Conjugating the antibodies to protein A–Sepharose beads prior to adding them to the cytosolic extracts minimizes the time the samples are incubated with the antibodies, minimizing exposure of the kinases to phosphatases and proteinases in the extracts. This procedure also ensures that only antibodies recognized by protein A will be used for the immunoprecipitation. If polyclonal antibodies are added to the cytosolic extracts, antibodies that are not recognized by protein A can bind to the desired antigen but will not be precipitated when protein A–Sepharose beads are added, and will reduce the efficiency of immunoprecipitation.

- 12b. Microcentrifuge protein A–Sepharose bead/cytosolic extract mixture 1 min at 14,000 $\times g$, 4°C. Discard supernatant, add 1 ml ice-cold RIPA buffer, and centrifuge as before. Repeat centrifugation twice with 1 ml ice-cold 0.5 M LiCl and twice with 1 ml ice-cold kinase buffer.

These stringent washes remove most of the protein kinases that can nonspecifically interact with the protein A–Sepharose beads.

- 13b. After the last wash, completely remove kinase buffer from the conjugated beads by removing supernatant, microcentrifuging 1 min at 14,000 $\times g$, 4°C, without adding more buffer, and gently removing residual buffer from above beads.

- 14b. Resuspend beads in 15 μl water. Prepare the laboratory bench for working with small amounts of radioactivity.

Determination of enzymatic activity is not always accurate when enzymes are bound to beads. The kinase(s) of interest can be released from the beads at step 14b or 15b by the addition of excess immunizing peptide, allowing the phosphorylation reaction (steps 15b to 17b) to be performed without the interference of the beads. The activity can then be measured as described below (steps 18b to 24b) or by paper assay. If by paper assay, terminate the phosphorylation reaction by spotting 20 μl of each cytosolic extract on a phosphocellulose paper square (Whatman P81) and washing immediately with 150 mM phosphoric acid. Measure phosphate incorporation using scintillation cocktail and counter.

- 15b. Add 10 μl RM $\times 3$ to each tube.

The most important components of RM $\times 3$ are the Mg^{2+} and $[\gamma\text{-}^{32}\text{P}]\text{ATP}$, which are essential for the phosphorylation reaction. The use of 100 μM ATP with ~ 4000 cpm/pmol $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ provides a good linear range and reproducible results. When the enzymatic activity of the kinases is low, which makes detection of phosphorylation difficult, the concentration of unlabeled ATP should be reduced to 10 to 20 μM and the amount of $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ increased to 50,000 cpm/pmol. Addition of $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ alone is not recommended because this will result in a nanomolar concentration of ATP, which is considerably below the K_M for ATP and may lead to nonspecific phosphorylation.

The β -glycerophosphate in the reaction mixture serves as a buffer, but can also inhibit residual phosphatases that may have nonspecifically bound to the beads. BSA serves as a carrier protein; it can be eliminated if purity is required. EGTA chelates Ca^{2+} , which may interfere with some kinase activities, DTT keeps the proteins reduced, and sodium orthovanadate inhibits tyrosine phosphatases.

- 16b. Add 5 μ l of 2 mg/ml MBP to each tube and place the mixture in a 30°C Thermomixer or water bath.

MBP is probably not a physiological substrate for any MAPK, but it is a good general substrate for many kinases, including ERKs, in vitro. Substrates should be well phosphorylated by the desired kinases to allow accurate detection of the phosphorylation reaction.

- 17b. Incubate 20 min at 30°C with either constant or frequent shaking.

If a Thermomixer is not available, a water bath or other heating device can be used.

- 18b. Add 10 μ l of 4 \times SDS-PAGE sample buffer to each tube to stop the phosphorylation reaction.

- 19b. Boil for 5 min. Centrifuge for 1 min at 14,000 \times g, room temperature.

- 20b. Prepare a 15% separating gel with a 3% stacking gel (UNIT 10.2A).

- 21b. Load samples and prestained protein markers on the gel.

Load prestained markers into the first or second lane of the gel so that the first lane can be located on the dried gel and the molecular weights of the detected proteins determined.

- 22b. Run the gel at 150 V, constant voltage, until the bromphenol blue dye is 0.5 cm from the bottom of the gel (~1 hr).

- 23b. Place the gel in a flat container, add 50 ml staining solution, and let stand for 20 min at room temperature. Remove staining solution and add 50 ml destaining solution for 30 min. Repeat destaining three times with 50 ml destaining solution for 30 min each time.

This extensive destaining removes excess free [γ -³²P]ATP which would affect the background radioactivity levels. Extensive destaining is not necessary if the phosphorylation of the desired proteins is very high. Alternatively, the proteins can be transferred to a nitrocellulose membrane (UNIT 10.8) and then exposed as below.

- 24b. Place the gel on Whatman 3MM filter paper, cover with plastic wrap, and dry the gel in a gel dryer for 1.5 hr at 80°C. Expose the gel in a phosphoimager or on X-ray film (UNIT 10.5 or APPENDIX 3A).

Bands should appear at 16 to 21 kDa, which is the molecular weight of the four MBP isoforms.

IN-GEL KINASE ASSAY

If the identity of the kinase is not known or there are no specific antibodies available for the kinase, an in-gel kinase assay can be used in place of immunoprecipitation. This in-gel protocol involves copolymerizing a substrate with SDS and polyacrylamide and running the protein sample on the resulting SDS-polyacrylamide gel. After several rounds of denaturation and renaturation, a phosphorylation reaction is performed on the gel and the phosphorylated bands are visualized by autoradiography or by a phosphoimager (UNIT 10.5). With this method, the molecular weight of the protein kinase is revealed and novel protein kinases can be identified. Not all protein kinases can be renatured under the conditions of this protocol, however, and the linear range of this assay is usually limited; therefore, this method should not be used routinely to monitor and characterize known protein kinases.

BASIC PROTOCOL 2

Analysis of Protein Phosphorylation

18.12.9

Materials

Cell lysates from serum-starved, EGF-stimulated Rat1 cells (Support Protocol 1, steps 1 to 8) or cytosolic extracts (see Basic Protocol 1, steps 1 to 3)
4× SDS-PAGE sample buffer (see recipe)
2 mg/ml myelin basic protein (MBP)
1.5 M Tris·Cl, pH 8.8 (APPENDIX 2)
30% acrylamide/0.8% bisacrylamide (UNIT 10.2A)
10% ammonium persulfate
Stacking gel (UNIT 10.2A)
TEMED
20% isopropanol/50 mM HEPES, pH 7.6
Renaturation buffer: 50 mM HEPES (pH 7.6)/5 mM 2-mercaptoethanol
Renaturation buffer/0.05% Tween 20
6 M urea in kinase buffer (see recipe for kinase buffer)
In-gel kinase buffer: 20 mM HEPES (pH 7.6)/20 mM MgCl₂
In-gel kinase buffer/2 mM DTT/20 μM ATP/100 μCi [γ -³²P]ATP
5% trichloroacetic acid (TCA)/1% sodium pyrophosphate (NaPPi)
Water bath, 30°C, with proper shielding for radioactive work

Additional reagents and equipment for SDS-PAGE (UNIT 10.2A) and autoradiography (APPENDIX 3A)

Procedure

1. Determine protein concentration of cell lysates (Support Protocol 1, steps 9 to 12) or cytosolic extracts (see Basic Protocol 1, steps 4 to 8). Based on the calculated protein concentrations, transfer a volume of each cell lysate containing 30 to 80 μg protein to a fresh 1.5-ml microcentrifuge tube.
2. Add ¼ vol of 4× SDS-PAGE sample buffer to each tube and mix thoroughly. Keep at 4°C.

IMPORTANT NOTE: *Do not boil the samples.*
3. Prepare 8 ml of 12% polyacrylamide gel (separating gel) containing MBP by mixing the following:
 - 0.7 ml H₂O
 - 2.0 ml MBP
 - 2.0 ml of 1.5 M Tris·Cl, pH 8.8
 - 3.2 ml 30% acrylamide/0.8% bisacrylamide
 - 100 μl of 10% ammonium persulfate
 - 6 μl TEMED.

After the separating gel polymerizes, add a 3% stacking gel (UNIT 10.2A).

4. Load samples and prestained markers onto gel and run at 100 V until the dye front has reached 0.5 cm from the bottom of the gel (~90 min).

The gel should not be heated above 30°C; therefore, the voltage used for electrophoresis should be ≤100 V.
5. Remove the gel from the apparatus, cut off the stacking gel, and carefully place the gel in a flat container. Wash twice with 100 ml of 20% isopropanol/50 mM HEPES, pH 7.6, for 30 min each at room temperature. Repeat washing twice with 100 ml renaturation buffer for 30 min each at room temperature and twice with 100 ml of 6 M urea in kinase buffer for 15 min each at room temperature.

The second wash with 20% isopropanol/50 mM HEPES, pH 7.6, can be done overnight at 4°C.

6. Place the gel in 4°C cold room, remove 50 ml of washing solution, add 50 ml renaturation buffer/0.05% Tween 20, and shake for 15 min. Repeat twice, removing 50 ml of the washing solution, adding 50 ml renaturation buffer/0.05% Tween 20, and shaking for 15 min each time. Wash the gel three times with 100 ml renaturation buffer/0.05% Tween 20 for 15 min each time. Shake the gel overnight in the cold room.
7. Remove washing buffer and incubate the gel in 30 ml in-gel kinase buffer for 30 min at 30°C. Remove the buffer, add 20 ml in-gel kinase buffer/2 mM DTT/20 μM ATP/100 μCi [γ -³²P]ATP, and incubate in 30°C water bath for 2 hr.

The amount of radioactive material is very high at this stage and the reaction should be performed with proper shielding. Make sure that the gel is straight in the flat container. Unequal distribution of the phosphorylation buffer can interfere with the phosphorylation reaction.

8. Wash the gel carefully four times with 5% TCA/1% NaPPi for 15 min each at room temperature. If the gel is still very radioactive, continue washing overnight.
9. Dry the gel (see Basic Protocol 1, step 24b) and subject to autoradiography.

Bands should appear where kinases phosphorylated the MBP copolymerized in the gel (see Fig. 18.12.2).

JNK ASSAY

Protein kinases can sometimes be isolated without using specific antibodies. For example, with JNK it is possible to exploit the tight and specific binding of the three forms of JNK (p46, p52, and p54) to their substrate, Jun (Hibi et al., 1993). Thus, glutathione-*S*-transferase (GST)–Jun bound to glutathione-conjugated beads can be used to specifically isolate the JNKs, while stringent washings remove irrelevant protein kinases. Phosphorylation using [γ -³²P]ATP and Mg²⁺ is then performed with the bead-bound kinase and is detected by autoradiography after SDS-PAGE. This affinity purification method has been successfully used in many recent studies. When GST-Jun on glutathione-conjugated beads is used as the substrate, this method gives more accurate results than the purification of JNKs by immunoprecipitation (Basic Protocol 1). The amount of immobilized Jun is the limiting factor, and the linear range of this assay is limited. Preparation of the GST-Jun beads is described below (see Support Protocol 2).

Materials

- Cytosolic extracts from serum-starved, EGF-stimulated Rat1 cells (see Basic Protocol 1, steps 1 to 3)
- 10× binding buffer (see recipe)
- GST-Jun beads: GST-Jun(1–91) bound to glutathione-conjugated beads (see Support Protocol 2)
- HB1B buffer (see recipe), ice cold
- JNK kinase buffer (see recipe), ice cold and room temperature
- 10× ATP mix: 20 mM unlabeled ATP/2 μCi [γ -³²P]ATP, freshly prepared
- 4× SDS-PAGE sample buffer (see recipe)
- 12% SDS-polyacrylamide gel (UNIT 10.2A)
- 1.5-ml microcentrifuge tubes, prechilled
- Microcentrifuge, 4°C
- Tube heater/shaker (e.g., Eppendorf Thermomixer) or water bath, 30°C
- Additional materials and equipment for SDS-PAGE (UNIT 10.2A)

BASIC PROTOCOL 3

Analysis of Protein Phosphorylation

18.12.11

Procedure

1. Determine the protein concentration of cytosolic extracts (see Basic Protocol 1, steps 4 to 8).
2. Place 150 μ l cytosolic extract or cell lysate (50 to 500 μ g protein), 30 μ l of 10 \times binding buffer, 100 μ l water, and 20 μ l GST-Jun beads in prechilled 1.5-ml microcentrifuge tubes.

The amount of GST-Jun beads can vary according to the amount of the protein conjugated to the beads. Amounts of 2 to 4 μ g protein per 20 μ l beads usually give good results. The truncated form of Jun (residues 1 to 91) is recommended for these experiments, but similar results can be obtained with the full-length or 1-to-74 constructs.

3. Incubate 1 hr at 4°C with constant shaking. Microcentrifuge 2 min at 14,000 \times g, 4°C, and discard the supernatant.

The JNKs bind to the GST-Jun on the beads during this incubation.

4. Resuspend pelleted beads in 1 ml ice-cold HB1B buffer and microcentrifuge for 2 min at 14,000 \times g, 4°C. Discard supernatants and repeat centrifugation twice with 1 ml ice-cold HB1B buffer each time and once with 1 ml ice-cold JNK kinase buffer.

Remove the supernatant completely after each centrifugation.

5. Add 30 μ l JNK kinase buffer at room temperature to the pelleted beads and place the tubes in 30°C Thermomixer or water bath. Add 3 μ l of 10 \times ATP mix. Close the tubes and incubate 20 min with shaking.

Take proper precautions when working with radioactive material.

6. Add 11 μ l of 4 \times SDS-PAGE sample buffer. Boil the samples 5 min.
7. Prepare 12% SDS-polyacrylamide gel with a 3% stacking gel (UNIT 10.2A).
8. Load samples and prestained protein markers onto the gel. Run the gel at 150 V, constant voltage, until the bromphenol blue reaches 0.5 cm from the bottom of the gel (~1 hr).
9. Stain, dry, and analyze the gel (see Basic Protocol 1, steps 23b and 24b).

A band should be detected at 46 kDa (the molecular weight of the truncated GST-Jun). In many cases, an additional band is observed at 30 kDa, which represents a degradation product of GST-Jun and is a good indication of JNK activity as well.

SUPPORT PROTOCOL 1

PREPARATION OF EGF-STIMULATED RAT1 CELL EXTRACT

This protocol describes EGF stimulation of Rat1 cells, but with minor changes can be used with almost all tissue culture cell lines, homogenized animal organs, and even whole lower organisms.

Materials

Rat1 cells
Dulbecco's modified Eagle medium containing 10% heat-inactivated fetal bovine serum (DMEM/10% FBS; APPENDIX 3F)
Starvation medium: DMEM/0.1% FBS
Epidermal growth factor (EGF) buffer: phosphate-buffered saline (PBS)/0.5 mg/ml bovine serum albumin (BSA, crystalline)
50 μ g/ml EGF in EGF buffer
PBS (APPENDIX 2), ice cold
Homogenization buffer (see recipe), ice cold
Lysis buffer: homogenization buffer/1% Triton X-100, ice cold
Kinase buffer (see recipe), ice cold

Protein standards: 5, 10, 20, 50, 100, and 200 µg/ml BSA in homogenization buffer/0.03% Triton X-100

Coomassie protein assay reagent (Pierce)

6-cm tissue culture plates

1.5-ml microcentrifuge tubes, prechilled to 4°C (four sets of six, each set labeled 1 to 6)

Stopwatch

1-ml pipet tips, prechilled to 4°C

Microcentrifuge, 4°C

96-well flat-bottomed microtiter plate

Microtiter plate reader, 595-nm wavelength

Additional reagents and equipment for tissue culture (*APPENDIX 3F*)

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique should be used accordingly.

NOTE: All tissue culture incubations should be performed in a humidified 37°C, 5% to 10% CO₂ incubator unless otherwise specified.

Prepare cellular extracts

1. Grow six 6-cm tissue culture plates of Rat1 cells in DMEM/10% FBS to subconfluency ($\sim 0.5 \times 10^6$ cells/plate).
2. Remove culture medium, add 2 ml starvation medium to each plate, and culture a further 18 hr.

Make sure that the plates remain flat and that the medium covers the entire plate. Serum starvation makes the cells quiescent, which can be achieved under these conditions within 14 to 24 hr. Starvation for too long or any change in temperature or pH may be stressful to the cells and may induce activation of one or more signaling pathways.

3. Add 2.5 µl of 50 µg/ml EGF to three plates (stimulated) and 2.5 µl EGF buffer to three plates (control). Return the plates to the incubator for 5, 15, and 45 min.

Add EGF or EGF buffer first to the plates with the longest incubation, then at appropriate intervals to the plates with the next longest incubation. It is useful to make and use a time chart to ensure that stimuli will be given at the appropriate times and the cells harvested within a short period of time (5 to 10 min).

If the influence of the stimulating agent on the particular cells being used is not yet known, a positive control should be included—for example, peroxovanadate (0.1 mM vanadate/0.2 mM hydrogen peroxide), which nonspecifically activates many signaling events in most tissue culture cells.

4. After 5, 15, or 45 min, remove medium from plates. Rinse plates twice with 5 ml ice-cold PBS and once with 5 ml ice-cold homogenization buffer.

Since slowing and arresting of biological processes is desired at this stage, the plates should be placed on ice. Washing and harvesting each plate takes 0.5 to 1.5 min; all six plates should be harvested within 5 to 10 min.

5. Add 350 µl ice-cold lysis buffer to each plate, tilt the plate gently (on ice), and scrape the cells into the buffer using a plastic scraper or rubber policeman. Using prechilled 1-ml pipet tips, transfer the cells and buffer to prelabeled, prechilled 1.5-ml microcentrifuge tubes.

The sample being harvested may become slightly viscous; the 1-ml pipet tips can be cut to make the tip opening wider, allowing easy collection of these samples.

Detergents other than Triton X-100, such as 0.5% Nonidet P-40 (NP-40; Igepal), can also be used.

6. Continue the cell lysis for an additional 10 min on ice.

A nonionic detergent is used for membrane disruption because it extracts proteins from membranal, cytosolic, and some nuclear fractions of the cell, and because the determination of protein concentration in such extracts is relatively easy (steps 9 to 12). Alternatively, a more stringent mix of detergents (RadioImmunoPrecipitation Assay [RIPA] buffer, see Reagents and Solutions), which causes complete extraction of proteins from most cell compartments, can be used for membrane disruption, although it might interfere with the protein determination. Cells can also be disrupted by sonication (two 7-sec, 50-W pulses for a 0.5-ml sample) on ice, which extracts proteins from the cytosolic and nuclear fractions, but not from membranes. The extraction by sonication is performed in homogenization buffer without detergents, and allows easy determination of protein concentration.

7. Microcentrifuge the cellular extracts 15 min at $15,000 \times g$, 4°C . Transfer supernatants to fresh, prechilled, and prelabeled microcentrifuge tubes.

The supernatants contain the protein extracts to be examined for phosphorylation.

8. Transfer 5- to 10- μl aliquots of each extract to labeled microcentrifuge tubes for determination of protein concentration, and store the remainder of the extracts on ice until needed.

The protein concentration is determined at this stage so that identical amounts of proteins from the different samples can be compared and the relative amount of phosphoproteins can be determined accurately. Comparing samples based on cell number, rather than protein concentration, can result in differences of up to 20% in the amount of protein; such large differences can cause even larger ones when phosphorylation is assessed immunologically.

Determine protein concentration

9. Add 145 μl kinase buffer to each 5- μl aliquot of cellular extract.

High concentrations of Triton X-100 can interfere with colorimetric measurements of the Coomassie brilliant blue; therefore, dilutions of $\geq 1:20$ are necessary. Similar or higher dilutions are required for sonicated and RIPA extracts as well, because of high detergent or protein concentrations. The Lowry method of protein determination cannot be used because of the dithiothreitol used to prevent degradative oxidation in the extraction buffer.

10. Transfer 10 μl of each of the protein standards into two wells of a 96-well flat-bottomed microtiter plate.

Protein standards should be prepared in the same buffer as was used for cell extraction.

11. Transfer 10 μl of each of the diluted cellular extracts into two wells of the same microtiter plate. Add 200 μl Coomassie protein assay reagent to all wells.

12. Place the microtiter plate in a microtiter plate reader and measure the absorbance of the standards and samples at 595 nm (A_{595}). Use the absorbance of the standards to construct a standard curve (absorbance versus concentration). Calculate the protein concentrations of the samples by comparing the absorbance of the sample with the standard curve.

SUPPORT PROTOCOL 2

PREPARATION OF GST-JUN-GLUTATHIONE BEADS

Materials

Bacteria transformed with GST-Jun(1–91)-expressing plasmid (plasmid is available from several investigators; alternatively, similar proteins can be obtained from, e.g., Calbiochem)

LB medium with appropriate antibiotics (UNIT 1.1)

100 mM isopropyl- β -D-thiogalactopyranoside (IPTG; store in aliquots <1 year at -20°C)

PBS/protease inhibitors (see recipe), ice cold
Washed glutathione beads (see recipe)
PBS/protease inhibitors/20% (v/v) glycerol, ice cold
End-over-end rotator

1. Grow bacteria transformed with GST-Jun-expressing plasmid at 30°C in 4 liters LB medium until optical density at 600 nm (OD_{600}) is 0.6 (~3 to 4 hr).
2. Add IPTG to 0.4 nM final and grow bacteria an additional 4 hr at 30°C.
3. Centrifuge 10 min at $6000 \times g$, 4°C.
4. Resuspend pellet in 80 ml ice-cold PBS/protease inhibitors, sonicate, and centrifuge 10 min at $15,000 \times g$, 4°C. Transfer supernatant to a fresh tube and repeat centrifugation.
5. Discard pellet, add 3 ml washed glutathione beads to supernatant, and rotate end over end 2 hr at 20 rpm, 4°C.
6. Wash beads with ice-cold PBS three times. Add 8 ml PBS/protease inhibitors/20% glycerol.

Beads can be stored 1 to 2 days at 4°C or <4 months at -20°C in ice-cold PBS/protease inhibitors/20% glycerol before being used in Basic Protocol 3.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Binding buffer, 10×

1.5 M NaCl
220 mM HEPES, pH 7.7
20 mM $MgCl_2$
0.75% (v/v) Triton X-100
200 mM β -glycerophosphate
1 mM EDTA
1 mM sodium orthovanadate
1 mM phenylmethylsulfonyl fluoride (PMSF)
10 μ g/ml aprotinin
10 μ g/ml leupeptin
2 μ g/ml pepstatin A
Store 2 months at 4°C

This buffer is derived from Hibi et al. (1993).

Glutathione beads, washed

Add 50 ml ice-cold PBS (APPENDIX 2) to 3 ml glutathione beads, centrifuge 5 min at $2000 \times g$, 4°C, and discard supernatant. Repeat centrifugation three times, adding 50 ml ice-cold PBS each time.

HB1B buffer

20 mM HEPES, pH 7.7
50 mM NaCl
0.1 mM EDTA
25 mM $MgCl_2$
0.05% (v/v) Triton X-100
Store 2 months at 4°C

Homogenization buffer

50 mM β -glycerophosphate, pH 7.3
1.5 mM EGTA
1.0 mM EDTA
0.1 mM sodium vanadate
1.0 mM benzamidine
10 μ g/ml aprotinin
10 μ g/ml leupeptin
2.0 μ g/ml pepstatin A
1.0 mM DTT (*APPENDIX 2*)
Store up to 3 months at 4°C without DTT
Add DTT just before use

This buffer is derived from the work of Ahn et al. (1990) and Seger et al. (1994).

JNK kinase buffer

20 mM HEPES, pH 7.7
20 mM MgCl_2
20 mM β -glycerophosphate
0.1 mM sodium orthovanadate
2 mM dithiothreitol (DTT; *APPENDIX 2*), added fresh
Store without DTT for 2 months at 4°C

Kinase buffer

50 mM β -glycerophosphate, pH 7.3
1.5 mM EGTA
1.0 mM EDTA
0.1 mM sodium vanadate
1.0 mM dithiothreitol (DTT; *APPENDIX 2*)
Store up to 3 months at 4°C without DTT
Add DTT just before use

This buffer is derived from the work of Ahn et al. (1990).

PBS/protease inhibitors

PBS containing:

10 μ g/ml leupeptin (from 10 mg/ml stock solution)
10 μ g/ml aprotinin (from 2 mg/ml stock solution)
2 μ g/ml pepstatin A (from 10 mg/ml stock solution)
1 mM phenylmethylsulfonyl fluoride (PMSF)
Prepare fresh

Leupeptin and aprotinin are prepared in water; pepstatin is prepared in ethanol or methanol. All stock solutions are stored <1 year at -20°C.

Protein A-Sepharose beads

Place protein A-Sepharose beads (~150 μ l) in a 1.5-ml microcentrifuge tube, add 1 ml PBS (*APPENDIX 2*), and let the beads swell for 10 min at room temperature. Add 1 ml PBS to swollen beads and microcentrifuge 1 min at 15,000 \times g, room temperature. Discard the supernatant. Repeat for a total of three washes.

Although protein A-Sepharose is recommended for this method, other commercially available protein A-conjugated resins (e.g., agarose, HiTrap) can be used. Protein G-coupled resins are required to immunoprecipitate certain types of monoclonal antibodies.

Some resins are supplied as ready-to-use solutions and will not require this swelling step.

RadioImmunoPrecipitation Assay (RIPA) buffer

20 mM Tris·Cl, pH 7.4 (*APPENDIX 2*)
137 mM NaCl
10% (v/v) glycerol
0.1% (w/v) SDS
0.5% (w/v) deoxycholate
1% (v/v) Triton X-100
2.0 mM EDTA
1.0 mM PMSF (*APPENDIX 2*; add fresh)
20 μ M leupeptin
Store up to 3 months at 4°C

Reaction mixture, 3 \times (RM \times 3)

75 mM β -glycerophosphate, pH 7.3
30 mM MgCl₂
0.9% (w/v) BSA
3 mM DTT (*APPENDIX 2*)
3 mM EGTA
0.3 mM sodium orthovanadate
100 μ M [γ -³²P]ATP (~4000 cpm/pmol)
Store without [γ -³²P]ATP for 1 year at -20°C

SDS-PAGE sample buffer, 4 \times

200 mM Tris·Cl, pH 6.8 (*APPENDIX 2*)
40% (v/v) glycerol
8% (w/v) SDS
0.2% (w/v) bromphenol blue
8% (v/v) 2-mercaptoethanol
Store up to 12 months at -20°C

COMMENTARY

Background Information

The MAPK cascades

Sequential activation of kinases (protein kinase cascades) is a common mechanism of signal transduction in many cellular processes (Campbell et al., 1995). Several related intracellular signaling cascades, collectively known as mitogen-activated protein kinase (MAPK) signaling cascades, have been elucidated so far (Davis, 1994; Seger and Krebs, 1995; Kyriakis and Avruch, 1996; Marshall, 1996; Robinson and Cobb, 1997). Each cascade seems to consist of up to five levels of protein kinases that sequentially activate each other by phosphorylation. The similarities between the enzymes that comprise each level in the various cascades make these kinases part of a superfamily of kinases.

The activation of each of these cascades is initiated either by small GTP-binding proteins or by adaptor proteins that transmit the signal to protein kinases, commonly referred to as MAPK kinase kinase (MAP4Ks). Then

the signal from each of these branches is transmitted downstream through the cascade by enzymes at the next levels that are referred to as MAP3K (MAPK kinase kinase), MAPKK (MAPK kinase), MAPK, and MAPK-activated protein kinases (MAPKAPKs). The existence of four to five levels in each MAPK cascade allows for signal amplification, determination of specificity, and tight regulation of the transmitted signal.

The four distinct MAPK cascades that are currently known are named according to the subgroup of their MAPK components: the ERK (extracellular signal-related protein kinase), JNK (c-Jun NH₂-terminal kinase), p38MAPK (SAPK 2-4), and BMK (big MAPK or ERK 5) cascades. These MAPK cascades cooperate to transmit signals to their intracellular targets, thereby initiating cellular processes such as proliferation, differentiation, development, stress response, and apoptosis. In this section, the various MAPK cascades will be briefly reviewed.

The ERK cascade, also known as the p42, p44 MAPK cascade, was the first MAPK cascade elucidated (Seger and Krebs, 1995). This cascade is initiated by the small G protein Ras, which upon stimulation causes membrane translocation and activation of the protein serine/threonine kinase Raf1. Once activated, Raf1 continues transmission of the signal by phosphorylating two regulatory serine residues located in the activation loop of MEK, causing its full activation. Other kinases that can also activate MEK are A-Raf, B-Raf, Mos, TPL2, and MEKK2 (Seger and Krebs, 1995; Salmeron et al., 1996; Wang et al., 1996), which all seem to phosphorylate the same regulatory residues of MEK. Activated MEK is a dual-specificity protein kinase that appears to be the only kinase capable of specifically phosphorylating and activating the next kinase in this cascade, which is ERK.

ERK activation requires phosphorylation of two regulatory residues, threonine and tyrosine, that reside in a TEY phosphorylation motif (Payne et al., 1991; Canagarajah et al., 1997). Phosphorylation of threonine and tyrosine residues is essential for the activation of all MAPKs. In the other cascades, however, the identity of the middle amino acid in the TXY motif of the MAPK varies and determines the specificity of the signal.

ERK appears to be an important regulatory molecule. ERK, which by itself can phosphorylate regulatory targets in the cytosol such as phospholipase A₂ (PLA₂; Lin et al., 1993), can translocate into and phosphorylate substrates in the nucleus such as ELK1 (Chen et al., 1992; Marais et al., 1993) and can transmit the signal to the MAPKAPK level. The main MAPKAPK of the ERK cascade is RSK, which can also translocate to the nucleus upon activation and phosphorylate a set of nuclear substrates different from those phosphorylated by ERK. MNK and MSK are other MAPKAPKs, but these are activated also by the p38 MAPK cascade (Fukunaga and Hunter, 1997; Waskiewicz et al., 1997; Deak et al., 1998). Activation of the ERK cascade was initially implicated in the transmission and control of mitogenic signals; this cascade is now known to be important also for differentiation, development, stress response, learning and memory, and morphology determination.

ERKs are activated primarily by mitogenic signals, whereas other MAPK cascades are activated mainly by cellular stress, such as heat shock, ischemia, UV irradiation, and cytokines

(Woodgett et al., 1996) and are referred to as stress-activated protein kinase (SAPK) cascades (Kyriakis and Avruch, 1996). The SPK (p38 MAPK) cascade consists of MAPKs that contain a glycine residue in their TXY activation motif (TGY; Han et al., 1994).

Many kinases in the MAP3K and MAP4K levels have been implicated in the SPK cascade (Fig. 18.12.1), but their individual roles are not yet known. GCK1 and HPK1 (Kiefer et al., 1996; Pombo et al., 1995), and probably also PAK1 (Zhang et al., 1995), may belong to the MAP4K level of SPK, although it is not clear whether they are involved in the activation of SAPKs. Twelve distinct kinases have already been implicated in the MAP3K level of this cascade: MEKK1 to 5, MTK1, MLK2, MLK3, ASK1, TPL2, DLK, and TAK1 (Yamaguchi et al., 1995; Blank et al., 1996; Fan et al., 1996; Salmeron et al., 1996; Wang et al., 1996; Deacon and Blank, 1997; Gerwins et al., 1997; Takekawa et al., 1997; Wang et al., 1997). At the MAPKK level, MKK3 (MEK3), MKK6 (MEK6), and, to a lesser extent, also MKK4 (MEK4) seem to play a role in the activation of p38 MAPK (Kyriakis and Avruch, 1996).

The MAPK level components of the p38MAPK cascade are also known as RK, Hog, SAPK2a, and CSBP (Han et al., 1994), SAPK2b, SAPK3, and SAPK4 (Kyriakis et al., 1994; Cuenda et al., 1997; Goedert et al., 1997). Once these p38 MAPKs are activated, they either transmit the signal to the MAPKAPK level components MAPKAPK 2 and 3 (Stokoe et al., 1992; McLaughlin et al., 1996), MNK, and MSK, or phosphorylate regulatory molecules such as PLA₂ (Kramer et al., 1996) and the transcription factors ATF2, ELK1 (Karin, 1995), CHOP (Wang and Ron, 1996), and MEF2C (Han et al., 1997).

JNKs (also called SAPK1), which comprise a third MAPK subgroup, are also SAPKs. However, these enzymes are distinct from the p38 MAPKs, mainly because they contain TPY rather than TGY residues in their activation motif. Like the other MAPK cascades, the JNK cascade is triggered by the small GTPases (Crespo et al., 1997) Rac and CDC42, and can also be activated by specific adaptor proteins. The signals are then transmitted via MAP4K and MAP3K components that are largely shared with the p38 MARK cascades. Since the SPK and JNK cascades are not always simultaneously activated, the signals must be separately regulated to allow separate cascades. These distinct activations are likely to be regulated by

various scaffold proteins, specific to each one of these cascades.

At the MAPKK level, the JNKs can be activated by two dual-specificity enzymes (JNKKs): MKK4 (SKK1, JNKK1; Yan et al., 1994) and MKK7 (Holland et al., 1997; Tournier et al., 1997; Lu et al., 1997). All three JNKKs seem to be able to activate the components at the MAPK level, JNK1 to 3, which have molecular weights 46, 54, and 52 kDa, respectively. No enzymes at the MAPKAPK level and no cytosolic targets have been identified for JNKs, but these enzymes appear to be major regulators of nuclear processes, in particular transcription. Shortly after activation, JNKs translocate into the nucleus where they physically associate with and activate their target transcription factors (e.g., c-Jun, ATF, Elk, etc.).

The BMK comprise another MAPK subgroup (Zhou et al., 1995; Abe et al., 1996) with molecular weights of ~110 kDa. BMK1 (also known as ERK5) and MEK5 are the only known components of this MAPK cascade. Like ERKs, BMK contain a TEY phosphorylation motif. They seem to be involved in stress processes, as well as in regulation of proliferation (Kato et al., 1998). The C terminus of BMK is unique, and appears to act as a transcription factor by itself. Thus, BMK may have a dual enzymatic activity, and this fact singles it out among the other MAPKs.

Kinase cascades other than the MAPK cascades are also activated in response to mitogenic stimulation. These include the NIK-IKK1/2 (DiDonato et al., 1997; Regnier et al., 1997) and PI3K-PDK-AKT-GSK3 (Cohen et al., 1997) Rho-dependent pathways (Leung et al., 1995) and the phosphokinase A (PKA)-phosphorylase kinase pathway (Campbell et al., 1995). Because of their distinct characteristics, these pathways are usually not considered to be genuine MAPK cascades, although they are involved in transmission of many extracellular signals.

All the pathways mentioned are apparently activated to some extent by distinct extracellular agents and, as a result of their action in an elaborate network, determine the outcome of each stimulation. The full dimensions of this network, the mode of regulation of its components, and the mechanisms by which these cascades determine cell fates in response to various stimuli have yet to be fully elucidated.

Analysis of cascade enzymes

The relative strength and the duration of the signals transmitted in each MAPK cascade are thought to be major determinants of signaling specificity. Accurate detection of the signals transmitted via various MAPK cascades towards target molecules is important, therefore, in the study of intracellular signaling. The activity of one component of the MAPK level of each cascade (e.g., ERK, JNK, SPK) is usually a sufficient indicator of the transmitted signal. Sometimes, however, the activity of additional components at upstream or downstream levels must be determined because of cross-talk between various cascades. For example, p38MAPK can be activated by as many as three distinct MAPKKs (MKK3, 4, or 6; Kyriakis and Avruch, 1996), and it is important to determine which of these MAPKKs is the immediate activator in different systems.

Most components of the MAPK cascades belong to the large family of protein kinases, which consists of several hundred distinct members. For studying protein kinases in general and MAPK components in particular, specific detection of the activity or phosphorylation of the desired protein kinase is essential. The activity of a particular protein kinase can be singled out from a multitude of related activities that might mask its activity in two main ways. One method uses a specific substrate that is recognized only by the desired protein kinase. This method is good for detecting kinases like MEK, which seems to specifically and selectively phosphorylate its downstream component, ERK. The other method is to isolate the protein kinase and then use general substrates as indicators of its activity. This method has been used successfully in studies of MAPK cascades. However, in most studies, anti-phospho-MAPKs are used to detect the level of MAPK phosphorylation, which is well correlated to its activity (Yung et al., 1997).

In one of the first methods used for the systematic detection of protein kinases involved in growth factor signaling, protein kinases were isolated using Mono Q fast protein liquid chromatography (FPLC; Ahn et al., 1990). This method involves stimulating tissue culture cells, fractionating the cytosolic extracts of these cells on a Mono Q column (Pharmacia Biotech), and examining the resulting fractions for protein kinase activity. Since fractionation with Mono Q columns is extremely reproducible, kinases that are activated upon stimulation can be detected by comparing

the elution profiles of kinases from activated and unactivated cells. The advantages of this method are (1) the ability to identify novel kinases and measure their activity, (2) the ability to detect the overall activity of many protein kinases, and (3) its good linear range, which allows determination of the ratio between the activities of distinct protein kinases at a given time. The main disadvantage of this method is that separation of various protein kinases is not always complete. In addition, this is a very laborious method and it is difficult to examine more than one sample per day.

Another method that the authors have found useful in detecting novel protein kinases is the in-gel kinase assay (see Basic Protocol 2; Kameshita and Fujisawa, 1989). This technique involves copolymerization of a given substrate in an SDS-polyacrylamide gel, electrophoresis of the samples of interest on the copolymerized gel, and in-gel phosphorylation in the presence of [γ - 32 P]ATP. The advantage of this method is that it reveals the molecular weight of the kinases with the desired specificity, which helps to identify the enzymes of interest. Also, several samples can be examined simultaneously. The main disadvantages are that (1) not all protein kinases can be renatured in the SDS gel, (2) each in-gel assay takes ~3 days, and (3) there is a narrow linear range of protein kinase activities, which can interfere with detection of the increase in induction of protein kinases upon stimulation.

The Mono Q fractionation and in-gel kinase assay methods are mainly used to identify or characterize novel protein kinases. The resolution of these two methods is not always adequate, however, and more specific and convenient methods are recommended for the characterization of a given protein kinase. Such specific methods often require the isolation of the protein kinase of interest, although a specific activator or substrate can sometimes be used (as is the case with PKA or MEK). In studies of MAPKs, the desired protein kinases are often isolated by immunoprecipitation with specific antibodies directed to the C-terminal domain of the kinase or by immunoblot analysis with antibodies to the activated kinase. Antibodies can also be used to detect slower migration on SDS-polyacrylamide gel electrophoresis (PAGE) that occurs upon phosphorylation of regulatory residues of some MAPKs. This gel shift does not always correlate with enzymatic activity, however, as was shown for ERK and for Raf1. Methods for affinity purification that do not involve antibod-

ies can sometime be used to isolate given protein kinases (see Basic Protocol 3). Although affinity techniques (including immunoprecipitation) are often used, it should be noted that the attachment to a solid support that occurs in this method can interfere with the accurate detection of the kinase activity.

Critical Parameters

Several points should be considered when using immunoprecipitation followed by phosphorylation. One of the most important parameters for the success of this procedure is the method of protein extraction used. Since MAPKs are localized within cells, the cellular membranes must be disrupted to access the desired targets. The protein kinases of interest must then be obtained and preserved in their active form, and the amount of irrelevant kinases reduced. For example, activated Raf-1 can be present in mitochondrial membranes, which might not be disrupted by some extraction procedures but are disrupted if RadioImmunoPrecipitation Assay (RIPA) buffer is used for extraction. The method for cellular extraction described in Basic Protocol 1 can be effectively used to detect most MAPKs by immunoprecipitation or other methods. Sonication disrupts the plasma membrane but does not solubilize it; therefore the resulting extracts should contain both cytosolic and some nuclear fractions. Depending on the subcellular localization of the proteins of interest, other extraction methods can be used. For example, cellular extracts obtained with detergents such as Triton X-100 usually contain membrane, cytosolic, and some nuclear components. Cellular extracts obtained with RIPA buffer should contain solubilized proteins from most cellular compartments. Cellular extraction by the addition of hot SDS-PAGE sample buffer to cells is not recommended, because it may free chromatin, which causes formation of a gel that is hard to handle. Extraction by freeze/thawing is also not recommended, because molecular degradation can occur during thawing.

Another consideration for successful detection of phosphoproteins is minimization of protein degradation and dephosphorylation. During extraction, most cellular organelles break, exposing phosphoproteins to phosphatases and proteinases. To minimize the effects of these enzymes, specific inhibitors of phosphatases and proteinases can be added to the extraction buffers and extraction can be performed at low temperature. Phosphatases are usually efficient enzymes, however, and extractions should be

performed as fast as possible even if these precautions are taken.

The success of the immunoprecipitation protocol also depends on the quality and specificity of the antibodies used. The antibodies employed should recognize only the desired protein kinase, not isoforms or irrelevant enzymes. The antibodies should also not interfere with the enzymatic activity of the enzymes tested. In addition, the amount of protein in the different samples and the dilution of antibodies should be optimized to avoid nonspecific recognition of excess proteins. Stringent washing of the immunoprecipitates is necessary to reduce nonspecific precipitation of contaminating kinases. Washing may not completely prevent coimmunoprecipitation of protein kinases other than those desired, however, and these might interfere with the phosphorylation reaction. In this case, it may be necessary to use a specific substrate or direct assaying methods (e.g., in-gel kinase assay).

Other parameters that should be considered for accurate comparison of protein kinases are: (1) starvation of the cells before activation may interfere with activation of the desired protein kinase or may cause activation of some SAPKs; (2) the optimal length of stimulation may vary from cell to cell and from one protein kinase to the other; therefore, appropriate time points for each kinase should be determined; and (3) for accurate comparison of the activities of protein kinases, detection should be performed in the linear range of the phosphorylation reaction. Thus, the amount of protein used for immunoprecipitation, the concentration of antibodies, the length of the phosphorylation reaction, and the exposure to X-ray film or to the phosphoimager should be optimized in order to reach linearity. If necessary, a standard curve with the protein kinases of interest can be made, and serial dilutions of the cytosolic extracts or a time course of the phosphorylation can be used to ensure one is working in a linear range.

Anticipated Results

In Basic Protocol 1, which describes immunoprecipitation followed by phosphorylation, extracts from nonstimulated Rat1 cells contain very little phosphorylated myelin basic protein (MBP; Fig. 18.12.2), which represents the activity of both ERK1 and ERK2 in these cells. Upon addition of EGF to the cells, the amount of phosphate incorporated into MBP should increase with time, peaking at 30 min after stimulation and declining thereafter. This pattern of phosphorylation represents the transient

activation of MAPK by EGF in these cells. When the in-gel assay is used (Basic Protocol 2), both ERK1 and ERK2 should be detected at positions corresponding to molecular weights of 44 and 42 kDa, respectively, and the kinetics of activation of both should be similar to that of the MBP phosphorylation obtained with the immunoprecipitation. JNK activation (Basic Protocol 3) should peak at 30 min and decline thereafter.

Time Considerations

After cell harvesting, the immunoprecipitation protocol requires extraction (0.5 hr), immunoprecipitation and washing (3 to 4 hr), the phosphorylation reaction (0.5 to 1.0 hr), SDS-PAGE (2.5 hr), and processing of the gel (6 to 16 hr). Since this procedure usually takes more than a single working day, it can be interrupted after boiling the samples in sample buffer or at any time during the destaining period. The in-gel kinase assay can take 2 to 3 days and the JNK assay usually takes 24 hr, including SDS-PAGE processing.

