriction fragment to subclone, one must first decide what exon(s) the completed vector will be designed to target. There are several factors to consider when choosing an exon to target. If possible, target the exon containing the initiating methionine, since it is then possible to build a promoterless targeting vector in which the initiating methionine of *neo^r* precisely replaces the initiating methionine of the targeted gene. However, avoid targeting the first exon, since the left arm of such a targeting vector would contain promoter elements of the gene itself, reducing the efficiency of the promoterless selection. If the initiating methionine is in the first exon, choose an internal exon and use an IRES-*neo^r* based strategy (Sedivy and Dutriaux, 1999). There are two main issues to consider when targeting an internal exon with an IRES-*neo^r*. First, it is desirable to target an early exon and therefore create a protein that is as dramatically altered as possible. Second, it is desirable to target an exon which, if it were skipped by the splicing machinery, would change the reading frame and result in a premature stop codon.

- Using published or Web-based human genomic sequence information (*UNITS 19.2 & 19.3*), make a sequence-based restriction map of the desired genomic region (see *UNITS 3.2, 3.3 & 7.7*). Identify several suitable restriction fragments for subcloning into the yeast shuttle vector.

When choosing potential restriction fragments, keep in mind that one arm of the final targeting vector will need to be short enough to PCR amplify across (i.e., less than ~2 kb) when identifying gene-targeted cell lines.

- Using the RepeatMasker Web site (<http://repeatmasker.genome.washington.edu>), analyze the sequence within and surrounding these restriction fragments to identify repeat elements such as *Alu* and *LINE-1*.

It is important to avoid designing targeting vectors composed largely of repeat elements, since the arms of such targeting vectors will not provide the unique homologies required to guide homologous recombination in human cells.

- To perform the actual subcloning, first digest both the BAC DNA and the yeast shuttle vector with the appropriate restriction enzyme or enzymes (see *UNIT 3.1* and documentation for shuttle vector).

*There are numerous yeast shuttle vectors available for use in this subcloning step. The authors generally use one of five different yeast shuttle vectors available from ATCC: *YEp24*, *pRS423*, *pRS424*, *pRS425*, and *pRS426* (Botstein et al., 1979; Christianson et al., 1992). *YEp24* is a *pBR322*-based, low-copy-number vector, whereas the *pRS* series are *pBluescript*-based, high-copy-number vectors. All work well for creating targeting vectors via homologous recombination; however, in the authors' experience it is slightly easier to clone larger fragments (>5 kb) into low-copy-number vectors such as *YEp24*.*

- Treat the linearized vector with calf intestinal alkaline phosphatase (CIP; *UNIT 3.10*) to limit recircularization of the vector during ligation.
- Ligate the linearized, CIP-treated vector to the digested BAC DNA fragments (*UNIT 3.16*). Transform or electroporate appropriate *E. coli* cells with the ligated plasmid vector (*UNIT 1.8*). After plating on the appropriate selective medium, grid ~500 colonies (*UNIT 1.3*). Also grid bacteria harboring various BACs to serve as positive and negative controls for the next step.
- Identify bacteria harboring the desired recombinant plasmid by performing colony hybridizations with a radiolabeled oligonucleotide probe (*UNIT 6.3*).

*It is often possible to use one of the PCR primers from in step 1, above, as the probe. Note that the positive signals produced by bacteria harboring high-copy-number recombinant plasmids (e.g., *pRS423-6*) will be much stronger than the signals produced by bacteria harboring low-copy-number recombinant plasmids (e.g., BACs, *YEp24*).*

- Streak out the bacteria (*UNIT 1.3*) in positive grid positions to purify individual colonies. Prepare plasmid DNA using the Nucleobond Plasmid kit or equivalent (also see *UNIT 1.7*).
- Confirm the integrity of the subclones by restriction analysis and sequencing of junctions (Chapter 7).

It is important to identify and avoid subclones with multiple, concatamerized inserts.

Identify priming sites and restriction sites for PCR and Southern blot-based identification of gene-targeted cell lines

It is important to identify these sequence features before completing the targeting vector, since the sequence comprising a PCR primer and possibly a restriction site will be built into the targeting vector during the final step of construction.

14. To identify suitable PCR primers, design (UNIT 7.7) and synthesize (as described in UNIT 2.11; or order from synthesis facility) three sense and three antisense primers that meet the following criteria:
 - a. By convention, one primer is located in the genomic DNA just adjacent to the shorter homology arm of the targeting vector.
 - b. The other primer is not located in the *neo^r* gene (or IRES-*neo^r* gene) itself, but is instead located in the genomic region deleted by the targeting vector.

*Importantly, this priming site will be built into the targeting vector itself at the junction of the short homology arm and the *neo^r* gene. Homologous integration of the targeting vector deletes the endogenous site and moves it, altering the size of the PCR product (generally shortening it).*

15. Test all nine permutations of these primers on genomic DNA derived from the parental cell line (e.g., HCT116) at several different annealing temperatures, as described in UNIT 15.1. Choose the most robust primer pair for eventual screening of putative gene-targeted clones.

As described above (see Strategic Planning), the authors use a strategy for PCR-based diagnosis of knockouts that is slightly different from the conventional strategy used to identify knockouts in mouse embryonic stem cells. This strategy is preferable to the conventional PCR-based screen, since it includes a positive internal control with each PCR reaction.

16. To identify candidate restriction sites for Southern blot–based diagnosis of knockouts, make a computer-generated restriction map of the genomic region using published or Web-based genomic sequences (UNIT 7.7). Identify suitable sites based on the following criteria:
 - a. The site should be *present* at a defined location in the genomic DNA at least 500 nucleotides outside one homology arm of the completed targeting vector (to allow for placement of a Southern blot probe; also see UNIT 10.8).
 - b. The site should be *absent* in that homology arm itself.
 - c. The site should be *present* at a defined location either in the other homology arm or in the genomic DNA adjacent to the other homology arm.
 - d. Furthermore, the site should either be present in the *neo^r* gene itself, or should be added to the targeting vector (generally at a junction of a homology arm and *neo^r*) during the final step in vector construction.

By following these guidelines, homologous integration of the targeting vector will alter the genomic restriction map in a way that should be easily measurable by Southern blot analysis (UNIT 10.8).

Replace critical exon(s) with a promoterless *neo^r* or IRES-*neo^r* gene via homologous recombination in *S. cerevisiae*

17. Using sequence analysis software (UNIT 7.7), identify candidate restriction sites for linearization of the recombinant yeast shuttle vector created in steps 8 to 13. Confirm location and uniqueness of candidate site(s) via routine restriction analysis (UNIT 3.1).
18. Once an appropriate site has been chosen, perform a larger-scale preparative digest using approximately 2.5 µg of the recombinant shuttle vector plasmid DNA from step 12. Phenol extract and ethanol precipitate the linearized plasmid (UNIT 2.1A).
19. Design (UNIT 7.7) and synthesize (as described in UNIT 2.11; or order from synthesis facility) PCR primers for amplification of the *neo^r* or IRES-*neo^r* gene with appropriate ends to add the PCR priming sites and restriction sites and to add 40 to 50 nucleotides of sequence homology to direct homologous recombination in *S. cerevisiae*.

The authors order primers PAGE-purified from Integrated DNA Technologies. If using the neo^r gene as the template, the authors generally use the pMC1neoPolyA plasmid as the template and use the following PCR priming sites: sense 5'-ATGGGATCGGCCATTGAA-CAA-3', antisense 5'-GTCGACGGATCCGAACAAACG-3'. Of note, the first three nucleotides of the sense primer comprise the initiating methionine of neo^r. If using IRES- neo^r (available from John Sedivy at Brown University) as the template, the authors use the following PCR priming sites: sense 5'-AACGTTACTGGCCGAAGCCGC-3', antisense 5'-TCCCAACTCATCCCGGCCTC-3'.

20. Perform high-fidelity PCR with the pMC1neopolyA plasmid or IRES-*neo^r* as template, to create the *neo^r* PCR product, using the EXPAND High Fidelity PCR System or equivalent (also see *UNIT 15.1*).
21. Gel purify the PCR product using the QIAX Gel Extraction Kit or equivalent (also *UNITS 2.5A, 2.7, or 2.8*).
22. Cotransform (*UNIT 13.7*) 150 ng of linearized recombinant shuttle vector (from step 18) together with an estimated 500 ng of gel-purified PCR product (from step 21) into *S. cerevisiae*. Include negative controls consisting of vector alone and PCR product alone.

*The authors generally use either commercially available competent yeast (strain MaV203; Invitrogen) or prepare competent yeast from strain INVSc1 (Invitrogen) using the Frozen-EZ Yeast Transformation II kit (Zymo Research). The choice of yeast strain depends on which auxotrophic marker is needed. Specific protocols for transformation are available in each kit. Also see *UNIT 13.7* for additional information relating to yeast transformation.*

23. Plate the transformation mixes on the appropriate selective medium (available from Qbiogene), and incubate at 30°C for 2 to 4 days.

*General considerations for the growth of S. cerevisiae are presented in *UNIT 13.2*. Expect to see ~5-fold more colonies in the experimental reactions than in vector alone. There should be no colonies in insert alone.*

24. Grid approximately 20 colonies from the vector + insert transformation mix (see *UNIT 13.2*). Also grid some vector-only colonies to serve as negative controls for the subsequent PCR reaction.
25. Design and synthesize (as described in *UNIT 2.11*; or order from synthesis facility) a set of PCR primers that flank the recombination event.

Such a primer pair will create PCR products of different sizes in recombined and nonrecombined plasmids.

26. Test yeast from individual grid positions by PCR to identify those in which a recombination event has occurred.

The authors generally use the yeast itself as a PCR template after pretreatment with zymolyase to destroy the cell wall. The authors use the Yeast PCR Kit (Qbiogene) for this purpose.

27. Once yeast-harboring recombinant plasmids have been identified, sequence the ends of the PCR products to demonstrate that the recombination junctions are intact and free of mutations. Design (*UNIT 7.7*) and synthesize (as described in *UNIT 2.11*; or order from synthesis facility) sequencing primers for the purpose of sequencing the junctions from “inside out,” making it possible to generate sequence from the very end of the PCR products. Sequence the PCR products (see Chapter 7).

Transfer completed targeting vectors into E. coli for large-scale DNA preparation

28. Prepare a miniprep of the recombinant yeast DNA using the Yeast RPM kit.
29. Electroporate the miniprep DNA into *E. coli* as described in *UNIT 1.8*. Plate on the appropriate selective medium (*UNIT 1.3*). Streak out individual colonies to purify.
30. Perform large-scale plasmid preps as described in *UNIT 1.7*.

The authors generally use Nucleobond kits (Clontech).

31. Confirm the integrity of the resultant plasmid via restriction analysis and resequencing of the critical junctions (see Chapter 7) using the sequencing primers used in step 27 above.
32. Linearize the vector for transfection (Support Protocol).

SUPPORT PROTOCOL

LINEARIZATION OF THE COMPLETED TARGETING VECTOR PRIOR TO TRANSFECTION INTO HUMAN CELLS

The completed targeting vector must be linearized prior to transfection, since homologous recombination is more efficient with linear DNA. As such, it is necessary to identify a suitable restriction enzyme that cuts only in the vector backbone. There are generally sites for rare-cutting enzymes (e.g., *SalI* or *NotI*) in the polylinker of the yeast shuttle vector that are useful for this purpose

Materials

Completed targeting vectors (Basic Protocol 1)
TE buffer (*APPENDIX 2*)

Additional reagents and equipment for restriction digestion (*UNIT 3.1*), agarose gel electrophoresis (*UNIT 2.5A*), and phenol extraction and ethanol precipitation of DNA (*UNIT 2.1A*)

1. Identify an appropriate restriction enzyme (*UNIT 3.1*) for linearization of the completed targeting vector in the vector backbone. Confirm that the enzyme cuts the targeting vector singly and in the predicted location by performing small-scale restriction digests and analyzing an aliquot by agarose gel electrophoresis (*UNIT 2.5A*).
2. Perform a preparative digest of 50 to 100 μg of the targeting vector with the chosen enzyme (*UNIT 3.1*). Phenol extract and ethanol precipitate the digest (*UNIT 2.1A*), then resuspend in TE buffer to a final concentration of 0.5 $\mu\text{g}/\mu\text{l}$.
3. Confirm the efficiency of digestion by analyzing an aliquot of the digest by agarose gel electrophoresis (*UNIT 2.5A*).

The authors generally prepare linearized DNA from three identical targeting vectors derived from different yeast colonies, in the unlikely event that one or several of the vectors has a PCR-generated inactivating mutation in the neo' (or IRES-neo') gene.

BASIC PROTOCOL 2

TRANSFECTION OF THE LINEARIZED TARGETING VECTOR INTO CULTURED HUMAN CELLS AND IDENTIFICATION OF HETEROZYGOUS KNOCKOUT CELLS

The authors generally use HCT116 cells for the initial gene-targeting experiments, since these cells divide rapidly, grow well as individual clones in 96-well plates, and are generally well established as suitable for human somatic cell gene targeting. Once the targeting vector has been shown to work efficiently in HCT116 cells, attempts can be made to target the gene in other cell lines as well.

Two sequential transfections are performed in this step. Initially, the cells are transfected, and colonies are selected directly in 25-cm² tissue culture flasks and stained with crystal violet. This preliminary experiment demonstrates whether the new targeting vector(s) can create G418-resistant colonies, and identifies any targeting vectors that may harbor inactivating mutations in their *neo*^r (or IRES-*neo*^r) gene. Also, based on the number of colonies produced, it is possible to estimate the dilutions needed for creation of single colonies via limiting dilution in 96-well plates.

Next, the HCT116 cells are retransfected and set up in a large number (50 to 100) of 96-well plates for obtaining individual drug-resistant clones by limiting dilution. Once single colonies have formed (first identifiable ~10 days post-transfection), they are expanded (at ~20 days post-transfection) for cryopreservation and preparation of genomic DNA. The authors generally work up 200 to 500 colonies in this step.

Finally, the genomic DNAs are tested by PCR to identify heterozygous knockout cell lines. Knockouts are then thawed, and are grown up to create more frozen vials and to reprepare genomic DNA. The genotype of the cell lines is then reconfirmed by PCR and Southern blotting.

Materials

- Complete McCoy's 5A medium (see recipe) with and without 0.6 µg/ml G418 (geneticin, Life Technologies; see *UNIT 9.5*)
- HCT116 cells (ATCC #CCL 247)
- Lipofectamine reagent (Invitrogen; see *UNIT 9.4*)
- Linearized targeting vector (Support Protocol)
- Plasmid unrelated to targeting vector and lacking *neo*^r gene (negative control for colony formation)
- PMC1neopolyA plasmid (Stratagene)
- CMV β-gal plasmid (Clontech)
- Hanks' Balanced Salt Solution (HBSS, Life Technologies; also see *APPENDIX 2*)
- 0.05% (w/v) trypsin/0.53 mM tetrasodium EDTA (Life Technologies)
- 25-cm² and 75-cm² tissue culture flasks
- 8-channel pipettor (e.g., Easy Step with 8-port manifold from Continental Laboratory Products) with 50-ml reservoir (Brinkmann 22-49-614-0)
- 96-well tissue culture plates
- 24-well tissue culture plates
- 15-ml conical centrifuge tubes
- Additional reagents and equipment for culture of mammalian cells (*APPENDIX 3F*), transfection of mammalian cells (*UNIT 9.4*), Xgal staining of cultured cells (*UNIT 9.10*), crystal violet staining of cultured cells (as for plaque assay; see *UNIT 16.16*, Support Protocol), preparation of genomic DNA (*UNIT 2.2*), PCR (*UNIT 15.1*), and Southern blotting (*UNIT 2.9A*)

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

NOTE: All reagents and equipment coming into contact with live cells must be sterile, and aseptic technique should be used accordingly.

Determine if target vector is capable of creating *neo*^r clones

1. Grow HCT116 cells (see *APPENDIX 3F* for culture techniques) to 60% to 70% confluence in complete McCoy's 5A medium (without selective agent). Transfect HCT116 cells with linearized targeting vectors using Lipofectamine reagent as described in

UNIT 9.4 and in the manufacturer's instructions, using 3 µg DNA per 25-cm² tissue culture flask of 60% to 70% confluent cells. Also transfect:

- a. A plasmid harboring a *neo^r* gene driven by a heterologous promoter (e.g., pMC1neopolyA) as a positive control for colony formation.
- b. An unrelated plasmid lacking a *neo^r* gene as a negative control for colony formation.
- c. CMV β-Gal plasmid as a control for transfection efficiency.

Do not add selective medium to the cells yet.

The authors recommend transfecting ~10 to 20 25-cm² flasks in this step.

2. The day after transfection, stain the CMV β-Gal transfected cells with Xgal (UNIT 9.10; expect to see 20% to 40% blue cells). Change the medium on the remaining flasks to complete McCoy's 5A medium containing 0.6 µg/ml G418.

The authors generally use the β-Gal Staining Kit (Roche).

3. Replace the medium with fresh complete McCoy's 5A medium containing 0.6 µg/ml G418 every 3 days (colonies should begin to appear at approximately day 10). Stain the colonies with crystal violet (see UNIT 16.16, Support Protocol) on approximately day 15.

*In the authors' experience, high-efficiency promoterless targeting vectors generally create between 30 and 200 colonies per transfected 25-cm² flask of HCT116 cells, whereas vectors harboring *neo^r* genes driven by heterologous promoters generally produce thousands of colonies per transfected 25-cm² flask.*

Perform selection on *neo^r* clones

4. Once the pilot experiment described in steps 1 to 3 above demonstrates that targeting vector is capable of creating *neo^r* clones, repeat to generate hundreds of individual *neo^r* clones. To do this, repeat the transfection strategy described above, including the positive and negative controls. At 18 to 24 hr after transfection, stain the CMV β-Gal-transfected control cells and feed the other control cells with complete McCoy's 5A medium containing 0.6 µg/ml G418.

The remainder of the flasks will be trypsinized and transferred to 96-well plates, as described is step 5.

5. Wash the cell monolayers in the 25-cm² flasks with 5 ml HBSS, then add 1 ml of 0.05% trypsin/0.53 mM EDTA and swirl gently to detach the cells. In a sterile, disposable beaker, mix the trypsinized cells with complete McCoy's 5A medium containing 0.6 µg/ml G418.

The volumes to be used depend on the dilution and the number of 96-well plates to be created from the cell suspension (25 ml of medium per 96-well plate). Initially, try three different "dilutions" of cells to increase the likelihood of obtaining wells with single colonies: 1, 1/5, and 1/20th of a 25-cm² flask in a 96-well plate.

6. Place an aliquot of the cell suspension in each well of the appropriate number of 96-well plates using an 8-channel pipettor with a sterile 50-ml reservoir. Stack plates, cover with plastic wrap to prevent evaporation, and begin incubating.
7. Identify wells containing single colonies as early as possible (after 10 days to 2 weeks).

As colonies become larger, cells tend to detach and form "satellite" colonies. Also, over time, two initially distinct colonies may merge together and appear to be a single colony.

8. When colonies cover at least 50% of the surface area of the well, transfer to 24-well plates. To do this, wash the well once with 250 μ l HBSS, then add 100 μ l of 0.05% trypsin/0.53 mM EDTA. Transfer each colony to a separate well of a 24-well plate containing 1 ml of complete McCoy's 5A medium containing 0.6 μ g/ml G418.
9. As the wells become confluent, expand the cultures to 25-cm² flasks. To do this, wash the well once with 1 ml HBSS, then add 250 μ l 0.05% trypsin/0.53 mM EDTA. Transfer the trypsinized cells to a 25-cm² flask containing 5 ml of complete McCoy's 5A medium containing 0.6 μ g/ml G418.

Harvest cells and identify knockouts

10. As the 25-cm² flasks become confluent, harvest the cells: use 1/3 to prepare genomic DNA; cryopreserve the remaining 2/3. To harvest:
 - a. Wash the monolayer once with 2 ml HBSS, then add 1 ml of 0.05% trypsin/0.53 mM EDTA.
 - b. Transfer 1/3 and 2/3 of the cells to separate 15-ml conical tubes, each containing 5 ml of complete McCoy's 5A medium (without selective agent).
 - c. Centrifuge 7 min at 250 \times g, room temperature, to create a cell pellet.
11. Prepare genomic DNA from the tube containing 1/3 of the cells (*UNIT 2.2*) and cryopreserve the cells in the tube containing 2/3 of the cells (*APPENDIX 3F*).
12. Test genomic DNAs by PCR as described in Basic Protocol 1 and *UNIT 15.1* to identify knockouts.
13. Thaw PCR-positive clones into a 75-cm² tissue culture flask containing 20 ml of complete McCoy's 5A medium with 0.6 μ g/ml G418. Expand into a 225-cm² flask for cryopreservation of nine cryovials (*APPENDIX 3F*) and reparation of genomic DNA (*UNIT 2.2*).
14. Retest by PCR (*UNIT 15.1*) and confirm via Southern blotting (*UNIT 2.9A*).

RESTORATION OF G418 SENSITIVITY VIA Cre-MEDIATED EXCISION OF THE *neo*^r GENE

In order to recycle the targeting vector to disrupt the remaining allele, it is necessary to excise the *neo*^r gene (or IRES-*neo*^r gene) from heterozygous knockouts via expression of Cre recombinase. Generally, a recombinant Cre-expressing adenovirus is used for this purpose.

Materials

- High-titer Cre-expressing adenovirus (e.g., Microbix Biosystems)
- Heterozygous knockout cell lines (see Basic Protocol 2) growing at 50% confluence in 25-cm² tissue culture flasks
- Complete McCoy's 5A medium (see recipe) with and without 0.6 μ g/ml G418 (geneticin, Life Technologies; see *UNIT 9.5*)
- Hanks' Balanced Salt Solution (HBSS, Life Technologies; also see *APPENDIX 2*)
- 0.05% (w/v) trypsin/0.53 mM tetrasodium EDTA (Life Technologies)
- 25-cm² tissue culture flasks
- 96-well tissue culture plates
- 24-well tissue culture plates
- Additional reagents and equipment for culture of mammalian cells (including counting and cryopreservation; *APPENDIX 3F*), plating cells at limiting dilution (as for hybridoma cells; *UNIT 11.8*), and crystal violet staining of cultured cells (as for plaque assay; see *UNIT 16.16*, Support Protocol)

BASIC PROTOCOL 3

Introduction of DNA into Mammalian Cells

9.15.15

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

NOTE: All reagents and equipment coming into contact with live cells must be sterile, and aseptic technique should be used accordingly.

1. Add 1 µl recombinant adenovirus to heterozygous knockout cells at 50% confluence in a 25-cm² tissue culture flasks containing 5 ml complete McCoy's 5A medium without selective agent (G418). Incubate 24 hr.
2. Wash cells twice with HBSS, then trypsinize (see Basic Protocol 2) and count cells (*APPENDIX 3F*).
3. Plate out at limiting dilution (*UNIT 11.8*) in 96-well plates in complete McCoy's 5A medium without selective agent, to obtain single colonies. To be sure to obtain single colonies, set up a variety of 96-well plates, e.g., with 1 cell/well, 5 cells/well, and 10 cells/well.
4. Identify single colonies after 10 days, and trypsinize at ~2 weeks as described in Basic Protocol 2. Expand each clone to a well in a 24-well plate, and then to two 25-cm² tissue culture flasks.

One of the 25-cm² flasks will be used to test the G418 sensitivity, and the other will be used for cryopreservation.
5. Add complete McCoy's 5A medium containing 0.6 µg/ml G418 to one of the 25-cm² flasks when it reaches 50% confluence. Continue incubating for ~10 to 14 days, feeding every 3 days. Cryopreserve the cells in the other 25-cm² flask when it reaches confluence, as described in *APPENDIX 3F*.
6. After ~10 to 14 days, stain the 25-cm² flask containing the cells exposed to selective agent with crystal violet as described in *UNIT 16.16*. Identify those cell lines that are now completely G418-sensitive, and use them to disrupt the remaining allele (see Basic Protocol 4).

ALTERNATE PROTOCOL

SWAPPING SELECTABLE MARKERS IN THE TARGETING VECTOR

An alternative to recycling the *neo^r* targeting vector (see Basic Protocol 3) is to modify the targeting vector to switch selectable markers, replacing *neo^r* with *hyg^r*. It should be noted that the authors have been consistently unable to generate drug-resistant colonies when using *puro^r*, *IRES-hyg^r*, or *IRES-puro^r* (C. Lee, J. S. Kim, T. Waldman, unpub. observ.).

To do this, repeat Basic Protocol 1 with PCR amplification of a *hyg^r* gene. Perform Basic Protocol 2 as written, except substitute 0.1 µg/ml hygromycin for G418.

BASIC PROTOCOL 4

TARGETING OF THE REMAINING ALLELE

The principles and protocols needed for targeting the remaining allele are virtually identical to those already described for targeting the first allele. If recycling the *neo^r* targeting vector, one should repeat Basic Protocol 2, using G418-sensitive heterozygous knockout cell lines (see Basic Protocol 3) as the "parental" cells. If swapping selectable markers in the targeting vector, use *neo^r* heterozygous knockout cell lines as the "parental" cells. Of the homologous integration events obtained, approximately half should represent homozygous knockouts, and the other half should have targeted the already targeted allele. After confirmation of the homozygous knockout with PCR (*UNIT 15.1*) and Southern blotting (*UNIT 2.5A*), the authors generally perform an immunoblot (*UNIT 10.8*) to confirm the absence of protein.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Complete McCoy's 5A medium

McCoy's 5A medium (Life Technologies cat. no. 16600-082)

10% fetal bovine serum (FBS, Life Technologies; also see APPENDIX 3F)

1× penicillin/streptomycin (Life Technologies cat. no. 15140-122)

Store up to 4 months at 4°C

COMMENTARY

Background Information

History of human somatic cell gene targeting

The first descriptions of successful gene targeting in cultured human cells appeared in 1991, when two groups reported heterozygous targeting of different genes. Heterozygous targeting of the *6-16* gene, an interferon-inducible transcript, was reported by Itzhaki and Porter (1991). The frequency of homologous integration was extremely low (estimated at 1 per 1550 colonies screened), leading these authors to employ an unusual screen involving integration of a human growth hormone gene (*hGH*) and the screening of conditioned media from putative clones via hGH ELISA. That same year, heterozygous targeting of the *HPRT* gene was reported (Zheng et al., 1991). That publication was a proof-of-principle study in which the authors were able to directly select for heterozygous knockout cell lines. In 1993, the first homozygous (or complete) knockout of a gene in human cells was reported (Porter and Itzhaki, 1993). Using a promoterless targeting vector, Porter and Itzhaki were able to disrupt the remaining allele of *6-16* in the heterozygous gene-targeted cells described in their 1991 paper. These three early studies demonstrated the feasibility of gene targeting in human cells; they also demonstrated that it was a very labor-intensive process.

In 1993, a landmark paper in the history of human somatic cell gene targeting was published, reporting the heterozygous gene targeting of the K-ras oncogene in two human colon cancer cell lines (Shirasawa et al., 1993). Although this was not the first manuscript to describe human somatic cell gene targeting, it pointed out the potential utility of somatic cell gene targeting for studying human cancer. In particular, these authors created derivatives of both HCT116 and DLD1 cells in which either the wild-type or the oncogenic allele of K-ras

had been deleted. They went on to show that the K-ras oncogene was absolutely required for the tumorigenic properties of both cell lines. They reported an extremely high frequency of knockouts (8/93 in HCT116; 7/24 in DLD1), attributing it to the use of a promoterless *neo^r* gene. Furthermore, they introduced the use of HCT116 and DLD1 cells for gene targeting.

In 1995, a careful study was published that examined the merits of promoterless versus conventional targeting vectors for somatic cell gene targeting (Hanson and Sedivy, 1995). Their conclusion bolstered the work done by Shirasawa et al. (1993) showing that promoterless targeting vectors were virtually essential to achieve high frequencies of homologous recombination. They also reported that negative selectable markers commonly used for gene targeting in embryonic stem cells were of limited utility for somatic cell gene targeting. Furthermore, they pointed out that while the *neo^r* gene was extremely useful for gene targeting, the *hyg^r* gene seemed to work poorly. Subsequent studies, mostly unpublished, confirmed these seminal observations.

Also in 1995, homozygous deletion of the p21 cdk inhibitor in human HCT116 cells was reported (Waldman et al., 1995). This study brought together several of the most recent technical advances, such as the use of promoterless targeting vectors, the lack of a need for negative selectable markers, and the value of HCT116 cells. Importantly, this study demonstrated the feasibility and utility of human somatic cell gene targeting for the study of tumor suppressor gene pathways.

Other important incremental technical gains have been made as well. Advances have been made that simplify the construction of human promoterless targeting vectors, such as the use of homologous recombination in *Saccharomyces cerevisiae* (see UNIT 13.10). An important modification to the standard PCR screen for knockouts has made identification of gene tar-

ged cell lines simpler and more robust (see *UNIT 13.10*). Cre-*loxP* recombination (see *UNITS 9.5 & 13.3*) has been successfully employed to overcome difficulties associated with creation of homozygous knockouts by making it possible to recycle the same targeting vector for both alleles of a gene.

Today, through the implementation of these advances, human somatic cell gene targeting has emerged as an important tool for the study of gene function in human cells.

Critical Parameters and Troubleshooting

The frequency of homologous recombination in human cells is 3 to 5 orders of magnitude lower than the frequency of nonhomologous recombination. As such, the vast majority of drug-resistant clones formed after transfection of a conventional targeting vector represent random integration events. Identification of the tiny fraction of gene-targeted clones can be extremely challenging. It should be noted that the frequency of homologous integration in human cells is thought to be significantly lower than the frequency of homologous integration in murine embryonic stem (ES) cells. This fact, coupled with the fact that creation of homozygous knockouts in human cells requires sequential targeting of both alleles (unlike in mice, in which heterozygous knockouts are mated to homozygosity), renders promoter-containing targeting vectors unsuitable for human somatic cell gene targeting. Instead, promoterless targeting vectors are required. In such targeting vectors, the selectable marker gene (generally *neo^r*) lacks its own promoter and is instead fused in-frame with the gene being targeted.

The most important critical parameter is the efficiency with which the targeting vector creates gene-targeted cell lines. Vectors vary in their efficiency from <0.1% to 40%. Unfortunately, it is not known why some targeting vectors work extremely well and others do not. In general, the authors recommend building targeting vectors in which the bigger homology arm is as long as possible, and which lack repeat elements in the homology arms. Unfortunately, it is difficult to troubleshoot a vector that either does not create knockouts (yet creates G418-resistant colonies) or does so with very low efficiency. In general, the authors attempt to create another targeting vector based on different homology arms that target a different exon. Studies have demonstrated that different targeting vectors for the same gene can work with

dramatically different efficiencies (Park et al., 2001).

Another critical parameter that is often difficult to predict ahead of time is whether the gene being targeted is an essential gene. One often does not learn this until after the homozygous targeting step, when each of the homologous integration events has disrupted the already targeted allele (and none has disrupted the remaining wild-type allele). For an example of this, see Kim et al. (2002b). One way to solve this problem is to modify the targeting vector to create a conditional knockout. Though creation of conditional knockouts is beyond the scope of this protocol, it is described in Cortez et al. (2001).

Anticipated Results

Upon completion of this protocol, one should have generated an isogenic set of human cells that differs only in the presence or absence of the targeted gene.

Time Considerations

Creation of gene-targeted human cell lines is a technically demanding and time-consuming process. It can take anywhere from 3 to 9 months to create a new targeting vector, and another 6 to 12 months to create homozygous knockout cell lines.

CHAPTER 10

Analysis of Proteins

INTRODUCTION

The purification and analysis of proteins is integral to designing oligonucleotide probes for gene cloning, confirming DNA sequence data, and synthesizing peptides for eliciting anti-peptide antibodies. This chapter presents protocols for the detection, separation, and purification of proteins. Additional aspects of protein analysis are covered elsewhere in this manual—e.g., in Chapter 12 (DNA-protein interactions), Chapter 16 (protein expression), Chapter 17 (protein glycosylation), Chapter 18 (protein phosphorylation), Chapter 19 (bioinformatics and sequence databases), Chapter 20 (protein-protein interactions), Chapter 21 (chromatin assembly and analysis), Chapter 24 (generation and use of combinatorial libraries), and Chapter 27 (RNA-protein interactions).

WHAT IS THE PROTEIN PROBLEM?

Briefly put, the protein problem is to try to understand the diversity, distribution, and function of proteins based on specific characteristics that can be determined using current technology. Whether one studies a solitary protein (if there is such a reality) or protein complexes involved in a biological function, one should ask the following questions: What is the molecular mass of the protein being studied? What are the shape and charge of the protein and its various molecular forms? Is the protein membrane-bound? Does the protein have more than one biological function? What is the copy number of the protein in the cell? What are the instantiation differences among cell types and physiological state of the cells from which the protein is being isolated? Is the protein found in protein complexes? If so, in how many different complexes? What are the kinetics and thermodynamics of protein complex formation? Do the structure and function of the protein complex depend on cell physiology? Is the protein present in more than one cellular compartment? How many molecular forms of the protein are there (i.e., variations in co- and post-translation, functional degra-

dition products, and complex inhibition or activation)?

Why is it important to answer these questions? Protein molecular mass varies between low (<6,000 Da) and high (>1,000,000 Da). A protein's molecular mass will affect the choice of purification method, since chromatographic matrices and polyacrylamide gels vary in pore size (defining molecular exclusion limits). The shape of an isolated protein is either globular (usually, an oblate ellipsoid) or fibrillar. Most proteins are globular in their native state (although this generalization may not apply intracellularly for all proteins), and most purification and analysis methods are tailored to working with globular proteins. The charge of most proteins is negative, although some are positively charged (e.g., histones). This is important to remember when choosing between anionic and cationic ion-exchange matrices (in general, choose anionic exchange). Proteins are arrays of hydrophilic or hydrophobic amino acids, and subtle changes in the distribution of charge and hydrophobicity can lead to changes in biological function and intracellular distribution. Proteins can be free or membrane-bound (i.e., bound to a lipid bilayer). Free proteins allow the use aqueous buffers during purification and analysis (occasionally requiring addition of mild nonionic detergents, e.g., for high-molecular-mass proteins or protein complexes); membrane-bound proteins always require the use of ionic detergents (i.e., SDS) or nonionic detergents (e.g., Tween, Triton X-100) to keep the protein in solution.

The function of any protein (or protein complex) is defined by a specific biological assay. In describing protein function, it is essential to remember that a protein characterized by one assay may function quite differently in another, and that an assay might reveal an artifact rather than the "true" biological function of a protein (or protein complex). Further, an assay is generally designed to comply with current biological dogma, and a class-specific protein assay will only reveal the expected

protein function. The number of protein-coding genes is agreed upon for many organisms. However, the number of distinct proteins contained in any cell and their copy numbers have not been determined unequivocally, since purification methods are innately destructive and detection methods can at best resolve proteins present at intermediate (100 to 1000 copies per cell) and high (>1000 copies per cell) copy numbers. Low-copy-number proteins (<100 copies per cell) are lost to non-specific binding on surfaces (tubes, tubing, and glass) or to natural or nonspecific protein complex interactions, where they remain undetectable by contemporary analytical methods. Protein instantiation (i.e., the variation among expressed protein types) represents the diversity between cell types and between cells of a given population. Until unicellular analysis of complete protein ensembles is possible, the complexity of intracellular protein diversity will remain a daunting challenge. Clearly, it is simplest to isolate a protein known to be enriched in a single organ (e.g., insulin from pancreas; erythropoietin from kidney). However, identifying each of the proteins that differentiate a pancreatic cell from a renal cell is beyond current protein purification and analysis methods.

Are all proteins associated with protein complexes? If one had a molecular device that could selectively pick a member of a protein complex and gently pull it from a cell, would every other protein in the complex come along? Would that complex be tethered to others that would in turn be recoverable? If so, what are the boundaries to such a network of complexes—i.e., a compartment, an entire cell? What are the relationships of a protein complex and its associated protein complexes with a defined biological pathway? How are the thermodynamics and kinetics of the complex regulated?

Proteins may be present simultaneously in more than one cellular compartment, as is known from regulatory pathways (e.g., the MAP kinase system). Does a given protein have the same biological function in each compartment? Are its molecular form (i.e., mass, charge, shape, and modification) and interactions with other proteins identical? If not, how do they differ?

The determination of the number of discrete molecular forms of a protein is beyond the capability of current methods of purification and analysis. This limitation is the result of variations in copy number, co- and post-translational modifications, folding

states, compartmental and complex distributions, degradation products, and combinations of these causes. In a higher eukaryotic cell, there may be >500,000 discrete proteins with subtle and possibly duplicative biological function, depending on their involvement in different pathways. There is no currently available purification or analysis method that would allow the deconvolution of this molecular system.

Answering these questions is at the heart of solving the protein problem. This chapter deals with what is known about protein purification and characterization. New innovations in protein science will be required to address the questions posed above.

The increasing expansion and sophistication of technologies for protein production and purification have encouraged the editors of *Current Protocols* to continue to expand the coverage of these issues. Thus, not only do several chapters of this manual now deal with specific aspects of protein analysis, but a companion volume in this series, *Current Protocols in Protein Science (CPPS)* (Coligan et al., 2006), is wholly devoted to strategies and protocols for purification and characterization of proteins. *CPPS* provides specific strategies and recommendations for experimental design of protein purification schemes for both native and recombinant proteins. In addition, it covers in depth and detail such topics as detection and separation of proteins from complex mixtures; computational, structural, and functional analyses; and detection and analysis of post-translational modifications. Throughout this introduction, reference is made, wherever appropriate, to the relevant chapters or units within *Current Protocols in Molecular Biology* and *CPPS*.

OVERVIEW OF PROTEIN PURIFICATION AND CHARACTERIZATION

Aims and Objectives

Most of the methods used in protein purification were established by the 1960s and 1970s, at least in their principles. More recent developments in protein purification have been mainly in instrumentation designed to optimize the application of each methodology. Developments in instrumentation have been stimulated by the rapid progress in molecular biology, because gene isolation has often been preceded by isolation of the gene product. Because such products can now be characterized sufficiently (i.e., partially sequenced)

using minute amounts of protein, the need for large-scale or even moderate-scale procedures has decreased. Hence there has been an explosive development of modern equipment designed specifically for dealing with amounts of protein in the milligram to microgram range. On the other hand, structural studies using X-ray crystallography and nuclear magnetic resonance (NMR) require hundreds of milligrams of pure protein, so larger-scale equipment and procedures are still needed in the research laboratory.

As more proteins, and particularly enzymes, were purified and crystallized, they started to be used increasingly in diagnostic assays and enzymatic analyses, as well as in the large-scale food, tanning, and detergent industries. Many enzymes used in industry are not in fact very pure, but as long as they do the job needed, that is sufficient. "Process" enzymes such as α -amylase, proteases, and lipases are produced in ton quantities, mainly as secretion products in bacterial cultures, and to minimize costs may undergo only limited purification processes. At the other extreme, enzyme products for research and analysis require a high degree of purification to ensure that contaminating activities do not interfere with the intended use. Anyone familiar with molecular biology enzymes will appreciate how minute levels of contamination with DNase or RNase can completely destroy carefully planned experiments.

The nature of the proteins studied has also changed substantially. Whereas enzymes were once the most favored subjects for research, they have now been superseded by nonenzymatic proteins such as growth factors, hormone receptors, viral antigens, and membrane transporters. Many of these are present in minute amounts in their natural source, and their purification can be a major task. Heroic efforts in the past have used kilogram quantities of rather unpleasant starting materials, such as human organs, and ended up with a few micrograms of pure product. It is now more usual, however, to take the genetic approach: clone the gene before the protein has been isolated or even properly identified, then express it in a suitable host cell culture or organism. The expression level may be orders of magnitude higher than in the original source, which will make purification a relatively simple task. It can be useful to know beforehand some physical properties of the protein, to facilitate the development of a suitable purification protocol from the recombinant source. On the other hand, there are now several ways of

preparing fusion proteins, which can be purified by affinity techniques without any knowledge of the properties of the target protein (see Chapter 16). Moreover, there are ways of modifying the expressed product to simplify purification further (*UNITS 10.11B & 20.2*).

Thus, the approach to protein purification must first take into account the reason it is being done, as the methods will vary greatly with different requirements. At one extreme is the one-of-a-kind purification, in a well-financed and equipped laboratory, that is carried out to obtain a small amount of product for sequencing so that gene isolation can proceed. Here, the expense of equipment and reagents may pose no problem, and a very low overall recovery of product can be acceptable, provided the product is pure enough. At the other extreme are the requirements of commercial production of a protein in large amounts on a continuing basis, where high recovery and economy of processing are the chief parameters to be considered. There are many intermediate situations as well.

Many publications in the area of protein research are entitled "Purification and characterization of . . .," and describe a purification procedure in sufficient detail that it can be reproduced in another laboratory. The characterization section may include structural, functional, and genetic information, and carrying out such studies is likely to require at least milligram quantities of pure protein. Ideally the purification should involve a small number of steps, with good recovery at each step. If the recovery is poor (<50% at any step), however, there should be some indication of what happened to the missing activity. Has it been discarded in the other fractions for the sake of purity, or does it represent a true loss of activity? If the latter, then the end-product may be less than fully active despite apparent homogeneity indicated by standard analysis. The choice between recovery and purification at each step can be problematical; taking a narrow cut of a chromatographic peak may provide a very pure fraction at the expense of losing a good deal of less pure active component on either side. In making such decisions, the objective of the exercise must be kept in mind: if yield is not important, then the tradeoff of poor yield for the sake of purity may be logical.

By far the most important requirement of a publication is reproducibility of the method reported. It is not sufficient to have carried out a process only once if it is expected that other investigators will want to repeat it. There are always factors that influence the process

but may be overlooked at first, and that can have a major effect on the purification procedure even if varied only slightly. The process being reported should always be repeated exactly as described before a manuscript is submitted for publication. There is one exception, namely, the case where purification was conducted simply to obtain enough protein for sequencing and gene isolation; if those objectives were achieved, there should be no need to provide instructions for repetition.

Sources of Material for Protein Purification

For many people embarking on a protein purification project, there is no choice of material. They are studying a particular biological tissue or organism, and the objective is to purify a protein from that source. However, there may be approaches that can make the project simpler. If, for instance, the source is difficult to obtain in large amounts, it may be best to carry out at least preliminary trials on a source species more readily obtained. The most obvious and relevant example is when the species being studied is *Homo sapiens*, and tissue samples are not readily available for practical or ethical reasons, or both. In this case, it is usual to go to where mammalian tissue is readily available (i.e., an abattoir) and work with bovine, ovine, or porcine sources. Alternatively, if quantity of tissue is not a problem, the humble laboratory rat may suffice. Once a protocol for purifying the protein from substitute sources has been worked out, it will be much easier to develop one using human material—the identical procedure may work satisfactorily. Proteins differ to a fairly small extent between species that have diverged within ~100 million years, a time frame that groups together most higher mammals. Thus, the behavior of proteins derived from different animals with respect to the various fractionation procedures is likely to be similar, and a protocol worked out for pig tissues is likely to need only minor adjustments for application to human tissues.

A second example is where the interest is mainly in the function of a protein, especially an enzyme, for which functions and actions have generally been strongly conserved through evolution. In that case, a preliminary screening of potential sources or, better still, the literature should provide a raw material that is best suited to the investigator's purposes. Considerations should include the following: (1) What functions are required of the end product? For instance, an enzyme having a

low K_m may be needed, so selecting the source with the highest activity may not suffice. (2) How convenient is it to grow or obtain the raw material, and are there problems relating to pathogenicity or extractability? (3) Does the quantity of the protein vary with growth conditions or age, and does the protein deteriorate in situ if left too long? Obviously one requires a source that reliably produces the highest amount of the desired protein per unit volume to maximize the chances of developing a good purification procedure. (4) What storage conditions are required for the raw material? It is important to consider that fresh raw material may not be immediately available whenever a purification is attempted.

The above considerations are relevant to the traditional situation for commencing a protein purification project. It is becoming increasingly common, however, for proteins to be purified as recombinant products using techniques in which the gene is expressed in a host organism or in cultured cells. This of course requires that the gene encoding the protein of interest be available. Until the mid-1980s, such material was usually obtained by hybridization of an oligonucleotide synthesized according to amino acid sequence information. This required the protein to have been purified first, so the initial task of protein purification still needed to be done at least once. More recently, genetic techniques have permitted the isolation of many genes encoding known proteins, even though the proteins may never have been studied directly. Moreover, with the completion of the Human Genome Project and related DNA sequencing efforts, many genes for both known and unknown proteins have become available and can be expressed in recombinant form without ever being purified from the host species. As a result some completely new considerations for protein purification come into play, including the possibility of modifying the gene structure not only to increase expression level and alter the protein product itself to enhance a desired function, but, equally importantly, to aid in purification. Recombinant proteins may be expressed in bacteria, yeasts, insect cells, and animal tissue cultures. Further details may be found in Chapter 16.

Detection and Assay of Proteins

During a protein purification procedure there are two measurements that need to be made, preferably for each fraction: total protein and amount of the desired protein (usually assessed in terms of bioactivity). Details of the most commonly used assay methods are

given in *UNIT 10.1A*. It is not possible to isolate a protein without a method of determining whether it is present; an assay, either quantitative or at least semiquantitative, indicating which fraction contains the most of the desired protein is essential.

Assays may range from the quick-and-easy type (e.g., instantaneous spectrophotometric measurement of enzyme activity) to long and tedious bioassays that may take days to produce an answer. The latter situation is very difficult, because by the time one knows where the protein is, it may be “was,” owing to degradation or inactivation. Moreover, this may not become clear until the next step has been completed and its products assayed. Any assay that is quick is therefore advantageous, even if this means sacrificing accuracy for speed.

Measurement of total protein is useful, as it indicates the degree of purification at each step. However, unless the next step critically depends on how much protein is present, measurement of total protein is not extremely important: a small sample can be put aside and measured later, when the purification is complete. It is, however, very important to know how much protein is present in the final, presumed pure sample, as this will indicate the specific activity (if the protein has an activity), which can be compared with that of other preparations. The general object is to obtain as high a specific activity as possible (taking into account recovery considerations), which means retaining as much of the desired protein as possible while ending up with as little total protein as possible.

Methods for Separation and Purification of Proteins

The methods available for protein purification range from simple precipitation procedures used since the nineteenth century to sophisticated chromatographic and affinity techniques that are constantly undergoing development and improvement. Methods can be classified in several alternative ways; perhaps one of the best is based on the properties of the proteins that are being exploited. Thus, the methods can be divided into four distinct but interrelated groups depending on protein characteristics: surface features, size and shape, net charge, and bioproperties.

Methods based on surface features

Surface features include charge distribution and accessibility, surface distribution of hydrophobic amino acid side chains, and, to a lesser extent, net charge at a given pH (see

discussion of net charge, below). Methods exploiting surface features depend mainly on solubility properties. Differences in solubility result in precipitation by various manipulations of the solvent in which the proteins are solubilized. Methods for obtaining an extract containing the desired protein in soluble form are given in Chapter 4 of *CPPS*. The solvent, nearly always water containing a low concentration of buffer salts, can be treated to alter properties such as ionic strength, dielectric constant, pH, temperature, and detergent content, any of which may selectively precipitate some of the proteins present. Conversely, proteins may be selectively solubilized from an insoluble state by manipulation of the solvent composition. The surface distribution of hydrophobic residues is an important determinant of solubility properties; it is also exploited in hydrophobic chromatography, both in the reversed-phase mode (*UNITS 10.12-10.14*) and in aqueous-phase hydrophobic-interaction chromatography.

Also included in this category is the highly specific technique of immunoaffinity chromatography (*UNIT 10.11A*), in which an antibody directed against an epitope on the protein surface is used to pull out the desired protein from a mixture.

Methods based on whole structure:

Size and shape

Although the size and shape of proteins can have some influence on solubility properties, the chief method of exploiting these properties is gel-filtration chromatography (*UNIT 10.9*). In addition, preparative gel electrophoresis makes use of differences in molecular size. Proteins range in size from the smallest classified as proteins rather than polypeptides (~5000 Da) up to macromolecular complexes of many million daltons. Many proteins in their bioactive states are oligomers of more than one polypeptide, and these can be dissociated, though normally with loss of overall structure. Thus, many proteins have two “sizes”: that of the native state and that (or those) of the polypeptides in the denatured and dissociated state. Gel-filtration procedures normally deal only with native proteins, whereas electrophoretic procedures commonly involve separation of dissociated and denatured polypeptides.

Methods based on net charge

Two separation techniques exploit the overall charge of proteins: ion-exchange chromatography (by far the most important) and

electrophoresis (*UNITS 10.2A, 10.3 & 10.4*; see also Chapter 10 of *CPPS*). Ion exchangers bind charged molecules, and there are essentially only two types of ion exchangers, anion and cation. The net charge of a protein depends on the pH—positive at very low pH, negative at high pH, and zero at some specific point in between, termed the isoelectric point (pI). It should be stressed that at its pI a protein has a great many charges; it just happens that at this pH the total negatives exactly equals the total positives. The most charged state (disregarding the charge sign) is in the pH range 6.0 to 9.0. This is the most stable pH range for most proteins, as it encompasses common physiological pH values. Ion exchangers consist of immobilized charged groups and attract oppositely charged proteins. They provide the mode of separation that has the highest resolution for native proteins. High-performance reversed-phase chromatography has equivalent or even better resolution, but it generally involves at least partial denaturation during adsorption and is not recommended for sensitive proteins such as enzymes. Protein purification using ion-exchange chromatography has mainly employed positively charged anion exchangers, for the simple reason that the majority of proteins are negatively charged at neutral pH (i.e., have a low isoelectric point). Details of this methodology are found in *UNIT 10.10*.

Methods based on bioproperties (affinity)

A powerful approach for separating the desired protein from others is to use a biospecific method in which the particular biological property of the protein is exploited. One such property is the affinity between a protein's binding site and its ligand: the ligand, when immobilized, attracts the protein from a mixture, while other molecules are washed away (*UNITS 10.11B & 24.5*). This general approach is known as affinity chromatography; there are also nonchromatographic methods of exploiting the same concept (*UNITS 10.20, 10.21, 10.24 & 10.27*). Although this direct affinity is limited to proteins with a natural binding activity, most proteins of interest do have specific ligands: enzymes have substrates and cofactors, and hormone-binding proteins, growth factors, and receptor molecules are designed to bind specifically and tightly to their natural partners. There are also other related affinity methods for nonbinding proteins. One is immunoaffinity chromatography (*UNIT 10.11A*), in which the "ligand" is an antibody to the protein in question. An equally important and

now widely used method is the creation of a fusion protein whose fused portion has a strong affinity toward an immobilized ligand (Chapter 16). For this latter technique it is not necessary for the protein of interest to have any binding property of its own; the fusion portion possesses a strong affinity for standardized immobilized ligands.

Characterization of the Protein Product

Once a pure protein is obtained, it may be employed for a specific purpose such as enzymatic analysis (e.g., glucose oxidase and lactate dehydrogenase) or as a therapeutic agent (e.g., insulin and growth hormone). However, it is normal, when a protein has been isolated for the first time, to characterize it in terms of structure and function. Several features are generally expected to be addressed (and reported in the literature) in the characterization of a new protein. One is the molecular weight, or at least the size of the subunit(s), which is determined by SDS-PAGE (*UNITS 10.2A-10.5*) and/or gel filtration (*UNIT 10.9*). Spectral properties such as the UV spectrum (Trp and Tyr content) and circular dichroism (CD) spectrum (secondary structure), and special characteristics of proteins with prosthetic groups (e.g., quantitation and spectra), may also be described. For glycoproteins, the number and nature of substituent carbohydrates should be determined (Chapter 17). Furthermore, if the gene has not already been reported, some amino-terminal sequence analysis should be given, if at all possible, along with the results of a database search for similar sequences (*UNIT 19.3*). Functional proteins should be demonstrated to have the appropriate function, and detailed kinetic characterization is appropriate for enzymes. Ultimately the full three-dimensional structure of the protein may be determined, which will require crystals; any successful crystallization attempts should be reported.

The Protein Purification Laboratory

The requirements for a protein purification laboratory cannot be exactly formulated because they depend greatly on the types and amounts of proteins being isolated. To cover all eventualities, it would be necessary to have one set of equipment to deal with submicrogram quantities and another set to deal with multi-gram quantities—a range of $\sim 10^8$! One laboratory dedicated to protein purification may not need small-scale equipment if, for example, its work involves plasma proteins that are

always available in large quantities. Another may have all the latest in high-performance equipment but not be able (nor need) to handle quantities of protein in excess of a few milligrams.

If it is assumed that neither extreme in quantity is to be attempted, and that the laboratory is handling a variety of protein types and sources, then certain basic pieces of equipment are needed. Obtaining the starting material and making an extract of it require homogenization equipment and centrifuges to remove insoluble residues. Preliminary fractionation starting from a crude extract of tissue or cells requires equipment and materials that will not become clogged by particulates. Adsorbents and similar materials used at the first step should be relatively inexpensive so that when performance falls off after a few uses, owing to intransigent impurity buildup, they can be discarded. It is also relevant that a larger amount is handled at the initial step than later steps; therefore, reagent expense can be an important consideration. After the first one or two steps, the sample should be sufficiently clean and clear to permit use of high-performance equipment.

High-performance liquid chromatography (HPLC) is a term with a variety of meanings (see *UNITS 10.12-10.14*). To some it refers exclusively to reversed-phase chromatography (here distinguished as RP-HPLC); to others it includes all sorts of chromatography, provided that the equipment is fully automated and high-performance adsorbents are used. A high-performance system designed specifically for proteins—produced by Amersham Pharmacia Biotech (see *APPENDIX 4*) under the name Fast Protein Liquid Chromatography or FPLC—uses standard protein chromatographies such as ion exchange, hydrophobic interaction, and gel filtration. Scaleup is possible with larger equipment based on the FPLC design, so that laboratory development can be quickly translated to large-scale production. FPLC is designed to separate proteins in their native active configuration, whereas RP-HPLC often causes at least transient denaturation during adsorption and elution. RP-HPLC has a high resolving power, but it is best suited to peptides and proteins smaller than ~30 kDa. Chromatography run with older-style low-pressure adsorbents is sometimes referred to as “low-performance” or “open-column” chromatography; neither of those descriptions is necessarily accurate. These methods require simple fraction collector and monitoring equipment. This equipment will be used for larger-scale

operations (tens of milligrams of protein and upward), probably at an earlier stage in the protocol than with HPLC.

Various columns, both prepacked with proprietary adsorbents and empty for self-packing, will be needed, with the sizes and types depending on the scale of operations. Several anion-exchange columns of different sizes, one or two cation-exchange columns, and gel-filtration media are all essential, along with a range of alternative adsorbents such as hydrophobic interaction materials, dyes, hydroxyapatite, and chromatofocusing and specialist affinity media.

Fully equipped protein purification laboratories should also have preparative electrophoresis and isoelectric focusing apparatuses for the rare occasions when other techniques fail to give sufficient separation.

In addition to equipment used in the actual fractionation processes, a variety of other items are needed. In particular it is important to be able to change buffers quickly and to concentrate protein solutions with ease. These operations require such items as dialysis membranes (*UNIT 10.5 & APPENDIX 3C*), ultrafiltration cells (*APPENDIX 3C*), and gel-filtration columns of various sizes (*UNIT 10.9*).

Finally, equipment for assaying and analyzing the preparations is needed. Most such equipment is fairly standard in biochemical laboratories and includes spectrophotometers, scintillation counters, analytical gel and capillary electrophoresis apparatuses, immunoblotting materials, and immunochemical reagents. A listing of standard equipment is found in *APPENDIX 2*.

STRATEGIES FOR PROTEIN PURIFICATION

Classification of Proteins

As with most heterogeneous collections of things, proteins can be classified in several different ways, such as by function, by structure, or by physicochemical characteristics. Each protein species consists of identical molecules with exactly the same size, amino acid sequence, and three-dimensional shape. In this way a solution of a mixture of proteins differs from a solution of synthetic polymers or sheared DNA, both of which contain a complete spectrum of possible sizes centered around the average. The protein mixture has only discrete sizes of molecules corresponding to each type of protein present. Although it would be possible to classify proteins by size, it would be of limited use, as there is

Table 10.0.1 Classification of Proteins by Structural Characteristics

Structural characteristic	Examples	Comments
Monomeric	Lysozyme, growth hormone	Usually extracellular; often have disulfide bonds
Oligomeric		
Identical subunits	Glyceraldehyde-3-phosphate dehydrogenase, catalase, alcohol dehydrogenase, hexokinase	Mostly intracellular enzymes; rarely have disulfide bonds
Mixed subunits	Aspartate carbamoyltransferase, pertussis toxin	Allosteric enzymes; different subunits have separate functions
Membrane-bound		
Peripheral	Mitochondrial ATPase, alkaline phosphatase	Readily solubilized by detergents
Integral	Porins, cytochromes P ₄₅₀ , insulin receptor	Require lipid for stability
Conjugated	Glycoproteins, lipoproteins, nucleoproteins	Many extracellular proteins contain carbohydrate

Table 10.0.2 Classification of Proteins by Function

Function	Examples
Amino acid storage	Seed proteins (e.g., gluten), milk proteins (e.g., casein)
Structural	
Inert	Collagen, keratin
With activity	Actin, myosin, tubulin
Binding	
Soluble	Albumin, hemoglobin, hormones
Insoluble	Surface receptors (e.g., insulin receptor), antigens (e.g., viral coat proteins)
With activity	Enzymes, membrane transporters (e.g., amino acid uptake systems, ion pumps)

usually no obvious relationship between size and function.

A more useful structural classification takes into consideration shape and oligomeric structure (Table 10.0.1). In part, structure reflects biological location and origin. Simple, fairly rigid protein molecules occur in the extracellular environment, more complex and readily deactivated molecules are found intracellularly, and hydrophobic proteins are associated with membranes.

Classification by function is even more relevant (Table 10.0.2). Proteins can be simply stores of amino acids, can be structural, or can have specific binding functions. The most

“functional” proteins are enzymes, which have both binding and catalytic roles. In part, this reflects the degree to which the detailed structure is a requirement for the protein’s function, which in turn relates to conservation of structure through evolution. But as with every attempt at classification, there will always be examples that do not fit the pattern well. Most proteins of interest to the pharmaceutical industry belong to the general class of binding proteins: for instance, hormones (e.g., insulin and bovine somatostatin), viral antigens (e.g., hepatitis B antigen), growth factors [e.g., interferons, interleukins and colony-stimulating factors (CSFs)], and antibodies.

Strategies Based on Classification

Soluble extracellular proteins

The source of soluble extracellular proteins is the extracellular medium, whether it be an animal source such as blood or spinal fluid, or a culture medium in which bacterial, fungal, animal, or plant cultures have been grown. Generally these do not contain a large number of different proteins (blood is an exception), and the desired protein may be a major component, especially if produced as the result of recombinant expression. Nonetheless, the protein in the starting material may be quite dilute, and a large volume may therefore need to be processed. The starting fluid may also contain many compounds other than proteins, whose behavior must be taken into account. The first stage should aim mainly to reduce the volume and remove as much nonprotein material as possible; some protein-protein separation is also useful, but not essential. No general rules can be given, but a batch adsorption method using an inexpensive material such as hydroxyapatite, ion-exchange resin, immobilized metal affinity chromatography (IMAC) medium, or affinity adsorbent is best, if feasible. Following the first step, the sample should be in a form that is amenable to standard purification processes such as precipitation and column chromatography (see Chapter 8 of *CPPS*).

Intracellular (cytoplasmic) proteins

To obtain soluble intracellular proteins (which are mainly enzymes), cells must be broken open or lysed to release their soluble contents. The ease with which cell disruption can be accomplished varies considerably; animal cells are readily broken, as are many bacteria, but plants and fungi have tough cell walls. Methods for obtaining cell extracts are given in Chapter 4 of *CPPS*. The macromolecular soluble contents of cells are mainly proteins, with nucleic acids as a minor but significant component. Bacterial extracts may be viscous unless DNase is added to break down the long DNA molecules. Although chromatographic procedures can be applied to crude extracts, valuable high-performance materials should not be employed in the first step, as there are always compounds, including unstable proteins, that may bind to them and be difficult to remove.

Membrane-associated proteins

There are two approaches to isolating a membrane-associated protein. In one method, the relevant membrane fraction can first be prepared and then used to isolate the protein. Alternatively, whole tissue can be subjected to

an extraction that solubilizes the membranes and releases the cytoplasmic contents as well. The former approach is much better in that purification is accomplished by isolating the membranes: the specific activity of the solubilized membrane fraction will be much higher than with the second method. However, the process of purifying the membrane fraction may lead to substantial losses, and it may be difficult to scale up. If total recovery of the protein is more important than purity, a whole-tissue extract is likely to be more appropriate. Although this means that a greater degree of purification is needed, the fact that membrane proteins, by definition, have properties somewhat different from those of cytoplasmic proteins permits some very effective purification steps (e.g., hydrophobic chromatography).

Peripheral membrane proteins are only loosely attached and may be released by gentle conditions such as high pH, EDTA, or low (nonionic) detergent concentrations. Once in solution, some peripheral proteins no longer require the presence of detergent to maintain their solubility. Integral membrane proteins are much more demanding—they require high concentrations of detergent for solubilization (i.e., complete solubilization of the membrane is needed to release them) and generally are neither soluble nor stable in the absence of detergent. It is sometimes necessary to maintain natural phospholipids in association with the proteins in order to maintain activity. Even when the final objective does not require activity (e.g., protein sequencing), it is generally necessary to maintain bioactivity so that an assay can be used to monitor the presence of the protein during the purification process. If a particular band on a gel is known to be the desired protein, then no other assay is needed and loss of bioactivity can be allowed.

Purification processes may be affected by the presence of detergents. The problem of association with detergent micelles makes purifying integral membrane proteins difficult; the close association of the different proteins originating from membranes often results in very poor separation in conventional fractionation procedures.

Insoluble proteins

Natural proteins that are insoluble in normal solvents are generally structural proteins, which are sometimes cross-linked by post-translational modification. The first stage of purification is obvious—it involves extracting and washing away all proteins that are soluble, leaving the residue containing the desired

material. Further purification in a native state, however, may be impossible; extracting away other proteins using more vigorous solvents or attempting to solubilize the target protein may destroy the natural structure. Cross-linked proteins such as elastin or collagen cannot be dissolved without breaking the cross-links, and the individual proteins may even be cross-linked together.

Insoluble recombinant proteins (inclusion bodies)

A major new class of insoluble proteins are recombinant proteins expressed (usually in *E. coli*) as inclusion bodies. These are dense aggregates found inside cells that consist mainly of a desired recombinant product, but in a nonnative state. Inclusion bodies may form for a variety of reasons, such as insolubility of the product at the concentrations being produced, inability to fold correctly in the bacterial environment, or inability to form correct, or any, disulfide bonds in the reducing intracellular environment. Their purification is simple, as the inclusion bodies can be separated by differential centrifugation from other cellular constituents, giving almost pure product; the problem is that the protein is not in a native state and is insoluble. Some methods for obtaining an active product from inclusion bodies are described in *CPPS* (Palmer and Wingfield, 2004).

Soluble recombinant proteins

Recombinant proteins that are not expressed in inclusion bodies either will be soluble inside the cell or, if an excretion vector is being used, will be extracellular (or, if *E. coli* is the host, possibly periplasmic). They can be purified by conventional means. In some systems, expression is so good that the desired product is the major protein present and its purification is relatively simple. In systems where the expression level is low, the purification process can be tedious—though easier, it can be hoped, than isolation from the natural source. It should be remembered that a procedure developed for isolating a protein from natural sources may not work successfully with the recombinant product, because the nature of the other proteins present influences many fractionation procedures.

Many recombinant proteins are now produced in a fusion form in which the fusion portion is designed to facilitate purification by affinity chromatography (*UNIT 10.11B*). A variety of “fusion tags” are available as part of the expression vector (see *UNITS 16.6–16.8*

and Sassenfeld, 1990, for specific examples). These include whole proteins such as protein A, glutathione-S-transferase, and maltose-binding protein, as well as short peptide segments that may be recognized by a specific antibody, become biotinylated in the host cell, or bind tightly to an immobilized metal ion adsorbent. Nearly complete purification can be achieved in one step by passing the crude extract through an appropriate adsorbent and eluting specifically. A further advantage of the fusion approach is that expression levels are likely to be determined more by the transcription and translation signals for the fusion peptide (which have been optimized in the vector) than by the structural features of the inserted gene. The only remaining task is to remove the fusion peptide, though for some purposes this is not necessary (see *UNIT 16.4B*). This requires a proteolytic step: highly specific proteases such as blood clotting factors are generally used, their recognition sites having been incorporated in the sequence joining the fusion peptide. It is sometimes convenient to “digest” the fusion protein from the adsorbent using the protease.

Unstable proteins may be modified by the molecular biological technique of site-directed mutagenesis to remove the site of instability—for instance, an oxidizable cysteine. Such techniques are appropriate for commercial production of proteins, but may of course alter natural functioning parameters. One modification that can be useful is increased thermostability, although it is not easy to predict mutations that will improve that parameter. Thermostable proteins originating from thermophilic bacteria do not need structural modification and, if expressed in large amounts, can be purified satisfactorily in one step by simply heat-treating the extract at 70°C for 30 min, which will denature virtually all the host proteins (e.g., see Oka et al., 1989).

The host bacteria used for production of recombinant proteins are usually *E. coli* or *Bacillus subtilis*; they may express proteins at anywhere from 1% to >50% of the cellular protein, depending on such variables as the source, promoter structure, and vector type. Generally the proteins are expressed intracellularly, but leader sequences for excretion may be included. In the latter case, the protein is generally excreted into the periplasmic space, which limits the amount that can be produced. Excretion from gram-positive species such as *B. subtilis* sends the product into the culture medium, with little feedback limitation on the total expression level.

PROTEIN PURIFICATION FLOW CHARTS

Protein purification flow charts are presented to give a broad outline of the methods used for different types of proteins. They cannot give any detail, as the process appropriate for each protein will have its own variations at each stage. In most cases, the first stage is to obtain a solution containing the desired protein, after which it can be dealt with by the many separation techniques described in the following chapters. In some cases the insolubility of the desired protein can be exploited by removing soluble fractions. Purification procedures are commonly divided into three stages: (1) the primary steps deal with crude mixtures of proteins and other molecules present in the raw material; (2) the secondary processing generates a product near homogeneity; and (3) the polishing steps remove minor contaminants, a process that is especially important for therapeutic proteins.

Soluble Recombinant Proteins

Proteins expressed in a recombinant manner may be (1) soluble in the cytoplasm, (2) insoluble as inclusion bodies, (3) excreted from the cells into the culture medium, (4) excreted into the periplasmic space (e.g., in gram-negative bacteria), or (5) associated with organelles or membrane fractions. In addition they may be expressed (6) as the normal, mature, naturally occurring protein, (7) containing a natural leader peptide that would normally be processed, (8) as a fusion protein with a peptide that is not natural to the protein, or (9) lacking glycosylation or other posttranslational modification, or modified incorrectly. Possibilities (1) to (5) affect the method of extraction used to obtain the starting material for purification. Cases (6) to (9) can affect the methods used for purification.

The scheme for purifying soluble recombinant proteins is outlined in Figure 10.0.1. The first stage is to obtain a clarified solution containing the desired protein, with as little in the way of unwanted proteins as possible. For soluble cytoplasmic proteins, case (1), it is not normally possible to exclude any significant amount of unwanted soluble proteins, but in cases (2) to (5) the compartmentalization away from the cytoplasm allows such separation in the initial stage.

It may be necessary to carry out a concentration step before proceeding, especially if the protein has been excreted into the culture medium. Normally ultrafiltration is used (see APPENDIX 3C), although other tech-

niques are possible, especially if the extract contains particulates that block ultrafiltration membranes.

Recombinant expression in the cytoplasm of bacteria followed by extraction via total cell disruption results in large amounts of nucleic acids being solubilized with the protein. A number of treatments to remove nucleic acids are possible. Streptomycin is used to precipitate ribosomal material, and cationic polymers such as protamine (a basic protein) and polyethylenimine will form insoluble complexes (at low ionic strength) with nucleic acids. In addition, viscosity caused by DNA can be reduced by adding small amounts of DNase.

Insoluble Recombinant Proteins

It has been found that many proteins do not fold correctly when expressed in bacteria (mainly in *E. coli*), and as a result aggregation occurs, leading to large insoluble inclusion bodies within the cytoplasm of the cells (see Chapter 6 of CPPS). Although this creates major difficulties in obtaining satisfactory amounts of active native product, it greatly simplifies the initial stage of purification.

The purification scheme for recombinant insoluble proteins is outlined in Figure 10.0.2. After cell disruption, inclusion bodies can be obtained in a fairly pure state by differential centrifugation. They must then be solubilized, however, and the active protein generated by encouraging correct folding. Solubilization is usually accomplished with guanidine hydrochloride and/or urea, and thiols such as 2-mercaptoethanol or glutathione are included to disrupt any disulfides that have formed and prevent more from forming. Folding the protein correctly may require a variety of additions to the solution, as well as slow removal of the denaturant. The latter can be carried out by simple dilution or by dialysis (APPENDIX 3C). Folding occurs best at low protein concentrations, so dilution may be adequate. If the native protein does contain disulfides, then it is important to create redox conditions such that some (but not excessive) oxidation of thiols can occur. A combination of oxidized and reduced glutathione is commonly used. In addition, the action of the enzyme protein disulfide isomerase, which can make and unmake disulfides by exchange reactions, has been found to be beneficial in many cases. If the native protein is of intracellular origin, it probably will not contain disulfides; it will, however, contain cysteines, so a full reducing potential should be maintained.

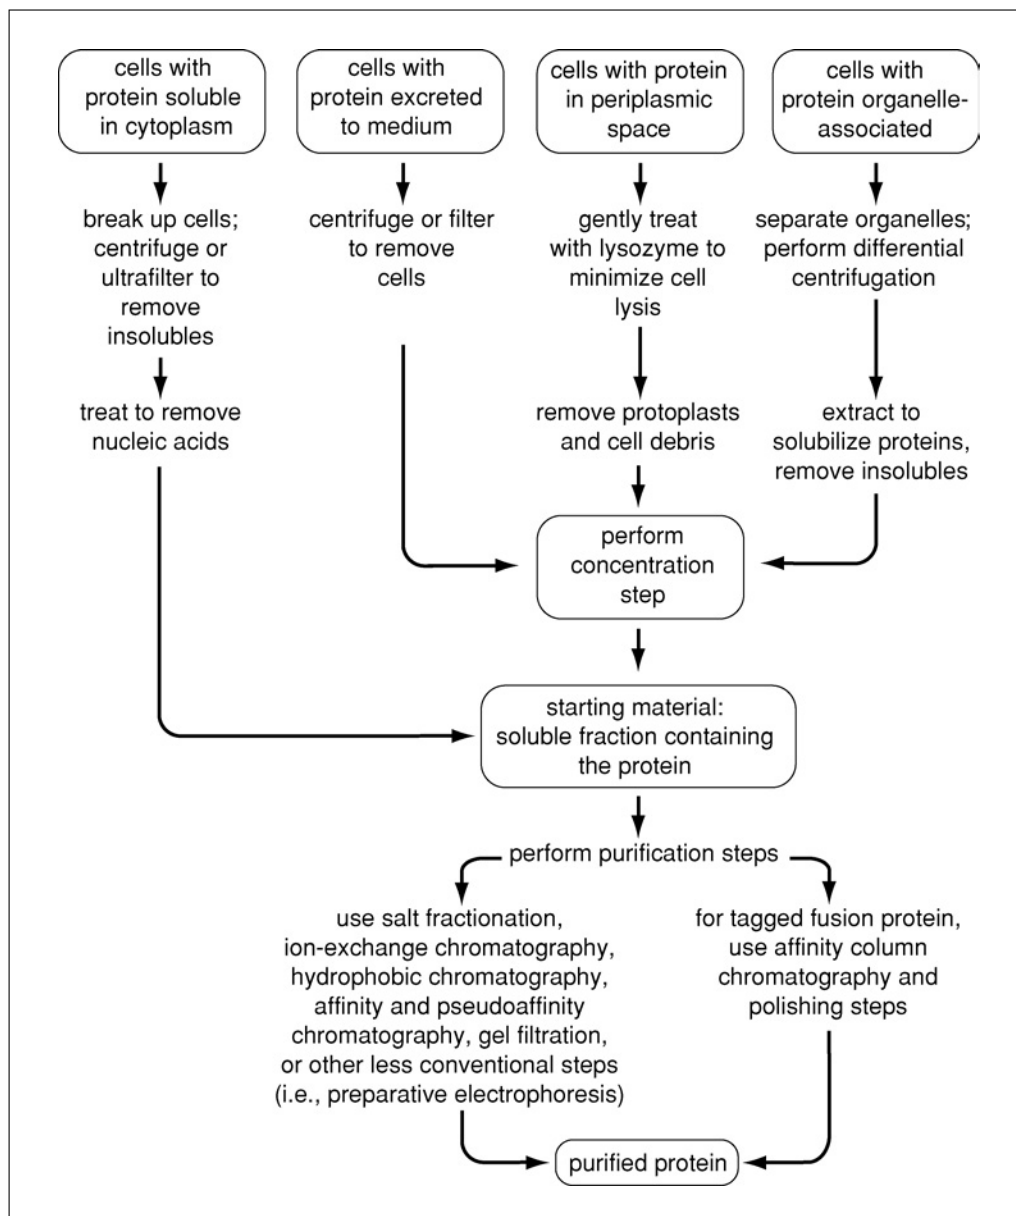

Figure 10.0.1 Purification scheme for soluble recombinant proteins, which may be excreted or located in the periplasm, the membrane fraction, or most commonly the cytoplasm. The first step is to obtain an extract containing the desired protein in soluble form. After this, conventional purification steps may be carried out, or affinity purification of tagged fused proteins can be performed.

Specific methodology is discussed in *CPPS* (Wingfield, 1995; Wingfield et al., 1995).

Not all proteins can fold unassisted by other cellular components. Chaperonins are proteins whose role is to assist in folding proteins including those unfolded by heat shock (Zeilstra-Ryalls et al., 1991). The ones most studied, which are just becoming commercially available as of 1996, are the *E. coli* chaperonins GroEL and GroES, both of which are needed, together with ATP, to renature many proteins. Proline residues can adopt two isomeric conformations in proteins, and the wrong con-

formation is switched to the correct one by the enzyme prolyl isomerase, aiding the process of protein folding. At present these are not large-scale prospects, both because of the cost of the chaperonins and because the agents operate best in vitro at very low protein concentrations.

Once the proteins are folded, the purification process consists of removing small amounts of still incorrectly folded protein plus any other host proteins that were trapped with the original inclusion bodies. The former may be difficult, as incorrectly folded species have

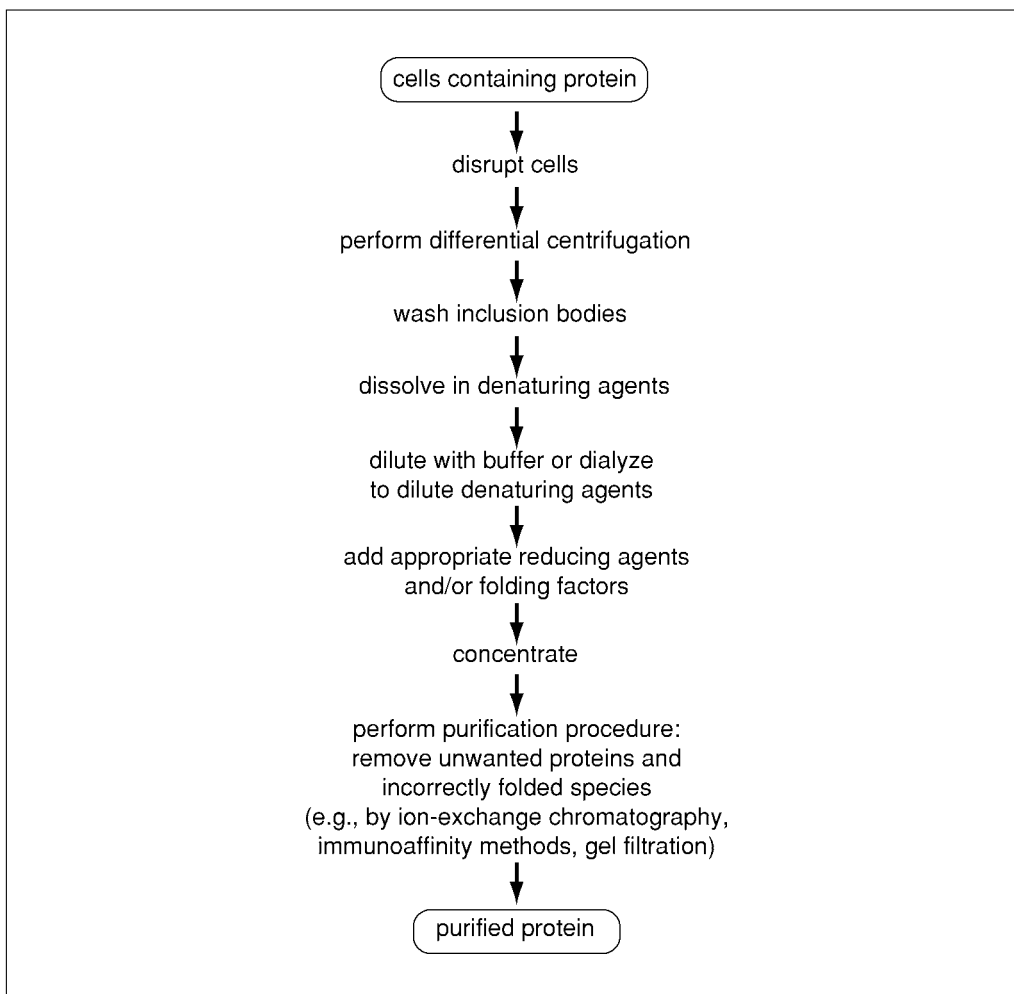

Figure 10.0.2 Purification scheme for insoluble recombinant proteins that are produced as inclusion bodies in the cytoplasm of host cells. The cells must be broken open and the insoluble inclusion bodies separated by differential centrifugation. Solubilization is achieved by the use of denaturing solvents, and renaturation of the dissolved protein occurs on removal of the denaturant. Further polishing steps will be needed to remove small amounts of contaminating proteins as well as incorrectly folded species. Additional information can be found in *CPPS* (see Pain, 1995; Wingfield et al., 1995; Palmer and Wingfield, 2004).

a size and charge similar to those of the correct product. However, subtle differences arising from the folded conformation can be exploited by chromatographic techniques. In ideal cases immunoaffinity techniques using antibodies specific for either the incorrectly folded form or the correct one can be used to resolve the mixture.

Soluble Nonrecombinant Proteins

There are so many sources of soluble proteins that it is not possible to give a complete overview of methods used to obtain starting extracts from which a desired protein can be isolated. The sources can be classified as either microorganisms, plants, or animals, as shown in Figure 10.0.3, but these in turn should be subdivided according to how the starting ex-

tract is obtained. In particular there is a distinction between extracellular and intracellular proteins. With the latter it is necessary to disrupt the cells and release the proteins, whereas with the former, if the extracellular fluid can be obtained directly, there need be no contamination with intracellular proteins. Extracellular sources include microorganism culture medium, plant and animal tissue culture medium, venoms, milk, blood, and cerebrospinal fluids. Soluble proteins may also occur within organelles such as mitochondria; these may best be obtained by first isolating the organelle, then disrupting it to release the contents.

The starting extract normally contains between 5 and 20 mg protein per milliliter, though lesser concentrations can be dealt with,

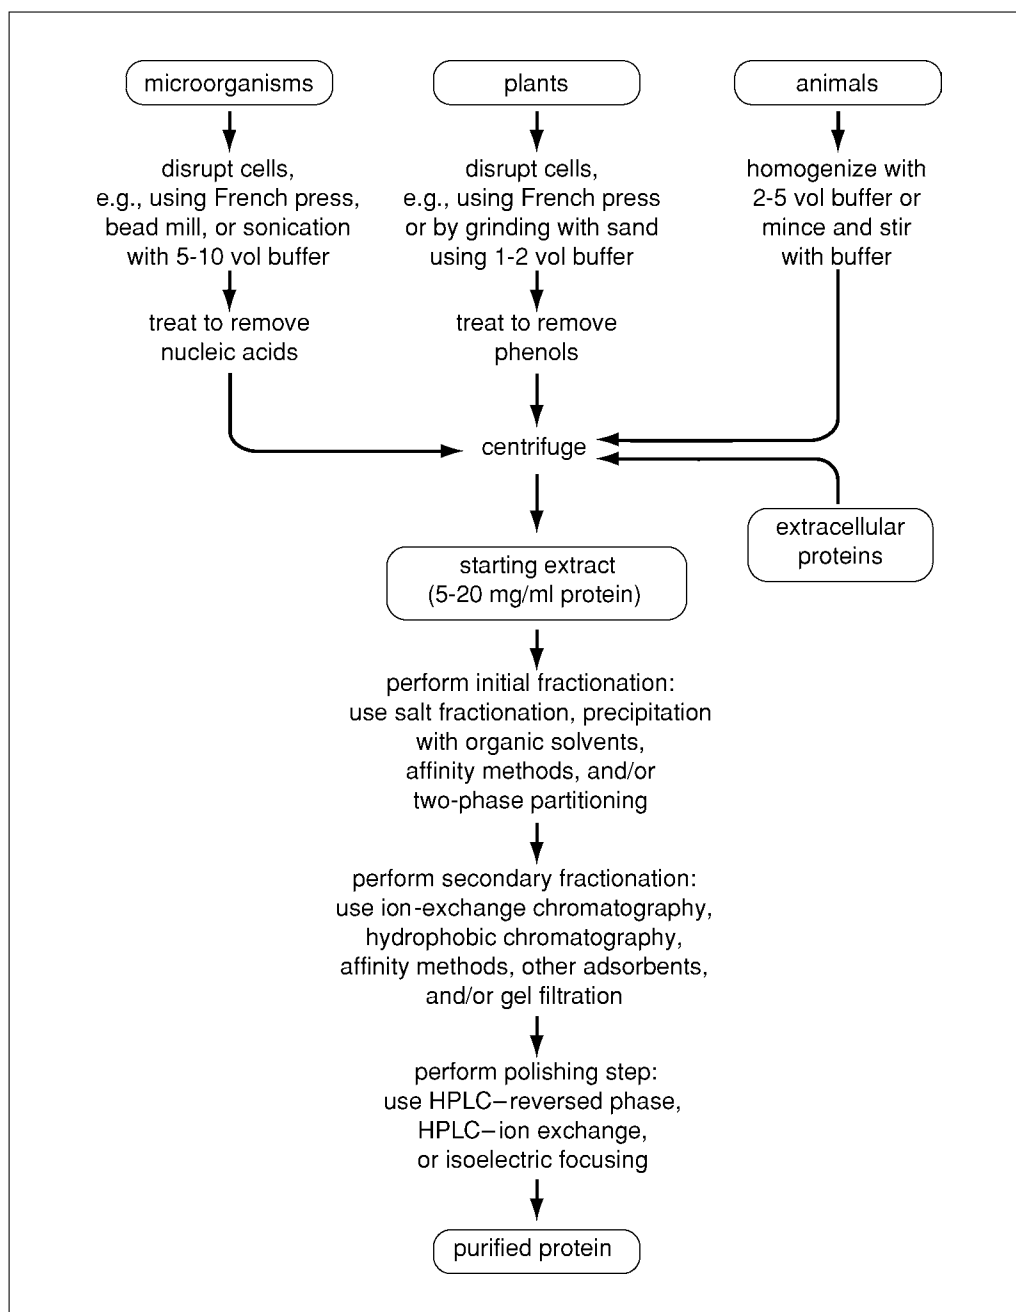

Figure 10.0.3 Purification scheme for soluble proteins present in their natural host cells. Cells must be disrupted to release the proteins, usually in the presence of 2 to 10 ml of a suitable buffer per gram weight. After removal of insoluble material, the process will generally require several steps, using various standard fractionation procedures in a suitable order. For production of highly pure protein, a final polishing step may be required to remove final trace contaminants. Additional information can be found in *CPPS* (see Wingfield, 2005).

especially if working on a small scale. It may be necessary to include a concentration step before starting the purification process in order to approach that level. There are exceptions to every rule, however, and very high protein concentrations can be handled, for example, with two-phase partitioning (Walter and Johansson, 1994). When isolating proteins on

a large scale, the volumes being manipulated become of increasing concern, so maximizing protein concentration can be an important aim. The starting extract should be clarified, usually by centrifugation; on a large scale, ultrafiltration methods (*APPENDIX 3C*) are becoming more widely used. Pretreatment of certain extracts to remove excessive amounts of nucleic

acids, phenolics, and lipids may be necessary in order to obtain an extract that is amenable to standard fractionation procedures.

Fractionation procedures can somewhat arbitrarily be divided into three steps: initial fractionation, secondary fractionation, and polishing. In initial processing, which deals with a large amount of extract that is not all protein, materials may become soiled and may be unable to be used many times. Consequently, methods that do not require expensive reagents or adsorbents are preferred. Classic salt fractionation and the less-used organic solvent fractionation can achieve, if not a high degree of purification, a useful level of concentration and removal of much unwanted nonproteinaceous material. Alternatively, a highly selective affinity procedure may be used as the first step, but only if the affinity material is inexpensive to make and/or the extract is a simple, clear solution as opposed to a turbid whole-cell homogenate.

Secondary processing achieves the main purification, and in difficult situations may involve two or more steps. Ion-exchange (*UNIT 10.10*) and hydrophobic-interaction chromatography, gel filtration (*UNIT 10.9*), and affinity techniques (*UNITS 10.11B & 20.2*) are the main procedures. Finally, it may be necessary to remove traces of contaminants by “polishing” using high-resolution procedures such as RP-HPLC (*UNITS 10.13 & 10.14*) and isoelectric focusing (IEF; *UNITS 10.3 & 10.4*). Because every protein has unique characteristics, it is impossible to make general statements about procedures to be followed.

Membrane-Associated and Insoluble Nonrecombinant Proteins

Proteins that are not physiologically soluble can be purified after extracting and removing soluble proteins, thereby achieving a substantial degree of purification at the extraction step (Fig. 10.0.4; also see Wingfield, 2002, 2005). To carry out a purification it is nearly always necessary to obtain the desired protein in a soluble form, which will often require the addition of solubilizing agents such as detergents. Some proteins remain insoluble even with detergent treatment, and so can be substantially purified by removing the soluble fractions. Some membrane-associated proteins become partly solubilized during breaking up of the tissue, and recovery in the particulate fraction may be poor. In such cases it may be best to solubilize the whole tissue by including detergent in the homogenizing buffer. Extraction of insoluble residues using

detergents can be done differentially; some proteins are released at low detergent concentration, whereas others require complete solubilization of the membrane fraction. Suitable detergents include nonionic (e.g., Triton) and weakly acidic types (e.g., cholic acid derivatives). Strongly acidic detergents such as sulfate esters (e.g., sodium dodecyl sulfate) usually cause denaturation.

Detergents can be removed either by adsorption of the protein on a column and subsequent elution without detergent, by use of special detergent-adsorbing beads, or even by extraction with nonmiscible organic solvents in which the detergent partitions. On the other hand, many membrane proteins require the presence of detergent at all times in order to remain in solution and in a native conformation. These include most integral membrane proteins, for example cytochrome P₄₅₀, transmembrane receptors, and transporters. The most sensitive proteins require a particular combination of natural lipids (in addition to the detergent) to maintain structural integrity. Purification methods include most of those used for soluble proteins, but some techniques are not recommended if detergent is needed at all times. For instance, ammonium sulfate precipitation will often cause a detergent-protein complex to come out of solution and float rather than sink on centrifugation; this can be useful, but the “floatate,” when redissolved, may have a high detergent content. Hydrophobic chromatography can be very useful, as membrane proteins are naturally hydrophobic.

Integral membrane proteins that are completely insoluble in normal detergents may be solubilized by denaturation using compounds such as sodium dodecyl sulfate and guanidine hydrochloride. Some cross-linked proteins such as elastin are not soluble without disruption of the covalent linkages.

WHAT THIS CHAPTER COVERS

This chapter consists of protocols that permit researchers to obtain answers to the questions described above: How much protein is there? Is the protein pure? Does the protein have subunits? How many protein subunits are there? How is the protein isolated? How can the protein be synthesized *in vitro*? How can a protein be biosynthetically labeled? How can amino-terminal sequences of scarce proteins be determined? How can internal sequences be derived from N-terminally blocked proteins?

As indicated in Figure 10.0.5, the answer to the first question is provided by colorimetric and spectrophotometric methods (*UNIT 10.1A*)

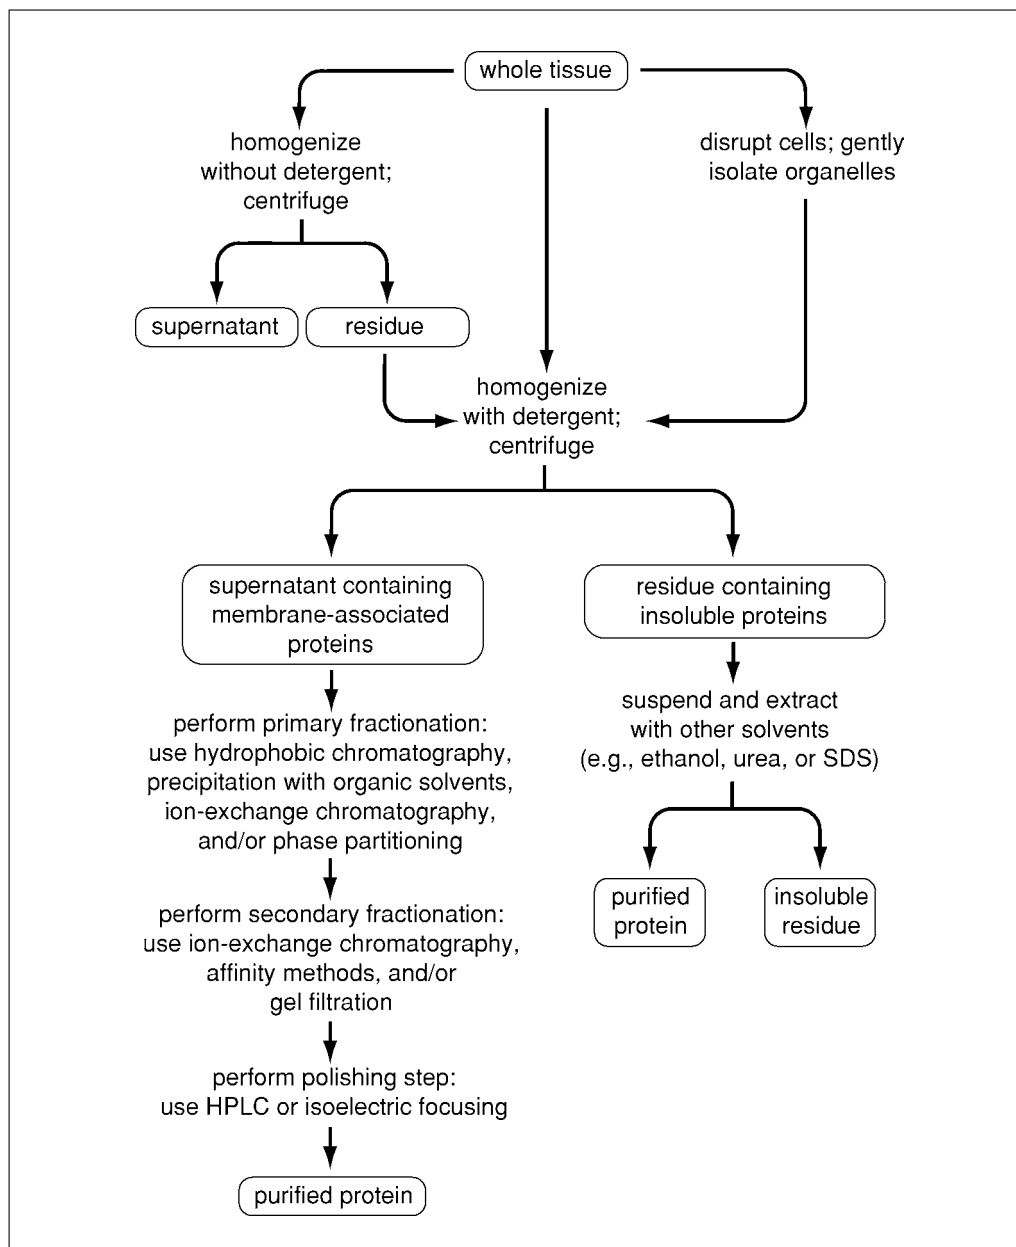

Figure 10.0.4 Purification scheme for membrane-associated and poorly soluble proteins (nonrecombinant). An initial purification can be achieved by isolation of organelles containing the desired protein. Membrane proteins are normally solubilized with a nonionic detergent, although loosely associated proteins may be extracted without detergent at high pH, with EDTA, or with small amounts of an organic solvent such as *n*-butanol. Normal fractionation procedures may need some modification if the detergent is required throughout to maintain the integrity of the protein.

and by amino acid analysis (UNIT 10.1B). The amount of protein can also be determined by comparing the staining intensity of an unknown protein to the staining intensity of protein standards separated by either one- or two-dimensional polyacrylamide gel electrophoresis (PAGE; UNITS 10.2A-10.4). UNIT 10.5 describes the process required for digital imaging of one- and two-dimensional gels from image capture using scanners to image manipulation and analysis using advanced imag-

ing software. Digital imaging is an immensely useful technique for analyzing changes in protein expression and is a mainstay for functional genomic analysis. Proteins can also be stained while they are still within the polyacrylamide gel (UNIT 10.6) or after they have been transferred to a blot transfer membrane (UNITS 10.7 & 10.19). In addition, protein-specific monoclonal or polyclonal antibodies can be used for detection by immunoblotting (UNIT 10.8).

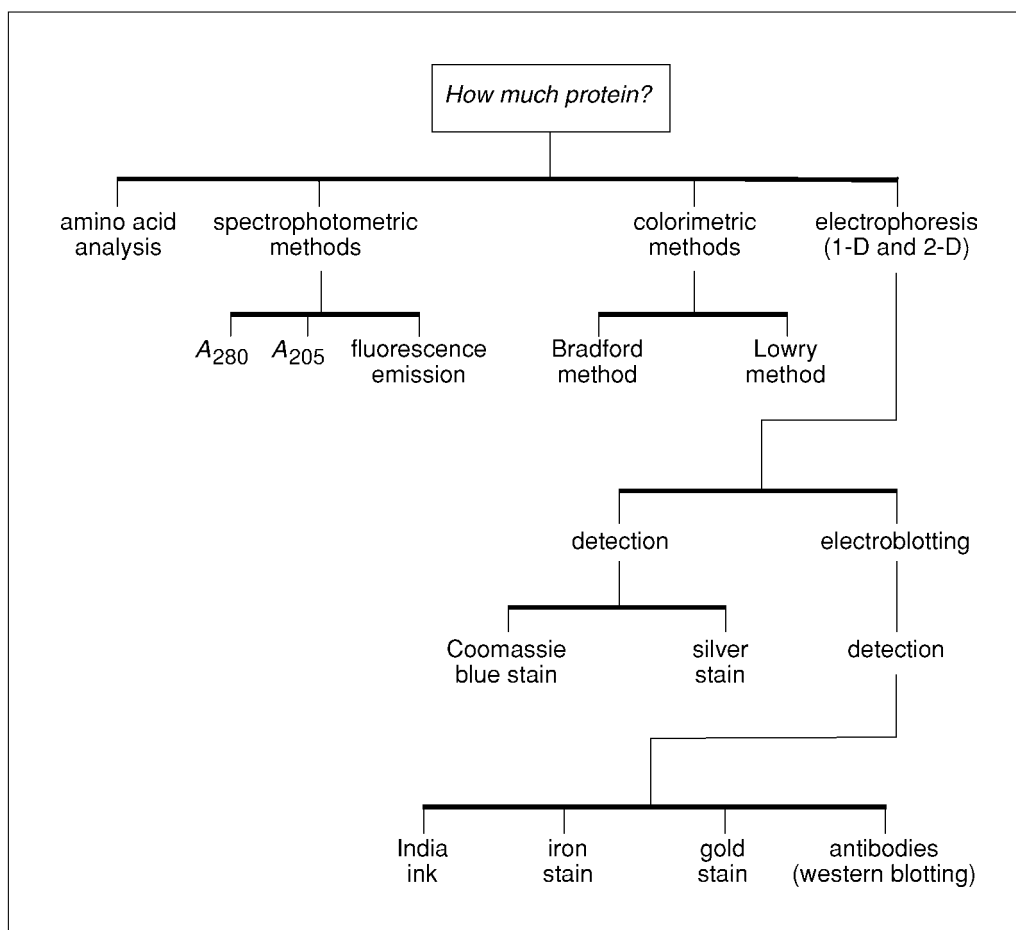

Figure 10.0.5 Quantitation of proteins.

Another method for quantifying a protein (or peptide) in a sample is the radioimmunoassay (RIA), which is presented as a solution-based assay in *UNIT 10.24*. A solution RIA determines the amount of a specific protein in an unknown sample by comparison to a standard curve developed using known amounts of the same protein. The amount of protein in the unknown sample and standards is determined based on the protein's ability to compete with radiolabeled protein (the tracer) for binding to an antibody against the protein. A secondary antibody and PEG are used to precipitate the antibody-protein complexes. Because this is a competition assay, the amount of radioactivity in the complex is inversely proportional to the amount of protein in the sample. Under ideal conditions, an RIA is capable of measuring picograms of antigen, but the tracer must be radiolabeled at a high specific activity. Radioiodine (either ^{125}I or ^{131}I) is the label of choice. The solid-phase RIA (*UNIT 11.17*) may also be used for proteins and polypeptides, but is not appropriate for peptides, since the solid-phase method requires that two antigenic sites be present in the antigen being measured. Al-

though two or more antigenic sites are likely in the case of proteins and polypeptides, they are unlikely in the case of short peptides.