Isolation of Phosphopeptides by Immobilized Metal Ion Affinity Chromatography

UNIT 18.13

This unit describes mass spectrometric (MS) analysis of phosphopeptides and different approaches to enrich the phosphopeptides from complex protein samples prior to MS analysis. Basic Protocol 1 involves manual or automated prefractionation of peptides by cation-exchange chromatography followed by immobilized metal ion affinity chromatography (IMAC) using commercially available spin columns. It is suitable when larger amounts of complex material are available (at least 100 μg), and can be performed in any molecular biology laboratory because it requires no specialized chromatographic or mass spectrometric equipment. The eluted samples can be sent for MS analysis at a suitable facility. The Alternate Protocol describes the use of anion-exchange chromatography and IMAC. Basic Protocol 2 describes an online IMAC method optimized for highly selective and sensitive detection of phosphopeptides from complex mixtures using methyl esterification of peptides. Basic Protocol 3 describes a new method for analysis of tyrosine phosphorylation from complex mixtures using IMAC. Prefractionation of samples by multidimensional chromatography at either the peptide or protein level considerably increases the number of identified phosphopeptides for Basic Protocols 1 and 2.

MANUAL PEPTIDE FRACTIONATION BY CATION-EXCHANGE CHROMATOGRAPHY AND IMAC

**BASIC
PROTOCOL 1**

This protocol describes the fractionation of a complex peptide mixture by cation-exchange chromatography, followed by immobilized metal ion affinity chromatography (IMAC) of each individual fraction. No specialized large equipment (such as FPLC or HPLC) is needed, and the procedure, up to the elution of the purified phosphopeptides, can be performed in any molecular biology laboratory.

The first consideration is the preservation of the *in vivo* phosphorylation state in the cell extract. Total soluble proteins can be extracted under denaturing conditions to prevent dephosphorylation, but if subcellular fractionation is performed, native buffers with generous amounts of appropriate phosphatase inhibitors must be used (e.g., EDTA, sodium pyrophosphate, sodium fluoride, β -glycerophosphate, and calyculin A for serine/threonine phosphatases; sodium orthovanadate for tyrosine phosphatases). It is also worth considering the inhibition of protein kinases after breaking the cells to avoid nonspecific *in vitro* phosphorylation in the extract; addition of EDTA may be sufficient to block kinase activity by chelating magnesium, but more specific inhibitors like K-252a can also be used.

The use of volatile buffers in all steps from digestion to IMAC has the considerable advantage of preventing sample losses through the desalting steps (Gruhler et al., 2005). Triethylammonium bicarbonate (TEAB) is more volatile than ammonium bicarbonate and is preferred for both trypsin digestion and anion-exchange chromatography (see Alternate Protocol). The salt component in cation-exchange chromatography is ammonium formate. IMAC is very sensitive to salt, and ammonium formate is easily removed from the eluted fractions by lyophilization or by concentration in a Speedvac evaporator.

**Analysis of
Protein
Phosphorylation**

18.13.1

Peptide trap cartridges are offered by a variety of vendors and allow manual sample preparation with a syringe. Optimize Technologies offers cation-exchange cartridges (Opti-Lynx) with different capacities and a holder with fittings. A high-capacity cartridge of this type is also supplied with Applied Biosystem's iTRAQ kit. This protocol using cation exchange is compatible with iTRAQ labeling for quantitative experiments. It is an adaptation of the manufacturer's protocol for manual sample cleanup after labeling with the iTRAQ reagent (an amine-labeling reagent for multiplexed relative and absolute protein quantitation). The method described here uses the ion-exchange cartridge supplied by the manufacturer with the solvents described in Gruhler et al. (2005). This provides a simple manual setup that requires little specialized equipment, but for greater reproducibility of fractionation and greater loading capacity (milligram range), the use of an HPLC or FPLC system with an SCX column is recommended (see Beausoleil et al., 2004; Gruhler et al., 2005).

A variety of IMAC materials have become commercially available, including different combinations of metals and chelating resins and options for batch or spin-column chromatography. In side-by-side tests, these were at least as good as hand-made micro-columns packed with Fe³⁺-charged POROS-MC resin (Nühse et al., 2003). For ease of use and reproducibility, this protocol uses Phos-Select IMAC resin (Sigma).

This protocol is universally applicable to complex soluble or membrane protein samples. In the latter case, washing the membrane preparation with a high-pH buffer removes more soluble proteins and leads to more peptide identifications from integral membrane proteins.

Materials

- Protein sample (100 to 500 µg)
- 100 mM sodium carbonate (Na₂CO₃)
- 50 and 500 mM triethylammonium bicarbonate (TEAB) in ddH₂O, diluted from 1 M stock solution (Sigma)
- Sequencing-grade modified trypsin
- 2.5% (v/v) formic acid/30% (v/v) acetonitrile
- Cation-exchange cartridge (e.g., Optimize Technologies Opti-Lynx or Applied Biosystems iTRAQ), with holder and syringe adapter
- SCX start buffer (see recipe)
- SCX step elution buffers (10, 20, 30, 40, 60, and 100 mM salt; see recipe)
- SCX cleaning buffer (see recipe)
- Sodium azide, optional
- Phos-Select IMAC resin (Sigma)
- IMAC load/wash buffer (see recipe)
- IMAC elution buffer (see recipe)
- 10% (v/v) formic acid
- 11 × 34-mm polycarbonate ultracentrifuge tubes
- Ultracentrifuge (e.g., Beckman Optima tabletop ultracentrifuge with a TLA120 rotor)
- 37°C water bath
- Lyophilizer or Speedvac evaporator
- 1.5- and 2-ml microcentrifuge tubes
- End-over-end rotator
- Fritted spin columns (e.g., Mobicols, MoBiTec; Handee Mini Spin columns, Pierce)

Digest sample

For insoluble, particulate, or membrane protein samples

- 1a. Resuspend protein/membrane pellet in 100 mM Na₂CO₃ in a 11 × 34-mm polycarbonate ultracentrifuge tube and incubate 10 min on ice to remove peripheral proteins. Ultracentrifuge 30 min at 100,000 × g, 4°C.

This step is only necessary when there is a particular focus on integral membrane proteins. Peripheral membrane proteins can make up ≥50% of a microsomal pellet and are efficiently stripped off the membrane with the alkaline carbonate solution. At the same time, integral membrane proteins are partially denatured.

- 2a. Resuspend the pellet in 0.8 ml of 500 mM TEAB and centrifuge again 30 min at 100,000 × g, 4°C.
- 3a. Resuspend the pellet in 0.2 ml of 50 mM TEAB and measure the protein concentration.

Ammonium bicarbonate is the traditional buffer for digestion and can be used, but TEAB evaporates much more readily.

- 4a. Start with 100 to 500 μg protein and add sequencing-grade modified trypsin at a trypsin/protein ratio of 1:50 to 1:20 (2 to 25 μg trypsin). Digest overnight at 37°C.

For larger ion-exchange columns with a higher capacity, up to several milligrams of protein can be digested.

Sequencing-grade modified trypsin is used to avoid the low chymotrypsin-like activity that is present in unmodified trypsin.

The digested sample can be stored for several weeks at -70°C if required, but some sample loss may occur.

- 5a. Lyophilize or concentrate in a Speedvac evaporator to 10 to 20 μl. Proceed to step 6.

For soluble protein samples

- 1b. Digest proteins as described in Basic Protocol 2, steps 1c to 6c, and then desalt according to Basic Protocol 2, steps 12 to 17. Proceed to step 6.

Perform cation-exchange chromatography

6. Redissolve the dried peptide sample in 0.5 ml of 2.5% formic acid/30% acetonitrile.

The sample should ideally have zero salt and be at pH ≤2.7. Since ammonium formate does not buffer at this pH, the peptides are loaded in dilute acid rather than the start buffer.

7. Centrifuge 10 min at 15,000 × g, room temperature, to remove insoluble material.
8. Prepare the cation-exchange cartridge by washing at ~1 ml/min with the following:

2 ml SCX start buffer
2 ml SCX cleaning buffer
2 ml SCX start buffer
1 ml 2.5% formic acid/30% acetonitrile.

9. Slowly (~200 μl/min) load the cleared sample onto the cartridge. Collect flowthrough, if desired.

In the authors' experience, few phosphopeptides are recovered from the unbound fraction, but this may vary in different types of samples.

10. Wash with 2 ml wash buffer. Elute with 0.5 ml each of 10, 20, 30, 40, 60, and 100 mM SCX step elution buffers for highly complex samples, or with 25, 50, and 100 mM SCX step elution buffers for less complex samples.

11. Lyophilize fractions or concentrate in a Speedvac evaporator to ~20 μ l.

Lyophilization is easier if the fractions are first concentrated in the Speedvac to half of the original volume, because the acetonitrile lowers the freezing point of the liquid. Thawed samples will “boil over” in the vacuum of the lyophilizer.

12. Clean cartridge with 2 ml cleaning buffer and then re-equilibrate with 2 ml start buffer or with 2 ml start buffer plus 3 mM sodium azide for long-term storage.

Perform IMAC

13. Resuspend Phos-Select IMAC resin to homogeneity.

14. Pipet an aliquot of the 50% slurry (40 to 80 μ l per SCX fraction per IMAC experiment) into a 2-ml microcentrifuge tube. Centrifuge 2 min at $500 \times g$, room temperature. Remove as much of the manufacturer's glycerol-containing storage buffer as possible.

15. Add 1 ml IMAC load/wash buffer, mix by inverting a few times, centrifuge again, and remove wash buffer. Repeat at least three times.

16. Distribute equal aliquots of the slurry into tubes for each SCX fraction to be analyzed.

17. Redissolve each concentrated or dried peptide fraction from ion-exchange chromatography in 0.3 ml IMAC load/wash buffer. If insoluble material remains, clear samples by centrifuging 5 min at $15,000 \times g$, room temperature.

18. Add dissolved peptide fractions to the tubes with Phos-Select resin. Incubate by end-over-end rotation for 1 to 2 hr at room temperature.

19. Prepare a fritted spin column with a 2-ml collection tube for each sample. Flick down liquid droplets and resin from the lid of the tube, transfer the complete slurry to the spin columns, and centrifuge 30 sec at $8200 \times g$, room temperature. Collect flowthrough (nonphosphorylated peptides) if desired.

20. Add 200 μ l IMAC load/wash buffer to the beads and resuspend by pipetting the slurry up and down. Centrifuge 30 sec at $8200 \times g$, room temperature.

Unlike with prepacked spin columns, it is not sufficient to simply add the wash solution to the top of the tube. The beads should be resuspended by pipetting up and down.

21. Wash one additional time with IMAC load/wash buffer and then one time with ddH₂O.

22. Transfer spin columns to clean 1.5-ml microcentrifuge tubes.

23. Add 30 μ l IMAC elution buffer, resuspend well, and incubate 1 to 2 min at room temperature. Centrifuge 10 sec at $8200 \times g$ and collect the eluate.

24. Repeat elution with IMAC elution buffer and combine eluates.

Take care not to leave the Phos-Select resin in the alkaline buffer for longer than ~5 min total.

25. Concentrate eluates in the Speedvac to ~10 to 20 μ l and acidify with 1 to 2 μ l of 10% formic acid.

The samples are ready for mass spectrometric analysis. Rapid sample losses due to adsorption occur if the tubes are kept at room temperature or 4°C, but it is possible to store them at -70°C for a short time (up to several days).

MANUAL PEPTIDE FRACTIONATION BY ANION-EXCHANGE CHROMATOGRAPHY AND IMAC

ALTERNATE
PROTOCOL

This protocol uses a microcolumn setup with POROS HQ anion-exchange resin and a volatile buffer system at alkaline pH. If the sample digest has been performed in dilute TEAB without urea or other additives (as in the case of membrane or insoluble proteins, which can be washed in trypsin buffer after denaturing as described in Basic Protocol 1), the digest can be applied directly to the column after adding acetonitrile and pelleting the insoluble material.

Additional Materials (also see Basic Protocol 1)

POROS HQ strong anion-exchange resin
SAX start buffer (see recipe)
SAX step buffer (see recipe)
SAX step elution buffers (50, 100, 200, and 500 mM; see recipe)
GELoader tips (Eppendorf)

1. Prepare POROS HQ resin by washing ~100 μ l of settled material in 1 ml SAX start buffer.
2. Prepare a microcolumn in a GELoader tip (see Support Protocol 1). Load the slurry into the prepared column to a packed height of ~2 to 3 cm in the wider part of the tip (i.e., 3 to 10 mm below the wide neck).
3. Wash with 50 μ l each of SAX start buffer, SAX step buffer, and again SAX start buffer.
4. Prepare the sample digest in SAX start buffer: if the digest is in trypsin buffer, by adding 0.75 vol each ddH₂O and acetonitrile; if it is in buffers containing urea or salts, by reversed-phase cleanup (see Basic Protocol 2, steps 12 to 14; use 500 μ l of 20 mM TEAB/50% acetonitrile for elution).
5. Slowly load the sample onto the microcolumn with a syringe and adapter (see Support Protocol 1).
6. Wash three times with 50 μ l SAX start buffer.
7. Elute with 50 μ l SAX step elution buffers (50, 100, 200, and 500 mM salt).

The number of steps depends on the complexity of the sample; most phosphopeptides elute between 100 and 200 mM salt.

8. Lyophilize the eluates as in Basic Protocol 1, step 11.

MANUAL CHROMATOGRAPHY WITH MICROCOLUMNS

SUPPORT
PROTOCOL 1

Conventional sample preparation methods are often not appropriate for the microgram to nanogram amounts of material available for MS experiments. Gobom et al. (1999) introduced a manual microchromatographic method for reversed-phase (RP) purification and concentration of peptides for analysis by matrix-assisted laser desorption/ionization mass spectrometry (MALDI-MS). The RP material is packed into the narrow capillary tip of a gel-loading pipet tip with a constricted end. A column of 2 to 3 cm packing height has a volume of only a few microliters, and thus reduces sample loss from nonspecific adsorption. This format is very versatile, and virtually any chromatographic material with a bead size of ~20 μ m or larger can be used. To create columns with slightly higher capacity, the wider-bore part of the pipet tip can also be packed to a volume of up to ~50 μ l (e.g., for ion-exchange separation of several hundred micrograms of digest). The disadvantage of this method is that preparation of multiple samples is time-consuming and most likely not as reproducible as automated approaches.

Analysis of
Protein
Phosphorylation

18.13.5

Figure 18.13.1 Constriction of a GELoader tip for use as a microcolumn.

The only pipet tips that work satisfactorily for this technique are original Eppendorf GELoader tips; the capillaries are soft enough to be constricted so they retain the chromatography material. A 1-ml plastic Luer-type syringe is also needed, and a 200- μ l pipet tip trimmed on both ends with a razor blade is used as a tight adapter between the Luer syringe and the GELoader tip.

To constrict the GELoader tip, lay the tip flat on the benchtop and press with a semi-blunt plastic item (e.g., the back end of a pen; Fig. 18.13.1) at a point \sim 1 to 2 mm away from the end of the fine capillary. Use considerable pressure, but be careful not to sever the tip off. Pipet 10 μ l acetonitrile into the tip and hold upright. If the tip is sufficiently compressed, the drop will not move or drop out. If it does, the tip is not narrow enough to hold the POROS beads; try again with a fresh tip. Fit the syringe and adapter onto the tip and apply full pressure. Ideally, there should be resistance at first, and then the liquid should come out. It should now be possible to load the slurry into the tip.

Pipet the slurry, sample, wash, and elution buffers as far down into the tip as possible and then flick the tip down with a quick wrist motion. Fit the syringe onto the tip and press the liquid through. Depending on the backpressure from the medium, full compression of a 1-ml syringe may be necessary. For larger column volumes, take care not to run the material dry. Microcolumns packed only into the capillary end of the tip are less sensitive to drying out briefly, provided no chromatographic resolution is required.

**BASIC
PROTOCOL 2**

**ENRICHMENT OF PHOSHOPEPTIDES THROUGH METHYL ESTER
FORMATION AND IMAC**

Background binding of peptides containing a high percentage of acidic amino acids to the IMAC column can lead to significant contamination of the enriched phosphopeptide samples, and thus difficulty in applying IMAC alone to satisfactorily enrich phosphopeptides from complex cellular lysates (Brill et al., 2004). This protocol describes IMAC enrichment of phosphopeptide methyl esters for increased IMAC selectivity (Ficarro et al., 2002, 2005; Salomon et al., 2003; Brill et al., 2004; Ndassa et al., 2006). Although this procedure requires the use of an HPLC pump and practice working with capillary columns, it provides unparalleled sensitivity and efficiency due to the highly selective enrichment of phosphopeptides from complex cell-derived samples. All separations and sample transfers occur column-to-column (“online”) without exposure to plastic, including microcentrifuge tubes or 96-well plates, thereby minimizing peptide loss. Sensitivity arises from the use of capillary chromatography coupled with nanospray mass spectrometry at flow rates approaching 20 nl/min. This protocol describes preparation of the phosphopeptide methyl esters, IMAC enrichment, and MS analysis. The

**Isolation of
Phosphopeptides
by IMAC**

18.13.6

IMAC enrichment procedure is performed with the use of a pressure bomb and a total of four custom-made capillary columns. This IMAC protocol incorporates newly developed improvements in IMAC buffer solutions, is optimized for reduced competition on the IMAC column between singly- and multiply-phosphorylated peptides, and improves overall yield of phosphopeptides (Ndassa et al., 2006).

Protocols for elution of phosphopeptides from the precolumn over the analytical column and into the mass spectrometer will vary depending on the configuration and type of chromatography and mass spectrometry equipment available. The method described here works well for the LTQ, LTQ-FTICR, or LTQ-Orbitrap and Agilent 1100 quaternary pump.

Materials

Protein sample (1×10^8 cells or ~ 100 fmol purified protein)
Cell lysis buffer A (see recipe), optional
Immunoprecipitation resin: anti-phosphotyrosine agarose (e.g., clone PT66, Sigma), optional
Immunoprecipitation wash buffer (see recipe), optional
Trypsin digestion buffer with urea (see recipe)
Milli-Q water
Sequencing-grade modified trypsin (Promega)
Dialysis buffer (see recipe), optional
Trizol LS (Invitrogen), optional
DC protein assay kit (Bio-Rad) containing:
 Alkaline copper tartrate solution
 Folin reagent
 Surfactant solution
 Bovine gamma-globulin standard
Angiotensin II phosphate (EMD Biosciences) or other synthetic phosphopeptide
1 M HCl
Reversed-phase loading buffer: 0.1% acetic acid in Milli-Q water
Reversed-phase elution buffer (see recipe)
Macrotrap wash buffer 1: 20:80 (v/v) dimethylsulfoxide (DMSO)/methanol
Macrotrap wash buffer 2: 45:45:10 (v/v/v) isopropanol/water/formic acid
Methylation solution (see recipe)
Nitrogen source
Fe(III)-activated IMAC column (see Support Protocol 2)
IMAC preparation buffer 1: 50 mM EDTA, pH 8
IMAC preparation buffer 2: 100 mM FeCl₃ (99.99+%, Sigma)
Desalting column (see Support Protocol 2)
HPLC buffer A (IMAC): 0.01% acetic acid in Milli-Q ddH₂O
HPLC buffer B (IMAC): 0.01% acetic acid in acetonitrile (99.8%; HPLC grade)
IMAC wash buffer (see recipe)
Precolumn (see Support Protocol 2)
IMAC elution buffer: 25 mM Na₂HPO₄, pH 9.0
Analytical column (see Support Protocol 2)
HPLC buffer C (reversed-phase): 0.1 M acetic acid in Milli-Q ddH₂O
HPLC buffer D (reversed-phase): 0.1 M acetic acid in acetonitrile (99.8%; HPLC grade)

1-ml syringes and 27-G needles
50-ml conical tubes
1.5-ml microcentrifuge tubes
95°C heating block
0.45- μ m, 4-mm syringe filters (e.g., Millipore Millex), optional

200- and 1000- μ l pipets (Rainin)
10,000 MWCO Slide-A-Lyzer (Pierce), optional
Reversed-phase C18 peptide macrotrap (Michrom Bioresources)
1.5-ml screw-top microcentrifuge tubes (Sarstedt)
Speedvac evaporator (Thermo Savant)
Inline microfilters (Upchurch Scientific)
HPLC pump (e.g., Agilent 1100 Quaternary Pump)
Fused silica capillaries (360- μ m o.d. \times 50-, 75-, and 200- μ m i.d.; Polymicro Technologies)
Microtee (Upchurch Scientific)
Laser Puller P2000 (Sutter Instruments), optional
Mass spectrometer (e.g., LTQ-FTICR and LTQ available from Thermo)
Valco trap holder (Michrom Bioresources)
Multiple-syringe infusion pump
500- μ l Hamilton syringe
Platinum wire (Sigma)

NOTE: All sample preparation procedures involving intact proteins are carried out at 4°C unless otherwise specified.

Prepare sample

For mammalian cell phosphorylation analysis

- 1a. Lyse cells in 25 ml cell lysis buffer A per 1×10^9 cells.
- 2a. Centrifuge 20 min at $12,000 \times g$, 4°C, and collect supernatant (total cellular lysate).
- 3a. Store samples, if necessary, at -80°C . Proceed to step 11.

For an individual protein or a subset of total cellular phosphorylated proteins

- 1b. Immunoprecipitate phosphorylated proteins from the total cellular lysate using CNBr-agarose-conjugated antibodies. Add 200 μ l of immunoprecipitation resin per 1×10^9 cell equivalents in 25 ml (in a 50-ml tube) and incubate 4 hr with tumbling.

CNBr linkage is preferable for coupling antibodies to agarose beads compared to noncovalent linkages such as protein A/G due to its resistance to the urea used in the elution of proteins in this protocol, and the high density of antibody on the resin resulting in reduced amounts of resin. For isolation of the tyrosine phosphoproteome, anti-phosphotyrosine agarose clone PT66 (Sigma) works well. Clone 4G10 works very poorly for immunoprecipitation of native proteins. Tyrosine phosphorylation represents only a small fraction (~0.1%) of cellular phosphorylation, necessitating an additional affinity enrichment step before IMAC to enrich the population of tyrosine phosphorylated proteins relative to serine and threonine phosphorylated proteins. For serine and threonine phosphorylation, no pre-enrichment step is necessary before IMAC.

- 2b. Wash beads once with 50 ml cell lysis buffer A and once with 50 ml immunoprecipitation wash buffer in a 50-ml conical tube. Centrifuge 5 min at $1700 \times g$, 4°C, and then aspirate the supernatant.

It is critical to be thorough in the removal of the wash buffer, because detergent (Triton X-100) will significantly contaminate the IMAC and reversed-phase columns, resulting in high background detergent peaks in the MS spectra and dramatic reduction of the number of phosphorylation sites identified.

- 3b. Add 1 ml of immunoprecipitation wash buffer to beads and transfer beads into a 1.5-ml microcentrifuge tube using a 1000- μ l pipet tip with 3 mm of the tip cut off.
- 4b. Insert a 27-G needle attached to a 1-ml syringe along the side of the tube and withdraw residual wash buffer to thoroughly dry beads.

- 5b. Elute immunoprecipitated proteins by incubating with 200 μ l trypsin digestion buffer with urea in a 1.5-ml microcentrifuge tube for 5 min at 95°C.
- 6b. Repeat elution with another 200 μ l trypsin digestion buffer with urea for 5 min at room temperature, without additional heating. Insert needle along the side and to the bottom of the tube to withdraw all of the supernatant, being careful not to contaminate with resin.
- 7b. (Optional) Filter the eluted proteins with 0.45- μ m, 4-mm syringe filters into 1.5-ml microcentrifuge tubes to remove any residual resin.
- 8b. Measure volume of eluant with a 200- μ l pipet and dilute precisely 1:1 with Milli-Q water for a final urea concentration of 4 M.
- 9b. Add 10 μ g sequencing-grade modified trypsin per 1×10^9 immunoprecipitated cell equivalents in a 1.5-ml microcentrifuge tube and incubate overnight at 37°C.
Do not reduce and alkylate proteins prior to trypsin digestion and IMAC enrichment because this frequently reduces the number of phosphorylation sites discovered.
- 10b. Store trypsin-digested samples, if necessary, at -80°C. Proceed to step 11.

For total cellular phosphorylation

- 1c. Dialyze total cellular lysate 1:1000 (v/v) in dialysis buffer in a 10,000 MWCO Slide-A-Lyzer three times, 3 hr each time, at 4°C.
- 2c. Extract proteins by Trizol LS according to manufacturer's instructions.
- 3c. Solubilize the Trizol pellet in trypsin digestion buffer with urea for 5 min at 95°C.
- 4c. Dilute 1:1 with Milli-Q water for a final urea concentration of 4 M.
- 5c. Measure the protein concentration using the Bio-Rad DC protein assay kit according to the manufacturer's instructions.
- 6c. Add sequencing-grade modified trypsin to the protein at a ratio of 1:20 (w/w) trypsin/total protein and incubate overnight at 37°C.
Do not reduce and alkylate proteins prior to trypsin digestion and IMAC enrichment because this frequently reduces the number of phosphorylation sites discovered.
- 7c. Store trypsin-digested samples, if necessary, at -80°C. Proceed to step 11.

Prepare peptide methyl esters

11. Add 10 pmol of angiotensin II phosphate or another synthetic phosphopeptide per 1×10^9 cell equivalents to digested peptides as a control for methylation.
Many synthetic tyrosine phosphorylated peptides are available from Anaspec.
12. Acidify peptide solution to pH 3 with 1 M HCl. Load sample on a reversed-phase C18 peptide macrotrap (placed in a Valco trap holder) that has been pre-equilibrated by washing with 500 μ l of reversed-phase loading buffer (delivered by a 500- μ l Hamilton syringe attached to a multiple syringe infusion pump).
13. Wash macrotrap with 1 ml of reversed-phase loading buffer.
This step removes urea and salts from samples.
14. Elute peptides with 500 μ l of reversed-phase elution buffer into 1.5-ml screw-top microcentrifuge tubes.
Loss of peptides due to nonspecific absorption to tubes and plates is a major concern. In the authors' experience, Sarstedt tubes provide the lowest nonspecific peptide binding and should be used for macrotrap elution and methylation.

15. Regenerate macrotrap columns by washing with 500 μl of macrotrap wash buffer 1 followed by 500 μl of macrotrap wash buffer 2.

Carryover of peptides on C18 columns is a persistent concern that must be monitored carefully. This regeneration procedure is designed to minimize this carryover and prevent contamination of subsequent samples.

16. Reequilibrate macrotrap with 500 μl of reversed-phase loading buffer and repeat steps 12 through 16 until all samples are processed.

17. Completely dry peptides in a Speedvac evaporator without heat for 2 hr with rotation.

It is imperative that all water be removed at this point to optimize the yield of the methylation procedure.

18. Mix 400 μl of methylation solution with each dried peptide sample and layer nitrogen on top of the reaction prior to closing cap.

19. Mix on vortex mixer for 5 sec and allow reaction to proceed for 2 hr.

20. Dry methylated peptides for 2 hr in a Speedvac evaporator without heat and with rotation. Make sure methylation solution is fully removed after 2 hr.

21. Store dried, methylated peptides, if desired, at -80°C .

Enrich peptide methyl esters by IMAC

22. Prepare an Fe(III)-activated IMAC column by washing with IMAC preparation buffer 1, then IMAC preparation buffer 2, and finally reversed-phase loading buffer for 5 min each at a rate of 20 $\mu\text{l}/\text{min}$.

23. Connect an inline microfilter as a frit to the outlet of a desalting column and equilibrate it with reversed-phase loading buffer.

For elution of peptides from the desalting column to the IMAC column, an inline microfilter is used as a union to attach the columns in series.

24. Reconstitute the dried, methylated peptides with reversed-phase loading buffer and immediately load on the desalting column.

Typical reconstitution volumes are from 10 to 100 μl , but the actual volume is not critical. Peptides should only be reconstituted immediately before IMAC enrichment.

25. Wash column for 10 min at 7 $\mu\text{l}/\text{min}$ with reversed-phase loading buffer.

Column flow rates are not absolutely critical, but may be controlled by adjusting the air pressure to the pressure bomb and measuring the flow rate using a 5- μl measured capillary and a stopwatch (500 psi is a good starting point).

26. Connect the inlet of the IMAC column to the outlet of the desalting column using the inline microfilter already attached.

27. Attach the inlet of the desalting/IMAC column pair to the outlet of the HPLC pump. Elute to the activated IMAC column by washing 20 min at 1.8 $\mu\text{l}/\text{min}$ with reversed-phase elution buffer or using a 17-min HPLC gradient of 0% to 70% HPLC buffer B at 1.8 $\mu\text{l}/\text{min}$.

A step-elution method would not require use of an HPLC pump, but reveals approximately half the number of phosphopeptide species from a complex cell lysate.

28. Remove IMAC column from desalting column. Wash IMAC column with IMAC wash buffer for 5 min followed by reversed-phase loading buffer for 2.5 min, both at 20 $\mu\text{l}/\text{min}$.

29. Connect precolumn to IMAC column through the inline microfilter.

30. Elute with 12 μl IMAC elution buffer at 2 $\mu\text{l}/\text{min}$.
31. Wash precolumn with 10 μl HPLC buffer A at 5 $\mu\text{l}/\text{min}$.

Analyze by MS

32. Connect the washed precolumn to the analytical column through an inline microtee with one side coupled to a platinum wire for the application of electrospray voltage.
33. Use the “vented column” approach to control flow rate through the precolumn and analytical column. Connect an empty 50- μm capillary (called a restrictor) to a microtee junction between the incoming HPLC capillary and the precolumn. Configure the flow rate through the precolumn and analytical column by adjusting the length of the restrictor such that 0.25 ml/min HPLC pump output produces \sim 200 nl/min flow rate at the electrospray tip.

This configuration allows rapid delivery of the gradient to the precolumn and is preferable to nanoHPLC, which is more expensive and results in long delays for gradient changes to be conveyed to the precolumn and analytical column.

34. Elute peptides into the analytical column with a 30-min gradient from 0% to 70% HPLC buffer D.

Optionally, the flow rate may be reduced during the peptide elution part of the gradient by adjusting the flow rate at the HPLC pump down to 0.05 ml/min. This reduction in flow rate, called peak parking, is useful in increasing the sensitivity for detection of peptide ions and spreading out the peptides so that the time to acquire MS and MS/MS data for individual peptides is increased.

35. Acquire spectra with data-dependent scanning (one MS scan followed by five MS/MS scans of the most abundant ions). Set collision energy at 35% with a 3-Da window, and set dynamic exclusion at a repeat count of one and an exclusion time of 1.5 min.

Dynamic exclusion prevents the redundant acquisition of MS/MS spectra.

36. Assign MS/MS spectra with the Sequest or Mascot search algorithms. Search for a variable addition of 79.9663 Da on Ser, Thr, and Tyr (indicating phosphorylation), and a static modification of 17.0342 Da on Asp, Glu, and the peptide C terminus (indicating D3-methylation).

CONSTRUCTION OF COLUMNS FOR IMAC AND REVERSED-PHASE SEPARATION OF METHYL ESTER-DERIVITIZED PEPTIDES

The enrichment of phosphopeptide methyl esters by IMAC requires the use of a total of four columns. A large-capacity desalting column is used after peptide methylation to remove residual acid from the methylation reaction for better IMAC retention. An IMAC column loaded with Fe^{3+} enriches phosphopeptides. These phosphopeptides are then eluted to a precolumn with phosphate, and the phosphate is removed by washing. Peptides are then eluted by a reversed-phase gradient from the precolumn, through the analytical column, and into the mass spectrometer. These columns should be prepared and utilized in close collaboration with a mass spectrometry facility. Generally, this technique is compatible with any electrospray mass spectrometer capable of nanospray. In the authors' experience, the LTQ-FTICR and LTQ from Thermo are excellent instruments for phosphorylation analysis due to their impressive scan rate and sensitivity. Other instruments such as quadrupole time-of-flight (QTOF) mass spectrometers would likely provide enough sensitivity and mass accuracy, but require longer gradients for complex samples due to their slow scan rate.

Flow rates or volumes are measured with a 5- μl measured capillary and a stopwatch. Collect column flowthrough in a capillary over a 1-min period and then use a ruler to

SUPPORT PROTOCOL 2

Analysis of Protein Phosphorylation

18.13.11

measure the number of microliters collected in the measured capillary over this time period.

Use of the pressure bomb: Pressure bombs are used both to pack slurries of chromatographic resin as well as to load samples into 50- to 250- μm -i.d. capillaries. It is not feasible to provide the necessary pressure of >500 psi to prepare a column using a syringe. Although HPLC pumps can provide these sorts of pressures, it is not convenient to pass an emulsion of resin through the flow path of the HPLC. The pressure bomb (GNF commercial systems; Fig. 18.13.2) works by application of 500 to 1000 psi of nitrogen pressure to the 1/8-in. stainless steel tubing in the side of the bomb. A Swagelok three-position 1/8-in. ball valve is attached to the tubing to allow for the controlled release of pressure from the bomb. The sample is placed inside the bomb and a small glass capillary containing a porous frit is inserted into the sample solution through a 1/16-in. to 0.5-mm Teflon one-hole ferrule (Chromatography Research) in the top. The sample can be a mixture of reversed-phase or IMAC resin in 95% acetonitrile/5% isopropanol, column wash solution, or analytical sample. The pressure bomb is placed on a standard laboratory magnetic stirrer and all emulsions of resins are stirred in the bomb in small glass vials. Various materials may be used for the resin-retaining frit, including LiChrosorb Si60 (5 μm ; EMD Biosciences) or Kasil (PQ Corporation). Most conveniently, an inline microfilter from Upchurch can simply be screwed onto the end of the capillary. Once the bomb is closed with the two top screws, application of high pressure (typically through a Swagelok three-way valve) from a nitrogen gas tank causes the sample to be passed onto

Figure 18.13.2 A pressure bomb used for packing resins and loading samples.

the column. The flow rate or volume through the column is gauged with a Drummond 5- μ l calibrated pipet and can be adjusted by altering the gas pressure at the regulator.

Construction of desalting and IMAC columns: The fused silica columns may be cut to the desired length with a fused silica cutter (Alltech), being sure that all cuts are straight (check under microscope). All columns are packed on a pressure bomb as described above and fritted with inline microfilters. The desalting column is packed with 12 cm of POROS 10R2 (a C18 resin available from Applied Biosystems) in 360- μ m o.d. \times 200- μ m i.d. fused-silica tubing, and the IMAC column is packed with 15 cm of POROS 20MC (Applied Biosystems) in a 360- μ m o.d. \times 200- μ m i.d. fused silica capillary. After packing, both columns are washed once for 5 min under 500 psi of bomb-applied pressure with acetonitrile and then with reversed-phase loading buffer.

Construction of precolumn: The precolumn is prepared by first preparing a LiChrosorb Si60 frit in a 360- μ m o.d. \times 75- μ m i.d. fused silica capillary. To prepare this type of frit, dip the capillary into the powdered LiChrosorb powder ten times and then flame the tip with a nitrous oxide flame three times for 1 sec each pass. A nitrous oxide flame may be created with a microflame gas torch set (VWR) by first starting a butane flame, minimizing its intensity, and then increasing the nitrous oxide until a uniform blue flame is produced. Adjust the capillary flame timing such that the LiChrosorb material is in the flame long enough to cause a brilliant white glow. Pack the precolumn with 2 cm of 5- μ m Monitor C18 (100- Å , Column Engineering) on the pressure bomb and wash with acetonitrile and then reversed-phase loading buffer.

Construction of an analytical column with integrated electrospray emitter tip: There are two possible configurations of the analytical column. For optimal sensitivity, analytical columns may be prepared with integrated electrospray emitter tips (Fig. 18.13.3) on a P2000 laser puller (Sutter Instruments). Useful recommendations for the tuning of the laser puller are provided in the manufacturer's manual. Remove 3 cm of the polyimide coating from a 360- μ m o.d. \times 75- μ m i.d. fused silica capillary by flaming with butane and removing debris with isopropanol. On the exposed section of the capillary, pull a 5- μ m-i.d. tip, being careful to avoid the polyimide. Obtaining a 5- μ m tip requires adjustment of the heat, velocity, delay, and pull settings on the puller. Good starting values are heat = 290, filament = 0, velocity = 15, delay = 127, and pull = 10. To maintain reproducible pulling, clean the puller mirror regularly with spectroscopy-grade isopropanol or acetone. Determine the diameter of the tip by bomb loading 3- μ m silica (Bangs Labs) into the column after pulling the tip. Two 3- μ m beads should have lodged into the tip. If the tip is occluded by one bead, it is too narrow; try decreasing the heat setting. After fritting the analytical column with 3- μ m silica, pack 12 cm of 5- μ m Monitor C18 (100- Å , Column Engineering) into the column.

Figure 18.13.3 A 5- μ m emitter tip (under a microscope at 200 \times magnification).

Construction of analytical column attached to a picotip: If a laser puller is not available, picotips (8- μ m; New Objective) may be purchased. This configuration is less sensitive but may be adequate for some analyses. Pack a 360- μ m-o.d. \times 75- μ m-i.d. fused silica capillary, fritted with an inline microfilter, with 12 cm of 5- μ m Monitor C18 (100- \AA , Column Engineering). The analytical column is then attached to the picotip through the inline microfilter.

**BASIC
PROTOCOL 3**

**ENRICHMENT OF TYROSINE-PHOSPHORYLATED PEPTIDES
VIA PEPTIDE IMMUNOPRECIPITATION AND IMAC**

Unlike phosphotyrosine immunoprecipitation (IP) at the protein level (see Basic Protocol 2, steps 1b to 10b), peptide IP employs phosphotyrosine-specific antibodies to isolate tyrosine-phosphorylated peptides directly from a total cell lysate of digested cellular proteins (Rush et al., 2005). The advantage of protein IP is that it permits the more extensive analysis of all serine, threonine, and tyrosine phosphorylation sites on tyrosine-phosphorylated proteins as well as all phosphorylation sites on proteins that interact in a complex with tyrosine-phosphorylated proteins. The advantage of phosphotyrosine peptide IP is that it is more sensitive for detection of tyrosine phosphorylation due to the increased efficiency of capture of the phosphorylated peptides by the PTyr100 antibody relative to the PT66 antibody. Another advantage of the peptide IP procedure is that it provides higher-quality quantitative analysis, because peptide chemical isotopic labeling such as with the popular iTRAQ reagent does not interfere significantly with the IP step. With protein IP, peptides must be labeled after the IP step.

In the peptide IP procedure, cells are lysed and digested, then the digests are desalted and immunoprecipitated by antibody-conjugated protein G beads (Rush et al., 2005). Peptides are eluted from beads by IP elution buffer (Zhang et al., 2005). A second enrichment of phosphopeptides is accomplished by IMAC as described in Basic Protocol 2, but without methylation. IMAC is necessary after peptide IP due to unacceptably high carryover levels of unphosphorylated peptides through the IP. The strategy of enhancing the selectivity of IMAC using peptide methyl esters is unnecessary in this procedure due to the selective enrichment afforded by the phosphotyrosine peptide IP. Although, in theory, methyl ester formation would diminish the low levels of nonspecific unphosphorylated peptides that appear after peptide IP and IMAC, the decrease in overall peptide yield through the methyl ester reaction results in overall net decrease in phosphopeptides identified with this method.

Materials

- Anti-phosphotyrosine antibody (clone PTyr100, Cell Signalling Technology)
- Antibody coupling buffer: 20 mM sodium phosphate, pH 7.0
- Protein G-agarose beads (Roche)
- Protein sample (3×10^7 cells or ~ 100 fmol purified protein)
- Cell lysis buffer B (see recipe)
- Dithiothreitol (DTT)
- Iodoacetamide
- 100 mM ammonia bicarbonate, pH 8.9
- DC protein assay kit (Bio-Rad) containing:
 - Alkaline copper tartrate solution
 - Folin reagent
 - Surfactant solution
 - Bovine gamma-globulin standard
- Affinity purified, TPCK-treated trypsin (Promega)
- Concentrated HCl
- Sep-Pak C18 plus column (Waters)

100% acetonitrile
Sep-Pak loading buffer: 0.1% acetic acid in Milli-Q water
Sep-Pak elution buffer: 25% acetonitrile/0.1% acetic acid in Milli-Q water
Peptide immunoprecipitation (IP) buffer (see recipe), 4°C
Synthetic phosphopeptide external standard
pTyr-100 immobilized antibody
Peptide IP wash buffer 1 (see recipe)
Peptide IP wash buffer 2 (see recipe)
Peptide IP elution buffer: 100 mM glycine, pH 2.5
Tyrosine-phosphorylated standard peptides (e.g., angiotensin II phosphate, EMD Biosciences; or various pTyr peptides, Anaspec)

End-over-end rotator, 4°C
56°C water bath
15-ml conical tubes
1.5-ml screw-top microcentrifuge tubes (Sarstedt)
18- and 27-G needles
Speedvac evaporator (Thermo Savant)

Additional reagents and equipment for IMAC enrichment and MS analysis
(see Basic Protocol 2)

NOTE: All sample preparation procedures involving intact proteins are carried out at 4°C unless otherwise specified.

Prepare antibody

1. Prepare the pTyr-100 immobilized antibody by mixing soluble pTyr-100 in antibody coupling buffer with protein G–agarose beads at a concentration of 2.25 mg antibody/ml resin. Incubate overnight at 4°C with end-over-end rotation.

The pre-immobilized pTyr-100 currently sold from Cell Signaling Technologies is much less efficient than immobilized antibody prepared with protein G–agarose for peptide immunoprecipitation.

Prepare sample for immunoprecipitation

2. On the same day, lyse cells in 2 ml cold cell lysis buffer B per 3×10^7 cells and incubate 20 min on ice.
3. Centrifuge lysate 15 min at $14,000 \times g$, 4°C, and retain the supernatant.
4. Add DTT to a concentration of 10 mM to reduce proteins, and incubate 1 hr in a 56°C water bath.
5. Add iodoacetamide to a concentration of 55 mM and incubate 1 hr at room temperature in the dark.
6. Dilute lysate five times with 100 mM ammonia bicarbonate, pH 8.9, to a final urea concentration of 1.6 M. Measure the protein concentration using the DC protein assay kit according to the manufacturer's instructions.
7. Add affinity-purified, TPCK-treated trypsin to protein at a ratio of 1:100 (w/w) trypsin/total protein and incubate overnight at room temperature.

A trypsin concentration of 1:40 is optimal but may be cost prohibitive. The 1:40 ratio would afford ~10% more phosphopeptides and a lower rate of missed cleavage sites. A 1:300 ratio of trypsin provides unacceptably high rates of miscleavage and greatly diminishes the number of phosphopeptides identified. Promega affinity-purified and TPCK-treated trypsin works best.

8. Acidify tryptic digests to pH 2 with concentrated HCl and centrifuge acidified digests 5 min at $2000 \times g$ to remove any precipitate.

9. Pre-equilibrate a Sep-Pak C18 plus column by washing once with 5 ml of 100% acetonitrile and then twice with 3.5 ml of Sep-Pak loading buffer.

The flow rate for steps 8 through 11 is ~1 to 10 ml/min. Within this range, a lower flow rate gives a better loading efficiency. The control of flow rate can be accomplished by adjusting the intensity of the vacuum.

10. Load precleared digested peptides onto washed Sep-Pak plus column.
11. Wash column with 10 ml Sep-Pak loading buffer to remove salts.
12. Elute peptides from column with 10 ml Sep-Pak elution buffer into a 15-ml conical tube.
13. Dispense eluents into 1.5-ml screw-top microcentrifuge tubes with their tops perforated using an 18-G needle.
14. Dry peptides in a Speedvac evaporator without heat for 6 hr with rotation. Combine eluents from all tubes when the total volume fits in one tube, before peptides are completely dried.