The answers to the next three questions come from an analysis of the data derived from a combination of electrophoresis and chromatography—i.e., conventional gel filtration or size-exclusion high-performance liquid chromatography (HPLC; see Fig. 10.0.6). For a protein without subunits or a protein with identical subunits, detection of a single protein band after one-dimensional gel electrophoresis under denaturing conditions or a single spot after two-dimensional gel electrophoresis indicates that the protein is pure. If the protein consists of multiple subunits of different molecular sizes, purity is confirmed by detecting a single stainable band after gel electrophoresis under nondenaturing conditions. Once the protein is demonstrated to be pure, an estimate of the molecular size of the protein is made by comparing the elution volume of the protein from a conventional gel-filtration or high-performance size-exclusion column to the elution volumes of standard proteins. An estimate of the size of the subunits can

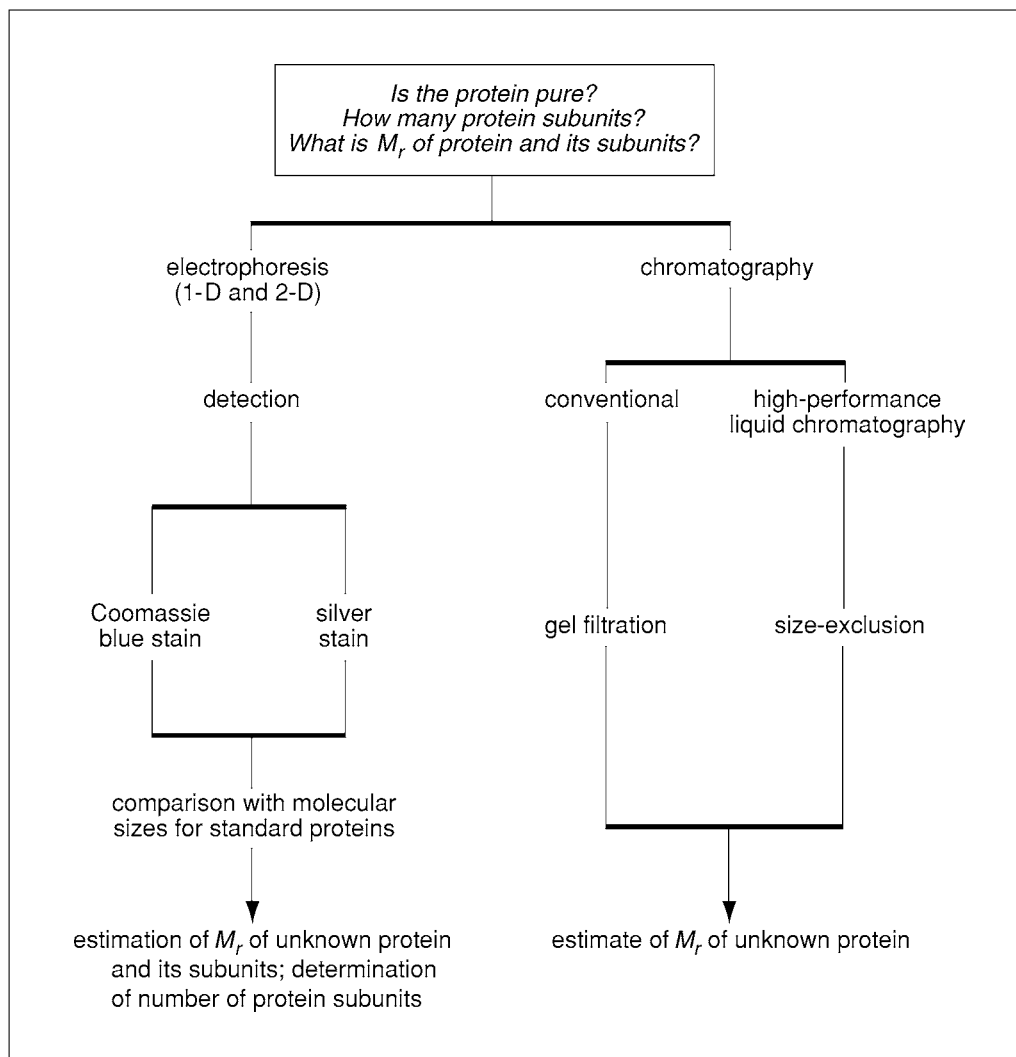

Figure 10.0.6 Analysis of protein purity, molecular weight, and subunit structure.

be determined by subsequent electrophoresis under denaturing conditions. The number of each subunit is then deduced by comparing the molecular size of “native” (i.e., nondenatured) protein and the molecular size(s) of the subunit(s).

To determine how a protein or protein fragment should be isolated, the following factors must be considered: (1) the amount of a protein in the available starting material, (2) the cost of preparing starting material (e.g., cell culture, fermentation, or organs) and the cost of labor, (3) the molecular size of the protein, and (4) the physical properties of the protein. In most cases a protein is being isolated and purified in order to ascertain partial protein sequence information by automated Edman degradation using a commercially available protein sequencer. However, almost all proteins are isolated by a combination of conventional chromatography, HPLC, and electrophoresis (Fig. 10.0.7).

Each of these isolation methods is discussed in detail in the following sections of this introduction.

Both one- and two-dimensional gel electrophoresis are high-resolution separation methods, yielding protein whose sequence can be determined after electroblotting onto polyvinylidene difluoride (PVDF) membrane filters (which are compatible with a gas-phase protein sequencer; UNIT 10.19) or capillary electrophoresis (UNITS 10.14 & 10.20). In most cases, electrophoretic methods are used after several successive modes of conventional chromatography or HPLC have been used to purify progressively a given protein from a crude protein mixture. However, if the protein is separated under denaturing conditions, the biological activity of a desired protein will likely be lost. This is a reason for utilizing gel electrophoresis last when purifying a protein whose identity is based on a functional assay.

advantages of HPLC over conventional chromatography are that small amounts (<1 nmol) of a given protein can be handled and purified, less time is required for a separation (<3 hr), and reduced chromatographic peak volume is achieved. RP-HPLC is primarily useful for purifying small proteins (molecular weight <20,000) and protein fragments (discussed below).

UNIT 10.15 describes epitope tagging, an innovative technique whereby an epitope (i.e., an antigenic site) is genetically engineered into a protein to provide a convenient tag to isolate the expressed protein from complex protein mixtures (such as cell lysates). Antibodies directed at the antigenic site interact with the tagged protein to form immune complexes, known as immunoprecipitates. Immunoprecipitation is another method of protein purification (*UNIT 10.16*) by which a specific protein can be selectively precipitated from a complex protein mixture, provided that specific antibodies directed against the protein are available. Both conventional and monoclonal antibodies may be employed for immunoprecipitation. Studies involving protein-protein interactions (*UNITS 20.1–20.6*), far western analysis (*UNIT 20.6*), chromatin assembly analysis (*UNIT 21.3*), aptamer-protein interactions (*UNITS 24.2–24.4*), and RNA-protein interactions (*UNITS 27.3 & 27.4*) are variations of these affinity approaches.

Another approach is the *in vitro* synthesis of proteins by transcription and translation of cloned genes (*UNIT 10.17*). Such *in vitro*-synthesized proteins are extremely useful for a variety of purposes including analysis of DNA-protein interactions and studies of mutant proteins obtained from mutagenesis of cloned DNA. In this approach, the protein-coding sequences are cloned into a vector containing a promoter for SP6 or T7 RNA polymerase. Messenger RNA encoding the protein is generated by transcribing the DNA template with the appropriate bacteriophage RNA polymerase. The essentially pure mRNA is then translated *in vitro* using wheat germ extracts or reticulocyte lysates. By using [³⁵S]methionine during the translation reaction, the protein is synthesized as a radiolabeled species. For most applications, *in vitro*-synthesized proteins can be used directly without any further purification. A major advantage of this method is that any desired mutant protein can be generated simply by altering the DNA template.

Biosynthetic labeling techniques are commonly used in the study of biochemical properties, processing, intracellular transport, secretion, and degradation of proteins. Methods for labeling many secreted and membrane proteins are presented *UNIT 10.18*.

Many proteins, however, are normally synthesized with the α -N₂ group blocked by an acyl (e.g., acetyl) moiety and are consequently refractory to Edman degradation. Therefore, it is wise to fragment a protein (by chemical and/or enzymatic methods) after it has been purified to homogeneity by a combination of separation methods including SDS-PAGE, and to isolate the individual protein fragments by RP-HPLC (*UNIT 10.19*). The partial sequence analysis of several peptides may then be completed. These data may be used collectively to confirm the identity of an unknown gene or to form the basis for the synthesis of oligodeoxynucleotides (i.e., primers or probes) or peptides.

UNIT 10.20 presents capillary zone electrophoresis of proteins and peptides, an extraordinarily high-resolution technique that may be used to separate a variety of proteins of differing properties. Capillary electrophoresis is ideally suited to preparation of proteins for protein sequence analysis (*UNITS 10.14 & 10.20*) and for separating proteins while the capillary is interfaced to a mass spectrometer (*UNITS 10.14 & 10.20*).

UNIT 10.21 provides an overview of peptide and protein analysis by mass spectrometry, an analytical technique that all molecular biologists who are interested in defining the primary structure, disulfide bonding, and translational modifications of proteins need to understand. *UNIT 10.22* extends the principles and techniques of the previous unit and describes state-of-the-art methods for identifying proteins by mass spectrometry using peptide-mass data analysis, peptide-sequence tags, uninterpreted fragment-ion searching, and *de novo* sequencing by tandem mass spectrometry (MS/MS). The incredible resolving power of two-dimensional gel electrophoresis (*UNITS 10.3 & 10.4*), RP-HPLC (*UNITS 10.13 & 10.14*), and capillary electrophoresis (*UNITS 10.14 & 10.20*), coupled with the analytical power of mass spectrometry, is among the drivers of functional genomic research, and direct mass spectroscopic analysis of gel-separated proteins is thoroughly described. The extent and complexity of translational modification of proteins remains poorly

understood for most proteins, and over 400 distinct chemical modifications have been described. The detection and chemical identification of such modifications is one of the frontiers of cell biology.

UNIT 10.23 describes differential gel electrophoresis (DIGE), a technique for labeling proteins with three unique cyanine fluorescent dyes (called Cy2, Cy3, and Cy5), which differ in their fluorescence spectral properties. The Cy dyes are covalently attached to the proteins in a mixture using an active ester coupling procedure (using *N*-hydroxysuccinimide ester derivatives of the various Cy dyes), which results in minimal (1% to 2%) labeling of the ϵ -amino group of lysine residues of the various proteins in a mixture. Because the net charge of a lysine residue or a Cy dye molecule is -1 , there is no appreciable change in the isoelectric point. In addition, there is no detectable change in the molecular mass of the labeled proteins, unless they are very low molecular mass, since the mass of a Cy molecule is ~ 500 . The labeled proteins from different protein samples are analyzed by 2-D electrophoresis using a multiplex analysis format (i.e., two or three samples are mixed and applied to the same gel) and the individual separation patterns (between two or among three Cy-labeled mixtures) are revealed by scanning the gels with excitation wavelengths corresponding to the maxima of the different dyes. Because the Cy dyes are detected with the sensitivity of silver-stained gels, the DIGE method is also useful for comparing the expression of recombinant proteins under different expression conditions, protein mixtures fractionated by conventional chromatography or HPLC, and membrane protein mixtures from different strains. Importantly, Cy dye-labeled proteins eluted from gels or separated chromatographically are compatible with subsequent mass spectrometric analysis.

UNIT 10.24 describes the use of solution radioimmunoassays to determine picomolar amounts of proteins in complex biological samples. The method requires the initial purification of a sufficient quantity of the unknown protein so that it may be used as an immunogen for generating polyclonal or monoclonal anti-protein antibodies, as radioiodinated protein tracer, and as control protein for constructing a standard curve. Proteins are routinely radioiodinated in trace amounts by either Bolton-Hunter reagent (labeling lysyl residues) or by lactoperoxidase (labeling tyrosine residues).

CONCLUSION

Through proteomics, structural genomics, and cell biology, the post-genomic era is addressing aspects of the protein problem that are now tractable. The currently intractable aspects will only be elucidated when new technologies are developed that move us beyond the limitations of purification and analysis methods that are the state of the art described in this chapter. Without a concerted effort to move beyond the limitations of contemporary methods, which were developed to isolate industrial quantities of proteins (beginning in the 1940s) and were premised upon proteins existing as solitary molecules with invariant function (the “one gene, one protein” hypothesis, which is largely the realm of molecular biology), a real understanding of the diversity, distribution, and functions of proteins will remain an illusory goal.

QUANTITATION OF PROTEINS

The success or failure of protein-centered projects can frequently be traced to the quality of the analytical procedures used to characterize the sample at different stages. Qualitative and quantitative analysis can aid in definition of the sample for the purpose of designing separations. A knowledge of the properties of the desired protein (e.g., whether it has a high aromatic amino acid content) can suggest methods of analysis that will help locate the desired protein in a complex mixture. Establishing the properties of an isolated protein creates benchmarks that future researchers can use to evaluate their protocols and final product. Accurate quantitation of the amount of protein at the beginning, middle, and end of a series of steps is the only valid way to evaluate the overall yield of a procedure. The observation of significant loss of protein, without a substantial increase in the purity of the desired protein, following a particular purification procedure would indicate that the procedure should be omitted or revised.

Several spectroscopic procedures for characterizing protein samples are described in *UNIT 10.1A*. Measuring the absorbance of the aromatic amino acids in a protein at difference wavelengths yields a very useful measure of protein concentration. This is non-destructive and requires very little sample or time. A more qualitative, but much more sensitive, evaluation is provided by fluorescence spectroscopy. Quantitation of the amount of protein contained in a solution also can be conveniently accomplished using colorimetric methods. The Bradford and the Lowry methods are the most frequently used and reliable procedures. The method of choice is the Bradford method, which is easy and rapid to complete.

Another approach is amino acid analysis—qualitative analysis to determine purity and quantitative analysis to provide concentrations—both of which are presented in *UNIT 10.1B*. Procedures are also given for calculating amino acid composition from primary analytical data. Significant advances that have improved the precision and sensitivity of amino acid analysis have reinvigorated this method, which had for some years been neglected.

Spectrophotometric and Colorimetric Determination of Protein Concentration

UNIT 10.1A

This unit describes spectrophotometric and colorimetric methods for measuring the concentration of a sample protein in solution. In Basic Protocol 1, absorbance measured at 280 nm (A_{280}) is used to calculate protein concentration by comparison with a standard curve or published absorptivity values for that protein (a_{280}). In Alternate Protocol 1, absorbance measured at 205 nm (A_{205}) is used to calculate the protein concentration. The A_{280} and A_{205} methods can be used to quantitate total protein in crude lysates and purified or partially purified protein. Both of these methods are simple and can be completed quickly. The A_{280} method is the most commonly used. The A_{205} method can detect lower concentrations of protein and is useful for dilute protein samples, but is more susceptible to interference by reagents in the protein sample than the A_{280} method. Basic Protocol 2 uses a spectrofluorometer or a filter fluorometer to measure the intrinsic fluorescence emission of a sample solution; this value is compared with the emissions from standard solutions to determine the sample concentration. The fluorescence emission method is used to quantitate purified protein. This simple method is useful for dilute protein samples and can be completed in a short amount of time. The Bradford colorimetric method, based upon binding of the dye Coomassie brilliant blue to an unknown protein, is presented in Basic Protocol 3; the Lowry method, which measures colorimetric reaction of tyrosyl residues in an unknown, is given in Alternate Protocol 2.

USING A_{280} TO DETERMINE PROTEIN CONCENTRATION

Determination of the concentration of protein in a solution by absorbance measurements at 280 nm (A_{280}) is based on the inherent absorbance of UV light by the aromatic amino acids tryptophan and tyrosine, as well as by cystine (disulfide-bonded cysteine residues). The measured absorbance of a protein sample solution is used to calculate the concentration either from its published absorptivity at 280 nm (a_{280}) or by comparison with a calibration curve prepared from measurements with standard protein solutions. This assay can be used to quantitate solutions with protein concentrations of 20 to 3000 $\mu\text{g/ml}$.

Materials

- 3 mg/ml spectrophotometric standard protein solution (see recipe; optional)
- Sample protein
- Spectrophotometer with UV lamp
- Quartz cuvette

1. For calibrating with standards, use the 3 mg/ml standard protein solution to prepare dilutions of 20, 50, 100, 250, 500, 1000, 2000, and 3000 $\mu\text{g/ml}$ in the same solvent used to prepare the sample protein. Prepare a blank consisting of solvent alone.

Ideally, for purified or partially purified protein, the protein standard should have an aromatic amino acid content similar to that of the sample protein. For the total protein of a crude lysate, an average absorptivity (step 5a) can be used to calculate the protein concentration directly from the measured A_{280} without standards. Bovine serum albumin (BSA) is commonly used as a standard for spectrophotometric quantitation of protein concentration of crude lysates. However, the a_{280} for BSA is 0.6 ml/mg, which is less than one half the calculated average a_{280} (1.3 ml/mg) from 80 proteins (Pace et al., 1995). Therefore, use of BSA as a standard for protein quantitation could result in an underestimation of protein concentration of a given sample that has a greater aromatic amino acid content than BSA.

**BASIC
PROTOCOL 1**

**Analysis of
Proteins**

10.1A.1

2. Turn on the UV lamp of the spectrophotometer and set the wavelength to 280 nm. Allow the instrument to warm up 30 min before taking measurements.

3. Zero the spectrophotometer with the solvent blank.

When removing solutions from the cuvette, do not remove the cuvette from the spectrophotometer. Leaving the cuvette in the spectrophotometer between readings will result in greater reproducibility of the absorbance readings. Use of an aspirator pump and thin tubing is the ideal method for completely removing the solutions from the cuvette. If this is not available, use a pipettor and tip to remove the solutions from the cuvette.

4. Measure the absorbance of the protein standard and unknown solutions.

If the A_{280} of the sample protein is >1.5 , dilute the sample further in the same solvent and measure the A_{280} again.

5a. *If the a_{280} of the protein is known:* Calculate the unknown sample concentration from its absorbance value using the following equation, where a_{280} has units of ml/mg cm and b is the path length in cm.

$$\text{concentration (mg/ml)} = \frac{A_{280}}{a_{280} \times b}$$

Because most cuvettes have a 1-cm path length, the b term can usually be ignored in this equation. For calculation of the protein content of crude lysates, an average a_{280} of 1.3 ml/mg cm can be used. This value was determined from absorptivities of 80 proteins (Pace et al., 1995).

5b. *If standard solutions are used for quantitation:* Create a calibration curve by either plotting or performing regression analysis of the A_{280} versus concentration of the standards. Use the absorbance of the sample protein to determine the concentration from the calibration curve.

ALTERNATE PROTOCOL 1

USING A_{205} TO DETERMINE PROTEIN CONCENTRATION

Determination of protein concentration by measurement of absorbance at 205 nm (A_{205}) is based on absorbance by the peptide bond. The concentration of a protein sample is determined from the measured absorbance and the absorptivity at 205 nm (a_{205}). This assay can be used to quantitate protein solutions with concentrations of 1 to 100 $\mu\text{g/ml}$ protein.

Additional Materials (also see Basic Protocol 1)

Brij 35 solution: 0.01% (v/v) Brij 35 (Sigma) in an aqueous solution appropriate for dissolving or diluting the sample protein

1. Dissolve or dilute the protein sample in Brij 35 solution.
2. Turn on the UV lamp of the spectrophotometer and set the wavelength to 205 nm. Allow the instrument to warm up 30 min before taking measurements.
3. Zero the spectrophotometer with the Brij 35 solution alone.
4. Measure the absorbance of the sample protein.

When removing solutions from the cuvette, do not remove the cuvette from the spectrophotometer. Leaving the cuvette in the spectrophotometer between readings will result in greater reproducibility of the absorbance readings. Use of an aspirator pump and thin tubing is the ideal method for completely removing the solutions from the cuvette. If this is not available, use a pipettor and tip to remove the solutions from the cuvette.

- 5a. *If the a_{205} of the protein is known:* Use the equation relating A_{280} and protein concentration (see Basic Protocol 1, step 5a) to calculate the concentration of the sample protein, *except* substitute the appropriate values for A_{205} and a_{205} .
- 5b. *If the a_{205} is not known:* Estimate the concentration of the sample protein from its measured absorbance using the following equation, where the absorptivity value, 31, has units of ml/mg cm and b is the path length in cm.

$$\text{concentration (mg/ml)} = \frac{A_{205}}{31 \times b}$$

The absorptivity value of 31 ml/mg cm is an average derived from measurement of ten purified proteins (Scopes, 1974). The proteins were first dried and then several dilutions were made in buffer; the a_{205} for each protein was calculated from the absorbance readings of the dilutions.

USING FLUORESCENCE EMISSION TO DETERMINE PROTEIN CONCENTRATION

BASIC PROTOCOL 2

Protein concentration can also be determined by measuring the intrinsic fluorescence based on fluorescence emission by the aromatic amino acids tryptophan, tyrosine, and/or phenylalanine. Usually tryptophan fluorescence is measured. The fluorescence intensity of the protein sample solution is measured, and the concentration of the protein sample solution calculated from a calibration curve based on the fluorescence emission of standard solutions prepared from the purified protein. This assay can be used to quantitate protein solutions with concentrations of 5 to 50 $\mu\text{g/ml}$.

Materials

Spectrophotometric protein standard solution (see recipe) prepared using the purified protein
Sample protein
Spectrofluorometer *or* filter fluorometer with an excitation cutoff filter at ≤ 285 nm and an emission filter at > 320 nm
Quartz fluorometer cuvette

1. Prepare dilutions of the purified protein at 5, 7.5, 10, 25, and 50 $\mu\text{g/ml}$ in the same solvent as the sample protein. Prepare a blank consisting of solvent alone.
2. Turn on the lamp of the instrument and allow it to warm up 30 min before taking measurements.

If a spectrofluorometer is used, set the excitation wavelength to 280 nm and the emission wavelength to between 320 and 350 nm. If the exact emission wavelength is not known, determine it empirically by scanning the standard solution with the excitation wavelength set to 280 nm. If the instrument is a filter fluorometer, use an excitation cutoff filter at ≤ 285 nm and an emission filter at > 320 nm.

3. Zero the instrument with the solvent blank.
4. Measure the fluorescence of the protein standard and sample protein solutions.
5. Create a calibration curve by either plotting or performing regression analysis of the fluorescence intensity versus concentration of the standards. Using the fluorescence intensity of the sample protein, determine the concentration from the calibration curve.

Fluorescence emission is a linear function of concentration only over a limited range.

Analysis of Proteins

10.1A.3

**USING THE BRADFORD METHOD TO DETERMINE PROTEIN
CONCENTRATION**

The Bradford method depends on quantitating the binding of a dye, Coomassie brilliant blue, to an unknown protein and comparing this binding to that of different amounts of a standard protein, usually BSA. It is designed to quantify 1 to 10 μg protein. Protein determinations in the range of 10 to 100 μg may be carried out by increasing the volume of the dye solution 5-fold and using larger tubes.

Materials

Colorimetric standard protein solution (0.5 mg/ml BSA; see recipe)
0.15 M NaCl
Coomassie brilliant blue solution (see recipe)
1 ml, 1-cm-path-length microcuvette

1. Into eight microcentrifuge tubes place duplicate aliquots of 0.5 mg/ml BSA (5, 10, 15, and 20 μl) and dilute each to 100 μl with 0.15 M NaCl. Into two more microcentrifuge tubes, place 100 μl each of 0.15 M NaCl; these are blank tubes.
2. Add 1 ml Coomassie brilliant blue solution and vortex. Allow to stand 2 min at room temperature.
3. Determine the A_{595} using a 1-cm-path-length (1 ml) microcuvette and make a standard curve by plotting absorbance at 595 nm versus protein concentration. Determine the absorbance for the unknown and use the standard curve to determine the concentration of protein in the unknown.

If the unknown protein concentration is too high, dilute the protein, assay a smaller aliquot of the unknown, or generate another standard curve in a higher concentration range (e.g., 10 to 100 μg).

**USING THE LOWRY METHOD TO DETERMINE PROTEIN
CONCENTRATION**

The Lowry method depends on quantitating the color obtained from the reaction of Folin-Ciocalteu phenol reagent with the tyrosyl residues of an unknown protein and comparing this color value to the color values derived from a standard curve of a standard protein, usually BSA. This assay is designed to quantify 1 to 20 μg protein. Protein determinations in the range of 5 to 100 μg may be carried out by increasing all the volumes 5-fold.

Additional Materials (also see Basic Protocol 3)

0.15% (w/v) sodium deoxycholate
72% (w/v) trichloroacetic acid (TCA)
Copper tartrate/carbonate (CTC) solution (see recipe)
20% (v/v) Folin-Ciocalteu reagent

1. Into eight microcentrifuge tubes place duplicate aliquots of 0.5 mg/ml BSA (10, 20, 30, and 40 μl) and dilute each to 200 μl with water. Into two more microcentrifuge tubes, place 200 μl water; these are blank tubes.
2. Add 20 μl of 0.15% sodium deoxycholate to each tube and vortex. Allow to stand 10 min at room temperature.
3. Add 20 μl of 72% TCA to each tube and vortex.
4. Microcentrifuge 15 min at $3000 \times g$, then decant supernatant (protein will be in the precipitate).
5. Dissolve protein pellets in 200 μl water. Add 200 μl water to the blank tubes.

6. Add 200 μl CTC solution, vortex, and allow to stand 10 min at room temperature.
7. Add 100 μl of 20% Folin-Ciocalteu reagent, *immediately* vortex, and allow to stand 30 min at room temperature.
8. Determine the A_{750} and compare against standard curve (see Basic Protocol 3, step 3).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Colorimetric standard protein solution (0.5 mg/ml BSA)

Prepare a 10 mg/ml solution of BSA and measure its A_{280} in a 1-cm-path-length microcuvette. The A_{280} should equal 6.61 (i.e., a 0.5 mg/ml solution will have an $A_{280} = 0.33$).

Coomassie brilliant blue solution

In a 1-liter volumetric flask, dissolve 100 mg Coomassie Brilliant Blue G-250 in 50 ml of 95% ethanol. Add 100 ml of 85% phosphoric acid. Bring to volume with water. Filter through Whatman no. 1 filter paper. Store at 4°C.

Commercial kits are available from Pierce and Bio-Rad.

Copper tartrate/carbonate (CTC) solution

Stock solution: To 50 ml of a solution of 0.2% (w/v) $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ and 0.2% (w/v) potassium tartrate, slowly add, while vigorously stirring, 50 ml of a solution of 20% sodium carbonate. This solution is stable >8 weeks at room temperature.

Working solution: Mix equal volumes of CTC stock solution, 0.8 M NaOH solution, 10% (w/v) SDS solution, and water. The reagent is stable 1 to 2 weeks at room temperature.

Spectrophotometric standard protein solution, 3 mg/ml

Weigh out dry protein and prepare a stock solution at a concentration of 3 mg/ml in the same solvent as used for the sample protein. Store up to 3 months at -20°C .

To prepare calibration standard solutions, dilute the stock solution in solvent to give the desired final concentrations for the standard curve.

Bovine serum albumin (BSA, fraction V; Sigma) is frequently used as a protein standard solution. A 3 mg/ml solution of BSA should have an A_{280} of 1.98, based on an A_{280} of 6.61 for a 1% (w/v) solution.

For quantitation of a purified or partially purified protein, the protein standard should, if possible, have an aromatic amino acid content similar to that of the sample protein.

COMMENTARY

Background Information

Measuring absorbance at 280 nm (A_{280}) is one of the oldest methods for determining protein concentration (Warburg and Christian, 1942; Layne, 1957). This method is still widely used, because it is simple and does not require incubating the sample with exogenous chromophores. However, the detection limit is higher than with colorimetric methods and therefore higher concentrations of protein are necessary. To reduce the amount of

sample required for the A_{280} method, either microcuvettes, which use 50 μl of sample, can be used or the method can be adapted to microtiter plate readers capable of UV absorbance detection. The A_{280} method requires that the protein being quantitated contain aromatic amino acids, primarily tryptophan and tyrosine. Because of the variability in aromatic amino acid content among different proteins, their absorptivity at 280 nm (a_{280}) also varies. Therefore, if calibration standards are

Table 10.1A.1 Absorption Maxima and Molar Absorptivity (ϵ) of Amino Acids^a

Amino acid	Wavelength maxima (nm)	$\epsilon \times 10^{-3}$ ($M^{-1} \text{ cm}^{-1}$)
Cysteine	250	0.3
Histidine	211	5.9
Phenylalanine	188	60.0
	206	9.3
	257	0.2
Tryptophan	219	47.0
	279	5.6
Tyrosine	193	48.0
	222	8.0
	275	1.4

^aValues are for aqueous solutions at pH 7.1 (Freifelder, 1982; Fasman, 1989).

Table 10.1A.2 Molar Absorptivity (ϵ) of Amino Acids at 280 nm^a

Amino acid	$\epsilon \times 10^{-3}$ ($M^{-1} \text{ cm}^{-1}$)
Cystine	0.110
Phenylalanine	0.0007
Tryptophan	5.559
Tyrosine	1.197

^aValues are for aqueous solutions at pH 7.1 except for cystine, which is for water (Fasman, 1989).

used for quantitation, the aromatic amino acid content of the standard must be similar to that of the sample protein for accurate results. Accordingly, the quantitation of proteins by peptide bond absorption at 205 nm (A_{205}) is more universally applicable. Furthermore, the absorptivity for a given protein at 205 nm is several-fold greater than that at 280 nm (Scopes, 1974; Stoscheck, 1990). Thus, lower concentrations of protein can be quantitated with the A_{205} method. The disadvantage of this method is that some buffers and other components absorb at 205 nm (Stoscheck, 1990).

In addition to the aromatic amino acids, several others have absorption maxima in the UV range. Table 10.1A.1 shows the wavelengths of absorption maxima and corresponding molar absorptivity (ϵ) for the amino acids with appreciable absorbance in the UV range. Only tryptophan has an absorption maximum near 280 nm, although tyrosine will absorb somewhat at that wavelength. The ϵ_{280} for tryptophan is nearly 5-fold greater than that

for tyrosine and 50-fold greater than that for cystine (Table 10.1A.2). The contribution to the absorbance at 280 nm of the third aromatic amino acid, phenylalanine, is negligible. Several amino acids other than those in Table 10.1A.1 absorb light below 205 nm (Fasman, 1989), but either the molar absorptivities are too low to be significant or the wavelengths are too short for practical absorbance measurements.

The aromatic amino acids also exhibit fluorescence emissions when excited by light in the UV range. Table 10.1A.3 gives the excitation wavelength, fluorescence emission wavelength, and quantum yield (Q) for tryptophan, tyrosine, and phenylalanine. The quantum yield is the ratio of photons emitted to photons absorbed. Typically, phenylalanine fluorescence is not detected in the presence of tyrosine and tryptophan due to low Q . Furthermore, tyrosine fluorescence is nearly completely quenched if the tyrosine residue is ionized or near an amino group, a carboxyl group, or a tryptophan residue (Teale, 1960;

Table 10.1A.3 Fluorescence Properties of Aromatic Amino Acids^a

Amino acid	Excitation wavelength	Emission wavelength	Quantum yield
Phenylalanine	260 nm	283 nm	0.04
Tryptophan	285 nm	360 nm	0.20
Tyrosine	275 nm	310 nm	0.21

^aValues are for aqueous solutions at pH 7 and 25°C (Hawkins and Honigs, 1987; Fasman, 1989).

Freifelder, 1982). Therefore, tryptophan fluorescence is what is customarily measured.

Measurement of intrinsic fluorescence by aromatic amino acids is primarily used to obtain qualitative information (Freifelder, 1982). However, with a protein standard whose aromatic amino acid content is similar to that of the sample, intrinsic fluorescence can be used for quantitation (Hawkins and Honigs, 1987). An additional consideration is that the tertiary structure of a protein will influence the fluorescence, e.g., adjacent protonated acidic groups in a protein molecule will quench tryptophan fluorescence (Freifelder, 1982).

The most frequently employed colorimetric methods for determining protein concentration are those of Bradford (1976) and Lowry et al. (1951). The Bradford method, which is faster than the Lowry method, is the method of choice for determining protein concentration. It is possible to miniaturize the Bradford assay by using a 96-well microtiter plate assay as described by Brogdon and Dickinson (1983).

The Lowry method (as modified by Peterson, 1977) is dependent on the unknown and the standard protein having a similar content of tyrosine per microgram protein. If the protein has fewer (or more) tyrosines/ μg than BSA, then the protein concentration determined will be too low (or too high). This method is not appropriate for proteins without tyrosine residues, since the assay relies on the reaction of these residues with the reagent.

Critical Parameters and Troubleshooting

A 1-cm-path-length quartz cuvette is most often used for spectrophotometric detection. However, quartz cuvettes with shorter path lengths (0.01 to 0.5 cm) are available (e.g., from Hellma Cells or Beckman); these allow higher concentrations of protein solutions to be measured. The equations relating absorbance and protein concentration (see Basic Protocol 1 and Alternate Protocol 1) assume the cuvette has a path length of 1 cm; when cuvettes of shorter path length are used, the

correct value for b must be substituted in the equation.

Glass cuvettes can be used for colorimetric detection. Quartz cuvettes are not recommended for the Bradford assay because the dye adheres more readily to quartz than to glass.

Spectrophotometric detection

The solvent pH and polarity will affect the absorbance and fluorescence properties of a protein. A notable example of pH effects on absorbance is seen with tyrosine residues, where a change in pH from neutral to alkaline results in a shift of the absorbance maximum to a longer wavelength and an increase in absorptivity due to dissociation of the tyrosine phenolic hydroxyl group (Freifelder, 1982; Fasman, 1989). An example of solvent polarity effects on fluorescence is that observed with tryptophan, where a decrease in solvent polarity results in a shift in fluorescence emission to shorter wavelengths and an increase in intensity (Freifelder, 1982). Because of these effects, the following precautions should be taken for accurate results: (1) when calibration curves are used for quantitation by absorbance or fluorescence, standards must be in the same solvent as the samples; and (2) when a published absorptivity at a given wavelength is used for quantitation, the solvent composition of the sample must be the same as that used in obtaining the published data.

Many buffers and other reagents can interfere with A_{280} and A_{205} spectrophotometric measurements. Stoscheck (1990) lists the concentration limits for many such reagents used in these spectrophotometric methods. The more commonly used reagents that absorb at 280 and 205 nm are listed in Table 10.1A.4. In addition, reagents that contain carbon-carbon or carbon-oxygen double bonds can interfere with the A_{205} method.

Because stray light can affect the linearity of absorbance versus concentration, absorbance values >2.0 should not be used for sample proteins measured by the A_{280} or A_{205} method. Samples with absorbance >2.0

Table 10.1A.4 Concentration Limits of Interfering Reagents for A_{205} and A_{280} Protein Assays^a

Reagents ^b	A_{205}	A_{280}
Ammonium sulfate	9% (w/v)	>50% (w/v)

should be diluted further in the appropriate buffer to obtain absorbances <2.0.

Nucleic acids have substantial absorbance at 280 nm and can interfere with A_{280} quantitation of protein in crude samples. To resolve the protein concentration in such samples, measure the absorbance at 260 nm and 280 nm and calculate the protein concentration as follows (Warburg and Christian, 1942; Layne, 1957): protein concentration (mg/ml) = $1.55 \times A_{280} - 0.76 \times A_{260}$.

This estimation of protein concentration is valid up to 20% (w/v) nucleic acid or an A_{280}/A_{260} ratio <0.6.

Colorimetric detection

Many substances will interfere with the Bradford protein assay, including glycerol, detergents, 2-mercaptoethanol, acetic acid, ammonium sulfate, Tris, and certain alkaline buffers, but the appropriate controls can be used to correct this interference.

Many substances will interfere with the Lowry protein assay (Peterson, 1979). If detergents, denaturants, organic buffers, and/or thiols are present in the unknown protein solution, it is important to assess their effects on absorbance by creating standard curves

based on data taken in both the presence and the absence of these compounds. Precipitation of a protein with deoxycholate/trichloroacetic acid will eliminate many of these interfering substances while allowing a quantitative recovery of cytosolic and membranous proteins (Peterson, 1979). Although the standard curve for BSA is nonlinear, the simplicity, sensitivity, and reproducibility of the method make it worthwhile. The A_{750} will decrease at a rate of 1% to 2% per hour at room temperature.

If the unknown protein solution contains detergents such as 1% Triton X-100, 1% Tween 20, 1% Nonidet P-40, or 0.75% cetyltrimethyl-ammonium bromide, the addition of ~4% SDS will prevent precipitation of the Folin reagent (Cadman et al., 1979).

Anticipated Results

Depending on the protein, the concentration range for the A_{280} method is 20 to 3000 $\mu\text{g/ml}$, for the A_{205} method is 1 to 100 $\mu\text{g/ml}$, and for the fluorescence emission method is 5 to 50 $\mu\text{g/ml}$.

Published absorptivities of proteins at 280 nm are usually given as the absorbance for a 1% (w/v) protein solution per cm, $A^{1\%}$, or as the molar absorptivity, ϵ , which has units

of liters/mol cm (also expressed as $M^{-1} \text{ cm}^{-1}$). To convert these published coefficients to units of mg/ml, use one of the following equations:

$$\text{concentration (mg/ml)} = \frac{A_{280} \times 10}{A^{1\%} \times b} \text{ or}$$

$$\text{concentration (mg/ml)} = \frac{A_{280} \times \text{molecular weight}}{\epsilon_{280} \times b}$$

Depending on the reagent volumes used, it is possible to quantitate protein in the range of 1 to 100 μg using the Bradford or Lowry assay.

Time Considerations

When the absorptivity for a protein is known, the A_{280} and A_{205} measurements require <30 min depending on the number of samples. When standards are used for quantitation with these assays or for intrinsic fluorescence quantitation, 1 hr is required.

The Bradford method requires ~30 min. The Lowry method requires 2 hr to generate a standard curve and to run several unknown protein samples.

Quantitative Amino Acid Analysis

UNIT 10.1B

The use of quantitative amino acid analysis in the characterization of protein samples is often overlooked in many laboratories. This is typically due to the difficulties involved in obtaining reliable amino acid composition data, as well as to the advent of colorimetric dye-binding assays as alternative methods to determine protein concentration. However, many proteins do not bind dyes in the same way as the proteins normally used as standards, making quantitation by those techniques difficult. Fortunately, at many institutions, the creation of protein chemistry core laboratories devoted mainly to protein sequence analysis and peptide synthesis has provided new instrumentation that yields the necessary precision. This unit describes the information that can be derived from quantitative amino acid analysis, presents some details on sample preparation, and gives examples of the calculations that are needed.

INFORMATION OBTAINED FROM AMINO ACID ANALYSIS

The benefits of amino acid composition data are two-fold. First, identifying the nature of the amino acids present in a sample can provide an important qualitative measure of the purity of the preparation. Amino acid analysis does not depend on the shape, charge, or function of a protein because the hydrolysis completely destroys structure and reduces the protein to its constituent amino acids. Although large proteins typically contain a mixture of all the commonly occurring amino acids, certain residues are relatively rare: Trp, Met, His, Cys, and occasionally Arg are present at lower than average ratios compared to Gly, Ala, Ser, and Leu. For a pure protein, the ratios of the amino acids should approach the theoretical levels to within ~10%, with a few caveats. For a sample from a column fraction, for example, the presence of a higher than expected ratio of a certain amino acid is a very good indication that the sample is not pure and that further fractionation is indicated. In the same way, a lower than expected ratio could also indicate impurity—for example, the presence of a second protein that has a lower ratio of some significant amino acid present in higher amounts in the protein of interest. Because the expression of a protein in bacteria or other hosts utilizes a gene of known sequence, the expected amino acid composition is also known (see Chapter 16 for expression and purification of recombinant proteins).

Second, averaged composition yields an excellent measure of the amount of protein in a sample. On the ion-exchange-based Beckman 6300 amino acid analyzer running with ninhydrin detection chemistry, the minimum amount of the standard (a mixture of amino acids used to derive integration parameters as well as elution times) that is required is typically 1 nmol of each amino acid. Amounts as low as 250 pmol (0.25 nmol) of an amino acid can be measured with confidence from protein hydrolyzates. For a protein of 50 kDa mass, 1 nmol is 50 μ g, an amount that can be obtained readily by preparation of the protein from a high-expression system followed by purification by standard methods. For isolation of a trace protein from a natural source, this required amount may be too large to be feasible. However, a protein of 50 kDa mass contains ~400 amino acids, or roughly 20 copies of each amino acid on average. Thus, the actual amount of protein required for detection and semiquantitative analysis could be as low as 0.05 nmol, or 2.5 μ g. At that level, rare amino acids cannot be accurately quantitated, but the more common ones can be measured easily. Obviously, the more material available, the more accurate the analysis. Users should check with their local facility for specific advice on the amount of sample that can be processed by existing technologies.

The advent of advanced instrumentation, such as the Applied Biosystems 420 amino acid analyzer and the Waters PicoTag system, has provided another increment in sensitivity. These instruments utilize precolumn derivatization followed by separation based on reversed-phase high-performance liquid chromatography (HPLC). With such analyzers, 100 pmol of each amino acid, or 5 pmol of the 50-kDa protein described above, can be quantitated accurately.

Another important consideration in the design of a purification scheme that can be elucidated through the use of amino acid quantitation is the compilation of the mass balance—the relationship between how much protein is applied to the chromatography column and how much is recovered in a particular step. Amino acid analysis of a measured aliquot of the sample taken before application (typically $\leq 1\%$), along with aliquots of column fractions or pools, can be used to calculate the amounts of protein loaded and recovered. These calculations can provide essential information to as-

Analysis of
Proteins

10.1.11

Supplement 35

sess the success of a particular purification procedure.

SAMPLE PREPARATION

The success or failure of quantitative amino acid analysis is strongly dependent upon the quality of the sample, as well as upon the exact composition of the sample matrix (i.e., the aggregate of all components including salts, detergent, and dirt). The following section gives a few key recommendations for successful sample preparation.

Sample Concentration

An ideal sample for amino acid analysis would contain 1 to 10 nmol protein in a volume of 10 to 100 μ l water. A sample that has been dialyzed against a low concentration of buffer (if needed to maintain solubility) or pure water is optimal, because the presence of salt, detergent, high concentrations of buffers, or other agents may interfere with either hydrolysis or subsequent analysis.

A sample that has been lyophilized to dryness is also usually acceptable, with some important considerations. First, lyophilization should be done in such a way as to concentrate the lyophilized residue at the bottom of a conical tube. Drying a sample in a round-bottom flask may leave the protein sample spread over a large surface area; such samples are extremely difficult to handle and will not give satisfactory results. Second, lyophilization of a buffered solution will concentrate the salts as well as the protein. Therefore, it is recommended that the total ionic strength of the solution be $<50 \mu$ M before lyophilization.

Estimate of Total Protein

An estimate of the total amount of protein present is very helpful in planning an accurate analysis. This can be based on a colorimetric dye-binding assay, an A_{280} measurement, or an activity assay in which the results are compared to a standard value.

All information about the sample should be communicated to the individual charged with conducting the analysis to ensure the maximum return on the sample. Many facilities provide a form with a series of questions to be answered concerning the sample.

Samples from PVDF Blots

With the advent of more sensitive analyzers based on phenylthiohydantoin (PTH) chemistry, it is now possible to obtain compositional data on samples separated by electrophoresis

and blotted onto membranes (UNITS 10.8 & 10.19) such as are used for protein sequence analysis. This is especially helpful in cases where a protein sample fails to yield any sequence during gas-phase Edman degradation. Acid hydrolysis and analysis of sample blot pieces recovered from the sequencer sample compartment yield a rough estimate of the amount of protein present. If the amount is larger than that normally required for sequence analysis (10 pmol), it may then be concluded that the protein sample was N-terminally blocked.

CALCULATION OF THE AVERAGE COMPOSITION

Table 10.1B.1 presents the results of analysis of a 24-kDa recombinant protein. The initial sample volume was 1.0 ml and it was expected to contain ~ 4 mg total protein. A 30- μ l aliquot was taken for analysis and was estimated to contain 120 μ g, or ~ 5 nmol. The aliquot was transferred to a glass tube for hydrolysis and dried by application of a vacuum at room temperature. One milliliter of 6 M HCl was added, the tube was cooled in a dry ice bath, then a vacuum was applied and the tube sealed by heating in a gas flame. Hydrolysis was conducted for 24 hr at 124°C, followed by removal of the HCl under vacuum. The sample was taken up in 1.0 ml application buffer, 50 nmol norleucine was added as an internal standard, and a 50- μ l aliquot was analyzed by ion-exchange chromatography on a Beckman 6300 system with ninhydrin detection.

1. The total number of nanomoles of amino acids detected is first calculated by summing the second column of Table 10.1B.1, yielding 1446 nmol.

2. The total nanomoles is then divided by the total number of expected amino acids (based on protein sequence; in this case, 212) to obtain the average number of nanomoles per residue; $1446 \text{ nanomoles} / 212 \text{ residues} = 6.82 \text{ nmol per residue}$. If the total number of amino acids is not known, it may be estimated by dividing the mol. wt. of the protein by 110.

3. The number of nanomoles of each amino acid measured is divided by the average number of nanomoles per residue (step 2) to give the ratio¹ observed for that amino acid. For Asp, $155 \div 6.82 = 22.7$.

The resulting ratios are given in the fourth column and may be compared to the ratio expected listed in the third column. For most of the amino acids, the ratio¹ observed agrees with the ratio expected.

The value of average nanomoles per residue

Table 10.1B.1 Data Used to Calculate Amino Acid Composition for a 24-kDa Protein

Amino acid	Nanomoles measured	Ratio expected ^a	Ratio ¹ observed	Ratio ² observed
Asp	155	23	22.7	21.8
Thr	78	13	11.4	10.9
Ser	63	13	9.2	8.9
Glu	153	21	22.4	21.5
Pro	52	7	7.6	7.3
Gly	157	22	23.0	22.1
Ala	90	12	13.1	12.6
Val	159	23	23.3	22.3
Met	24	5	3.5	3.4
Ile	88	13	12.9	12.3
Leu	138	19	20.2	19.4
Tyr	43	6	6.3	6.1
Phe	56	8	8.2	7.9
His	16	3	2.3	2.3
Lys	121	17	17.7	17.0
Arg	53	7	7.8	7.4

^aRatio expected based on amino acid sequence of protein.

calculated in step 2 is based on the analysis of a 30- μ l sample; the total sample of 1 ml contains ~5.46 mg of protein (average moles/residue \times grams/mole protein \times 1000/30). This analysis utilized only 50 μ l of the 1.0 ml final solution, so a sample size smaller than 3% of the original sample could have been used. Using an excess, however, provides the flexibility to repeat the determination if the first analysis gives peaks that are either too large or too small for accurate integration.

The ratio¹ observed for Ser, Thr, His, and Met are in this sample are ~30%, 13%, 24%, and 30% below the expected values, respectively. These results are typical for these four amino acids, but for different reasons. The Ser and Thr results are low because these amino acids undergo partial degradation during acid hydrolysis. Ser and Thr losses of 10% to 40% are normal. The lower than expected values for His and Met are an anomaly that is most likely caused by the relatively low copy number of those two amino acids in the protein. Due to these known problems, most investigators choose to delete the values for sensitive residues (Ser and Thr) as well as the values for those amino acids appearing in low amounts (in this case, His and Met) and calculate the average number of nanomoles per residue independently of those amino acids. This gives the

corrected ratios shown in the last column of Table 10.1B.1 (ratio² observed). In this example, the recalculated values are changed by as much as 0.9 due to the higher average number of nanomoles per residue (7.11).

The deviation of ratio¹ observed from the expected ratio ranges from 1% to 32% for the various amino acids, with an average error of 8.8%. When the high variation for Ser (32%), Met (32%), and His (24%) removed from consideration, the average deviation of ratio² observed from expected ratio drops to 4.1%. By standard criteria, this sample would be judged to be pure; of course, this result needs to be combined with electrophoretic separation (*UNIT 10.2*), chromatographic purification (*UNITS 10.9-10.11B*), and perhaps mass spectroscopic analyses before a final assessment of the purity of the sample can be made.

ELECTROPHORETIC SEPARATION OF PROTEINS

Protein separations in vertical slab gels are performed in a variety of formats. Typically, the separating gel size is in the range of 14 × 14-cm. Smaller formats (6 × 8-cm) are also popular and have been termed minigels. Due to the limited separation area, minigels do not offer the same level of resolution when compared to larger-format gels. However, any procedure performed in the standard format works equally well with minigels, and minigels use less reagent and separate proteins much faster.

One-dimensional gel electrophoresis of proteins can provide information about the molecular size and purity of proteins, as well as the number and molecular size of subunits. By analyzing proteins before and after deglycosylation, it is possible to learn about the carbohydrate content. Information about sulfate, phosphate, and carbohydrate content can be determined for proteins analyzed after various radiolabeling procedures. Furthermore, separated proteins can be recovered from polyacrylamide gels by electroelution (*UNIT 10.5*) for subsequent studies.

The purity and molecular size of a peptide or protein can be assessed by analytical separation in the presence of 0.1% SDS on one-dimensional gels (*UNIT 10.2*) or two-dimensional gels (*UNITS 10.3 & 10.4*). By adding a reducing agent (e.g., 2-mercaptoethanol or dithiothreitol) to the sample, it is possible to determine the number and size of subunits in a pure protein. Nondenaturing gels can be used to examine and isolate the “native” protein.

Two-dimensional gel electrophoresis separates proteins in the first dimension by isoelectric focusing and in the second dimension by electrophoresis in the presence of SDS. By separating proteins in this manner, information is obtained not only about size, as in one-dimensional gels, but also about the charge of a protein. Two-dimensional gels are superior for resolving complex mixtures and for assessing protein purity.

Both one- and two-dimensional gel electrophoreses are high-resolution separation methods that yield protein whose sequence can be determined after either electroelution (*UNIT 10.5*) or electroblotting onto polybrene-coated, derivatized glass fiber sheets or polyvinylidene difluoride (PVDF) membrane filters; all are compatible with gas-phase protein sequencers). In many cases, electrophoretic methods are used after successive modes of conventional types of column chromatography (*UNITS 10.9-10.11*) or HPLC (*UNITS 10.12-10.15*) have been used to increasingly purify a given protein from a crude protein mixture. If the protein is separated under denaturing conditions, any biological activity will likely be lost and, therefore, gel electrophoresis should definitely be the last purification step for a protein whose identity is based on a functional assay.

One-Dimensional SDS Gel Electrophoresis of Proteins

Electrophoresis is used to separate complex mixtures of proteins, (e.g., from cells, subcellular fractions, column fractions, or immunoprecipitates) to investigate subunit compositions, and to verify homogeneity of protein samples. It can also serve to purify proteins for use in further applications. In polyacrylamide gel electrophoresis, proteins migrate in response to an electrical field through pores in the gel matrix; pore size decreases with higher acrylamide concentrations. The combination of gel pore size and protein charge, size, and shape determines the migration rate of the protein.

The standard Laemmli method (see Basic Protocol 1) is used for discontinuous gel electrophoresis under denaturing conditions, that is, in the presence of sodium dodecyl sulfate (SDS). The standard method for full-size gels (e.g., 14 × 14 cm) can be adapted for the minigel format (e.g., 7.3 × 8.3 cm; see Basic Protocol 2). Minigels provide rapid separation but give lower resolution.