Perform immunoprecipitation

15. Reconstitute peptides with 500 μ l cold (4°C) peptide IP buffer and add 10 pmol of a synthetic phosphopeptide external standard for quantitation of relative phosphopeptide abundance, as well as to control for variations in peptide IP efficiency.

A variety of synthetic tyrosine phosphorylated peptides are available from Anaspec.

16. Add 20 μ l (bed volume) of pTyr-100 immobilized antibody to peptide solution and incubate with gentle tumbling overnight at 4°C.
17. Wash resin two times with 400 μ L peptide IP wash buffer 1 for 10 min at 4°C, and microcentrifuge 5 min at 2000 \times g, 4°C, to bring down the resin. Remove supernatant as completely as possible by inserting a 27-G needle along the side and to the bottom of the microcentrifuge tube to remove any trace amounts of detergent.
18. Wash resin two times with 400 μ l peptide IP wash buffer 2 for 5 min at 4°C.
19. Elute phosphopeptides from resin with 100 μ L of peptide IP elution buffer 1 hr at room temperature. Spin down 5 min at 2000 \times g, room temperature, and collect all eluent by inserting a 27-G needle along the side and to the bottom of the microcentrifuge tube.
20. Add 200 fmol of another tyrosine phosphorylated standard peptide such as angiotensin II phosphate to the eluent as a quantitative control for the remaining steps.
21. Perform IMAC enrichment and MS analysis as in Basic Protocol 2, steps 22 through 36, but replace the database search parameters in step 36 with a static modification of +57.0215 Da on Cys and a variable modification of +79.9663 Da on Ser, Thr, and Tyr.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Cell lysis buffer A

- 20 μ g/ml aprotinin
- 50 mM Tris·Cl, pH 7.5 (APPENDIX 2)
- 100 mM NaCl

1% (v/v) Triton X-100
10% (v/v) glycerol
20 µg/ml leupeptin
1 mM Pefabloc
2 mM Na₃VO₄ (prepared fresh)
1 mM EDTA
10 mM β-glycerophosphate
Prepare fresh and keep at 4°C

Cell lysis buffer B

8 M urea
1 mM sodium orthovanadate
100 mM ammonium bicarbonate, pH 8.0
Prepare fresh and keep at 4°C

Dialysis buffer

50 mM ammonium bicarbonate, pH 8.3
4 M urea
Prepare fresh and keep at 4°C

IMAC elution buffer

0.4 M ammonium hydroxide
30% (v/v) acetonitrile

This buffer is for use with Phos-Select resin (Sigma); for other affinity resins, the manufacturers' instructions should be followed.

IMAC load/wash buffer

250 mM acetic acid
30% (v/v) acetonitrile

This buffer is for use with Phos-Select resin (Sigma); for other affinity resins, the manufacturers' instructions should be followed.

IMAC wash buffer

25% (v/v) acetonitrile
75% (v/v) ddH₂O
0.01% (v/v) acetic acid
100 mM NaCl

Immunoprecipitation wash buffer

20 mM Tris, pH 7.4 (APPENDIX 2)
120 mM NaCl

Methylation solution

Layer nitrogen gas over the reaction at each point in its preparation. Add 0.75 ml of 99.8% methanol-*d*₄ (Cambridge Isotope Labs) to a small dry glass vial with stirring (methanol-*d*₄ is used primarily because it is supplied very dry in ampules). Add 120 µl of 98+% acetyl chloride (Sigma) to methanol-*d*₄ dropwise with stirring (popping occurs if acetyl chloride is added too quickly). Incubate 5 min at room temperature and add immediately to dried peptides. The volume of this solution should be scaled up such that all related samples are methylated with the same methylation solution (use 400 µl of solution for each sample).

This solution must be very dry due to the reversible nature of the methylation reaction.

Peptide immunoprecipitation buffer

30 mM Tris·Cl, pH 7.4 (*APPENDIX 2*)
30 mM NaCl
0.3% (v/v) nonidet P-40 (NP-40)

Peptide immunoprecipitation wash buffer 1

100 mM Tris·Cl, pH 7.4 (*APPENDIX 2*)
100 mM NaCl
0.3% (v/v) nonidet P-40 (NP-40)

Peptide immunoprecipitation wash buffer 2

100 mM Tris·Cl, pH 7.4 (*APPENDIX 2*)
100 mM NaCl

Reversed-phase elution buffer

70% (v/v) acetonitrile
29.9% (v/v) Milli-Q water
0.1% (v/v) acetic acid (final concentration)

SAX start buffer

20 mM triethylammonium bicarbonate (TEAB)
30% (v/v) acetonitrile
The pH is ~8 or 9. No adjustment is necessary.

SAX step buffer

20 mM triethylammonium bicarbonate (TEAB)
1 M ammonium formate
30% (v/v) acetonitrile

SAX step elution buffers

Mix SAX start buffer (see recipe) and SAX step buffer (see recipe) to yield ammonium formate concentrations ranging from 50 to 500 mM.

These concentrations are appropriate for POROS HQ resin. For other anion-exchange resins, the concentrations may need to be adjusted.

SCX cleaning buffer

1 M ammonium formate
30% (v/v) acetonitrile
Adjust to pH 3 with formic acid

This requires a large amount of formic acid, and it is virtually impossible to bring the pH below 3.

SCX start buffer

5 mM ammonium formate
30% (v/v) acetonitrile
Adjust to pH 2.7 with formic acid

SCX step elution buffers

Mix SCX start buffer (see recipe) and SCX cleaning buffer (see recipe) to yield total ammonium formate concentrations ranging from 10 to 100 mM.

In Opti-Lynx cartridges, most phosphopeptides elute between 10 and 50 mM salt. For other column materials, the appropriate salt concentrations must be determined empirically.

Trypsin digestion buffer with urea

100 mM ammonium bicarbonate, pH 8.3

8 M urea

Urea solution MUST be prepared fresh before each use.

COMMENTARY

Background Information

Most cellular processes are regulated at some level by protein phosphorylation, be it developmental, hormonal, stress, or disease signaling. Of all posttranslational modifications, phosphorylation is the best understood, probably most widespread, and arguably the most important. To understand and investigate the role phosphorylation plays in cellular signaling, it is essential to know not only the identity of the phosphorylated proteins but also the exact site of modification. Site-directed mutagenesis of the phosphorylatable residue to a phospho-amino acid mimetic or a non-phosphorylatable residue reveals the biological significance of the modification, and ultimately the circuitry of the signaling pathway.

The determination of phosphorylation sites on individual proteins of interest was once an arduous task involving *in vivo* or *in vitro* labeling with radioactive phosphate, separation of labeled peptides by column or thin-layer chromatography, and Edman sequencing. These tools are still indispensable in some cases, but the rapid development of highly sensitive and accessible mass spectrometry techniques makes this an invaluable addition to the toolbox.

Phosphopeptides have a number of properties that make their analysis by mass spectrometry substantially more difficult than that of other peptides. Small phosphopeptides are so hydrophilic that they may not be retained on the reversed-phase matrices typically used in LC-MS (Larsen et al., 2004). In addition, phosphorylation sites of signaling proteins are often extremely difficult to detect due to their low abundance and low stoichiometry of phosphorylation in a cellular context of abundant background proteins. Several approaches have been developed to overcome these limitations by increasing the scale of the experiment through multidimensional chromatography (MudPIT; Washburn et al., 2001) or low-pH strong-cation exchange (Beausoleil et al., 2004). These unspecific methods have a lower efficiency in purification of phosphopeptides than affinity methods such as immobilized metal ion affinity chromatography (IMAC), making them better suited as a prefraction-

ation step prior to affinity chromatography for extremely complex protein mixtures such as total cell lysates. Phosphopeptide tandem mass spectra frequently have poor quality due to a combination of poor signal-to-noise ratio (arising from the low abundance and poor ionization of phosphorylated peptides) and poor peptide backbone fragmentation (due to abundant neutral loss of phosphate from phosphoserine and phosphothreonine residues). Since a phosphoprotein is often identified from a single phosphopeptide spectrum, it is necessary to “manually” inspect the quality of the database match for every candidate MS/MS spectrum. This time-consuming limitation could potentially be overcome by increasing the quality of the data through the use of high mass accuracy spectrometers that narrow down the database search (Mann and Jensen, 2003), better fragmentation methods such as electron transfer dissociation (Syka et al., 2004), and more highly selective chromatography (Ficarro et al., 2002; Brill et al., 2004; Ndassa et al., 2006), as well as the development of new statistical algorithms (MacCoss et al., 2002). The limited dynamic range of mass spectrometers necessitates selective enrichment of phosphopeptides to obtain the highest numbers of phosphorylation sites from a complex mixture. Furthermore, peptide MS/MS spectra are routinely obtained in the positive ion mode, *i.e.*, from fragmentation of the protonated peptide cations, where the additional negative charge of the phosphate group reduces the ionization efficiency of phosphopeptides relative to unphosphorylated peptides. While it is not possible to change the phosphate group itself when looking for definitive proof of the modification from the mass spectrum, it is possible to overcome the ionization problem by enriching the sample as much as possible for phosphopeptides.

By far the most successful method for enriching phosphopeptides is immobilized metal ion affinity chromatography (IMAC; UNIT 10.11B). A range of variations has been published, using different chromatographic materials, metal ions, and manual or automated setups (Neville et al., 1997; Posewitz and Tempst, 1999; Stensballe et al., 2001;

Ficarro et al., 2005; Olsen et al., 2006). Often, it is much easier to isolate phosphopeptides from complex mixtures than to identify a certain phosphopeptide(s) from individual proteins.

Affinity chromatography of proteins on chelated metal ions has been used for a long time and enjoys widespread popularity in the form of a nickel-nitrilotriacetic (NTA) or iminodiacetic acid (IDA) resin for the purification of hexahistidine-tagged proteins. Andersson and Porath (Andersson and Porath, 1986) were the first to notice that Fe^{3+} -chelated IDA has a strong affinity for highly phosphorylated proteins. While the use of IMAC for full-length proteins has been limited, at least until the recent availability of an IMAC-based commercial kit for enrichment of phosphoproteins, the isolation of phosphopeptides has been successful in a large number of cases. One of the first uses of the technique was in the study of phosphopeptides from casein in a nutritional context (Scanff et al., 1991). A large number of technical publications on new concepts for phosphopeptide isolation with IMAC or other procedures demonstrate feasibility exclusively with digests of β -casein. The reader should be wary of claims of the universality of these approaches until successfully applied to mixtures of proteins. IMAC with Fe^{3+} or other metals such as Ga^{3+} , or more recently TiO_2 (Olsen et al., 2006), is the longest established and most widely, used phosphoenrichment technique. IMAC has allowed the identification of phosphorylation sites in individual proteins (e.g., Michel et al., 1988; Neville et al., 1997; Fuglsang et al., 1999) as well as in complex mixtures (Vener et al., 2001; Ficarro et al., 2002; Nühse et al., 2003; Salomon et al., 2003; Olsen et al., 2006).

The mechanism of phosphoamino acid binding to chelated Fe^{3+} is a combination of ion exchange, i.e., binding of the negatively charged phosphate groups to the positive metal ion, and a more specific coordination of phosphate in the metal ligand sphere (Holmes and Schiller, 1997). It is easy to see why highly acidic peptides can bind to IMAC material as contaminants—the ion exchange function applies to them just as to phosphopeptides. Typical chromatographic conditions for IMAC make it more specific for phosphorylated peptides, and at least for some types of samples, the degree of purity is sufficient for large-scale mass spectrometric analysis (Nühse et al., 2003). For more complex sample analysis such as for total lysates or total cellular tyrosine phosphorylation, methyl esterifi-

cation of carboxyl groups provides remarkable selectivity and efficiency in phosphopeptide isolation (Ficarro et al., 2002; Salomon et al., 2003).

To increase the number of phosphorylation sites discovered, very complex samples may be fractionated at the peptide or protein level prior to IMAC and LC-MS. In the case of phosphoproteins, one-dimensional gel electrophoresis or affinity purification may be helpful. For phosphopeptides, anion- or cation-exchange chromatography is useful. Both have a double effect of “deconvoluting” the sample as well as enriching phosphopeptides to some extent over the bulk of unmodified peptides. In cation exchange chromatography, many phosphopeptides bind weakly and elute very early or do not bind at all, while many unphosphorylated peptides bind well. Although not as selective as IMAC, this reasonably selective enrichment in the early eluting fractions may be sufficient for analysis without IMAC, especially at low pH (Beausoleil et al., 2004). In anion exchange chromatography, the bulk of phosphopeptides binds better than other peptides and is eluted over a wider range of salt concentrations (Nühse et al., 2003). This orthogonal subfractionation of phosphopeptides may provide added benefits over cation exchange chromatography, where the interesting fraction elutes over a very narrow salt range.

Critical Parameters and Troubleshooting

The most typically encountered problems are too many unphosphorylated peptides in the IMAC eluates, too few phosphopeptides, or both.

Following Basic Protocol 1, an abundance of non-phosphopeptides means that the IMAC procedure was not specific enough. If spin columns are used for IMAC, it is critical to resuspend the resin well in the various wash buffers and to not simply add the buffers onto the column. To improve specificity, additional wash steps can be introduced but need to be balanced against the phosphopeptide yield—their affinity to the medium is not high enough to withstand extensive washing. Alternatively, different suppliers of IMAC resin can be tested. Similar sets of peptides have been successfully identified with both Sigma's Phos-Select and Pierce's gallium-loaded IMAC spin columns, but results may vary depending on the sample. If acidic peptides are the major contaminating non-phosphopeptides, methyl ester derivitization

of peptides is recommended (see Basic Protocol 2).

There are many possible reasons for finding too few phosphopeptides. The *in vivo* phosphorylation status of proteins needs to be preserved by harvesting cells rapidly and either isolating proteins under denaturing conditions until digesting with trypsin, or by adding sufficient amounts of phosphatase inhibitors to the native extract. It may be worth increasing inhibitor concentrations above levels published in the literature, and in some cases a substantially higher yield of phosphopeptides can be achieved by adding calyculin A (5 to 20 nM) as a phosphatase inhibitor even during the tryptic digestion. Although performing the protein digestion overnight is the most convenient way, it can be detrimental for smaller amounts of protein to be left at 37°C for too long; a few hours may be sufficient. The addition of RapiGest detergent (Waters) speeds up tryptic digestion and is, in the authors' experience, compatible with IMAC, provided acid hydrolysis of the detergent is performed according to the manufacturer's instructions and the digest is cleaned up by cation exchange separation.

If too few phosphopeptides are recovered from IMAC columns following Basic Protocol 1, the incubation time of the sample with the resin may be increased, washes shortened, and elution times prolonged, although the manufacturers' protocols are generally optimized.

In Basic Protocols 2 and 3, phosphopeptide yield is fully optimized by direct elution of phosphopeptides from the reversed-phase desalt column to the IMAC column to the reversed-phase precolumn and gradient elution into the mass spectrometer via the analytical column. In this method, the peptide never encounters plastic once the phosphopeptides are enriched providing an ideal yield in their separation.

After elution of phosphopeptides from the beads in Basic Protocol 1, it is crucial to bear in mind that even with a very good yield, the phosphopeptide solution is dilute and total amounts are low. Any delay before the analysis should be kept to a minimum; ideally, IMAC purification is scheduled to be directly followed by mass spectrometric analysis. If necessary, isolated phosphopeptides can be frozen at -80°C if they are not too dilute, but freezing total (or fractionated) protein digests is always preferable. Freeze-dried samples should not be refrozen; they are very hygroscopic and degrade when wet.

Finally, it is self-evident that high-sensitivity sequencing of phosphopeptides requires optimal calibration and sensitivity of the mass spectrometer. Optimal sensitivity is achieved through minimization of the electrospray flow rate (<20 nl/min) and electrospray emitter tip diameter.

Anticipated Results

The number of sequenced phosphopeptides depends on the amount and complexity of the sample, the detected abundance of phosphopeptides in the sample (which in turn depends on the natural abundance of the phosphoproteins and on each phosphopeptide's unique and unpredictable ionization efficiency) and the sensitivity and speed of the mass spectrometer. Following Basic Protocol 1, several tens to >100 phosphopeptide sequences can be identified from an enriched sample analyzed in a single LC-MS run, and ~100 to 200 with manual prefractionation of the sample. With a larger input of sample, more extensive fractionation and possibly multiple repeated LC-MS runs for each IMAC-enriched sample, this figure can be increased to several thousand identified peptides. With most types of samples, ~70% to 90% pure phosphopeptides have been obtained using samples prefractionated by ion-exchange chromatography.

With Basic Protocols 2 and 3, hundreds to thousands of phosphopeptides are identified routinely depending on the nature of the sample and the amount of prefractionation of proteins and peptides performed prior to IMAC.

If the isolated phosphopeptides are analyzed on an ion trap mass spectrometer, serine- and threonine-phosphorylated peptides typically display a prominent neutral loss, i.e., an abundant fragment ion corresponding to loss of phosphoric acid (-98 Da for +1; -49 *m/z* for +2; -32.7 Da for +3 precursor ions) that often completely dominates the spectrum and reduces the quantity and quality of useful b and y ion peaks. Rapidly evolving mass spectrometry methodologies such as MS³ (Olsen and Mann, 2004), pseudo MS³ (Schroeder et al., 2004), and ETD (Syka et al., 2004) aim to overcome this significant problem.

It is important to note that tyrosine phosphorylation is substantially less frequent than serine or threonine phosphorylation. Without enrichment of phosphotyrosine-containing proteins or peptides by immunoprecipitation, peptides containing this residue will be outnumbered several hundred fold in

the protein digest by serine- and threonine-phosphorylated peptides.

Time Considerations

The entire procedure from sample preparation to mass spectrometric analysis will take between 2 and 3 days; there are several steps where samples can be frozen before continuing. Protein extracts are prepared on day 1 and will require between a few hours and a full day, depending on whether subcellular fractionation and, optionally, immunoprecipitation is performed. In almost all cases, the digestion is performed overnight. On the second day, the lyophilization before ion exchange chromatography (see Basic Protocol 1) requires several hours, and for ion exchange fractions, >0.5 ml, the lyophilization of these fractions will preferably be done overnight again. On the third day, the IMAC purification will take ~2 hr for up to twelve separate samples. For Basic Protocol 2, peptide methylation or peptide IP takes 1 day and the entire procedure of desalting the peptides, IMAC enrichment, and reversed-phase elution into the instrument can be accomplished in 3 hr.

CHAPTER 19

Informatics for Molecular Biologists

INTRODUCTION

Biological information—including DNA sequence and gene mapping data as well as their associated literature—is growing exponentially, especially with the advent of large genome projects that generate enormous amounts of DNA sequence data (see Fig. 19.2.1). To many, this flood of information is overwhelming. How can it be collected, sorted, accessed, and manipulated? Recently, significant progress has been made in the development of computer programs that navigate this sea of information. Many databases have been developed that store the data, and much progress has been made toward interconnecting them in ways that are transparent (user-friendly) to the average over-worked molecular biologist. The key to the new information age is the worldwide Internet computer network, and that is where this chapter begins.

Traditionally, the Internet has primarily been used to retrieve software or database files and to allow research centers to communicate with one another. Now, however, new uses for the Internet are being developed and are starting to change the way information is obtained. These new services provide methods for submitting interactive queries to a distant database, making an enormous amount of information freely available to any scientist with access to the Internet. Even a geographically isolated researcher can gain access to the same information that colleagues at a large metropolitan laboratory take for granted, simply by arranging access to an institution that is connected to the Internet. Although the network services are free, the institution or department must buy and maintain the equipment required for the network connection.

This chapter provides an introduction to the vast array of biological information freely available via the Internet and focuses on the software tools required for access to and analysis of data contained in DNA and protein sequence databases (e.g., GenBank, SWISS-PROT) and the associated biomedical literature. Its aim is to facilitate the understanding and use of the most-commonly employed informatic tools used by biologists. The *Current Protocols in Bioinformatics* series provides additional depth and breadth.

UNIT 19.1 provides an overview of the Internet for biologists, and describes basic tools for electronic information retrieval from public data repositories and newsgroups. This unit presents a simple introduction to the tools necessary for exchanging information on the Internet, including a brief description of how to send and receive information by electronic mail (e-mail) and participate in network newsgroups. Navigational strategies and tools are described that allow the user either to browse or conduct a directed search. The World Wide Web (WWW), for example, is an expanding information retrieval system for documents from all over the world, based upon cross-references set up as “hypertext” links. Perhaps the most significant navigational tool for the World Wide Web is the graphical browser Mosaic from the National Center for Supercomputer Applications. Detailed methods are described for searching and downloading information using anonymous file transfer protocol (FTP), Gopher, and the World Wide Web. A final section on so-called “client-server” applications provides introductions to several important programs for biologists. These include BLAST for rapid comparison of experimental sequences against the DNA and protein sequence databases, Entrez for rapid sequence comparison and MEDLINE

literature surveys, GDB Accessor for accessing gene mapping data, and XGRAIL for rapidly scanning experimental sequence data for coding regions.

UNIT 19.2 describes integrated informational retrieval from sequence, structure, and literature databases using the Entrez system (the Entrez client software will actually be included in a future supplement of *CP on CD* with software for MACAW, the Multiple Alignment Construction and Analysis Workbench). Entrez is a user-friendly program that integrates DNA and protein sequence data with its associated abstracts and citations contained in the MEDLINE database. It is therefore possible using Entrez to search the databases by bibliographic associations (e.g. author name, gene family, or map location) as well as by sequence homology. The submission of new data, updates, and corrections to the sequence databases is an important, but often neglected, topic that is also described in this unit.

UNIT 19.3 provides detailed descriptions of methods for homology searching of DNA and protein sequence databases using the popular Basic Local Alignment Search Tool (BLAST) family of programs. The basic algorithm is compared and contrasted with FASTA. Notably, many tricks and tips for avoiding common pitfalls in homology searching are discussed. An explanation of how to judge the statistical significance of search results is also included.

UNIT 19.4 describes how to access a multitude of protein databases to obtain a variety of information about protein sequences. Searching these databases is an important early step in the characterization of a newly identified gene or protein, often providing key information concerning function. In many cases, phylogenetic information is available about the evolution of a particular protein or protein family, often providing additional insights into function. Protein databases include both small and large experimental ones that primarily catalog information about protein sequences and secondary databases that reorganize, annotate, and manipulate the data in the experimental ones. This unit provides a guide to these important resources.

UNIT 19.5 describes basic protein sequence analysis focused on enabling the biologist to make a more informed prediction of the likely molecular function of their protein of interest. It builds on the information presented in *UNITS 19.3 & 19.4*. Specifically, it discusses how to identify structural and functional domains, predict helical transmembrane regions, assess the subcellular localization of the protein, and predict key functional residues and potential sites for post-translational modifications *in silico*. A discussion of the critical parameters and assumptions for these tools, as well as guidelines for assessing the reliability of the findings are presented. These predictions can then be strengthened or confirmed by assessing experimental information. For example, one could determine whether a protein predicted to be plastid-localized has been identified by proteomics as residing in the plastid (e.g., see The Plastid Proteome Database, <http://cbsusrv01.tc.cornell.edu/users/ppdb/>).

A cautionary note: It is critical to remember that these informatic analyses are dependent on an accurate protein sequence. Certain transit peptides (such as chloroplast transit sequences) are often missed using annotation programs. In addition, there may be alternative forms of the enzyme (e.g., due to alternative splicing). Therefore, it is important to assess the validity of the sequence of interest manually by comparison with expressed sequence tag (EST) databases, alternative splicing event databases (e.g., see http://rarge.gsc.riken.jp/a_splicing/index.pl), tiling array expression databases such as the Arabidopsis Tiling Array Transcriptome Express Tool (<http://signal.salk.edu/cgi-bin/atta>), proteomic databases, and the primary literature.

Frederick Ausubel, Nicholas C. Dracopoli, and Mary Wildermuth

With the explosion of sequence and structural information available to researchers, the field of bioinformatics is playing an increasingly large role in the study of fundamental biomedical problems. The challenge facing computational biologists will be to aid in gene discovery and in the design of molecular modeling, site-directed mutagenesis, and experiments of other types that can potentially reveal previously unknown relationships with respect to the structure and function of genes and proteins. This challenge becomes particularly daunting in light of the vast amount of data that has been produced by the Human Genome Project and other systematic sequencing efforts to date.

Before embarking on any practical discussion of computational methods in solving biological problems, it is necessary to lay the common groundwork that will enable users to both access and implement the algorithms and tools discussed in this book. We begin with a review of the Internet and its terminology, also discussing major classes of Internet protocols, without becoming overly engaged in the engineering minutiae underlying these protocols. A more in-depth treatment on the inner workings of these protocols may be found in a number of well-written reference books intended for the lay audience (Krol and Klopfenstein, 1996; Rankin, 1996; Kennedy, 1999). This unit will also discuss matters of connectivity, ranging from simple modem connections to digital subscriber lines (DSL). Finally, we will address one of the most common problems that has arisen with the proliferation of Web pages throughout the world—i.e., finding useful information on the World Wide Web.

INTERNET BASICS

Despite the impression that the Internet is a single entity, it is actually a network of networks, composed of interconnected local and regional networks in more than 100 countries. While work on remote communications began in the early 1960s, the true origins of the Internet lie with a research project on networking at the Advanced Research Projects Agency of the U.S. Department of Defense in 1969 named ARPANET. The original ARPANET connected four nodes on the West Coast, with the immediate goal of being able to transmit information on defense-related research between laboratories. A number of different network projects subsequently surfaced, with the next landmark developments coming over ten years later. In 1981, BITNET (“Because It’s Time”) was introduced, providing point-to-point connections between universities for the transfer of electronic mail and files. In 1982, ARPA introduced the Transmission Control Protocol (TCP) and Internet Protocol (IP); TCP/IP allowed different networks to be connected to and communicate with one another, creating the system that is in place today.

A number of references chronicle the development of the Internet and communications protocols in detail (Quarterman, 1990; Froehlich and Kent, 1991; Krol and Klopfenstein, 1996). Most users, however, are content to leave the details of *how* the Internet works to their systems administrators; the relevant fact to most is that it *does* work.

Once the machines on a network are connected to one another, there needs to be some way to unambiguously specify a single computer so that messages and files find their intended recipient. To accomplish this, all machines directly connected to the Internet have an **IP number**. IP numbers are unique, identifying one and only one machine. The IP number is made up of four numbers separated by periods; for example, the IP number for the main file server at the National Center for Biotechnology Information (NCBI) at the National Institutes of Health (NIH) is *130.14.25.1*. The numbers themselves represent,

from left to right, the domain (*130.14* for the NIH), the subnet (*.25* for the National Library of Medicine at NIH), and the machine itself (*.1*). While the use of IP numbers aids the computers in directing data, they are obviously very difficult for users to remember. Therefore, an IP number often has a **fully-qualified domain name** (FQDN) associated with it, which is dynamically translated in the background by a **domain name server**. Going back to the NCBI example, instead of using *130.14.25.1* to access the NCBI computer, a user could instead use *ncbi.nlm.nih.gov* and achieve the same result. Reading from left to right, the IP number goes from least to most specific, while the FQDN equivalent goes from most specific to least. The name of any given computer can then be thought of as taking the general form *computer.domain*, with the top-level domain (the portion coming after the last period in the FQDN) falling into one of the six broad categories shown in Table 19.1.1. Outside the United States, the top-level domain names may be replaced with a two-letter code specifying the country where the machine is located (e.g., *.ca* for Canada and *.uk* for the United Kingdom).

In an effort to anticipate the needs of Internet users in the future, as well as to try to erase the arbitrary line between top-level domain names based on country, the now-dissolved International Ad Hoc Committee (IAHC) was charged with developing a new framework of generic top-level domains (gTLD). The new, recommended gTLDs were set forth in a document entitled *The Generic Top Level Domain Memorandum of Understanding* (gTLD-MOU); these gTLDs are overseen by a number of governing bodies and are also shown in Table 19.1.1.

The most concrete measure of the size (and, thereby, the success) of the Internet lies in actually counting the number of machines physically connected to it. The Internet Software Consortium conducts an Internet Domain Survey twice each year to count these machines, otherwise known as **hosts**. In performing this survey, ISC considers not only how many hostnames have been assigned, but how many of those are actually in use; a

Table 19.1.1 Top-Level Domain Names

Top-level domain names	
Inside U.S.	
<i>.com</i>	Commercial site
<i>.edu</i>	Educational site
<i>.gov</i>	Government site
<i>.mil</i>	Military site
<i>.net</i>	Gateway or network host
<i>.org</i>	Private (usually not-for-profit) organizations
Examples of top-level domain names used outside the United States	
<i>.ca</i>	Canadian site
<i>.ac.uk</i>	Academic site in the United Kingdom
<i>.co.uk</i>	Commercial site in the United Kingdom
Generic top-level domains proposed by IAHC	
<i>.firm</i>	Firms or businesses
<i>.shop</i>	Businesses offering goods to purchase (stores)
<i>.web</i>	Entities emphasizing activities relating to the World Wide Web
<i>.arts</i>	Cultural and entertainment organizations
<i>.rec</i>	Recreational organizations
<i>.info</i>	Information sources
<i>.nom</i>	Personal names (e.g., <i>yourlastname.nom</i>)

hostname might be issued, but the requestor may be holding the name in abeyance for future use. To test for this, a representative sample of host machines are sent a probe (a “ping”), with a signal being sent back to the originating machine if the host was indeed found. The rate of growth of the number of hosts has been phenomenal; from a paltry 213 hosts in August 1981, the Internet has in excess of 60 million hosts now. The doubling time for the number of hosts is on the order of 18 months. Most of this growth has come from the commercial sector, capitalizing on the growing popularity of multimedia platforms for advertising and communications such as the World Wide Web.

CONNECTING TO THE INTERNET

Of course, before being able to use all of the resources that the Internet has to offer, one needs to actually make a physical connection between one’s own computer and “the information superhighway.” For purposes of this discussion, the elements of this connection have been separated into two discrete parts: the actual, physical connection (meaning the “wire” running from one’s computer to the Internet backbone) and the service provider, who handles issues of routing and content once connected. Keep in mind that, in practice, these are not necessarily treated as two separate parts—for instance, one’s service provider may also be the same company that will run cables or fibers right into one’s home or office.

Copper Wires, Coaxial Cables, and Fiber Optics

Traditionally, users who were attempting to connect to the Internet away from the office have had one and only one option—a modem, which uses the existing copper twisted-pair cables carrying telephone signals to transmit data. Data transfer rates using modems are relatively slow, allowing for data transmission in the range of 28.8 to 56 kilobits per second (Kbps). The problem with using conventional copper wire to transmit data lies not in the copper wire itself, but in the switches that are found along the way that route information to their intended destinations. These switches were designed for the efficient and effective transfer of voice data, but were never intended to handle the high-speed transmission of data. While most people still use modems from their homes, a number of new technologies are already in place and will become more and more prevalent for accessing the Internet away from hard-wired Ethernet networks. The maximum speeds at which each of the services that are discussed below can operate are shown in Figure 19.1.1.

The first of these “new solutions” is the integrated services digital network, or ISDN. While the advent of ISDN was originally heralded as the way to bring the Internet into the home in a speed-efficient manner, it required that special wiring be brought into the home. It also required that users be within a fixed distance from a central office, on the order of 20,000 feet or less. The cost of running this special, dedicated wiring, along with a per-minute pricing structure, effectively placed ISDN out of reach of most individuals. While ISDN is still available in many areas, this type of service is quickly being supplanted by more cost-effective alternatives.

In looking at alternatives that did not require new wiring, cable television providers began to look at ways in which the coaxial cable already running into a substantial number of households could be used to also transmit data. Cable companies are able to use bandwidth that is not being used to transmit television signals (effectively, unused channels) to push data into the home at very high speeds, up to 4.0 megabits per second (Mbps). The actual computer is connected to this network through a cable modem, which uses an Ethernet connection to the computer and a coaxial cable to the wall. Homes in a given area all share a single cable, in a wiring scheme very similar to that by which individual computers are connected via the Ethernet in an office or laboratory setting. While this branching

Figure 19.1.1 Performance of various types of Internet connections, by maximum throughput. The numbers indicated in the graph refer to peak performance; often the actual performance of any given method may be on the order of one-half slower, depending on configurations and system conditions.

arrangement can serve to connect a large number of locations, there is one major disadvantage—as more and more homes connect through their cable modems, service effectively slows down as more signal attempts to pass through any given node. One way of circumventing this problem is the installation of more switching equipment and reducing the size of a given “neighborhood.”

Since the local telephone companies were the primary ISDN providers, they quickly turned their attention to ways in which the existing, conventional copper wire already in the home could be used to transmit data at high speed. The solution here is the digital subscriber line, or DSL. By using new, dedicated switches that are designed for rapid data transfer, DSL providers can circumvent the old voice switches that slowed down transfer speeds. Depending on the user’s distance from the central office and whether a particular neighborhood has been wired for DSL service, speeds are on the order of 0.8 to 7.1 Mbps. The data transfers do not interfere with voice signals, and users can use the telephone while connected to the Internet; the signals are “split” by a special modem that passes the data signals to the computer and a microfilter that passes voice signals to the handset. There is a special type of DSL called **asynchronous DSL**, or ADSL. This is the variety of DSL service that is becoming more and more prevalent. Most home users download much more information than they send out, so systems are engineered to provide super-fast transmission in the “in” direction, with transmissions in the “out” direction being 5 to 10 times slower. Using this approach maximizes the amount of bandwidth that can be used without necessitating new wiring. One of the advantages of ADSL over cable is that ADSL subscribers effectively have a direct line to the central office, meaning that they do not have to compete with their neighbors for bandwidth. This, of course, comes at a price; at the time of this writing, ADSL connectivity options were on the order of twice as expensive as cable Internet.

Some of the newer technologies involve wireless connections to the Internet. These include using one’s own cell phone or a special cell phone service (such as Ricochet) to upload and download information. These cellular providers can provide speeds on the order of 28.8 to 128 Kbps, depending on the density of cellular towers in the service area. Fixed-point wireless services can be substantially faster, since the cellular phone does not have to “find” the closest tower at any given time. Along these same lines, satellite providers are also coming on-line. These providers allow for data download directly to a

satellite dish with a southern exposure, with uploads occurring through traditional telephone lines. While the satellite option has the potential to be amongst the fastest of the options discussed, current operating speeds are only on the order of 400 Kbps.

Content Providers versus ISPs

Once an appropriately fast and price-effective connectivity solution is found, users will then need to actually connect to some sort of service that will enable them to traverse the Internet space. The two major categories in this respect are **on-line services** or **Internet service providers (ISPs)**. On-line services such as America Online (AOL) and CompuServe offer a large number of interactive digital services, including information retrieval, electronic mail (e-mail), bulletin boards, and “chat rooms” where users who are on line at the same time can converse with each other about any number of subjects. While the on-line services now provide access to the World Wide Web (see discussion of The World Wide Web), most of the features and services available through these systems reside within a proprietary, closed network; once a connection is made between the user’s computer and the on-line service, accessing the special features, or content, of these systems does not require ever leaving the on-line system’s host computer. Specialized content can range from access to on-line travel reservation systems to encyclopedias that are constantly being updated—items that would not be available to anyone unless they subscribed to that particular on-line service.

Internet service providers, or ISPs, take the opposite tack. Instead of focusing on providing content, the ISPs provide the tools necessary for users to send and receive e-mail, upload and download files, and navigate around the World Wide Web to find information at remote locations. The major advantage of ISPs is connection speed; ISPs often provide faster connections than the on-line services. Most ISPs charge a monthly fee for unlimited use.

The line between on-line services and ISPs has already begun to blur. AOL’s now monthly flat fee pricing structure allows users to obtain all of the proprietary content found on AOL as well as all of the Internet tools available through ISPs, often at the same cost as a simple ISP connection. The extensive AOL network puts access to AOL as close as a local phone call in most of the United States, providing access to e-mail no matter where the user is located—a feature that small, local ISPs cannot match.

Not to be outdone, many of the major national ISP providers now also provide content through the concept of **portals**. Portals are Web pages that can be customized to the needs of the individual user and which serve as a jumping-off point to other sources of news or entertainment on the Net. In addition, many national firms such as Mindspring are able to match AOL’s ease of connectivity on the road, and both ISPs and online providers are becoming more and more generous in providing users the capacity to publish their own Web pages. Developments such as this, coupled with the move of local telephone and cable companies into providing Internet access through new, faster fiber optic networks, foretell major changes in how people will access the Net in the future, changes that should favor the end-user both in price and performance.

ELECTRONIC MAIL

Most people are introduced to the Internet through the use of electronic mail (**e-mail**). The use of e-mail has become practically indispensable in many settings owing to its convenience as a medium for sending, receiving, and replying to messages. Its advantages are many:

It is much quicker than postal, or “snail mail.” Messages tend to be much clearer and more to the point than is the case in typical telephone or face-to-face conversations.

Recipients have more flexibility in deciding whether a response needs to be sent immediately, relatively soon, or at all, giving individuals more control over workflow.

It provides a convenient method by which messages can be filed or stored.

There is little or no cost involved in sending an e-mail message.

While these and other advantages have pushed e-mail to the forefront of interpersonal communication in both industry and the academic community, users should be aware of several major disadvantages. First is the issue of security. As mail travels towards its recipient, it may pass through a number of remote nodes. The message could be intercepted and read at any one of those nodes by someone with high-level access, such as a systems administrator. Second is the issue of privacy. In industrial settings, e-mail is often considered to be an asset of the company for use only in official communication and, as such, is subject to monitoring by supervisors. The opposite is often true in academic, quasi-academic, or research settings; for example, National Institutes of Health policy encourages personal use of e-mail within the bounds of certain published guidelines. The key words here are “published guidelines”; no matter what the setting, users of e-mail systems should always be informed as to their organization’s policy regarding the appropriate use and confidentiality of e-mail so that they may use the tool properly and effectively. An excellent, basic guide to the effective use of e-mail is highly recommended (Rankin, 1996).

Sending E-Mail

E-mail addresses take the general form *user@computer.domain*, where *user* is the name of the individual user and *computer.domain* specifies the actual computer that the e-mail account is located on. Like a postal letter, an e-mail message is comprised of an **envelope** or **header**, showing the e-mail addresses of the sender and recipient, a line indicating the subject of the e-mail, and information about how the e-mail message actually travelled from the sender to the recipient. The header is followed by the actual message, or **body**, analogous to what would go inside the postal envelope. Figure 19.1.2 illustrates all the components of an e-mail message.

E-mail programs vary widely, depending on both the platform and the needs of the users. Usually the characteristics of the local area network (LAN) dictate what types of mail programs can be used, and the decision is often left to systems administrators rather than individual users. Among the most widely used e-mail packages with a graphical user interface are Eudora for the Macintosh and both Netscape Messenger and Microsoft Exchange for Macintosh, Windows, and UNIX platforms. Text-based e-mail programs, which are accessed by logging into a UNIX-based account, include Elm and Pine.

Bulk E-Mail

As with postal mail, there has been an upsurge in “spam” or “junk e-mail,” where companies compile bulk lists of e-mail addresses for use in commercial promotions. Since most of these lists are compiled from on-line registration forms and similar sources, the best defense for remaining off of these bulk e-mail lists is to be selective as to whom e-mail addresses are provided. Most newsgroups keep their mailing lists confidential; if in doubt and this is a concern, one should ask.

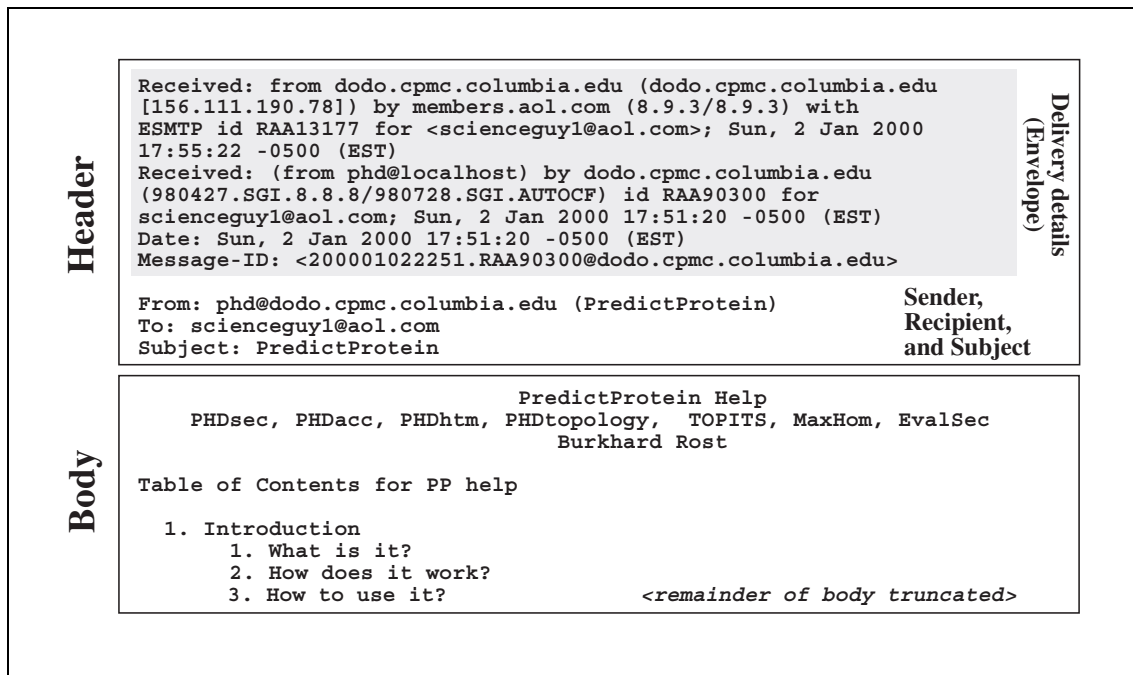

Figure 19.1.2 Anatomy of an e-mail message, with relevant components indicated. This message is an automated reply to a request for help file for the PredictProtein E-mail server.

E-mail Servers

Most often, e-mail is thought of as a way to simply send messages, whether it be to one recipient or many. It is also possible to use e-mail as a mechanism for making biological predictions or retrieving records from biological databases. Users can send e-mail messages in a predefined format, defining the action to be performed for remote computers known as **servers**; the servers will then perform the desired operation and e-mail back the results. While this method is not interactive (in that the user cannot adjust parameters or have control over the execution of the method in real time), it does place the responsibility of hardware maintenance and software upgrades on the persons maintaining the server, allowing users to concentrate on their results instead of on programming. For most servers, sending the message *help* to the server e-mail address will return a detailed set of instructions for using that server, including the way in which queries need to be formatted.

Aliases and Newsgroups

In the example in Fig. 19.1.2, the e-mail message is being sent to a single recipient. One of the strengths of e-mail is that a single piece of e-mail can be sent to a large number of people. The primary mechanism for doing this is through **aliases**; a user can define a group of people within their mail program and give the group a special name, or alias. Instead of using the individual e-mail addresses for all of the people in the group, the user can just send the e-mail to the alias name, and the mail program will handle broadcasting the message to each person in that group. Setting up alias names is a tremendous time-saver even for small groups; it also ensures that all members of a given group actually receive all e-mail messages intended for the group.