Several alternate protocols are provided for specific applications. The first two alternate protocols cover electrophoresis of peptides and small proteins, separations that require modification of standard buffers: either a Tris-tricine buffer system (see Alternate Protocol 1), or modified Tris buffer in the absence of urea (see Alternate Protocol 2). Continuous SDS-PAGE is a simplified method in which the same buffer is used for both gel and electrode solutions and the stacking gel is omitted (see Alternate Protocol 3). Other protocols cover the preparation and electrophoresis of various types of gels: ultrathin gels (see Alternate Protocol 4), multiple single-concentration gels (see Support Protocol 1), gradient gels (see Alternate Protocol 5), multiple gradient gels (see Support Protocol 2), and multiple gradient minigels (see Support Protocol 3). Proteins separated on gels can be subsequently analyzed by immunoblotting (UNIT 10.8), autoradiography or phosphor imaging (APPENDIX 3A), or staining with protein dyes (UNIT 10.6).

CAUTION: Before any protocols are used, it is extremely important to read the following section about electricity and electrophoresis.

ELECTRICITY AND ELECTROPHORESIS

Many researchers are poorly informed concerning the electrical parameters of running a gel. It is important to note that the voltages and currents used during electrophoresis are dangerous and potentially lethal. Thus, safety should be an overriding concern. A working knowledge of electricity is an asset in determining what conditions to use and in troubleshooting the electrophoretic separation, if necessary. For example, an unusually high or low voltage for a given current (milliamperes) might indicate an improperly made buffer or an electrical leak in the chamber.

Safety Considerations

1. Never remove or insert high-voltage leads unless the power supply voltage is turned down to zero and the power supply is turned off. Always grasp high-voltage leads one at a time with one hand only. Never insert or remove high-voltage leads with both hands. This can shunt potentially lethal electricity through the chest and heart should electrical contact be made between a hand and a bare wire. On older or homemade instruments, the banana plugs may not be shielded and can still be connected to the

power supply at the same time they make contact with a hand. Carefully inspect all cables and connections and replace frayed or exposed wires immediately.

2. Always start with the power supply turned off. Have the power supply controls turned all the way down to zero. Then hook up the gel apparatus: generally, connect the red high-voltage lead to the red outlet and the black high-voltage lead to the black outlet. Turn the power supply on with the controls set at zero and the high-voltage leads connected. Then, turn up the voltage, current, or power to the desired level. Reverse the process when the power supply is turned off: i.e., to disconnect the gel, turn the power supply down to zero, wait for the meters to read zero, turn off the power supply, and then disconnect the gel apparatus one lead at a time.

CAUTION: If the gel is first disconnected and then the power supply turned off, a considerable amount of electrical charge is stored internally. The charge will stay in the power supply over a long time. This will discharge through the outlets even though the power supply is turned off and can deliver an electrical shock.

Ohm's Law and Electrophoresis

Understanding how a gel apparatus is connected to the power supply requires a basic understanding of Ohm's law: voltage = current \times resistance, or $V = IR$. A gel can be viewed as a resistor and the power supply as the voltage and current source. Most power supplies deliver constant current or constant voltage. Some will also deliver constant power: power = voltage \times current, or $VI = I^2R$. The discussion below focuses on constant current because this is the most common mode in vertical SDS-PAGE.

Most modern commercial equipment is color-coded so that the red or positive terminal of the power supply can simply be connected to the red lead of the gel apparatus, which goes to the lower buffer chamber. The black lead is connected to the black or negative terminal and goes to the upper buffer chamber. This configuration is designed to work with vertical slab gel electrophoreses in which negatively charged proteins or nucleic acids move to the positive electrode in the lower buffer chamber (an anionic system).

When a single gel is attached to a power supply, the negative charges flow from the negative cathode (black) terminal into the upper buffer chamber, through the gel, and into the lower buffer chamber. The lower buffer chamber is connected to the positive anode (red) terminal to complete the circuit. Thus, negatively charged molecules, such as SDS-coated proteins and nucleic acids, move from the negative cathode attached to the upper buffer chamber toward the positive anode attached to the lower chamber. SDS-PAGE is an anionic system because of the negatively charged SDS.

Occasionally, proteins are separated in cationic systems. In these gels, the proteins are positively charged because of the very low pH of the gel buffers (e.g., acetic acid/urea gels for histone separations) or the presence of a cationic detergent (e.g., cetyltrimethylammonium bromide, CTAB). Proteins move toward the negative electrode (cathode) in cationic gel systems, and the polarity is reversed compared to SDS-PAGE: the red lead from the lower buffer chamber is attached to the black outlet of the power supply, and the black lead from the upper buffer chamber is attached to the red outlet of the power supply.

Most SDS-PAGE separations are performed under constant current (consult instructions from the manufacturer to set the power supply for constant current operation). The resistance of the gel will increase during SDS-PAGE in the standard Laemmli system. If the current is constant, then the voltage will increase during the run as the resistance goes up.

Power supplies usually have more than one pair of outlets. The pairs are connected in parallel with one another internally. If more than one gel is connected directly to the outlets

Figure 10.2A.1 Series and parallel connections of gel tanks to power supply.

of a power supply, then these gels are connected in parallel. In a parallel circuit, the voltage is the same across each gel. In other words, if the power supply reads 100 V, then each gel has 100 V across its electrodes. The total current, however, is the sum of the individual currents going through each gel. Therefore, under constant current it is necessary to increase the current for each additional gel that is connected to the power supply. Two identical gels require double the current to achieve the same starting voltages and electrophoresis separation times.

Multiple gel apparatuses can also be connected to one pair of outlets on a power supply. This is useful with older power supplies that have a limited number of outlets. When connecting several gel units to one outlet, make certain the connections between the units are shielded and protected from moisture. The gels can be connected in parallel or in series (Fig. 10.2A.1). In the case of two or more gels running off the same outlet in series, the current is the same for every gel. If 10 mA is displayed by the power supply meter, for example, each gel in series will experience 10 mA. The voltage, however, is additive for each gel. If one gel at a constant 10 mA produces 100 V, then two identical gels in series will produce 200 V (100 V each) and so on. Thus, the voltage can limit the number of units connected in series on low-voltage power supplies.

Gel thickness affects the above relationships. A 1.5-mm gel can be thought of as consisting of two 0.75-mm-thick gels run in parallel. Because currents are additive in parallel circuits, a 0.75-mm gel will require half the current of the 1.5-mm gel to achieve the same starting voltage and separation time. If a gel thickness is doubled, then the current must also be doubled. There are limits to the amount of current that can be applied. Thicker gels require more current, generating more heat that must be dissipated. Unless temperature control is available in the gel unit, a thick gel should be run more slowly than a thin gel.

NOTE: Milli-Q-purified water or equivalent should be used throughout the protocols.

**DENATURING (SDS) DISCONTINUOUS GEL ELECTROPHORESIS:
LAEMMLI GEL METHOD**

One-dimensional gel electrophoresis under denaturing conditions (i.e., in the presence of 0.1% SDS) separates proteins based on molecular size as they move through a polyacrylamide gel matrix toward the anode. The polyacrylamide gel is cast as a separating gel (sometimes called resolving or running gel) topped by a stacking gel and secured in an electrophoresis apparatus. After sample proteins are solubilized by boiling in the presence of SDS, an aliquot of the protein solution is applied to a gel lane, and the individual proteins are separated electrophoretically. 2-Mercaptoethanol (2-ME) or dithiothreitol (DTT) is added during solubilization to reduce disulfide bonds.

This protocol is designed for a vertical slab gel with a maximum size of 0.75 mm × 14 cm × 14 cm. For thicker gels, or minigels (see Basic Protocol 2 and Support Protocol 3), the volumes of stacking and separating gels and the operating current must be adjusted. Additional protocols describe the preparation of ultrathin gels (see Alternate Protocol 4) and gradient gels (see Alternate Protocol 5), as well as the use of gel casters to make multiple gels, both single-concentration gels (see Support Protocol 1) and gradient gels (see Support Protocol 2).

Materials

- Separating and stacking gel solutions (Table 10.2A.1)
- H₂O-saturated isobutyl alcohol
- 1× Tris·Cl/SDS, pH 8.8 (dilute 4× Tris·Cl/SDS, pH 8.8; Table 10.2A.1)
- Protein sample to be analyzed
- 2× and 1× SDS sample buffer (see recipe)
- Protein molecular-weight-standards mixture (Table 10.2A.2)
- 6× SDS sample buffer (see recipe; optional)
- 1× SDS electrophoresis buffer (see recipe)

- Electrophoresis apparatus: Protean II 16-cm cell (Bio-Rad) or SE 600/400 16-cm unit (Amersham Pharmacia Biotech) with clamps, glass plates, casting stand, and buffer chambers
- 0.75-mm spacers
- 0.45-μm filters (used in stock solution preparation)
- 25-ml Erlenmeyer side-arm flask
- Vacuum pump with cold trap
- 0.75-mm Teflon comb with 1, 3, 5, 10, 15, or 20 teeth
- 25- or 100-μl syringe with flat-tipped needle
- Constant-current power supply (see Electricity and Electrophoresis, above)

Pour the separating gel

1. Assemble the glass-plate sandwich of the electrophoresis apparatus according to manufacturer's instructions using two clean glass plates and two 0.75-mm spacers.
If needed, clean the glass plates in liquid Alconox or RBS-35 (Pierce). These aqueous-based solutions are compatible with silver and Coomassie blue staining procedures.
2. Lock the sandwich to the casting stand.
3. Prepare the separating gel solution as directed in Table 10.2A.1, degassing using a rubber-stoppered 25-ml Erlenmeyer side-arm flask connected with vacuum tubing to a vacuum pump with a cold trap. After adding the specified amount of 10% ammonium persulfate and TEMED to the degassed solution, stir gently to mix.

Table 10.2A.1 was prepared as a convenient summary to aid in the preparation of separating and stacking gels. The stacking gel is the same regardless of the separating gel used.

The desired percentage of acrylamide in the separating gel depends on the molecular size of the protein being separated. Generally, use 5% gels for SDS-denatured proteins of 60 to 200 kDa, 10% gels for SDS-denatured proteins of 16 to 70 kDa, and 15% gels for SDS-denatured proteins of 12 to 45 kDa (Table 10.2A.1).

4. Using a Pasteur pipet, apply the separating gel solution to the sandwich along an edge of one of the spacers until the height of the solution between the glass plates is ~11 cm.

Use the solution immediately; otherwise it will polymerize in the flask.

Sample volumes <10 μ l do not require a stacking gel. In this case, cast the resolving gel as you normally would, but extend the resolving gel into the comb to form the well. The proteins are then separated under the same conditions as used when a stacking gel is present. Although this protocol works well with single-concentration gels, a gradient gel is recommended for maximum resolution (see Alternate Protocol 5).

5. Using another Pasteur pipet, slowly cover the top of the gel with a layer (~1 cm thick) of H₂O-saturated isobutyl alcohol, by gently layering the isobutyl alcohol against the edge of one and then the other of the spacers.

Be careful not to disturb the gel surface. The overlay provides a barrier to oxygen, which inhibits polymerization, and allows a flat interface to form during gel formation.

The H₂O-saturated isobutyl alcohol is prepared by shaking isobutyl alcohol and H₂O in a separatory funnel. The aqueous (lower) phase is removed. This procedure is repeated several times. The final upper phase is H₂O-saturated isobutyl alcohol.

6. Allow the gel to polymerize 30 to 60 min at room temperature.

A sharp optical discontinuity at the overlay/gel interface will be visible on polymerization. Failure to form a firm gel usually indicates a problem with the ammonium persulfate, TEMED (N, N, N', N'-tetramethylethylenediamine), or both. Ammonium persulfate solution should be made fresh before use. Ammonium persulfate should "crackle" when added to the water. If not, fresh ammonium persulfate should be purchased. Purchase TEMED in small bottles so, if necessary, a new previously unopened source can be tried.

Pour the stacking gel

7. Pour off the layer of H₂O-saturated isobutyl alcohol and rinse with 1 \times Tris-Cl/SDS, pH 8.8.

Residual isobutyl alcohol can reduce resolution of the protein bands; therefore, it must be completely removed. The isobutyl alcohol overlay should not be left on the gel longer than 2 hr.

8. Prepare the stacking gel solution as directed in Table 10.2A.1.

Use the solution immediately to keep it from polymerizing in the flask.

9. Using a Pasteur pipet, slowly allow the stacking gel solution to trickle into the center of the sandwich along an edge of one of the spacers until the height of the solution in the sandwich is ~1 cm from the top of the plates.

Be careful not to introduce air bubbles into the stacking gel.

10. Insert a 0.75-mm Teflon comb into the layer of stacking gel solution. If necessary, add additional stacking gel to fill the spaces in the comb completely.

Again, be careful not to trap air bubbles in the tooth edges of the comb; they will cause small circular depressions in the well after polymerization that will lead to distortion in the protein bands during separation.

11. Allow the stacking gel solution to polymerize 30 to 45 min at room temperature.

A sharp optical discontinuity will be visible around wells on polymerization.

Table 10.2A.1 Recipes for Polyacrylamide Separating and Stacking Gels^a**SEPARATING GEL**

Stock solution ^b	Final acrylamide concentration in separating gel (%) ^c									
	5	6	7	7.5	8	9	10	12	13	15
30% acrylamide/ 0.8% bisacrylamide	2.50	3.00	3.50	3.75	4.00	4.50	5.00	6.00	6.50	7.50
4× Tris·Cl/SDS, pH 8.8	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75
H ₂ O	8.75	8.25	7.75	7.50	7.25	6.75	6.25	5.25	4.75	3.75
10% (w/v) ammonium persulfate ^d	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05
TEMED	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01

Preparation of separating gel

In a 25-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution, 4× Tris·Cl/SDS, pH 8.8 (see reagents, below), and H₂O. Degas under vacuum ~5 min. Add 10% ammonium persulfate and TEMED. Swirl gently to mix. Use immediately.

STACKING GEL (3.9% acrylamide)

In a 25-ml side-arm flask, mix 0.65 ml of 30% acrylamide/0.8% bisacrylamide, 1.25 ml of 4× Tris·Cl/SDS, pH 6.8 (see reagents, below), and 3.05 ml H₂O. Degas under vacuum 10 to 15 min. Add 25 μl of 10% ammonium persulfate and 5 μl TEMED. Swirl gently to mix. Use immediately. Failure to form a firm gel usually indicates a problem with the persulfate, TEMED, or both.

REAGENTS USED IN GELS**30% acrylamide/0.8% bisacrylamide**

Mix 30.0 g acrylamide and 0.8 g *N,N'*-methylenebisacrylamide with H₂O in a total volume of 100 ml. Filter the solution through a 0.45-μm filter and store at 4°C in the dark. The 2× crystallized grades of acrylamide and bisacrylamide are recommended. Discard after 30 days, as acrylamide gradually hydrolyzes to acrylic acid and ammonia.

CAUTION: *Acrylamide monomer is neurotoxic. A mask should be worn when weighing acrylamide powder. Gloves should be worn while handling the solution, and the solution should not be pipetted by mouth.*

4× Tris·Cl/SDS, pH 6.8 (0.5 M Tris·Cl containing 0.4% SDS)

Dissolve 6.05 g Tris base in 40 ml H₂O. Adjust to pH 6.8 with 1 N HCl. Add H₂O to 100 ml total volume. Filter the solution through a 0.45-μm filter, add 0.4 g SDS, and store at 4°C up to 1 month.

4× Tris·Cl/SDS, pH 8.8 (1.5 M Tris·Cl containing 0.4% SDS)

Dissolve 91 g Tris base in 300 ml H₂O. Adjust to pH 8.8 with 1 N HCl. Add H₂O to 500 ml total volume. Filter the solution through a 0.45-μm filter, add 2 g SDS, and store at 4°C up to 1 month.

^aThe recipes produce 15 ml of separating gel and 5 ml of stacking gel, which are adequate for a gel of dimensions 0.75 mm × 14 cm × 14 cm. The recipes are based on the SDS (denaturing) discontinuous buffer system of Laemmli (1970).

^bAll reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.

^cUnits of numbers in table body are milliliters. The desired percentage of acrylamide in the separating gel depends on the molecular size of the protein being separated. See annotation to step 3, Basic Protocol 1.

^dBest to prepare fresh.

Prepare the sample and load the gel

12. Dilute a portion of the protein sample to be analyzed 1:1 (v/v) with 2× SDS sample buffer and heat 3 to 5 min at 100°C in a sealed screw-cap microcentrifuge tube. If the sample is a precipitated protein pellet, dissolve the protein in 50 to 100 μl of 1× SDS sample buffer and boil 3 to 5 min at 100°C. Dissolve protein-molecular-weight standards mixture in 1× SDS sample buffer according to supplier's instructions; use these standards as a control (Table 10.2A.2).

For dilute protein solutions, consider adding 5:1 protein solution/6× SDS sample buffer to increase the amount of protein loaded. Proteins can also be concentrated by precipitation in acetone, ethanol, or trichloroacetic acid (TCA), but losses will occur.

For a 0.8-cm-wide well, 25 to 50 μg total protein in <20 μl is recommended for a complex mixture when staining with Coomassie blue, and 1 to 10 μg total protein is needed for samples containing one or a few proteins. If silver staining is used, 10- to 100-fold less protein can be applied (0.01 to 5 μg in <20 μl depending on sample complexity).

To achieve the highest resolution possible, the following precautions are recommended. Prior to adding the sample buffer, keep samples at 0°C. Add the SDS sample buffer (room temperature) directly to the 0°C sample (still on ice) in a screw-top microcentrifuge tube. Cap the tube to prevent evaporation, vortex, and transfer directly to a 100°C water bath for 3 to 5 min. Let immunoprecipitates dissolve for 1 hr at 56°C in 1× SDS sample buffer prior to boiling. DO NOT leave the sample in SDS sample buffer at room temperature without first heating to 100°C to inactivate proteases (see Critical Parameters and Troubleshooting). Endogenous proteases are very active in SDS sample buffer and will cause severe degradation of the sample proteins after even a few minutes at room temperature. To test for possible proteases, mix the sample with SDS sample buffer without heating and leave at room temperature for 1 to 3 hr. A loss of high-molecular-weight bands

Table 10.2A.2 Molecular Weights of Protein Standards for Polyacrylamide Gel Electrophoresis^a

Protein	Molecular weight
Cytochrome <i>c</i>	11,700
α-Lactalbumin	14,200
Lysozyme (hen egg white)	14,300
Myoglobin (sperm whale)	16,800
β-Lactoglobulin	18,400
Trypsin inhibitor (soybean)	20,100
Trypsinogen, PMSF treated	24,000
Carbonic anhydrase (bovine erythrocytes)	29,000
Glyceraldehyde-3-phosphate dehydrogenase (rabbit muscle)	36,000
Lactate dehydrogenase (porcine heart)	36,000
Aldolase	40,000
Ovalbumin	45,000
Catalase	57,000
Bovine serum albumin	66,000
Phosphorylase <i>b</i> (rabbit muscle)	97,400
β-Galactosidase	116,000
RNA polymerase, <i>E. coli</i>	160,000
Myosin, heavy chain (rabbit muscle)	205,000

^aProtein standards are commercially available in kits (e.g., Amersham Pharmacia Biotech, Life Technologies, Bio-Rad, or Sigma).

and a general smearing of the banding pattern indicate a protease problem. Once heated, the samples can sit at room temperature for the time it takes to load samples.

- Carefully remove the Teflon comb without tearing the edges of the polyacrylamide wells. After the comb is removed, rinse wells with 1× SDS electrophoresis buffer.

The rinse removes unpolymerized monomer; otherwise, the monomer will continue to polymerize after the comb is removed, creating uneven wells that will interfere with sample loading and subsequent separation.

- Using a Pasteur pipet, fill the wells with 1× SDS electrophoresis buffer.

If well walls are not upright, they can be manipulated with a flat-tipped needle attached to a syringe.

- Attach gel sandwich to upper buffer chamber following manufacturer's instructions.

- Fill lower buffer chamber with the recommended amount of 1× SDS electrophoresis buffer.

- Place sandwich attached to upper buffer chamber into lower buffer chamber.

- Partially fill the upper buffer chamber with 1× SDS electrophoresis buffer so that the sample wells of the stacking gel are filled with buffer.

Monitor the upper buffer chamber for leaks and if necessary, reassemble the unit. A slow leak in the upper buffer chamber may cause arcing around the upper electrode and damage the upper buffer chamber.

- Using a 25- or 100- μ l syringe with a flat-tipped needle, load the protein sample(s) into one or more wells by carefully applying the sample as a thin layer at the bottom of the wells. Load control wells with molecular weight standards. Add an equal volume of 1× SDS sample buffer to any empty wells to prevent spreading of adjoining lanes.

Preparing the samples at approximately the same concentration and loading an equal volume to each well will ensure that all lanes are the same width and that the proteins run evenly. If unequal volumes of sample buffer are added to wells, the lane with the larger volume will spread during electrophoresis and constrict the adjacent lanes, causing distortions.

The samples will layer on the bottom of the wells because the glycerol added to the sample buffer gives the solution a greater density than the electrophoresis buffer. The bromphenol blue in the sample buffer makes sample application easy to follow visually.

- Fill the remainder of the upper buffer chamber with additional 1× SDS electrophoresis buffer so that the upper platinum electrode is completely covered. Do this slowly so that samples are not swept into adjacent wells.

Run the gel

- Connect the power supply to the cell and run at 10 mA of constant current for a slab gel 0.75 mm thick, until the bromphenol blue tracking dye enters the separating gel. Then increase the current to 15 mA.

For a standard 16-cm gel sandwich, 4 mA per 0.75-mm-thick gel will run ~15 hr (i.e., overnight); 15 mA per 0.75-mm gel will take 4 to 5 hr. To run two gels or a 1.5-mm-thick gel, simply double the current. When running a 1.5-mm gel at 30 mA, the temperature must be controlled (10° to 20°C) with a circulating constant-temperature water bath to prevent "smiling" (curvature in the migratory band). Temperatures <5°C should not be used because SDS in the running buffer will precipitate. If the level of buffer in the upper chamber decreases, a leak has occurred.

22. After the bromphenol blue tracking dye has reached the bottom of the separating gel, disconnect the power supply.

Refer to Safety Considerations under Electricity and Electrophoresis.

Disassemble the gel

23. Discard electrode buffer and remove the upper buffer chamber with the attached gel sandwich.
24. Orient the gel so that the order of the sample wells is known, remove the sandwich from the upper buffer chamber, and lay the sandwich on a sheet of absorbent paper or paper towels.
25. Carefully slide one of the spacers halfway from the edge of the sandwich along its entire length. Use the exposed spacer as a lever to pry open the glass plate, exposing the gel.
26. Carefully remove the gel from the lower plate. Cut a small triangle off one corner of the gel so the lane orientation is not lost during staining and drying. Proceed with protein detection.

The gel can be stained with Coomassie blue or silver (UNIT 10.6), or proteins can be electroeluted, electroblotted onto a polyvinylidene difluoride (PVDF) membrane for subsequent staining or sequence analysis, or transferred to a membrane for immunoblotting UNIT 10.8. If the proteins are radiolabeled, they can be detected by autoradiography (APPENDIX 3A).

ELECTROPHORESIS IN TRIS-TRICINE BUFFER SYSTEMS

Separation of peptides and proteins under 10 to 15 kDa is not possible in the traditional Laemmli discontinuous gel system (see Basic Protocol 1). This is due to the comigration of SDS and smaller proteins, obscuring the resolution. Two approaches to obtain the separation of small proteins and peptides in the range of 5 to 20 kDa are presented: the following Tris-tricine method and a system using increased buffer concentrations (see Alternate Protocol 2). The Tris-tricine system uses a modified buffer to separate the SDS and peptides, thus improving resolution. Several precast gels are available for use with the tricine formulations (Table 10.2A.3).

**ALTERNATE
PROTOCOL 1**

Table 10.2A.3 Vertical Format Precast Gel Compatibility

Gel type and compatibility	Gel supplier

**Analysis of
Proteins**

10.2A.9

Additional Materials (also see *Basic Protocol 1*)

Separating and stacking gel solutions (Table 10.2A.4)
2× tricine sample buffer (see recipe)
Peptide molecular-weight-standards mixture (Table 10.2A.5)
Cathode buffer (see recipe)
Anode buffer (see recipe)
Coomassie blue G-250 staining solution (see recipe)
10% (v/v) acetic acid

1. Prepare and pour the separating and stacking gels (see *Basic Protocol 1*, steps 1 to 11), using Table 10.2A.4 in place of Table 10.2A.1.
2. Prepare the sample (see *Basic Protocol 1*, step 12), but make the following changes for tricine gels. Substitute 2× tricine sample buffer for the 2× SDS sample buffer. Dilute an aliquot of the protein or peptide sample to be analyzed 1:1 (v/v) with 2× tricine sample buffer. Treat the sample at 40°C for 30 to 60 min prior to loading.

If proteolytic activity is a problem, heating samples to 100°C for 3 to 5 min before loading the wells may be required (see Basic Protocol 1, annotation to step 12). Use the peptide molecular-weight-standards mixture for peptide separations (Table 10.2A.5).
3. Load the gel and set up the electrophoresis apparatus (see *Basic Protocol 1*, steps 13 to 20) with the following alterations. Remove comb and, using the tricine-containing

Table 10.2A.4 Recipes for Tricine Peptide Separating and Stacking Gels^a

SEPARATING AND STACKING GELS

Stock solution ^b	Separating gel	Stacking gel
30% acrylamide/0.8% bisacrylamide	9.80 ml	1.62 ml
Tris·Cl/SDS, pH 8.45	10.00 ml	3.10 ml
H ₂ O	7.03 ml	7.78 ml
Glycerol	4.00 g (3.17 ml)	—
10% (w/v) ammonium persulfate ^c	50 μl	25 μl
TEMED	10 μl	5 μl

Prepare separating and stacking gel solutions separately.

In a 50-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (Table 10.2A.1), Tris·Cl/SDS, pH 8.45 (see reagents, below), and H₂O. Add glycerol to separating gel only. Degas under vacuum 10 to 15 min. Add 10% ammonium persulfate and TEMED. Swirl gently to mix, use immediately. Failure to form a firm gel usually indicates a problem with the persulfate, TEMED, or both.

ADDITIONAL REAGENTS USED IN GELS

Tris·Cl/SDS, pH 8.45 (3.0 M Tris·Cl containing 0.3% SDS)

Dissolve 182 g Tris base in 300 ml H₂O. Adjust to pH 8.45 with 1 N HCl. Add H₂O to 500 ml total volume. Filter the solution through a 0.45-μm filter, add 1.5 g SDS, and store at 4°C up to 1 month.

^aThe recipes produce 30 ml of separating gel and 12.5 ml of stacking gel, which are adequate for two gels of dimensions 0.75 mm × 14 cm × 14 cm. The recipes are based on the Tris-tricine buffer system of Schagger and von Jagow (1987).

^bAll reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.

^cBest to prepare fresh.

Table 10.2A.5 Molecular Weights of Peptide Standards for Polyacrylamide Gel Electrophoresis^a

Peptide	Molecular weight (Da)
Myoglobin (polypeptide backbone)	16,950
Myoglobin 1-131	14,440
Myoglobin 56-153	10,600
Myoglobin 56-131	8,160
Myoglobin 1-55	6,210
Glucagon	3,480
Myoglobin 132-153	2,510

^aPeptide standards are commercially available from Sigma.

cathode buffer, or water, rinse once and fill wells. Fill the lower buffer chamber with anode buffer, assemble the unit, and attach the upper buffer chamber. Fill the upper buffer chamber with cathode buffer and load the samples.

4. Connect the power supply to the cell and run 1 hr at 30 V (constant voltage) followed by 4 to 5 hr at 150 V (constant voltage). Use heat exchanger to keep the electrophoresis chamber at room temperature.
5. After the tracking dye has reached the bottom of the separating gel, disconnect the power supply.

Refer to Safety Considerations under Electricity and Electrophoresis.

Coomassie blue G-250 is used as a tracking dye instead of bromphenol blue because it moves ahead of the smallest peptides.

6. Disassemble the gel (see Basic Protocol 1, steps 23 to 26). Stain proteins in the gel for 1 to 2 hr in Coomassie blue G-250 staining solution. Follow by destaining with 10% acetic acid, changing the solution every 30 min until background is clear (3 to 5 changes). For higher sensitivity, use silver staining as a recommended alternative.

Prolonged staining and destaining will result in the loss of resolution of the smaller proteins (<10 kDa). Proteins diffuse within the gel and out of the gel, resulting in a loss of staining intensity and resolution.

NONUREA PEPTIDE SEPARATIONS WITH TRIS BUFFERS

A simple modification of the traditional Laemmli buffer system presented in Basic Protocol 1, in which the increased concentration of buffers provides better separation between the stacked peptides and the SDS micelles, permits reasonable separation of peptides as small as 5 kDa.

Additional Materials (also see Basic Protocol 1)

Separating and stacking gel solutions (Table 10.2A.6)

2× SDS electrophoresis buffer (see recipe)

2× Tris·Cl/SDS, pH 8.8 (dilute 4× Tris·Cl/SDS, pH 8.8; Table 10.2A.1)

1. Prepare and pour the separating gel (see Basic Protocol 1, steps 1 to 6) using Table 10.2A.6 in place of Table 10.2A.1.
2. Prepare and pour the stacking gel (see Basic Protocol 1, steps 7 to 11), using 2× Tris·Cl/SDS, pH 8.8, rather than 1× Tris·Cl/SDS buffer, for rinsing the gel after removing the isobutyl alcohol overlay.

**ALTERNATE
PROTOCOL 2**

**Analysis of
Proteins**

10.2A.11

- Prepare the sample and load the gel (see Basic Protocol 1, steps 12 to 20) and substitute 2× SDS electrophoresis buffer for the 1× SDS electrophoresis buffer.

Table 10.2A.5 lists the standards for small protein separations.

- Run the gel (see Basic Protocol 1, steps 21 and 22).

Note that the separations will take ~25% longer than those using Basic Protocol 1. The increased buffer concentrations lead to faster transit through the stacking gel but lower mobility in the resolving gel.

- Disassemble the gel (see Basic Protocol 1, steps 23 to 26).

Proteins in the gel may now be stained.

Table 10.2A.6 Recipes for Modified Laemmli Peptide Separating and Stacking Gels^a

SEPARATING AND STACKING GELS

Stock solution ^b	Separating gel	Stacking gel
30% acrylamide/0.8% bisacrylamide	10.00 ml	0.65 ml
8× Tris·Cl, pH 8.8	3.75 ml	—
4× Tris·Cl, pH 6.8	—	1.25 ml
10% (w/v) SDS	0.15 ml	50 μl
H ₂ O	1.00 ml	3.00 ml
10% (w/v) ammonium persulfate ^c	50 μl	25 μl
TEMED	10 μl	5 μl

Prepare separating and stacking gel solutions separately

In a 25-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (see Table 10.2A.1), 8× Tris·Cl, pH 8.8 (separating gel) or 4× Tris·Cl, pH 6.8 (stacking gel), 10% SDS (see reagents, below), and H₂O. Degas under vacuum 10 to 15 min. Add 10% ammonium persulfate and TEMED. Swirl gently to mix; use immediately. Failure to form a firm gel usually indicates a problem with the persulfate, TEMED, or both.

ADDITIONAL REAGENTS USED IN GELS

4× Tris·Cl, pH 6.8 (0.5 M Tris·Cl)

Dissolve 6.05 g Tris base in 40 ml H₂O. Adjust to pH 6.8 with 1 N HCl. Add H₂O to 100 ml total volume. Filter the solution through a 0.45-μm filter and store up to 1 month at 4°C.

8× Tris·Cl, pH 8.8 (3.0 M Tris·Cl)

Dissolve 182 g Tris base in 300 ml H₂O. Adjust to pH 8.8 with 1 N HCl. Add H₂O to 500 ml total volume. Filter the solution through a 0.45-μm filter and store up to 1 month at 4°C.

10% (w/v) SDS

Mix 1 g SDS in 10 ml of H₂O. Use immediately.

^aThe recipes produce 15 ml of separating gel and 5 ml of stacking gel, which are adequate for one gel of dimensions 0.75 mm × 14 cm × 14 cm. The recipes are based on the modified Laemmli peptide separation system of Okajima et al. (1993).

^bAll reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.

CONTINUOUS SDS-PAGE

With continuous SDS-PAGE, the same buffer is used for both the gel and electrode solutions. Although continuous gels lack the resolution of the discontinuous systems, they are extremely versatile, less prone to mobility artifacts, and much easier to prepare. The stacking gel is omitted.

Additional Materials (also see *Basic Protocol 1*)

- Separating gel solution (Table 10.2A.7)
- 2× and 1× phosphate/SDS sample buffer (see recipe)
- 1× phosphate/SDS electrophoresis buffer (see recipe)

1. Prepare and pour a single separating gel (see *Basic Protocol 1*, steps 1 to 4), except use solutions in Table 10.2A.7 in place of those in Table 10.2A.1 and fill the gel sandwich to the top. Omit the stacking gel. Insert the comb (see *Basic Protocol 1*, step 10) and allow the gel to polymerize 30 to 60 min at room temperature.
2. Mix the protein sample 1:1 with 2× phosphate/SDS sample buffer and heat to 100°C for 2 min.

*For large sample volumes or samples suspended in high ionic strength buffers (>50 mM), dialyze against 1× sample buffer prior to electrophoresis. Note that the precautions about proteases (see *Basic Protocol 1*, step 12) apply here.*

Table 10.2A.7 Recipes for Separating Gels for Continuous SDS-PAGE^a**SEPARATING GEL**

Stock solution ^b	Final acrylamide concentration in separating gel (%) ^c											
	5	6	7	8	9	10	11	12	13	14	15	
30% acrylamide/ 0.8% bisacrylamide	2.5	3.00	3.50	4.00	4.50	5.00	5.50	6.00	6.50	7.00	7.50	
4× phosphate/SDS, pH 7.2	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	
H ₂ O	8.75	8.25	7.75	7.25	6.75	6.25	5.75	5.25	4.75	4.25	3.75	
10% (w/v) ammonium persulfate ^d	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	
TEMED	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01	

Preparation of separating gel

In a 25-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (see Table 10.2A.1), 4× phosphate/SDS, pH 7.2, and H₂O. Degas under vacuum about 5 min. Add 10% ammonium persulfate and TEMED. Swirl gently to mix. Use immediately.

ADDITIONAL REAGENTS USED IN GELS**4× phosphate/SDS, pH 7.2 (0.4 M sodium phosphate/0.4% SDS)**

Mix 46.8 g NaH₂PO₄·H₂O, 231.6 g Na₂HPO₄·7 H₂O, and 12 g SDS in 3 liters H₂O.

Store at 4°C for up to 3 months.

^aThe recipes produce 15 ml of separating gel, which is adequate for one gel of dimensions 0.75 mm × 14 cm × 14 cm. The recipes are based on the original continuous phosphate buffer system of Weber et al. (1972). The stacking gel is omitted.

^bAll reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.

^cUnits of numbers in table body are milliliters. The desired percentage of acrylamide in the separating gel depends on the molecular size of the protein being separated. See *Basic Protocol 1*, annotation to step 3.

^dBest to prepare fresh.

**ALTERNATE
PROTOCOL 4**

3. Assemble the electrophoresis apparatus and load the sample (see Basic Protocol 1, steps 13 to 20), using the phosphate/SDS electrophoresis buffer and loading empty wells with 1× phosphate/SDS sample buffer.
4. Connect the power supply and start the run with 15 mA per 0.75-mm-thick gel until the tracking dye has entered the gel. Continue electrophoresis at 30 mA for 3 hr (5% gel), 5 hr (10% gel), 8 hr (15% gel), or until the dye reaches the bottom of the gel.
Use temperature control if available to maintain the gel at 15° to 20°C. SDS will precipitate below 15°C in this system.
5. Disassemble the gel (see Basic Protocol 1, steps 23 to 26).
See Safety Considerations in introduction. Proteins in the gel may now be stained.

CASTING AND RUNNING ULTRATHIN GELS

Ultrathin gels provide superb resolution but are difficult to handle. In this application, gels are cast on Gel Bond, a Mylar support material. Silver staining is recommended for the best resolution. Combs and spacers for gels <0.5 mm thick are not readily available for most protein electrophoresis units. However, by adapting combs and spacers used for DNA sequencing, casting gels from 0.2 to 0.5 mm thick is straightforward.

Additional Materials (also see Basic Protocol 1)

- 95% (v/v) ethanol
 - Gel Bond (FMC BioProducts) cut to a size slightly smaller than the gel plate dimensions
 - Glue stick
 - Ink roller (available from art supply stores)
 - Combs and spacers (0.19 to 0.5 mm; sequencing gel spacers and combs can be cut to fit)
1. Wash gel plates with water-based laboratory detergent followed by successive rinses with hot tap water, deionized water, and finally 95% ethanol. Allow to air dry.
Gel plates must be extremely clean for casting thin gels.
Gloves are needed throughout these procedures to prevent contamination by proteins on the surface of skin.
 2. Apply a streak of adhesive from a glue stick to the bottom edge of the glass plate. Quickly position the Gel Bond with the hydrophobic side down (a drop of water will bead up on the hydrophobic surface). Apply pressure with Kimwipe tissue to attach the Gel Bond firmly to the plate. Finally, pull the top portion of the Gel Bond back, place a few drops of water underneath, and roll flat with an ink roller.
Make sure the Gel Bond does not extend beyond the edges of the upper and lower sealing surface of the plate. This will cause it to buckle on sealing. Reposition the Gel Bond if needed to prevent it from extending beyond the glass plate. Material may also be trimmed to fit flush with the plate edge.
 3. Assemble the gel cassette according to the manufacturer's instructions (also see Basic Protocol 1, steps 1 and 2). Just prior to assembly, blow air over the surface of both the Gel Bond and the opposing glass surface to remove any particulate material (e.g., dust).
Sequencing gel spacers can be easily adapted. First, cut the spacers slightly longer than the length of the gel plate. Position a spacer along each edge of the glass plate and assemble the gel sandwich, clamping in place. With a razor blade, trim the excess spacer at top and bottom to get a reusable spacer exactly the size of the plate.

4. Prepare and pour the separating and stacking gels (see Basic Protocol 1, steps 3 to 9). In place of the Teflon comb, insert a square well sequencing comb cut to fit within the gel sandwich. Allow the stacking gel to polymerize 30 to 45 min at room temperature.

Less solution is needed for ultrathin gels. For example, a 0.5-mm-thick gel requires 33% less gel solution than a 0.75-mm gel.

5. Prepare the sample and load the gel (see Basic Protocol 1, steps 12 to 20).

When preparing protein samples for ultrathin gels, 3 to 4 μ l at 5 μ g protein/ μ l is required for Coomassie blue R-250 staining, whereas 10-fold less is needed for silver staining.

6. Run the gel (see Basic Protocol 1, steps 21 and 22), except conduct the electrophoresis at 7 mA/gel (0.25-mm-thick gels) or 14 mA/gel (0.5-mm-thick gels) for 4 to 5 hr.

7. When the separation is complete, disassemble the unit and remove the gel (see Basic Protocol 1, steps 23 to 26) with the Gel Bond still attached. With a gloved hand, wash away the adhesive material from the back of the Gel Bond under a stream of water before proceeding to protein detection.

Either Coomassie blue or silver staining may be used, but silver staining produces particularly fine resolution with thin Gel Bond-backed gels. Compared to staining thicker (>0.75 mm) gels, thin (<0.75 mm) gels stain and destain more quickly. Although the optimum staining times must be empirically determined, all steps in Coomassie blue and silver staining procedures are generally reduced by half.

CASTING MULTIPLE SINGLE-CONCENTRATION GELS

Casting multiple gels at one time has several advantages. All the gels are identical, so sample separation is not affected by gel-to-gel variation. Furthermore, casting ten gels is only slightly more difficult than casting two gels. Once cast, gels can be stored for several days in a refrigerator.

Additional Materials (also see Basic Protocol 1)

Separating and stacking gels for single-concentration gels (Table 10.2A.8)

H₂O-saturated isobutyl alcohol

Multiple gel caster (Bio-Rad, Amersham Pharmacia Biotech)

100-ml disposable syringe and flat-tipped needle

Extra plates and spacers

14 × 14-cm acrylic blocks or polycarbonate sheets

250- and 500-ml side-arm flasks (used in gel preparation)

Long razor blade *or* plastic wedge (Wonder Wedge, Amersham Pharmacia Biotech)

Resealable plastic bags

Pour the separating gel

1. Assemble the multiple gel caster according to the manufacturer's instructions.

With the Amersham Pharmacia Biotech unit make sure to insert the large triangular space filler plug in the base of the caster. The plug is removed when casting gradient gels (see Support Protocol 2).

2. Assemble glass sandwiches and stack them in the casting chamber. Stack up to ten 1.5-mm gels and fill in extra space with acrylic blocks or polycarbonate sheets to hold the sandwiches tightly in place. Make sure the spacers are straight along the top, right, and left edges of the glass plates and that all edges of the stack are flush.

The presence of loosely fitting sandwiches in the caster will lead to unevenly cast gels, creating distortions during electrophoresis. Polycarbonate inhibits gel polymerization.

SUPPORT PROTOCOL 1

Analysis of Proteins

10.2A.15

Table 10.2A.8 Recipes for Multiple Single-Concentration Polyacrylamide Gels^a**SEPARATING GEL**

Stock solution ^b	Final acrylamide concentration in separating gel (%) ^c										
	5	6	7	8	9	10	11	12	13	14	15
30% acrylamide/0.8% bisacrylamide	52	62	72	83	93	103	114	124	134	145	155
4× Tris·Cl/SDS, pH 8.8	78	78	78	78	78	78	78	78	78	78	78
H ₂ O	181	171	160	150	140	129	119	109	98	88	78
10% (w/v) ammonium persulfate ^d	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0
TEMED	0.21	0.21	0.21	0.21	0.21	0.21	0.21	0.21	0.21	0.21	0.21

Preparation of separating gel

In a 500-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (see Table 10.2A.1), 4× Tris·Cl/SDS, pH 8.8 (Table 10.2A.1), and H₂O. Degas under vacuum ~5 min. Add 10% ammonium persulfate and TEMED. Swirl gently to mix; use immediately.

STACKING GEL

In a 250-ml side-arm flask, mix 13.0 ml 30% acrylamide/0.8% bisacrylamide solution, 25 ml 4× Tris·Cl/SDS, pH 6.8 (Table 10.2A.1), and 61 ml H₂O. Degas under vacuum ~5 min. Add 0.25 ml 10% ammonium persulfate and 50 μl TEMED. Swirl gently to mix. Use immediately. Failure to form a firm gel usually indicates a problem with the persulfate, TEMED, or both.

^aThe recipes produce about 300 ml of separating gel and 100 ml of stacking gel, which are adequate for ten gels of dimensions 1.5 mm × 14 cm × 14 cm. Volumes were measured using 1.5-mm spacers. For thinner spacers or fewer gels, calculate volumes using the equation in the annotation to step 4. The recipes are based on the SDS (denaturing) discontinuous buffer system of Laemmli (1970).

^bAll reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.

^cUnits of numbers in table body are milliliters. The desired percentage of acrylamide in separating gel depends on the molecular size of the protein being separated. See Basic Protocol 1, annotation to step 3.

^dBest to prepare fresh.

Therefore, if polycarbonate sheets are placed in the caster before and after the set of glass sandwiches, the entire set will slide out as one block after polymerization. Placing polycarbonate sheets between each gel sandwich makes them easier to separate from one another after polymerization.

- Place the front sealing plate on the casting chamber, making sure the stack fits snugly. Secure the plate with four spring clamps and tighten the bottom thumb screws.
- Prepare the separating (resolving) gel solution (Table 10.2A.8).

A 12-cm separating gel with a 4-cm stacking gel is recommended.

If fewer than ten gels are prepared (Table 10.2A.8), use the following formula to estimate the amount of separating gel volume needed:

$$\text{Volume} = \text{gel number} \times \text{height (cm)} \times \text{width (cm)} \times \text{thickness (cm)} + 4 \times \text{gel number} + 10 \text{ ml.}$$

- Using a 100-ml disposable syringe with flat-tipped needle, inject the resolving gel solution down the side of one spacer into the multiple caster. A channel in the silicone plug distributes the solution throughout the whole caster. Avoid introducing bubbles by giving the caster a quick tap on the benchtop once the caster is filled.

6. Overlay the center of each gel with 100 μ l H₂O-saturated isobutyl alcohol and let polymerize for 1 to 2 hr.
7. Drain off the overlay and rinse the surface with 1 \times Tris-Cl/SDS, pH 8.8. If the gels will not be used immediately, skip to step 12.

Pour the stacking gel

8. Prepare the stacking gel solution either singly (see Basic Protocol 1, step 8) or for all the gels at once (Table 10.2A.8).

The stacking gel solution should be prepared just before pouring the gel.

9. Fill each sandwich in the caster with stacking gel solution.
10. Insert a comb into each sandwich and let the gel polymerize for 2 hr.

Insert the combs at a 45° angle to avoid trapping air underneath the comb teeth. Air bubbles will inhibit polymerization and cause dents in the wells and a distorted pattern of protein bands.

11. Remove the combs and rinse wells with 1 \times SDS electrophoresis buffer.

Remove the gels from the caster

12. Remove the gels from the caster and separate by carefully inserting a long razor blade or knife between each gel sandwich.

A plastic wedge (Amersham Pharmacia Biotech's Wonder Wedge) also works well.

13. Clean the outside of each gel plate with running water to remove the residual polymerized and unpolymerized acrylamide.
14. Overlay gels to be stored with 1 \times Tris-Cl/SDS, pH 8.8, place in a resealable plastic bag, and store at 4°C until needed (up to 1 week).

SEPARATION OF PROTEINS ON GRADIENT GELS

Gels that consist of a gradient of increasing polyacrylamide concentration resolve a much wider size range of proteins than standard uniform-concentration gels (see Critical Parameters and Troubleshooting). The protein bands, particularly in the low-molecular-weight range, are also much sharper. Unlike single-concentration gels, gradient gels separate proteins in a way that can be represented easily to give a linear plot from 10 to 200 kDa. This facilitates molecular weight estimations.

The quantities given below provide separating gel solution sufficient for two 0.75-mm gels (~7 ml of each concentration) or one 1.5-mm gel (~14 ml of each concentration). Volumes can be adjusted to accommodate gel sandwiches of different dimensions.

Additional Materials (also see *Basic Protocol 1*)

Light and heavy acrylamide gel solutions (Table 10.2A.9 and Table 10.2A.10)
 Bromphenol blue (optional; for checking practice gradient)
 TEMED

Gradient maker (30 to 50 ml, Amersham Pharmacia Biotech SG30 or SG50; or 30 to 100 ml, Bio-Rad 385)

Tygon tubing with micropipet tip

Peristaltic pump (optional; e.g., Markson A-13002, A-34040, or A-34105 minipump)

Whatman 3MM filter paper

***ALTERNATE
 PROTOCOL 5***

Set up the gradient maker and prepare the gel solutions

1. Assemble the magnetic stirrer and gradient maker on a ring stand as shown in Figure 10.2A.2. Connect the outlet valve of the gradient maker to Tygon tubing attached to a micropipet tip that is placed over the vertical gel sandwich. If desired, place a peristaltic pump in line between the gradient maker and the gel sandwich.

A peristaltic pump will simplify casting by providing a smooth flow rate.

2. Place a small stir-bar into the mixing chamber of the gradient maker (i.e., the chamber connected to the outlet).
3. Using the recipes in Table 10.2A.9 and Table 10.2A.10, prepare light and heavy acrylamide gel solutions. Do not add ammonium persulfate until just before use (step 7).
4. With the outlet port and interconnecting valve between the two chambers closed, pipet 7 ml of light (low-concentration) acrylamide gel solution into the reservoir chamber for one 0.75-mm-thick gradient gel.

Recommended gradient ranges are 5% to 20% for most applications (to separate proteins of 10 to several hundred kilodaltons).

A practice run with heavy and light solutions is recommended. Bromphenol blue should be added to the heavy solution to demonstrate linearity of the practice gradient.

5. Open the interconnecting valve briefly to allow a small amount (~200 μ l) of light solution to flow through the valve and into the mixing chamber.

The presence of air bubbles in the interconnecting valve may obstruct the flow between chambers during casting.

Deaeration is not recommended for either the light or heavy solution. Omitting the deaeration will allow polymerization to proceed more slowly, letting the gradient establish itself in the gel sandwich before polymerization takes place.

6. Add 7 ml of heavy (high-concentration) acrylamide gel solution to the mixing chamber.

Keep the heavy solution on ice until use. Once the ammonium persulfate is added to the heavy solution, it will polymerize without TEMED, albeit more slowly; keeping the solution on ice prevents this. The gel solution will come to room temperature during casting. The higher the percentage of acrylamide, the more severe the problem of premature polymerization.

Figure 10.2A.2 Gradient gel setup. A peristaltic pump, though not required, will provide better control.

Table 10.2A.9 Light Acrylamide Gel Solutions for Gradient Gels^a

Stock solution	Acrylamide concentration of light gel solution (%) ^b									
	5	6	7	8	9	10	11	12	13	14
30% acrylamide/ 0.8% bisacrylamide ^c	2.5	3.0	3.5	4.0	4.5	5.0	5.5	6.0	6.5	7.0
4× Tris·Cl/SDS, pH 8.8 ^c	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75
H ₂ O	8.75	8.25	7.75	7.25	6.75	6.25	5.75	5.25	4.75	4.25
10% (w/v) ammonium persulfate ^d	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05

^aTo survey proteins ≥10 kDa, 5%-20% gradient gels are recommended. To expand the range between 10 and 200 kD, a 10%-20% gel is recommended.

^bNumbers in body of table are milliliters of stock solution. Deaeration is not required. Keep solution at room temperature prior to adding TEMED no longer than 1 hr.

^cSee Table 10.2A.1 for preparation.

^dBest to prepare fresh.

Table 10.2A.10 Heavy Acrylamide Gel Solutions for Gradient Gels^a

Stock solution	Acrylamide concentration of heavy gel solution (%) ^b											
	10	11	12	13	14	15	16	17	18	19	20	
30% acrylamide/ 0.8% bisacrylamide ^c	5.0	5.5	6.0	6.5	7.0	7.5	8.0	8.5	9.0	9.5	10.0	
4× Tris·Cl/SDS, pH 8.8 ^c	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	
H ₂ O	5.0	4.5	4.0	3.5	3.0	2.5	2.0	1.5	1.0	0.5	0	
Sucrose (g)	2.25	2.25	2.25	2.25	2.25	2.25	2.25	2.25	2.25	2.25	2.25	
10% (w/v) ammonium persulfate ^{b,d}	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	

^aDeaeration is not recommended for gradient gels.