The second mechanism for broadcasting messages is through **newsgroups**. This model works slightly differently in that the list of e-mail addresses is compiled and maintained on a remote computer through subscriptions, much like magazine subscriptions. For example, the BIOSCI newsgroups are amongst the most highly-trafficked, offering a

forum for discussion or the exchange of ideas in a wide variety of biological subject areas. To begin receiving the messages posted to the automated sequencing discussion group within BIOSCI, a user would send a message to *biosci-server@net.bio.net* with the wording *subscribe autoseq* in the body of the message. The user would then receive all future postings to that group and be able to participate in the discussions. If a user wished to be removed from the group, a message would be sent to the same address, but this time, the body of the message would read *unsubscribe autoseq*. For more information on BIOSCI, including a complete list of discussion groups, an e-mail message can be sent to *biosci-server@net.bio.net*; in this case the subject line should be left blank and the words *info faq* typed in the body of the message. The BIOSCI server will then return a copy of the Frequently Asked Questions (FAQ) in response, with detailed information on each newsgroup overseen by BIOSCI.

It is also possible to participate in newsgroups without having each and every piece of e-mail flood into one's private mailbox. Instead, interested participants can use newsreading software, such as NewsWatcher for the Macintosh, which provides access to the individual messages making up a discussion. The major advantage is that the user can pick and choose which messages to read by scanning the subject lines; the remainder can be discarded by a single operation. NewsWatcher is an example of what is known as a **client-server application**—the client software (here, NewsWatcher) runs on a client computer (a Macintosh), which in turn interacts with a machine at a remote location (the server). Client-server architecture is interactive in nature, with a direct connection being made between the client and server machines.

Once NewsWatcher is started, the user is presented with a list of newsgroups available to them (Fig. 19.1.3); this list will vary, depending on the user's location, as systems administrators have the discretion to allow or block certain groups at a given site. From the rear-most window in the figure, the user double-clicks on the newsgroup of interest (here, *bionet.genome.arabidopsis*), which spawns the window shown in the center. At the top of the center window is the current unread message count, and any message within the list can be read by double-clicking on that particular line. This, in turn, spawns the last window (in the foreground), showing the actual message. If a user decides not to read any of the messages, or is done reading individual messages, the balance of the messages within the newsgroup (center) window can be deleted by first choosing *Select All* from the *File* menu, then selecting *Mark Read* from the *News* menu. Once the newsgroup window is closed, the unread message count is reset to zero. Every time NewsWatcher is restarted, it will automatically poll the news server for new messages that have been created since the last session.

As with most of the tools that will be discussed in this unit, news-reading capability is built into Web browsers such as Netscape Navigator and Microsoft Internet Explorer.

FILE TRANSFER PROTOCOL

Despite the many advantages afforded by e-mail in transmitting messages, experienced e-mail users have no doubt experienced frustration in trying to transmit files (**attachments**) along with an e-mail message. The mere fact that a file can be attached to an e-mail message and sent does not mean that the recipient will be able to detach, decode, and actually use the attached file. While more cross-platform e-mail packages such as Microsoft Exchange are being developed, the use of different e-mail packages by people at different locations means that sending files via e-mail is not an effective, foolproof method, at least in the short term. One solution to this problem is through the use of a **file transfer protocol** (or **FTP**). The workings of FTP are quite simple—a connection is made

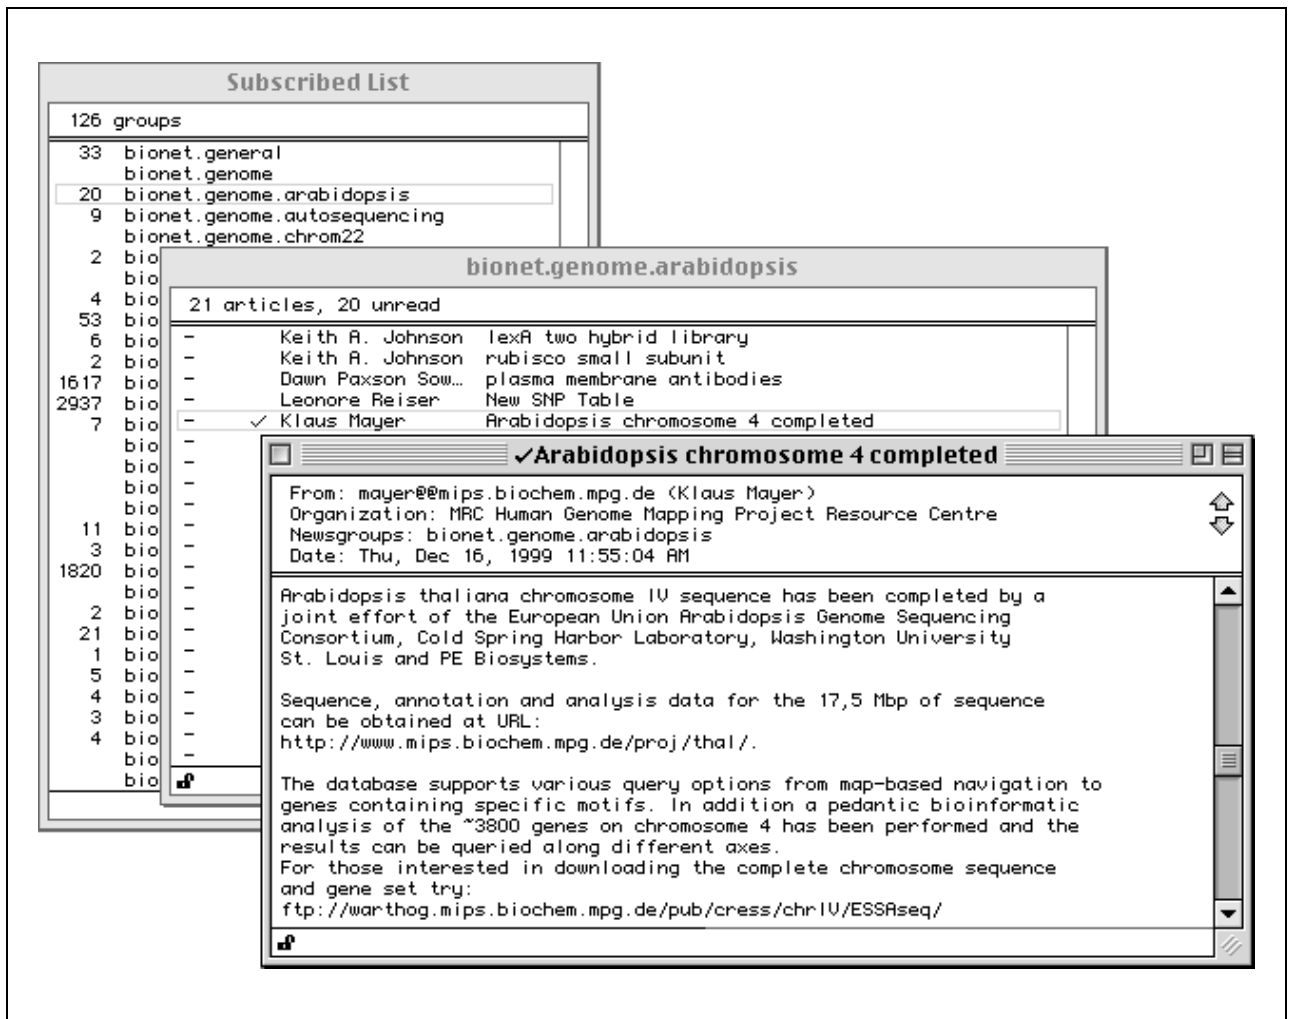

Figure 19.1.3 Using NewsWatcher to read postings to newsgroups. The list of newsgroups that the user has subscribed to is shown in the *Subscribed List* window (*left*). The list of new postings for the highlighted newsgroup (*bionet.genome.arabidopsis*) is shown in the center window. The window in the foreground shows the contents of the posting selected from the center window.

between a user's computer (the **client**) and a remote server, and that connection remains in place for the duration of the FTP session. File transfers are very fast, at rates on the order of 5 to 10 kilobytes per second, with speeds varying with time of day, distance between the client and server machines, and overall traffic on the network.

In the ordinary case, making an FTP connection and transferring files requires that a user have an account on the remote server. However, there are many files and programs that the academic community makes freely available, and access to those files does not require having an account on each and every machine where these programs are stored. Instead, connections are made using a system called **anonymous FTP**. Under this system, the user connects to the remote machine, and instead of entering a username/password pair, types *anonymous* as the username and enters an e-mail address in place of a password. Providing one's e-mail address allows the server's systems administrator to compile access statistics which may, in turn, be of use to those actually providing the public files or programs. An example of an anonymous FTP session using UNIX is shown in Fig. 19.1.4.

Figure 19.1.4 Using UNIX FTP to download a file. An anonymous FTP session is established with the molecular biology FTP server at the University of Indiana to download the ClustalW alignment program. The user inputs are shown in boldface.

Although FTP occurs within the UNIX environment, Macintosh and PC users can employ programs that utilize graphical user interfaces (GUI, pronounced “gooey”) to navigate through the UNIX directories on the FTP server. Users need not have any knowledge of UNIX commands to download files; they can instead rely on pop-up menus and the ability to point-and-click their way through the UNIX file structure. The most popular FTP program on the Macintosh platform for FTP sessions is Fetch.

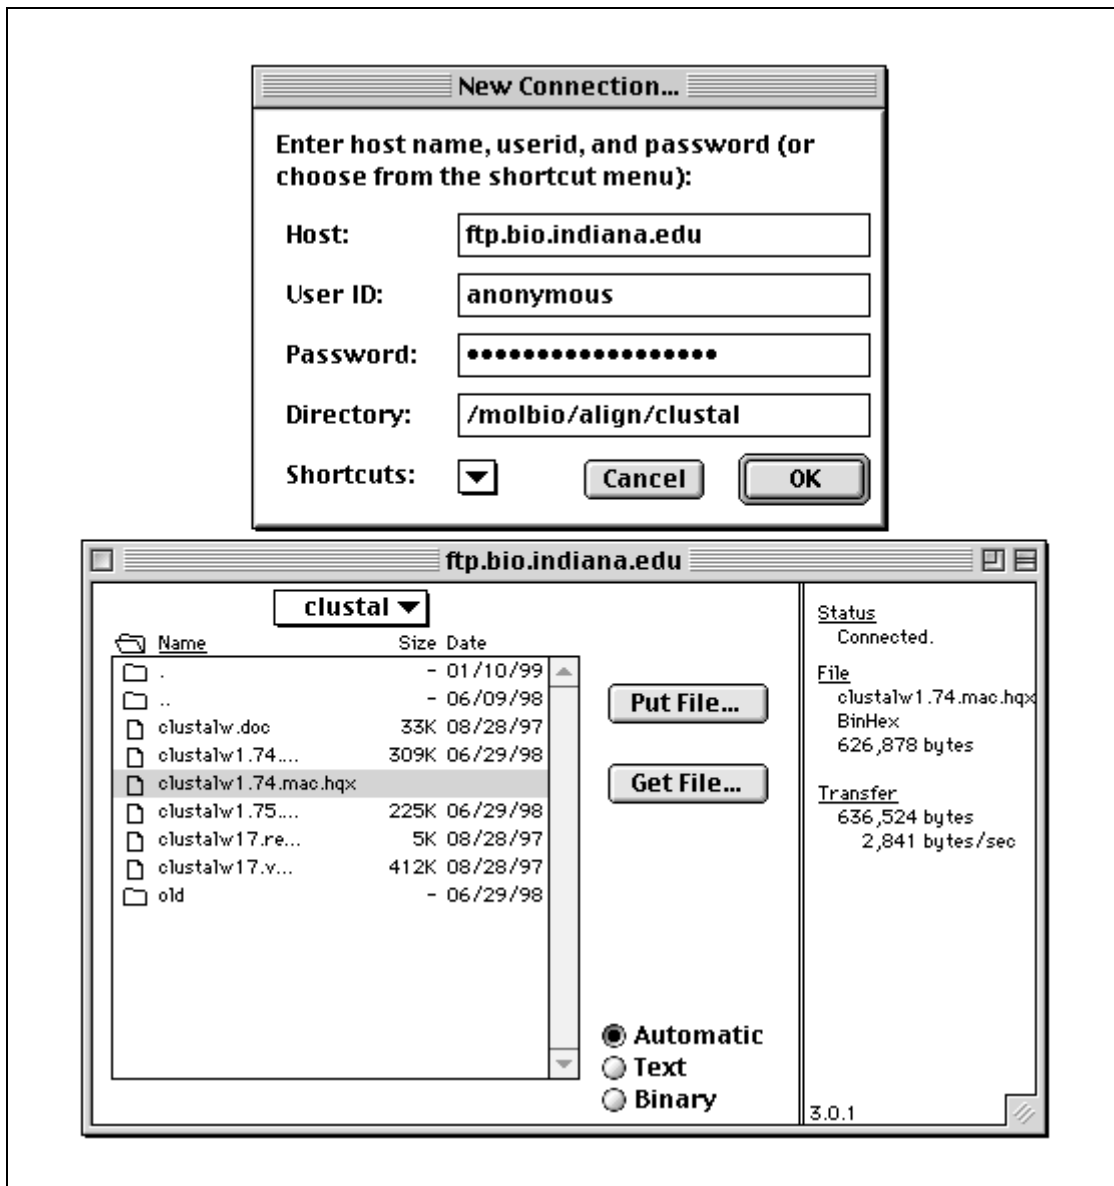

Figure 19.1.5 Using Fetch to download a file. An anonymous FTP session is established with the molecular biology FTP server at the University of Indiana (top) to download the ClustalW alignment program (bottom). Notice the difference between this GUI-based program and the UNIX equivalent illustrated in Figure A.3J.4.

A sample Fetch window is shown in Figure 19.1.5 to illustrate the difference between using a GUI-based FTP program and the equivalent UNIX FTP in Figure 19.1.4. In the figure, notice that the *Automatic* radio button (near the bottom of the second window under the *Get File* button) is selected, meaning that Fetch will determine the appropriate type of file transfer to perform. This may be manually overridden by selecting either *Text* or *Binary*, depending on the nature of the file being transferred. As a rule, text files should be transferred as *Text*, programs or executables as *Binary*, and graphic format files such as PICT and TIFF files as *Raw Data*.

THE WORLD WIDE WEB

While FTP is of tremendous use in the transfer of files from one computer to another, it does suffer from some limitations. When working with FTP, once a user enters a particular directory, they can only see the names of the directories or files. In order to actually view

what is within the files, it is necessary to physically download them onto one's own computer. This inherent drawback led to the development of a number of **distributed document delivery systems (DDDS)**, interactive client-server applications that allowed information to be viewed without having to perform a download. The first generation of DDDS development led to programs like Gopher, which allowed plain text to be viewed directly through a client-server application. From this evolved the most widely known and widely used DDDS, namely the World Wide Web. The Web is an outgrowth of research performed at the European Nuclear Research Council (CERN) in 1989 that was aimed at sharing research data between several locations. That work led to a medium through which text, images, sounds, and videos could be delivered to users on demand, anywhere in the world.

Navigation on the World Wide Web

Navigation on the Web does not require advance knowledge of the location of the information being sought. Instead, users can navigate by clicking on specific text, buttons, or pictures. These clickable items are collectively known as **hyperlinks**. Once one of these hyperlinks is clicked, the user is taken to another Web location, which could be at the same site or halfway around the world. Each document displayed on the Web is called a **Web page**, and all of the related Web pages on a particular server are collectively called a **Web site**. Navigation strictly through the use of hyperlinks has been nicknamed "Web surfing."

Users can take a more direct approach to finding information by entering a specific address. One of the strengths of the Web is that the programs used to view Web pages (appropriately termed **browsers**) can be used to visit Gopher and FTP sites as well, somewhat obviating the need for separate Gopher or FTP applications. As such, a unified naming convention was introduced to indicate to the browser program both the location of the remote site and, more importantly, the type of information at that remote location so that the browser could properly display the data. This standard-form address is known as a **uniform resource locator (URL)**, and takes the general form *protocol://computer.domain*, where *protocol* specifies the type of site and *computer.domain* specifies the location (Table 19.1.2). The *http* used for the protocol in World Wide Web URLs stands for *hypertext transfer protocol*, the method used in transferring Web files from the host computer to the client.

Browsers

Browsers, which are used to look at Web pages, are client-server applications that connect to a remote site, download the requested information at that site, display the information on the user's monitor, then disconnect from the remote host. The information retrieved from the remote host is in a platform-independent format called **hypertext markup language (HTML)**. HTML code is strictly text-based, and any associated graphics or sound for that document exist as separate files in a common format. For example, images

Table 19.1.2 Uniform Resource Locator (URL)
Format for Each Type of Transfer Protocol

Site	URL format (example)
General form	<i>protocol://computer.domain</i>
FTP site	<i>ftp://ftp.ncbi.nlm.nih.gov</i>
Gopher site	<i>gopher://gopher.iubio.indiana.edu</i>
Web site	<i>http://www.nhgri.nih.gov</i>

may be stored and transferred in GIF format, developed by CompuServe for the quick and efficient transfer of graphics; while GIF format is most commonly used for graphics, other formats such as JPEG and BMP may also be used. Because of this, a browser can display any Web page on any type of computer, whether it be a Macintosh, IBM-compatible, Linux, or UNIX machine. The text is usually displayed first, then the remaining elements are placed on the page as they are downloaded. With minor exceptions, a given Web page will look the same when the same browser is used on any of the above platforms.

The two major players in the area of browser software are Netscape, with their Communicator product, and Microsoft, with Internet Explorer. As with many other areas where multiple software products are available, the choice between Netscape and Internet Explorer comes down to one of personal preference. While the computer literati will debate the fine points of difference between these two packages, for the average user, both packages perform equally well and offer the same types of features, adequately addressing the Web-browser needs of most users.

It is worth mentioning that, while the Web is by definition a visually based medium, it is also possible to travel through Web space and view documents without the associated graphics. For users limited to line-by-line terminals, a browser called Lynx is available. Developed at the University of Kansas, Lynx allows users to use their keyboard arrow keys to highlight and select hyperlinks, using their return key the same way that Netscape and Internet Explorer users would click their mouse.

Internet versus Intranet

The World Wide Web is normally thought of as a way to communicate with people at a distance, but the same infrastructure can be used to connect people within an organization. Such **intranets** provide an easily accessible repository of relevant information, capitalizing on the simplicity of the Web interface. It also provides another channel for broadcast or confidential communication within the organization. Having an intranet is of particular value when members of an organization are physically separated, whether it be in different buildings or different cities. Intranets are protected in such a way that people who are not on the organization's network are prohibited from accessing the internal Web pages; additional protections through the use of passwords are also common.

Finding Information on the World Wide Web

Most people find information on the Web the old fashioned way—by word of mouth either by using lists such as Table 19.1.3 or by simply following hyperlinks put in place by Web authors. Continuously clicking from page to page can be a highly ineffective way of finding information, especially when the information sought is of a very focused nature. One way of finding interesting and relevant Web sites is to consult **virtual libraries**, which are curated lists of Web resources arranged by subject. Virtual libraries of special interest to biologists include the WWW Virtual Library, maintained by Keith Robison at Harvard and the EBI BioCatalog, based at the European Bioinformatics Institutes. The URLs for these sites can be found in Table 19.1.3.

It is also possible to directly search the Web by using **search engines** such as Alta Vista and Excite, among others. A search engine is simply a specialized program that can perform full-text or keyword searches on databases that catalog Web content. The result of a search is a hyperlinked list of Web sites fitting the search criteria from which the user can visit any or all of the found sites. However, search engines use slightly different methods in compiling their databases. One variation is the attempt to capture most or all of the text of every Web page that the search engine is able to find and catalog (“Web crawling”). Another technique is to catalog only the title of each Web page rather than its

prostate cancer	14,044	53,940	24,376	33,538	60	57

entire text. A third is to consider words that must appear next to each other or only relatively close to one another. Because of these differences in search-engine algorithms, the results returned by issuing the same query to a number of different search engines can produce wildly different results (Table 19.1.4). It may also be noted from Table 19.1.4 that most of the numbers are exceedingly large, reflecting the overall size of the World Wide Web. Unless a particular search engine ranks its results by relevance (for example, by scoring words in a title higher than words in the body of the Web page), the results obtained may not be particularly useful. It is also necessary to keep in mind that, depending on the indexing scheme that the search engine is using, the found pages may actually no longer exist, leading the user to the dreaded “404 Not Found” error.

Compounding this problem is the issue of **coverage**—the number of Web pages that any given search engine is actually able to survey and analyze. A comprehensive study by Lawrence and Giles (1998) indicates that the coverage provided by any of the search engines studied is both small and highly variable. For example, the HotBot engine produced 57.5% coverage of what was estimated to be the size of the “indexable Web,” while Lycos had only 4.41% coverage, a full order of magnitude less than HotBot. The most important conclusion from this study was the extent of coverage increased as the number of search engines are increased and the results from those individual searches are combined. Combining the results obtained from the six search engines examined in this study produced coverage approaching 100%.

To address this point, a new class of search engines called **meta-search engines** have been developed. These programs will take the user’s query and poll anywhere from five to ten of the “traditional” search engines. The meta-search engine will then collect the results, filter out duplicates, and return a single, annotated list to the user. One big advantage is that the meta-search engines take relevance statistics into account, returning much smaller lists of results. Even though the hit list is substantially smaller, it is much more likely to contain sites that directly address the original query. Since the programs must poll a number of different search engines, searches conducted this way obviously take longer to perform, but the higher degree of confidence in the compiled results for a given query outweighs the extra few minutes (sometimes only seconds) of search time. Reliable and easy-to-use meta-search engines include SavvySearch and MetaCrawler (see Table 19.1.3).

Sequence Databases: Integrated Information Retrieval and Data Submission

UNIT 19.1 discusses general tools for electronic information retrieval, giving only brief glimpses of the databases of interest to molecular biologists. This unit provides a more thorough overview of biomedical information resources, focusing on sequence data, structure information, and the associated literature—and also discusses how nucleotide sequence data gets into the databases in the first place—an often neglected but nevertheless important topic. UNIT 19.3 covers sequence homology searching in detail.

First it is important to appreciate not only the variety of available data but also how rapidly it is expanding (Fig. 19.2.1A). The biomedical literature, as represented by MEDLINE, is growing at a rate of 400,000 articles per year. MEDLINE, produced by the U.S. National Library of Medicine (NLM), currently contains bibliographic information and journal abstracts from more than 11,000,000 publications indexed from ~4,300 biomedical journals.

Genetic and physical mapping data are expanding rapidly, as are protein crystal and NMR structures; DNA and protein sequence data have been growing exponentially for years (Fig. 19.2.1B to D). Even faster growth rates are anticipated for cDNA and concerted genome sequencing as technology advances. In mid-1997 complete sequences of *Saccharomyces cerevisiae* and seven bacterial genomes were available and the sequencing phase of the Human Genome Project was initiated. By January 2000, there were 24 bacterial and archaeal genomes completed and another 70 in progress. *Drosophila melanogaster* and *Caenorhabditis elegans* were both essentially done. Other eukaryotes for which substantial genomic sequencing had been done included human, mouse, *Arabidopsis thaliana*, rice, corn and the malaria parasite (*Plasmodium falciparum*).

GenBank is a comprehensive repository of sequence data and associated annotation, built and distributed by the National Center for Biotechnology Information (NCBI) at the NLM in Bethesda, Maryland. GenBank is part of an international collaboration with the DNA Database of Japan (DDBJ) in Mishima and the European Molecular Biology Laboratory (EMBL) Data Library at the European Bioinformatics Institute near Cambridge, United Kingdom. Because these partners exchange data daily, what we refer to here as simply “GenBank” actually contains sequences from GenBank, EMBL, and DDBJ.

In the 1990s, new types of sequence data became a major part of the database entries. For example, “expressed sequence tags” or ESTs are partial sequences that are derived from automated, “single-pass” sequencing on clones that are randomly selected from cDNA libraries, usually with the intent of surveying expressed genes (Adams et al., 1991; Kahn et al., 1992; Okubo et al., 1992; Waterston et al., 1992). These data present certain analytic challenges (Boguski et al., 1993) that are dealt with in UNIT 19.3, and they also require special procedures for batch submission to sequence databases (see discussion of submitting expressed sequence tags (EST), sequence tag site (STS), or genome survey sequence (GSS) data). Short genomic sequences, including those derived from “exon trapping” or “exon amplification” and genomic survey sequences (Church et al., 1993; Smith et al., 1994) present analytical challenges similar to those for ESTs. There are special procedures for submission of these “GSS” entries, similar to the procedures for EST submission. Large-scale sequencing of complete genomes has required additional methods for submission and has spurred development of new ways to access and display the data.

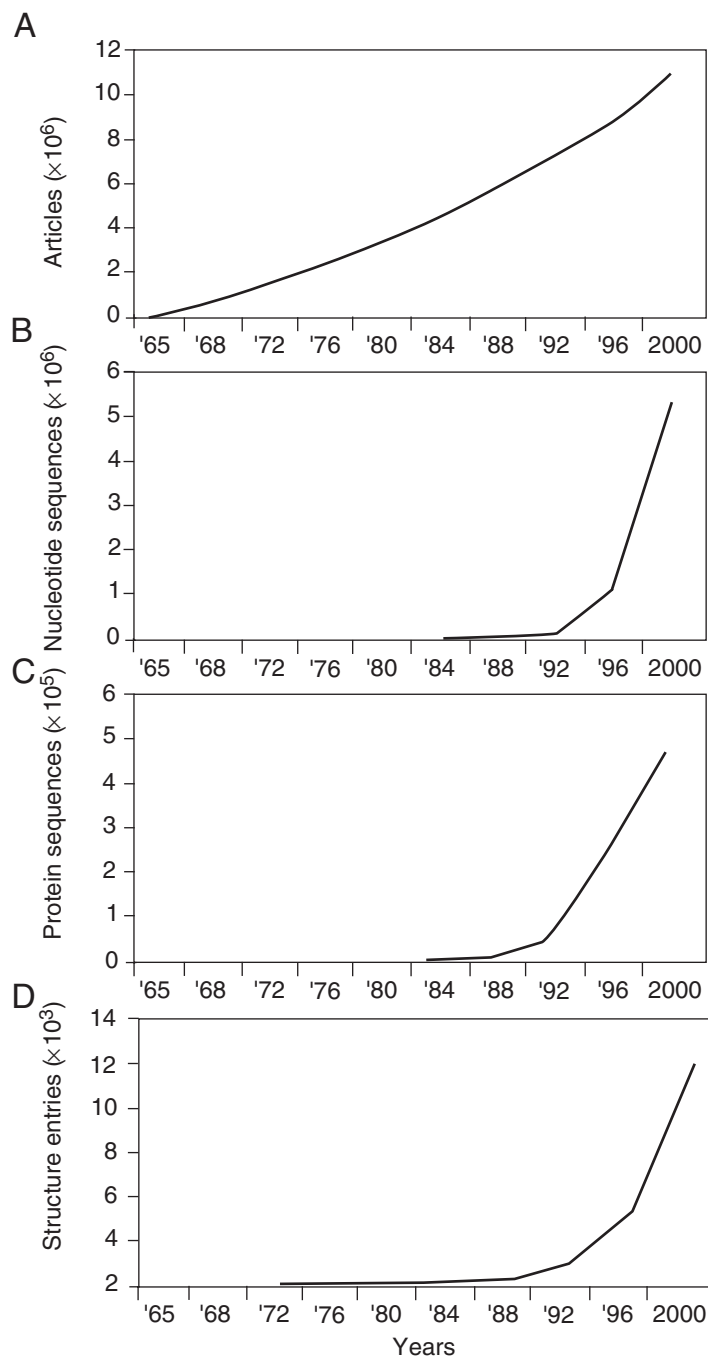

Figure 19.2.1 The cumulative growth of biomedical research data. **(A)** Growth of MEDLINE. **(B)** Growth in the number of nucleotide sequences in GenBank (Benson et al., 2000). **(C)** Growth in the number of protein sequences in the “nonredundant” set of proteins in GenBank. **(D)** Growth of protein and nucleic acid three-dimensional structures represented in the Brookhaven Protein Data Bank, April 2000 (<http://www.rcsb.org/pdb/>). These figures occasionally induce panic or despair in individuals who fear that it is impossible to make sense of so much data; however, modern information retrieval systems such as *Entrez* (Fig. 19.2.2) have succeeded in integrating this data, reducing redundancy, and providing powerful and convenient user interfaces.

Retrieval of records by electronic mail and anonymous FTP are covered in *UNIT 19.1*, as well as access to databases via the World Wide Web. Database homology searching is described in detail in *UNIT 19.3*. The present unit focuses on the wide variety of sequence, structure, and bibliographic databases—as well as how they have been integrated (Fig. 19.2.2) into a single, easy-to-use retrieval environment called *Entrez*, which provides users with “one stop shopping” over the Internet.

INTRODUCTION TO *ENTREZ*

Entrez (Fig. 19.2.2) ties together a diverse set of information resources: it accesses nucleotide and protein sequences from a number of databases as well as genome data from the NCBI Genomes division, three-dimensional structures from MMDB (Molecular Modeling Database of NCBI), human disease data from OMIM (Online Mendelian Inheritance in Man), genetic locus data from LocusLink, and bibliographic citations from PubMed (discussed below). *Entrez* is available through the World Wide Web (<http://www.ncbi.nlm.nih.gov/Entrez/>) and in a client/server version (available by FTP, see <http://ncbi.nlm.nih.gov/Entrez/Network/nentrez.overview.html> or ftp://ncbi.nlm.nih.gov/entrez/README_1). In the case of the client/server application, Network *Entrez* (*NetEntrez*), the client runs on the user’s local machine and interacts with the server at NCBI. Versions of the client program are available for Macintosh, Microsoft Windows, Unix/X-windows and some other systems. *Entrez* for the World Wide Web (*WebEntrez*) works through standard WWW browsers. *NetEntrez* and *WebEntrez* have similar func-

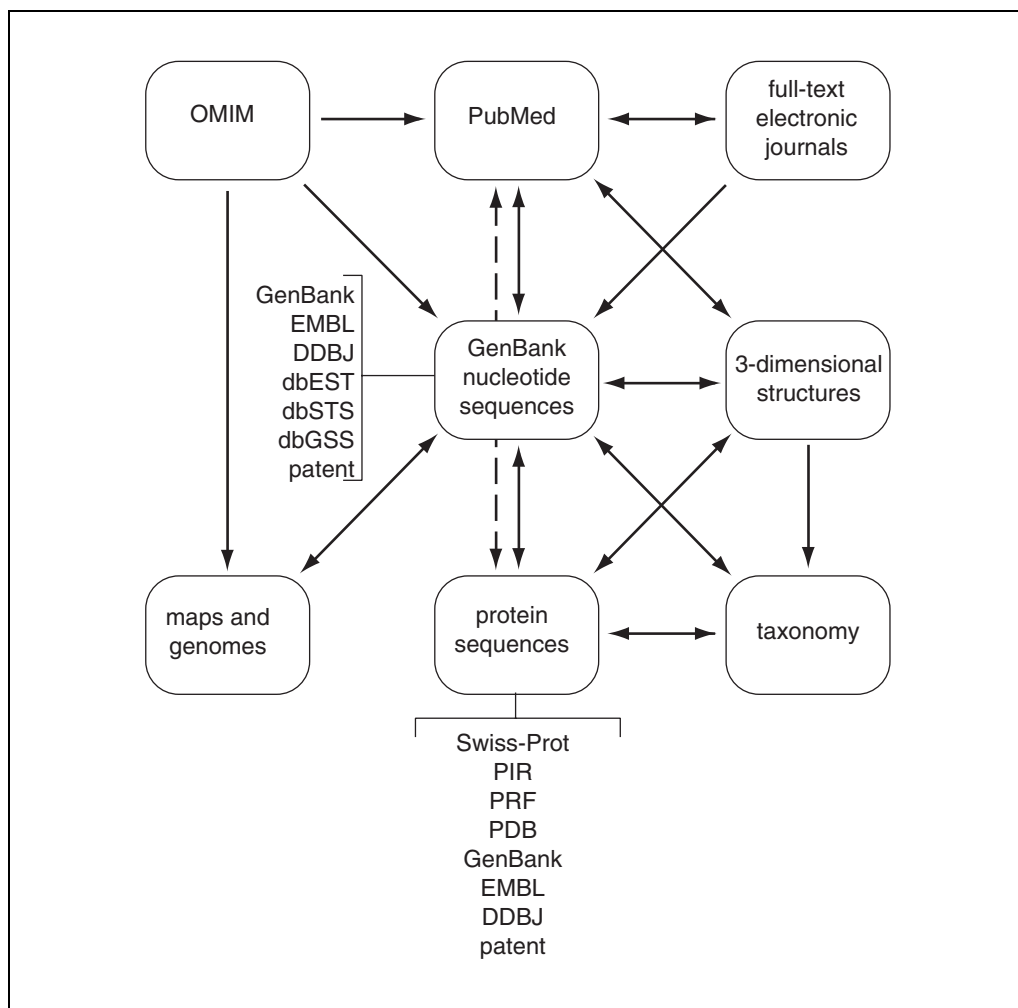

Figure 19.2.2 Data sources and links that constitute the *Entrez* system.

tionality, but there are differences in the way that they are used. *WebEntrez* has the advantage of additional links—e.g., to WebBLAST outputs and to full-text articles for some journals. The *NetEntrez* interface is more intuitive and is often easier to use for complex queries. *Entrez* can be used in many ways and some common scenarios are presented below.

Suppose we have just done a similarity search and have observed a number of promising matches on the “hit list.” The information on this list is often insufficient to allow us to reach even preliminary conclusions about the biological implications of our discovery. Thus, we want to find the publication describing this sequence, which meant, until recently, that we had to use a separate retrieval system to obtain the database record corresponding to the sequence. In this database record we would find the literature citation, and then we would have to take a trip down to the library to actually pull the printed copy of the journal. The “activation energy” for this process is high enough that one sometimes decides it is not worth it for “borderline” matches. Even if our motivation is high enough, perhaps there is no literature citation in the database record, or it involves a journal to which our library does not subscribe. In addition to finding the corresponding publication to confirm our search results, we may also want to retrieve some of the matching sequences and perform additional searches and alignments with these. All together, this is quite an involved process.

Entrez substantially lowers the activation energy by combining all of these activities in an easy-to-use system with a mouse-driven, graphical user interface. *Entrez* establishes all of the requisite links between DNA sequences, the proteins they encode, and the literature that describes their biology. The literature component of *Entrez* comes from the PubMed database, which includes abstracts. While an abstract is not a substitute for the full text of a paper, one can frequently go an amazingly long way in the analysis and interpretation of sequence homology results by the information contained in an abstract. For an increasing list of journals, the Web version of *Entrez* also has links to full-text articles. For many human disease genes, there are also links from PubMed records to the description of the disease in the Online Mendelian Inheritance in Man (OMIM) database. The PubMed database of bibliographic information contains citations from MEDLINE and PreMEDLINE (preliminary citations that eventually become MEDLINE records).

Entrez not only contains explicit links between different data sources, but also implicit or computed links within the data itself. Daily, the entire set of DNA and protein sequence databases are compared among one another and all significant homologies are computed and stored in the system. Thus, it is possible to instantly retrieve the homologs of any sequence in *Entrez* with the click of a mouse, without having to manually perform a new database search. Thus *Entrez* contains within it thousands of answers to questions that have not yet been asked. In one interesting case, this automated system actually “discovered” a significant homology prior to its recognition by a human biologist (Boguski and McEntyre, 1994).

In addition to precomputed sequence homologies, *Entrez* performs a similar operation on PubMed records. It is possible to compute a statistical relationship between two articles based on their frequency of use of significant terms. To indicate what constitutes a significant term, consider two negative examples: i.e., the terms “novel” and “important” are not significant terms because they appear in most scientific papers and thus are not of use in distinguishing one paper from another in terms of specific content. The set of “related articles” (sometimes referred to as “neighbors”) is recomputed daily. This constitutes a very powerful information resource. You can enter *Entrez* via an author name or keyword and retrieve not only a specific paper but an entire bibliography of related material. You can then branch out (or “neighbor out”) to other areas of the information

space and effortlessly go back and forth between the literature and the sequences. Specific examples have appeared in reviews (Baxevanis et al., 1997; Cockerill, 1994; Harper, 1994; Schuler et al., 1996). Further examples can also be found on the NCBI Coffee Break web site (<http://www.ncbi.nlm.nih.gov/Coffeekbreak/>). These pages describe recent biological discoveries and include tutorials demonstrating the linkage between various components of *Entrez* and other bioinformatics tools.

Finding information on sequence homologs using the Web version of *Entrez* is made even easier by the connections between *Entrez* and Web-based BLAST output. For example, it is possible to do a BLAST search using WebBLAST, and the hit list will have hypertext links to protein or nucleotide entries in *Entrez*.

Other features of *Entrez* include taxonomy-based sequence retrieval; from the Web page for the NCBI Taxonomy Browser you can scan through organism names and phylogenetic trees and select the full set of nucleotide or protein sequences for any species. There are now links in *Entrez* from sequences and the literature to protein three-dimensional structures in NCBI's Molecular Modeling Database (MMDB). A three-dimensional structure viewer called Cn3D has also been added to the system. Cn3D can be run as a client/server program or as a "Helper" application integrated into a standard Web browser.

Another special viewer is available for the *Entrez* Genomes division. The genome-level views presented by *Entrez* are built from sequences of complete chromosomes, from composites of sequence fragments, and from integrated genetic and physical maps. *Entrez* allows the user to visualize the sequence information at varying levels of detail, either graphically or as text. The chromosome views are tightly linked to the other *Entrez* component databases, allowing the user to jump effortlessly between maps, sequences, and bibliographic components.

DATA SUBMISSION: GENERAL CONSIDERATIONS

During the late 1970s, when DNA sequencing technology was still new, the *Journal of Biological Chemistry* required that any submitted manuscript containing sequence data be accompanied by the actual autoradiograms, so that reviewers could check the accuracy of the sequence data. We have come a long way since then. Currently, journals prefer not to even publish sequence data because it takes up a great deal of space and is much more usable in electronic form. Most journals, however, require proof in the form of a database accession number that the authors of a publication have sent their data to GenBank, EMBL, or DDBJ. Accession numbers are unique identifiers (consisting of one letter followed by five digits or two letters followed by six digits) that serve as confirmation that the data has been submitted and allow the scientific community to retrieve it. Making sequences available by depositing them in the public databases is recognized as an important responsibility of researchers to the community.

GenBank, the EMBL Data Library, and the DDBJ are partners in the international database collaboration; authors may submit their sequences to whichever database is most convenient without regard to where papers describing those sequences may be published. Sequences should be submitted to a single site; data submitted to one site are exchanged with the others on a daily basis.

Sequences by themselves have little meaning; hence, thorough, accurate biological annotation is very important. One important source of annotation is the published article referring to the sequence; indeed, NCBI has made every effort to link citations to the sequences via MEDLINE and *Entrez*. However, electronic annotation obtained from authors at the time of submission is becoming even more critical as the amount of data

grows (Fig. 19.2.1B), because the only realistic way of searching through this much data is by computer. The database staff are very helpful in assisting submitters in the proper annotation of their data.

Sequences submitted to any of the sequence databases go through a series of validation checks conducted by the database staff. Accession numbers are returned to the authors, usually within 24 hr, or less, if there are no problems with the submission(s). The accession number should be included in any manuscript that deals with the sequence, preferably in a footnote on the first page of the article (or in the manner prescribed by the individual journal). The full text of the provisional record is passed back to the authors for their review prior to being released. Authors may request that the data be kept confidential until publication. See Internet Resources for URLs and e-mail addresses of the sequence databases.

SUBMITTING A SEQUENCE TO THE NUCLEOTIDE DATABASE

Submission Methods

As mentioned above, a sequence can be submitted to any of the three sequence databases (see discussion of Data Submission: General Considerations; also see Internet Resources). A submission to GenBank is described in this section, but readers should keep in mind that the example could apply to DDBJ or EMBL submissions. Researchers should submit their sequences to whichever database is most convenient. The important point is to only submit to one database.

If the researcher has access to the World Wide Web, the easiest way to submit data to GenBank is to use the BankIt form on the NCBI home page (or for DDBJ and EMBL submissions, use Sakura or WebIn, respectively; see Internet Resources). BankIt (<http://www.ncbi.nlm.nih.gov/BankIt/>) allows one to simply copy and paste most of the submission information and data directly out of one's word processor or sequence-analysis package into an electronic form. BankIt was designed to handle the most common types of GenBank submissions, such as mRNAs or short genomic records.

NCBI also has developed a platform-independent submission program called Sequin, which runs stand-alone or over the network. Sequin is suitable for a wide range of sequence lengths and complexities, including traditional (gene-sized) nucleotide sequences, segmented entries (e.g., genomic sequences of a spliced gene where not all of the intronic sequences have been determined), long (genome-sized) sequences with many annotated features, and sets of related sequences (i.e., population, phylogenetic, or mutation studies of a particular gene, region, or viral genome). It also has a number of built-in validation functions for enhanced quality assurance. The validator checks such things as missing organism information, incorrect coding-region lengths (compared to the attached protein sequence), internal stop codons in coding regions, mismatched amino acids, or nonconsensus splice sites. Sequin can present various views of the data, including GenBank-, FASTA-, and EMBL-formatted files, and a graphical view of the sequence including features and alignments. A sequence editor is built into Sequin; this editor automatically adjusts feature intervals as the sequence is edited. Additional capabilities include sequence-analysis functions—e.g., a coding region translator, an ORF finder, and a function that will replace a sequence with the sequence of the complementary strand and simultaneously adjust the positions of the features.

Sequin is available from NCBI by anonymous FTP (UNIT 19.1); see <http://www.ncbi.nlm.nih.gov/Sequin/index.html> for further details on Sequin, including full detailed documentation.

BankIt is best suited for submitting one or a small number of sequences. Sequin provides more of a data “workbench” environment that can accommodate large as well as small contigs with detailed annotation that can be added over time and which can finally be used to submit data to GenBank. In addition to these methods, NCBI provides streamlined submission procedures for large data sets—e.g., expressed sequence tags (ESTs), sequence-tagged sites (STSs), genome survey sequences (GSSs), and high-throughput genome sequences (HTGSs). NCBI provides a means for interacting with the laboratory information-management systems of genome-sequencing centers to ensure the efficient, timely, and accurate submission of their data. These options are discussed in more detail in subsequent sections (see discussion of Submitting EST, STS, or GSS Data, and Submitting High-Throughput Genome Sequences).

Instructions and Tips for Preparing Sequence Submissions

The most important item is, of course, the new DNA sequence itself. It should be free of sequencing errors, cloning artifacts, etc.; standard things to check for in this regard are described below. In the special case of “single-pass” sequences such as ESTs, the data often contain ambiguities and sequencing errors; in these cases it is important to note it as “single-pass” data.

What does one need to know about a sequence to submit it to GenBank? The sequence record contains references to the article in which the sequence is published, information on the submitters, and information on the source organism. The record also should describe the sequence as fully as possible. Significant regions of the sequence, such as coding region, promoter region, and transcription boundaries, are labeled with defined feature names. These features are detailed in the GenBank Feature Table document, available by anonymous FTP (UNIT 19.1) from <ftp://ncbi.nlm.nih.gov> in the directory */genbank/docs*, or on the Web at <http://www.ncbi.nlm.nih.gov/collab/FT/index.html>. This list of features (along with their syntax and qualifiers) is somewhat overwhelming, and it is much easier to familiarize oneself with this system by simply looking at some well-done examples of existing GenBank records (see Appendix to this unit).

The DEFINITION line (see Appendix to this unit for illustrations of this and other elements of the GenBank record) is a short description of the biological sequence in the record and the organism from which it was derived. The LOCUS field contains the length of the sequence, the type of sequence, and the date that it was released to the public (or re-released following any updates, corrections, or modifications). The ORGANISM field in the SOURCE section contains a complete phylogenetic classification. The REFERENCE section contains one or more citations, the name and address of the submitter, and the date that the sequence was originally submitted to the database. The COMMENT field may be used to include annotations that cannot be accommodated in the FEATURES table. REFERENCES and COMMENTS that apply to the complete record are referred to as “descriptors.” Whenever possible, annotations should be expressed as “legal” FEATURES, using the proper syntax, because this is the only manner in which they are computer-readable. A more complex example, illustrating detailed annotation of a human breakpoint cluster region, is the GenBank record with the accession number U07000, which can be obtained from *Entrez* (see Introduction to *Entrez*, above) or the e-mail server. A few other examples are: accession numbers AF010398-AF010400, a segmented set with three segments (see Appendix to this unit, Example 4); AF018073, a bacterial sequence with multiple genes; and AF015226, a mitochondrial sequence with multiple genes (see Appendix to this unit, Example 3).

Further details on submission to the sequence databases can be found on the database Web sites and in Kans and Ouellette (1998). The following are seven important questions that should be asked when preparing a sequence for submission.

1. *What organism is the source of this DNA?*

Taxonomic classification of the organism from which the sequence was isolated is very important when using GenBank to ensure that the correct genetic code is used when translating the DNA to generate the protein product from a coding sequence (CDS) feature (see item 4). If the wrong taxa are used, or if a mitochondrial origin is not indicated, then an erroneous translation will be produced and may go undetected. Correct taxonomic classifications are also important for retrieval purposes via *Entrez*.

Over 60,000 species are represented in GenBank. The ten most common at this time are: *Homo sapiens* (human), *Mus musculus* (mouse), *Drosophila melanogaster* (fruit fly), *Caenorhabditis elegans* (nematode worm), *Arabidopsis thaliana* (thale cress), *Oryza sativa* (rice), *Rattus norvegicus* (lab rat), *Danio rerio* (zebrafish), *Saccharomyces cerevisiae* (baker's yeast), and *Lycopersicon esculentum* (tomato).

A sequence submission in most cases need only include the genus and species, which the database staff use to obtain the complete classification from NCBI's Taxonomy Database. If precise information is not available, the researcher should send in the best conjecture as to the genus, species, and/or common name, and the database staff will attempt to determine the proper classification.

Because there is great biodiversity among microbial organisms used for research, it is often important to include the strain name or number with the DNA sequence for microbial submissions. These will appear as a qualifier, for example, */strain="S288c"*, and are quite useful when doing sequence comparisons or trying to explain certain sequence conflicts. Strain information is also important in the context of genetic mapping data from the mouse (e.g., */strain="BALB/c"*) and other organisms.

2. *Is this a genomic or mRNA (cDNA) sequence?*

The sequenced molecule is most often DNA, but the annotation should indicate the biological identity of the starting material. For example, cDNA (i.e., an mRNA that was made into a DNA molecule using reverse transcriptase so that it could be cloned) should be annotated in the database as an mRNA. HIV is an interesting case. HIV sequences, as well as those from other retroviruses, may be classified in different ways: as cDNA corresponding to genomic RNA (therefore as "RNA"); as nonintegrated, nonproviral DNA (therefore as single-stranded DNA or "ssDNA"); or as integrated, proviral DNA, (therefore as double-stranded DNA or "dsDNA").

3. *If this is a genomic sequence, are there introns for which the sequence has not been determined?*

In many cases only parts of a gene have been sequenced—e.g., the exons with only a few nucleotides of flanking intron. In this case it is necessary to create what is known as a "segmented entry." What this means is that the researcher will create individual submissions for each discrete sequence and indicate the relationships between them—i.e., their linear order. Additionally, if the approximate distances (in base pairs or kilobase pairs) between the segments of a set are known, this information should be included. This will permit the complete gene to be reassembled automatically by software programs. It should be noted that this is an example of a type of entry for which Sequin is the best tool.

4. Is there a coding sequence (CDS) or other RNA product (rRNA or tRNA) on this DNA? If so, what are their positions in the DNA sequence?

If this is an mRNA, or if it is a DNA molecule encoding a protein product, it is important to indicate that a coding region is present and to supply its start and stop codons. RNA products also have boundaries or coordinates that should be indicated. An important check that is done with all submissions is to verify that the coordinates submitted correspond with the indicated feature(s). If there are any discrepancies, these are resolved by the database annotation staff in consultation with the submitter.

As described above under question 1, a common problem occurs when the taxonomic information is incorrect or incomplete, leading to the use of an improper genetic code. Fifteen different genetic codes are presently in use, as outlined in the GenBank Feature Table Document (also see information on BLAST parameters in the BLAST unit, see *UNIT 19.3*.) Any codon usage that is not represented in this list must use the translation exception qualifier (*/transl_except*) to indicate the discrepancy.

Sequin has a built-in tool for analyzing open reading frames. The user can set the minimum size of the open reading frames and the genetic code and the “ORF Finder” will graphically display all open reading frames in a sequence. There is also a separate Web version of the ORF Finder (<http://www.ncbi.nlm.nih.gov/gorf/gorf.html>).

5. If there is a CDS, what is gene name and the name of the encoded protein? If the gene product is an enzyme, what is the EC number?

Putting a protein or gene product name on a CDS is the best way of labeling the protein encoded by the DNA. It is possible to add more than one qualifier, but a */product*, */gene*, and */EC_number* (if the product is an enzyme) are quite sufficient. This is the label that will be carried over to the protein databases—e.g., GenPept or Swiss-Prot. Enzyme Commission (EC) numbers can be obtained or verified using the World Wide Web (*UNIT 19.1*) at <http://www.expasy.ch/enzyme/enzyme-search-ec.html>.

6. Is there information about your sequence for which there does not seem to be an appropriate place on the forms?

There are sometimes problems finding the appropriate place to put a given feature in the BankIt or Sequin forms. In such cases, just attach a note to the submission and the database staff will find the correct place or contact you for more information.

7. Is this sequence ready for submission? Has it been tested for the presence of vector contamination, mitochondrial DNA, ribosomal and tRNAs, and repetitive (e.g., Alu) elements?

Potential problems can be detected by using the BLAST programs to compare a new sequence against special data sets that represent common “contaminants.” The network-aware version of Sequin will allow you to run BLASTN against vector and mitochondrial databases. The VecScreen system has recently been developed for quickly finding vector contamination in sequences. VecScreen is automatically run on BankIt sequences and it can be run from within Sequin. It can also be used independently from its own web page (<http://www.ncbi.nlm.nih.gov/VecScreen/VecScreen.html>). Other validation routines are built into both the Sequin and BankIt submission tools. These routines include a comparison of the conceptual translation of a coding region with the submitted amino acid sequence, a check that actual data length matches the given length, a check for correct use of qualifiers on features, and a check for illegal characters. Although the database staff applies a number of

validation tests to each new sequence, it is more expeditious for authors themselves to catch any problems prior to submission.

SUBMITTING AN UPDATE OR CORRECTION TO AN EXISTING GENBANK ENTRY

Authors are encouraged to submit updates or corrections to their sequence records. In fact anyone who notices a problem, error or omission in a database record should bring this to the attention of the database staff. It is not uncommon for the authors to forget to notify the databases that a previously confidential sequence may now be released. If an accession number is seen in a published article and the sequence cannot be retrieved, this is almost certainly the case. The databases will release the data if the complete journal citation is supplied, including the full title of the paper, or if a copy of the title page plus the page showing the accession number is faxed to the databases (see Internet Resources for contact information).

Update information consisting of a simple revision, such as a citation change or release of information, can be submitted by sending an e-mail message in paragraph form explaining the change. The message must include the accession number of the sequence to be updated along with all update, correction, or publication information.

Updates can also be submitted using BankIt or Sequin. See the BankIt or Sequin Web pages for details (see Submitting a Sequence to the Nucleotide Database, Submission Methods).

SUBMITTING EST, STS, OR GSS DATA

Expressed-sequence tags (ESTs), sequence-tagged sites (STSs), and genome survey sequences (GSSs) are usually submitted to GenBank and the specialized databases dbEST, dbSTS, or dbGSS as batches of dozens to thousands of entries, with a great deal of redundancy in the citation, submitter, and library information. For these data, there are special procedures designed to improve the efficiency of the submission process. A special “tagged flat file” input format is used. Documents describing the format can be obtained by sending a request to *info@ncbi.nlm.nih.gov*. They are also available from the dbEST, dbSTS, or dbGSS Web pages at: <http://www.ncbi.nlm.nih.gov/dbEST/>, <http://www.ncbi.nlm.nih.gov/dbSTS/>, and <http://www.ncbi.nlm.nih.gov/dbGSS/>, respectively. Once the data are ready to submit, they should be e-mailed to *batch-sub@ncbi.nlm.nih.gov*. For large data sets, an account can be set up into which the data can be deposited by FTP. For more information write to *info@ncbi.nlm.nih.gov*.

SUBMITTING HIGH-THROUGHPUT GENOME SEQUENCES (HTGS)

Some groups may find that their needs are not conveniently met by the standard means for data submission—e.g., a genome center that has its own internal information system or a group assembling a very large contig. The staff of NCBI, EBI, or DDBJ are happy to discuss these issues and make special arrangements with such groups so that their data can be conveniently incorporated into the databases. This includes setting up automatic exchange of data, creation of special FTP accounts, and the generation of tools to ensure data exchange in the most useful format. At NCBI, for example, FTP accounts have been set up for all submitting genome sequencing centers and a variety of tools have been created for accelerating the submission of high-throughput genome sequences (HTGS).

For large sequencing operations that wish to develop an integrated direct submission system, or for those researchers who have a data submission problem that does not seem

to be addressed by the standard tools, e-mail can be sent to *info@ncbi.nlm.nih.gov*. The situation should be explained in as much detail as possible and a phone number and postal address should be provided so that the GenBank staff can contact the investigators to discuss their situation.

CONCLUSION

The Handbook of Nucleic Acid Sequences (Barrell and Clark, 1974) contained all known DNA and RNA sequences available at that time. The book was only about half an inch thick and contained 51 tRNA sequences, 11 5S rRNA sequences, some assorted viral and mRNAs, and 9 DNA sequences—the longest of which was an 89-nucleotide sequence from bacteriophage f1. All together, this “database” amounted to ~10,000 nucleotides. If the current data in GenBank (5.8 billion nucleotides in 5.6 million entries) were published in a comparable printed form the stack of books would be about the height of Mount McKinley (20,320 feet).

The early history of electronic sequence databases is covered in part by Smith (1990). Developments since 1990 can be surveyed by consulting the annual database issues of *Nucleic Acids Research* (e.g., Benson et al., 2000) and the authors recommend scanning this special issue occasionally to learn about new databases and services. There has been a great proliferation of electronic data resources and a revolution in their delivery to the scientific community via the Internet, as described in *UNIT 19.1*.

This unit has discussed retrieval and submission of sequence data and associated literature as well as access to precomputed homology results via the *Entrez* system. But the real power of sequences is the possibility of making new and sometimes profound discoveries by computing on the data. The information content of sequences is a fundamental link between genotype and phenotype, and it is possible to infer much about genes and proteins—their functions, structures, evolution, and regulation—by the simple discovery of a sequence homology. For detailed discussion of how to effectively search for homologies in sequence databases, consult the BLAST unit (*UNIT 19.3*).

APPENDIX: SAMPLE GENBANK RECORDS

Note that these examples present data in a format called the “GenBank report.” This file format is available with Sequin or *Entrez*, but other formats for viewing the data are also available, including the “EMBL” format, FASTA format (see *UNIT 19.3*), and a graphical view.

Example 1: A Human mRNA Sequence Record with the Feature Labels and Other Landmarks Underlined

This is a typical record for an mRNA sequence with a coding region (*CDS*) and *gene* features. The *CDS* feature includes */gene*, *standard_name*, and */function* qualifiers, which are a few of many qualifiers that could be used. There is also the */translation* qualifier with the amino acid sequence for the coding region. The position of the coding region on the nucleotide sequence is given by the interval 731..3616. The record also has a *source* feature. This feature is required for all GenBank entries. A *source* feature must at a minimum include an */organism* qualifier. There are two citations associated with the record. *REFERENCE 1* is the publication in which the sequence is described and the accession number is published. *REFERENCE 2* shows the name and address of the submitter of the record and the date of submission. The *ORGANISM* field contains the name of the organism (the same as that given in the */organism* qualifier) and the phylogenetic classification. The *DEFINITION* gives a brief summary of the identity of the sequence. The typical basic *DEFINITION* consists of the organism name, gene product, gene symbol in parentheses, molecule type (e.g., mRNA), and a statement about the completeness of the coding region. The *LOCUS* field gives the length of the sequence in the record, the molecule type (mRNA, DNA, RNA, etc.), and the date the current version of the record was released to the public. Note that GenBank report qualifiers are underlined in Example 1 for ease of identification, but not in actual GenBank reports.

Example 2: A Bacterial Genomic Sequence Record

This bacterial genomic sequence contains several genes. The record has three *CDS* features for two complete protein coding regions (*mutS* and *mutL*) and one partial coding region (*cotE*). There are additional features in the record: ribosome binding sites (*RBS*), promoter regions (*-10_{signal}*) and *stem_{loop}* regions. The *DEFINITION* includes the name of all three genes and indication of the completeness of the coding regions. *REFERENCE 2* is the main citation for this entry. *REFERENCE 1* cites a paper that pertains only to nucleotides 1 to 81 of the sequence.

Example 3: A Mitochondrial DNA Record

This is a mitochondrial sequence and is similar to the bacterial genomic sequence record (see Example 2). It has two partial protein coding regions (*COI* and *COII*) and also a region encoding a tRNA (*tRNA* feature). The *source* feature includes a */mitochondrion* qualifier to show that the nucleotide sequence is from mitochondrial DNA. This is also indicated in the *ORGANISM* field and in the *DEFINITION*.

Example 4: A Human Genomic Sequence in Three Segments

This is a set of three records for a human gene. The sequence in an individual GenBank entry must be contiguous with no gaps. In the case of this genomic sequence there are gaps between exon 1 and exon 2 and between exon 2 and exon 3. Thus the gene sequence is entered as three entries. These are, however, linked together in what is termed a “segmented set”. Each entry includes a *SEGMENT* line showing the total number of segments in the set and the segment number of the individual entry. The three records together include the complete coding region for the gene. The *CDS* feature appears in the file on the last segment containing coding sequence in the set. It indicates which parts of each sequence make up the coding region and gives the full translation.

Sequence Similarity Searching Using the BLAST Family of Programs

Database sequence similarity searching is carried out thousands of times each day by researchers worldwide. Scientists in traditional laboratories use search results, for example, to infer the functions of newly discovered cDNAs, predict new members of gene families, and explore evolutionary relationships between sequences. In turn, they populate sequence databases with biochemically and/or genetically characterized sequences. With the advent of whole-genome sequencing, a new breed of scientist is now using these characterized sequences to predict the location and function of coding and regulatory regions in large segments of genomic DNA. Their contribution to the sequence databases is the submission, at a rapid pace, of generally uncharacterized mRNA and genomic DNA sequences. These data can then be used by the first group of scientists to enhance the understanding of their sequences. Both types of sequencing efforts have greatly increased the size and quality of the sequence databases in recent years. Thus, sequence similarity searching has become a valuable research tool for all molecular biologists (Altschul et al., 1994; Schuler, 1998).

Over the years, a number of algorithms have been implemented that allow searching of sequence databases. The most useful of these tools should share the following characteristics: (1) Speed. Because today's databases are so large, the programs must be fast in order to process megabases of sequence in seconds. (2) Sensitivity. The programs must report all potentially interesting similarities. (3) Rigorous statistics. The programs must provide a way to evaluate the significance of the results. (4) Ease of use. Scientists with no formal training in sequence-analysis algorithms should understand how to use the programs and interpret the results. Advanced users should have the option to tailor the programs to their needs. (5) Access to up-to-date databases. The doubling time of GenBank is currently ~16 months. It is important to search the most recent version of the database.

The BLAST (Basic Local Alignment Search Tool) family of sequence similarity search programs satisfies the above criteria. In short, users input either a nucleotide or amino acid query sequence, and search a nucleotide or amino acid sequence database. The program returns a list of the sequence "hits," alignments to the query sequence, and statistical values. This unit describes how to choose an appropriate BLAST program and database, perform the search, and interpret the results.

ACCESSING BLAST PROGRAMS AND DOCUMENTATION

The National Center for Biotechnology Information (NCBI) currently supports two versions of BLAST free of charge: BLAST 2.0 (gapped BLAST) and Position-Specific Iterated BLAST (PSI-BLAST). BLAST 2.0 is the standard version of BLAST, which allows a user to search a sequence database with a nucleotide or protein sequence of interest. BLAST 2.0 places gaps into the query and target sequences so that separate areas of similarity between the two sequences can be returned as one hit. PSI-BLAST is an iterative BLAST search, which is optimized for finding distantly related sequences.

Other BLAST programs are also available from the NCBI Web page. "BLAST 2 sequences" uses the BLAST search engine to produce an alignment of two sequences entered by the user. On the Specialized BLAST pages, researchers can use the BLAST engine to search sequences that are not in GenBank. At present, these databases include unfinished microbial genomes, *P. falciparum* (the human malaria parasite), and tentative

human consensus (THC) sequences from The Institute for Genomic Research (TIGR). The content of these pages is, however, subject to change.

The easiest and most popular way to access the BLAST suite of programs is through the NCBI World Wide Web site, at <http://www.ncbi.nlm.nih.gov/BLAST/>. All versions of BLAST are accessible from this site, and can be used to query all sequence databases available at the NCBI. Documentation, which includes an overview of BLAST, BLAST frequently asked questions (FAQs), a “What’s New” page, the BLAST manual, and a list of references, is also available here.

For users who want to run BLAST against private local databases or downloaded copies of NCBI databases, the NCBI offers a stand-alone version of the BLAST program. BLAST binaries and documentation are provided for the latest versions of IRIX, Solaris, DEC OSF1, and Win32 systems. BLAST 2.0 executables may be found on the NCBI anonymous FTP server at <ftp://ncbi.nlm.nih.gov/blast/executables/>.

BLAST can also be run as a client-server program, in which the user installs client software on a local machine that communicates across the network with a server at NCBI. This setup is useful for researchers who run large numbers of searches on NCBI databases, because they can automate the process to run on their local computer. The BLAST client may be found on the NCBI anonymous FTP server at <ftp://ncbi.nlm.nih.gov/blast/network/netblast>.

The NCBI BLAST e-mail server is the best option for people without convenient access to the Web. A similarity search can be performed by sending a properly formatted e-mail message containing the nucleotide or protein query sequence to blast@ncbi.nlm.nih.gov. The query sequence is compared against a specified database and the results are returned in an e-mail message. For more information on formulating e-mail BLAST searches, please send a message consisting of the word HELP to the same address, blast@ncbi.nlm.nih.gov.

This unit concentrates on the BLAST searches which can be performed from the NCBI Web site. The other implementations are mainly for advanced users of BLAST, or those with special needs. For any of these services, questions should be directed to blast-help@ncbi.nlm.nih.gov.

INTRODUCTION TO BLAST

Basic Versus Advanced BLAST Searches

BLAST 2.0 is available in a basic or advanced version. In both versions, the user can select the type of BLAST program and the database to be searched, and choose whether to filter the query sequence to mask low-complexity regions (see below). The advanced version allows the user to change parameters as well. For most researchers, the Basic version, which uses the default parameters, is adequate. For a discussion of BLAST parameters, see Appendix A at the end of this unit.

BLAST Programs

Five types of the BLAST program have been developed to support sequence similarity searching using a variety of nucleotide and protein sequence queries and databases. These programs are listed and described in Table 19.3.1. The type of BLAST search to be carried out is dependent on the type of information that is desired.

Table 19.3.1 BLAST Search Programs

Program	Query sequence	Database sequence	Comments
BLASTP	Protein	Protein	Can be run in standard mode or in a more sensitive iterative mode (PSI-BLAST), which uses the previous search results to build a profile for subsequent rounds of similarity searching.
BLASTN	Nucleotide (both strands)	Nucleotide	Parameters optimized for speed, not sensitivity; not intended for finding distantly related coding sequences. Automatically checks complementary strand of query.
BLASTX	Nucleotide (six-frame translation)	Protein	Very useful for preliminary data containing potential frameshift errors (ESTs, HTGs, and other “single-pass” sequences).
TBLASTN	Protein	Nucleotide (six-frame translation)	Essential for searching protein queries against EST database. Often useful for finding undocumented open reading frames or frameshift errors in database sequences.
TBLASTX	Nucleotide (six-frame translation)	Nucleotide (six-frame translation)	Should be used only if BLASTN and BLASTX produce no results. Restricted for search against EST, STS, HTGS, GSS, and Alu databases.

NCBI Databases

One frequent mistake in sequence similarity searching is failure to search an up-to-date database. The NCBI produces GenBank (Benson et al., 1998; <ftp://ncbi.nlm.nih.gov/genbank/gbrel.txt>) and updates it daily. It also shares data on a daily basis with the DNA Data Bank of Japan (DDBJ; Tateno et al., 1998) and the European Molecular Biology Laboratory (EMBL; Stoesser et al., 1998). A search of the NCBI databases using the BLAST Web page, client, or e-mail server guarantees access to the most recent database. The NCBI supports a number of databases for sequence similarity searching. These databases are subject to change, and a current list and description are available on the NCBI Web site at http://www.ncbi.nlm.nih.gov/BLAST/blast_databases.html. This section describes some of the commonly used NCBI databases. Examples demonstrating the utility of various BLAST programs and NCBI databases are given in the next section.

Peptide sequence databases for BLASTP and BLASTX

nr: The *nr* (nonredundant) database is the most comprehensive. GenBank, DDBJ, and EMBL are nucleotide sequence databases. If any nucleotide sequence in any of the databases is annotated with a coding sequence (CDS), this CDS appears in *nr*. *nr* also contains protein sequences obtained from PDB (sequences associated with 3-dimensional structures in the Brookhaven Protein Data Bank), Swiss-Prot (a curated database of protein sequences; Bairoch and Apweiler, 1998), PIR (Protein Identification Resource, a comprehensive collection of protein sequences; Barker et al., 1998), and PRF (Protein Research Foundation). Although *nr* may contain multiple copies of similar sequences, identical sequences are merged into one entry. To be merged, two sequences must have identical lengths and every residue at every position must be the same. There are *nr* databases for both peptide and nucleotide sequences. The peptide database is automatically selected for BLASTP and BLASTX searches.

month. The month database receives its sequences from the same sources as nr, but contains only those sequences released within the last 30 days. All sequences in month are also present in nr.

Alu. The Alu database contains six-frame translations of representative *Alu* repeats from all *Alu* subfamilies (Claverie and Makalowski, 1994). If a query sequence containing an *Alu* repeat is used in a BLAST search of nr or month, many of the resulting high-scoring hits will also contain *Alu* sequences. It may be useful, especially with a genomic sequence query, to perform a search of the Alu database to identify the location of any *Alu* repeats that might produce high-scoring and potentially misleading hits in queries of other databases.

Nucleotide sequence databases for BLASTN, TBLASTN, and TBLASTX

nr. The nr (nonredundant) database contains all nucleotide sequences present in GenBank, EMBL, and DDBJ. It also contains nucleotide sequences obtained from PDB (sequences associated with 3-dimensional structures in the Brookhaven Protein Data Bank). nr comprises only sequences that are normally well annotated, so it does not contain expressed sequence tag (EST), sequence-tagged site (STS), genome survey sequence (GSS), or high-throughput genomic (HTG) sequences. Although nr may contain multiple copies of similar sequences, identical sequences are merged into one entry. To be merged, two sequences must have identical lengths and every nucleotide at every position must be the same.

month. The month database contains all nucleotide sequences present in GenBank, EMBL, DDBJ, and PDB that were released within the last 30 days. Unlike nr, it also contains EST, STS, GSS, and HTG sequences released within the last month.

EST. EST accesses a nonredundant copy of all ESTs present in GenBank, EMBL, and DDBJ (Boguski et al., 1993). ESTs are short sequences, a few hundred nucleotides in length, which are derived by partial, single-pass sequencing of inserts of randomly selected cDNA clones (Adams et al., 1991). Since the number of ESTs is increasing rapidly, it is an important database to search for novel cDNAs. As of August, 1998, ~70% of the sequences in GenBank were ESTs; of these, 61% were from human, 20% from mouse.

STS. STS contains a nonredundant copy of all STSs present in GenBank, EMBL, and DDBJ. An STS is a short unique genomic sequence that is used as a sequence landmark for genomic mapping efforts (Olson et al., 1989). As of August, 1998, 83% of the sequences in the STS database were from human.

HTGS. HTGS contains “unfinished” DNA sequences generated by the high-throughput sequencing centers (Ouellette and Boguski, 1997). A typical HTG record might consist of all the first-pass sequence data generated from a single cosmid, BAC, YAC, or P1 clone. The record is composed of two or more sequence fragments that have a total length of ≥ 2 kb and contain one or more gaps. The sequences are normally updated by the sequencing centers as more data become available. A single accession number is assigned to this collection of sequences. The accession number does not change as the record is updated, and only the most recent version of the record remains in GenBank. Phase 1 HTG sequences are unordered, unoriented contigs with gaps. Phase 2 HTG sequences are ordered, oriented contigs with or without gaps. All HTG records contain a prominent warning that the sequence data is unfinished and may contain errors. When a record is considered finished, it becomes a Phase 3 HTG and is moved to the nr database with the same accession number. HTGS is a valuable source of new genomic sequences not yet in nr.

GSS. GSS includes short, single-pass genomic data identified by various means (Smith et al., 1994). Many of the sequences have been mapped. As of August, 1998, 80% of the sequences in GSS were from human, 14% from *Arabidopsis thaliana*.

Alu. The Alu database contains representative *Alu* repeats from all *Alu* subfamilies (Claverie and Makalowski, 1994). If a query sequence containing an *Alu* repeat is used in a BLAST search of the above nucleotide databases, many of the resulting high-scoring hits will also contain *Alu* sequences. It may be useful, especially with a genomic sequence query, to perform a search of the Alu database to identify the location of any *Alu* repeats that might produce high-scoring and potentially misleading hits in queries of other databases.

Vector. The Vector database contains nucleotide sequences of a number of standard cloning vectors. New sequences should be screened against the Vector database to assure that they do not contain any vector contamination.

Mito. The Mito database contains representative mitochondrial sequences from many families. Nuclear-derived sequences may be screened against the Mito database to assure that they do not contain any mitochondrial contamination.

Formatting the Query Sequence

Users of the BLAST Web page can initiate a search either by entering the sequence itself, or, if the sequence is already in the sequence database, by entering the accession number or gi (see Appendix B at the end of this unit). The preferred format for entering new sequences is the so-called FASTA format; however, if the sequence is not in FASTA format or the sequence is interspersed with numbers and spaces, BLAST will still accept the query. A sequence in FASTA format begins with a single-line description, followed by lines of sequence data. The description line is distinguished from the sequence data by a > symbol (greater than) in the first column. An example sequence in FASTA format is:

```
>aaseq Human choroideremia protein
MADNLPTEFDVVIIGTGLPESILAAACSRSGQRVLIHIDRSRYGGNWFSSFSGLLSWLKEYQQNDIGE
ESTVWQDLIHETEEAITLRKKDETIQHTEAFPYASQDMEDNVVEIGALQKNPSLGVSNFTFEVLDSALP
EESQLSYFNSDEMPAKHTQKSDTEISLEVTDVVEESVEKEKCYGDKTCMHTVSDKDGDKDESKSTVEDKAD

ADVFNKELTMVEKRMLMKFLTFCLEYEQHPDEYQAFRQCSFSEYLNKTKKLT PNLQHFVLHSIAMTSESS
CTTIDGLNATKNFLQCLGRFGNTPFLLFPLYGQGEIPQGFRCMCAVFGGIYCLRHVKVQCFVVDKESGRCKA
IIDHFGQRINAKYFIVEDSYLSEETCSNVQYKQISRAVLITDQSI LKTDLDQQTSILIVPPAEPGACAVR
VTELCSSMTMCKDTYLVHLTCSSSKTAREDLSEVVKLFTPYTETINEEELTKPRLWLALYFNMRDSS
GISRSSYNGLP SNVYVCSGPDGCLGNEHAVKQAETL FQEIFPTEEF C P P P P N P E D I I F D G D D K Q P E A P G T
NNVVMAKLESSEESKNLESPEKHLQN
```

Alternatively, the user can enter the database accession number or gi. The above sequence is in fact already in the database with a gi identifier of 116365 and a Swiss-Prot accession number of P26374. Either of these sequence identifiers can be entered on the BLAST page. The type of identifier (for nucleotide or protein sequence) must match the type of query sequence used in that search (Ostell and Kans, 1998; Ouellette, 1998). Sequences in manuscripts are often referred to by their GenBank accession number; however, this accession number refers to a nucleotide (not protein) sequence, and cannot be used to initiate a BLASTP or TBLASTN search, both of which require a protein sequence query. The identifier of the protein sequence encoded by a nucleotide accession number can be obtained by searching the NCBI's Entrez nucleotide database, at <http://www.ncbi.nlm.nih.gov/Entrez>.

Filtering Sequences

Both nucleotide and protein sequences may contain regions of low complexity, i.e., regions with homopolymeric tracts, short-period repeats, or segments enriched in one or only a few residues. Such low-complexity regions commonly give spuriously high BLAST scores that reflect compositional bias rather than significant position-by-position alignment (Altschul et al., 1994). For example, two protein sequences that contain low-complexity regions rich in the same amino acids may produce high-scoring alignments in those regions even though other parts of the proteins are entirely dissimilar. Because these alignments do not reflect a common ancestry, no functional inference is justified despite their high statistical significance. Filtering the query sequence (that is, replacing the repeated sequence with strings of n for nucleotide sequence or X for protein sequence) can eliminate potentially confounding matches, such as hits to low-complexity, proline-rich regions or poly(A) tails present in the database.

By default, all searches performed through the NCBI BLAST Web page automatically filter the query sequence, as do the BLAST clients, e-mail server, and stand-alone programs. However, filtering can be turned off, even on the Basic BLAST page. Filtered sequence is represented in the final BLAST report as a string of n or X (e.g., nnnnnnnnnn or XXXXXXXXXX). BLASTN queries are filtered with DUST (R.L. Tatusov and D.J. Lipman, pers. comm.). Other BLAST queries use SEG (Wootton and Federhen, 1993, 1996).

Viewing the BLAST Results

The NCBI BLAST Web page can return results in one of three ways. The default is to display the results in the browser window from which the user initiated the search. The document will have hypertext links that make it easier to analyze the results. BLAST queries are processed in the order in which they are received, except that less computationally intensive jobs (e.g., BLASTN, BLASTP, and smaller databases such as month) are given priority. In the middle of the afternoon, the BLAST server may be busy. Thus, it is sometimes more efficient to receive the BLAST results by e-mail. E-mail results are sent either as plain text or in HTML format. The HTML-formatted results must be opened in a Web browser, and the resulting document contains hypertext links.

EXAMPLES OF BLAST SEARCHES

In this section, interpretation of BLAST results is explained using examples for BLASTP, BLASTX, TBLASTN, BLASTN, and PSI-BLAST. An example is not shown for TBLASTX, as it is a tool of last resort and not useful for the majority of users. The first example, for BLASTP, contains general information, and should be read by all BLAST users. GenBank increases in size by thousands of sequences every week; thus, results obtained from running the same searches again will differ from those shown in the examples.

BLASTP

The BLASTP program compares a protein query to a protein database. A typical search is shown in Figure 19.3.1. The Swiss-Prot database has been selected and the program has been changed to BLASTP. A query in FASTA format has been entered in the input box. The query is the human choroideremia protein, implicated in hereditary blindness (Seabra et al., 1993).

The top of the results page for this search is shown in Figure 19.3.2. It begins with some header information about the type of program (BLASTP), the version (2.0.5), and a release

Figure 19.3.2 Example of the top portion of a BLASTP report.

Distribution of 40 Blast Hits on the Query Sequence

Figure 19.3.3 Example of the graphical view of a BLASTP report. The bars are color coded by the strength of the database match. The strongest matches (those with a bit score >200) are red, followed by pink (bit score 80 to 200), green (50 to 80), blue (40 to 50), and black (<40).

date. The version and release date will change as the program is updated. Also listed are a reference, the query definition line, and a summary of the database used. Figure 19.3.3 presents a graphical overview of the results. The database hits are shown aligned to the query, which is the numbered bar at the top. The next three bars show high-scoring database matches that align to the query sequence throughout its length. The next nine bars show lower-scoring matches that align to two regions of the query—one from residue 3 or 4 of the query up to about residue 60, and the other from about residues 220 to 500. For these nine bars the solid segments (on the left and right) indicate aligned regions; the cross-hatched segment indicates that the two alignments (i.e., the solid portions) are from the same database sequence, but that there is no alignment where the bar is cross-hatched. If there is no cross-hatching between two or more bars in the same row (i.e., the thirteenth row), this denotes different alignments with unrelated database sequences. These bars are presented on the same line to conserve space in the graphical view. Moving the cursor over a bar in the graphic (“mousing over”) causes the identifier and definition line of the database match to be shown in the window. If the results of a BLAST search are sent by e-mail, this graphical view is not included.

The hit list produced by the BLASTP search is shown in Figure 19.3.4. Each line of the hit list is composed of four fields. The first field contains the database designation, accession number, and locus name for the matched sequence, separated by vertical bars (see Appendix B at the end of this unit for more information). The second field contains a brief textual description of the sequence, the definition line. The content of the definition line varies between and within databases, but usually includes information on the organism from which the sequence was derived, the type of sequence (e.g., mRNA or DNA), and some information about function or phenotype. The definition line is often truncated in the hit list to keep the display compact, but is fully displayed in association with the local alignments (see below). The third field contains the alignment score in bits. Higher scoring hits are found at the top of the list. In very general terms, this score is calculated from a formula that takes into account the alignment of similar or identical

Figure 19.3.4 Example of the hit list from a BLASTP report.

residues, as well as any gaps that must be introduced in order to align the sequences. A key element in this calculation is the “substitution matrix,” which assigns a score for aligning any possible pair of residues. The BLOSUM-62 matrix is the default for BLAST, and it works well for most searches. The fourth field contains the Expect (*E*) value, which provides an estimate of statistical significance. *E* values reflect how many times one expects to see such a score occur by chance. A statistician would consider an *E* value <0.05 to be significant. However, an inspection of the alignments (see below) is required to determine biological significance. The maximum number of hits displayed in the hit list is set at a default value of 500. This number can be changed on the advanced BLAST page with the *descriptions* option.

For the first hit in the list, the database designation is sp (for Swiss-Prot), the accession number is P26374, the locus name is RAE2_HUMAN, the definition line begins RAB PROTEINS, the score is 1223, and the *E* value is 0.0.

The higher the score and the lower the *E* value, the more statistically significant is the hit. Note that the first thirteen hits all have very low *E* values (<10⁻¹⁴) and are either RAB proteins or GDP dissociation inhibitors. The next eighteen database matches have much higher *E* values (≥0.35), meaning that roughly one match with that score would be expected by chance. Furthermore, the definition lines no longer show the same consistency. Given the combination of inconsistent definition lines and high *E* values, caution should be used in assuming an evolutionary relationship between the query and the eighteen lower-scoring database hits. It would be necessary to examine the alignments in order to make a final determination.

The pairwise alignments between the query and the database hits are displayed below the hit list. Figure 19.3.5 shows one sequence alignment between the query sequence and a

Figure 19.3.5 Example of a BLASTP alignment.

database hit; other alignments are omitted for brevity. The alignment is preceded by the sequence identifier, the full definition line, and the length, in amino acids, of the database sequence. Next comes the score of the match in bits (the raw score is in parentheses), the Expect value (*E* value) of the hit, the number of identical residues in the alignment (identities), the number of conservative substitutions (positives) according to the scoring system (e.g., BLOSUM-62), and, if applicable, the number of gaps in the alignment. Finally the actual alignment is shown, with the query on top and the database match labeled as subject (Sbjct). Since both the query and the match are amino acid sequences, the numbers at left and right refer to the position in the amino acid sequence. The center line between the two sequences indicates the similarities between the sequences. If the residue is identical between the query and the subject, the residue itself is shown; conservative substitutions, as judged by the substitution matrix, are indicated with a + sign. One or more dashes (-) within a sequence indicates insertions or deletions. Query residues masked for low complexity are replaced by Xs (see fourth and eleventh blocks, Fig. 19.3.5). By default, a maximum of 500 pairwise alignments are displayed. This number can be changed on the advanced BLAST page with the *alignments* option.

Results generated on the NCBI BLAST Web page contain text hyperlinks that assist the user in navigating around the page. Clicking on a colored bar in the graphical view (Fig. 19.3.3) moves the user to the sequence alignment (Fig. 19.3.5). The database sequence identifiers, visible both in the one-line descriptions of the database matches (Fig. 19.3.4) and in the sequence alignment (Fig. 19.3.5), link to the Entrez record that describes the sequence. Entrez may provide more information about the sequence, including links to relevant publication abstracts in PubMed. The score (to the right of the one-line description; Fig. 19.3.4) provides a link within the page to the alignment between that hit and the query.

BLASTX

BLASTX searches involve a six-frame translation of a nucleotide sequence queried against a protein database (Gish and States, 1993). Researchers most often use a BLASTX search if they have sequenced a DNA molecule and do not know the reading frame of the coding sequence, the beginning or end of the open reading frame, or the function of the encoded protein. It is also useful for analyzing preliminary sequence data containing potential sequencing or frameshift errors, such as ESTs, HTGs, or GSSs. A BLASTX search of the nr protein database can quickly highlight any similarities between all the open reading frames in a nucleotide sequence and any characterized proteins.

In the example illustrated here, the mRNA sequence encoding human ataxia telangiectasia (ATM; accession number U33841; Lavin and Shiloh, 1997) was queried against the nr protein database. The output is similar to that from BLASTP. At the top (not shown) is information about the search, including the query, database, and type of BLAST program used. Next is the graphical overview representing the alignment of the database hits to the query sequence (Fig. 19.3.6), followed by a list of the hits, including their definitions, scores, and *E* values (Fig. 19.3.7 shows the top portion of the list). Pairwise alignments between the query and hit sequences follow (selected alignments are shown in Fig. 19.3.8).

The top-scoring seven hits, which have scores >2600, are to other orthologs of the ATM gene (Fig. 19.3.7). Most of these hits align with the query sequence over its entire length (in Fig. 19.3.6, the first five bars span the entire length of the query sequence; note also the longer bars in the sixth and seventh lines). The 3' end of the ATM mRNA (carboxy terminal end of the resulting protein translation), aligns with the catalytic domain of a number of phosphatidylinositol 3-kinases or similar proteins—such as the yeast TEL1 gene (a phosphatidylinositol kinase involved in controlling telomere length), the yeast ESR1 gene (a putative phosphatidylinositol kinase required for mitotic cell growth, DNA repair, and meiotic recombination), and the yeast TOR1 protein (a phosphatidylinositol kinase required for cell cycle progression). The alignment with these proteins starts in different places depending on the protein; one group starts around nucleotide 4700 of ATM (lines 9, 10, and 15 in Fig. 19.3.6), and other groups start around nucleotide 5800 (lines 17 to 19), 6800 (lines 7, 8, and 12 to 14), and 8000 (lines 20 to 60). Such similarities have provided insight into the role of ATM in response to DNA damage and cell cycle control (Lavin and Shiloh, 1997). The ATM gene also shares similarity with viral capsid proteins around nucleotides 2500 and 6000 (short bars on lines 6 to 14). However, these hits have low scores and high *E* values (not shown) and are not likely to be significant.

The hits to the orthologs of ATM reveal the location of the coding sequence within the query nucleotide sequence. In a BLASTX output, position in the query sequence (the top line of a pairwise alignment) is described as a nucleotide position, while the position in the database hit (the bottom line of the alignment) is described as an amino acid position (Fig. 19.3.8). For example, amino acids 1 to 3066 of the mouse ortholog of ATM, gi

Figure 19.3.6 Example of the graphical view of a BLASTX report.

1469394, align with the translation of nucleotide positions 190 through 9357 of the query sequence. The exact location of the ATM coding sequence cannot be easily determined from the hits to the yeast sequences, as the similarity does not extend throughout the length of the protein (Fig. 19.3.8, bottom). However, the hits to the yeast sequences do provide confirmation about the phase of the reading frame, and possibly the location of specific domains conserved between humans and yeast.

TBLASTN

TBLASTN searches involve a protein sequence queried against the six-frame translation of a nucleotide sequence database. TBLASTN searches are especially useful for finding novel similarities to a protein sequence in the open reading frames from uncharacterized, sometimes lower-quality nucleotide sequences, such as those found in EST, STS, HTGS, and GSS databases. The translations of these sequences are not present in nr because the sequences are not annotated. The most common use of TBLASTN is to search for ESTs that are similar to a protein of interest. These ESTs might represent orthologs of the protein from a different species, or just additional members of a gene family.

Figure 19.3.7 Example of the hit list from a BLASTX report.

The following example shows a TBLASTN search of HTGS, a database that contains unfinished and uncharacterized genomic sequences generated by genome sequencing centers. Since HTGs are genomic and often contain introns, the results can be more difficult to interpret than those from an EST search. However, HTGs can also provide insight into the chromosomal organization of genes.

In this case, the six-frame translation of HTGS is searched with the amino acid sequence of the disintegrin-like domain of mouse ADAM 1 (Wolfsberg et al., 1995). TBLASTN output is similar to that of BLASTP and BLASTX. Figure 19.3.9 shows the graphical overview of the alignment, Figure 19.3.10 shows the list of database hits, and Figure

Figure 19.3.10 Example of the hit list from a TBLASTN report.

19.3.11 shows selected pairwise alignments between the query sequence and the hits. For TBLASTN searches, the top line (Query) of the alignment contains protein sequence, and the location refers to amino acids. The bottom line (Sbjct) of the alignment contains a translated nucleotide sequence, and the location refers to the nucleotide location.

Disintegrin-like domains contain a characteristic pattern of cysteines, so it is usually easy to identify the true hits by checking for conservation in the number of cysteine residues, and the spacing between them. The first hit, a 627-kb *C. elegans* clone, aligns with the

Figure 19.3.11 Example of a TBLASTN alignment.

Figure 19.3.12 Example of the graphical view of a BLASTN report.

query sequence in two regions. Both alignments encompass the full length of the query sequence, and both contain a characteristic alignment of cysteine residues. The first region (the first aligned block) comprises nucleotides 322651-322911 of the *C. elegans* clone. The second region consists of the second and third alignment blocks. The first 55 amino acids of the disintegrin domain align with nucleotides 102880-103107 of the clone, and the last 25 amino acids align with nucleotides 103155-103232 of the clone. Thus, this *C. elegans* clone appears to encode two distinct disintegrin-like domains, and these two sequences are likely linked in the *C. elegans* genome. The region between nucleotides 103107-103155 of the clone may contain an intron. The second database hit is to a shorter *C. elegans* clone that, from the sequence of its encoded disintegrin domain, appears to contain some of the same sequence as the first *C. elegans* clone. The third database hit is to a human clone. As amino acids 1 to 16 of the query aligns with nucleotides 53178 to 53225 of the hit, and amino acids 24 to 49 align with nucleotides 53474 to 53551, the human sequence may contain an intron between nucleotides 53225 and 53474. There is a likely second intron between nucleotides 53551 and 57012.