^bNumbers in body of table are milliliters of stock solution (except sucrose). Do not add the ammonium persulfate until just before use. The heavy acrylamide will polymerize, albeit more slowly, without the addition of TEMED. Keep the heavy solution on ice after adding ammonium persulfate.

^cSee Table 10.2A.1 for preparation.

^dBest to prepare fresh.

7. Add the specified amount of 10% ammonium persulfate and ~2.3 μl TEMED per 7 ml acrylamide solution to each chamber. Mix the solutions in each chamber with a disposable pipet.

Form the gradient and cast the gel

8. Open the interconnecting valve completely.

Some of the heavy solution will flow back into the reservoir chamber containing light solution as the two chambers equilibrate. This will not affect the formation of the gradient.

9. Turn on the magnetic stirrer and adjust the rate to produce a slight vortex in the mixing chamber.

10. Open the outlet of the gradient maker slowly. Adjust the outlet valve to a flow rate of 2 ml/min. If using a peristaltic pump, calibrate the flow rate with a graduated cylinder prior to casting the gel.

Some adjustment of the flow rate may be necessary during casting. If the light solution is not flowing into the mixing chamber, a bubble may be caught in the interconnecting valve.

Quickly close the outlet and cover the top of the reservoir chamber with a gloved thumb. Push down with the thumb to increase the pressure in the chamber and force the air bubble out of the center valve.

11. Fill the gel sandwich from the top. Place the pipet tip against one side of the sandwich so the solution flows down one plate only. The heavy solution will flow into the sandwich first, followed by progressively lighter solution.
12. Watch as the last of the light solution drains into the outlet tube and adjust the flow rate to ensure that the last few milliliters of solution do not flow quickly into the gel sandwich and disturb the gradient.
13. Overlay the gradient gel with H₂O-saturated isobutyl alcohol. Allow the gel to polymerize ~1 hr.

In this gel system, the gel will polymerize from the bottom (i.e., heavy solution) up. Because polymerization is an exothermic reaction, heat can be felt evolving from the bottom of the gel sandwich during polymerization. A sharp optical discontinuity at the gel-overlay interface indicates that polymerization has occurred. In general, 1 hr is adequate for polymerization.

14. Remove the H₂O-saturated isobutyl alcohol and rinse with 1× Tris-Cl/SDS, pH 8.8. Cast the stacking gel (see Basic Protocol 1, steps 8 to 11).

The gel can be covered with 1× Tris-Cl/SDS, pH 8.8, sealed in a plastic bag, and stored for up to 1 week.

Load and run the gel

15. Prepare the protein sample and protein molecular-weight-standards mixture. Load and run the gel (see Basic Protocol 1, steps 13 to 26).

The gel can be stained with Coomassie blue or silver (UNIT 10.6).

16. After staining, dry the gels onto Whatman 3MM or equivalent filter paper.

Gradient gels >0.75 mm thick require special handling during drying to prevent cracking. The simplest approach to drying gradient gels is to use thin gels; ≤0.75-mm gradient gels with ≤20% acrylamide solutions will dry without cracking as long as the vacuum pump is working properly and the cold trap is dry at the onset of drying. For gradient gels >0.75 mm thick, add 3% (w/v) glycerol to the final destaining solution to help prevent cracking. Another method is to dehydrate and shrink the gel in 30% methanol for up to 3 hr prior to drying. Then place the gel in distilled water for 5 min before drying.

SUPPORT PROTOCOL 2

CASTING MULTIPLE GRADIENT GELS

Casting gradient gels in a multiple gel caster has several advantages. In addition to the time savings, batch casting gives gels that are essentially identical. This is particularly important for gradient gels, where slight variations in casting technique can cause variations in protein mobility. The gels may be stored for up to 1 week after casting to ensure internal consistency from run to run during the week. Furthermore, gels with several ranges of concentrations (e.g., 5% to 20% and 10% to 20% acrylamide) can be cast and stored, giving much more flexibility to optimize separations.

Additional Materials (also see Alternate Protocol 5)

Plug solution (see recipe)

Light and heavy acrylamide gel solutions for multiple gradient gels (Table 10.2A.11 and Table 10.2A.12)

TEMED

H₂O-saturated isobutyl alcohol

Multiple gel caster (Bio-Rad, Amersham Pharmacia Biotech)
Peristaltic pump (25 ml/min)
500- or 1000-ml gradient maker (Bio-Rad, Amersham Pharmacia Biotech)
Tygon tubing

Set up system and pour separating gel

1. Assemble the multiple caster as in casting multiple single-concentration gels (see Support Protocol 1, steps 1 to 3), making sure to remove the triangular space filler plugs in the bottom of the caster.

The plug is used only when casting single-concentration gels.

2. Set up the peristaltic pump (Fig. 10.2A.3). Using a graduated cylinder and water, adjust the flow rate so that the volume of the gradient solution plus volume of plug solution is poured in ~15 to 18 min (~25 ml/min).
3. Set up the gradient maker. Close all valves and place a stir-bar in the mixing chamber, which is the one with the outlet port. Attach one end of a piece of Tygon tubing to the outlet of the gradient maker. Run the other end of the tubing through the peristaltic pump and attach it to the red inlet port at the bottom of the caster.

Choose a gradient maker that holds no more than four times the total volume of the gradient solution to be poured (i.e., a 1000- or 500-ml gradient maker).

4. Prepare solutions for the gradient maker (Table 10.2A.11 and Table 10.2A.12).
5. Add the TEMED to both heavy and light solutions (54 μ l/165 ml) and immediately pour the light (low-concentration) solution into the mixing chamber (the one with the port). Open the mixing valve slightly to allow the tunnel to fill and to avoid air bubbles. Close the valve again and pour the heavy (high-concentration) acrylamide solution into the reservoir chamber.
6. Start the magnetic stirrer and open the outlet valve; then start the pump and open the mixing valve.

In units for casting multiple gels, acrylamide solution flows in from the bottom. To use a multiple casting unit, the light solution is placed in the mixing chamber and the heavy solution in the reservoir. This is the reverse of casting a single gel (see Alternate Protocol 5).

Figure 10.2A.3 Setup for casting multiple gradient gels. Casting multiple gradient gels requires a peristaltic pump and a multiple gel caster. Gel solution is introduced through the bottom of the multiple caster.

Table 10.2A.11 Light Acrylamide Gel Solutions for Multiple Gradient Gels^{a,b}

Stock solution	Acrylamide concentration of light separating gel solution (%) ^c									
	5	6	7	8	9	10	11	12	13	14
30% acrylamide/ 0.8% bisacrylamide ^d	28	33	39	44	50	55	61	66	72	77
4× Tris·Cl/SDS, pH 8.8 ^d	41	41	41	41	41	41	41	41	41	41

10% (w/v) ammonium persulfate ^e	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55

^aDeaeration is not recommended for gradient gels.

^bRecipes produce 10 ml extra solution to account for losses in tubing.

^cNumbers in body of table are milliliters of stock solution (except sucrose). Do not add the ammonium persulfate until just before use. The heavy acrylamide will polymerize, albeit more slowly, without the addition of TEMED. Keep the heavy solution on ice after adding ammonium persulfate.

^dSee Table 10.2A.1 for preparation.

^eBest to prepare fresh.

Thus, light solution enters the multiple caster first, followed by progressively heavier solution. Finally, the acrylamide solution is stabilized in the multiple caster with a heavy plug solution and allowed to polymerize (see step 8 and manufacturer's instructions).

- When almost all the acrylamide solution is gone from the gradient maker, stop the pump and close the mixing valve. Tilt the gradient maker toward the outlet side and remove the last milliliters of the mix. Do not allow air bubbles to enter the tubing.
- Add the plug solution to the mixing chamber and start the pump. Make sure that no bubbles are introduced. Continue pumping until the bottom of the caster is filled with plug solution to just below the glass plates; then turn off the pump. Clamp the tubing close to the red port of the casting chamber.
- Quickly overlay each separate gel sandwich with 100 μl H₂O-saturated isobutyl alcohol. Use the same amount on each sandwich.

Failure to use the same amount of overlay solution will cause the gel sandwiches to polymerize at different heights.

10. Drain off the overlay and rinse the surface of the gels with 1× Tris-Cl/SDS, pH 8.8.

Pour stacking gel and remove gels from caster

11. Prepare and cast the stacking gel as in casting multiple single-concentration gels (see Support Protocol 1, steps 8 to 11).
12. Remove gels from the caster and clean the gel sandwiches (see Support Protocol 1, steps 12 and 13). Store gels, if necessary, according to the instructions for multiple single-concentration gels (see Support Protocol 1, step 14).

ELECTROPHORESIS IN SINGLE-CONCENTRATION MINIGELS

Separation of proteins in a small-gel format is becoming increasingly popular for applications that range from isolating material for peptide sequencing to performing routine protein separations. The unique combination of speed and high resolution is the foremost advantage of small gels. Additionally, small gels are easily adapted to single-concentration, gradient, and two-dimensional SDS-PAGE procedures. The minigel procedures described are adaptations of larger gel systems.

This protocol describes the use of a multiple gel caster. The caster is simple to use, and up to five gels can be prepared at one time with this procedure. Single gels can be prepared using adaptations in the manufacturer's instructions. A multiple gel caster is the only practical way to produce small linear polyacrylamide gradient gels (see Support Protocol 3).

Materials

- Minigel vertical gel unit (Amersham Pharmacia Biotech Mighty Small SE 250/280 *or* Bio-Rad Mini-Protean II) with glass plates, clamps, and buffer chambers
- 0.75-mm spacers
- Multiple gel caster (Amersham Pharmacia Biotech SE-275/295 *or* Bio-Rad Mini-Protean II multicasting chamber)
- Acrylic plate (Amersham Pharmacia Biotech SE-217 *or* Bio-Rad 165-1957) *or* polycarbonate separation sheet (Amersham Pharmacia Biotech SE-213 *or* Bio-Rad 165-1958)
- 10- and 50-ml syringes
- Combs (Teflon, Amersham Pharmacia Biotech SE-211A series *or* Bio-Rad Mini-Protean II)
- Long razor blade
- Micropipet
- Additional reagents and equipment for standard denaturing SDS-PAGE (see Basic Protocol 1)

Pour the separating gel

1. Assemble each gel sandwich by stacking, in order, the notched (Amersham Pharmacia Biotech) *or* small rectangular (Bio-Rad) plate, 0.75-mm spacers, and the larger rectangular plate. Be sure to align the spacers properly, with the ends flush with the top and bottom edge of the two plates, when positioning the sandwiches in the multiple gel caster (Fig. 10.2A.4).

The protocol described is basically for the Amersham Pharmacia Biotech system. For other systems, make adjustments according to the manufacturer's instructions. Alternatively, precast minigels can be purchased from a number of suppliers (see Table 10.2A.3).

The multiple casters from Amersham Pharmacia Biotech have a notch in the base designed for casting gradient gels. A silicone rubber insert fills up this space when casting

Figure 10.2A.4 Minigel sandwiches positioned in the multiple gel caster. Extra glass or acrylic plates or polycarbonate sheets are used to fill any free space in the caster and to ensure that the gel sandwiches are held firmly in place.

single-concentration gels. The Amersham Pharmacia Biotech spacers are T-shaped to prevent slipping. The flanged edge of the spacer must be positioned against the outside edge of the glass plate. Placing a sheet of wax paper between the gel sandwiches will help separate the sandwiches after polymerization.

2. Fit the gel sandwiches tightly in the multiple gel caster. Use an acrylic plate or polycarbonate separation sheet to eliminate any slack in the chamber.

Loosely fitting sandwiches in the caster will lead to unevenly cast gels, creating distortions during electrophoresis.

3. Place the front faceplate on the caster, clamp it in place against the silicone gasket, and verify alignment of the glass plates and spacers.
4. Prepare the separating gel solution as directed in Table 10.2A.1. For five 0.75-mm-thick gels, prepare ~30 ml solution (i.e., double the volumes listed).

To compute the total gel volume needed, multiply the area of the gel (e.g., 7.3×8.3 cm) by the thickness of the gel (e.g., 0.75 mm) and then by the number of gels in the caster. If needed, add ~4 to 5 ml of extra gel solution to account for the space around the outside of the gel sandwiches.

Do not add TEMED and ammonium persulfate until just before use.

5. Fill a 50-ml syringe with the separating gel solution and slowly inject it into the caster until the gels are 6 cm high, allowing 1.5 cm for the stacking gel.

- Overlay each gel with 100 μ l H₂O-saturated isobutyl alcohol. Allow the gels to polymerize for ~1 hr.

Pour the stacking gel

- Remove the isobutyl alcohol and rinse with 1 \times Tris-Cl/SDS, pH 8.8.

Stacking gels can be cast one at a time with the gel mounted on the electrophoresis unit, or all at once in the multiple caster.

- Practice placing a comb in the gel sandwiches before preparing the stacking gel solution. Press the comb against the rectangular or taller plate so that all teeth of the comb are aligned with the opening in the gel sandwich, then insert into the sandwich. Remove combs after practicing.
- Prepare the stacking gel solution (2 ml per gel) as directed in Table 10.2A.1. Fill a 10-ml syringe with stacking gel solution and inject the solution into each gel sandwich.
- Insert combs, taking care not to trap bubbles. Allow gels to polymerize 1 hr.
- Remove the front faceplate. Carefully pull the gels out of the caster, using a long razor blade to separate the sandwiches.

If the gels are left to polymerize for prolonged periods, they will be difficult to remove from the caster.

The gels can be stored tightly wrapped in plastic wrap with the combs left in place inside a sealable bag to prevent drying for ~1 week. Without the stacking gel, the separating gel can be stored for 2 to 3 weeks. Keep gels moist with 1 \times Tris-Cl/SDS, pH 8.8, at 4°C. Do not store gels in the multiple caster.

Prepare the sample, load the gel, and conduct electrophoresis

- Remove the combs and rinse the sample wells with 1 \times SDS electrophoresis buffer. Place a line indicating the bottom of each well on the front glass plate with a marker.
- Fill the upper and lower buffer chambers with 1 \times SDS electrophoresis buffer. The upper chamber should be filled to 1 to 2 cm over the notched plate.
- Prepare the protein sample and protein-standards mixture (see Basic Protocol 1, step 12).
- Load the sample using a micropipet. Insert the pipet tip through the upper buffer and into the well. The mark on the glass plate will act as a guide. Dispense the sample into the well.

For a complex mixture, 20 to 25 μ g protein in 10 μ l SDS sample buffer will give a strongly stained Coomassie blue pattern. Much smaller amounts (1 to 5 μ g) are required for highly purified proteins, and a 10- to 100-fold smaller amount of protein in the same volume (e.g., 10 μ l) is required for silver staining.

- Electrophorese samples at 10 to 15 mA per 0.75-mm gel until the dye front reaches the bottom of the gel (~1 to 1.5 hr).
- Disassemble the gel (see Basic Protocol 1, steps 23 to 26). Proceed with detection of proteins.

PREPARING MULTIPLE GRADIENT MINIGELS

Polyacrylamide gradients not only enhance the resolution of larger-format gels but also greatly improve protein separation in the small format. Casting gradient minigels one at a time is not generally feasible because of the small volumes used, but multiple gel casters make it easy to cast several small gradient gels at one time. The gels are cast from the bottom in multiple casters, with the light acrylamide solution entering first. This is the opposite of casting one gel at a time, in which the heavy solution enters from the top of the gel sandwich and flows down to the bottom.

Additional Materials (also see *Basic Protocol 2*)

Plug solution (see recipe)

Additional reagents and equipment for preparing gradient gels (see *Alternate Protocol 5*)

Set up the system and prepare the gel solutions

1. Assemble minigel sandwiches in the multiple gel caster as described for single-concentration minigels (see *Basic Protocol 2*, steps 1 to 3).
2. Set up the 30-ml gradient maker, magnetic stirrer, peristaltic pump (optional), and Tygon tubing as in Figure 10.2A.3. Connect the outlet of the 30-ml gradient maker to the inlet at the base of the front faceplate of the caster.

The monomer solution will be introduced through the inlet at the bottom of the front faceplate of the caster first, followed by progressively heavier solution.

3. Prepare light (Table 10.2A.9) and heavy (Table 10.2A.10) acrylamide gel solutions. Use ~12 ml of each solution for five 0.75-mm-thick minigels.

Adjust volumes if a different thickness or number of gels is needed. Do not add ammonium persulfate until just before use. Deaeration is not recommended for gradient gels.

4. With the outlet and interconnecting valve closed, add the heavy solution to the reservoir chamber. Briefly open the interconnecting valve to let a small amount of heavy solution through to the mixing chamber, clearing the valve of air.
5. Fill the mixing chamber with light solution. Add 4 μ l TEMED per 12 ml acrylamide solution to each chamber and mix with a disposable pipet.

Form the gradient and cast the gels

6. Turn on the magnetic stirrer. Open the interconnecting valve and allow the chambers to equilibrate. Then slowly open the outlet port to allow the solution to flow from the gradient maker to the multiple caster by gravity (a peristaltic pump may be used for better control). Adjust the flow rate to 3 to 4 ml/min.

Faster flow rates are possible and will also produce good gradients. However, a fast flow increases the potential for introduction of bubbles into the caster.

7. Close the outlet port as the last of the gradient solution leaves the mixing chamber, just before air enters the outlet tube. Fill the two chambers with plug solution and slowly open the outlet once again.
8. Allow the plug solution to push the acrylamide in the caster up into the plates. Close the outlet when the plug solution reaches the bottom of the plates.

A discontinuity between the bottom of the gels and the plug solution will be obvious.

9. Quickly add 100 μ l H₂O-saturated isobutyl alcohol to each gel sandwich. Let the gels polymerize undisturbed for ~1 hr.
10. Prepare and pour the stacking gel (see *Basic Protocol 2*, steps 9 and 10).

Disassemble the system

11. Disconnect the gradient maker, place the caster in a sink, and remove the front faceplate. The plug solution will drain out from the bottom of the caster.
12. Remove the gels (see Basic Protocol 2, step 11).

Gradient minigels can be stored as described for single-concentration minigels (see Basic Protocol 2, step 11 annotation). For instructions on preparing, loading, and running the gels, see Basic Protocol 2, steps 12 to 17.

REAGENTS AND SOLUTIONS

Use Milli-Q water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Anode buffer

121.1 g Tris base (0.2 M final)
500 ml H₂O
Adjust to pH 8.9 with concentrated HCl
Dilute to 5 liters with H₂O
Store at 4°C up to 1 month

Final concentration is 0.2 M Tris·Cl, pH 8.9.

Cathode buffer

12.11 g Tris base (0.1 M final)
17.92 g tricine (0.1 M final)
1 g SDS [0.1% final; recrystallization (see recipe) optional]
Dilute to 1 liter with H₂O
Do not adjust pH
Store at 4°C up to 1 month

Coomassie blue G-250 staining solution

200 ml acetic acid (20% final)
1800 ml H₂O
0.5 g Coomassie blue G-250 (0.025% final)
Mix 1 hr and filter (Whatman no. 1 paper)
Store at room temperature indefinitely

Phosphate/SDS electrophoresis buffer

Dilute 500 ml of 4× phosphate/SDS, pH 7.2 (Table 10.2A.7) with H₂O to 2 liters.
Store at 4°C up to 1 month.

Final concentrations are 0.1 M sodium phosphate (pH 7.2)/0.1% (w/v) SDS.

Phosphate/SDS sample buffer, 2× (for continuous systems)

0.5 ml 4× phosphate/SDS, pH 7.2 (Table 10.2A.7; 20 mM sodium phosphate final)
0.2 g SDS [2% final; recrystallization (see recipe) optional]
0.1 mg bromphenol blue (0.001% final)
0.31 g DTT (0.2 M final)
2.0 ml glycerol (2% final)
Add H₂O to 10 ml and mix

Plug solution

0.125 M Tris·Cl, pH 8.8 (APPENDIX 2)
50% (w/v) sucrose
0.001% (w/v) bromphenol blue
Store at 4°C up to 1 month

Recrystallized SDS (optional)

High-purity SDS is available from several suppliers, but for some sensitive applications (e.g., protein sequencing) recrystallization is useful. Commercially available electrophoresis-grade SDS is usually of sufficient purity for most applications.

Add 100 g SDS to 450 ml ethanol and heat to 55°C. While stirring, gradually add 50 to 75 ml hot H₂O until all SDS dissolves. Add 10 g activated charcoal (Norit 1, Sigma) to solution. After 10 min, filter solution through Whatman no. 5 paper on a Buchner funnel to remove charcoal. Chill filtrate 24 hr at 4°C and 24 hr at -20°C. Collect crystalline SDS on a coarse-frit (porosity A) sintered-glass funnel and wash with 800 ml -20°C ethanol (reagent grade). Repeat crystallization without adding activated charcoal. Dry recrystallized SDS under vacuum overnight at room temperature. Store in a desiccator over phosphorous pentoxide (P₂O₅) in a dark bottle.

If proteins will be electroeluted or electroblotted for protein sequence analysis, it may be desirable to crystallize the SDS twice from ethanol/H₂O (Hunkapiller et al., 1983).

SDS electrophoresis buffer, 5×

15.1 g Tris base (0.125 M final)
72.0 g glycine (0.96 M final)
5.0 g SDS [0.5% final; recrystallization (see recipe) optional]
H₂O to 1000 ml
Dilute to 1× or 2× for working solution, as appropriate

Do not adjust the pH of the stock solution, as the solution is pH 8.3 when diluted. Store at 0° to 4°C until use (up to 1 month).

SDS sample buffer, 2× (for discontinuous systems)

25 ml 4× Tris·Cl/SDS, pH 6.8 (Table 10.2A.1)
20 ml glycerol (20% final)
4 g SDS [4% final; recrystallization (see recipe) optional]
2 ml 2-ME or 3.1 g DTT (0.2% 2-ME or 0.2 M DTT final)
1 mg bromphenol blue (0.001% final)
Add H₂O to 100 ml and mix
Store in 1-ml aliquots at -70°C

To avoid reducing proteins to subunits (if desired), omit 2-ME or DTT (reducing agent) and add 10 mM iodoacetamide to prevent disulfide interchange.

SDS sample buffer, 6× (for discontinuous systems)

7 ml 4× Tris·Cl/SDS, pH 6.8 (Table 10.2A.1)
3.0 ml glycerol (30% final)
1 g SDS [10% final; recrystallization (see recipe) optional]
0.93 g DTT (0.6 M final)
1.2 mg bromphenol blue (0.012% final)
Add H₂O to 10 ml (if needed)
Store in 0.5-ml aliquots at -70°C

Tricine sample buffer, 2×

2 ml 4× Tris·Cl/SDS, pH 6.8 (Table 10.2A.1; 0.1 M)
2.4 ml (3.0 g) glycerol (24% final)
0.8 g SDS [8% final; recrystallization (see recipe) optional]
0.31 g DTT (0.2 M final)
2 mg Coomassie blue G-250 (0.02% final)
Add H₂O to 10 ml and mix

COMMENTARY

Background Information

Polyacrylamide gels form after polymerization of monomeric acrylamide into polymeric polyacrylamide chains and cross-linking of the chains by *N,N'*-methylenebisacrylamide. The polymerization reaction is initiated by the addition of ammonium persulfate, and the reaction is accelerated by TEMED, which catalyzes the formation of free radicals from ammonium persulfate. Because oxygen inhibits the polymerization process, deaerating the gel solution before the polymerization catalysts are added will speed up polymerization; deaeration is not recommended for the gradient gel protocols because slower polymerization facilitates casting of gradient gels.

Precast gels for commonly used vertical minigel and standard-sized SDS-PAGE apparatuses are available from several manufacturers (Table 10.2A.3). Flatbed (horizontal) isoelectric focusing (IEF) and SDS-PAGE gels are not listed. Amersham Pharmacia Biotech supplies a range of horizontal gels for a variety of applications and should be consulted for further information. When using precast gels, pay strict attention to shelf life. In general, manufacturers overrate the shelf life, and the sooner the gels are used, the better. When reasonably fresh, precast gels provide excellent resolution that is as good or better than a typical gel cast in the laboratory.

The most widely used method for discontinuous gel electrophoresis is the system described by Laemmli (1970). This is the denaturing (SDS) discontinuous method used in Basic Protocol 1. A discontinuous buffer system uses buffers of different pH and composition to generate a discontinuous pH and voltage gradient in the gel. Because the discontinuous gel system concentrates the proteins in each sample into narrow bands, the applied sample may be more dilute than that used for continuous electrophoresis.

In the discontinuous system the sample first passes through a stacking gel, which has large pores. The stacking gel buffer contains chloride ions (called the leading ions) whose electrophoretic mobility is greater than the mobility of the proteins in the sample. The electrophoresis buffer contains glycine ions (called the trailing ions) whose electrophoretic mobility is less than the mobility of the proteins in the sample. The net result is that the faster migrating ions leave a zone of lower conductivity between themselves and the migrating protein.

The higher voltage gradient in this zone allows the proteins to move faster and to “stack” in the zone between the leading and trailing ions. After leaving the stacking gel, the protein enters the separating gel. The separating gel has a smaller pore size, a higher salt concentration, and higher pH compared to the stacking gel. In the separating gel, the glycine ions migrate past the proteins, and the proteins are separated according to either molecular size in a denaturing gel (containing SDS) or molecular shape, size, and charge in a nondenaturing gel.

Proteins are denatured by heating in the presence of a low-molecular-weight thiol (2-ME or DTT) and SDS. Most proteins bind SDS in a constant-weight ratio, leading to identical charge densities for the denatured proteins. Thus, the SDS-protein complexes migrate in the polyacrylamide gel according to size, not charge. Most proteins are resolved on polyacrylamide gels containing from 5% to 15% acrylamide and 0.2% to 0.5% bisacrylamide (see Table 10.2A.1). The relationship between the relative mobility and log molecular weight is linear over these ranges (Fig. 10.2A.5). With the use of plots like those shown in Figure 10.2A.5, the molecular weight of an unknown protein (or its subunits) may be determined by comparison with known protein standards (Table 10.2A.2). In general, all of the procedures in this unit are suitable for radiolabeled and biotinylated proteins without modification.

Basic Protocol 1 relies on denaturing proteins in the presence of SDS and 2-ME or DTT. Under these conditions, the subunits of proteins are dissociated and their biological activities are lost. A true estimate of a protein's molecular size can be made by comparing the relative mobility of the unknown protein to proteins in a calibration mixture (Fig. 10.2A.5). Gradient gels (Alternate Protocol 5) simplify molecular-weight determinations by producing a linear relationship between log molecular weight of the protein and log % T over a much wider size range than single-concentration gels. Although percent acrylamide monomer is a more common measure of gel concentration, % T, the percentage of total monomer (acrylamide plus bisacrylamide) in the solution or gel, is used for molecular weight calculations in gradient gels. The % T of a stained protein is estimated assuming the acrylamide gradient is linear. For example, proteins in the gel shown in Figure 10.2A.6 were separated in a 5.1% to 20.5% T acrylamide gradient. The % T of the point

Figure 10.2A.5 Typical calibration curves obtained with standard proteins separated by nongradient denaturing (SDS) discontinuous gel electrophoresis based on the method of Laemmli (1970). (A) Gel with 7% polyacrylamide. (B) Gel with 11% polyacrylamide. (Redrawn with permission from Sigma.)

halfway through the resolving gel is 12.5% T. Simply plotting log molecular mass versus distance moved into the gel (or R_f) also produces a relatively linear standard curve over a fairly wide size range.

If two proteins have identical molecular sizes, they more than likely will not be resolved with one-dimensional SDS-PAGE, and two-dimensional SDS-PAGE should be considered. Unusual protein compositions can cause anomalous mobilities during electrophoresis (see Critical Parameters and Troubleshooting), but similar-sized proteins of widely different amino acid composition or structure may still be resolved from one another using one-dimensional SDS-PAGE. Purified protein complexes or multimeric proteins consisting of subunits of different molecular size will be resolved into constituent polypeptides. Comparison of the protein bands obtained under nonreducing and reducing conditions provides information about the molecular size of disulfide cross-linked com-

ponent subunits. The individual polypeptides can be isolated by electroelution or electroblotting, and the amino acid sequences can be determined.

Both the tricine (Schagger and von Jagow, 1987) and the modified Laemmli (Okajima et al., 1993) peptide separation procedures presented here (Alternate Protocols 1 and 2) are simple to set up and provide resolution down to 5 kDa. To separate peptides below 5 kDa, the tricine procedure must be modified by preparing a 16.5% T, 2.7% C resolving gel that uses a 10% T spacer gel between the stacking and resolving gel (Schagger and von Jagow, 1987). % C is the percentage of cross-linker (bisacrylamide) in the total monomer (acrylamide plus bisacrylamide).

Continuous electrophoresis, where the same buffer is used throughout the tank and gel, is popular because of its versatility and simplicity. The phosphate system described in Alternate Protocol 3 is based on that of Weber et al.

Figure 10.2A.6 Separation of membrane proteins by 5.1% to 20.5% T polyacrylamide gradient SDS-PAGE. Approximately 30 μ l of 1 \times SDS sample buffer containing 30 μ g of Alaskan pea (*Pisum sativum*) membrane proteins was loaded in wells of a 14 \times 14-cm, 0.75-mm-thick gel. Standard proteins were included in the outside lanes. The gel was run at 4 mA for ~15 hr.

(1972). Although unable to produce the high-resolution separations of the discontinuous SDS-PAGE procedures, continuous SDS-PAGE uses fewer solutions with one basic buffer and no stacking gel. Artifacts are also less likely to occur in continuous systems. Pepsin, for example, migrates anomalously on Laemmli-based discontinuous SDS-PAGE but has the expected mobility after electrophoresis in the phosphate-based continuous system described here. This is also true of cross-linked proteins.

Multiple gel casting (Support Protocols 1 to 3) is appropriate when gel-to-gel consistency is paramount or when the number of gels processed exceeds five a week. The variety of multiple gel casters, gradient makers, and inexpensive pumps available from major suppliers simplifies the process of casting gels in the laboratory. Alternatively, precast gradient gels are available for most major brands of gel apparatuses (Table 10.2A.3).

Minigels (Basic Protocol 2) are generally considered to be in the 8 \times 10-cm size range, although there is considerable variation in exact size. Every technique that is used on larger systems can be translated with little difficulty into the minigel format. This includes standard and gradient SDS-PAGE and separations for immunoblotting and peptide sequencing. Two-dimensional SDS-PAGE electrophoresis also adapts well, but here the limitation of separa-

tion area becomes apparent; for high-resolution separations, large-format gels are required. Gradient minigels (Support Protocol 3) are popular due to the combination of separation range and resolution (Matsudaira and Burgess, 1978). They are particularly useful for separation of proteins prior to peptide sequencing.

Mylar support (Gel Bond) provides a practical way of casting, running, and, staining extremely thin gels. When gels <0.75 mm thick are used, reagents have much better access both into and out of the gel, reducing staining time in both Coomassie blue and silver staining. Double and broadened images caused by differential migration of the protein across the thickness of the gel are minimized, improving resolution.

Critical Parameters and Troubleshooting

If an electrophoretically separated protein will be electroeluted or electroblotted for sequence analysis, the highest-purity reagents available should be used. If necessary, SDS can be purified by recrystallization following the procedure given in Reagents and Solutions.

If the gels polymerize too fast, the amount of ammonium persulfate should be reduced by one-third to one-half. If the gels polymerize too slowly or fail to polymerize all the way to the top, use fresh ammonium persulfate or increase the amount of ammonium persulfate by one-

third to one-half. The overlay should be added slowly down the spacer edge to prevent the overlay solution from crashing down and disturbing the gel interface.

After a separating gel is poured, it may be stored with an overlay of the same buffer used in the gel. Immediately prior to use, the stacking gel should be poured; otherwise, there will be a gradual diffusion-driven mixing of buffers between the two gels, which will cause a loss of resolution.

The protein of interest should be present in 0.2- to 1- μ g amounts in a complex mixture of proteins if the gel will be stained by Coomassie blue (UNIT 10.6). Typically, 30 to 50 μ g of a complex protein mixture in a total volume of <20 μ l is loaded on a 0.75-mm-thick slab gel (16 cm, 10 wells).

When casting multiple gradient gels, eliminate all bubbles in the outlet tubing of the gradient maker. If air bubbles get into the outlet tube, they may flow into the caster and then up through the gradient being poured, causing an area of distortion in the polymerized gel. Air bubbles are not so great a problem when casting single gradient gels from the top. As the gels are cast, the stirrer must be slowed so that the vortex in the mixing chamber does not allow air to enter the outlet.

Uneven heating of the gel causes differential migration of proteins, with the outer lanes moving more slowly than the center lanes (called smiling). Increased heat transfer eliminates smiling and can be achieved by filling the lower buffer chamber with buffer all the way to the level of the sample wells, by maintaining a constant temperature between 10° to 20°C, and by stirring the lower buffer with a magnetic stirrer. Alternatively, decrease the heat load by running at a lower current.

If the tracking dye band is diffuse, prepare fresh buffer and acrylamide monomer stocks. If the protein bands are diffuse, increase the current by 25% to 50% to complete the run more quickly and minimize band diffusion, use a higher percentage of acrylamide, or try a gradient gel. Lengthy separations using gradient gels generally produce good results (Fig. 10.2A.6). Check for possible proteolytic degradation that may cause loss of high-molecular-weight bands and create a smeared banding pattern.

If there is vertical streaking of protein bands, decrease the amount of sample loaded on the gel, further purify the protein of interest to reduce the amount of contaminating protein applied to the gel, or reduce the current by 25%.

Another cause of vertical streaking of protein bands is precipitation, which can sometimes be eliminated by centrifuging the sample or by reducing the percentage of acrylamide in the gel.

Proteins can migrate faster or slower than their actual molecular weight would indicate. Abnormal migration is usually associated with a high proportion of basic or charged amino acids (Takano et al., 1988). Other problems can occur during isolation and preparation of the protein sample for electrophoresis. Proteolysis of proteins during cell fractionation by endogenous proteases can cause subtle band splitting and smearing in the resulting electrophoretogram (electrophoresis pattern). Many endogenous proteases are very active in SDS sample buffers and will rapidly degrade the sample; thus, first heating the samples to 70° to 100°C for 3 min is recommended.

In some cases, heating to 100°C in sample buffer will cause selective aggregation of proteins, creating a smeared layer of Coomassie blue-stained material at the top of the gel (Gallagher and Leonard, 1987). To avoid heating artifacts and also prevent proteolysis, the use of specific protease inhibitors during protein isolation and/or lower heating temperatures (70° to 80°C) have been effective (Dhugga et al., 1988).

Although continuous gels suffer from poor band sharpness, they are less prone to artifacts caused by aggregation and protein cross-linking. If streaking or aggregation appear to be a problem with the Laemmli system, then the same sample should be subjected to continuous SDS-PAGE to see if the problem is intrinsic to the Laemmli gel or the sample.

If the protein bands spread laterally from gel lanes, the time between applying the sample and running the gel should be reduced in order to decrease the diffusion of sample out of the wells. Alternatively, the acrylamide percentage should be increased in the stacking gels from 4% to 4.5% or 5% acrylamide, or the operating current should be increased by 25% to decrease diffusion in the stacking gel. Use caution when adding 1 \times SDS electrophoresis buffer to the upper buffer chamber. Samples can get swept into adjacent wells and onto the top of the well arm.

If the protein bands are uneven, the stacking gel may not have been adequately polymerized. This can be corrected by deaerating the stacking gel solution thoroughly or by increasing the ammonium persulfate and TEMED concentrations by one-third to one-half. Another cause

of distorted bands is salt in the protein sample, which can be removed by dialysis, gel filtration, or precipitation. Skewed protein bands can be caused by an uneven interface between the stacking and separating gels, which can be corrected by starting over and being careful not to disturb the separating gel while overlaying with isobutyl alcohol.

If a run takes too long, the buffers may be too concentrated or the operating current too low. If the run is too short, the buffers may be too dilute or the operating current too high.

If double bands are observed, the protein may be partially oxidized or partially degraded. Oxidation can be minimized by increasing the 2-ME concentration in the sample buffer or by preparing a fresh protein sample. If fewer bands than expected are observed and there is a heavy protein band at the dye front, increase the acrylamide percentage in the gel.

Anticipated Results

Polyacrylamide gel electrophoresis done under denaturing and reducing conditions should resolve any two proteins, except two of identical size. Resolution of proteins in the presence of SDS is a function of gel concentration and the size of the proteins being separated. Under nondenaturing conditions, the biological activity of a protein will be maintained.

Comparison of reducing and nonreducing denaturing gels can also provide valuable information about the number of disulfide cross-linked subunits in a protein complex. If the subunits are held together by disulfide linkages, the protein will separate in denaturing gels as a complex or as smaller-sized subunits under nonreducing or reducing conditions, respectively. However, proteins separated on nonreducing denaturing gels appear more diffuse and exhibit less overall resolution than those separated on reducing gels.

Gradient gels provide superior protein-band sharpness and resolve a larger size range of proteins, making them ideal for most types of experiments in spite of being more difficult to prepare. Molecular-weight calculations are simplified because of the extended linear relationship between size and protein position in the gel. Increased band sharpness of both high- and low-molecular-weight proteins on the same gel greatly simplifies survey experiments, such as gene expression studies where the characteristics of the responsive protein are not known. Furthermore, the increased resolution dramatically improves autoradiographic analysis. Preparation of gradient gels is straightfor-

ward, although practice with gradient solutions containing dye is recommended. The gradient gels can be stored for several days at 0° to 4°C before casting the stacking gel.

Time Considerations

Preparation of separating and stacking gels requires 2 to 3 hr. Gradient gels generally take 5 min to cast singly. Casting multiple single-concentration gels requires an additional 10 min for assembly. Casting multiple gradient gels takes 15 to 20 min plus assembly time. It takes 4 to 5 hr to run a 14 × 14-cm, 0.75-mm gel at 15 mA (70 to 150 V), and 3 to 4 hr to run a 0.75-mm gel at 20 mA (80 to 200 V). Overnight separations of ~12 hr require 4 mA per 0.75-mm gel. It takes 4 to 5 hr to run a 1.5-mm gel at 30 mA. Electrophoresis is normally performed at 15° to 20°C, with the temperature held constant using a circulating water bath. For air-cooled electrophoresis units, lower currents and thus longer run times are recommended.

It takes ~1 hr to run a 0.75-mm minigel at 20 mA (100 to 120 V). Separation times are not significantly different for gradient minigels.

One-Dimensional Electrophoresis Using Nondenaturing Conditions

Nondenaturing or “native” electrophoresis—i.e., electrophoresis in the absence of denaturants such as detergents and urea—is an often-overlooked technique for determining the native size, subunit structure, and optimal separation of a protein. Because mobility depends on the size, shape, and intrinsic charge of the protein, nondenaturing electrophoresis provides a set of separation parameters distinctly different from mainly size-dependent denaturing sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE; *UNITS 10.2A*) and charge-dependent isoelectric focusing (IEF; *UNITS 10.3 & 10.4*). Two protocols are presented below. Continuous PAGE (see Basic Protocol) is highly flexible, permitting cationic and anionic electrophoresis over a full range of pH. The discontinuous procedure (see Alternate Protocol) is limited to proteins negatively charged at neutral pH but provides high resolution for accurate size calibration.

CONTINUOUS ELECTROPHORESIS IN NONDENATURING POLYACRYLAMIDE GELS

BASIC PROTOCOL

Separation of proteins by nondenaturing electrophoresis requires the same type of equipment used for denaturing slab gels (*UNIT 10.2A*) and is adaptable to a range of gel sizes (e.g., from 7.3 × 8.3–cm minigels to 14 × 16–cm full-size gels) and matrix types (e.g., single-concentration and gradient gels). This protocol outlines straightforward procedures for making acrylamide solutions, casting separating gels (stacking gels are omitted), loading samples, and conducting electrophoresis. Continuous systems, although flexible, do not give the high-resolution separation found in discontinuous systems (see Alternate Protocol).

Separation in a continuous system (i.e., in which the same buffer is used for preparing acrylamide solutions and filling electrophoresis chambers) is governed by pH, and this protocol describes four types of buffers useful over discrete ranges from pH 3.7 to pH 10.6. Use of unadjusted acetic acid gel buffer can extend the range to pH 2.0. The choice of pH and thus the buffer system depends on the protein being studied (i.e., its isoelectric point) and often must be determined empirically. In general, the system should be between pH 5.0 and 8.0 for optimal results. Extremes of pH can lead to precipitation or denaturation of the protein. Acrylamide concentrations are empirically determined, but the higher the percent acrylamide, the sharper the protein bands.

It is important to include native protein standards in the electrophoresis runs. Several manufacturers supply standards for isoelectric focusing that are also suitable for native electrophoresis. The standards have a range of isoelectric points and will carry a net positive, negative, or zero charge depending on the pH of the gel system. Alternatively, Sigma supplies a standard kit that is useful for calculating molecular weights under neutral pH, nondenaturing conditions. The samples and standard proteins, should be used at concentrations of ~1 to 2 μg/μl.

Materials

- 4× acetic acid gel buffer (200 mM acetic acid, pH 3.7 to 5.6; see recipe)
- 4× phosphate gel buffer (400 mM sodium phosphate, pH 5.8 to 8.0; see recipe)
- 4× Tris gel buffer (200 mM Tris·Cl, pH 7.1 to 8.9; see recipe)
- 4× glycine gel buffer (200 mM glycine, pH 8.6 to 10.6; see recipe)
- 300 mM sodium sulfite (0.38 g in 10 ml H₂O; used in acetic acid gel preparation)
- Protein samples to be analyzed

Two-Dimensional Gel Electrophoresis Using the ISO-DALT System

Two high-resolution electrophoretic procedures (isoelectric focusing and SDS-polyacrylamide gel electrophoresis) are combined to provide much greater resolution than either of the individual procedures (O'Farrell, 1975). Solubilized proteins are first separated according to their isoelectric point by isoelectric focusing in a 1.5×140 -mm tube gel. This first-dimension gel is then applied to the top of an SDS-polyacrylamide slab gel and electrophoresed. The proteins in the first-dimension gel migrate into the second-dimension gel where they are further separated on the basis of their molecular size. The ISO-DALT system was specifically designed for running multiple high-resolution two-dimensional gels at one time.

FIRST-DIMENSION (ISOELECTRIC FOCUSING) GELS

BASIC PROTOCOL

Materials

Urea
Ampholytes
30% acrylamide/1.8% bisacrylamide
Nonidet P-40 (NP-40)
TEMED (*N, N, N', N'*-tetramethylethylenediamine)
10% ammonium persulfate in H₂O
0.85% phosphoric acid in H₂O
10 M NaOH in H₂O
Bromphenol blue solution
25-ml, 10-ml, 1-ml, and 50- μ l syringes
Vacuum pump with cold trap
0.2- or 0.45- μ m filter capsule (Acrodisk, Gelman Sciences)
Single-edge razor blades
22-G hypodermic needle (2-in. long)
1-dram vials
First-dimension gel apparatus (ISS or Hoefer Scientific)

NOTE: Distilled, deionized water should be used throughout this protocol.

Pour isoelectric focusing gels

1. Assemble parts (clean and dry) of a 20-gel first-dimension gel apparatus.
2. In a vacuum flask (~100 ml) place 8.25 g urea, 6 ml water, 0.75 to 0.8 ml ampholytes (BDH pH 4.0 to 8.0), and 2 ml of 30% acrylamide/1.8% bisacrylamide. Swirl under warm tap water (~37°C) until all the urea dissolves. This makes 15 ml of gel solution.
3. Degas by applying vacuum for 3 to 4 min, add 0.3 ml NP-40, and swirl until dissolved.
4. Pour solution into a 25-ml syringe fitted with a 0.2- or 0.45- μ m filter capsule and force the liquid through the filter.
5. Add 10 μ l TEMED and 70 μ l of 10% ammonium persulfate; mix by swirling.
This solution will polymerize in ~2¹/₂ min, so work quickly!
6. Fill gel trough with gel solution and carefully overlay the gel solution with water from a pipet.
7. Slowly lower the gel tube assembly into the lower buffer tank containing ~2 liters of water. As gel tube assembly is lowered into water, gel tubes will fill uniformly with

acrylamide solution. Add water to the lower buffer tank to bring the acrylamide solution to the desired height in gel tubes.

For future reference, place a mark on the lower buffer tank to indicate the final water level. After the gel tube assembly has been removed, place another mark on the lower buffer tank to indicate initial water level.

Prepare isoelectric focusing gels

8. Allow at least 1 hr for polymerization, then remove the gel tube assembly from the lower buffer tank. Carefully remove the gel trough (but not the gel retainer), and using a new single-edge razor blade, cut between the retainer and the tubes. Cut flush with the bottoms of the gel tubes. The gel retainer can now be removed, and excess acrylamide rinsed from the gel tubes with deionized tap water.
9. In a vacuum flask degas 2 liters of water. To 1800 ml of the degassed water, add 200 ml of 0.85% phosphoric acid and pour the solution into the lower buffer tank. Place the gel tube assembly in the lower buffer tank.
10. Add 0.3 ml of 10 M NaOH to 150 ml degassed water, mix, and pour into the upper buffer tank. The gel tubes can be filled with the upper buffer from a 10-ml syringe fitted with a 2-in., 22-G needle.

Take care that no air bubbles remain in the gel tubes.

11. Connect the power supply (negative lead goes to upper tank) and pefocus the gels 1 hr at 200 V.

Load and run isoelectric focusing gels

12. Disconnect the power supply and load solubilized samples (see support protocol) by layering them on the top of each gel with a 50- μ l syringe.

Up to 30 μ l of sample can be applied.

13. Reconnect the power supply and set output for 800 V constant voltage. Run 16 to 18 hr (12,800 to 14,400 V-hr).

Optimum run time and voltage should be determined experimentally, but 12,800 V-hr usually gives satisfactory results.

14. End isoelectric focusing (IEF) by turning power supply off and disconnecting leads.

Extrude isoelectric focusing gels

15. Remove gel tube assembly from lower buffer tank and pour out upper buffer. Using a 50- μ l syringe, place \sim 1 μ l bromphenol blue solution on the top of each gel.

The dye marks the basic end of the gel and acts as a tracking dye in the second-dimension gel.

16. Remove the gel tube apparatus from its holder and set it on two short pieces of 4 \times 4 timber or similarly shaped objects in order to elevate the unit enough to allow easy access to the bottoms of the tubes.

17. The IEF gels can be extruded into numbered vials (1 dram) by water pressure from a 1-ml syringe fitted with a small (200- μ l) Eppendorf pipet tip.

Approximately $\frac{1}{4}$ in. of the large end of the tip must be removed so that it will fit on the syringe. With a little practice the gels can be extruded into the vials with almost no liquid entering the vials. The gels can be stored at -70°C for later use or can be used immediately.

18. Clean IEF tubes by soaking overnight in chromic acid cleaning solution; then rinse under deionized tap water 10 to 15 min.

A beaker large enough for the IEF tubes, but not the plastic legs, to fit in can be used as a chromic acid bath. Chromic acid can severely damage the plastic.

CAUTION: Face and eye protection should be worn when pouring chromic acid solutions.

19. Remove excess water from IEF tubes with vacuum suction and allow tubes to air dry.

SECOND-DIMENSION (GRADIENT) GELS

BASIC PROTOCOL

Materials

30% acrylamide/0.8% bisacrylamide
L10 buffer
L20 buffer
10% sodium dodecyl sulfate (SDS)
TEMED
10% ammonium persulfate solution
Blue glycerol (working solution)
Isobutyl alcohol, H₂O saturated
DALT tank buffer salts
Equilibration buffer
Agarose solution
Protein molecular weight standards (Table 10.2.2)
Gel plates
Gel identification tags
Gel casting box (ISS or Hoefer Scientific)
Carpenter's level
Gradient maker (ISS or Hoefer Scientific)
DALT tank (ISS or Hoefer Scientific)
Loading lectern (ISS or Hoefer Scientific)
Nylon screen

The ISO-DALT gradient maker and gel casting box are shown in Figure 10.3.1.

NOTE: Distilled, deionized water should be used throughout this protocol.

Prepare the casting box and gradient maker

1. Remove the front plate from the gel casting box and fill the box with 24 gel plates.
2. Replace the front plate and place a gel identification tag into the right-hand corner of each plate.

Consecutive numbers typed on Whatman No. 1 filter paper make convenient identification tags.

3. Mount the casting box on its stand, level it, and then tilt the box ~30° toward the side the acrylamide enters.

In new versions of the casting box, the gels are poured with the box level at all times.

4. Check the entire gel casting system to be sure that it is clean and free of polymerized acrylamide.
5. Close 20% acrylamide chamber (valve A) and place clamps at points 1, 2, and 3 on the delivery line from the gradient maker.

Figure 10.3.1 Gradient maker and gel casting box. The gradient maker is shown on the left. Valve A controls the flow of 20% acrylamide solution; valve B controls the flow of 10% acrylamide. The acrylamide solutions flow through the delivery line, in which a mixer (M) is used to ensure complete mixing of the two solutions before entering the casting box. Clamping points on the delivery line are indicated by arrows 2, 4, and 5. Arrow 1 indicates the clamping point on the vacuum line and arrow 3 the clamping point (clamp in place) on the blue glycerol line.

Prepare acrylamide solutions

6. Acrylamide solutions for pouring 24 plates are prepared in 1-liter vacuum flasks by making additions as follows:

20% acrylamide solution:
 400 ml 30% acrylamide/
 0.8% bisacrylamide
 200 ml L20 buffer
 6 ml 10% SDS
 30 μ l TEMED
 4 ml 10% ammonium persulfate

10% acrylamide solution:
 247 ml 30% acrylamide/
 0.8% bisacrylamide
 503 ml L10 buffer
 7.5 ml 10% SDS
 140 μ l TEMED
 9 ml 10% ammonium persulfate

7. Add acrylamide/bisacrylamide and L buffer to each flask and degas before adding SDS.
8. Add TEMED and swirl.

The amount of TEMED may need to be adjusted, depending on temperature and acrylamide supplier.