BLASTN

Figure 19.3.12 presents the graphical overview of a BLASTN search of accession number U93237 against the human EST database. U93237 is the 9.2-kb genomic sequence of the human menin (MEN1) gene for multiple endocrine neoplasia type I. This example demonstrates the power of a BLAST search to confirm exons in a genomic sequence, as well as the danger of accepting results without further investigation. The matches on the

Figure 19.3.13 Example of the hit list from a BLASTN report.

right half of the diagram (base pairs 4000 to 9000) confirm the locations of exons 2 to 10 of the MEN1 gene (Chandrasekharappa et al., 1997; Zhang and Madden, 1997). The large number of matches on the left side of the figure (base pairs 500 to 1000 and 3000 to 3600) appear at first glance to be interesting matches, but are actually caused by the presence of *Alu* elements in the query and EST sequences. One can determine this by checking the definition lines of the matches in this region, as many of these ESTs are annotated as being similar to *Alu* elements. It is important to remember, though, that the definition line summaries (e.g., Fig. 19.3.13) contain truncated definition lines, and that it is necessary to look at the full definition line (provided in the alignment section, Fig. 19.3.14) to see the *Alu* annotation. One can also perform a BLASTN search of U93237 against the *Alu* database.

Fig. 19.3.13 shows the top portion of the list of database hits for the BLASTN search of U93237 against human ESTs. Fig. 19.3.14 presents one alignment of the query sequence with an EST containing an *Alu* repeat. Vertical bars connect bases that are identical in the query and subject. Since both the query and the subject are nucleotide sequences, the numbers shown refer to nucleotide sequence locations. Nucleotides in the query sequence that have been masked for low complexity are replaced by the letter n (e.g., nnnnnnn in the third block). BLASTN checks the plus and minus strand of the query against the plus strand of the database sequence. The alignment shown here presents the plus strand of the query to the minus strand of the database sequence, which is equivalent to showing the minus strand of the query against the plus strand of the database sequence.

BLASTN is optimized for speed, not sensitivity. The algorithm uses a simple system to assess the alignments; matches are given a positive score, mismatches a negative score. BLASTN should only be used when a direct comparison of nucleotide sequences is desired. BLASTN results should not be used to make any predictions about the functions of the encoded proteins. Generally, searches that involve protein comparisons are more sensitive, owing to the larger alphabet (twenty residues versus four nucleotides) and the

Figure 19.3.14 Example of a BLASTN alignment.

degeneracy of the genetic code (two codons, with different third bases often coding for the same protein). The more sophisticated scoring system used with protein comparisons also takes into account similarities between different residues.

PSI-BLAST

A major new feature of the BLAST version 2.0 is the iterative search. Position-specific iterated BLAST (PSI-BLAST) first performs a normal BLASTP run, but then internally computes a profile using the most significant hits (Altschul et al., 1997). A profile may be understood as a table that lists the probability of finding a residue at each position in a conserved protein domain. Conserved regions between the query and the most-significant matches are used to compute the profile. These regions are presumably important to the function of the protein. The profile is then used to perform another search (or iteration), at which point the new hits are also added into the profile. The cycle may then be repeated, with a new profile computed from the results of the last iteration. Each PSI-BLAST iteration takes into account the most significant sequences found in the previous round (i.e., those below the threshold for inclusion in the profile). The algorithm is more sensitive than BLASTP, and more likely to lead to the discovery of distantly related sequences. At present, such iterative searching is only available with the BLASTP program.

The PSI-BLAST output is different from the other programs. Figure 19.3.15 shows the one-line summaries from the first PSI-BLAST iteration (i.e., the first search using the profile) of a mouse adenosine deaminase (Swiss-Prot accession P03958) against the nr database. The one-line summaries are divided into two groups, those with an E value better (lower) than that used to build the profile (Fig. 19.3.15; the default value is 0.001), and those with a worse E value (not shown). Matches better than the threshold, which will be included in the profile, are checked. The user may check (or uncheck) matches, causing them to be included (or excluded) from the profile used in the next iteration. Matches found on a previous iteration are marked with a green ball. New sequences are

Figure 19.3.15 Example of the hit list from a PSI-BLAST report.

marked with a yellow “new”. The page also alerts the user when convergence is achieved (i.e., no new sequences below the threshold for inclusion in the profile were found in that iteration).

In the hit list in Figure 19.3.15, the first iteration of PSI-BLAST finds many adenosine deaminase sequences (marked with a green ball) found in the previous (standard) BLASTP search. In addition, PSI-BLAST identifies a number of AMP deaminase sequences (marked with “new”). Indeed, there is a well-known homology between adenosine deaminase and AMP deaminase (Chang et al., 1991; Holm and Sander, 1997) that would not normally be found by BLASTP, but is found by PSI-BLAST.

If one wants to report the *E* value for a hit found with a PSI-BLAST search, one should use the *E* value calculated during the first iteration that the match is below the threshold

for inclusion in the profile (i.e., when the hit is marked with a “new” flag). However, if the hit is found in the first BLASTP run, then the reported *E* value should be from this run. In either case, in subsequent iterations, the hit itself is used to compute the profile, and the reported *E* value is not representative of the true value.

SEARCHING STRATEGIES

Filtering for Low-Complexity Regions

Low-complexity regions tend to result in misleading database search results. The residue frequencies within such regions differ dramatically from the database as a whole, disrupting the statistics used by BLAST. This can produce alignments that are based purely on compositional bias rather than a significant position-by-position alignment. By default, low-complexity sequences are filtered out of query sequences and replaced by strings of n (nucleotide) or X (protein). A BLASTP search of a proline-rich, DNA-directed RNA polymerase (Swiss-Prot accession P11414) against the nr database illustrates the differences in output resulting from a filtered or unfiltered query sequence. Twenty-four database matches with an *E* value better than 10 are found if filtering is enabled; 4873 are found if filtering is disabled.

The top-scoring database matches for the unfiltered search are shown in Figure 19.3.16; high-scoring matches that are not found in a filtered search are marked. Note that the definition lines of most of the new matches indicate that the sequences are proline-rich, like the query, but do not provide information about the function of the protein. Other hits to RNA polymerases, found near the top of the list in a filtered search, are buried much deeper in the list of matches. The match to “splP14248,” apparently a good match based on the definition line, does not appear in a filtered BLAST search. An examination of the alignment (not shown) indicates that the match is based on solely on proline-rich regions.

Reporting BLAST Results

The most reliable indicator of the importance of a BLAST alignment is the Expect (*E*) value (the number of chance database matches one expects to see at the same score). This number takes into account the length of the query and size of the database as well as the scoring system. Neither the bit nor the raw score is a reliable indicator, as their significance cannot be judged independently of the information used to calculate the *E* value. Normal intuition fails when one is faced with databases of the current size (e.g., the EST database contains ~700 million base pairs at this time), as chance alignments are likely and it is impossible for a user to know at what score matches become significant. Statistical significance also varies from database to database (e.g., a hit with a certain score may be statistically significant in a search of the relatively small month database, but not in a search of nr), so that reporting a certain score without the context of the database size can be misleading. The percentage identity is also a poor indicator of statistical significance for the same reasons; additionally, there is really no way to estimate an *E* value or even a score from a percentage identity, making it impossible to even guess whether a hit could be due to chance or not.

Analyzing mRNA Sequences

1. Identify the open reading frame to obtain the protein sequence. Perform a BLASTX search of the cDNA sequence against the nr protein database. Any resulting hits may identify the correct reading frame for the protein sequence and provide information about its function.

Figure 19.3.16 Example of a hit list from a BLASTP report in which the query sequence was not filtered. Black squares, added manually by the authors, indicate hits that would not appear if the query had been filtered.

- Determine whether the protein sequence is similar to that of any previously identified proteins. Perform a BLASTP and a PSI-BLAST (iterative) search against the nr protein database using the protein sequence as a query.
- Determine whether the protein sequence is similar to the translation products of any uncharacterized DNA sequences whose translations are not in nr. Perform a TBLASTN search of the EST, STS, GSS, and HTGS databases.
- After the initial search, perform a monthly search of the month nucleotide and protein sequence databases to provide information about newly added sequences. A BLASTP

search of the month protein database will reveal newly characterized protein sequences. A TBLASTN search of the month nucleotide database will reveal new open reading frames in nr, EST, HTGS, STS, and GSS. PSI-BLAST searches of nr should also be conducted occasionally, as new sequences may be added to the profile that will, in turn, help identify more distantly related sequences.

5. If the protein sequence contains multiple functional domains, it may be useful to perform the searches with each of these domains individually.

Analyzing Genomic DNA Sequences

1. Identify a potential transcribed segment. Perform a BLASTN search of the nucleotide sequence against the DNA sequences in the EST database to determine if any mRNAs are derived from the genomic sequence. EST hits will highlight the location of exons. A BLASTN search against nr may identify transcripts or previously characterized genomic segments.
2. Identify potential open reading frames. Perform a BLASTX search against the nr protein database. Any resulting hits may identify the correct reading frame of a protein sequence and provide information about its function. If no results are found with the previous methods, a TBLASTX search (translated nucleotide query versus a translated nucleotide database) against EST, GSS, HTGS, and STS may identify other open reading frames.
3. After the initial search, a monthly search of the month nucleotide (with BLASTN) and protein (with BLASTX) sequence databases will provide information about newly added sequences.
4. Any potential transcribed sequences can be analyzed as per the above instructions for mRNA sequences.

Searching Short Sequences

Short sequences can only produce short alignments. Such short alignments need to be relatively strong (i.e., have a high percentage of matching residues) to rise above the background noise. Short, but strong, alignments are more easily detected using a matrix with a higher relative entropy than that of the default BLOSUM-62 (Altschul, 1991). Relative entropy is basically the average information available per position to distinguish the alignment from chance. The BLOSUM series of matrices does not include any that are suitable for the shortest queries, so it is recommended to use the PAM matrices instead (Dayhoff et al., 1978; Schwartz and Dayhoff, 1978). These matrices may be chosen from a menu on the Advanced BLAST page. Suggested matrices for different query lengths are shown in Table 19.3.2 (S.F. Altschul, pers. comm.).

Table 19.3.2 Substitution Matrices for Short Sequences

Query length (amino acids)	Matrix
<35	PAM-30
35-50	PAM-70
50-85	BLOSUM-80
>85	BLOSUM-62

SEQUENCE ALIGNMENT ALGORITHMS

There are two types of pairwise sequence alignments, global and local. Global strategies attempt to align along the entire length of both sequences, while local alignments focus on sequence similarity over shorter regions. Historically, local alignments have been very successful at identifying similarities between proteins. Subsequences of similarity, surrounded by unrelated sequences, can identify, for example, active sites that are conserved between proteins or exons in genomic sequence. Smith and Waterman (1981) were the first to develop a local alignment algorithm. However, such rigorous alignment algorithms are often quite slow and impractical for searching current databases on a routine basis.

Heuristic algorithms implement certain shortcuts to allow a comparison against an entire database within a reasonable time. They are not exhaustive searches in the sense that they do not explore possibilities that seem unlikely to be interesting. Some programs allow the user to adjust parameters that increase the sensitivity of the search (i.e., explore more possibilities), but this must be balanced against the slower speed of the search. Studies have shown that heuristic algorithms, with default settings, approach the sensitivity of exhaustive searches (Altschul et al., 1997). BLAST (Altschul et al., 1990, 1997) and FASTA (Pearson, 1990; Pearson and Lipman, 1988) are two popular heuristic programs. The rest of this discussion will focus on the newest version (2.0) of BLAST.

BLAST calculates a statistical significance for every alignment it produces. Significance is expressed in terms of the *E* value, which is the number of matches with a given score (the calculation of the score is described below) that one would expect by chance. The *E* value depends on the size of the database and the length of the query, as increasing either of these parameters increases the number of chance matches. Calculation of the *E* value is performed with Karlin-Altschul statistics (Karlin and Altschul, 1990, 1993).

The raw score of an alignment is calculated with a scoring system, which is a table of residue substitution scores and penalties for the existence and extension of a gap. For normal protein/protein comparisons, a matrix (i.e., table of residue substitution scores) provides a score for each possible alignment of two amino acids. For example, L aligned with I gets a positive score, while L aligned with E gets a negative score. BLOSUM-62 is the default matrix, and experimentation has shown that it is among the best for detecting weak protein similarities (Henikoff and Henikoff, 1992). PSI-BLAST uses a table that lists the frequency of finding a certain residue at each position in a conserved protein domain. This table is calculated “on the fly” for each iteration from the best matches to the database. BLASTN uses a simple scheme where matches have a positive score and mismatches have a negative score. Gaps are opened or extended when one sequence is longer than another over a certain region. BLAST charges the score $-a$ for the existence of a gap and $-b$ for each letter in a gap, so that a gap of length k letters is penalized $-(a + bk)$. Gap costs of this form are known as affine gap costs. These gap costs may be changed by the user.

The scoring system determines the raw score of an alignment. A bit score can be calculated from the raw score using the following formula:

$$S_{\text{bit}} = [\lambda \times S_{\text{raw}} - \ln(K)] / \ln(2)$$

where λ and K are Karlin-Altschul parameters that depend on the scoring system. The statistical significance corresponding to the resulting bit score is independent of the scoring system used. This allows one to compare the bit scores obtained from two different BLAST runs, each performed using different matrices or gap extension and existence values. Nevertheless, it is more meaningful to compare the results of different BLAST

runs using their *E* values rather than their bit scores, as the *E* value takes into account the size of the database.

A word-based approach is used to find matches in BLAST. An ungapped search, with BLASTN, may be used to demonstrate the concept of a word. First a list is made of all the subsequences in the nucleic acid query sequence that are of a certain length (called the word size), and the positions are recorded. The database is then scanned, looking for words that are in the list. If a match is found between a query and a database word, the alignment is extended (without allowing gaps) until the corresponding score drops a certain amount below the maximum found, at which point that maximum score (and the corresponding alignment) is used. The aligned region is a local alignment. With BLASTN, only exact matches are extended and the default word size is 11 bp.

The procedure is more complicated for the other programs (BLASTP, BLASTX, TBLASTN, and TBLASTX). Exact word matches are not required and the default word size is three residues. A match between a query word and a database word is based on the scoring matrix, which specifies whether two residues result in a positive, negative, or neutral match. If three residues in a query word are compared with three residues in a database sequence, and the score is above a certain threshold, this word warrants further consideration. The default behavior in BLAST version 2.0 is that two words (on the query) must match with two words (on the database sequence) within a window of 40 residues before the match is extended, as described for BLASTN. The effect of looking for two word matches is to eliminate random matches, increasing the speed of BLAST by a factor of three.

Ungapped alignments are used as a starting point for the gapped alignments that BLAST produces. The eleven highest-scoring letters are determined and the center letter is used as the start of the gapped alignment. The alignment is then extended, with gaps allowed. This extension is not exhaustive; if the score drops by more than a certain amount from the maximum found so far, that maximum (and the corresponding alignment) is used (Altschul et al., 1997; Zhang et al., 1998).

The default BLAST parameters are tuned for a balance of speed and sensitivity. It is possible that significant matches may be missed, especially if small databases are searched. In that case, it may be advisable to use a shorter word size for BLASTN or a lower-threshold word for the other programs.

It is important to remember that BLAST calculates similarity. Homology is an evolutionary relationship that must be proved by further analysis.

APPENDIX A: BLAST PARAMETERS

The Advanced BLAST page offers the possibility to change a number of BLAST parameters. The most important options supported are listed below.

Descriptions (pull-down menu) restricts the number of one-line descriptions to the number specified. The default is 500.

Alignments (pull-down menu) restricts the number of database hits for which alignments are shown. Several alignments may be associated with one database sequence, so the number of alignments may actually be larger than this number. The default is 500.

Expect value (pull-down menu; also known as the *E* value) is the statistical significance threshold for reporting matches. The default value is 10, such that ten alignments are expected to be found merely by chance, according to the stochastic model of Karlin and Altschul (1990). Lower *E* thresholds are more stringent, leading to fewer chance matches being reported. Fractional values are acceptable.

Filtering (pull-down menu) masks off segments of the query sequence that have low compositional complexity, as determined by the SEG program (Wootton and Federhen, 1993, 1996) or, for BLASTN, by the DUST program (R.L. Tatusov and D.J. Lipman, pers. comm.). Filtering is only applied to the query sequence (or its translation products), not to database sequences. Default filtering is DUST for BLASTN, SEG for other programs.

Genetic code (pull-down menu) selects the genetic code to be used for a BLASTX translation of the query. The default setting is the universal code. The choice of code is determined by the source of the query sequence (e.g., species, mitochondrial).

Graphical overview (checkbox) selects whether an overview of the database sequences aligned to the query sequence will be shown. The score of an alignment is indicated by one of five different colors, which divides the range of scores into five groups. If more than one alignment is displayed for a database sequence, the two alignments are connected by a cross-hatched bar. Mousing over a match causes the definition and score to be shown in the window at the top; clicking on a bar takes the user to the associated alignments. The overview is on by default.

Matrix (menu) allows one to change the matrix from the default of BLOSUM-62. This is useful for searches against short sequences (see Searching Short Sequences). It is also possible to change the gap existence and extension penalties, but the defaults for a given matrix are recommended.

Organism (pull-down menu) limits the search by organism. The menu provides a list of the most common organisms; others may be entered in a text box.

APPENDIX B: SEQUENCE IDENTIFIER SYNTAX

The syntax of sequence header lines used by the NCBI BLAST server depends on the database from which each sequence was obtained. Table 19.3.3 lists the identifiers for the databases from which the sequences were derived. For example, an identifier might be *gb|M73307|AGMA13GT*, where the *gb* tag indicates that the identifier refers to a GenBank sequence, *M73307* is its GenBank accession number, and *AGMA13GT* is its GenBank locus.

NCBI assigns *gi* identifiers for all sequences contained within NCBI's sequence databases (Ostell and Kans, 1998). The *gi* identifier provides a uniform and stable naming convention whereby a specific sequence is assigned its unique *gi* identifier. If a nucleotide or protein sequence changes, a new *gi* identifier is assigned, even if the accession number of the record remains unchanged. Thus, *gi* identifiers provide a mechanism for identifying the exact sequence that was used or retrieved in a given search.

For searches of the *nr* protein database where the sequences are derived from conceptual translations of sequences from the nucleotide databases the *gi* syntax is *gi|gi_identifier*. An example would be *gi|451623 (U04987) env [Simian immunodeficiency...*, where *451623* is the *gi* identifier and *U04987* is the accession number of the nucleotide sequence from which it was derived.

Users may select the *-gi* option for BLAST output, which will produce a header line with the *gi* identifier concatenated with the database identifier of the database from which it was derived. For example, *gi|176485|gb|M73307|AGMA13GT* would be used for a match from a nucleotide database, and *gi|129295|sp|P01013|OVAX_CHICK* for a protein database.

The *gnl* (general) identifier allows databases not listed in Table 19.3.3 to be identified with the same syntax. An example here is the PID identifier *gnl|PID|e1632*. PID stands for Protein-ID, and the *e* in *e1632* indicates that this ID was issued by EMBL. As mentioned above, use of the *-gi* option produces the NCBI *gi* (in addition to the PID), which users can also use to retrieve sequences of interest.

Table 19.3.3 Identifier Syntax for Sequence Databases

Database	Identifier syntax
GenBank	<i>gb accession locus</i>
EMBL Data Library	<i>embl accession locus</i>
DDBJ (DNA Data Bank of Japan)	<i>dbj accession locus</i>
NBRF PIR	<i>pir entry</i>
Protein Research Foundation	<i>prf name</i>
Swiss-Prot	<i>sp accession entry name</i>
Brookhaven Protein Data Bank	<i>pdb entry chain</i>
Patents	<i>pat country number</i>
GenInfo Backbone Id	<i>bbs number</i>
General database identifier	<i>gnl database identifier</i>

Protein databases have become a crucial part of modern biology. Huge amounts of data for protein structures, functions, and particularly sequences are being generated. These data cannot be handled without using computer databases. Searching databases is often the first step in the study of a new protein. Without the prior knowledge obtained from such searches, known information about the protein could be missed, or an experiment could be repeated unnecessarily. Comparison between proteins and protein classification provide information about the relationship between proteins within a genome or across different species, and hence offer much more information than can be obtained by studying only an isolated protein. In this sense, protein comparison through databases allows one to view life as a forest instead of individual trees. In addition, secondary databases derived from experimental databases are also widely available. These databases reorganize and annotate the data or provide predictions. The use of multiple databases often helps researchers understand evolution, structure, and function of a protein.

Protein databases are especially powered by the Internet. Unlike traditional media, such as the CD-ROM, the Internet allows databases to be easily maintained and frequently updated with minimum cost. Researchers with limited resources can afford to set up their own databases and disseminate their data quickly. Notably, many small databases on specific types of proteins, such as the EF-Hand Calcium-Binding Proteins Data Library (http://structbio.vanderbilt.edu/cabp_database/) and O-GlycBase (<http://www.cbs.dtu.dk/databases/OLYCBASE/>), became widely available. Users worldwide can easily access the most up-to-date version through a user-friendly interface. Most protein databases have interactive search engines so that users can specify their needs and obtain the related information interactively. Many protein databases also allow submitters to deposit data interactively, and allow database servers to check the format of the data and provide immediate feedback.

Although some protein databases are widely known, they are far from being fully utilized in the protein science community. This unit provides a starting point for readers to explore the potential of protein databases on the Internet. Databases for different aspects of proteins are discussed, with the focus on sequence, structure, and family. The strengths and weaknesses of the databases will be addressed. For Web addresses of the databases discussed in this unit, see Internet Resources and Table 19.4.1. From hundreds of on-line protein databases, several major databases are discussed as examples to illustrate their features and how they can be used effectively. Most other protein databases can be explored in a similar way.

PROTEIN SEQUENCE DATABASES

Thanks to the Human Genome Project and other sequencing efforts, new sequences have been generated at a prodigious rate. A large number of DNA sequences, which are equivalent to hundreds of new proteins, are determined each day for the human genome alone. It is expected that 10,000 genomes will be sequenced in the next decade. These sequences provide a rich information source and the core of the revolutionary movement toward “large-scale biology.”

Various databases contain protein sequences with different focuses. SwissProt (Bairoch and Apweiler, 1999) provides more annotations than any other sequence database, with a minimal level of redundancy, through human input or integration with other databases. However, the labor-intensive enhancement process prevents many sequences from being added to SwissProt quickly. As a supplement of SwissProt, the TrEMBL database

^aNA, size not available at time of printing. The data are as of March, 2003.

(Bairoch and Apweiler, 1999) contains all the translations of EMBL nucleotide sequence entries (Rodriguez-Tom et al., 1996) that have not been integrated into SwissProt. Another protein sequence database, the Protein Identification Resource (PIR; Barker et al., 1999), attempts to build a complete and nonredundant database from a number of protein and nucleic acid sequence databases. Identical and highly similar sequences from the same species are merged into a single entry. Each entry in PIR provides bibliographic and annotated information for the protein. The nr protein database is used for BLAST searching (Altschul et al., 1997), which is described in *UNIT 19.3* of this book. It includes entries from the nonredundant GenBank (Benson et al., 1999) translations, SwissProt, PIR, Protein Research Foundation (PRF) in Japan, and the Protein Data Bank (PDB). Only entries with absolutely identical sequences are merged.

Most of the sequence databases have a sequence search tool and cross-references to entries of other protein and gene databases. Many sequence databases, such as SwissProt and PIR, also provide text searching using, for instance, protein names or key words. To study a new protein, the authors recommend first performing a sequence search using BLAST in nr if the protein sequence is available. The search often gives entry names in the protein databases included in nr. Even when the protein is not found in nr, it is likely that a homologous protein will be hit, which can often lead to some useful information, such as the function of the query protein. If the sequence of the query protein is unavailable, doing a text search in SwissProt or PIR usually identifies the protein. SwissProt is probably the place to obtain the most information about a protein if it can be found in SwissProt. However, some additional information may be found by checking other sequence databases. For example, PIR provides some useful information on protein family classification for each entry, and the Kyoto Encyclopedia of Genes and Genomes (KEGG; Ogata et al., 1999) annotates some gene entries with information about

metabolic and regulatory pathways. If the query protein is not available in nr, one may find a gene model (predicted protein sequence) by searching genetic sequence databases that contain predicted genes from nucleotide sequences (e.g., the Genome Channel; Mural et al., 1999). Although predicted sequences generated by computational gene-finding tools may contain errors, such databases cover a large number of proteins and are often reliable enough to provide useful information.

SwissProt, as a curated protein sequence database, offers a wide range of annotations, covering areas such as function, domain parsing, post-translational modifications, and variants. SwissProt can be accessed at <http://www.expasy.ch/sprot/sprot-top.html> (home server, Switzerland), <http://us.expasy.org/sprot/sprot-top.html> (USA), <http://ca.expasy.org/sprot/sprot-top.html> (Canada), <http://cn.expasy.org/sprot/sprot-top.html> (China), <http://kr.expasy.org/sprot/sprot-top.html> (Korea), and <http://tw.expasy.org/sprot/sprot-top.html> (Taiwan). SwissProt is integrated into many other databases, such as SRS (see SRS below).

Human vitronectin is used here as an example for searching protein sequence databases. To locate the SwissProt entry for this protein, one can search either the entry name (VTNC_HUMAN) or the accession number (P04004) obtained from a BLAST search. Alternatively, one can use the full-text search at the SwissProt Web page to search by protein name (human vitronectin) or key words (e.g., serum spreading, as vitronectin is also called serum spreading factor s-protein). A combination of several entries can be used in a search.

The entry name in SwissProt has the general format X_Y, where X is a mnemonic code of up to four characters indicating the protein name (in this case, VTNC), and Y is a mnemonic species identification code of up to five characters for the biological source of the protein. Some codes used for Y are full English names, e.g., HORSE, HUMAN, MAIZE, MOUSE, PIG, RAT, SHEEP, YEAST (baker's yeast, *Saccharomyces cerevisiae*), and WHEAT. Some are abbreviations, including BOVIN (bovine), CHICK (chicken), ECOLI (*Escherichia coli*), PEA (garden pea, *Pisum sativum*), RABIT (rabbit), SOYBN (soybean, *Glycine max*), and TOBAC (common tobacco, *Nicotina tabacum*).

An entry name may have several accession numbers if they have been merged. An accession number is always conserved from release to release, and therefore allows unambiguous citation.

Each entry contains the following items shown in table format in the NiceProt View layout: (1) general information about the entry, (2) name and origin of the protein, (3) references providing the protein sequence, (4) comments (e.g., annotated functions, subunits, similar proteins), (5) cross-references (links to other databases), (6) key words, (7) features, and (8) sequence information. The text in the comments entry provides a function annotation for the protein (e.g., "Vitronectin is a cell adhesion and spreading factor found in serum and tissues. Vitronectins interact with glycosaminoglycans and proteoglycans. ."). Cross-references lists the annotations of the protein by other databases, such as GeneCards (Rebhan et al., 1998) and ProDom (Corpet et al., 1999). GeneCards, a database of human genes, shows chromosomal location and the involvement of the protein in certain diseases (if applicable). ProDom contains protein domain families by automated sequence comparisons. Clicking the link to ProDom from SwissProt leads to a nice graphic view for domain parsing, as shown in Figure 19.4.1 for vitronectin.

Figure 19.4.1 Domain parsing of human vitronectin by ProDom in SwissProt.

Various research results are given under features. Some of the features items for VTNC_HUMAN are as follows:

SIGNAL	1	19	
CHAIN	20	398	V65 SUBUNIT.
CHAIN	399	478	V10 SUBUNIT.
PEPTIDE	20	63	SOMATOMEDIN B.
DOMAIN	150	287	HEMOPEXIN-LIKE 1.
DOMAIN	288	478	HEMOPEXIN-LIKE 2.
SITE	64	66	CELL ATTACHMENT SITE.
SITE	398	399	CLEAVAGE.
MOD_RES	75	75	SULFATATION.
CARBOHYD	86	86	
DISULFID	293	430	
BINDING	362	395	HEPARIN.
CONFLICT	50	50	C → N (IN REF. 5).

where SIGNAL represents the extent of a signal sequence (prepeptide), MOD_RES indicates a post-translationally modified residue (sulfatation, in this case), CARBOHYD shows the glycosylation site, DISULFID means that a disulfide bond exists between the two indicated residues (293 and 430), and CONFLICT shows that different papers report differing sequences.

PROTEIN STRUCTURAL DATABASES

Searching structure databases is becoming more and more popular in molecular biology. The three-dimensional structures of proteins not only define their biological functions, but also hold a key in rational drug design. Traditionally, protein structures were solved at a low-throughput mode. However, recent advances in new technologies, such as synchrotron radiation sources and high-resolution nuclear magnetic resonance (NMR), accelerate the rate of protein structure determination substantially. There is an overwhelming consensus in the structural biology community that protein structures can be solved en masse (an effort called structural genomics), in a similar fashion as for determining DNA sequences, and that impact of this approach can be compared with that of the Human Genome Project.

The only international repository for the processing and distribution of protein structures is the PDB (Bernstein et al., 1977). The structures in the PDB were determined experimentally by X-ray crystallography (~86%) and NMR (~14%). Theoretical models have been removed from PDB, effective July 2, 2002, based on the new PDB policy. The PDB also contains some structures of chemical ligands and nucleotides. Each PDB entry is represented by a four-character identifier (PDB ID), where the first character is always a number from 0 to 9 (e.g., 1cau, 256b). The PDB can be accessed through the home server (<http://www.rcsb.org/pdb/> or <http://www.pdb.org> in the USA) or through one of

many mirror sites from around the world, as listed at the home server. Some of the mirror sites are as follows:

Rutgers University, Piscataway, NJ, United States: <http://rutgers.rcsb.org/>

NIST, Gaithersburg, MD, United States: <http://nist.rcsb.org/>

Cambridge Crystallographic Data Centre, United Kingdom: <http://pdb.ccdc.cam.ac.uk/>

National University of Singapore, Singapore: <http://pdb.bic.nus.edu.sg/>

Osaka University, Japan: <http://pdb.protein.osaka-u.ac.jp/>

Universidade Federal de Minas Gerais, Brazil: <http://www.pdb.ufmg.br/>

Max Delbrück Center for Molecular Medicine, Germany: <http://www.pdb.mdc-berlin.de/>

The PDB offers three search methods: search by PDB ID, by SearchLite, and by SearchFields. SearchLite is a simple key-word search that uses, for instance, protein name or author's name. A search using SearchFields, as an advanced search engine, allows a user to specify features of the protein, such as Enzyme Commission (EC) number, name of binding ligand, range of protein size, range of resolution in the X-ray structure, and secondary structure content.

The PDB stores structural information in two formats: the PDB file format (Bernstein et al., 1977) and the macromolecular crystallographic information file (mmCIF) format (Bourne et al., 1997). The PDB file format is still the dominant format used in the protein community. It contains three parts: annotations, coordinates, and connectivities. The connectivity part, which shows chemical connectivities between atoms, is optional. It is listed at the end of the PDB file, beginning the line with the key word CONECT. The coordinate part uses each line for a three-dimensional coordinate of an atom, starting from ATOM (for standard amino acids) or HETATM (for nonstandard groups). The following shows an example of the PDB file format:

```

Each line shows the atom serial number, atom type, residue type, chain identifier (in case of multi-chain structure), residue serial number, orthogonal coordinates (three values), occupancy, temperature factor, and segment identifier.

The annotation part of the PDB file format contains dozens of possible record types, including: HEADER (name of protein and release date), COMPND (molecular contents of the entry), SOURCE (biological source), AUTHOR (list of contributors), SS-BOND (disulfide bonds), SLTBRG (salt bridges), SITE (groups comprising important sites), HET (nonstandard groups or residues [heterogens]), MODRES (modifications to standard residues), SEQRES (primary sequence of backbone residues), HELIX (helical substructures), SHEET (sheet substructures), and REMARK (other information and comments).

The PDB allows a user to view a molecule structure interactively through a Virtual Reality Modeling Language (VRML) viewer, RasMol (Sayle and Milner-White, 1995), Chime, or QuickPDB (a Java applet for viewing sequence and structure) when the browser is

configured to support these free rendering tools. The PDB provides related information about the protein, such as secondary structure assignment and geometry. Each PDB entry also links to a wide range of annotations from secondary databases, including (1) summary and display databases such as Graphical Representation and Analysis of Structure Server (GRASS; Nayal et al., 1999), Image Library (Shnel, 1996), Molecular Modelling Database (MMDB; Marchler-Bauer et al., 1999) in Entrez, PDBsum (Laskowski et al., 1997), and Sequence to and within Graphics (STING); (2) domain partition information from 3Dee (Siddiqui and Barton, 1995); (3) the MEDLINE bibliography; (4) structure quality assessment in PDBREPORT from WHAT IF (Vriend, 1990); (5) protein movements recorded in Database of Macromolecular Movement (MolMovDB; Gerstein and Krebs, 1998); (6) structure families (CATH, CE, FSSP, SCOP, and VAST, as discussed later in this unit); and (7) geometry analyses of the protein, such as CSU Contacts of Structural Units (Sobolev et al., 1999) and castP Identification of Protein Pockets & Cavities (Liang et al., 1998).

Several structure databases that are not linked by the PDB can also provide useful information. WPDB (Shindyalov and Bourne, 1995) can be used to visualize and analyze a PDB entry from Microsoft Windows. BioMagResBank (University of Wisconsin, 1999) is a repository for NMR spectroscopy data on proteins, peptides, and nucleic acids. Particularly, it provides partial NMR data (e.g., chemical shifts) before the full structure is solved.

PROTEIN FAMILY DATABASES

Proteins can be classified according to their evolutionary, structural, or functional relationships. A protein in the context of its family is much more informative than the single protein itself. For example, residues conserved across the family often indicate special functional roles. Two proteins classified in the same functional family may suggest that they share similar structures, even when their sequences do not have significant similarity.

There is no unique way to classify proteins into families. Boundaries between different families may be subjective. The choice of classification system depends in part on the problem; in general, the authors suggest looking into classification systems from different databases and comparing them. Three types of classification methods are widely adopted, based upon the similarity of sequence, structure, or function. Sequence-based methods are applicable to any proteins whose sequences are known, while structure-based methods are limited to the proteins of known structures, and function-based methods depend on the functions of proteins being annotated. Sequence- and structure-based classifications can be automated and are scalable to high-throughput data, whereas function-based classification is typically carried out manually. Structure- and function-based methods are more reliable, while sequence-based methods may result in a false positive result when sequence similarity is weak (i.e., two proteins are classified into one family by chance rather than by any biological significance). In addition, since protein structure and function are better conserved than sequence, two proteins having similar structures or similar functions may not be identified through sequence-based methods.

Databases for Sequence-Based Protein Families

Sequence-based protein families are classified according to a profile derived from a multiple-sequence alignment. The profile can be shown across a long domain (typically 100 residues or more) or can be revealed in short sequence motifs. Classification methods based on profiles across long domains tend to be more reliable but less sensitive than those based on short sequence motifs.

Several sequence-based methods focus more on profiles across long domains, including Pfam (Bateman et al., 1999), ProDom (Corpet et al., 1999), SBASE (Murvai et al., 1999),

and Clusters of Orthologous Group (COG; Tatusov et al., 1997). These methods differ in the techniques used to construct families. Pfam builds multiple-sequence alignments of many common protein domains using hidden Markov models. The ProDom protein domain database consists of homologous domains based on recursive PSI-BLAST searches (UNIT 19.3). SBASE is organized through BLAST neighbors and is grouped by standard protein names that designate various functional and structural domains of protein sequences. COG aims toward finding ancient conserved domains by delineating families of orthologs across a wide phylogenetic range.

The following shows an example of Pfam for the GRIP domain (accession number PF01465). Pfam lists some useful information for the entry as follows:

The GRIP (golgin-97, RanBp2alpha, Imh1p and p230/golgin-245) domain is found in many large coiled-coil proteins. It has been shown to be sufficient for targeting to the Golgi. The GRIP domain contains a completely conserved tyrosine residue.

The references of the above annotation are also given. In addition, Pfam gives the alignment between the family members:

```

The alignment shows accession numbers and the range of each sequence. One can identify some features of the family through this pattern (i.e., from particularly conserved residues at specific alignment positions).

Some methods are based on “fingerprints” of small conserved motifs in sequences, as with PROSITE (Hofmann et al., 1999), PRINTS (Attwood et al., 1999), and BLOCKS (Heniko et al., 1999). In protein sequence families, some regions have been better conserved than others during evolution. These regions are generally important for the function of a protein or for the maintenance of its three-dimensional structure, and hence are suitable for fingerprinting. The fingerprints can be used to assign a newly sequenced protein to a specific family. Fingerprints are derived from gapped alignments in PROSITE and PRINTS, but are derived from ungapped alignments (corresponding to the highly conserved regions in proteins) in BLOCKS. A fingerprint in PRINTS may contain several motifs from PROSITE, and thus may be more flexible and powerful than a single PROSITE motif. Therefore, PRINTS can provide a useful adjunct to PROSITE. It should be noted that some functionally unrelated proteins may be classified together due to chance matches in short motifs.

Other sequence-based protein family databases consist of multiple sources. The ProClass database (Wu et al., 1999) is a nonredundant protein database organized according to family relationships as defined collectively by PROSITE patterns and PIR superfamilies. The MEGACLASS server (States et al., 1993) provides classifications by different methods, including Pfam, BLOCKS, PRINTS, ProDom, and SBASE. The MOTIF search engine at <http://motif.genome.ad.jp/> includes PROSITE, BLOCKS, ProDom, and PRINTS.

Figure 19.4.2 Structure superposition between glycolate oxidase (1gox, in black) and inosine monophosphate dehydrogenase (1ak5, in gray). This figure was made using MOLSCRIPT (Kraulis, 1991).

Databases for Structure-Based Protein Families

The hierarchical relationship among proteins can be clearly revealed in structures through structure-structure comparison. Structure families often provide more information on the relationship between proteins than what sequence families can offer, particularly when two proteins share a similar structure but no significant sequence identity. Figure 19.4.2 shows an example of a structure-structure alignment between two proteins. Sometimes, sequence similarity between two proteins exists but is not strong enough to produce an unambiguous alignment. In this case, the alignment between two structures can generate better alignment in terms of biological significance, and thus may pinpoint the active sites more accurately.

Different structure-structure comparison methods yield different structure families. CATH (Class, Architecture, Topology and Homologous superfamily; Orengo et al., 1997) is a hierarchical classification of protein domain structures. CE (Combinatorial Extension of the optimal path; Shindyalov and Bourne, 1998) provides structural neighbors of the PDB entries with structure-structure alignments and three-dimensional superpositions. FSSP (Fold classification based on Structure-Structure alignment of Proteins; Holm and Sander, 1996) features a protein family tree and a domain dictionary, in addition to whole-chain-based classification, sequence neighbors, and multiple structure alignments. SCOP (Structural Classification of Proteins; Murzin et al., 1995) uses augmented manual classification, class, fold, superfamily, and family classification. VAST (Vector Alignment Search Tool; Gibrat et al., 1996) contains representative structure alignments and three-dimensional superpositions. Among these five databases, SCOP provides more function-related information. However, due to the manual work involved, SCOP is not updated as frequently as the others (as of June, 2003, it was last updated for the PDB release on March 1, 2003), whereas FSSP and CATH follow the PDB updates closely.

SCOP is used here as an example to show the features of structure-based families. SCOP can be accessed through its home server in the UK (<http://scop.mrc-lmb.cam.ac.uk/scop/>). It is also widely mirrored around the world, including:

<http://pdb.wehi.edu.au/scop/> (Australia)
<http://mdl.ipc.pku.edu.cn/scop/> (China)
<http://www.cdfd.org.in:5555/scop/> (India)
<http://pdb.weizmann.ac.il/scop/> (Israel)
<http://loki.polito.it/scop/> (Italy)
<http://scop.protres.ru/> (Russia)
<http://scop.bic.nus.edu.sg/> (Singapore)
<http://scop.life.nthu.edu.tw/> (Taiwan)
<http://scop.berkeley.edu/> (USA)

SCOP describes the hierarchical relationship among proteins through the major levels of (homologous) family, superfamily, and fold. Proteins are clustered together into a (homologous) family if they have significant sequence similarity. Different families that have low sequence similarity but whose structural and functional features suggest a common evolutionary origin are placed together in a superfamily. Different superfamilies are categorized into a fold if they have the same major secondary structures in the same arrangement and with the same topological connections (the peripheral elements of secondary structure and turn regions may differ in size and conformation). Two superfamilies in the same fold may not have a common evolutionary origin. Their structural similarities may arise from the physics and chemistry of proteins favoring certain packing arrangements and chain topologies (Murzin et al., 1995). Figure 19.4.3 shows the SCOP interface using an example of protein 1gox in the PDB.

Structural Classification of Proteins

Protein: Glycolate oxidase from spinach (*Spinacia oleracea*)

Lineage:

1. Root: [scop](#)
2. Class: [Alpha and beta proteins](#)
Mainly parallel beta sheets (beta-alpha-beta units)
3. Fold: [beta/alpha \(TIM\)-barrel](#)
contains parallel beta-sheet barrel, closed; n=8, S=8; strand order 12345678
4. Superfamily: [FMN-linked oxidoreductases](#)
5. Family: [FMN-linked oxidoreductases](#)
6. Protein: Glycolate oxidase
7. Species: [spinach \(*Spinacia oleracea*\)](#)

PDB Entry Domains:

1. [1gox](#)                                       

Databases for Function-Based Protein Families

There are various protein functional families classified from different perspectives. The ENZYME data bank (Bairoch, 1993) contains the following data for each enzyme: EC number, recommended name, alternative names, catalytic activity, cofactors, pointers to the SwissProt entry, and pointers to any disease associated with a deficiency of the enzyme. PROCAT is a database of three-dimensional enzyme active site templates (Wallace et al., 1996). PDD (Protein Disease Database; Lemkin et al., 1995; Merril et al., 1995) correlates diseases with proteins observable in serum, urine, and other common human body fluids based on biomedical literature. There are also a growing number of databases dedicated to special types of proteins, such as antibodies, G-protein-coupled receptors, HIV proteases, glycoproteins, and RNases, as shown in Table 19.4.1.

OTHER DATABASES

Protein Binding Databases

Protein binding includes protein-substrate docking and protein-protein association. ReLiBase (Hendlich, 1998) is a database system for analyzing receptor-ligand complexes in the PDB. DIP (Database of Interacting Proteins) records protein pairs that are known to bind with each other. The information in DIP may provide information related to signaling pathways, multiple interactions, and complex systems.

Protein Energetics Databases

There are few databases for protein energetics, due to the low-throughput nature of the data source. One useful energetics database can be found in ProTherm (Thermodynamic Database for Proteins and Mutants; Gromiha et al., 1999). It contains thermodynamic data on mutations, including Gibbs free energy, enthalpy, heat capacity, and transition temperature. These data are important for understanding the structure and stability of proteins.

Bibliographic Databases

Searching for protein information through traditional bibliographic databases, such as MEDLINE or Grateful Med, can be rewarding. In addition, some bibliographic reference databases dedicated to proteins may provide certain information more directly. For example, SeqAnalRef stores papers dealing with sequence analysis.

COMBINED DATABASES

By integrating different types of protein databases together, a database of databases (or a data warehouse) can be built. Such combined databases not only serve as “one-stop shopping,” but also provide cross-references between entries in different databases. Two combined databases, Entrez and SRS, have been very successful.

Entrez

Entrez (Schuler et al., 1996) is a combined database consisting of literature, protein sequence and structure, nucleotide sequence, and taxonomy. Different types of information are interconnected through the grouping of sequences/structures and references by computed similarity scores. Entrez can be used through a variety of media, including CD-ROM, a custom Graphical Interface client, a World Wide Web browser, a command line browser (CLEVER), and the National Center for Biotechnology Information's (NCBI's) toolkit written in C.

SRS

SRS (Sequence Retrieval System; Etzold et al., 1996) is the most comprehensive database for molecular biology. The home server at <http://srs.ebi.ac.uk> supports 264 biological databases (as of March, 2003), including almost all the major protein/genetic databases. As an indexing system, it provides fast access to different databases through searches by sequence or by key words from various data fields. SRS also builds indices using cross-references between databases. An entry from one database can be linked to other databases that contain the entry. However, it should be noted that the contents of SRS may lag behind the other databases in updating (i.e., some new entries in the original databases may not be included in SRS).

SUMMARY

This unit reviews several major protein databases on the Internet, and shows what kind of information users can expect from protein databases. Although all technical procedures cannot be described here, most of the protein databases are easy to use and provide detailed on-line manuals so that even users with little computer skill can learn them quickly.

Protein databases may not always be easily accessible or usable through the Internet. Sometimes a database server may be down or the Internet connection may be interrupted. Some structures or image files are very large (several megabytes), and the download time may be long. It can be helpful to use a mirror site of the database at a close location in order to accelerate the access speed. For a frequent user, it may be worthwhile to install the database on a local machine. On the other hand, it must be kept in mind that a mirror site or a local copy may contain an older version of the database than the one on the home server.

It is important to assess the quality of the data. There are three types of data in protein databases. (1) Experimental data are generally very reliable. However, some entries may contain errors (e.g., some protein sequences) or may be based on low-resolution data (e.g., some protein structures determined by NMR). (2) Annotation data uses computational techniques on experimental data, for example, secondary structure assignment and domain partition in structure. These data depend on the quality of the experimental data and the computational methods used. Different methods may yield different results. (3) Prediction data includes, for example, sequence domain parsing and three-dimensional structure prediction. No matter how good the method, the results are still predictions and should be subjected to experimental verification. In addition, different methods typically give different predictions.

In summary, caution is needed when using the data from databases to draw a conclusion. It is worthwhile to check the same type of data from different databases and compare them. It is sometimes necessary to use additional computational tools (e.g., tools to assess the quality of a structure) for further analysis.

ACKNOWLEDGMENTS

The authors thank Drs. Edward C. Uberbacher, Michael A. Unseren, Jay Snoddy, and Gwo-liang Chen for helpful discussions. This work is supported by the Office of Biological and Environmental Research, U.S. Department of Energy, under Contract DE-AC05-00OR22725, managed by UT-Battelle, LLC.

Basic Protein Sequence Analysis

UNIT 19.5

Protein sequence analysis can be performed from many perspectives and with a vast array of bioinformatics methods. This unit will focus on those analyses that can be performed using only a computer (desktop workstation or laptop), Internet access, and a laboratory notebook to record results. All the resources needed are accessible via publicly available Web servers and databases, and require little or no computational expertise. These tools enable biologists to predict the structure of a protein, the presence of functional motifs or domains, cellular localization (e.g., membrane-bound, secreted, chloroplast, or nuclear), and post-translational modifications. Integration of all these data enables the biologist to make a more informed prediction of the likely molecular functions of proteins of interest.

A plethora of tools are available for these tasks, and in choosing preferred methods for each of the separate protocols, the authors have been guided primarily by two criteria: user-friendliness and utility. Some tools are extremely powerful, but inappropriate for the computational novice. Other tools may be easy to use, but relatively ineffectual. We have kept working biologists in mind, and asked ourselves which tools our biologist colleagues would find easiest to use and understand. With these criteria in mind, we selected one or two protocols for each task. Identifying structural domains using different types of servers are presented (Basic Protocol 1 and Alternate Protocols 1 and 2), as are procedures for predicting transmembrane regions and subcellular localization (Basic Protocol 2 and Alternate Protocol 3) and key functional residues and motifs (Basic Protocol 3). Each procedure also includes a brief discussion of some of the Web servers and databases that we feel deserve attention. Support Protocols for each method present a strategy for the integration of the results from the different procedures (Support Protocols 1, 2, 3, 4, 5, 6, and 7).

IDENTIFYING STRUCTURAL AND FUNCTIONAL DOMAINS USING INTEGRATED META-SERVERS

**BASIC
PROTOCOL 1**

Below is a protocol for the use of integrated meta-servers. Meta-servers include prediction results from several independent prediction tools to produce a consensus prediction. This helps a biologist avoid false positive predictions. Our primary protocol for this task involves the use of the SMART (Simple Modular Architecture Research Tool) server provided by the European Molecular Biology Laboratory (EMBL) at Heidelberg (Schultz et al., 1998; Letunic et al., 2004). This server integrates structure and function prediction tools with pre-calculated analyses (including domain structure prediction, intron/exon boundary detection and ortholog identification) for proteins in the Swiss-Prot and TrEMBL databases (Boeckmann et al., 2003) and all proteomes analyzed by the Ensembl group (Hubbard et al., 2002). The extensive results and appealing interface make a biologist's work much easier, and this is our reason for recommending the use of this server.