9. Add ammonium persulfate and swirl.

Pour gradient gels

10. Pour the 10% acrylamide solution into the right side of the gradient maker.
11. Open valve A just enough to allow 10% solution to displace the air from the tube between the two sides of the gradient maker.
12. Fill the left side of the gradient maker with the desired amount of 20% acrylamide solution.

13. Place the end of the delivery line in the flask containing the 10% acrylamide solution, release clamp at point 2 in order to flush all air bubbles from the tubing, and replace clamp.

Pinching the line at the site of air bubbles will aid in their removal.

14. Connect the delivery line to the casting box.
15. Refill the right side of the gradient maker with desired amount of 10% solution.
Normally more 10% acrylamide solution than 20% acrylamide solution is used in order to form a layer of 10% acrylamide at the top of the gels.
16. Turn on mixer and close 10% acrylamide chamber (valve B).
17. Release the clamp at point 2.
18. Open valve B to deliver desired flow.
19. As the level of the 10% solution approaches that of the 20% solution, open valve A (20% acrylamide chamber) so that the level of both solutions stays the same.

The gradient maker should empty in 4 to 6 min.

20. Begin bringing the casting box back to level when the acrylamide solution nears the upper corner of the gel plates.

The box should be brought to level in small increments. The final position should be checked with a carpenter's level.

21. When the level of acrylamide in the casting box reaches the desired height (allow ~1.5 cm for addition of blue glycerol), clamp the delivery line at point 2.
22. Release the clamp on the vacuum line (point 1) to remove any remaining acrylamide solution from the gradient maker.
23. Slowly release the clamp on the blue glycerol line (point 3). Bring the level of the blue glycerol to slightly below the bottom of the gel plates.

While the blue glycerol is flowing into the casting box, release the clamp at point 2 just enough to displace the acrylamide from the delivery line.

24. Final adjustment of the blue glycerol level in the casting box is made by raising or lowering the reservoir funnel. Do not clamp the line between the funnel and the casting box before polymerization of the acrylamide is complete.
25. Apply a thin layer of isobutyl alcohol (water saturated) to the tops of the gels (a glass plant spritzer works well).

The gels will be ready to be removed from the box in 1½ hr.

26. Turn off the vacuum and place the waste line in sink.
27. Rinse the gradient maker with at least 2 liters of water.
28. Dispose of the acrylamide in the vacuum flask trap.

Remove plates from casting box

29. Place clamps at points 2, 3, 4, and 5.
30. Disconnect the delivery line from the casting box between points 4 and 5.
31. Place the casting box in the sink and release the clamp at point 5.
32. Remove the wing nuts and front plate from the casting box.

33. After all liquid has drained from the box, set it on the side of the sink.
34. Remove the plates from the casting box by inserting a single-edge razor blade between the back of the first plate and the front of the second plate, then prying forward.

Rubber gloves such as those used for dishwashing should be worn.

35. As each plate is removed, wash it under tap deionized water to remove excess acrylamide and isobutyl alcohol from the top of the gel.
36. Place washed gels on their side in a dish drainer so that excess water will drain from the top of the plates.

Gels may be used immediately or stored refrigerated for several days in an airtight plastic container.

Load and run second-dimension gels

37. Add DALT tank buffer salts to 3 liters of water and stir on a magnetic stirrer.
38. Pour the concentrated DALT tank buffer into a DALT tank and fill to appropriate level with water.
39. If frozen first-dimension (IEF) gels are to be used, they should be thawed on the laboratory bench before adding equilibration buffer.

It is best not to thaw more first-dimension gels at one time than can be loaded in ~20 min, because the protein bands will diffuse.

40. Add 1.5 ml equilibration buffer to each vial and rock for 0 to 30 min.

Some proteins are extracted during long (30 min) equilibration, while others run better. For most samples, 1 to 2 min of exposure to equilibration buffer is sufficient.

41. Pour the gel out of the vial onto a piece of stiff nylon screen large enough to cover a 200-ml beaker.
42. Transfer the gel to the top of the loading lectern and, using a metal spatula, lay the gel out straight (blue-stained—i.e., basic—end on your right) near the front edge of the lectern.

Have a second-dimension gel in place on the front of the lectern.

43. With one hand, dispense a small amount (~100 μ l) of agarose solution from a Pasteur pipet onto one corner of the top of the gel. With the other hand, immediately grasp both the lectern and the gel and tip the lectern ~45° so that the agarose will flow across the entire surface of the gel; then set the lectern back on the laboratory bench.
44. Move the first-dimension gel onto the top of the second-dimension gel by scooting it forward with a spatula.

Take care that no air bubbles get trapped between the first- and second-dimension gels and that the first-dimension gel does not get stretched or compressed.

45. Pipet a thin layer of agarose solution over the first-dimension gel.

Protein molecular weight markers may be run as one-dimensional separations on the sides of the second-dimension gel. Mix marker proteins 1:1 with 1% agarose and draw the hot solution up in a 0.2-ml (1.5 mm diameter) glass pipet. Extrude a short piece of the solidified agarose and apply it the same as the first-dimension gel.

46. After the agarose has solidified, place the gel in the DALT tank for electrophoresis.

For best results, put the rubber hinge on the gel plate in the down position; sample on the cathode (-) side.

47. Attach power supply leads to the DALT tank and turn on the power supply.

At constant voltage of 220 to 260 V, the run will require 4 to 6 hr depending on actual voltage used and tank buffer temperature. For an overnight run of ~16 hr, apply 100 to 150 V with the tank temperature near 10°C.

48. Remove the gels when the tracking dye reaches the end of the gel.

49. Pry the plates open with a spatula and carefully remove the gel.

The gels may stick along the spacers. Thus, it is advisable to free the gel from the spacers by running a thin spatula (or razor blade) between the gel and spacers before peeling the gel from the plate.

50. Place gels in fixative or staining solution (UNIT 10.6) or use autoradiography (APPENDIX 3) to detect radiolabeled protein spots. A representative two-dimensional gel pattern is shown in Figure 10.3.2.

ISOELECTRIC FOCUSING OF BASIC AND VERY ACIDIC PROTEINS

First-dimension isoelectric focusing gels run in the standard way using broad-range ampholytes will resolve proteins with pI values between ~3.8 and 8. Proteins that are more basic or more acidic may be resolved by modifying the first-dimension gels as described below.

ALTERNATE
PROTOCOLS

Figure 10.3.2 Coomassie-stained proteins separated by two-dimensional gel electrophoresis. In this gel, a broad range pH gradient (pH 3.5 to 9) was used for isoelectric focusing in the first dimension, and a 10 to 20% gradient SDS/polyacrylamide gel was used in the second dimension.

Analysis of
Proteins

10.3.7

For Basic Proteins

The procedure is the same as described in the basic protocol for first-dimension gels with the following exceptions in indicated steps. *Samples must be prepared in urea solubilization buffer for basic proteins.*

2. Use 2 to 11 pH ampholytes in gel solution.
9. Fill lower buffer tank with 2 liters of degassed 20 mM NaOH.
10. Fill upper tank with 250 ml of degassed 10 mM phosphoric acid.
11. Do not refocus gels. The anodic and cathodic solutions are reversed, so the negative lead now goes to the lower tank and the positive to the upper tank.
12. Overlay samples with degassed 4 M urea to protect proteins from phosphoric acid.
13. Focus 1 hr at 400 V and then 4 to 5 hr at 800 V for a total of ~4000 V-hr.

The blue glycerol applied to the top of the gel at the end of the run will now mark the acidic end, so load first-dimension gels on the second-dimension gel with the blue end to the left.

For Very Acidic Proteins

The procedure is the same as described in the basic protocol for first-dimension gels with the following exceptions in indicated steps:

2. Prepare the gel solution as follows:
 - 8.25 g urea
 - 2 ml 30% acrylamide/1.8% bisacrylamide
 - 1 ml of pH 2.5 to 4 ampholyte
 - 0.3 ml of pH 2 to 11 ampholyte
 - 5.5 ml H₂O
5. Degas the gel solution and add the following:
 - 0.3 ml NP-40
 - 90 µl 10% ammonium persulfate
 - 10 µl TEMED
9. Make lower buffer by adding 3 ml concentrated H₂SO₄ to 2 liters of water.
10. Make upper buffer by adding 1 ml of 2 to 11 pH ampholyte to 40 ml of degassed water.
13. Run 3600 to 4000 V-hr.

SUPPORT PROTOCOL

SAMPLE SOLUBILIZATION

Materials

Urea solubilization buffer (standard)
Urea solubilization buffer (for basic proteins)
SDS solubilization buffer

Dounce homogenizer
Pestles A and B

1. Weigh and place tissue samples in a Dounce homogenizer.
2. Add 1.5 ml SDS or urea solubilization buffer for each 100 mg of tissue.

3. Homogenize 50 strokes with pestle B, then 50 strokes with pestle A.

Cultured cells and body fluids do not normally require homogenization.

Enzymatic digestion may be required in addition to homogenization in order to remove cell walls from bacteria, yeast, or plant cells.

4. Let stand a few minutes, then transfer an aliquot to a centrifuge tube. Centrifuge 1 hr at $>200,000 \times g$.

If using SDS solubilization buffer, the sample should be placed in boiling water for 5 min before centrifugation.

Centrifugation should be done just prior to loading the sample on the first-dimension gel. Failure to centrifuge tissue samples is likely to cause plugging of the IEF gels, resulting in poor entry of proteins. The Beckman 42.2 Ti rotor, which accommodates 74 tubes of 200 μ l each, works well.

REAGENTS AND SOLUTIONS

NOTE: Distilled, deionized water should be used to prepare all reagents.

Acrylamide/bisacrylamide solutions

<i>30% acrylamide/1.8% bisacrylamide (first dimension):</i>	<i>30% acrylamide/0.8% bisacrylamide (second dimension):</i>
30 g acrylamide	300 g acrylamide
1.8 g bisacrylamide	8 g bisacrylamide
H ₂ O to 100 ml total volume	H ₂ O to 1 liter total volume

Store at 4°C in tightly capped amber bottle after filtering through 0.2- to 0.45- μ m filter. Discard after 30 days since acrylamide gradually hydrolyzes to acrylic acid and ammonia.

CAUTION: Acrylamide monomer is neurotoxic. Gloves should be worn while handling the solution, and the solution should not be pipetted by mouth.

Agarose solution

0.25 g agarose (Bio-Rad standard low- M_r)
50 ml DALT tank buffer

Add dry agarose to the DALT tank buffer in a 125-ml Erlenmeyer flask and place in boiling water bath.

10% ammonium persulfate in H₂O

10 g ammonium persulfate (Bio-Rad)
H₂O to 100 ml total volume
Store refrigerated ~2 weeks

Bromphenol blue solutions

<i>Concentrated:</i>	<i>Blue glycerol (working solution):</i>
50% aqueous glycerol (v/v) saturated with bromphenol blue	50% aqueous glycerol (v/v) + 5 to 10 ml/l concentrated bromphenol blue

DALT tank buffer salts

<i>For 36.7-liter tank:</i>	<i>For 26-liter tank:</i>
110.0 g Tris base	84.5 g Tris base
528.5 g glycine	375 g glycine
36.7 g SDS	26 g SDS (Bio-Rad)

It is convenient to use 1-quart plastic boxes to store measured buffer salt.

Equilibration buffer

200 ml H₂O
7.5 g Tris base
50 ml glycerol
10.5 g SDS

Dissolve Tris base in H₂O and bring to pH 6.8 with 6 N HCl. Add other ingredients and bring to 500 ml final volume with H₂O. To use, add 2 ml 2-mercaptoethanol (Kodak) or 130 mg of dithiothreitol (DTT) to 98 ml equilibration buffer. Can be stored refrigerated for ~3 weeks after addition of reducing agent.

L buffer

400 g Tris base
200 g Tris·Cl
~120 ml 6 N HCl
Adjust pH between 8.5 and 8.6 at room temperature with 6 N HCl
Add H₂O to 3 liters

L10 buffer

3 parts L buffer plus 5 parts water.

L20 buffer

3 parts L buffer plus 1 part glycerol.

SDS solubilization buffer

1.0 g CHES (2-[*N*-cyclohexylamino]ethanesulfonic acid)
2.0 g SDS
1.0 g dithiothreitol
10 ml glycerol
H₂O to 100 ml total volume
Adjust to pH 9.5 with NaOH
Store aliquots at -20°C

Standard urea solubilization buffer

54 g urea
4 ml NP-40
10 ml 20% (w/v) stock ampholyte (pH 9 to 11)
2 ml 2-mercaptoethanol (Kodak)
H₂O to 100 ml total volume
If pH is less than 9.5, add NaOH
Store aliquots at -20°C

Urea solubilization buffer, for basic proteins

54 g urea
4 ml NP-40
5 ml ampholyte (pH 3-10)
2 ml 2-mercaptoethanol (Kodak)
H₂O to 100 ml total volume
Adjust to pH 3.0 with H₃PO₄

COMMENTARY

Background Information

Two-dimensional gel electrophoresis is the combination of two independent electrophoretic techniques, isoelectric focusing and SDS-polyacrylamide gel electrophoresis (O'Farrell, 1975). It is an extremely powerful method for examining complex mixtures of proteins (Celis and Bravo, 1984). It is possible to resolve more than 1500 proteins on a single two-dimensional gel. In addition to analytical applications, two-dimensional gels can provide a means of collecting small amounts of extremely pure proteins for amino acid sequence analysis or antibody production.

The ISO-DALT system (Anderson and Anderson, 1978a,b) was designed to facilitate running large numbers of highly reproducible, high-resolution, two-dimensional gels. Investigators who run small numbers of two-dimensional gels can still take advantage of some of the features of this system. The first-dimension apparatus quickly and inexpensively produces 20 (or 40) identical IEF gels. Even if only a small number of samples (e.g., 3 to 5) are to be run, one may apply duplicate loads or a range of concentrations of each sample. Second-dimension gels are run in multiples of 10 with the original ISO-DALT system (available from Hoefer Scientific and ISS Enprotech).

Proteins may be visualized by staining procedures or by autoradiography of radiolabeled proteins (Celis and Bravo, 1984). Computer analysis of two-dimensional protein gel patterns (e.g., the QUEST system of Garrels et al., 1984, and the Visage system, marketed by Protein Databases and Bio Image, respectively) may be useful for data analysis.

Critical Parameters

Several steps in this procedure may require optimization for a particular sample. Sample solubilization, for example, may require some experimentation to determine the best solubilization buffer and the optimum ratio of buffer to sample. For most tissue samples 1.5 ml of urea solubilization buffer per 100 mg of tissue will give good results. If samples must be stored, it is better to store (-70°C) the original sample than the solubilized sample.

The quality of the first-dimension separation depends on the ampholytes used, voltage, volt-hours, and reagent quality. For good resolution over a broad pH range, blends of ampholytes from different suppliers may give better results than broad range ampholytes from a

single supplier; however, pH 4.0 to 8.0 ampholytes from BDH have been found to perform well in most applications. If possible, test all available lots of ampholytes and buy a large supply of the best lot. Optimum voltage and volt-hours must be determined experimentally. Once suitable conditions have been established, all steps must be done in exactly the same way for each run in order to have the best possible reproducibility.

Troubleshooting

If all steps in this protocol are done correctly, the resulting two-dimensional gels should contain numerous round or elliptical protein spots. Mammalian tissue or whole cell samples typically yield two-dimensional patterns of >1500 spots distributed throughout the second-dimension gel with only a few spots overlapping. Problems arising from the first-dimension separation usually result in spots that are elongated horizontally (poorly focused) or a spot pattern in which most of the proteins are crowded into a narrowed zone along the x axis of the gel.

Vertically elongated spots and spot patterns that are compressed along the y axis of the gel indicate problems with the second-dimension separation. Spot patterns that appear wavy are nearly always the result of disturbances in the acrylamide gradient.

The following checklists will help the beginner locate common problems associated with two-dimensional electrophoresis.

General. (1) Were all of the reagents fresh? (2) Were all of the reagents properly prepared? (3) Were the samples properly solubilized?

First-dimension. (1) Were the samples ultracentrifuged just prior to loading? (2) Were the desired number of volt-hours applied? (3) Were the correct ampholytes used? (4) Was the salt content of the sample low?

Second-dimension. (1) Were the tops of the gels flat and smooth? (2) Was the acrylamide gradient smooth and uniform from top to bottom? (3) Was the tank buffer fresh and the pH proper?

Anticipated Results

A two-dimensional gel electrophoretic separation of proteins similar to that shown in Figure 10.3.2 will be obtained. Proteins of 200,000 molecular weight migrate 1 to 2 cm into the slab gel while those of 10,000 molecular weight migrate 14 to 15 cm. The resulting

two-dimensional pattern is a collection of protein spots in which proteins between 250,000 and 10,000 molecular weight and with isoelectric points between pH 3.8 and 8 are clearly separated from each other.

Time Considerations

First-dimension gels can be used as soon as 1 hr after casting or they can be kept for >24 hr before use. It is convenient to start the first-dimension gels in the afternoon, so they can run overnight and be ready to take off early the following day. Second-dimension gels can be poured the day before they are to be used. The next day the electrophoresis is completed at high voltage (220 to 280 V) for ~5 hr. The two-dimensional gels will be ready to put in fixative or staining solution at the end of the day and can remain in that solution overnight or even over the weekend. Usually 3 working days are required to complete the entire procedure, including staining.

Native protein standards

Electrophoresis buffer: appropriate 4× gel buffer diluted to 1× with H₂O

75-ml side-arm flask (used in gel preparation)

Additional reagents and equipment for gel electrophoresis (UNIT 10.2A) and staining proteins in gels (UNIT 10.6)

Prepare the gel

1. Assemble the glass-plate sandwich of the gel electrophoresis unit and secure it to the casting stand.

Either single-concentration or gradient gels can be used in the minigel or standard-size format. Gradient gels will enhance the band sharpness of the separated proteins.

2. Prepare acrylamide solutions according to the recipes in Table 10.2B.1, Table 10.2B.2, Table 10.2B.3, or Table 10.2B.4, adding the ammonium persulfate and TEMED just before use.

Deaeration of the solution before the polymerization catalysts are added will speed polymerization by removing inhibitory oxygen, but is not generally required. The pH used depends on many factors. The most important are the pI values of both the protein of interest and any contaminants, as well as protein mobility and protein solubility. Determining which pH and thus which buffer system to use is largely empirical. However, extremes of pH (<4.0 and >9.0) can lead to denaturation and should be avoided. Prior knowledge of the pI of a protein (UNITS 10.3 & 10.4) allows determination of the net charge under the

Table 10.2B.1 Recipes for Acetic Acid Nondenaturing Polyacrylamide Gels^a: pH range 3.7 to 5.6^b

Stock solution ^c	Final acrylamide concentration in gel (%) ^d

TEMED ^f	0.02	0.02	0.02	0.02	0.02	0.02	0.02

Preparation of gel

In a 75-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (see Table 10.2A.1), 300 mM sodium sulfite, 4× acetic acid gel buffer (see Reagents and Solutions), and H₂O. If desired to speed polymerization, degas under vacuum ~5 min. Add 10% ammonium persulfate and TEMED. Swirl gently to mix. Use immediately.

^aThe recipes produce 40 ml gel solution, which is adequate for one gel of dimensions 1.5 mm × 14 cm × 16 cm or two gels of dimensions 0.75 mm × 14 cm × 16 cm.

^bThe pH range can be extended to ~2.0 (the pH of acetic acid) by using unadjusted acetic acid in place of 4× acetic acid gel buffer, although there is little buffering capacity at this pH.

^cAll reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.

^dUnits of numbers in table body are milliliters. The desired percentage of acrylamide in the gel solution depends on the molecular size of the protein being separated.

^eMust be freshly made. Sodium sulfite is needed for efficient polymerization at acid pH.

^fAdded just before polymerization.

^eAdded just before polymerization.

separation conditions (i.e., if gel pH < protein pI, the protein will have a net positive charge; if gel pH > protein pI, the protein will be negatively charged).

3. Pour gel to 2 cm from the top of the gel mold and insert the comb. Avoid trapping air bubbles under the comb teeth.

Air bubbles will cause small semicircular depressions in the well and lead to distortions in the protein banding pattern.

4. Allow gel solution to polymerize 1 to 2 hr.

Polymerization is indicated by a sharp optical discontinuity around the wells.

Prepare samples and load the wells

5. Solubilize the protein sample to be analyzed using 5% (w/v) sucrose in water or dilute (1 to 5 mM) gel buffer if possible. Also prepare native protein standards.

The concentration of protein will vary depending on the sample complexity and detection method. For Coomassie blue staining of highly enriched samples such as the standards, use 1 to 2 mg/ml (1 to 2 μg/μl). For more complex mixtures, use 5 to 10 mg/ml (5 to 10 μg/μl). Load 10- to 100-fold less for silver staining. In general, samples should be loaded in a minimum volume, preferably 10 to 20 μl for 0.75- and 1.5-mm-thick gels, respectively. With thin gels, this means using a more concentrated protein sample.

6. Remove comb carefully and rinse wells with electrophoresis buffer (appropriate 4× gel buffer diluted to 1×).

Rinsing with electrophoresis buffer is needed to remove residual unpolymerized acrylamide monomer, which will continue to polymerize after comb removal, creating uneven wells that may interfere with sample loading.

Table 10.2B.3 Recipes for Tris Nondenaturing Polyacrylamide Gels^a: pH range 7.1 to 8.9

Stock solution ^b	Final acrylamide concentration in gel (%) ^c

TEMED ^e	0.02	0.02	0.02	0.02	0.02	0.02	0.02

Preparation of gel

In a 75-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (see Table 10.2A.1), 4× Tris gel buffer (see Reagents and Solutions), and H₂O. If desired, degas under vacuum ~5 min to speed polymerization. Add 10% ammonium persulfate and TEMED. Swirl gently to mix. Use immediately.

^aThe recipes produce 40 ml gel solution, which is adequate for one gel of dimensions 1.5 mm × 14 cm × 16 cm or two gels of dimensions 0.75 mm × 14 cm × 16 cm.

^bAll reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.

^cUnits of numbers in table body are milliliters. The desired percentage of acrylamide in the gel solution depends on the molecular size of the protein being separated.

^dMust be freshly made.

^eAdded just before polymerization.

7. Fill wells with electrophoresis buffer. If desired, prerun gel.

The gel can be prerun at this point to remove any charged material such as ammonium persulfate from the gel prior to loading the sample. Assemble the electrophoresis unit and fill the buffer chambers with electrophoresis buffer. Run the gel at 300 V until the current no longer drops. This should take ~30 min. Disassemble the unit, discard the buffer, and proceed to the next step.

8. Carefully load up to 10 µl (0.75-mm gels) or 20 µl (1.5-mm gels) sample per lane as a thin layer at the bottom of the wells. Load control wells with native protein standards. Add an equal volume of electrophoresis buffer to any empty wells to prevent spreading of adjoining lanes.

Mobility (R_f) markers require special consideration in nondenaturing gel systems. For cationic systems, cytochrome c (pI ~9 to 10, 5 to 10 µg/lane) works well as an R_f marker. Bromphenol blue (10 µg/ml) is a suitable marker for anionic systems. The marker should be included in the solubilization buffer with the sample.

Perform the separation

9. Assemble the gel unit, fill the upper and lower buffer chambers with electrophoresis buffer, and connect the unit to the power supply. Set current to 30 mA for a 1.5-mm-thick gel (15 mA for a 0.75-mm-thick gel).

If the protein is negatively charged under the separation conditions, then the standard SDS-PAGE electrode polarity should be used (proteins will migrate to the anode or positive electrode; see UNIT 10.2A). If the protein is positively charged, then the electrodes should be reversed at the power supply (i.e., red high-voltage cable to the black output and black high-voltage lead to the red output) so the positively charged protein migrates to the negative cathode.

^aThe recipes produce 40 ml gel solution, which is adequate for one gel of dimensions 1.5 mm × 14 cm × 16 cm or two gels of dimensions 0.75 mm × 14 cm × 16 cm.

^bAll reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.

^cUnits of numbers in table body are milliliters. The desired percentage of acrylamide in the gel solution depends on the molecular size of the protein being separated.

^dMust be freshly made.

^eAdded just before polymerization.

10. Continue electrophoresis until the R_f marker reaches the bottom of the gel.

For minigels, electrophoresis will take 1 to 2 hr. Standard gels require 4 to 6 hr runs.

11. Turn off power supply, disassemble the unit, and remove gel from sandwich.

12. Stain the gel according to UNIT 10.6.

NATIVE DISCONTINUOUS ELECTROPHORESIS AND GENERATION OF MOLECULAR WEIGHT STANDARD CURVES (FERGUSON PLOTS)

ALTERNATE PROTOCOL

One straightforward approach to discontinuous native electrophoresis is to leave out the SDS and reducing agent (DTT) from the standard Laemmli SDS-PAGE protocol (UNIT 10.2A). The gels are prepared as described in UNIT 10.2A except that the sample buffer contains no SDS or DTT (samples are not heated), and the gel and electrophoresis solutions are prepared without SDS. This protocol illustrates the separation of standard proteins at four different concentrations of acrylamide and how the results are used to construct a molecular weight standard curve (Ferguson plot) without the need for SDS. By plotting relative mobility against %T (percentage weight per volume of acrylamide plus bisacrylamide in the gel), the presence of isoforms and multimeric proteins can also be detected.

Materials

4× Tris·Cl, pH 8.8 (1.5 M Tris·Cl; APPENDIX 2)

4× Tris·Cl, pH 6.8 (0.5 M Tris·Cl; APPENDIX 2)

Protein sample of interest

2× Tris/glycerol sample buffer (see recipe)

Analysis of Proteins

10.2B.5

Native protein standards (e.g., Sigma nondenatured protein molecular weight kit)
Tris/glycine electrophoresis buffer (see recipe)

1. Assemble the glass-plate sandwich of the gel electrophoresis unit and place it in the casting stand.
2. Prepare and cast the gels, using 4× Tris-Cl, pH 8.8, for the separating gel and 4× Tris-Cl, pH 6.8, for the stacking gel instead of the SDS-containing counterparts (Table 10.2A.1). Prepare a minimum of four separate gels at different acrylamide concentrations.

A typical range of concentrations is from 5% to 12.5% (e.g., 5%, 7.5%, 10%, 12.5% acrylamide). As with SDS-PAGE, typical gel thickness ranges from 0.75 to 1.5 mm. The 0.75-mm-thick gels are recommended because they offer a combination of fast staining and high resolution.

3. Mix protein sample of interest 1:1 with 2× Tris/glycerol sample buffer to attain a 1 to 2 μg/μl final concentration. Also prepare native protein standards. Remove comb, rinse wells, and load 10 to 20 μl per well for Coomassie brilliant blue staining, and 1 to 2 μl for silver staining.

Some proteins must be dissolved in 50 mM NaCl or water to become fully solubilized prior to mixing with the sample buffer (Sigma, 1986).

4. Assemble gel electrophoresis unit, using Tris/glycine electrophoresis buffer to fill both lower and upper buffer chambers. Connect power supply and conduct electrophoresis.

Conditions for separation are the same as for discontinuous SDS-PAGE (i.e., 30 mA for 1.5-mm-thick gels, 15 mA for 0.75-mm-thick gels). For standard-size gels the separation takes 4 to 5 hr; for minigels, 1 to 2 hr is required. Alternatively, standard gels can be run at 4 to 6 mA/gel overnight.

5. After the bromphenol blue R_f marker has reached the bottom of the gel, fix and stain the proteins in the gels according to UNIT 10.6. Estimate relative mobilities of the proteins.

An example of a stained gel is shown in Figure 10.2B.1. A minimum of four gel concentrations is recommended. In Figure 10.2B.1, Sigma native molecular weight standards were separated on 5%, 7.5%, 10%, and 12.5% acrylamide gels (5.1%, 7.7%, 10.3%, and 12.8% T, respectively).

6. Plot $\log R_f$ against gel concentration (% T) (Fig. 10.2B.2). Determine the slope of K_r using linear regression.
7. Plot $-\log K_r$ of the curves from step 6 against \log molecular weight of the standards (Fig. 10.2B.3). Determine the slope using linear regression.
8. Estimate the size of the standards and unknowns from the generated curve (Ferguson plot).

Use the curve generated by linear regression to estimate the predicted size of the standard for comparison to the actual size stated by the supplier. This indicates the accuracy of the curve. The $-\log K < D_r$ value (y) of the unknown is then used to predict the molecular weight (x).

Figure 10.2B.1 Separation of native protein standards under nondenaturing conditions by discontinuous polyacrylamide gel electrophoresis at 12.8% T. Approximately 20 μg protein was loaded per lane on a 1.5-mm-thick, 16-cm-long gel. The gel and samples were prepared according to the Alternate Protocol and were electrophoresed 16 hr at 6 mA. Proteins were stained with Coomassie blue.

Figure 10.2B.2 Effect of %T on the relative mobility of several native proteins. The relative mobility (R_f) of the standard proteins shown in Figure 10.2B.1 was determined at four different gel concentrations and plotted as $\log R_f$ against %T. See text for details. **(A)** BSA monomer (squares) and dimer (circles); **(B)** carbonic anhydrase isoforms.

Figure 10.2B.3 Native molecular weight standard curve. The $-\log$ slope of the line (K_r) from Figure 10.2B.2 is plotted against log molecular weight of the standards.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Acetic acid gel buffer, 4× (200 mM acetic acid, pH 3.7 to 5.6)

- 11.49 ml glacial acetic acid
- Add to 500 ml H₂O
- Adjust to pH 3.7 to 5.6 with 1 M NaOH
- Add H₂O to 1000 ml
- Store up to 1 month at 4°C

Glycine gel buffer, 4× (200 mM glycine, pH 8.6 to 10.6)

- 15.01 g glycine
- Add to 500 ml H₂O
- Adjust to pH 8.6 to 10.6 with 1 M NaOH
- Add H₂O to 1000 ml
- Store up to 1 month at 4°C

Phosphate gel buffer, 4× (400 mM sodium phosphate, pH 5.8 to 8.0)

- 55.2 g NaH₂PO₄·H₂O
- Add to 500 ml H₂O
- Adjust to pH 5.8 to 8.0 with 1 M NaOH
- Add H₂O to 1000 ml
- Store up to 1 month at 4°C

Tris gel buffer, 4× (200 mM Tris·Cl, pH 7.1 to 8.9)

24.23 g Tris base
Add to 500 ml H₂O
Adjust to pH 7.1 to 8.9 with 1 M HCl
Add H₂O to 1000 ml
Store up to 1 month at 4°C

2× Tris/glycerol sample buffer

25 ml 0.5 M Tris·Cl, pH 6.8
20 ml glycerol
1 mg bromphenol blue
Add H₂O to 100 ml and mix
Store in 1-ml aliquots up to 6 months at -70°C

Tris/glycine electrophoresis buffer

15.1 g Tris base
72.0 g glycine
H₂O to 5000 ml
Store up to 1 month at 4°C

COMMENTARY

Background Information

Under nondenaturing conditions, in which protein activity, native charge, and conformation are sustained, electrophoretic separation depends on many factors, including size, shape, and charge. Characteristics such as intrinsic molecular weight (i.e., in the absence of denaturation), the number of isoforms, and the presence of multimeric proteins can be determined with nondenaturing electrophoresis (often called native electrophoresis).

The most important application of nondenaturing electrophoresis is in the determination of native protein size (Alternate Protocol). Ferguson plots (reviewed by Andrews, 1986) were first described for starch gels (Ferguson, 1964) and then for polyacrylamide gels (Hedrick and Smith, 1968). Ferguson plots are prepared by separating proteins under nondenaturing conditions at several different gel concentrations. As the acrylamide concentration (%T) is increased, the relative mobility (R_f) of the protein decreases. This is plotted as log relative mobility (on the y axis) versus %T (on the x axis) to produce a straight line. The slope of this line is referred to as the retardation coefficient (K_r) and measures how effectively a protein is slowed by the increase in %T. Large proteins will be retarded much more significantly than small proteins with increasing gel concentration, with the size of the protein being proportional to the slope of the curve. Once the K_r plots for several size standards are generated (Fig. 10.2B.2), the K_r values are plotted against

the molecular weight of the standard proteins using a log-log graph (Fig. 10.2B.3). The retardation coefficient also depends on a large number of other variables including temperature, pH, buffer type, ionic strength, and %C (percent bisacrylamide cross-linker). All these factors should be kept constant for a given experiment.

In addition to estimated size, other types of information are available from the Ferguson plots (Rodbard and Chrambach, 1971; Andrews, 1986). For example, if two components differ in size but have the same charge per unit size (e.g., for a multimeric protein with identical subunits), curves similar to those illustrated by BSA monomer and dimer (Fig. 10.2B.2A) will result. Note that when the curve is extrapolated back to 0% T, it is evident that the monomer and the dimer have similar free solution mobilities. Furthermore, as the acrylamide concentration is increased, the separation between the two also increases. However, if two proteins have similar sizes but different amounts of charge, the curves will be parallel on the log plot. This is illustrated by the carbonic anhydrase isoforms (Fig. 10.2B.2B). In this example, optimal separation of the isoforms occurs at the lower concentrations of acrylamide as this is a log plot.

Further applications of nondenaturing electrophoresis include preparative purification. The pH of the gel determines the net charge on the protein. Below its isoelectric point (pI) a protein will have a net positive charge, whereas above its pI it will have a net negative charge.

In general, most proteins will be positively charged at pH 2.0 to 4.0; above pH 8.0, most proteins will be negatively charged. As these general guidelines imply, the majority of proteins have isoelectric points between pH 4.0 and 8.0. There are, however, many exceptions. A protein with a highly acidic isoelectric point (e.g., pepsin, with a pI of 2.2) will remain negatively charged at a pH down to its pI. Although a full range of pH options are given, extremes of pH (<4.0 and >9.0) should be avoided, if possible, to minimize denaturation or inactivation. By picking an appropriate electrophoresis pH, it is possible to ensure that the protein of interest will be either positively or negatively charged so that it can be selectively run into the gel, excluding a large proportion of contaminants that have the opposite or no charge. Furthermore, the pH conditions determine the mobility and can be adjusted to ensure a difference in mobility between the protein of interest and contaminants.

Continuous gel systems (see Basic Protocol) offer the most flexibility in terms of separation design. The pH can be tailored so that a given protein has a net positive, neutral, or negative charge. Depending on the polarity of the gel, the protein can then be excluded from or electrophoresed into the gel. Discontinuous gels have a fixed pH and gel polarity. For the nondenaturing Laemmli gel presented in the Alternate Protocol, the proteins of interest should have an isoelectric point of ≤ 7.0 in order to be negatively charged so that they move into the gel. Other more basic and more acidic discontinuous gel systems can be found in Hames (1990) and Schägger (1994).

Critical Parameters

The success of a gel separation under nondenaturing conditions depends on many factors, and two of the most important are protein solubility and isoelectric point. The protein must be soluble at the pH and the ionic strength of the gel, and it must be charged at that pH in order to move into the gel. If the protein experiences a pH below its isoelectric point, then it will have a net positive charge and will move to the negative electrode. Note that this is the reverse of typical SDS-PAGE. If the protein experiences a pH above its isoelectric point, it will have a net negative charge and will migrate to the positive electrode.

Solubility is a complex issue. Membrane-associated and other hydrophobic proteins are difficult to separate by nondenaturing electrophoresis (Schägger, 1994). Nonionic deter-

gents at concentrations up to 1% and solubilizing reagents such as urea (4 to 8 M) can be used, but these reagents, especially urea, are likely to alter the protein's conformation and most likely the isoelectric point by exposing previously hidden charged groups. If detergent or urea must be included for solubilization, the minimum required to solubilize the protein should be used. Schägger (1994) lists several nonionic detergents suitable for solubilization. Among the more popular are octylglucoside and CHAPS. In general, detergents should be used near the critical micelle concentration (CMC; 0.001% to 1%, depending on the detergent).

The gel concentration has a dramatic effect on resolution and should be optimized in order to achieve the best separation and band sharpness. In general, increasing the %T will improve band sharpness.

Troubleshooting

Gel polymerization at acid pH can be problematic, and sodium sulfite is needed for efficient polymerization (Andrews, 1986). Both the ammonium persulfate and the sodium sulfite must be freshly made, and the highest quality reagents available should be used. Furthermore, the gel solutions should be at room temperature for effective polymerization.

If the protein does not enter the gel and no stained material is present at the well surface, try reversing the polarity of the electrode. If material concentrates at the top of the gel, try lowering the acrylamide concentration. Stained material at the top of the gel may also indicate poor solubilization, and increasing the ionic strength of the solubilization buffer or adding a small amount of urea and/or nonionic detergent may be required.

Anticipated Results

Proteins will resolve depending on their solubility and native charge at the chosen pH. Ideally, a distinct band representing the protein of interest will be visible. If the band is diffuse, then increasing the gel concentration or using a gradient gel will improve resolution. If the band is not visible, then the protein may be at its isoelectric point or may have moved out of the gel because it had the wrong charge. Continuous gel systems, although more versatile, will give lower resolution than discontinuous gels. Detergents or other solubilizing agents such as urea may be needed to fully solubilize and resolve the protein. Once the conditions that resolve the protein are determined, Ferguson plots will give indications of multiple

subunit structure, native size, and potential isoform relationships.

Time Considerations

Separations will be complete when the tracking dye or protein reaches the bottom of the gel. For minigels, this generally takes 1 to 2 hr, using 15 or 30 mA for 0.75- or 1.5-mm-thick gels, respectively. Standard-format gels require 4 to 5 hr at 15 or 30 mA for 0.75- or 1.5-mm-thick gels, respectively. Standard-format gels can also run overnight at 4 to 6 or 8 to 12 mA for 0.75- or 1.5-mm-thick gels, respectively.

Two-Dimensional Gel Electrophoresis

Two-dimensional gel electrophoresis is the combination of two high-resolution electrophoretic procedures (isoelectric focusing and SDS–polyacrylamide gel electrophoresis) to provide much greater resolution than either procedure alone. In the first-dimension gel, solubilized proteins are separated according to their isoelectric point (pI) by isoelectric focusing. This gel is then applied to the top of an SDS-slab gel and electrophoresed. The proteins in the first-dimension gel migrate into the second-dimension gel where they are separated on the basis of their molecular weight.

The resulting two-dimensional gel contains numerous round or elliptical protein spots well separated from each other. A two-dimensional gel of whole cell or tissue lysate may easily contain 1500 protein spots if a sensitive protein detection method, such as silver staining (UNIT 10.6) or autoradiography (APPENDIX 3A), is used. One-dimensional separation of a similar sample would result in only about 100 protein bands, with many of the bands containing more than one protein. Therefore, two-dimensional electrophoresis is the method of choice when maximum resolution of proteins in a complex mixture is required. Even when dealing with purified protein samples such as immunoprecipitates (UNIT 10.16), two-dimensional electrophoresis offers the advantage of being able to simultaneously monitor changes in charge and/or molecular weight of proteins of interest. This can be especially helpful when working with recombinant proteins (which may vary slightly from those naturally expressed) and with processed proteins. Immunoprecipitated proteins can be solubilized in either the SDS or the urea solubilization buffer described in the reagents and solutions section of this unit using the procedures described in UNIT 10.16. Remember that urea solubilization buffer is never put in boiling water.

Basic Protocols 1 and 2 are based on the type of equipment originally described by O'Farrell (1975). Such equipment is relatively inexpensive and can produce satisfactory results in situations that do not require running large numbers of two-dimensional gels. Many variations of the original procedure have been described in the literature and by equipment suppliers. The procedures below are appropriate, with minor modifications, for different equipment available from commercial suppliers or custom-made equipment similar to that described by O'Farrell (1975); detailed instructions are usually supplied by the manufacturer. Alternate Protocol 1 describes modifications for very basic proteins and Alternate Protocol 2 describes modifications for very acidic proteins. Alternate Protocol 3 describes how two-dimensional electrophoresis can be performed using a minigel system. Protein sample preparation is presented in Support Protocol 1.

IEF systems are gaining in popularity, and a procedure for using immobilized pH gradients and tube gels with thin rectangular IEF gels supported by a plastic backing is included (see Alternate Protocol 4 and Support Protocol 2).

FIRST-DIMENSION (ISOELECTRIC-FOCUSING) GELS

This protocol is for broad-range first-dimension gels which resolve proteins with isoelectric points between about pH 4 to 8. Very basic proteins can be focused using Alternate Protocol 1 and very acidic proteins can be focused using Alternate Protocol 2. If increased resolution in a narrow pH range is needed, narrow-range ampholytes can be added to the broad-range ampholytes in a 2:1 ratio. For example, 0.50 ml of pH 5 to 7 ampholytes, plus 0.25 ml of pH 4 to 8 ampholytes, can be used instead of 0.75 ml of pH 4 to 8 ampholytes alone to increase the separation distance of proteins in the pH 5 to 7 range.

The first-dimension gels are poured in gel tubes, which are placed in a tube electrophoresis cell. After filling the reservoirs, the samples are loaded and the gels are run. The gels are

BASIC PROTOCOL 1

Analysis of Proteins

10.4.1

extruded using water pressure and can then be stored at -70°C or used immediately for the second-dimension gel (Fig. 10.4.1).

Materials

Urea (ultrapure)
30% acrylamide/1.8% bisacrylamide (see recipe)
Ampholytes, pH 4 to 8 (Bio-Rad, Serva, Invitrogen, Sigma-Aldrich)
Nonidet P-40 (NP-40)
TEMED (*N,N,N',N'* tetramethylethylenediamine)
10% ammonium persulfate (see recipe)
0.085% phosphoric acid (see recipe)
0.02 M NaOH (see recipe)
Protein samples (see Support Protocol 1)
Concentrated bromphenol blue (see recipe)
Chromic acid cleaning solution (see recipe)

1.0- to 3.0-mm-inner-diameter glass gel tubes (~1.5 in. longer than the width of the second-dimension gel; 4- to 6-mm outer diameter)
2.5- to 3.0-cm-inner-diameter gel-casting glass tube, ~2 cm shorter than gel tubes
Small vacuum flask
50- μl , 1-ml, and 20-ml syringes
0.2- or 0.45- μm filter capsule (Acrodisk; Gelman)
Single-edge razor blade
Rubber grommets
Tube cell (Bio-Rad, Topac, CBS Scientific, Scie-Plas)
22-G hypodermic needle (2-in. long)
200- μl pipettor tip
1-dram gel vials

NOTE: Distilled, deionized water should be used throughout this protocol.

Figure 10.4.1 Assembly of gel tubes in casting tube.

Prepare and pour the gels

1. Mark clean, dry 1.0- to 3.0-mm-i.d. gel tubes to indicate the desired height of the gel (usually the same as the width of the second-dimension gel).

Cleaning instructions are provided in step 26.

The most commonly used type of isoelectric focusing apparatus is the cylindrical unit (Bio-Rad or Hoefer). Gel tubes are available with a wide range of inside diameters; however, for the highest resolution, tubes of 1.5-mm i.d. are preferred. Tubes up to 3-mm i.d. may be used if it is necessary to load large sample volumes or larger amounts of protein.

2. Place a rubber band around the gel tubes so that they form a tight bundle (~12 tubes fit into a bundle; Fig. 10.4.1).
3. Hold the bundle vertically on a flat surface and push down on the tops of the tubes so that the bottoms are even.
4. Carefully seal one end of the 2.5- to 3.0-cm-i.d. gel-casting glass tube with three or four layers of Parafilm to form a strong, water-tight seal.
5. Place the bundle of gel tubes inside the gel casting tube and support the glass tube in a vertical position with a ring stand and clamp to allow the sealed end of the glass tube to rest on a solid surface.
6. Add 8.25 g urea, 6.0 ml water, 2.0 ml of 30% acrylamide/1.8% bisacrylamide, and 0.75 ml ampholytes, pH 4 to 8, to a small vacuum flask. Add a small stir bar to the flask. Place the flask in a warm water bath on a magnetic stirrer and stir just until the urea is in solution; do not heat the solution to $>30^{\circ}\text{C}$.

This makes 15 ml acrylamide solution, sufficient for twenty 1.5×160 -mm gels.

Although the BDH pH 4 to 8 Resolytes are highly recommended, one may wish to use a blend of ampholytes as a substitute. For a broad-range blend, mix 1 part ampholytes, pH 2 to 11 (Serva) and 2 parts ampholytes, pH 3.5 to 10 (Amersham Biosciences). For an alternative broad-range blend, use equal volumes of ampholytes, pH 3 to 10 (Bio-Rad) and pH 2 to 11 (Serva). Mix enough ampholytes at one time to last ≥ 1 year. This will improve run-to-run reproducibility. This alternative can be used if Resolytes are unavailable or for a custom pH gradient.

7. Deaerate the solution by applying a strong vacuum for 2 to 3 min.
 8. Add 0.3 ml NP-40 and swirl until dissolved.
- Do not add the NP-40 before deaeration because it will foam.*
9. Pour solution into a 20-ml syringe fitted with a 0.2- or 0.45- μm filter capsule and force through the filter.
 10. Add 10 ml TEMED and swirl. Add 70 ml of 10% ammonium persulfate and swirl. Immediately pipet the gel solution into the space between the gel tubes and the large glass tube.

Work quickly, as the gel solution will start to polymerize in ~3 min.

11. Gently run water down the outside of the gel tubes using a wash bottle. Add water until the level of the acrylamide solution inside the tubes reaches the desired height.

As water is layered on top of the gel solution it will force the solution up the tubes from the bottom. There is no need to overlay the gel solution inside the tubes. Allow ≥ 1 hr for polymerization.

Set up the gels in the tube cell

12. Remove the Parafilm from the bottom of the gel casting tube and push the gel tubes, containing the polymerized gel, out the bottom. Cut across the gel-tube bottoms to remove excess acrylamide with a single-edge razor blade. Rinse the bottom of the gel tubes under running deionized water to remove residual acrylamide.
13. Place rubber grommet on the top of each tube, making sure that the top surface of the gel is visible below the grommet; ~5 mm of the gel tube should be visible above the grommet.
14. Seat the tube and grommet assemblies in the holes of the upper buffer reservoir of the tube cell. Plug any unused holes with rubber stoppers.
15. Fill the lower reservoir with ~3 liters of 0.085% phosphoric acid.
16. Place the upper reservoir into lower reservoir and adjust lower buffer level if needed.

The buffer should cover the entire gel for good heat dissipation.
17. Fill the upper buffer reservoir with 250 ml of 0.02 M NaOH.
18. Fill the gel tubes to the top with 0.02 M NaOH using a 1-ml syringe equipped with a 22-G hypodermic needle. Be careful to eliminate any air bubbles in the gel tubes.
19. Connect the tube cell to the power supply. The black (–) lead goes to the upper reservoir. Prefocus the gel 1 hr at 200 V constant voltage (see *UNIT 10.2A* introduction for a discussion of electricity and electrophoresis). Disconnect the tube cell from the power supply.

Load the samples and run the gels

20. Layer protein samples on top of the gels through the upper buffer with a 50- μ l syringe.

The maximum amount of total protein that can be loaded onto a first-dimension gel varies depending upon the nature of the sample. Samples such as whole-cell lysates which contain a large number of proteins of widely varied isoelectric point (pI) can contain much more total protein than a sample of a single highly purified protein. As much as 100 to 150 μ g of a protein mixture can be loaded on a first-dimension gel 1.5-mm in diameter, while a tenth that amount of highly purified protein would probably be an overload. For gels 1.5-mm in diameter, 10 to 20 μ l of sample is preferred; however, up to 30 μ l can be applied.

Alternatively, place the samples directly on the gel, then overlay with 10 to 20 μ l half-strength solubilization buffer (diluted 1:2 with water). This will protect samples from exposure to the basic upper buffer. Fill the remainder of the tube with 0.02 M NaOH to eliminate any bubbles.

21. Place the lid on the upper reservoir and attach the electrical leads to a power supply.
22. Turn on the power supply and adjust to the desired settings at constant voltage.

For 1.5-mm-i.d., 16-cm-long gels, 700 to 800 V (constant voltage) for 16 hr (11,000 to 13,000 V hr) works well for most samples.

23. Reduce the voltage setting to zero and turn off the power supply to end the run. Add ~1 μ l concentrated bromphenol blue to the top of each gel with a 50- μ l syringe.

The bromphenol blue will quickly diffuse into the gel. At the end of the run, the gels may be noticeably shorter and the bromphenol blue may stop short of the top of the gel. In this case, the power can be applied for a few minutes and the dye will migrate into the top of the gels. The blue dye will mark the basic end of the first-dimension gel and serve as the tracking dye in the second-dimension separation.

Extrude the gels

24. Extrude the gels from the tubes using water pressure from a 1-ml syringe fitted with a 200- μ l pipettor tip (cut off ~1 cm of the large end of the tip so it fits on the syringe).

Gels with a diameter >2.0 mm may have to be loosened by inserting a blunt 26-G, 9-cm-long needle between the gel and the wall of the tube while injecting water. Rotate the tube so the needle will pass over the entire circumference of the gel while continuously injecting water. Repeat this operation at the opposite end of the tube and the gel should slide out easily.

25. Place each gel in a labeled gel vial. The gels can be stored at -70°C for many weeks or used immediately.
26. Soak gel tubes overnight in chromic acid cleaning solution, then rinse thoroughly under running deionized tap water for 15 min. Remove excess water from the gel tubes with suction and allow them to dry.

SOLUBILIZATION AND PREPARATION OF PROTEINS IN TISSUE SAMPLES

Tissue samples are solubilized in either SDS or urea solubilization buffer (see commentary) by Dounce homogenization. After centrifugation, the protein sample can be loaded onto the first-dimension gel.

Materials

Tissue samples
SDS or urea solubilization buffer (see recipes)
Dounce homogenizer with pestles A and B
200- μ l centrifuge tubes
Beckman 42.2-Ti rotor (or equivalent)

1. Weigh and place tissue samples in a Dounce homogenizer.
2. Add 1.5 to 2.0 ml SDS or urea solubilization buffer per 100 mg tissue.
3. Homogenize using 50 strokes with pestle B, then 50 strokes with pestle A.

Cultured cells and body fluids do not normally require homogenization.

4. Let stand a few minutes, then transfer an aliquot to a 200- μ l centrifuge tube. Centrifuge ≥ 2 hr at $100,000 \times g$, or 1 hr at $>200,000 \times g$, 20°C . Save the supernatant (protein sample) to load onto the first-dimension gel as described in Basic Protocol 1.

If using SDS solubilization buffer, place the sample in boiling water 5 min before centrifugation. Never heat samples in urea solubilization buffer. Heating proteins in a urea solution will cause carbamylation of proteins, and thus result in charge variants. Centrifugation should be done just prior to loading the sample onto the first-dimension gel. Failure to centrifuge tissue samples may cause plugging of the first-dimension gels, resulting in poor entry of proteins. The Beckman 42.2-Ti rotor, which accommodates seventy-four 200- μ l tubes, is recommended.

SECOND-DIMENSION GELS

A wide variety of equipment suitable for casting and running second-dimension gels is available. Nearly any SDS-PAGE slab-gel system will work. For the best possible resolution over a wide molecular-weight range, a 10% to 20% acrylamide gradient gel is recommended (UNIT 10.2A); however, for many applications, a conventional slab gel as described below is sufficient. The procedure described uses the Bio-Rad PROTEAN II system, but it can be easily adapted to similar equipment, such as the vertical slab-gel units from Hoefer.

SUPPORT PROTOCOL 1

BASIC PROTOCOL 2

Analysis of Proteins

10.4.5

The second-dimension gel is poured between glass plates. The first-dimension gel is then loaded onto the second-dimension gel and sealed in place with agarose. The gels are mounted in the cell and run. After disassembling the electrophoresis unit, the gel is stained and analyzed.

Materials

30% acrylamide/0.8% bisacrylamide (see recipe for acrylamide/bisacrylamide solutions)
Gel buffer (see recipe)
10% (w/v) SDS
TEMED
10% ammonium persulfate (see recipe)
Isobutyl alcohol, H₂O-saturated
Stacking gel buffer (optional; see recipe)
First-dimension gel (see Basic Protocol 1)
Equilibration buffer (see recipe)
Hot 0.5% and 1% agarose (see recipe; keep in boiling water bath)
Protein molecular weight standards (Table 10.2A.2; available as kits Bio-Rad or Amersham Biosciences)
SDS solubilization buffer (see recipe)
Reservoir buffer (see recipe), prechilled to 10° to 20°C
Coolant (from running tap water or circulating refrigerated water bath)

Gel plates, one long and one short
1.5-mm spacers (~14 cm × 14 cm × 0.75 mm)
Casting stand
Gel identification tag (e.g., typed consecutive numbers on filter paper)
Nylon screen
5 × 15-cm glass plate
PROTEAN II electrophoresis cell (Bio-Rad)

Prepare and pour the gel

1. Assemble the gel plates by placing 1.5-mm spacers vertically between a long and short gel plate. The side where the long plate protrudes is the top.

Gel thickness is usually equal to the diameter of the isoelectric focusing gels, but this is not absolutely necessary.
2. Position clamps on each side of the gel sandwich over the spacers and place on the casting stand. Be sure the plates and spacers are properly aligned, then tighten the clamps and cams to get a leak-proof seal. Make adjustments so that plates are level and vertical.
3. Place the gel identification tag between the glass plates so that it rests in the lower right hand corner.
4. Prepare the gel solution by combining 30% acrylamide/0.8% bisacrylamide, gel buffer, and water in a vacuum flask (Table 10.4.1).
5. Deaerate the solution by applying vacuum for 5 min.
6. Add 10% SDS and TEMED and swirl, then add 10% ammonium persulfate and swirl (Table 10.4.1).
7. Fill the gel sandwich to 5 mm below the top of the short plate and overlay with H₂O-saturated isobutyl alcohol or water.

Table 10.4.1 Solutions for Second-Dimensional Gels^a

Stock solutions	Final acrylamide concentration (%)			
	7.5	10	12.5	15
30% acrylamide/ 0.8% bisacrylamide	12.5	16.7	20.8	25.1
Gel buffer	12.5	12.5	12.5	12.5
H ₂ O	24.6	20.3	16.2	12.0
10% SDS	0.5	0.5	0.5	0.5
TEMED	0.026	0.026	0.026	0.026
10% ammonium persulfate	0.185	0.185	0.185	0.185

^aValues in table body are milliliters of stock solution. Preparation of solutions is described in steps 4 to 6 of protocol.

A stacking gel is not usually required when running second-dimension gels. If a stacker is desired, stop the gel 1.5 cm from the top of the short plate, overlay with H₂O-saturated isobutyl alcohol, and allow to polymerize 1 hr. Remove the overlay and fill the remaining space with stacking gel solution made by combining 4.8 ml stacking gel buffer, 3.8 ml water, and 1.4 ml 30% acrylamide/0.8% bisacrylamide (all deaerated) with 200 μ l of 10% ammonium persulfate and 8 μ l TEMED. Pipet onto the separating gel, overlay with H₂O-saturated isobutyl alcohol, and allow to polymerize 30 min.

8. Allow the second-dimension gel to polymerize \geq 1.5 hr.

Load first-dimension gel onto second-dimension gel

9. If first-dimension gel is frozen, thaw at room temperature. Add equilibration buffer to completely cover the gel.

The time the gel is in equilibration buffer containing SDS can vary from seconds to several minutes depending upon the sample. Most proteins run well without the introduction of SDS from equilibration buffer; however, a few proteins do not. Leaving gels in equilibration buffer for >10 to 15 min can result in loss of proteins.

10. Pour the gel and equilibration buffer onto a nylon screen placed over a beaker.
11. Place the first-dimension gel on a 5 \times 15-cm glass plate (Parafilm is not rigid enough). Using a spatula, lay the gel out straight along one edge of the glass plate.
12. Pipet a very thin layer of hot 0.5% agarose on the top of the slab gel to be loaded.

This can easily be done by putting ~0.1 ml hot agarose on the upper left corner of a gel and quickly tilting the gel to the right so that the agarose will flow across the gel surface.

13. Using a spatula, slide the first-dimension gel off the glass plate and place it across the top of the slab gel. Orient the first dimension gel with the blue (basic) end to your right (Fig. 10.4.2).

Take care that no air bubbles get trapped between the first- and second-dimension gels and that the first-dimension gel does not get stretched or compressed.

14. Pipet a thin layer of hot 0.5% agarose over the first-dimension gel to seal it in place. Allow the agarose to solidify.

Protein molecular-weight markers may be run as one-dimensional separations on the sides of the second-dimension gel. Solubilize marker proteins in SDS solubilization buffer by boiling for 5 min, then dilute 1:1 with hot 1% agarose solution and draw up the hot solution in a glass tube the same diameter as the first-dimension gel. A short piece of the solidified agarose can be applied to one or both sides of the second-dimension gel and held in place with 0.5% agarose.

Figure 10.4.2 Assembly of second-dimension gel.

Run and analyze the gel

15. Mount the gels on the PROTEAN II electrophoresis cell (the short plate goes toward the center of the unit).
16. Fill the upper and lower reservoirs with prechilled reservoir buffer.
17. Attach tubing for coolant to the in and out ports and start the flow of coolant to maintain the temperature of the tank buffer at 10° to 20°C during the run to ensure that the gels are adequately cooled.

The tank buffer should be the same temperature for each run.

18. Attach the electrical leads to the power supply (the upper reservoir is connected to the negative lead). Electrophorese at 15 to 20 mA/gel until the tracking dye reaches the end of the gel (or 3 to 5 mA/gel overnight).
19. Reduce the voltage setting to zero and turn off the power supply at the end of the run. Remove the gels from the electrophoresis unit and take off the clamps. Pry the glass plates apart with a spatula.
20. Stain the gels (*UNIT 10.6*), process the gels for immunoblotting (*UNIT 10.8*), or autoradiograph the gels (*APPENDIX 3A*).

***ALTERNATE
PROTOCOL 1***

ISOELECTRIC FOCUSING OF VERY BASIC PROTEINS USING NEPHGE

First-dimension IEF gels run in the standard way using broad-range ampholytes will resolve proteins with isoelectric points (pI) between 3.8 and 8. More basic or more acidic proteins may be resolved by modifying the first-dimension gels using nonequilibrium pH gradient electrophoresis (NEPHGE) as described below (Anderson, 1988).

Additional Materials (also see *Basic Protocol 1*)

- Ampholytes, pH 2 to 11 (Serva)
- 0.01 M phosphoric acid, deaerated
- 4 M urea, deaerated

To analyze very basic proteins, the procedure is the same as described in *Basic Protocol 1* for first-dimension gels with the following exceptions in the indicated steps:

- 6a. Use 0.75 ml ampholytes, pH 2 to 11, in gel solution.
- 15a. Fill the lower reservoir with ~3 liters deaerated 0.02 M NaOH.

- 17a. Fill the upper reservoir with 250 ml deaerated 0.01 M phosphoric acid.
- 19a. Do not refocus gels.
- 20a. Overlay samples with deaerated 4 M urea to protect proteins from phosphoric acid.
- 21a. Attach the negative lead to the lower tank and the positive to the upper tank (this is the reverse of the usual setup).
- 22a. Focus 1 hr at 400 V and then 4 to 5 hr at 800 V for a total of 4000 V-hr.

Because the bromphenol blue applied to the top of the gel at the end of the run now marks the acidic end, load first-dimension gels onto the second-dimension gel with the blue end to the left.

ISOELECTRIC FOCUSING OF VERY ACIDIC PROTEINS USING NEPHGE

Additional Materials (also see Basic Protocol 1)

Ampholytes, pH 2.5 to 4 (Pharmacia LKB)
Concentrated sulfuric acid
Water, deaerated

To analyze very acidic proteins, the procedure is the same as described in Basic Protocol 1 for first-dimension gels with the following exceptions in the indicated steps:

6b. Prepare the gel solution as follows:

8.25 g urea
5.5 ml H₂O
2.0 ml 30% acrylamide/1.8% bisacrylamide
1.0 ml ampholytes, pH 2.5 to 4 (Pharmacia LKB)
0.3 ml ampholytes, pH 2 to 11 (Serva).

- 10b. Add 90 μ l of 10% ammonium persulfate and swirl, then add 10 μ l TEMED and swirl.
- 15b. Prepare lower buffer by adding 4.5 ml concentrated sulfuric acid to 3 liters of water and fill the lower reservoir.
- 17b. Prepare upper buffer by adding 3 ml ampholyte, pH 2 to 11, to 120 ml deaerated water and place in the upper reservoir.
- 22b. Run at 800 V for 4.5 to 5.0 hr or 250 V for 16 hr for a total of 3600 to 4000 V-hr.

TWO-DIMENSIONAL MINIGELS

Though limited in resolving area, small two-dimensional SDS-PAGE is a quick way to separate proteins for a variety of applications. These include peptide sequencing, purity checks, and protocol development. Where a large-format two-dimensional SDS-PAGE separation might take two days, a minigel separation (*UNIT 10.2A*) takes 4 to 5 hr, including the first-dimension (IEF) gel. The solutions and procedures in the basic protocols directly translate to the small format, except that much less reagent is required and electrophoresis times are much shorter.

To perform two-dimensional SDS-PAGE in the small format, a few simple changes from the basic protocol are needed. Tube gel adaptors for IEF, such as the Hoefer SE 220 or the Bio-Rad Mini-Protean II Tube Cell, fit in the minigel unit (*UNIT 10.2A*). Because the tube gels are much shorter (6 to 8 cm), the isoelectric focusing time is less; 2 to 4 hr at 500 V is usually adequate. Furthermore, less protein is generally required. Stacking gels

**ALTERNATE
PROTOCOL 2**

**ALTERNATE
PROTOCOL 3**

**Analysis of
Proteins**

10.4.9

**ALTERNATE
PROTOCOL 4**

are not normally required, so the mini slab gel should be cast to within 0.5 to 1 cm of the top. The second-dimension gel is processed in the same way as a first-dimension minigel (*UNIT 10.2A*).

**TWO-DIMENSIONAL (2-D) ELECTROPHORESIS WITH IMMOBILIZED
pH GRADIENTS**

In Basic Protocol 1, first-dimension separation is performed in carrier ampholyte-containing polyacrylamide gels cast in narrow tubes. In this protocol, the carrier ampholyte-generated pH gradients have been replaced with immobilized pH gradients and the tube gels have been replaced with thin rectangular IEF gels supported by a plastic backing (Westermeier et al., 1983; Berkelman and Stenstedt, 1998; Görg et al., 2000). Such gradients produce superior resolution and reproducibility (Bjellqvist et al., 1982). This protocol describes the use of the Ettan IPGphor isoelectric focusing system (Amersham Biosciences), but the PROTEAN IEF System from Bio-Rad is also popular. The cost is higher than when Basic Protocols 1 and 2 are used, but many laboratories have adopted these systems. The use of commercial quality-controlled and standardized reagents and instrumentation greatly simplifies the process of 2-D analysis and makes it possible to obtain much more consistent results.

Materials

- Protein sample for analysis
- Sample solution: default sample solution, hydrophobic sample solution, or tissue sample solution (see recipes)
- Tissue homogenization solution (see recipe)
- Rehydration stock solution (see recipe)
- IPG buffer or Pharmalyte (same range as the IPG strip; Amersham Biosciences)
- Cleaning solution (e.g., Ettan IPGphor Strip Holder Cleaning Solution; Amersham Biosciences)
- IPG Dry Strip Cover Fluid (Amersham Biosciences)
- Vertical gel for SDS-PAGE (Basic Protocol 2 in *UNIT 10.2A*)
- SDS equilibration buffer (see recipe)
- SDS electrophoresis buffer (*UNIT 10.2A*)
- Molecular weight markers (*UNIT 10.2A*)
- Agarose sealing solution (see recipe)
- Isoelectric focusing system (Ettan IPGphor, Amersham Biosciences; PROTEAN IEF System, Bio-Rad)
- IPG strips (Amersham Biosciences)
- Toothbrush
- Platform rocker
- 100°C heating block
- Thin plastic ruler
- Additional reagents and equipment for second-dimension gel electrophoresis (see Basic Protocol 2)

Prepare the sample

- 1a. *For an unknown protein:* Dissolve sample in default sample solution.
- 1b. *For large and more hydrophobic proteins:* Dissolve sample in hydrophobic sample solution.
- 1c. *For proteins from tissues that are dilute sources of protein and contain high levels of interfering substances (e.g., plant tissues):* Grind tissue in mortar and pestle with liquid nitrogen. Suspend powder in tissue homogenization solution. Keep at -18°C

Table 10.4.2 Suitable Sample Loads for Silver and Coomassie Staining Using Rehydration Loading

Immobiline DryStrip		Suitable sample load (μg of protein)		Rehydration solution volume, per strip
Size	pH range	Silver stain	Coomassie stain	
7 cm	4–7	4–8	20–120	125 μl
	6–11	8–16	40–240	
	3–10, 3–10 NL	2–4	10–60	
11 cm	4–7	10–20	50–300	200 μl
	6–11	20–40	100–600	
	3–10 L	4–8	20–120	
13 cm	4–7	15–30	75–450	250 μl
	6–11	30–60	150–900	
	3–10, 3–10 NL	8–15	40–240	
18 cm	4–7	30–60	150–900	340 μl
	6–11, 6–9, narrow interval ^a	60–120	300–1500	
	3–10, 3–10 NL	15–30	75–450	
24 cm	4–7, 3–7	45–90	200–1300	450 μl
	6–9, narrow interval ^a	80–170	400–2000	
	3–10, 3–10 NL	20–40	100–600	

^aImmobiline DryStrip narrow intervals pH: 3.5–4.5, 4.0–5.0, 4.5–5.5, 5.0–6.0, and 5.5–6.7.

overnight and centrifuge. Wash pellet with acetone. Dry and suspend in tissue sample solution.

This method produces protein solutions substantially free of salts, nucleic acids, and other contaminants.

Rehydrate IPG strips

IPG strips must be rehydrated prior to IEF. With integrated IEF systems such as the Amersham IPGphor Isoelectric Focusing and Bio-Rad PROTEAN system, both rehydration of the IPG strip and IEF occur in individual strip holders or trays. Different strip holder lengths are available for different IPG strip lengths. If the strip holders are in use for IEF, rehydration may be carried out in the Immobiline DryStrip Reswelling Tray (see Support Protocol 2).

2. Just prior to use, slowly thaw a 2.5-ml aliquot of rehydration stock solution. Add the appropriate amount (see Reagents and Solutions) of IPG Buffer or Pharmalyte, if it is not already included in the rehydration stock solution, and add 7 mg DTT.

Sample may be applied now (“rehydration loading”), or at step 10. If rehydration loading is desired, refer to Table 10.4.2 for suitable sample loads.

DTT and the sample must be added fresh, just prior to use.

3. Select the strip holder(s) corresponding to the IPG strip length chosen for the experiment.

Handle the ceramic strip holders with care, as they are fragile.

4. Wash each strip holder with detergent to remove residual protein, using a neutral-pH detergent (e.g., Ettan IPGphor Strip Holder Cleaning Solution) as follows.

- a. Rinse off the strip holder.

A mild liquid soap may be used to remove any residual DryStrip cover fluid.

Table 10.4.3 Recommended Final Concentrations and Volumes of IPG Buffer/Pharmalyte for the Rehydration Solution^a

Strip holder	Rehydration and sample well loading	Vertical gels, flatbed	0.5% IPG Buffer (12.5 μ l per 2.5 ml)
Cup loading	Cup holder	Vertical gels, flatbed	2% IPG Buffer (50 μ l per 2.5 ml)

^aThe recommended IPG Buffer / Pharmalyte concentration for the IPGphor system is 0.5%, but up to 2% can be added if sample solubilization remains a problem.

- b. Squeeze a few drops of Ettan IPGphor Strip Holder Cleaning Solution into the strip holder slot. Use a toothbrush and vigorous agitation to clean the strip holder.
- c. Rinse well with distilled or deionized water. Thoroughly air dry the strip holders or dry well with a lint-free tissue prior to use.

The Ettan IPGphor Strip Holder Cleaning Solution has been specifically formulated for removing protein deposits and will not damage the strip holder.

Clean strip holders after each first-dimension IEF run. Do not let solutions dry in the strip holder. Cleaning may be more effective if the strip holders are first soaked a few hours overnight in a solution of 2% to 5% Ettan IPGphor Strip.

Recalcitrant or dried-on protein deposits may be removed with hot (up to 95°C) 1% (w/v) SDS. Add 1% (w/w) DTT for complete removal of sticky proteins. Rinse completely with distilled or deionized water after cleaning. Handle clean strip holders with gloves to avoid contamination. Strip holders may be baked, boiled, or autoclaved. Do not expose them to strong acids or bases, including alkaline detergents.

5. Pipet the appropriate volume of rehydration solution into each strip holder as indicated in Table 10.4.3. Deliver the solution slowly at a central point in the strip holder channel away from the sample application wells. Remove any larger bubbles.

To ensure complete sample uptake, do not exceed the recommended volume of rehydration solution (see Table 10.4.3).

6. Place the IPG strip in the strip holder as follows.
 - a. To prevent damage to the basic (square) end of the IPG strip, which is generally softer, remove the protective cover foil from the IPG strip starting at the acidic (pointed) end.
 - b. Position the IPG strip with the gel side down and the pointed (anodic) end of the strip directed toward the pointed end of the strip holder.
 - c. Pointed end first, lower the IPG strip onto the solution. To help coat the entire strip, gently lift and lower the strip and slide it back and forth along the surface of the solution, tilting the strip holder slightly as needed to assure complete and even wetting.
 - d. Finally, lower the cathodic (square) end of the IPG strip into the channel, making sure that the gel contacts the strip holder electrodes at each end.

The gel can be visually identified once the rehydration solution begins to dye the gel. Be careful not to trap air bubbles under the IPG strip.

7. Apply IPG Dry Strip Cover Fluid to minimize evaporation and urea crystallization. Pipet the fluid dropwise into one end of the strip holder until one half of the IPG strip is covered, then pipet the fluid dropwise into the other end of the strip holder, adding fluid until the entire IPG strip is covered.

8. Place the cover on the strip holder.

Pressure blocks on the underside of the cover assure that the IPG strip maintains good contact with the electrodes as the gel swells.

9. Allow the IPG strip to rehydrate.

For rehydration loading of sample (see annotation to step 2), there are two possible rehydration conditions: passive rehydration with no electric field applied during rehydration, and rehydration under voltage. In some cases, rehydration under a low voltage (30 to 120 V) facilitates the entry of high-molecular weight proteins.

Rehydration can proceed on the bench top or on the Ettan IPGphor unit platform. Ensure that the strip holder is on a level surface. A minimum of 10 hr is required for rehydration; overnight is recommended. The rehydration period can be programmed as the first step of an Ettan IPGphor protocol. This is especially convenient if temperature control during rehydration is a concern.

Perform first-dimension electrophoresis

10. If the sample was not applied as a part of the rehydration solution in step 2, pipet ≥ 7.5 μl of sample solution prepared in step 1a, b, or c (i.e., 15 μl per well or 30 μl total if both sides of both wells are used) to the lateral wells at either end of the strip holder, below the IPG DryStrip Cover Fluid. Replace cover on strip holder.

When using the alternative “cup loading” procedure (also see instrumentation manual) an increased sample concentration will lead to an increased risk of protein precipitation in the sample cup. A maximum concentration of 100 μg protein/100 μl sample solution (100 μl is the volume of the cup) is recommended. This is a general recommendation, which will work for most samples, but the maximum concentration that can be used varies greatly between sample types. For larger sample loads, rehydration loading (see annotation to step 2 and Table 10.4.2) is recommended.

The IPG strip backing is impermeable; do not apply the sample to the back of the strip.

11. Perform first-dimension IEF separation per manufacturer’s instructions. See Table 10.4.4 for guidelines on different experimental setups.

Equilibrate strips prior to second-dimension electrophoresis

The second-dimension vertical gel must be ready for use prior to IPG strip equilibration. See Basic Protocol 2 for preparation of vertical gels for 2-D SDS PAGE.

12. Place the IPG strips in individual tubes with the support film toward the wall of the tube. Add 10 ml SDS equilibration buffer (containing DTT) to each tube. Cap the tube, and place it on its side on a platform rocker. Equilibrate for 15 min.
13. If desired, perform a second equilibration with SDS equilibration buffer containing 250 mg/ml iodoacetamide (without DTT). Add 10 ml of solution per tube. Cap the tube, place it on its side on a platform rocker, and equilibrate for 15 min.

This second equilibration step reduces point streaking and other artifacts.

14. Dip the equilibrated IPG strip in SDS electrophoresis buffer to lubricate it.
15. *Optional:* Apply molecular weight marker proteins to a separate small strip.

Best results are obtained when the molecular weight marker protein solution is mixed with an equal volume of a hot 1% agarose solution prior to application to the IEF sample application piece. The resultant 0.5% agarose will gel and prevent the marker proteins from diffusing laterally prior to the application of electric current. Other alternatives are to apply the markers to a paper IEF sample application piece in a volume of 15 to 20 μl . For less volume, cut the sample application piece proportionally. Place the IEF application piece on a glass plate and pipet the marker solution onto it, then pick up the application piece with forceps and apply to the top surface of the gel next to one end of the IPG strip. The markers should contain 200 to 1000 ng of each component for Coomassie staining and about 10 to 50 ng of each component for silver staining.

16. Melt each aliquot of agarose sealing solution needed (each gel will require 1 to 1.5 ml) in a 100°C heat block (it takes ~10 min to fully melt the agarose; an ideal time to carry out this step is during IPG strip equilibration). Allow the agarose to cool until

Table 10.4.4 Guidelines for Ettan IPGphor with Rehydration Loading/IEF for Immobiline Dry Strips^a

Immobiline DryStrip	pH range(s)	Step and voltage mode	Step duration ^b (h:min)	Kilovolt-hours (kV-hr)
7 cm	3–10	1. Step and hold 500	0:30	0.25
	3–10 NL	2. Step and hold 1000	0:30	0.5
	4–7	3. Step and hold 5000 ^c	1:40	7.5
		Total	2:40	8.0
11 cm	3–10	1. Step and hold 500	1:00	0.5
	4–7	2. Step and hold 1000	1:00	1.0
		3. Step and hold 8000 ^c	1:50	12.5
		Total	3:50	14.0
13 cm	3–10	1. Step and hold 500	1:00	0.5
	3–10 NL	2. Step and hold 1000	1:00	1.0
	4–7	3. Step and hold 8000 ^c	2:00	14.5
		Total	4:00	16.0
18 cm	3–10	1. Step and hold 500	1:00	0.5
	3–10 NL	2. Step and hold 1000	1:00	1.0
	4–7	3. Step and hold 8000 ^c	4:00	30.5
		Total	6:00	32.0
	Narrow intervals ^d	1. Step and hold 500	1:00	0.5
		2. Step and hold 1000	1:00	1.0
		3. Step and hold 1000 ^c	7:30	58.5
		Total	9:30	60.0
24 cm	3–10	1. Step and hold 500	1:00	0.5
	3–10 NL	2. Step and hold 1000	1:00	1.0
	4–7	3. Step and hold 8000 ^c	8:20	62.5
		Total	10:20	64.0
	Narrow intervals ^d	1. Step and hold 500	1:00	0.5
		2. Step and hold 1000	1:00	1.0
		3. Step and hold 8000 ^c	10:30	94.5
		Total	12:30	96.0

^aVoltage step and hold mode, 50 μ A/IPG strip; 0.5% IPG buffer; 20°C for both rehydration and IEF. Rehydration time, 12 hr. The total rehydration time can be adjusted somewhat for convenience, but must be >10 hr.

^bThe sample entry phase step 1 and 2 should be extended for high protein loads, or for convenience, if the strips are to be run overnight.

^cThis voltage may not be reached within the suggested step duration.

^dNarrow intervals, 3.5–4.5, 4.0–5.0, 4.5–5.5, 5.0–6.0, and 5.5–6.7.

the tube can be held with fingers (60°C) and then slowly pipet the amount required to seal the IPG strip in place, avoiding introduction of bubbles. Only apply the minimum quantity of agarose sealing solution required to cover the IPG strip. Allow a minimum of 1 min for the agarose to cool and solidify.

In any vertical gel system, the agarose sealing serves to prevent the IPG strip from moving or floating in the electrophoresis buffer. If precast Ettan DALT gels are used for the second-dimension electrophoresis, the agarose sealing also serves to block the narrow gap(s) between the gel edge(s) and the lateral spacer(s) to prevent leakage of the upper buffer.

17. Center the IPG strip between the plates on the surface of the second-dimension gel with the plastic backing against one of the glass plates. With a thin plastic ruler, gently push the IPG strip down so that the entire lower edge of the IPG strip is in contact with the top surface of the slab gel. Ensure that no air bubbles are trapped between the IPG strip and the slab gel surfaces or between the gel backing and the glass plate.
18. Perform second-dimension electrophoresis (see Basic Protocol 2).

REHYDRATION OF IPG STRIPS USING THE IMMOBILINE DRYSTRIP RESWELLING TRAY

The IPG strips are rehydrated in the Immobiline DryStrip Reswelling Tray if strip holders are in use for IEF. The Immobiline DryStrip Reswelling Tray has 12 independent reservoir slots that can each hold a single IPG strip up to 24 cm long. Separate slots allow the rehydration of individual IPG strips in a minimal volume of solution.

Additional Materials (also see Alternate Protocol 4)

Immobiline DryStrip Reswelling Tray (Amersham Biosciences)

1. Slide protective lid of reswelling tray completely off the tray and level tray by turning the leveling feet until the bubble in the spirit level is centered. Ensure that tray is clean and dry.
2. Pipet appropriate volume of rehydration solution into each slot as indicated in Table 10.4.3. Mix with sample solution (see Alternate Protocol 2, step 1) for rehydration loading (see Alternate Protocol 4, step 2 annotation). Deliver solution slowly at a central point in the slot. Remove any larger bubbles.

To ensure complete fluid (and sample) uptake, do not apply excess rehydration solution.

3. Remove protective cover from IPG strip starting at the acidic (pointed) end. Position IPG strip with gel side down and pointed end of strip against the sloped end of the slot. Lower IPG strip onto solution. To coat the entire IPG strip, carefully lift and lower the strip and slide it back and forth along the surface of the solution. Do not trap bubbles under the IPG strip.
4. Overlay the IPG strip with 3 ml DryStrip Cover Fluid to minimize evaporation and prevent urea crystallization.
5. Slide lid onto reswelling tray and allow IPG strips to rehydrate at room temperature.

A minimum of 10 hr is required for rehydration; overnight is recommended.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Acrylamide/bisacrylamide solutions

30% acrylamide/1.8% bisacrylamide (first dimension):

30 g acrylamide

1.8 g bisacrylamide

H₂O to 100 ml

30% acrylamide/0.8% bisacrylamide (second dimension):

300 g acrylamide

8.0 g bisacrylamide

H₂O to 1 liter

Filter through 0.2- to 0.45- μ m filter. Store in tightly capped amber bottles at 4°C. Discard after 30 days, as acrylamide gradually hydrolyzes to acrylic acid and ammonia.

CAUTION: *Acrylamide monomer is neurotoxic. Gloves should be worn while handling the solution, and the solution should not be pipetted by mouth. Wear a mask when weighing out the solid acrylamide.*

Agarose sealing solution

100 ml SDS electrophoresis buffer (*UNIT 10.2A*)
0.5 g agarose (NuSieve GTG, Cambrex)
200 μ l 1% bromphenol blue stock (see recipe; 0.002% w/v final)

Combine all ingredients in a 500-ml Erlenmeyer flask. Swirl to disperse. Heat in a microwave oven on “low” or a stirring hotplate until the agarose is completely dissolved. Do not allow the solution to boil over. Dispense 2-ml aliquots into screw-cap tubes and store up to 1 week at 4°C.

Agarose solution, 0.5%

0.25 g agarose (standard low- M_r ; Bio-Rad)
50 ml reservoir buffer (see recipe)

Heat in a boiling water bath to dissolve the agarose and keep in a boiling water bath. Prepare fresh each time.

Agarose solution, 1%

Prepare as for hot 0.5% agarose solution (see recipe), substituting 0.5 g agarose for 0.25 g agarose.

Ammonium persulfate, 10%

10 g ammonium persulfate (Bio-Rad)
H₂O to 100 ml
Store refrigerated \leq 2 weeks

Bromphenol blue stock solution, 1%

100 mg bromphenol blue (Sigma; 1% w/v final)
60 mg Tris base (50 mM final)
Double-distilled H₂O to 10 ml
Prepare fresh

Chromic acid cleaning solution

Add a 25 ml bottle of Chromerge (Fisher) to a 9-lb bottle of concentrated sulfuric acid. Add ~5 ml at a time and stir.

CAUTION: *This is very corrosive and toxic. Carefully read and observe package instructions.*

Concentrated bromphenol blue

50% aqueous glycerol (v/v)
0.01 mg/ml bromphenol blue
Prepare fresh

Default sample solution

8 M urea
4% (w/v) CHAPS
60 mM DTT
2% (v/v) Pharmalyte 3–10 (Amersham Biosciences)
0.002% (w/v) bromphenol blue (add from 1% stock; see recipe)
Store up to 6 months at –20°C

Equilibration buffer

3.75 g Tris base
25 ml glycerol
5.25 g SDS
333 mg dithiothreitol (DTT)

Dissolve Tris base in H₂O and adjust pH to 6.8 with 6 M HCl. Add other ingredients. Add H₂O to 250 ml final volume. This buffer can be stored for up to 1 week at room temperature.

Gel buffer

Dissolve 90.8 g Tris base in 300 ml H₂O. Adjust to pH 8.6 with 6 M HCl. Add H₂O to 500 ml. This buffer can be stored for several weeks in the refrigerator.

Hydrophobic sample solution

7 M urea
2 M thiourea
4% (w/v) CHAPS
60 mM DTT
2% (v/v) Pharmalyte pH 3–10 (Amersham Biosciences)
0.002% (w/v) bromphenol blue (add from 1% stock; see recipe)
Store up to 6 months at –20°C

NaOH, 0.02 M

Just before using, add 0.5 ml of 10 M NaOH to 250 ml freshly deaerated water. Store up to 1 month at room temperature.

It is especially important to make 0.02 M NaOH with deaerated water.

Phosphoric acid, 0.085%

Just before using, dilute 300 ml of 0.85% phosphoric acid to 3.0 liters with deaerated water. Store up to 1 month at room temperature.

Rehydration stock solution

12 g urea (FW 60.06; 8 M final)
0.5 g CHAPS (2% w/v final)
50 µl 1% bromphenol blue stock (see recipe; 0.002% w/v final)
Double distilled H₂O to 25 ml
Store stock with above components in 2.5-ml aliquots up to 1 month at –20°C
Just prior to use add 7 mg DTT per 2.5-ml aliquot and IPG Buffer or Pharmalyte (same range as IPG strip) to 0.5% (for IPGphor apparatus) or 2% (for Multiphor II and Immobiline DryStrip kit). Use 125 µl IPG Buffer for a 0.5% concentration and 500 µl IPG Buffer for a 2% concentration. Use Pharmalyte 3–10 for Immobiline DryStrip 3–10 or 3–10 NL and Pharmalyte 5–8 for Immobiline DryStrip 4–7. For rehydration loading (see Alternate Protocol 4, step 2 annotation), also add sample to the 2.5 ml aliquot of rehydration solution just prior to use (see Table 10.4.2 for suitable sample loads).

If necessary, the concentration of urea can be increased to 9 or 9.8 M. Other detergents (Triton X-100, NP-40, and other nonionic or zwitterionic detergents) can be used instead of CHAPS.

Reservoir buffer

15.0 g Tris base
72.0 g glycine
5.0 g SDS
H₂O to 5 liters
For convenience, make up as a 10× stock or store the preweighed dry ingredients in packets for future use. The 10× stock can be stored for several weeks in the refrigerator.

SDS equilibration buffer

10 ml 1.5 M Tris·Cl, pH 8.8 (APPENDIX 2; 50 mM final)
72.07 g urea (FW 60.06; 6 M final)
69 ml 87% (v/v) glycerol (30% v/v final)
4 g SDS (FW 288.38; 2% w/v final)

continued

400 μ l 1% bromphenol blue stock (see recipe; 0.002% w/v final)
Double-distilled H₂O to 200 ml
Store solution with above components at -20°C
Just before use add:
100 mg DTT or 250 mg iodoacetamide

SDS solubilization buffer

0.1 g 2-(*N*-cyclohexylamino)ethanesulfonic acid (CHES)
0.2 g SDS
0.1 g DTT
1.0 ml glycerol
H₂O to 10 ml total volume
Store aliquots at -70°C

Stacking gel buffer

15.0 g Tris base
1.0 g SDS
Dissolve Tris base and SDS in 200 ml H₂O. Adjust to pH 6.8 with 6 M HCl. Add H₂O to 250 ml. The 5 \times stock can be stored for several weeks in the refrigerator.

Tissue homogenization solution

Prepare in acetone:
10% (w/v) trichloroacetic acid (TCA)
0.3% (w/v) DTT
Prepare fresh

Tissue sample solution

9 M urea
2% (w/v) CHAPS
1% (w/v) DTT
2% (v/v) Pharmalyte 3–10
Store up to 1 month at -20°C

Urea solubilization buffer

5.4 g urea
0.4 ml NP-40
1.0 ml 20% (w/v) stock ampholyte (pH 9 to 11)
0.2 ml 2-ME (Kodak)
H₂O to 10 ml total volume; if pH is <9.5 , add 2 M NaOH
Store aliquots up to 1 month at -70°C

COMMENTARY

Background Information

Two-dimensional gel electrophoresis is an extremely powerful analytical tool for characterization of complex protein mixtures (O'Farrell, 1975). No other procedure can resolve so many proteins in a single operation. Therefore, two-dimensional electrophoresis is an excellent way to examine protein changes between control and experimental samples. Because charge and molecular weight are monitored simultaneously, small alterations in proteins can be detected. Increased resolution with two-dimensional gels facilitates quantitative analy-

sis of proteins. With very few exceptions, each spot on a two-dimensional gel contains only one protein, whereas a band on a one-dimensional gel (UNIT 10.2A) may contain more than one protein. (Single proteins can yield multiple spots due to variability in sialylation. Treatment of samples with neuraminidase eliminates this type of heterogeneity; follow instructions from Genzyme for use of neuraminidase.) It is impossible to accurately assess quantitative changes with more than one protein in a band because individual proteins can change independently.

In addition to analytical applications, two-dimensional PAGE can provide a means of collecting small amounts of extremely pure protein for amino acid sequence analysis (Hirano, 1989) or antibody production (Dunbar, 1987). Preparative and analytical studies using two-dimensional gels require running a large number of gels. The ISO-DALT system (UNIT 10.3; Anderson, 1988) is specifically designed for running numerous two-dimensional gels.

Minigels (UNIT 10.2) have become popular for one-dimensional separation of proteins. The small size (8 × 10-cm, or 10 × 10-cm) of minigels makes it possible to run and stain the gels in much less time than standard sized gels. It is possible to use mini slab gels as the second dimension of a two-dimensional separation when small first-dimension gels (equipment available from Bio-Rad and Hoefer) are used. The mini two-dimensional systems can save a considerable amount of time and reagents, but they cannot resolve large numbers of proteins present in complex mixtures such as a whole-cell lysate. Therefore, it is recommended that the use of minigels be restricted primarily to simple protein mixtures.

Proteins on two-dimensional gels may be visualized by staining procedures (UNIT 10.6) or by autoradiography (APPENDIX 3A) of radiolabeled proteins (UNIT 10.18). A large number of extremely sensitive silver staining methods have been published. The most sensitive of these stains (Ochs et al., 1981) can detect ≤1 ng of most proteins. Although silver staining is a very sensitive method, impurities in reagents and water are often detected as well as proteins. The staining sensitivity can vary from one protein to another. This can be particularly troublesome when doing quantitative analysis of two-dimensional patterns.

A large and growing application of 2-D electrophoresis is “proteome analysis.” Proteome analysis is “the analysis of the entire PROTEin complement expressed by a genOME” (Wilkins et al., 1996). The analysis involves the systematic separation, identification, and quantification of many proteins simultaneously from a single sample. Two-dimensional electrophoresis is used in this technique due to its unparalleled ability to separate thousands of proteins simultaneously. Two-dimensional electrophoresis is also unique in its ability to detect post- and co-translational modifications, which cannot be predicted from the genome sequence. Applications of 2-D electrophoresis include proteome analysis, cell differentiation, detection of disease markers, moni-

toring therapies, drug discovery, cancer research, purity checks, and microscale protein purification. New mass spectrometry techniques have been developed that allow rapid identification and characterization of very small quantities of peptides and proteins extracted from single 2-D spots.

In the newer Immobiline systems (see Alternate Protocol 4), the 2-D process begins with sample preparation. Proper sample preparation is absolutely essential for a good 2-D result. The next step in the 2-D process is IPG strip rehydration. IPG strips are provided dry and must be rehydrated with the appropriate additives prior to IEF. First-dimension IEF is performed on a flatbed system at very high voltages with active temperature control. Next, strip equilibration in SDS-containing buffer prepares the sample for the second-dimension separation. Following equilibration, the strip is placed on the second-dimension gel for SDS-PAGE. The final steps are visualization and analysis of the resultant two-dimensional array of spots.

Principles of isoelectric focusing (IEF)

IEF is an electrophoretic method that separates proteins according to their isoelectric point (pI). Proteins are amphoteric molecules; they carry either positive, negative, or zero net charge, depending on the pH of their surroundings. The net charge of a protein is the sum of all the negative and positive charges of its amino acid side chains and amino and carboxyl-termini. The isoelectric point (pI) is the specific pH at which the net charge of the protein is zero. Proteins are positively charged at pH values below their pI and negatively charged at pH values above their pI. If the net charge of a protein is plotted versus the pH of its environment, the resulting curve intersects the x axis at the isoelectric point.

The presence of a pH gradient is critical to the IEF technique. In a pH gradient, under the influence of an electric field, a protein will move to the position in the gradient where its net charge is zero. A protein with a positive net charge will migrate toward the cathode, becoming progressively less positively charged as it moves through the pH gradient until it reaches its pI. A protein with a negative net charge will migrate toward the anode, becoming less negatively charged until it also reaches zero net charge. If a protein should diffuse away from its pI, it immediately gains charge and migrates back. This is the focusing effect of IEF, which concentrates proteins at their pIs and allows

proteins to be separated on the basis of very small charge differences.

The resolution is determined by the slope of the pH gradient and the electric field strength. IEF is therefore performed at high voltages (typically >1000 V). When the proteins have reached their final positions in the pH gradient, there is very little ionic movement in the system, resulting in a very low final current (typically below 1 mA). IEF of a given sample in a given electrophoresis system is generally performed for a constant number of volt-hours (V-hr), this unit being the integral of the volts applied over the time.

IEF performed under denaturing conditions gives the highest resolution and the cleanest results. Complete denaturation and solubilization is achieved with a mixture of urea and detergent, ensuring that each protein is present in only one configuration and aggregation and intermolecular interaction is minimized.

The original method for first-dimension IEF depended on carrier ampholyte-generated pH gradients in polyacrylamide gel rods in tubes (O'Farrell, 1975). Carrier ampholytes are small, soluble, amphoteric molecules with a high buffering capacity near their pI. Commercial carrier ampholyte mixtures are comprised of hundreds of individual polymeric species with pIs spanning a specific pH range. When a voltage is applied across a carrier ampholyte mixture, the carrier ampholytes with the highest pI (and the most negative charge) move toward the anode and the carrier ampholytes with the lowest pI (and the most positive charge) move toward the cathode. The other carrier ampholytes align themselves between the extremes, according to their pIs, and buffer their environment to the corresponding pHs. The result is a continuous pH gradient.

Although the technique described in Basic Protocol 1 is commonly used in 2-D electrophoresis studies, it has several limitations that have prevented its more widespread application. Carrier ampholytes are mixed polymers that are not well characterized and suffer from batch-to-batch manufacturing variations. These variations can reduce the reproducibility of the first-dimension separation. Carrier ampholyte pH gradients are unstable and have a tendency to drift, usually toward the cathode, over time. Gradient drift adversely affects reproducibility by introducing a time variable. Gradient drift also causes a flattening of the pH gradient at each end, particularly above pH 9, rendering the 2-D technique less useful at pH

extremes. Finally, the soft polyacrylamide tube gels used in this procedure have low mechanical stability. The gel rods may stretch or break, affecting reproducibility. Results are often dependent on the skill of the operator.

As a result of the limitations and problems with carrier ampholyte pH gradients, immobilized pH gradients (Alternate Protocol 4) were developed and Immobiline chemicals were introduced for the generation of this type of pH gradient. Westermeier (1983) and Görg et al. (2000) pioneered the development and use of IPG IEF for the first-dimension of 2-D electrophoresis. An immobilized pH gradient (IPG) is created by covalently incorporating a gradient of acidic and basic buffering groups into a polyacrylamide gel at the time it is cast. The buffers are composed of a single acidic or basic buffering group linked to an acrylamide monomer.

The general structure of Immobiline reagents is:

where R = weakly acidic or basic buffering group. Immobilized pH gradients are formed using two solutions, one containing a relatively acidic mixture of acrylamide buffers and the other containing a relatively basic mixture. The concentrations of the various buffers in the two solutions define the range and shape of the pH gradient produced. Both solutions contain acrylamide monomers and catalysts. During polymerization, the acrylamide portion of the buffers copolymerize with the acrylamide and bisacrylamide monomers to form a polyacrylamide gel. To help in handling and performance, the IPG gel is cast onto a plastic backing. It is then washed to remove catalysts and unpolymerized monomers, which could otherwise modify proteins and interfere with separation. Finally the gel is dried and cut into 3-mm-wide strips. The resulting IPG strips can be rehydrated with a rehydration solution containing the necessary components for first-dimension IEF.

In the Immobiline systems, IEF is performed horizontally on a flatbed electrophoresis unit. Because IEF requires high field strengths to obtain sharply focused bands, high voltages must be applied. A flatbed design is the most economical way to meet the necessary safety standards required to operate at such high voltages. It also allows for cooling and close temperature control, which can be effectively achieved on a horizontal ceramic cooling plate

connected to a thermostatic circulator or a Peltier cooling plate. The first-dimension separation is more reproducible because the covalently fixed gradient cannot drift.

Critical Parameters

Two-dimensional PAGE is not difficult to perform but it is easy for problems to arise. Careful attention to detail is essential.

Several steps in the procedure need to be optimized for particular samples. Sample solubilization, for example, may require some experimentation to determine the best solubilization buffer and the optimum ratio of buffer to sample. For most tissue samples, 1.5 to 2.0 ml of urea solubilization buffer per 100 mg of tissue will give good results; however, the ratio of tissue to buffer may have to be altered in some instances. If solubilized samples are stored frozen (-70°C), avoid thawing and re-freezing.

In general, keep the sample preparation strategy as simple as possible to avoid protein losses. Additional sample preparation steps may improve the quality of the final 2-D result, but at the possible expense of selective protein loss. The cells or tissue should be disrupted in such a way as to minimize proteolysis and other modes of protein degradation. Cell disruption should be done at as low a temperature as possible and with a minimum of heat generation. Cell disruption should ideally be carried out directly by placing the cells into a strongly denaturing solution containing protease inhibitors (*UNIT 10.2*). Preserve sample quality by preparing the sample just prior to IEF or storing samples in aliquots at -80°C . Do not expose samples to repeated thawing. Remove all particulate material by ultracentrifugation. Solid particles and lipids must be removed because they will block the gel pores.

The sample solubilization solutions are in general optimized for either Basic Protocol 1 or Alternate Protocol 4. For Basic Protocol 1, either urea- or SDS-based sample solubilization may be used. Most proteins are soluble in either SDS or urea solubilization buffer. However, some proteins are more soluble in one or the other; therefore, it may be necessary to try both types of solubilization for a particular sample. In general, urea is more effective than SDS for tissue solubilization. Samples that have been solubilized in SDS can only be used with isoelectric focusing (IEF) gels containing urea and NP-40. Otherwise, the SDS remains associated with the proteins, giving them a strong negative charge and causing them to

migrate to the acidic end of the gel. The IPG technique outlined in Alternate Protocol 4 is particularly sensitive to residual SDS, which must be removed or reduced in concentration to $<0.25\%$ by dilution of the sample into rehydration solution (see Reagents and Solutions) containing nonionic detergent (e.g., CHAPS) prior to isoelectric focusing (Berkelman and Stenstedt, 1998). To avoid modification of proteins, never heat a sample after adding urea. When the sample contains urea, it must not be heated over 37°C . Elevated temperatures cause urea to hydrolyze to isocyanate, which modifies proteins by carbamylation.

Immunoprecipitates prepared as described in *UNIT 10.16* and solubilized in either SDS or urea solubilization buffer can be analyzed by two-dimensional electrophoresis. The sample should not contain $>2\%$ SDS. Samples in SDS solubilization buffer may be heated in a boiling water bath for 5 min to aid in protein solubilization. Heating is not always required and should never be done with samples in urea solubilization buffer.

The quality of the first-dimension separation depends on the ampholytes used, voltage, volt-hours, and reagent quality. For good resolution over a broad pH range, blends of ampholytes from different suppliers generally give better results than broad-range ampholytes from a single supplier. However, ISO-DALT-grade Resolyte, pH 4 to 8, made by BDH Chemicals and sold in the United States by Hoefer, works very well. Optimum voltage and volt-hours must be determined experimentally. Once suitable conditions have been established, the same conditions must be used for each run to achieve reproducibility.

When using homogeneous slab gels, the acrylamide concentration of the gel must be matched to the sample. Low-molecular-weight proteins can be resolved on high-percentage (18% to 20% acrylamide) gels while high-molecular-weight proteins must be run on low-percentage (7.5% to 12.5% acrylamide) gels. Gradient gels, such as 10% to 20% acrylamide gradients, are able to resolve proteins over a wide size range (250 to 10 kDa) on a single gel. Pouring gradient gels is more difficult than pouring homogeneous slabs, but with some practice the technique can be mastered (*UNIT 10.2*). One alternative is to buy precast gradient gels from a commercial supplier, such as Integrated Separation Systems.

IEF in the Ettan IPGphor system is conducted at very high voltages (up to 8000 V) and very low currents (typically $<50\ \mu\text{A}$ per IPG

strip) due to the low ionic strength within IPG strips. During IEF, the current decreases while the voltage increases as proteins and other charged components migrate to their equilibrium positions. A typical IEF protocol generally proceeds through a series of voltage steps that begin at a relatively low value. Voltage is gradually increased to the final desired focusing voltage, which is held for several hours. A low initial voltage minimizes sample aggregation and allows the parallel separation of samples with differing salt concentrations. A gradual increase in voltage is particularly advised for higher protein loads (100 μg or more per IPG strip).

Many factors affect the amount of time required for complete focusing, and each specific set of conditions (e.g., sample and rehydration solution composition, IPG strip length, and pH gradient) requires an empirical determination for optimal results. An approximate time for complete focusing is given in the example protocols provided in Table 10.4.4. Factors that increase the required focusing time include residual ions, which must move to the ends of the IPG strips before protein focusing can occur, and the presence of IPG Buffers or Pharmalyte, which contribute to the ionic strength of the electrophoresis medium. A higher IPG buffer concentration increases the conductivity of the IPG strip, resulting in a lower final voltage when the system is limited by the maximum current setting. Longer focusing times may therefore be required at IPG Buffer/Pharmalyte concentrations higher than 0.5%.

For higher protein loads (up to 1 mg or more) the final focusing step of each protocol can be extended with an additional 20% of the total recommended V-hr (see Background Information) if necessary. Using preparative protein loads and high salt concentrations in the Ettan IPGphor Cup Loading Strip Holder may cause the cover oil to redistribute and leak out of the strip holder. This can be counteracted by using a longer voltage ramp-up time. Note that exceeding the current limit of 50 μA /IPG strip is not recommended, as this may result in excessive heat generation and may damage the IPG strip and/or strip holder. Under extreme circumstances, the IPG strip may burn. Overfocusing can sometimes occur on longer runs and may contribute to horizontal streaking, visible in the 2-D result.

Troubleshooting

If all steps in this protocol are done correctly, the resulting two-dimensional gels should con-

tain numerous round or elliptical protein spots. Mammalian tissue or whole-cell samples typically yield two-dimensional patterns of >1000 silver-stained protein spots distributed throughout the second-dimension gel, with only a few spots overlapping. Purified protein samples such as immunoprecipitation may have only one major protein and a few minor ones.

The following checklists will help the beginner locate common problems associated with two-dimensional electrophoresis.

General. (1) Were all of the reagents fresh? (2) Were all of the reagents properly prepared? (3) Were the samples properly solubilized?

First dimension. Spots that are elongated horizontally (poorly focused), or a spot pattern in which most of the proteins are crowded into a narrowed zone along x axis of gel, should trigger the following questions: (1) Were samples ultracentrifuged just prior to loading? (2) Were desired number of volt-hours applied? (3) Were correct ampholytes used? (4) Was salt content of the sample low?

Second dimension. Vertically elongated spots and spot patterns that are vertically compressed along the y axis of the gel should trigger the following questions: (1) Was the gel solution properly deaerated? (2) Were the tops of the gels flat and smooth? (3) Was the reservoir buffer at the desired temperature throughout the run? (4) Was the reservoir buffer fresh and the proper concentration?

Anticipated Results

A two-dimensional electrophoretic separation of proteins similar to that shown in Figure 10.3.2 will be obtained. In this case, a 10% to 12% acrylamide second-dimension gel was used. Proteins between 10 and 250 kDa and pI 3.8 to 8.0 can be seen on this gel. Protein spots on a two-dimensional gel should be round or elliptical and separated from each other. A complex protein mixture such as mammalian tissue or whole cells should give a two-dimensional pattern of ≥ 1000 silver-stained spots distributed over most of the gel area. Fewer spots will be seen if stains less sensitive than silver stain are used (e.g., Coomassie blue; UNIT 10.6). Few of the protein spots should touch each other.

The 2-D gel procedures described will be suitable for subsequent staining via protocols listed in UNIT 10.6 and Lilley (2002), which allow both pre- and post-staining of samples for documentation, quantitation, and analysis by tandem mass spectrometry (MS/MS; UNIT 10.22) techniques.

Time Considerations

Sample preparation takes 10 to 20 min/sample. First-dimension gels can be used as soon as 1 hr after casting or they can be kept for at least 24 hr before use. It is convenient to start the first-dimension gels in the afternoon, so they can run overnight and be ready for the second-dimension separation early the following day. Second-dimension gels can be poured up to a week before they are to be used, provided they are stored refrigerated in a humid, air-tight container to prevent drying. The second dimension run takes ~5 hr. The two-dimensional gels will be ready to put in fixative or staining solution at the end of the day and can remain in that solution overnight. Usually, 3 working days are required to complete the entire procedure, including sample preparation and gel staining. Two-dimensional minigels take 4 to 5 hr.

Gel electrophoresis has become a ubiquitous method in molecular biology for separating biomolecules. This prominence is the result of several factors, including the robustness, speed, and potential throughput of the technique. The results of this method are traditionally documented using silver-halide-based photography followed by manual interpretation. While this remains an excellent method for qualitative documentation of single-gel results, digital capture offers a number of significant advantages when documentation requires quantitation and sophisticated analysis. Digital images of gel electropherograms can be obtained rapidly using an image-capture device, and the images can be easily manipulated using image analysis software.

REASONS FOR DIGITAL DOCUMENTATION AND ANALYSIS

There are several reasons to consider digital documentation and analysis of electrophoresis results. These justifications can usually be categorized into issues of ease of handling, accuracy, reproducibility, and cost.

Ease of Handling

A major advantage of the digital revolution has been in storage and retrieval of information. Storage in notebooks and filing cabinets previously meant that searching for specific data or experiments was a tedious manual process. With digital information, modern search engines can quickly find specific information in a fraction of the time usually required for a manual search. Making backup copies of nondigital data can be difficult, expensive, and time consuming since it requires copying, retyping, or photographic reproduction. Copies of digital data can be generated more easily and at reduced costs.

Manipulation of information is also easier when it is in a digital format. While the cut-and-paste analogy comes from physical documentation, it takes on a new perspective when applied digitally. Electrophoresis images can be resized, cropped, and inserted into reports. Data can be passed to spreadsheets and statistical packages for analysis and later insertion into notebooks and reports. These reports can be distributed via the Internet to colleagues throughout the world. A single individual can do all this in a few hours.

Digital analysis also provides an easier method for handling the data when comparing large numbers of results or large numbers of separate experiments. Research that requires comparing the banding patterns on 1000 gels containing 50 lanes each can be an undertaking of heroic proportions if the analysis is performed manually. Database software can dramatically speed the analysis and handle the more mundane tasks, leaving the researcher free to interpret the data.

Accuracy

The human eye is an extremely versatile measuring instrument. It can handle light intensities covering a range of nearly nine orders of magnitude and is sensitive to a fairly wide spectrum of light (Russ, 1995). Yet the eye cannot accurately and reproducibly quantitate density and patterns, nor can it deal with large numbers of bands or spots. Accuracy of measurement is a primary reason for using digital analysis on electrophoretically separated proteins and nucleic acids. Two categories of accuracy are key to digital analysis: positional accuracy, which is important for mobility determinations such as molecular weight, and quantitative accuracy.

Positional accuracy is based on both resolution of the recording medium and measuring accuracy. Silver-halide-based recording has a theoretical resolution based on ~2000 imaging elements (silver grains) per inch. Measurement traditionally occurs using a ruler, with an accuracy of ~20 to 40 elements (50 to 100 elements per inch). In comparison, typical digital systems have 200 to 600 picture elements (pixels) per inch. The advantage that digital systems have is in measuring accuracy, which can occur at the level of a single imaging element.

Quantitative accuracy is also an issue. The amount of material represented by a band or spot is difficult to determine accurately from an image of a gel unless it is a digital image. On a digital image, the amount present is directly correlated with the derived volume of the band or spot—the volume is calculated using the intensity values of the pixels within the object.

Reproducibility

Any technique or measurement is only as good as its ability to be faithfully replicated. With software-defined routines, measurements are performed in the same manner every time. Allowing the computer to do repetitive tasks and complicated calculations minimizes the chance for individual errors. This does not imply that such measurements are correct, just that they are reproducible. An incorrect routine or algorithm can also invalidate data.

Cost

A consideration when evaluating any laboratory method is cost. Digital electrophoresis analysis equipment can be expensive. In many cases however, it offers the only method for achieving acceptable analysis performance. In other cases, equal performance can be achieved using silver-halide technology. However, traditional photography can also be expensive when the costs of consumable supplies such as film and developers and other expensive requirements such as developing tanks and dark rooms are included. Often, digital methods can be a good choice when all costs are considered.

KEY TERMS FOR IMAGING

There are several specialized terms encountered during digital image analysis. The most commonly encountered are contrast, brightness, gamma, saturation, resolution, and dynamic range. They describe controls on how the light detectors report a range of light intensities. Below is a brief description of each.

Contrast

Contrast describes the slope of the light intensity response curve. An increase in the contrast increases the slope of the curve. The result is a more detailed display over a narrowed range of intensities with less detail in the remaining portions of the intensity range. This is depicted in Figure 10.5.1A and 10.5.1B, where a normal, unadjusted image and a contrast-adjusted image are displayed, respectively. The contrast was increased on midrange intensity values in Figure 10.5.1B to highlight band intensity differences at the expense of background information. Images with a narrow range of informative intensities can benefit from increasing the contrast since it effectively increases the scale and improves detection of minor differences in intensity. Contrast settings should be lowered if information is being lost outside of the contrast range. For example, in Figure 10.5.1B, loss of background information between peaks indicates that this image should not be used for quantitation.

Figure 10.5.1 Examples of how altering image capture settings affects the image and the analysis. The graph on the left displays the light intensity response curve used for image capture while the image and resulting lane profile on the right display how the setting affects the image. The lane profile displays pixel position versus normalized pixel intensity (**A**). In this case, the output has not been altered, giving a straight line with a slope of 1 on the response curve. (**B**) The image acquisition was adjusted to increase the contrast of the displayed image. Although useful for images with a narrow range of informative intensity values, increasing the contrast can lead to a loss of low and high values. (**C**) Decreasing the brightness reduces peak values but also leads to a loss of the weak bands and original background. (**D**) Gamma adjusts raw data to appear more visually accurate. Note that this leads to a loss of fidelity between the adjusted image and the original. (**E**) Saturation indicates that the detector is reporting its maximum value or that the dynamic range for the visualization method has been exceeded.

Brightness

While brightness can have many different definitions, only one will be considered here. Brightness shifts the light intensity response curve without changing its slope as is shown in Figure 10.5.1C. Another name for brightness is black level since it is commonly used to control the number of black picture elements (pixels) in an image. Incorrect brightness levels can lead to either high background and potential image saturation or, as is illustrated in Figure 10.5.1C, to loss of background information entirely and partial loss of band information.

Gamma

Nonlinear corrections are often applied to images to compensate for how the eye perceives changes in intensity, how display devices reproduce images, or both. The most common correction is an exponential one with the exponent in the equation termed the gamma. A typical gamma value is 0.45 to 0.50 for camera-based systems and is illustrated in Figure 10.5.1D. This is a compromise value that compensates for the 2.2 to 2.5 gamma present in most video monitors and the print dynamics of most printers. Since it is a nonlinear correction, special care must be taken if quantitation is desired. Unless otherwise directed by the manufacturer, gamma values other than 1.0 should be avoided when quantitating. More information on gamma correction can be found on Poynton's Gamma FAQ (<http://www.inforamp.net/~poynton/Poynton-color.html>).

Dynamic Range

Dynamic range describes the breadth of intensity values detectable by a system and is usually expressed in logarithmic terms such as orders of magnitude, decades, or optical density (OD) units. A large dynamic range is important when trying to quantitate over a wide range of concentrations. The most accurate quantitation occurs in the linear part of the dynamic range, which is usually not the complete dynamic range of the system. An additional consideration is the dynamic range of the visualization method. Many popular visualization methods have linear dynamic ranges of 1 to 2.5 orders of magnitude. An imaging system with greater dynamic range analyzing the results of such a visualization method will not improve the dynamic range.

Saturation

Saturation occurs when a detector or visualization method receives input levels beyond the maximum end of the dynamic range. This results in a loss of detail and quantitative information from those data points that are saturated. For fluorescent and chemiluminescent samples, reduction in the sampling time can sometimes correct saturation problems. Optical density-based visualization techniques can also generate saturated images, as is illustrated in Figure 10.5.1E; this can sometimes be avoided with longer sampling times or increased detection source intensities. More often, it will be necessary to perform another electrophoresis with more dilute samples or to alter the visualization process to generate a less optically dense material.

Resolution

Resolution is the ability of a system to distinguish between two closely placed or similar objects. Three types of resolution are important for analysis—spatial resolution, intensity resolution, and technique-dependent resolution.

Spatial resolution is the ability to detect two closely placed objects in one-, two-, or three-dimensional space. It is most accurately described as the closest distance two objects can be placed and still be detected as separate objects. In practice, it is often defined

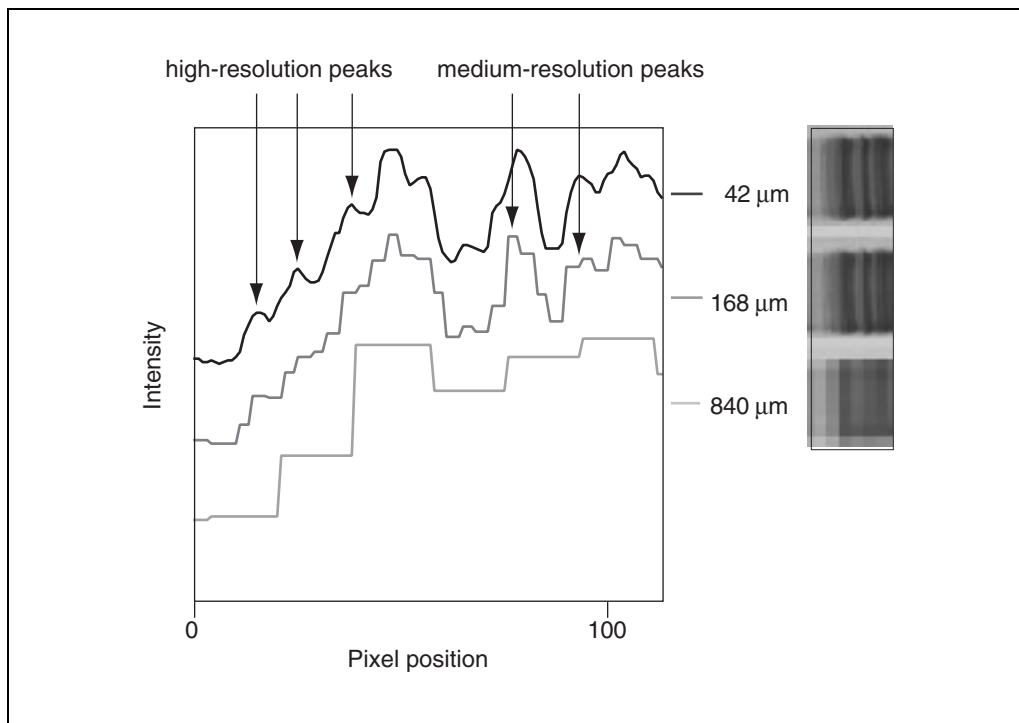

Figure 10.5.2 The effect of spatial resolution on the ability to detect closely spaced objects. Whole-cell protein lysates from *E. coli* were separated using SDS-PAGE and visualized with Coomassie blue staining. An image was captured at 42 μm (600 dpi), 168 μm (150 dpi), and 840 μm (30 dpi) from a segment of the lane, and a lane profile was generated for each image. The lane profiles have offset intensities to allow for comparison. Only major bands can be detected with the low-resolution image (840 μm); at higher resolutions more bands are detectable.

nominally in terms of the number of detectors per unit area such as dots per inch (dpi) or the number of detectors present in total or in each dimension such as 512×512 (262,144 total detectors). Actual resolution is less than half the nominal resolution due to the need for two detectors for every resolvable object (one for the object and one for the separation space) and the effects of optical resolution. Figure 10.5.2 demonstrates how spatial resolution can affect detection of objects. The 42- μm resolution image allows detection of closely spaced bands, the 168- μm resolution image detects fewer bands, and the 840- μm resolution image detects only major bands. For instruments with on-line detection systems, a pseudo spatial resolution is often reported in units of time from the start of the separation or the time interval between two objects crossing the detection path.

Intensity resolution is the ability to identify small changes in intensity. It is a function of both the dynamic range of a detector and the number of potential values that detector can report. Greater dynamic range decreases the intensity resolution of a given detector. The number of potential values a detector reports is described by its bit depth. An 8-bit detector can report 256 (2^8) different possible values, while a 12-bit detector can report 4,096 (2^{12}) values, and a 16-bit detector can report 65,536 (2^{16}) values. The higher the bit depth, the greater the intensity resolution.

Technique-dependent resolution directly affects the spatial and intensity resolution. Electrophoretic separation techniques that generate overlapping objects or that have object separation distances shorter than the spatial resolution will fail to provide reliable data. Many factors, including the amount of sample loaded, gel pore size, buffer constituents, and electrophoresis field strengths, can dramatically affect separation and resolution of biomolecules. Likewise, detection methods that can only generate a small range of discrete intensity values will not benefit from systems with improved intensity resolution.

IMAGE CAPTURE

Systems

Several components make up a digital imaging system (Fig. 10.5.3). These include: (1) a light source for illuminating the sample, either for nonfluorescent white-light imaging or for fluorescent excitation of a sample stained with a fluorescent dye; (2) a filter on the lens to act as a contrast or signal-to-noise (S/N) enhancer for nonfluorescent applications, or an emission wavelength isolation filter for fluorescent detection applications; (3) a fixed or zoom lens; (4) the CCD camera for acquiring the image; and (5) the computer and software for analysis.

Filters used for digital imaging have a number of functions depending on the application (Table 10.5.1). For nonfluorescent imaging, colored glass or wavelength-isolation filters are typically used to enhance the contrast and S/N. For example, a Coomassie blue-stained protein gel shows enhanced contrast over background illumination with use of an orange filter. This is very useful for acquiring faintly stained bands on a gel. With fluorescent applications, the lens filter acts to isolate and detect the emission wavelength from the fluorescent sample or gel. These filters are typically very accurate band-pass interference filters.

Devices

Capturing digital images involves a detection beam or source, a sensor for that beam or source, and some method of assembling a two-dimensional image from the data generated. Most systems use a light source for detection. The light wavelengths used range from ultraviolet (UV) to infrared (IR) and can be broad spectrum or narrow wavelength.

Figure 10.5.3 Typical light-tight desktop system for UV/visible colorimetric, chemiluminescent/bioluminescent, and fluorescent imaging.

Table 10.5.1 Filters for Digital Imaging Applications

Application	Desired effect	Typical filters	Source
Optical protein stains (e.g., Coomassie Blue)	Contrast enhancement	Colored glass Broad band-pass Short-pass Long-pass	Edmund Scientific, Omega Optical, Schott Glass
Fluorescent nucleic acid and protein stains, green fluorescent protein	Signal to noise (S/N) enhancement Excitation and emission wavelength isolation	Interference filters Broad and short band-pass Short-pass Long pass	Edmund Scientific, Omega Optical, Schott Glass

Broad-spectrum detection is more versatile since it can often be used for more than one detection wavelength. A typical UV light table will emit an broad excitation light that peaks at 302 nm, useful for excitation of many fluorescent stains. However, when compared to narrow-wavelength sources such as lasers, broad-spectrum detection suffers from reduced sensitivity and reduced dynamic range. While many types of light sensors have been used, including charge-coupled devices (CCDs), charge-injection devices (CIDs), and photon multiplier tubes (PMTs), technology advances in CCDs have led to their dominance. CCDs are semiconductor imaging devices that convert photons into charge. This charge is then read and converted into a digital format via an analog-to-digital converter (ADC).

The method of image assembly depends on the light source and detector geometry. One method is to capture the image all at once using a two-dimensionally arrayed CCD detector similar to the detectors found in digital and video cameras (see Advances in CCD Technology). Typically a camera-type sensor is paired with a light source that evenly illuminates the sample. This same sensor is often used with fluorescent and chemiluminescent detection methods as its ability to detect light continuously over the entire sample reduces image capture times. Another method of image assembly is to capture the image a line at a time. This typically involves a linearly arrayed CCD scanning slowly across the sample in conjunction with the detection beam of light. The data from each line are then compiled into a composite image. Spatial resolution in this method can be significantly better on large-format samples compared to the resolution of a camera-based system. This method is also advantageous when OD-based detection is used, since the more focused light beam is usually of higher intensity and can penetrate denser material. A third method of image assembly is to use a point light source and single-element detector on each point on a sample. The image is then compiled from each point sampled. This method is slower than the others but can offer extremely high resolution and sensitivity. A fourth commonly encountered method is that of generating a pseudoimage of electrophoresis results through the use of a finish line type of detection system. This is comprised of a light source positioned at the bottom of the gel (i.e., the end opposite of the site of sample loading) and light detectors positioned next to each lane to detect the transmitted light or emitted fluorescence. A lane trace is generated using time on the *x*-axis and light intensity on the *y*-axis. The pseudoimage is then generated from this data (Sutherland et al., 1987).

Capture Process

Prior to image capture, electrophoretic separation and any visualization steps are performed. To calibrate the separation process, standards are usually run at the edges of the gel and often at internal positions. If quantitation of specific proteins or nucleic acids is to be performed, a dilution series of standards with similar properties to the experimental

Table 10.5.2 Compatibility of Popular Image Capture Devices with Common Visualization Methods^a

Visualization method	Image capture device				
	Silver-halide photography	CCD camera	Desktop scanner	Storage phosphor	Fluorescent scanner
Optical density ^b	+	+	++	–	–
Fluorescence	+	+	–	–	++
Chemiluminescence	+	++	–	±	–
Radioactivity	+	–	–	++	–

^aThe device with the highest sensitivity and greatest dynamic range for a visualization method is marked with a ++, other devices that can detect this visualization method are indicated with a +, and devices that are not suitable for a visualization method are indicated with a –. A ± indicates that only some devices of this type can be used with this visualization method.

^bOptical density methods include Coomassie blue staining.

samples should also be included. After separation, the protein or nucleic acid is visualized if necessary. Visualization can include binding of a fluorochrome or chromophore (e.g., Coomassie blue), precipitation of metal ions (e.g., copper, silver, or gold), enzymatic reactions, and exposure of film or phosphor screens to radiant sources. These methods can be grouped based on the type of detection into optical density, fluorescence, chemiluminescence, and radioactivity. The suitability of popular detection devices with these methods is described in Table 10.5.2. Once visualization has occurred, image capture consists of the following steps: previewing the image while adjusting capture parameters, capturing the image, and saving the image for later analysis.

During the preview process, capture parameters are optimized for data content and for ease and rapidity of later processing steps. Typically, the first step is to place the sample so that when the image is captured, the rectangular edges of the gel are horizontal and vertical on the monitor and any lanes are either horizontal or vertical. Since band and spot detection will be much easier if the image is properly oriented, this eliminates the need to later rotate the image digitally. Image rotation is time consuming and can result in spatial linearity errors (a change in the size and shape of objects in image) resulting from rectangular image-capture device geometries. The next step for camera-based systems is to adjust magnification and to focus the sample image. For thicker samples, it might be necessary to reduce the aperture on camera-based systems to get a sufficient depth-of-field to focus the entire sample. Often at this point image imperfections—e.g., dust, liquid, or other foreign objects that will detract from later analysis—are detected, and they need to be removed. Next, image intensity is set. Within the area of interest on the image, band or spot peaks should have values less than the maximum saturated value, and the background should have nonzero values. This is usually accomplished through adjustment of the light-source intensity or the sensor signal integration. If the device allows precapture optimization of other parameters such as spatial resolution, contrast, brightness, gain, or gamma, they are adjusted next. Note that this only applies to controls that affect the response of the sensor or processing of the image prior to a data reduction step and not to controls that affect the image at later stages. The latter process can enhance visualization of specific features but is best left to adjustments in look-up tables (LUTs) in later analysis steps than during image capture since there is a risk of data loss during postacquisition image processing. LUTs are indexed palettes or tables where each index value corresponds to color or gray-scale intensity values present in an image. Many image analysis programs alter LUTs instead of image values directly since it is both faster and does not change the original image data.

Once all the capture parameters are optimized, the image capture process is initiated. This might take less than a second for images captured with camera-based detectors and up to hours for scanning single-point detectors. When the image has been captured, it should be carefully examined for content. It should fully capture the area of interest and the parameters should have been set so that all necessary information is detectable. Furthermore, it should be in a form that will allow for easy analysis. Extra time spent on optimizing the capture parameters will often result in a reduction in total image analysis time and in an increase in data quality. When the best possible image has been captured, it often contains information outside the area of interest. While this is unlikely to cause problems with later analysis, it is often advantageous to crop the image so that the only portion that is saved contains the area of interest. This reduces the amount of disk space necessary to store the image, and the image usually will load and analyze faster with the analysis software.

The last step in image capture is to save the image. Several options are available at this point, including choosing the location at which to save the image, what file type or format to use, and whether to use some form of compression.

The location where the image is saved is not as trivial a question as it might seem if the image will need to be transferred to another computer at some point. File sizes can easily exceed 15 megabytes on high-resolution images. This is a manageable size for hard drives but exceeds current floppy drive sizes by an order of magnitude. There are software utilities available that will subdivide files into disk-size chunks and then reassemble them at the next computer, but this is an inconvenient and slow method. If the computer used to help capture the image is connected to a network, the image files can easily be transferred this way or potentially saved on a central server. Alternatively, several types of high-capacity removable media are available (e.g., Zip, or Jazz). This usually requires the installation of additional hardware onto two or more computers but does make backing up data easier.

Since image files can be very large, compression techniques are sometimes used to reduce disk space requirements. Compression algorithms use several methods, typically by replacing frequent or repetitive values or patterns with smaller reference values and by replacing pixel values with the smaller difference values describing the change in adjacent pixels. When the file is later decompressed, the compressed values are then replaced with the original information. Not all images compress equally, with simple images containing mostly repetitive motifs compressible by $\geq 90\%$, while complex images will benefit much less from compression. Because compression is a much slower method of saving files and not every file will benefit from it, compression is not used to save all files. Several different forms of compression are available but are separable into two main classes, lossless and lossy. Lossless methods faithfully and completely restore the image when it is decompressed (no loss of data) but offer only moderate file compression. Compression values range from $\sim 10\%$ to 90% , depending on the image. Examples of lossless compression include Huffman coding (Huffman, 1952), RLE (Run Length Encoding), and LZW (Lempel, Ziv, and Welch; Welch, 1984). In comparison, lossy methods such as JPEG (Joint Photographic Experts Group), MPEG (Moving Picture Experts Group), or fractal compression schemes can reach compression values of $\geq 98\%$ (Russ, 1995). The trade-off is that not all information from the original file is recovered during decompression. Lossy compression is sometimes necessary for applications with extremely large image files such as real time video capture, but it usually represents an unacceptable loss of data if used with electrophoresis image capture.

Many different file types have been developed to store digital images. Some of these file types are proprietary or are hardware specific. For example, PICT is a Macintosh format

and BMP is a PC-compatible format (see descriptions of both systems, below). Each file type has its own structure. Some types do not allow compression, for others it is optional, and for some it is mandatory. They vary in the types of images they support, particularly in the number of colors or gray levels. Below is a brief description of a few of the more prevalent file types.

TIFF (Tagged-Image File Format) is one of the most commonly used formats. It is particularly versatile since it is an open format that can be modified for specific applications. One reason for its versatility is the ability to attach or tag data to the image. The tags can include information such as optical density calibration, resolution, experimenter, date of capture, and any other data that the application software supports. TIFF images can be monochrome, 4-, 8-, or 16-bit gray scale, or one of many color-image formats. Compression is optional, with LZW, RLE, and JPEG often supported (Russ, 1995). Since TIFF is supported by both Macintosh and PC computers, it is a good choice for multiple-platform environments. The versatility of TIFF can also be a weakness. Since there are many different tagging schemes and since not all programs support all possible compression and color schemes, it is sometimes not possible for one program to access the information in a TIFF file generated by a different program.

GIF (Graphics Interchange Format) is a file format that is widely encountered on the Internet due to its compactness and standardization. Its compactness is attributable to a mandatory modified LZW compression. Another feature of GIF is the use of a LUT to index the values in the image. One interesting ability of GIF is that it supports storing multiple images within a single file. This can offer some advantages for applications such as time-lapse image capture. A GIF image can contain no more than 256 individual color or gray levels and does not support intensity resolutions higher than 8 bit. In addition, since the image is implemented as a LUT, it also is not a true gray-scale image. Due to these limitations and others, alternative formats such as PNG have been developed to replace GIF.

PICT is a file format and graphics metafile language (it contains commands that can be played back to recreate an image) designed for the Apple Macintosh. It can contain both bitmap images and vector-based objects such as polygons and fonts. It supports a ≤ 256 -gray-level LUT, and monochrome images can be RLE compressed. Because it only offers a 256-gray-level LUT, it has the same weaknesses that GIF does with true gray-scale and high-intensity-resolution images. In addition, any vector objects in the image are difficult to translate on a PC since they are designed to be interpreted by Macintosh QuickDraw routines.

BMP is the native bitmap file format present on Windows-based PCs. It supports 2-, 16-, 256-, or 16-million level images. With images of ≤ 256 gray levels, it implements a LUT, while the highest-resolution image is implemented directly. RLE compression is optional for 16- and 256-gray-level images. Since compression is prohibited on 16 million-gray-level images and there is no intermediate level supported beyond 256 levels, BMP is not a good choice for images with high-intensity resolution requirements.

ADVANCES IN CCD TECHNOLOGY

Currently there is a growing emphasis on using CCDs to capture the intensity or spectral data produced in electrophoretic assays. A CCD offers great flexibility in data capture, since it provides both location and intensity information at the same time. Once the data are captured, they must be understood and interpreted. The most difficult component in this scheme is the experimental design necessary to meet the requirements of this type of detector, or the choice of the appropriate detector for a particular experimental design.

Then, it is necessary to know the influence of the detector on the data set. To make good choices in the experimental setup and proper interpretation of the data, a thorough and intimate knowledge of the detector is essential.

CCD detectors operate on a simple principle. When a photon of acceptable wavelength interacts with the CCD substrate (a silicon crystal lattice chip), the energy of the photon generates an electron and a “hole pair.” This effect produces a negative charge in that region of lattice, and the accumulation of these electrons and hole pairs is directly proportional to the number of photons that successfully interact with the silicon lattice. Short-wavelength photons interact near the surface of the lattice, and progressively longer wavelengths interact at progressively deeper depths of the lattice.

A CCD, substrate is electronically segregated into discrete regions called pixels by creating electrical currents and gates at the surface of a silicon wafer. This is the same process used in other semiconductor manufacturing processes to produce memory chips and other microelectronic devices. When appropriate voltages and timing signals are passed through the microcircuits, a CCD chip becomes divided into pixels and is able to convert incoming photons into an electron signal, create a two-dimensional map of this signal, and then transfer this signal to an amplifier. Each pixel in the CCD has an *X* and *Y* value, measured in microns plus a depth in the substrate. These values determine a volume of the pixel and how many electron hole pairs can be generated and segregated in each pixel. This capacity is referred to as the full-well capacity or saturation level of a pixel.

When the CCD chip is used to create a camera, the amplified signal is passed to a monitor or recording device for viewing or documentation. If the camera is designated as a digital camera, the analog signal is passed to an analog-to-digital converter (ADC) before being sent to a computer. A key point here is to remember that all CCDs are analog devices. Cameras may be analog or digital depending on how the camera is designed, but the CCD is always analog.

Why Use CCDs?

CCD technology is currently at the point where the conversion efficiency of photons to electron hole pairs can exceed 90%. This value is called the quantum efficiency of the CCD, and is the key factor in generating the signal in the detector (Fig. 10.5.4). On the opposite side of the signal level is how much noise is generated in the detector and the camera during the signal collection and transfer process. This relationship between the amount of signal collected and the amount of noise generated is called the signal-to-noise ratio, and is one of the key terms necessary to understand the choice of detector and choice of experimental design. In a CCD, this signal-to-noise ratio has reached the point where in most cases the limiting factor of the data accuracy is the signal itself. Few other detectors offer an equivalent signal-to-noise ratio at the data collection speeds of a CCD when a two-dimensional data array is required. CCD imagers range from relatively low cost for simple white light and fluorescent imaging to more sophisticated and costly cooled cameras for chemiluminescent and *in vivo* imaging (Table 10.5.3).

Glossary of CCD Terms

CCD Charge-coupled device, the basis of operation for each detector. A CCD is a silicon-based detector in which an electronic charge (an electron and a hole pair) is produced in the silicon lattice by a photon.

Pixel An electronically segregated area in the silicon lattice produced by microelectronic circuits on the surface of the silicon substrate, or chip.

Figure 10.5.4 Quantum efficiency of an extended range (ER-150; solid line) and standard (ICX285; broken line) CCD.

Photon The minimal unit of light, an electromagnetic energy with a particular wavelength (frequency) that interacts with the silicon lattice in a CCD to produce an electron and a hole pair.

Full-well capacity The maximum number of electron hole pairs that can be contained in a pixel. Also defined as the upper limit of detection, the point at which additional signals can no longer be detected, and the saturation level of a detector.

Noise A statistical description of the fluctuation in an otherwise stable current. Generally, noise is expressed as an RMS (root mean square) value. Noise terms are added or subtracted in quadrature; it is necessary to square each noise term, add or subtract the terms, then take the square root of the result.

Shot noise See Signal noise

Signal noise The fluctuation in the number of photons in a given amount of time from a stabilized, uniform light source. Under these conditions, the signal noise should be equal to the square root of the signal level, expressed in electrons. Signal noise is not a property of a CCD or a camera, only the signal itself.

Readout noise The fluctuation in a nominal zero level signal as it is transferred through the serial register and readout amplifier of a CCD. This noise is related to the speed of the readout (pixel clock speed) and the related circuit design. In modern cameras this is almost always the factor that limits the low-light detection capability.

Dark current The number of electrons that appear in a pixel when no light is falling on the detector. Dark current is caused by migration of electrons from areas outside the sensing area of the CCD into the sensitive area and is reduced by 50% with every 8°C reduction of the CCD temperature. Dark current is expressed as the number of electrons (e)/pixel (p)/sec (s). In modern cameras, this is generally so small that it can be disregarded at short exposure times.

Example: Specification for Dark Current = $25e/p/s = 25$ electrons per pixel per sec.

Table 10.5.3 CCD Camera Specifications

Price range	Low-end	Mid-range	High-end	Premium
Model/manufacture	C9260-001, Hamamatsu	C8484-51-03G, Hamamatsu	ORCA AG, Hamamatsu	ORCA 2ER, Hamamatsu
Pixel array/size	1344 × 1024/6.45 × 6.45 μm	1344 × 1024/6.45 × 6.45 μm	1344 × 1024/6.45 × 6.45 μm	1344 × 1024/6.45 × 6.45 μm
CCD size	2/3 in.	2/3 in.	2/3 in.	2/3 in.
Readout noise / frame rate	20 electrons/4 Hz	6 electrons/8.9 Hz	6 electrons/8.9 Hz	6 electrons at 5.6 Hz; 3 electrons at 0.8 Hz
Dark current (electrons/pixel/sec) at indicated temperature	8 electrons/pixel/sec at 20°C	0.1 electrons/pixel/ sec at -10°C	0.03 electrons/pixel/sec at 30°C	0.0045 electrons/pixel/sec at -60°C
Camera noise	21.5 electrons	6 electrons	6 electrons	6 electrons/3 electrons
Full-well capacity (1×1)/(2×2)	18,000/23,000 electrons	15,000 electrons	18,000 electrons	18,000 electrons/40,500 electrons
Dynamic range (1×1)/(2×2)	832:1/1070:1	2500:01:00	3000:01:00	3000:1/13,500;1
Bit depth/gray levels	12 bit/4096	12 bit/4096	12 bit/4096	12 bit/4096 and 14 bit/16,384
Digitizer gain (1×1)/(2×2)	4.3 electrons/5.6 electrons	3.7 electrons	4.4 electrons	4.4 electrons and 2.5 electrons
Maximum quantum efficiency (QE) at indicated wavelength	50% at 525 nm	72% at 550 to 570 nm	72% at 550 to 570 nm	72% at 550 to 570 nm
Binning	1 × 1, 2 × 2, 4 × 4	1 × 1, 2 × 2, 4 × 4, 8 × 8	1 × 1, 2 × 2, 4 × 4, 8 × 8	1 × 1, 2 × 2, 4 × 4, 8 × 8

Dark noise The amount of fluctuation in the dark current. This should equal the square root of the dark current.

Example 1: dark current (D) = 25 $e/p/s$; exposure time 1 sec:

$$\text{dark noise } (N_D) = \sqrt{25e} = 5e$$

Example 2: dark current (D) = 25 $e/p/s$; exposure time 0.5 sec:

$$\text{dark noise } (N_D) = \sqrt{\frac{25e}{0.5}} = \sqrt{12.5e} = 3.53e$$

Camera noise The sum of the readout noise and the dark noise. This term refers only to a camera, not to an image.

Example: camera with read noise = 10 e and dark noise = 5 e :

$$\text{camera noise} = C_N = \sqrt{(N_R)^2 + (N_D)^2} = \sqrt{(10e)^2 + (5e)^2} = \sqrt{100e + 25e} = 11.18e$$

Readout noise The fluctuation in a nominal zero level signal as it is transferred through the serial register and readout amplifier of a CCD. Often referred to as simply “read noise,” the noise is related to the speed of the readout (pixel clock speed) and the related circuit design. In modern cameras, this is almost always the factor that limits the low-light-detection capability.

Total noise The sum of the camera noise and the signal noise. This term only applies to an image.

$$\text{total noise} = \sqrt{(N_R)^2 + (N_D)^2 + (N_S)^2}$$

where N_R is read noise, N_D is dark noise and N_S is signal noise.

Example: 1-sec exposure, camera with $10e$ read noise, 5 e/p/s dark current, average gray value in one region of the image equals 3800, digitizer gain equals 4 electrons per count. To find the camera noise, the signal noise, and the total noise in the image:

1. read noise (N_R) = $10e$ (from camera data sheet or measured);
2. dark noise (N_D)

$$= \sqrt{D_s} = \sqrt{25e} = 5e$$

(from camera data sheet or measured);

3. camera noise (N_C)

$$= \sqrt{(R_N)^2 + (D_N)^2} = \sqrt{(10e)^2 + (5e)^2} = \sqrt{100e + 25e} = 11.18e$$

4. signal noise (N_S)

$$= \sqrt{S} = \sqrt{3800 \times 4e} = \sqrt{15,200e} = 123.2e$$

5. total noise (N_T)

$$= \sqrt{(N_R)^2 + (N_D)^2 + (N_S)^2} = \sqrt{(10e)^2 + (5e)^2 + (123e)^2} = \sqrt{15,325e} = 123.7e$$

Please note the difference the camera noise made in this image, only 0.5 electrons!

Dynamic range A calculation of the biggest difference in brightness detectable by a device. To obtain this value, divide the Full-Well Capacity (FWC) of a detector by the camera noise to get this range as a ratio.

Example: Camera with 20,000 electrons FWC and 10 electrons camera noise:

$$20,000e/10e = 2000:1 \text{ dynamic range.}$$

For dynamic range in decibels (dB), take the log of $2000 = 3.3 \times 20$ to get 66 dB.

Bit depth The number of gray levels that the digitizer will create from the maximum signal level of a device. Bits refers to the exponent of 2 used to create the number of gray levels.

Examples:

10-bit = $2^{10} = 1024$ gray levels,

12-bit = $2^{12} = 4096$ gray levels.

A 10-bit digitizer will divide the maximum signal (full-well capacity of a CCD) by 1024 gray levels to produce 1024 gray levels in the image. Bit depth is determined by the digitizer in a digital camera; not the CCD. See example under “digitizer gain,” below.

Digitizer gain/digitizer count The number of electrons in the signal used to represent each gray level in an image. This is an essential number for making quantitative calculations and comparisons of digital camera data. A close approximation may be determined by dividing the full-well capacity by the number of gray levels in the digitizer. Camera data sheets should include the exact number.

Example: Camera with FWC = 20,000 electrons; what is the digitizer gain?

10-bit = $2^{10} = 1024$ gray levels = 20,000 (electrons)/1024 (gray levels) = $19.5e$

12-bit = $2^{12} = 4096$ gray levels = 20,000 (electrons)/4096 (gray levels) = $4.9e$

14-bit = $2^{14} = 16384$ gray levels = 20,000 (electrons)/16384 (gray levels) = $1.2e$

Always compare data and results by number of electrons in the signal, not by gray level, since different cameras have different digitizer gains. In many cases, larger gray values may actually represent smaller data values when making comparisons or calculating the signal noise in an image.

Digitizer offset A value established in the analog-to-digital converter that represents the average zero value in an analog signal. Since a digitizer only has positive numbers but an analog signal will fluctuate both above and below an average value, a digitizer must have some positive values that can represent the negative portion of the analog signal to prevent clipping of the full data set. This range of positive values in the digitizer is called the digitizer offset. A digitizer with an offset of 200 means that the values from 1 to 199 are used to represent values less than zero in the analog signal. Gray level 200 represents the zero level signal and values above 200 represent signal levels above zero.

List of Typical Camera Features and Benefits

CCD camera features and their advantages and disadvantages that should be considered are listed below.

Number of pixels

A CCD camera has more spatial resolution when compared to another camera with the same size pixel, but fewer pixels. This means there is less sensitivity when compared to another camera with fewer, but larger, pixels. In addition, a camera has a potentially slower frame rate when compared to another camera with fewer pixels.

Size of pixels

Smaller pixels provide higher spatial resolution. Cameras with larger pixels provide larger full-well capacity, bigger dynamic range, and better accuracy, and collect signal faster than small pixels.

Size of detector

Larger detector dimensions mean a larger field of view, but require more expensive optics.

Cooling temperature

Temperature alone is not meaningful. The dark current at that temperature must be determined. Cooling reduces the dark current. Cooling temperature may not be relevant for fast exposures

Readout noise specification

Lower values improve low-light sensitivity, but slower readout speeds may be required to achieve lower values. Always be sure the readout noise specification is valid at the desired frame rate.

Quantum efficiency (QE) value

Higher QE is better if it is in the same wavelength range as the signal, but is a problem if it is in a range other than the signal—i.e., near-infrared! QE value must be considered along with other factors, such as camera noise.

Dark current

Lower dark current is better for dim signals and for dynamic range calculations. The cost of necessary cooling may not be worthwhile for very short exposures.

Dark noise

Dark noise is the square root of the dark current. It is important to use the dark noise to calculate camera noise, not dark current.

Major Considerations in Camera Selection

Detectability

Detectability is determined by the camera noise and QE as illustrated in the Figure 10.5.3. Once the camera noise is minimized, the largest gain in this area is obtained through greater QE.

Accuracy of a single measurement

Accuracy is determined by the noise of the signal itself in most applications. Since this noise is equal to the square root of the signal level, several points are worth noting. The signal level must always be calculated in electrons, using the digitizer gain value to multiply the gray levels in the image. The more signal that is collected, the better. Since the square root of a larger signal is a larger number, this concept is not always obvious. The importance is found in the signal-to-noise calculation (S/N). As the signal becomes bigger, the noise becomes a smaller percentage of the signal. This percentage is a good approximation of the limit of accuracy.

Examples:

$$\sqrt{100e} = 10e = 10\% \text{ accuracy}$$

$$\sqrt{500e} = 22e = 4\% \text{ accuracy}$$

The accuracy of data in different areas of an image is dependent upon the signal level in each area. The full-well capacity is the limit to accuracy for the CCD. In absorption studies (measuring dark regions in a bright background), the need for accuracy means that devices with extremely large full-well capacities are needed. The dark regions need to have high signal and the background areas must still not be saturated.

It is not uncommon for a typical CCD camera to have 20,000 electrons full-well capacity and a 12-bit digitizer. Under these conditions, each of the 4096 gray values will represent

~5 electrons of signal. With a digitizer offset of 200 gray levels, any signal from a sample will be superimposed on this 200 level.

In this example, we will assume that some region of the image has an average intensity of 500 gray levels and an adjacent region has an intensity of 600 gray levels. We want to find out how much confidence we can place in each of these measurements and how much different they are.

We first must subtract the digitizer offset from the indicated signal which leaves us with gray levels of 300 and 400 respectively.

Then we multiply each data set by 5 electrons to get the actual signal values: $1500e$ in one region and $2000e$ in the adjacent region.

Now we take the square root of each to get $39e$ and $45e$. These values represent the total noise in each region of the image. This is the amount of fluctuation we can expect in each signal. We can now make these numbers a percentage of the signal (2.6% and 2.3%) or convert them back to gray levels (8 gray levels and 9 gray levels) to establish the range of fluctuation, or accuracy, that we can expect from this data. If the expectation is accuracy of ~2%, we have enough data to make this statement. If the need for accuracy is 1%, we will have to find some way to improve our data set. We would need about 10,000 electrons in one image to get close to 1% accuracy.

Improving accuracy

Accuracy can be improved in two ways. First, one should collect more signals by increasing the QE, exposing longer, or increasing the signal intensity. These are the most common choices, but are not always possible. Second, measurements should be averaged. If it is possible to repeat the data collection process and mathematically average more than one image of the same data set, then the accuracy can be improved by the square root of the number of frames averaged. Even averaging two frames will increase the accuracy by 1.4 times.

ANALYSIS

Once the image has been captured, the data must be analyzed and distilled into information about the results of the electrophoresis experiment. Through the use of standards and experimenter input, this software-driven process can estimate mass and quantity of objects in an image and detect relationships between objects within one image and between similar images. The type of software used depends on the analysis to be performed. Images from single electrophoretic separations are examined by one-dimensional analysis software optimized for lane-based band detection. Images from two-dimensional electrophoresis are best handled by specific programs designed to detect spots and to assign two mobility values and a quantity value to the spot. After the initial characterization of bands and spots, comparisons are often made between bands or spots from different experiments through the use of database programs and matching algorithms.

Software for One-Dimensional Analysis

Table 10.5.4 lists popular sources of electrophoresis imaging software.

Lane positioning

For one-dimensional analysis, the first activity is to detect the lanes on the image. One of three different methods is commonly employed for this. For images with straight, well-defined lanes with a large number of bands, automatic lane-detection algorithms can quickly and accurately place the lanes. On images with very well-defined lanes, such as

pseudoimages from finish-line type electrophoresis equipment, automated lane calling based on image position is possible. For images with “smiling,” bent, or irregular lanes, manual positioning of the lanes is often the fastest and most accurate method of lane definition. Regardless of the method of identifying the lanes, the lane boundaries need to be carefully set for accurate quantitation and mass determinations. Lane widths should be wide enough so that the entire area of all bands in that lane are included, but they should not be so wide as to include bands from adjacent lanes. To accomplish this, curved or bent lanes might need to be used in order to follow the electrophoresis lane pattern. Lane length and position also must be adjusted as necessary so that all bands of interest are included. If mass determinations are necessary, the sample loading point should probably also be included in the lane or be the start of the lane. At this point, lines of equal mobility (often called R_f or iso-molecular-weight lines) are added to the image as necessary. These lines allow for correction of lane-to-lane deviations in the mobility of reference bands and generate more accurate measurements of mass. A similar form of correction is also possible for within-lane correction of mobilities. This correction is important for accurate detection and quantitation of closely spaced bands.

Band detection

Once the lanes have been defined, the bands present in each lane need to be detected. There are many methods for detecting bands. One method is to systematically scan the lane profile from one end to the other, identifying regions of local maxima as bands. Another common method is to use first and second order derivatives of the lane image or lane profile in order to find inflection points in the change of slope in pixel intensity values (Patton, 1995). Regardless of the method used, it is often necessary to alter the search parameters so that they perform reliably under a given experimental condition. Typical search parameters include ones for detection sensitivity, smoothing, minimum interband gaps, and minimum or maximum band peak size. Smoothing reduces the number of bands detected due to noise in the image. A minimum interband gap is often used to avoid detection of false secondary bands on the shoulders of primary bands. Limitations on peak sizes, especially for within-lane comparison to the largest band’s peak, can be a useful way to allow sensitive detection of bands in underloaded lanes without detecting false bands in overloaded lanes.

Band edges are often detected in addition to band peaks in order to further define bands or to quantitate band amounts. This can be accomplished by using local minima, derivatives of the lane profile, or fixed parameters such as image distances or a percentage of band peak height. The band edges can be applied as edges perpendicular to the long axis of the lane or as a contour of equal intensity circling the band. The perpendicular method is advantageous for bands with uneven distribution of material across the face of the band, while the latter method is better for “smiling” or misshapen bands.

Background subtraction

With nearly all electrophoresis procedures, the most informative images have a low level of signal intensity at each pixel that does not result from protein or nucleic acid. Instead, this background intensity is attributable to the gel medium, the visualization method, electronic noise, and other factors. Since this background tends to be nonuniformly distributed throughout the image, failure to subtract it can make band detection and quantitation less accurate. Many methods of background subtraction are possible. Sometimes it is possible to generate a second image under conditions that do not detect the protein or nucleic acid. The second image is then digitally subtracted from the data-containing image to remove the background. More often, background information must be obtained from a single image. If the background varies uniformly across the image, a line that crosses the variation can be defined at a point where no bands are present. The intensity values at each point on the line can be used as the background value for the pixels perpendicular to the line at that point. Commonly, background is also present as variations in intensity along the long axis within each lane. One simple method is to take the lowest point in the lane profile as the background. Another method is to use an average value of the edge of each band as the background for that band. More complicated methods such as valley-to-valley and rolling-disk use local minima points in the lane profile to define a variable background along the length of the lane. Because there can be many different causes and distributions of background, no single method of background determination can be recommended for all experiments.

Characterization

Once lanes and bands have been detected, it is possible to interpret the mobility of the nucleic acid or protein bands. Depending on the method of electrophoretic separation, information on mass (length or size), pI, or relative mobility (R_f) can be inferred from mobility information. The mobility is characterized using a standard curve with internal standards of known properties. The type of curve depends on several parameters. By definition, with R_f -based separation, a linear first-order curve is used since it represents the linear relationship between mobility and R_f . Similarly, pI and mobility are generally linear in isoelectric focusing separations. For separations based on size, a curve generated from mobility versus the log of the molecular weight provides a relatively good fit as measured by the correlation coefficient (R^2). Several other curves have been suggested for size-based separations, including modified hyperbolic curves and curves of mobility versus (molecular weight)^{2/3} that have good correlation coefficients (Plikaytis et al., 1986). In some cases, no single curve equation can adequately represent the data, and methods of fitting smooth contiguous curves using only neighboring points such as a Lagrange or spline fit (described in Hamming, 1973) are necessary. This is most common for size separations with a very large range of separation sizes and with nonlinear gradient gels. Care must be taken with multiple-curve techniques since they rely on only a few data points for any one part of the composite curve, and outlying data points can drastically affect the outcome.

For size and R_f determination, a uniform position must be found in each lane as a point from which to measure the mobility of each band. Many software analysis packages use

the end of the lane as the measuring start point, so for them it is important to position each lane start point at an iso-molecular-weight or iso- R_f point. A convenient point is the well or sample-loading position since it is usually easily detectable and at an equal mobility position in each lane. A consistent point on each band must also be chosen to measure mobility. A band's peak is easily defined in digital image analysis and is commonly used. Since peak positions are harder to detect visually than edges on silver-halide images, the leading band edge is sometimes used when comparing digital results with silver-halide-based results.