Materials

Input data

The sequence to be analyzed should be in FASTA format, or may alternatively be submitted as raw sequence (the single-letter representation of the protein sequence without the definition line). An example FASTA format is shown in Figure 19.5.1. In cases where the sequence of interest is in the Swiss-Prot or

```

Figure 19.5.1 FASTA format of AVR2_HUMAN protein sequence. The Swiss-Prot accession number is P27037 and the Swiss-Prot ID is AVR2_HUMAN.

TrEMBL databases, the accession number is normally sufficient to retrieve precalculated results. Otherwise, the protein sequence is required as described in the protocol below.

1. Point the browser at the SMART Web site (<http://smart.embl-heidelberg.de/>). On the SMART main page that appears, click either SMART MODE: NORMAL or SMART MODE: GENOMIC. In NORMAL SMART, the database contains Swiss-Prot, SP-TrEMBL and stable Ensembl proteomes. In GENOMIC SMART, only the proteomes of completely sequenced genomes are used. We recommend the use of NORMAL SMART. In the page that now appears, paste the sequence of interest in FASTA format in the box provided. If the sequence is from Swiss-Prot, TrEMBL, or the EMBL database, one could alternatively submit the Accession number or Entry name in the box marked Sequence ID or ACC (Fig. 19.5.2).
2. Select additional analyses. At this point, one can either click the Sequence SMART button or select additional analyses. In this example (shown in Fig. 19.5.3), we have selected all available analyses.
 - a. Outlier homologs.

This option will search sequence databases derived from proteins of solved structures and return the ID and E-value (see Table 19.5.1 for definition) of the top hit and the database searched. The search is done on PDB (Protein Data Bank, a database of solved structures) and position-specific iterated BLAST (PSI-BLAST) profiles derived from SCOP (Structural Classification Of Proteins; Table 19.5.1), a system of classifying proteins based on structural and functional similarity (Murzin et al., 1995).
 - b. PFAM domains.

This option searches for the presence of PFAM domains (Bateman et al., 2002) in the query sequence. Since SMART (as of November, 2004) has 667 HMMs, and PFAM (August, 2004) has 7503 hidden Markov models (HMMs), searching PFAM HMMs increases the likelihood of a match.
 - c. Signal peptides.

This gives information on whether the query sequence contains a signal peptide, using SigCleave program.
 - d. Internal repeats.

This option shows any repeated motifs found in the query.
3. Select the Sequence SMART button. This will retrieve precalculated results (when available) or search the sequence against the library of HMMs available.

Table 19.5.1 Definitions of Acronyms and Abbreviations Used in this Unit

Acronym/ abbreviation	Full name	Description
3D-PSSM	3-D Position Specific Scoring Matrix	The 3D-PSSM is a protein fold recognition server that uses 1-D and 3-D sequence profiles coupled with secondary structure and solvation potential information
BLAST	Basic Local Alignment Search Tool	BLAST is a sequence comparison algorithm optimized for speed, used to search sequence databases for optimal local alignments to a query. Variants of BLAST enable searches of protein databases using nucleotide queries and vice versa.
CDART	Conserved Domain Architecture Retrieval Tool	For a given protein query sequence, CDART displays the predicted functional/structural domains that make up the protein and lists proteins with similar domain architectures
EMBL	European Molecular Biology Laboratory	EMBL is an international research organization with its main laboratory in Heidelberg, Germany, and four outstations in Hinxton, U.K. (the European Bioinformatics Institute, EBI), Grenoble, France, Hamburg, Germany, and Monterotondo, Italy.
E-value	Expectation value	For a given score <i>S</i> and a database size, the E-value is the number of hits with scores equivalent to or better than <i>S</i> that are expected to occur in a database of that size by chance. The lower the E value, the more significant the score.
HMM	Hidden Markov Model	HMMs for proteins are statistical models (akin to profiles and PSSMs) that represent the amino acid preferences and insertion/deletion likelihoods at each position. They are used to detect remote homologs and to generate alignments of new sequences to a family.
MSA	Multiple Sequence Alignment	A multiple sequence alignment refers to an alignment of more than two sequences; pairwise alignment refers to an alignment of two sequences. Gap characters (typically, dots or dashes) are inserted between amino acids so that all sequences have the same length, and can be arranged in a matrix to display the amino acids conserved across the family. MSAs are used as input to construction of PSSMs and HMMs, to estimate phylogenetic trees, and for numerous other tasks.
NCBI	National Center for Biotechnology Information	The NCBI is the main resource for computational biologists in the U.S., and includes a number of important tools (e.g., BLAST) and databases. Databases include the CDD (Conserved Domain Database), GenBank (a comprehensive sequence database), PubMed (for retrieving papers in biomedical literature), OMIM (Online Mendelian Inheritance in Man), and a host of other important resources.

continued

Table 19.5.1 Definitions of Acronyms and Abbreviations Used in this Unit, *continued*

Acronym/abbreviation	Full name	Description
PFAM	Protein Families	PFAM is a large collection of multiple sequence alignments and hidden Markov models representing many protein domains and families. It has a web interface for identification of domains in a given protein, and includes hyperlinks to relevant literature and functional/structural information for many domains.
PSI-BLAST	Position-Specific Iterated BLAST	An iterative search using the BLAST algorithm and profile construction, enabling identification of remote homologs
PSIPRED		PSIPRED is a simple and reliable secondary-structure prediction method, incorporating two feed-forward neural networks, which perform an analysis on output obtained from PSI-BLAST to predict whether a position is likely to be found in an α helix, β strand, or coil.
PSSM	Position-specific scoring matrix	A PSSM is a statistical representation of the amino acids in a multiple sequence alignment, and is used to provide a log-odds score for each amino acid at each position in the alignment. PSSMs, HMMs, and profiles are related.
RasMol	Raster Display of Molecules.	Molecular visualization freeware to visualize 3-D structure of proteins
RPSBLAST	Reverse PSI-BLAST	RPS-BLAST (Reverse PSI-BLAST) searches a query sequence against a database of profiles (i.e., the reverse of PSI-BLAST that searches a profile against a database of sequences).
SAWTED	Structure Assignment With Text Description	SAWTED compares annotations of the query and closely related sequences with annotations associated with database hits having weak scores. This is included to improve the ability to differentiate between true homologs and spurious matches (i.e., SAWTED enables sequences with weak scores but similar annotations to be given more credence in homology search).
SCOP	Structure Classification of Proteins	The SCOP database classifies protein structural domains into a hierarchy (class, fold, superfamily and family), based on functional and structural data. Proteins in the same SCOP superfamily are expected to be related by divergent evolution from a common ancestral protein and to share a similar (albeit potentially high-level) function. Proteins in different SCOP folds are believed to not be homologous.
SMART	Simple Modular Architecture Research Tool	The SMART Web server allows rapid identification of the domain architecture of a given protein, and includes precomputed results for many sequences

Your sequence is identical to [swissprot|P27037|AVR2_HUMAN](#), displaying precalculated results.

Domains within the query sequence [gi|114722|sp|P27037|AVR2_HUMAN](#) of 513 residues

Figure 19.5.4 SMART results for AVR2_HUMAN. Integrated results from several servers show an N-terminal signal peptide, two PFAM domains, a transmembrane domain, and a low-complexity region. This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to <http://www.interscience.wiley.com/c-p/colorfigures.htm>.

4. Examine predicted domains and motifs. The features represented in the example (Fig. 19.5.4) are:
 - a. Signal peptide: the small red box at the N-terminus.
 - b. Two PFAM domains: Activin receptor and Pkinase.
 - c. Low-complexity region: pink box at C-terminus.
 - d. Transmembrane domain: Blue vertical box.
5. Place the mouse cursor over predicted domains and unidentified regions to see their start and end amino acid positions.
6. Click on the domains to get a detailed description of the domain.
7. Scroll down to see the E-value of the predicted matches.
8. Analyze results (see Support Protocol 1).

SUPPORT PROTOCOL 1

GUIDELINES FOR UNDERSTANDING RESULTS OF ANALYSES FROM INTEGRATED META-SERVERS

The domains in SMART (see Basic Protocol 1) are represented by seed alignments (alignments used to build the HMMs). Homologs are gathered by different iterative methods and included in a multiple sequence alignment (MSA) after estimating the statistical significance of sequence similarities and examining experimental biological information, if available. To reduce redundancy in a family of sequences representing a domain, a phylogenetic tree is constructed using the MSA of all the sequences in the family, and, from every branch that is less than a distance of 0.2 on the tree, only a single sequence is chosen. This corresponds to about 80% sequence identity. These sequences are then used in the seed alignment from which the profiles and HMMs representing a domain are constructed (Schulz et al., 1998).

Interpreting the Significance of a Match to a Profile

Most similarity search methods employ E-values (Expect values) to report the statistical significance of a match. How an E-value is calculated varies with each method. Generally, the E-value represents the number of matches expected to be found merely by chance. For instance if an E-value is 10, then 10 matches are expected to be found by chance alone. In general, an E-value <0.001 is a good indicator of the credibility of predicted homology, and the likelihood of a spurious result increases as the E-value approaches 1. A significant E-value implies similarity in structure; the functional specificity may have changed. To confirm functional similarity, it is critical to check for agreement at key functional residues (particularly active site residues in the case of an enzyme), and for a high percent identity (as a conservative rule of thumb, we recommend requiring

a minimum of 40%). If the profile or HMM represents a structural domain, the query should align over a significant fraction of the profile/HMM. As a basic rule of thumb, we recommend requiring a minimum of 75% coverage.

Note that the SMART output does not provide this information (i.e., percent identity, coverage of the profile and agreement with key positions); these criteria will need to be confirmed separately.

Factors Affecting E-Value

E-values are affected by the length of the profile or HMM, with longer profile/HMMs producing more significant E-values for related sequences and shorter profile/HMMs producing weaker E-values. Weak E-values are particularly common when the profile or HMM is based on very short motifs (e.g., the PFAM Leucine Rich Repeat HMMs, having between 20 and 25 residues). Because a near-exact match to a short motif can occur by chance alone, E-values will be correspondingly high (i.e., approaching or exceeding 1) even for closely related sequences. For this reason, many HMM and profile libraries employ empirically determined score cutoffs instead of E-values (see, e.g., the PFAM gathering threshold); these tend to be more relaxed for shorter profile/HMMs than for longer.

Another factor that affects E-values is the size of the database searched. The probability of finding a match by chance increases with the size of the database searched. The upshot of this is that a match between a given query and a hit will have different E-values depending on the database searched. For example, if the E-value of a match between query X and hit Y is 0.01 on searching the National Center for Biotechnology Information (NCBI) nonredundant database (2,182,528 sequences as of November, 2004), then it will be smaller (e.g., 0.001), and hence more significant, on searching Swiss-Prot (159,078 sequences as of November, 2004) using the same search method. The database size becomes an issue especially when E-values are not extremely significant.

IDENTIFYING STRUCTURAL AND FUNCTIONAL DOMAINS USING THE NCBI CD-SEARCH

ALTERNATE PROTOCOL 1

The Conserved Domain Database (CDD; Marchler-Bauer et al., 2003) at NCBI is a database of Position Specific Scoring Matrices (PSSMs) generated from alignments imported from PFAM and SMART and automated alignments from COGs (Cluster of Orthologous Groups; Tatusov, 2001) CD-Search is a tool that uses RPS-BLAST (Reverse PSI-BLAST) to search a sequence against a database of profiles, namely the CDD (Marchler-Bauer et al., 2004). This is the reverse of PSI-BLAST, which searches a profile against a database of sequences.

Materials

See Basic Protocol 1.

1. Point the browser at the CDD (<http://www.ncbi.nlm.nih.gov/Structure/cdd/cdd.shtml>).
2. Input a sequence in FASTA format (or, alternatively, the NCBI accession or GenBank accession number) in the box provided (Fig. 19.5.5).
3. Set the Search Database from the pull-down menu of that name. The default option is CDD, but users can also search SMART, PFAM, and COGs.
4. Set other parameters using the “click here for advanced options” link, if desired.
5. Click Submit.

6. The CDD results page returns a graphic display of domains in the query, the E-values for each hit, and the alignments (Fig. 19.5.6). Analyze results (see Support Protocol 2).

GUIDELINES FOR UNDERSTANDING RESULTS OF ANALYSES FROM THE NCBI CD-SEARCH

SUPPORT PROTOCOL 2

See Alternate Protocol 1 for steps in carrying out this search.

1. The first few lines give details about the version of RPS-BLAST used, the definition line of the query sequence, and the database searched. Because the CDD has regular updates, we recommend noting these data for record-keeping purposes.
2. In the graphic display, the query sequence is represented as a black bar with a ruler above indicating its length. Low-complexity regions are marked in cyan.
3. The domain matches are shown below in different colors depending on the E-value of the hits. The best hits are marked in red, the second best in blue and so on. The CDD contains multiple PSSMs for the same structural domains; these may have differences in length and coverage of the query, and have correspondingly different E-values. Hits to conserved domains that are related by the Conserved Domain Architecture Retrieval Tool (CDART; Geer et al., 2002; also see Table 19.5.1) resource are indicated by the same color. In the example in Figure 19.5.6, the hits to different PSSMs representing kinase domains are all colored red.
4. A jagged edge seen in the hit display indicates incomplete coverage of the domain (a default minimum of 80% coverage is used by the CD search). For example the SPS1 domain in Figure 19.5.6 contains a jagged right edge, indicating that the alignment to the query does not contain this region of the domain.
5. Below the graphical display is a list of hits along with their E-values. A pink dot before the hit indicates the presence of a structure for the predicted hit. Clicking on the dot will display the structure. Prior installation of Cn3D software is required (<http://www.ncbi.nlm.nih.gov/Structure/CN3D/cn3d.shtml>).
6. Scrolling down the page displays the pairwise alignment between the query and a representative sequence for the PSSM. Identical residues between the query and the hit sequence are colored red, similar residues are colored blue, and masked-out regions are in italics.

Viewing a multiple sequence alignment (MSA) of the query to a conserved domain

7. Clicking on the graphical display of a domain brings up a multiple sequence alignment of the query to selected PSSM training sequences (Fig. 19.5.7). By default, sequences with high similarity to the query protein are shown. This page gives information about the source of the domain alignment, PubMed references, description, and other relevant data. The default MSA viewing option is Hypertext; our guidelines for interpreting results assume this option is used.
8. Interpreting the MSA: aligned positions are in uppercase, unaligned positions are in lowercase, and gaps are indicated by dashes (-). Residues labeled “unaligned” are inserts between positions in the predicted consensus structure. Profiles and hidden Markov models (HMMs) are constructed to represent the conserved structural elements of a protein family or domain. Amino acids corresponding to additional structure (e.g., extended loop regions) will be displayed in lowercase. These lowercase letters are indicative of insertions relative to the consensus structure. Missing parts of the consensus structure are indicated with dash characters (--).

Figure 19.5.7 Multiple sequence alignment of AVR2_HUMAN kinase domain with a conserved kinase domain hit. The columns marked with # have been identified as central for kinase function.

9. For domains with a solved structure, one can view the structure using the View 3D Structure option. The coloring scheme of the alignment can be changed to indicate different levels of conservation. For instance using the option Identity from the “color bits” pull-down menu shows identical residues in the alignment in red, aligned residues in blue, and unaligned residues and columns containing many gaps in gray.
10. Features defining a family are highlighted with # above the corresponding columns in the MSA. The evidence for the feature is presented at the bottom of the MSA. This is useful to predict if the query sequence also contains residues important for the family. In our example, clicking on the S_TKc shows a catalytic loop as feature 1 and the 3-D structure as evidence.

Interpreting the significance of results

11. If E-values are weak, it may be helpful to examine the PSSM hits to see if all refer to the same structural or functional class, or if competing hypotheses for a region are presented by the CDD analysis. Checking for significant percent identity and coverage (as described in the SMART discussion earlier in this unit) is important to avoid spurious and misleading predictions.

12. The Advanced Search mode allows users to change the maximum allowed E-value cutoff. This is generally done if no matches are possible with more restrictive cutoffs. If a permissive threshold (e.g., E-value 1) is used, false positive matches should be expected.
13. Though the domains represented in CD are similar to those in PFAM and SMART, the search and scoring mechanisms are very different. While PFAM uses profile HMM scoring, CD-Search employs RPS-BLAST. Hence, the E-values that are reported from PFAM and CD-Search for the same PFAM domain may not be identical.

To interpret the significance of E-values and the effect of profile/HMM lengths on E-values, see the guidelines described in Support Protocol 1.

PREDICTING STRUCTURAL DOMAINS AND SECONDARY STRUCTURE USING 3D-PSSM

ALTERNATE PROTOCOL 2

3D-PSSM is a Web server designed explicitly and exclusively for protein structure prediction, which incorporates a variety of advanced remote homolog detection and threading methods (Kelley et al., 2000). We present the 3D-PSSM as a supportive procedure in cases where other servers are unable to provide clues to molecular function or structure for regions of the protein. In these cases, the advanced methods incorporated in the 3D-PSSM workflow can often give insights not available via other servers for identifying homologous structures. In contrast to PFAM, the NCBI CDD, and many other servers that model both structural domains and domains having no known structure, any match to a 3D-PSSM domain implies a solved structure for that region. One of the great benefits of 3D-PSSM is the automatic construction of a homology model for any regions in the query matching one or more of the 3D-PSSM models.

The 3D-PSSM server is continually updated. As of February, 2005, 3D-PSSM contains a library of 9864 PSSMs representing structural domains.

Materials

See Basic Protocol 1.

1. Point the browser at <http://www.sbg.bio.ic.ac.uk/servers/3dpssm/>.
2. Click on Recognise a Fold (Fig. 19.5.8A) for the sequence submission form.
3. Enter a valid e-mail address.
4. Paste the query sequence in FASTA format. The query sequence must be <800 residues. The maximum number of residues allowed per submission by 3D-PSSM is restricted to 800. If the protein of interest has >800 residues, we suggest that it be submitted in two parts with overlap. For example, for a protein of 1000 residues, submit region 1 to 600 first, and 400 to 1000 next.
5. Click Submit. Results of the run will be returned by e-mail. The e-mail also contains a hyperlink to the Web version of the results. Results are stored only for 5 days in the server (we recommend downloading results from the Web site).
6. Click on the hyperlink in the e-mail to open a Web page with the results (Fig. 19.5.8B). Analyze results (see Support Protocol 3).

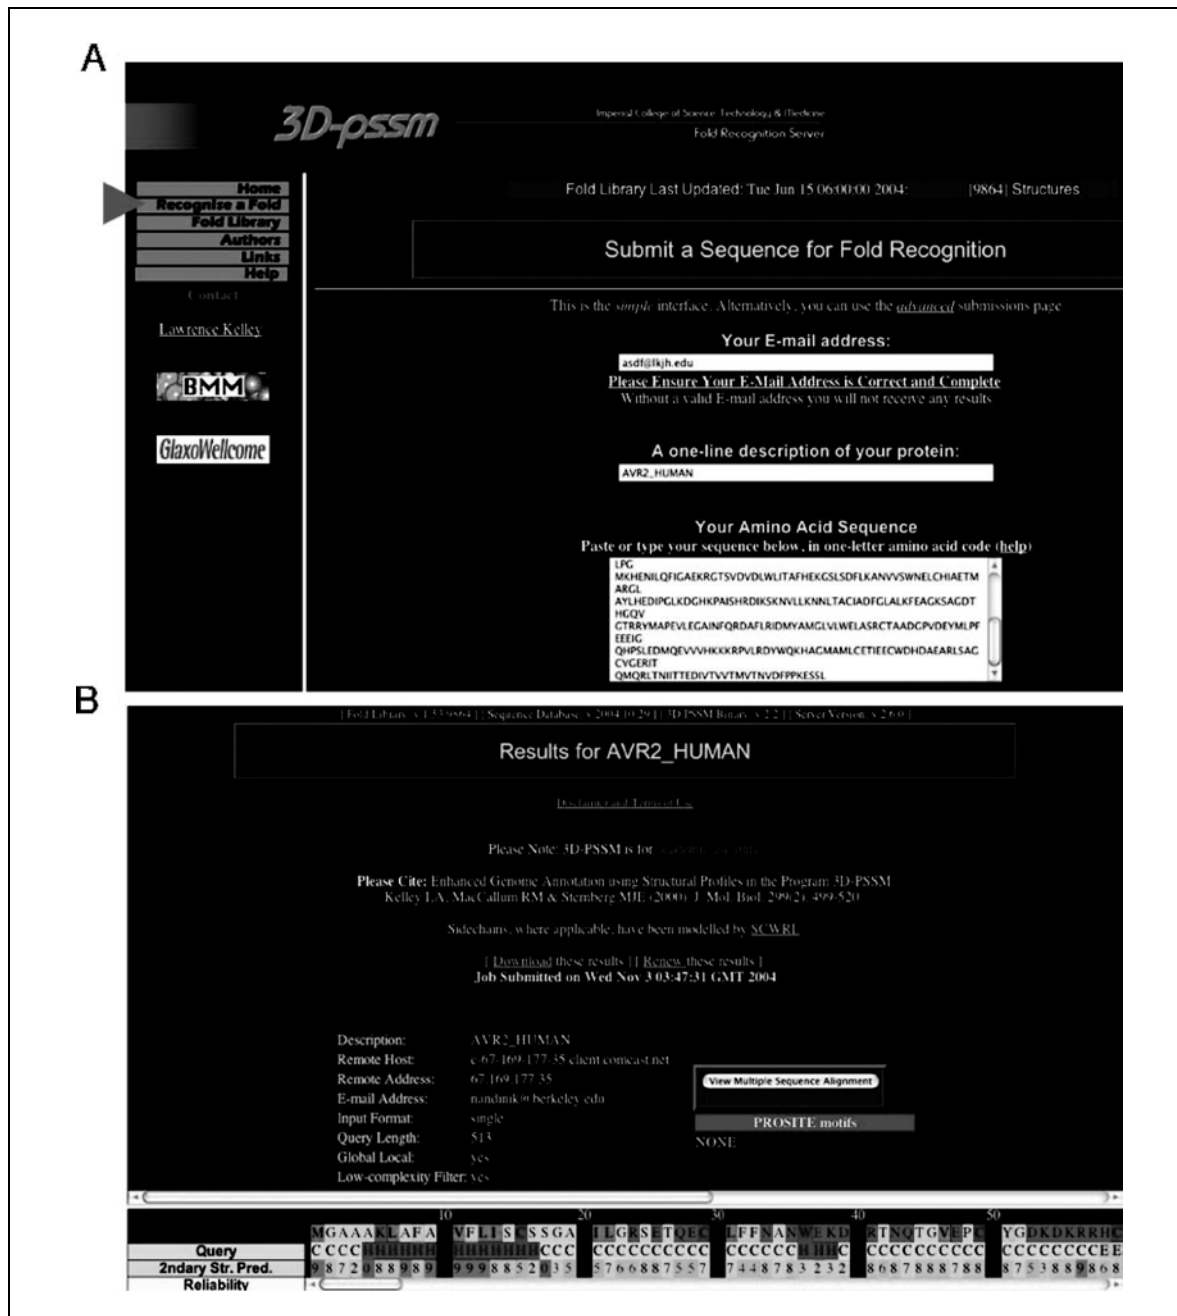

Figure 19.5.8 Submission form and results page from 3D-PSSM server. **(A)** The submission form; **(B)** the results page.

**SUPPORT
PROTOCOL 3**

**GUIDELINES FOR UNDERSTANDING RESULTS OF ANALYSES FROM
THE 3D-PSSM SERVER**

We recommend 3D-PSSM (see Alternate Protocol 2) as an alternative for domain identification for those cases where regions of a protein have no significant matches to domains in the CDD or SMART databases. In these cases, the advanced methods used by 3D-PSSM may be able to identify a weak but potentially significant match to a protein of solved structure and shed light on the functional role of the protein. Caution must be employed when examining the 3D-PSSM results where the E-value is only marginally significant (e.g., >0.001), as the potential for a false positive match increases as the E-value approaches 1.

**Basic Protein
Sequence Analysis**

19.5.12

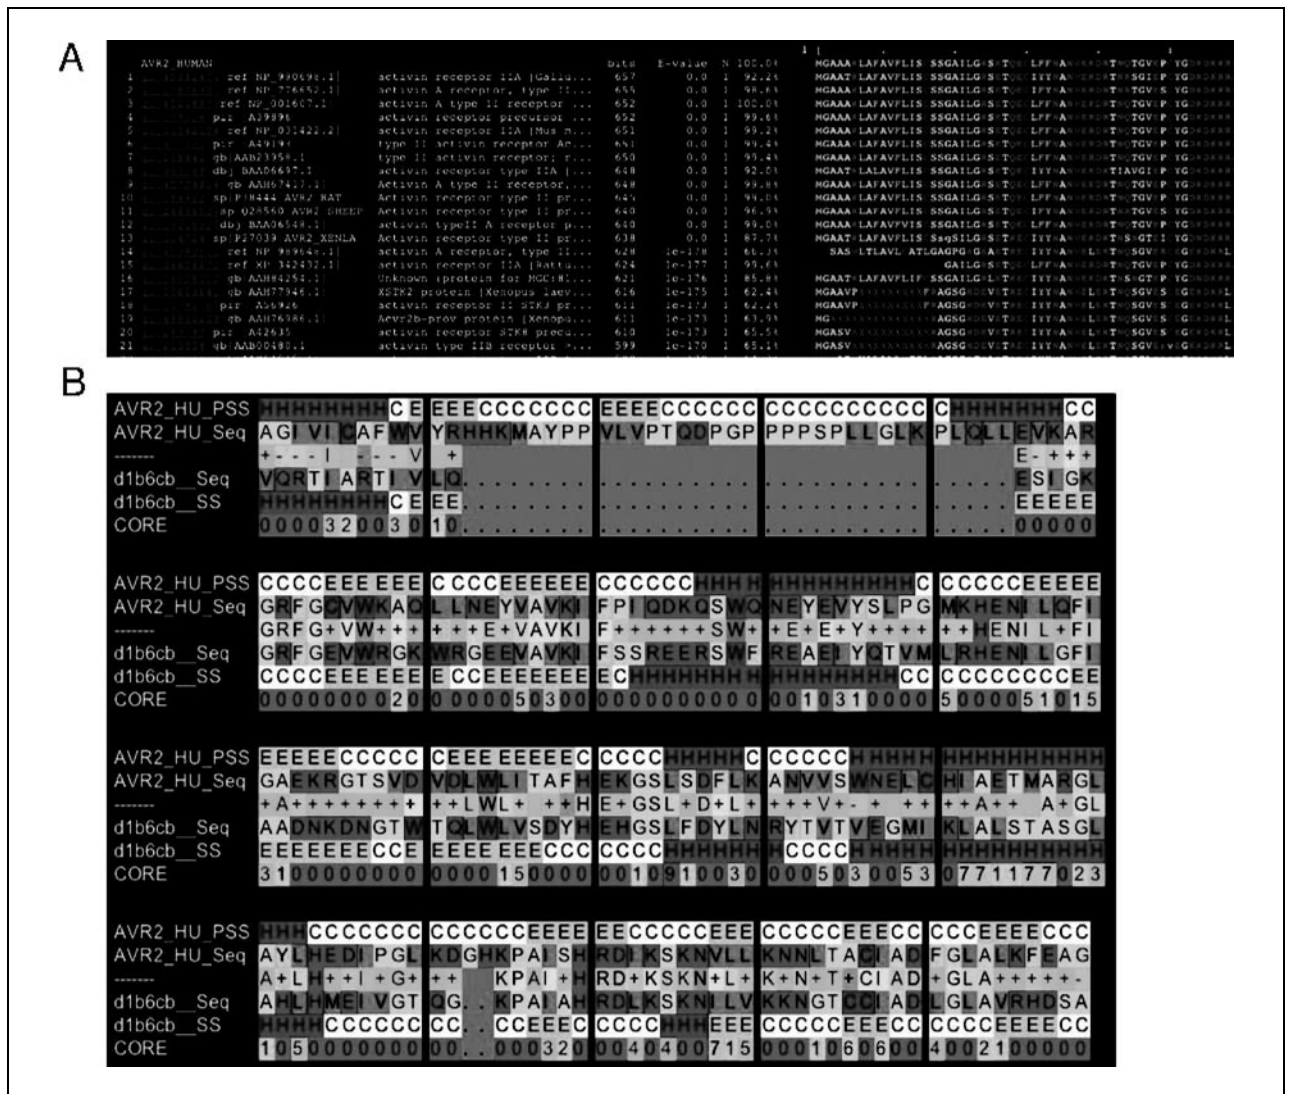

Figure 19.5.9 Sequence alignments produced by 3D-PSSM (A) Alignment of query to its homologs. (B) Pairwise alignment and comparison of secondary structure and solvent accessibility predictions for the query with that of the hit (structural domain). This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to http://www.interscience.wiley.com/c_p/colorfigures.htm.

The 3D-PSSM Web server produces a great deal of interesting and informative results, some of which are beyond the scope of this unit. In this protocol, we highlight a selection of the most interesting results. We encourage users to explore further.

1. The first page of the results is separated into two frames. The upper frame contains a summary of results. The lower frame shows the secondary structure of the query sequence predicted by PSIPRED (Jones, 1999; also see Table 19.5.1). We focus here on results in the upper panel.
2. Click on View Multiple Sequence Alignment to examine the alignment of the query and predicted sequence homologs (Fig. 19.5.9A). The 3D-PSSM Web server uses this alignment to construct a PSSM and score proteins of solved structure, as part of a bidirectional search for structural homologies. Each sequence in the alignment has a hyperlink to the corresponding GenBank file at NCBI. The scores and E-value of each hit, and percent ID to query are also available.

- Return to the original results page and scroll down to view matches to structural domains. The top 20 structural hits are shown in a tabular format. The table contains the following information.

- Alignment.

A link to the sequence alignment of the query to the hit (structural domain) and comparison of the secondary structure and solvent accessibility of residues between query and hit (Fig. 19.5.9B).

- Fold Library.

The ID of the structural hit (d[`pdbservice`] [`chain`] [`region`]), along with the pairwise ID between query and hit, are shown. Clicking on the ID brings up a page of the fold library containing information about the hit structural domain, including an MSA of the hit with its sequence and structural homologs.

- Models.

A link to the predicted 3-D model of the query protein based on the alignment to the hit which can be viewed by the protein visualization software RasMol (see Table 19.5.1) or Chime.

- E-value.

The E-value of the hit is shown, colored according to level of confidence, red indicating very high confidence.

- Other information.

The other information in the table includes SAWTED (Table 19.5.1) E-value for text matching between query and definitions of hits, SCOP classification of hit, and other data.

If the E-value to a structural hit is >.001, the following analyses are recommended to assess the credibility of the predicted homology

- Check the sequence alignment. The query and structure should align with few insertions or gap characters, and have significant pairwise identity. As a rule of thumb, a pairwise identity of 25% or more over 80 amino acids can be used to infer homology (assuming very few gaps). As the percent identity drops below this level, the potential for a spurious match by chance alone increases. In these cases, it is critical to confirm that the alignment shows agreement at known critical residues.
- Compare the agreement between predicted and known secondary structure. Compare the predicted secondary structure of the query with that of hit. The secondary structures are indicated as follows: H for Helix; E for Strand; C for Coil. Agreement between helical and sheet structure is generally more important than in the more variable coil regions.
- Compare the agreement in the conserved core structure. The hydrophobic core region of the structural domain hit is marked in the MSA page as Core (Fig. 19.5.9B), numerically labeled to indicate how buried the residues are (9 for very buried and making many contacts and 0 for exposed and making few contacts) and color coded to indicate important core residues (red for important core residues). Significant gaps or inserts in the conserved core elements of the structure should be considered evidence against the predicted homology.

An important issue to keep in mind is that 3D-PSSM may only identify one structural domain in a multidomain protein. To enable identification of domains in the remaining region(s) of the query, separate submissions of unknown regions are necessary.

There are a few other Web servers and databases enabling integrated searches, as shown in Table 19.5.2.

Table 19.5.2 Web Servers Providing Domain Identification Tools

PREDICTING HELICAL TRANSMEMBRANE REGIONS AND SUBCELLULAR LOCALIZATION

The molecular function of a protein is context-dependent; the subcellular localization of a protein plays a large role in determining its partners and pathway interactions. The cellular sorting machinery makes use of sequence signals targeting a protein for secretion, targeting it to different organelles, or targeting it for insertion into the membrane. Bioinformatics methods take advantage of these motifs and patterns as well as other sequence attributes to predict where a protein is localized. We review these in this protocol.

Our primary recommended resource for this protocol makes use of a variety of software tools developed by the Center for Biological Sequence Analysis at the Technical University of Denmark (<http://www.cbs.dtu.dk/services/>). This resource enables the detection of helical transmembrane domains, signal peptides, and other organellar targeting signals. Due to the biological importance of transmembrane proteins, we discuss the detection of these domains first.

Prediction of helical transmembrane regions in protein of interest

Transmembrane predictions involve not only the location of probable membrane helices in a protein, but also the full topology of the protein with respect to the membrane (i.e., which regions of the protein span the membrane, which regions are cytoplasmic, and which are extracellular). Among the several Web servers available for transmembrane prediction, we describe the use of the TMHMM server. The TMHMM server uses sophisticated hidden Markov models methodologies to predict transmembrane regions in proteins, incorporating information on hydrophobicity, helix length, charge bias, and topological constraints into its model (Krogh et al., 2001). It has a user-friendly Web interface, is fast in its searches, and allows batch mode submissions of up to 4000 sequences.

BASIC PROTOCOL 2

Informatics

19.5.15

Materials

Input data

Protein sequence file, in either raw or FASTA format (Fig. 19.5.1), or, if more than one sequence is used, a file containing all the input sequences in FASTA format can be used

1. Point the browser at the TMHMM server (<http://www.cbs.dtu.dk/services/TMHMM/>).
2. Paste in the sequence(s), or upload a file directly from the local computer (recommended when one wants to analyze large numbers of sequences). To upload a file, use the Browse button below the text “Submission of a local file in FASTA format.” Each file can contain at most 4000 sequences.
3. Set display options. If submitting a single sequence, we recommend setting the display as “Extensive, with graphics.” This will provide results in the most information-rich format (see below). The recommended option for multiple sequence search is “One line per protein.” This returns the results in a tab-delimited format that can be saved as a text file to be opened in a program like Excel.
4. Click Submit. After a short time the results will be displayed.
5. Only 10 job (including batch mode) submissions per day are allowed per user.
6. Analyze results (see Support Protocol 4).

SUPPORT PROTOCOL 4

GUIDELINES FOR UNDERSTANDING RESULTS OF PREDICTIONS OF HELICAL TRANSMEMBRANE REGIONS AND SUBCELLULAR LOCALIZATION

For steps in predicting helical transmembrane regions and subcellular localization, see Basic Protocol 2.

1. Depending on the selection during submission, the results could be either in “long” or “short” format. The long format is shown in Figure 19.5.10.
2. View summary of results containing the following information:
 - a. Length.
Length of query protein.
 - b. Number of predicted TMHs.
Number of predicted TM helices in the query.
 - c. Exp number of AAs in TMHs.
Number of amino acids predicted to be in TM helix. If this number is greater than 18, then it is predicted to be a TM.
 - d. Exp number, first 60 AAs.
Number of amino acids expected to be in TM helix in the first 60 residues. A warning POSSIBLE N-term signal sequence is generated if this number exceeds 10.
 - e. Total prob of N-in.
This represents the probability of N-terminal region being on the cytoplasmic side.
3. View plot. The plot summarizes the various signals used by the TM server. The *x* axis corresponds to the amino acid positions while the *y* axis corresponds to the likelihood of an individual position being predicted to be in a TM. Note that the *y* axis continues beyond a value of 1; the region above 1 is used to display the topology. Since the

Figure 19.5.10 TMHMM output for AVR2_HUMAN. Shown are results in the “extensive with graphics format.” A summary of results is followed by a graphic display. The x axis on the graph represents amino acid positions in the query sequence and the y axis represents the probability of a residue to be in a TM. The peaks indicate positions with higher probability of being a TM domain. The predictions of TM and topology are indicated above a y axis value of 1. The region predicted to be inside (cytoplasmic) is represented with a blue line (marked as INSIDE in this figure) and the region on the outside (extracellular) is represented in pink (labeled OUTSIDE in this figure). This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to http://www.interscience.wiley.com/c_p/colorfigures.htm.

TMHMM server integrates a variety of signals from the protein, occasionally the predicted number of helices is lower than the number of peaks in the plot.

4. View raw data. Below the plot is a hyperlink to the raw data for the plot.
5. Cautions

- a. Accuracy of topology predictions

The accuracy of topology prediction (i.e., which parts of the proteins are extracellular and which are cytoplasmic) is known to be one of the most challenging aspects of transmembrane predictions. Even when the location of transmembrane domains is predicted correctly, the topology can be reversed.

- b. Potential for false positives and false negatives.

All TM prediction servers are known to have problems with false positive and false negative predictions. False positives arise often for hydrophobic stretches and signal peptides. False negatives can arise for any number of reasons, and are particularly common in noncanonical TM stretches containing some polar or charged residues.

- c. Incorporating prediction of globular structure.

It can be helpful to integrate domain detection, particularly of globular domains, when interpreting TM predictions. If a predicted TM occurs in a region that has a significant match to a protein of solved structure, we recommend examining what is known about that structure. Some structures include transmembrane domains, but

these are few. The vast majority of solved structures represent globular (soluble) domains that do not include transmembrane domains. If a predicted TM domain has a significant match to a globular protein, and that region is not at the extreme N- or C-terminus of the domain, we would discount the likelihood of the TM domain.

**ALTERNATE
PROTOCOL 3**

**PREDICTING THE SUBCELLULAR LOCALIZATION OF A PROTEIN
USING TargetP**

Cells have evolved a complex machinery for enabling proteins to be targeted to specific sub-cellular locations. Targeted proteins have specific signals recognized by the machinery. For secreted proteins and those targeted to the organelles such as mitochondria or chloroplast, the targeting signals are amino-terminal peptides recognized by the translocation machinery (Schatz and Dobberstein, 1996).

The targeting signals for different locations have specific features. For instance, the amino-terminal signal peptide (~20 amino acids) that targets proteins for secretion starts with a positively charged segment followed by a central hydrophobic region and a polar segment containing the cleavage site recognized by the signal peptidase. Different approaches have been developed to predict protein localization (Emanuelsson and von Heijne, 2001). Most methods specialize in predicting one specific location (e.g., SignalP for predicting signal peptides). In this protocol we review TargetP, an integrated approach that distinguishes proteins targeted to different locations in the cell such as mitochondria, chloroplast, and the secretory pathway.

Materials

See Basic Protocol 2.

1. Point the browser at the TargetP server (<http://www.cbs.dtu.dk/services/TargetP/>).
2. Paste in the sequence(s), or upload a file directly from the local computer.
3. Identify the origin of the protein sequence (i.e., plant or animal). If it is of plant origin, TargetP will search for chloroplast localization signals.
4. Select the option to perform a cleavage site prediction.
5. Use default settings for specificity cutoffs. Click the “Submit sequence/file” button.
6. Analyze results (see Support Protocol 5).

**SUPPORT
PROTOCOL 5**

**GUIDELINES FOR UNDERSTANDING RESULTS PREDICTING THE
SUBCELLULAR LOCALIZATION OF A PROTEIN USING TargetP**

Results (see Alternate Protocol 3) include scores for different predicted cellular locations (Fig. 19.5.11).

SP : Signal peptide
mTP : Mitochondrial target peptide
cTP : Chloroplast (if plant sequence is used)
Other: For other locations

Along with the scores, a “reliability class” (RC) is also calculated. This gives information on the difference between the highest score and the second best.

RC 1: $\text{diff} > 0.800$
RC 2: $0.800 > \text{diff} > 0.600$
RC 3: $0.600 > \text{diff} > 0.400$
RC 4: $0.400 > \text{diff} > 0.200$
RC 5: $0.200 > \text{diff}$

Figure 19.5.11 TargetP prediction of the subcellular localization of AVR2_HUMAN.

Table 19.5.3 Cellular Localization Prediction

Web server	Description	URL
TMHMM	The TMHMM transmembrane helix prediction server	http://www.cbs.dtu.dk/services/TMHMM/
DAS	The DAS transmembrane helix prediction server	http://www.sbc.su.se/~miklos/DAS/
SignalP	The SignalP signal peptide prediction server	http://www.cbs.dtu.dk/services/SignalP/
ChloroP	The ChloroP chloroplast targeting prediction server	http://www.cbs.dtu.dk/services/ChloroP/
PredictNLS	Nuclear localization signal prediction	http://cubic.bioc.columbia.edu/predictNLS/

In interpreting TargetP results, it is important to consider both the predicted location as well as the RC score. Lower RC values imply greater expected accuracy; an RC of 1 or 2 is a good indicator of reliability. In our example, the score for SP is 0.853 and the RC value is 1, both supporting the prediction of presence of a signal peptide in the protein (Fig. 19.5.11). TargetP is known to have greater specificity in prediction compared to other methods in this class, but this comes at a cost of sensitivity. A null prediction does not imply that the protein is cytoplasmic. By contrast, cleavage-site prediction is less precise. Finally it is critical to indicate whether the input sequence is of plant or animal origin so that the appropriate localization tests can be performed; it is otherwise difficult to distinguish between chloroplast and mitochondrial signals.

Other resources for prediction of transmembrane helices or subcellular localization can be found in Table 19.5.3.

PREDICTING KEY FUNCTIONAL RESIDUES AND MOTIFS USING THE PROSITE WEB SERVER

Not all residues in a protein are created equal. Residues in active sites, e.g., the catalytic triad of serine proteases, are critical for enzymatic activity. Other positions may be involved in substrate recognition and binding. Still other positions may be conserved for structural reasons. Over the years, biologists have identified a large number of key residues and conserved motifs that are useful in defining and recognizing protein families.

Our primary recommended resource for this protocol is PROSITE. The PROSITE Web server enables a biologist to determine whether any experimentally characterized motifs are present in a sequence of interest (Sigrist et al., 2002; Hulo et al., 2004). This resource enables the detection of different protein motifs, post-translational modification sites, and domains. Since domain detection is provided through other servers (presented earlier in this unit), this protocol focuses on the use of the PROSITE Web server for detecting the presence of conserved motifs and functional residues.

**BASIC
PROTOCOL 3**

Informatics

19.5.19

Materials

Input data

Sequence in raw or FASTA format (Fig. 15.9.1)

1. Point the browser to the PROSITE Web site (<http://us.expasy.org/prosite/>).
2. Input the sequence in FASTA format in the sequence box provided.
3. Choose the option to exclude patterns with high probability of occurrence. This will decrease the likelihood of spurious predictions.
4. Click the Quick Scan button to search for conserved motifs in the PROSITE database.
5. Analyze results (see Support Protocol 6).

SUPPORT PROTOCOL 6

GUIDELINES FOR UNDERSTANDING RESULTS OF SEARCHES DONE USING THE PROSITE WEB SERVER

The PROSITE Web server (see Basic Protocol 3) includes both pattern and profile search. Profiles are usually constructed to represent domains and protein families, while patterns are confined to the representation of short conserved motifs and critical residues. When a query protein is submitted, both patterns and profiles are searched and the results are returned as “hits by profile” (Fig. 19.5.12A) and “hits by patterns” (Fig. 19.5.12B). For each detected feature, the position and the sequence motif are provided along with a link to detailed information about each feature. Placing the mouse cursor over predicted domains in the graphical display highlights the corresponding region in the sequence.

Pattern detection has certain advantages relative to profile search. First, pattern detection is extremely fast. Second, and potentially of greater interest to biologists, the results are easily interpreted; the motifs are typically quite short, and critical residues defining the motif can be examined easily.

There are two main disadvantages to pattern detection, relative to profile search. First, a strict agreement with a pattern is required, resulting in lower sensitivity than the more permissive profile searches, which allow substitutions. Second, the results from pattern searches are not given scores; the pattern is either present or it is not. This makes it difficult to evaluate the significance of the match. In addition, some patterns have a high associated false-positive rate (this is more common in very short or highly variable patterns). For example, the post-translational modification site for N-glycosylation is Asn-Xaa-Ser/Thr (where Xaa represents any amino acid). However, the presence of this motif may not be sufficient to ensure glycosylation, as the process is also dependent on the structure of the protein (Sigrist et al., 2002).

The PROSITE Web server contains information to help reduce the likelihood of errors. First, each pattern includes information regarding the number of hits obtained while scanning the Swiss-Prot database with that pattern, the number of false positives and false negatives, and results from pattern search using database randomization. These data should be consulted to obtain an understanding of the likely significance of a match to this pattern. In addition, the PROSITE profile searches can provide additional support for a functional classification based on motif and pattern detection. For instance, the presence of a serine/threonine protein kinase signature pattern along with detection of kinase domain for AVR2_HUMAN strengthens the significance of the prediction.

An example of a six-amino-acid PROSITE pattern is shown below.

G-{EDRKHPFYW}-x(2)-[STAGCN]-{P} [G is the N-myristoylation site]

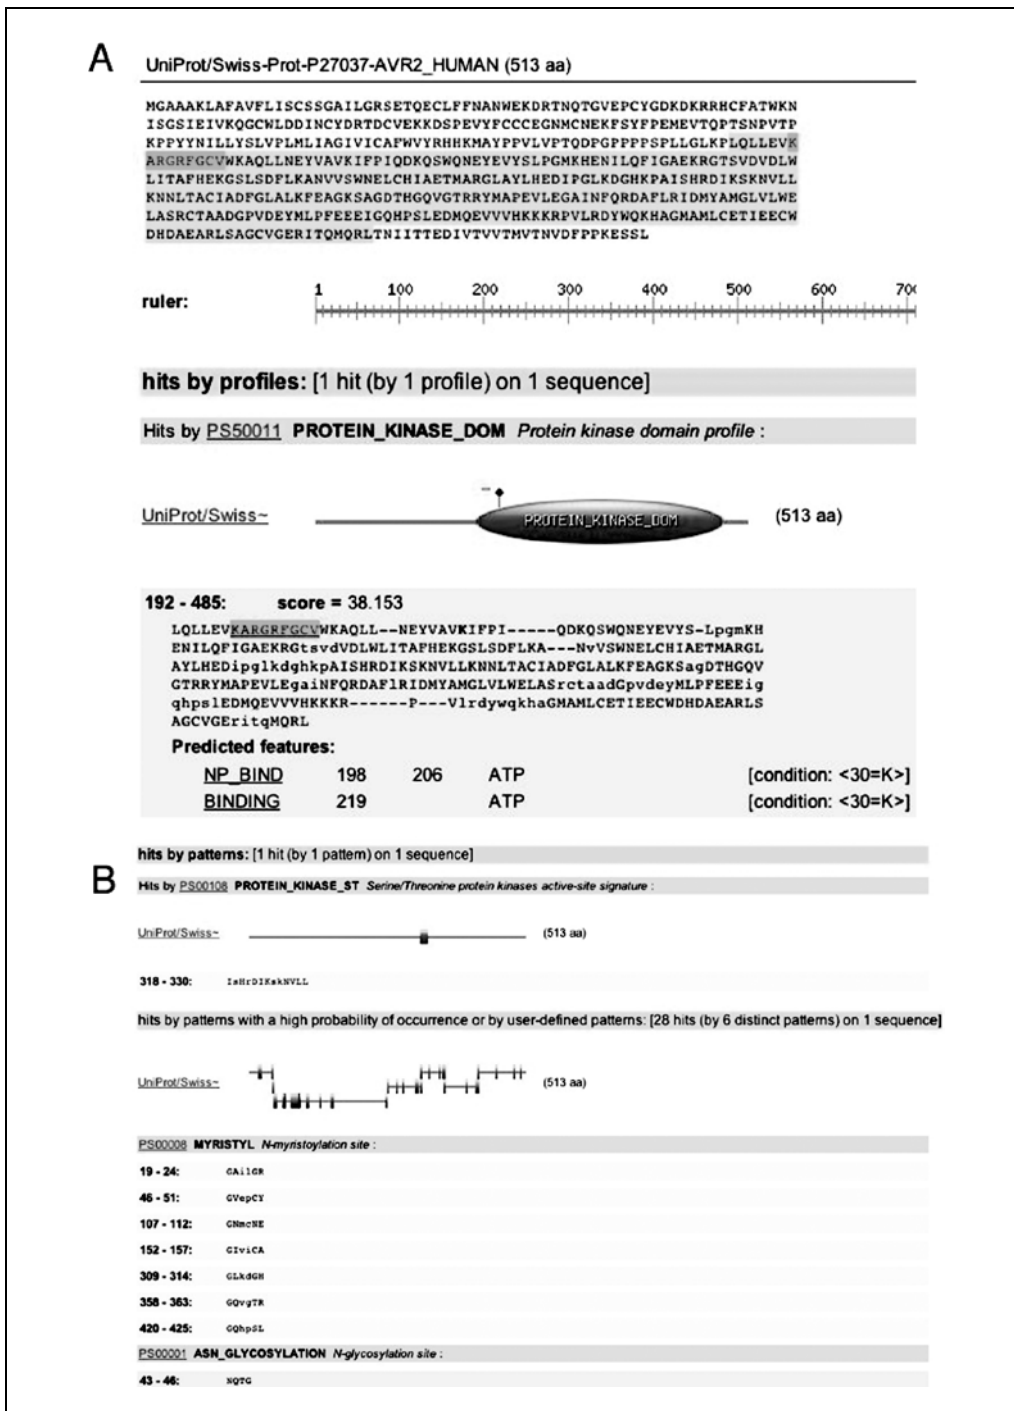

Figure 19.5.12 Prediction of patterns by PROSITE for AVR2.HUMAN. (A) results of profile search; (B) results of pattern search.

Residues in straight brackets ([]) designate residues that are favorable at a position. Residues in curly brackets ({}) designate those amino acids that are *not* allowed at a position (i.e., in this example, the amino acids EDRKHPFYW are not allowed at position 2). The sequence x (2) indicates any two amino acids.

Other resources for similar tasks can be found in Table 19.5.4.

SUPPORT PROTOCOL 7

HOMOLOG IDENTIFICATION

As a support protocol, we encourage biologists to gather homologs for their sequence of interest and to construct and analyze a multiple sequence alignment of these homologs. The BLAST family of methods (Altschul et al., 1990) is by far the most popular means for identifying homologs in database search; we refer readers to *UNIT 19.3* in this manual or the BLAST tutorial at the NCBI Website (<http://www.ncbi.nlm.nih.gov/Education/BLASTinfo/tut1.html>).

Homolog identification is useful for a variety of reasons. First, homologs can give clues to the overall molecular function of a protein. When inferring molecular function by homology, it is critical to confirm that the query and hit have the same overall fold (i.e., are globally alignable), that they are orthologous, and that the database annotation of the hit is based on experiment and not homology (reviewed in Eisen, 1998, and in Sjölander, 2004).

Gathering homologs is also the first step in construction of a multiple sequence alignment and the (somewhat esoteric) art of alignment gazing. Alignment gazing can help a biologist discriminate between true homologs and spurious inclusions, and assists in the identification of key functional residues. Sequences inserting large numbers of amino acids, that do not align over long regions, or that do not agree at conserved positions (especially longer conserved motifs) should be removed from the alignment. The final set of high-confidence homologs can be used to supplement the structure-prediction efforts (i.e., by parallel analyses using all the servers and approaches described in this unit). In addition, the multiple sequence alignment can be used as input into motif-discovery systems such as MEME. This is particularly helpful when there is limited (or no) success in analysis of the query sequence. Consensus approaches such as these have been shown to dramatically improve prediction accuracy.

COMMENTARY

Background Information

Each of the methods presented in this unit has the potential to produce errors of different types. When examining results, it is important to keep in mind the types of errors that are possible with each method, and to attempt to separate those predictions that are highly credible from those that are potentially misleading.

Homology-based function prediction is particularly prone to systematic error; domain shuffling, gene duplication, and speciation produce families of proteins sharing some regions of similarity but with different functions and

overall folds. Because of these issues, even a significant E-value between a query and a database hit is not sufficient for inference of molecular function. To avoid these errors, phylogenomic inference of a protein's molecular function in the context of its related family members is critical. A detailed description of this approach is beyond the scope of this unit; overviews of the issues and methodologies for phylogenomic analysis are presented in Eisen (1998) and Sjölander (2004).

For these reasons, this unit focuses less on obtaining a prediction of precise molecular

function and more on a structural annotation of a protein. The protocols presented here have been selected to enable a biologist to label regions in the protein as functional or structural domains, to identify key residues and motifs, and to predict a protein's cellular localization.

Most homolog-detection methods use either profile- or HMM-based strategies. Both profiles and HMMs are generalizations of multiple sequence alignment of homologs. They differ in how they estimate gap parameters; profiles have a fixed cost for insertions and deletions, while HMMs learn them from the training sequences used in the MSA, thus varying the cost for different positions. Both methods are dependent on precision of homolog gathering, alignment accuracy, and estimation of amino acid substitutions.

Domain-based approaches to protein annotation have a critical limitation. The profiles (and HMMs and PSSMs) used to detect the presence of these domains are typically optimized for remote homolog detection. This makes them very effective at providing clues to a protein's fold or function that might otherwise not be achievable. However, because some protein folds are able to provide a multiplicity of distinct functions, a significant score to a profile for a domain may mean only that the query has a similar *fold*, but may not actually imply a common molecular function. We strongly advise checking for agreement at key functional residues (where this information is available). The use of consensus approaches to predicting a protein's structure can help avoid errors, provided that the individual methods are orthogonal. For instance, since both SMART and the CDD include PFAM profile HMMs in their structure-prediction process, a consensus structure prediction between the NCBI CDD or SMART and PFAM is much less informative than a consensus of the NCBI CDD and the 3D-PSSM structure prediction Web server (which uses an entirely different approach).

Methods for predicting helical transmembrane domains often rely on weak nonspecific signals such as hydrophobicity, and hence have a fairly high frequency of false-positive as well as false-negative predictions (Chen et al., 2002). To boost accuracy in this task, we strongly encourage biologists to examine alternative hypotheses. Does the predicted transmembrane domain occur in a region predicted (with a significant E-value) to be a globular structure? Is it found at the amino-terminus (where it is more likely to be a signal peptide)? In either case, the probability of the

region being a transmembrane domain should be discounted.

In summary, our recommendation for enhancing prediction accuracy involves integrating results and information from a variety of different resources, and biological data should be incorporated wherever possible.

Critical Parameters and Troubleshooting

On occasion, a Web server will report an error for certain input sequences. In some cases, hidden characters may make identification of the problem difficult. If this happens, try truncating the definition line to the name of the protein, inserting a carriage return after the definition line, and then resubmitting the sequence.

Analysis and Management of Microarray Gene Expression Data

Microarray technology has been available to researchers for approximately 10 years, and over time a few aspects of its use have become standard. In this unit, the basic steps and common applications for microarray gene expression studies are covered, including pre-processing, analysis, and data management. Several different array-based platforms are available to analyze transcript abundance, including spotted cDNAs, spotted oligonucleotides, and in situ-synthesized oligonucleotides (i.e., Affymetrix or Nimblegen; see UNIT 22.4 for discussion of different platforms). The information provided in this unit will be generally applicable to the different platforms and special considerations noted. Microarrays are now used for purposes besides monitoring transcript abundance, including detecting mutations and protein binding (see also UNIT 22.1); however, these will not be addressed here, and microarray will always refer to a transcript abundance microarray in this unit.

Microarray practitioners have the benefit of standards that have been developed to specify what information should be recorded with a microarray experiment. The Microarray Gene Expression Data Society (MGED Society, see Internet Resources) has developed the Minimal Information About a Microarray Experiment (MIAME) checklist that has been adopted by many journals as a requirement for publication and has become an internationally accepted standard in this area. These journals typically also require deposition of data in public repositories such as ArrayExpress and the Gene Expression Omnibus (GEO; see Internet Resources). The MGED Society continues to work not only on standards but also on software applications to make them easier to utilize. The MGED effort has also provided standards for terminology (the MGED Ontology). These will be adhered to in this unit as much as possible to avoid ambiguous terms such as “probe,” which is often used in different settings to describe either the material that is labeled (as used in UNIT 22.1) or the material attached to the array. Instead, the material that is labeled is called the *labeled extract* and the material that is attached to the array is called the *reporter*. A

reporter represents a transcript, which in turn refers to a gene. For simplicity, the terms reporter, transcript, and gene may be used interchangeably in this unit. However, the signal measured after hybridization is that coming from a reporter and—unless signals from different reporters representing the same transcripts are combined (i.e., through averaging) and subsequently signals from different transcripts from the same gene are combined—the authors are actually referring to reporters. An *experiment* is a collection of *assays* (hybridizations) performed for a common purpose. An assay can be *one-channel* if only one labeled extract is hybridized to the array (e.g., nylon filter assays or Affymetrix assays) or *two-channel* if two labeled extracts are simultaneously hybridized to the array (e.g., one labeled with a Cy3 dye and one labeled with a Cy5 dye).

This unit starts with a quick overview of what microarrays are good for and what they are not good for. The most common uses are: (1) to find expressed genes in a given sample or experimental condition, (2) to find differentially expressed genes between two samples or experimental conditions, (3) to find expression signatures that define particular conditions or classes of samples, and (4) to find expression signatures that define particular sets of genes. There are many variations of these, but this unit will focus on these standard use cases. There are many things that microarrays are not good for, for example, determining the expression or differential expression of a single gene or small set of genes. In microarray studies, some accuracy and power for any given gene are sacrificed to obtain parallel measurements for thousands of genes. One would never measure a single gene or even a few genes using microarrays, which are generally far less accurate and sensitive than other methods such as PCR-based methods. Microarrays are also not very good at measuring relative expression levels between different genes in the same condition. The variation in hybridization affinity of the different reporters makes their intensities incomparable in principle. In practice, there is generally significant rank correlation between the true expression levels and the microarray

intensities of genes, but the comparison can be quite misleading for any given pair of genes. Therefore, one should only compare the intensity levels of the same reporter between experiments, and not of different reporters in the same experiment. It should also be kept in mind that microarrays measure the steady-state levels of RNA transcripts. Although often used as proxies for gene activity, they do not, in general, accurately reflect protein levels or their functional activity.

Figure 19.6.1 illustrates the flow of steps involved in carrying out a complete microarray experiment and these are addressed in this unit, which is organized in the following manner:

- Experimental Design
- Data Preprocessing
- Expression and Differential Expression
- Classification
- Looking at Gene Sets
- Databases

It should be noted that many aspects of microarray analysis remain issues of ongoing

debate. As such, it is impossible for any researcher to write a primer on microarray data analysis without a significant amount of author bias. Therefore, in order to be forthright before proceeding, it is necessary to point out that this discussion at times represents what the authors have found to be the most efficient and effective methods. This is a result of personal experience and perspective, and should be taken as such. For a discussion of some approaches that have become “consensus” in dealing with different aspects of preprocessing and analysis, most of which coincide with the authors’ current preferred approaches, refer to Allison et al. (2006).

Finally, it is important to keep in mind that biological conclusions should not be based solely on a microarray experiment. However, a microarray experiment can be of significant value in terms of narrowing down hypotheses. As such, microarrays are just a part of the iterative process of discovering important biological relationships and should not be considered the last word.

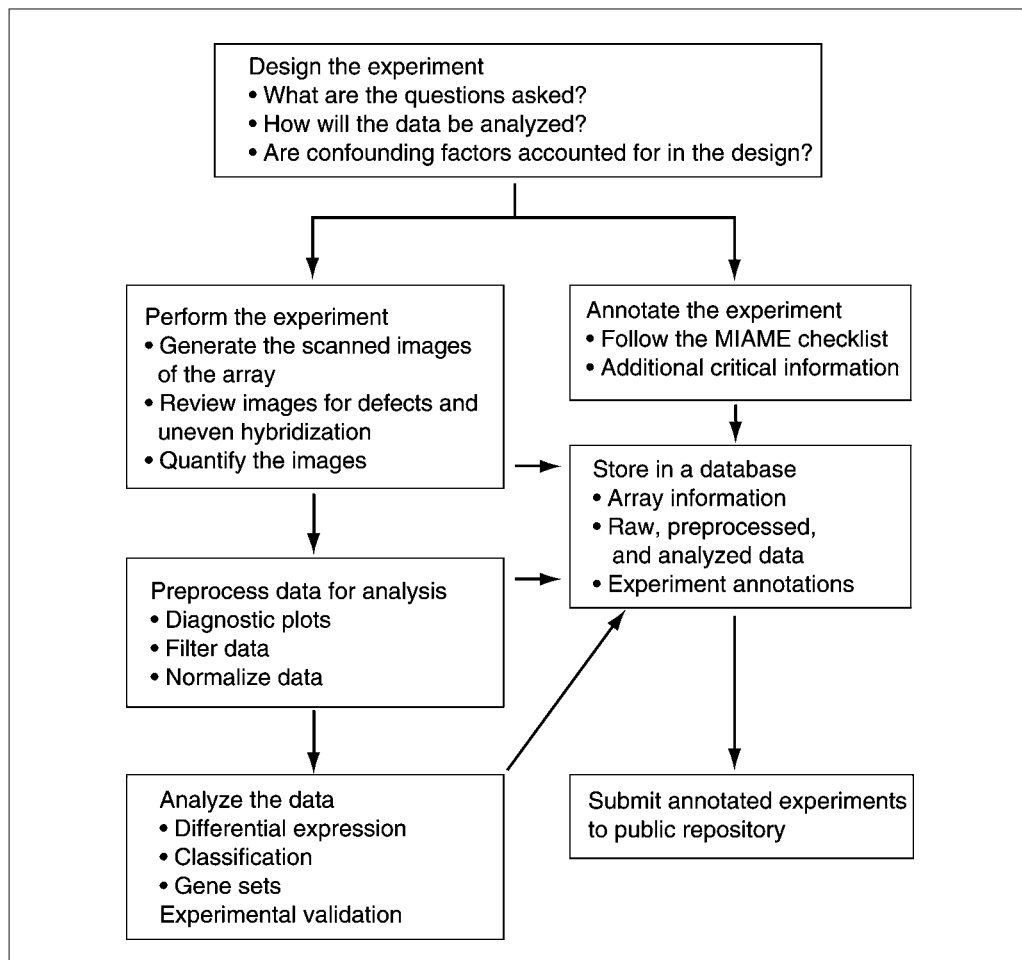

Figure 19.6.1 Steps involved in carrying out a complete microarray experiment.

EXPERIMENTAL DESIGN

The more time and care spent designing the experiment, the fewer headaches there will be during analysis. Experimental design depends on the study goal, but there are a few general principles that apply to all experiments. Perhaps the foremost issues are making sure there is sufficient replication and avoiding the introduction of confounding factors. Special considerations and issues related to design of two-channel assays are also considered below.

Replication

Even if a method delivered a perfect signal without any noise component, replication would be necessary, because one is generally interested in expression behavior in a population of samples, not in just one individual sample. For example, to understand the changes that take place between certain tumor and normal cells would require a representative random sample of both cell populations. As is typical in microarray studies, however, there might be an impossible trade-off in practice. Typically, only a limited number of assays can be performed, not enough for a truly random sample. This does not mean that one should not proceed; it just means that one must be careful about interpreting the results and do further follow-up to make sure the results generalize.

In microarray experiments, technical replicates (i.e., replicates of the same biological sample) should not be treated as independent replicates in the subsequent statistical analyses. Instead, technical replicates should be combined to obtain a single intensity per reporter for the same biological sample, e.g., by averaging the intensities or, in the case of two-channel data, averaging the log ratios. This way technical replicates can be used to provide a more reliable intensity for a given sample, but not as genuine replicates for the sample type under consideration. For Affymetrix, technical variability is usually quite low and (once established with a few technical replicates in a pilot study) technical replicates can be replaced with more biological replicates. Technical variability can be greater for two-channel platforms, especially due to differences in the fluorescent dyes used for labeling. Dye-swaps serving as a form of technical replicate are discussed below.

One can obtain multiple biological replicates and pool the starting materials to hybridize to a single array. This will decrease variation without requiring more arrays. It must be kept in mind, however, that there must be sufficient replicate assays in order to

perform statistical analysis. Thus, two replicates with a pool of five samples for each are not better than ten replicates each of individual samples. One should generate a reasonable number of assays per condition. If there are more samples available than arrays, then it makes sense to pool samples especially if the biological variability between samples in the same condition can be large and not related to the hypothesis being tested. Pooling should of course be done uniformly across all assays.

There is no hard and fast formula for determining the “right” number of replicates. The answer depends on knowing more about the nature of the particular expression levels in the samples, which, if known ahead of time, would eliminate the need to do the experiment. Thus, one is forced to make a judgment call based on the practicality of obtaining the samples and the cost of the arrays. Five or six replicates are always better than two or three. Ten or more is good if it is affordable and does not become so unwieldy that it introduces factors such as a change in technician. This is not to say one cannot ever extract meaningful results with two replicates per condition. If many of the planned assays fail, then one might do such an analysis, but it is generally not a good idea to design the experiment with such poor replication.

Confounding Factors

To illustrate the importance of controlling for confounding factors, first consider the simplest type of experiment where the goal is to compare conditions A and B on one-channel arrays. Suppose that appropriate random samples have been chosen to represent the two conditions. If all assays for condition A are processed together, and then all assays for condition B are processed together, there will be no way to know if the effects seen derive from the condition (A versus B) or from the processing batch. For example, since hybridization date is known to be an important factor in microarrays, one should ideally hybridize all samples together. If this is impossible, then one should hybridize half of the A samples and half of the B samples together in the first batch, and the remaining A and B samples together in the second batch. Although this will increase the variability within both groups, possibly decreasing the power of the downstream analyses from what could be obtained if all assays were done at once, this is necessary to avoid introducing a confounding factor that can lead to false results.

Another confounding factor to be aware of is the “individual.” Suppose for example that one is comparing condition A to condition B, and that the actual transcript abundance of gene *g* is typically twice as high in condition B compared to condition A. Suppose that one is interested in discovering this effect. One could measure condition A from each of *M* individuals and condition B from each of *N* different individuals. If there is very little variability across the individuals in each group, then an unpaired statistical test should have the power to detect the effect for relatively small values of *M* and *N* (see APPENDIX 31 for a discussion of unpaired and paired tests). However, if there is a lot of variability from individual to individual, then, even if the ratio of expression level for gene *g* in condition B versus condition A in the same individual is always two, the more variable the gene is within conditions A and B, the more replicates will be needed to achieve sufficient power to detect the effect. In this case, the distribution of the paired (within individual) intensity ratios for gene *g* will be very tightly centered around 2, while the separate distributions of intensities for gene *g* in conditions A and B will have large variance. If one expects such an effect, then one should design the experiment so as to have pairing by individual if possible.

There are many other factors that can potentially introduce unwanted variability, e.g., harvest conditions, RNA extraction date, sample preparation date, hybridization date. Sometimes it is impossible to randomize for all known effects. The hybridization date is an important factor to avoid confounding. When samples are harvested, extracted, prepared, and labeled all side-by-side but are then hybridized to the arrays on separate dates, the main effect in the data will often turn out to result from the hybridization date. This is not platform dependent, but appears to be the case across the spectrum of platforms from Affymetrix to two-channel spotted glass slide arrays.

Balancing Replication and Confounding Factors

Judgment calls as usual are unavoidable. For example, will it be better to do four replicates all together or to do six replicates but split over two batches? The answer to this question can rarely be determined ahead of time. Sometimes confounding factors are not readily apparent ahead of time, and will only be revealed after the experiment has been completed, for example, by doing quality control

clustering (see section on Classification below). If this step reveals factors that have inadvertently confounded the factors of interest, then a repeat of the experiment might be necessary. Even if an experimental factor (such as hybridization date) is not confounded with the factors of interest, it might still be necessary to take the experimental factor into account during the analysis (“block” analyses; see Expression and Differential Expression section). In any case, the three main concerns in experimental design are: (1) does the experimental design effectively address the questions and/or hypothesis of interest, (2) is there sufficient biological replication, and (3) are there any obvious confounding factors?

Two-Channel Assays

Greater challenges in experimental design come from the use of two-channel assays. The first thing to always keep in mind is that two-channel assays should not be thought of as two one-channel assays. In particular, the intensities coming from the two channels should not be used separately in analysis; instead one should work directly with their ratios. The variability (arising primarily from spot-to-spot inconsistencies) introduced by not taking ratios could be so dramatic as to affect all downstream analyses profoundly. Thus, all of the two-channel experimental designs discussed here will revolve around using ratios. Although a one-channel experiment might be easier to design, one might still opt to use two-channel arrays for practical reasons. For example, two-channel spotted arrays can be very inexpensive, as low as \$20 per slide, and can easily be produced in-house.

Direct comparison

Consider again the case where two experimental conditions A and B are to be compared. In this case, the simplest two-channel approach is to use a *direct comparison* where A is labeled for one channel and B is labeled for the other channel. For the sake of normalization (to be discussed in the Data Preprocessing section below), one might hybridize each pair of samples twice, swapping the channels for half the assays, and taking the reciprocals of the intensity ratios for those. Such *dye-swaps* represent technical replicates and should be combined to form one (more reliable) intensity ratio for each sample pair. In any case, with direct comparison data some form of statistical test can be performed on the ratios to test for differential expression between the two conditions (as described in the Expression

and Differential Expression section below). If, however, the goal is to compare multiple conditions, possibly also to perform a clustering or class prediction analysis (as discussed in the Classification section below), then simply having direct comparison ratios might not be sufficient.

Reference design

An alternative to the direct comparison design is the *reference design*. In this case, to compare conditions A and B, a third condition C is chosen as a reference condition. A number of assays are prepared with a sample of type A labeled for one channel and a sample of type C labeled for the other, and a number of assays are prepared with a sample of type B labeled for one channel and a sample of type C labeled for the other. The resulting A/C ratios and B/C ratios can be analyzed analogously to one-channel data. The reference sample C must be chosen judiciously, because it can have an impact on how well the data can be normalized. If there are a lot of differentially expressed genes between conditions A and C, and similarly for conditions B versus C, then there should not be gross asymmetry between the up-regulated and down-regulated genes. Otherwise, normalization will be problematic, as described in the section on Data Pre-processing below. Often C is taken as a pool of conditions A and B. Another popular approach is to use a universal reference, such as those sold by Stratagene (see Internet Resources). An advantage of a universal reference is that it might allow for comparisons across studies. However, using a universal reference can have a dramatic effect on the genes identified in a differential expression analysis. This is because genes with higher mean intensities also have higher variance. For example, if a gene is differentially expressed between conditions A and B but its abundance in both these conditions is at the low end of detectable signal, and if the abundance of this gene in the reference condition C is very high, the measured intensities of the latter could introduce enough variance to render the differential expression undetectable. This effect would be mitigated by a reference whose abundance for that gene is in a similar range as A and B, which is exactly what would be obtained using a pooled reference. Furthermore, a pooled reference would achieve this for every gene.

When comparing three conditions A, B, and C, one can choose a fourth sample D to use as common reference for all three conditions. It might still be preferable to construct a direct

comparison design, however. If one conducts N assays each of A/B, B/C, and C/A, then all possible comparisons can still be made. Once one has four or more conditions and wants to make all possible comparisons, it starts to become prohibitive to do direct comparisons between each pair of conditions and it becomes necessary to use a common reference for all assays. With four conditions there are six comparisons, with five conditions there are ten, and it grows quickly from there. Some authors suggest “daisy chaining” the samples in a large loop design, i.e., performing A/B assays, B/C assays, C/D assays, and so on (Kerr and Churchill, 2001). However, this kind of design limits the analysis methods available and makes the A/D comparison depend on the quality of the B/C assays. If there are many conditions this can be risky. Yang and Speed (2002) discuss this as well as additional design issues particularly pertinent to two-channel assays.

A variant of the reference design is the *blocked reference design*. Rather than using the same reference sample, independent references are matched (relative to some relevant factor) to the conditions that one wants to compare and are co-hybridized to each respectively. This type of design can be useful in time series experiments with a baseline and in drug experiments with a placebo group (see Steibel and Rosa, 2005).

DATA PREPROCESSING

Upon completion of the bench work which yields hybridized arrays, a series of steps needs to be carried out to generate the final data to be used as input to downstream analyses. The first step after the hybridization procedure is *image acquisition*, which entails generating digital images from the assays, e.g., using a phosphorimager (for radioactively labeled targets) or a scanning laser microscope (for fluorescently labeled targets). Once the images have been generated, it is necessary to derive quantified values from them. This process is referred to as *feature extraction*, *image quantification*, or *image analysis*. Then visual inspection and diagnostic plots can help assess and possibly filter the data. Finally, the data need to be *normalized*. These preprocessing steps, beginning with feature extraction, are discussed in detail below.

Feature Extraction

A variety of freeware and commercial software packages have been developed to address feature extraction and this remains an

active area of research. For spotted arrays, a feature extraction software (e.g., ArrayVision, GenePix, ScanAlyze, Spot, TM4 Spotfinder; see Internet Resources) typically produces the main signal measures and additional measures to help assess background noise and artifacts (e.g., background glow, dust, scratches, smears). Yang et al. (2002a) provide a detailed description of the various image analysis steps for spotted arrays as well as a comparison of some software packages, with a particular focus on two-channel data.

With probe set arrays like the Affymetrix chips, each transcript is represented by a set of short oligonucleotides. The array consists of *probe cells*, each containing (perfect match or single-mismatch) copies of the same short oligonucleotide; the collection of probe cells corresponding to the same transcript is called a *probe set* (i.e., the reporter). In this case, feature extraction entails first getting quantified values for the probe cells, then using these to generate a summary expression measure for each probe set. A variety of different algorithms have been proposed which generate probe cell and probe set values (typically accounting for background) as well as additional measures. To cite a few, the MAS 4.0 and the more recent (and substantially different) MAS 5.0 algorithms were developed at Affymetrix, with version 5.0 intended to subsume version 4.0. Details on this can be found in the Affymetrix statistical algorithms reference guide (see Internet Resources). The dChip software (for details, including publications and tutorials, see Web site indicated in Internet Resources) employs a model-based approach towards feature extraction, contingent on the availability of multiple assays in the experiment. The Robust Multichip Analysis (RMA) is another method to quantify Affymetrix data in the presence of multiple assays. A stand-alone implementation for Windows and Linux is provided by the RMA-Express software (see Internet Resources). Implementations of RMA and its variant gcRMA are also available in the affy and gcrma R packages from the Bioconductor project (see Internet Resources). Affymetrix has released another algorithm, named PLIER (Probe Logarithmic Intensity Error), which builds upon some of the above approaches.

These approaches to summarization of Affymetrix data typically incorporate normalization options (see below) and can produce substantially different results. Benchmark datasets have been made available to facilitate comparisons and performance assessments of

summarization methods for short oligonucleotide platforms, and various papers have been published to address these (e.g., Cope et al., 2003; Rajagopalan, 2003; Barash et al., 2004; Choe et al., 2005; Irizarry et al., 2006). Currently, the authors preferentially use gcRMA as a default Affymetrix quantification software. The gcRMA software package has performed well in the published comparisons just listed. As stated in Irizarry et al. (2006), gcRMA was one of the methods that “appear to be finding a balance between accuracy and precision that permits them to perform well across the range of gene expression.” The original RMA was noted to compress fold change ratios. gcRMA takes into account GC-content in the estimation of non-specific binding and is improved in this area.

Some feature extraction software output data only at a very raw level, leaving to the user further decisions on how to process these prior to analysis; others can automatically perform certain kinds of preprocessing and might offer the user various preprocessing choices. In any case, it is important to be aware of the main preprocessing steps to consider and of the assumptions that these make. There is no hard and fast rule that can be applied in all situations and the best choice of preprocessing depends on the experiment at hand, including the types of samples that are hybridized to the arrays and the collection of transcripts represented on the particular array used. Before using a preprocessing method, especially a normalization method, it is important to be aware of the assumptions made. Using these methods indiscriminately can lead to wrong conclusions, as errors will propagate through the cascade of subsequent steps. Some of the common preprocessing issues, methods, and assumptions are discussed below.

Background Correction

As mentioned above, part of the signal in an array image comes from background noise and does not reflect actual labeled extract hybridized to reporter. This means that each reporter's signal (sometimes referred to as the *foreground signal*) incorporates some background noise. There are various approaches that have been proposed to estimate background and to adjust the foreground signals using these estimates. Often these methods try to estimate background locally (i.e., estimating background as a function of location on the chip) and correct the foreground signal by subtracting background signal for the corresponding location on the chip. Different

quantification packages vary in the approaches used to perform background estimates. For spotted arrays, Yang et al. (2002a) illustrate some of the approaches. Typically, when working with most of the current spotted array quantification software (except for the Spot software), the authors do not apply background subtraction, but simply use the foreground measurements output by the software. This is because subtraction often introduces significant amounts of additional variability, especially at the low end of the intensity spectrum, and adds the complication of negative signal intensities.

Images, Diagnostic Plots, and Quality Measures

It is always recommended to examine the files (e.g., .TIF or .DAT) generated by the image acquisition process, as well as additional diagnostic plots of each assay, prior to proceeding with preprocessing. This can help identify obvious artifacts and eliminate from further analyses those reporters or assays that are of poor quality, as well as identify some of the sources of bias in the data that might have to be dealt with. Among the freeware providing diagnostic plot functionality, some of the Bioconductor packages (see Internet Resources) are very useful. For example, for two-channel arrays, the *marray* package has the capability to plot color-coded images of different measurements (e.g., the individual channels foreground and background, the difference of the log intensities in the two channels) laid over the spatial configuration of the array. The same package also provides functionality for various boxplots and for the very useful *M* versus *A* plots, where *M* represents the difference in \log_2 intensities in the two channels and *A* the average \log_2 intensity in the two channels. Namely, $M = \log_2(R) - \log_2(G)$ and $A = [\log_2(R) + \log_2(G)]/2$, where *R* and *G* are the signals (possibly background corrected) of the Cy5 (red) and Cy3 (green) channels, respectively. Figure 19.6.2A illustrates an example of such a plot. A clean self-self hybridization should yield points tightly clustered around the horizontal line $M = 0$ (intensity is the same in both channels). Those reporters that have higher average intensity between the two channels are further to the right in the graph. Albeit, an *M* versus *A* plot is merely obtained by a rotation and rescaling of the $\log_2(R)$ versus $\log_2(G)$ scatter plot, it makes it easier to visualize intensity-dependent red versus green effects (that is, biases which depend on the average \log_2 intensity *A*), which appear as deviations from the horizontal $M = 0$ line.

The TM4 Spotfinder software (Saeed et al., 2003) is another example of freeware providing some diagnostic plot capabilities.

Affymetrix provides a number of metrics that can be used to assess assay quality. Details can be found in the Data Analysis Fundamentals Manual (see Internet Resources). Hybridization and poly-A controls are spiked into the sample and therefore have expected signal intensities. Two genes, GAPDH and β -actin, are used as controls to assess the 3'-to-5' ratio. A high ratio indicates possible degraded RNA or an inefficient reaction during sample preparation. The other measures of quality are more subjective and one cannot generally say what the expected values should be. However, given replication, these measures should not vary tremendously. This is a general rule that applies to any array platform. One of the basic measures in an Affymetrix array is the percent of genes called present. Outliers from the distribution over all replicates in the experiment, or extremely high or low numbers of genes called present, indicate a poor quality assay. Similarly, the scaling factors (when the software is set to automatically normalize the assays, see below) should not vary tremendously from assay to assay. For more on this, the Affymetrix documentation should be consulted.

Two-channel quantification software packages generally offer fewer metrics; for example, there is no present call. However, with two-channel arrays, it can be useful to graph the correlation between pre- and post-normalized data from each assay and then to graph these correlations to identify outliers. Any assay that undergoes a significantly more extreme normalization than the rest of the assays is likely to have some quality issues.

Another very useful approach for identifying poor quality data is to use various clustering methods. The clustering approach is discussed below (see Classification).

Filtering

Typically, for each assay, some of the reporters on the array might need to be excluded from further processing and analyses, due to a variety of reasons. At times a whole assay might need to be discarded if it is of poor quality overall. Visual inspection of array images and color-coded plot images are the first tools that should be used to detect artifacts like scratches or splotches that might lead to the exclusion of a set of reporters, if not the whole assay. The quality metrics described above can be used to further filter out poor-quality assays. In addition, some of the image analysis

Figure 19.6.2 Legend at right.

packages provide measures that can be used to identify potentially bad reporters in an assay, which should be filtered out. Other reporters that one might want to exclude from further analyses might be specific controls, like anchors that are used to help in the feature extraction step, or blanks.

Normalization

In microarray jargon, *normalization* indicates the attempt to identify and remove systematic sources of variation in the measured intensities due to wide variety of factors including separate reverse transcription and labeling, different scanning parameters, print-tip differences (when multiple printing pins are used to print each array), other spatial effects, different dye labeling efficiencies, the quality of the microarray printing, or the quality of the mRNA used. As a simple example, if two assays use the same labeled extract and the images are scanned with different settings, a reporter on one of the images might be brighter than the corresponding reporter on the other image; hence, the resulting raw quantified intensity will be higher, even though in reality the two reporters should have the same intensity as they represent the RNA abundance level of the same transcript in identical samples. One should never knowingly introduce such variations in the scanner settings, but when it happens, one can attempt some kind of rescaling normalization to try to salvage the data set. In general, normalization puts the data on equal footing before intensity comparisons are made. Normalization is a very delicate step, however, that can have a dramatic effect on the results. If not done carefully, one can easily normalize out biological effects of interest. Methods have been developed for both one-channel and two-channel data and the most common are described below. This does not represent an exhaustive description of all methods published on the subject to date, as this is an active area of research. The goal of this discussion is to examine some of the subtleties of this process and of the common assumptions on which normalization techniques rely.

Two-channel assays

As mentioned in the section on Experimental Design, typically for this kind of assay, one should only work with the ratios of the intensities from the two channels (after possible background subtraction) rather than with the separate intensities in each of the channels, as the former approach can greatly reduce the spot-to-spot variation due to spot size and concentration. It is also very common to work in logarithmic scale (e.g., using the M values defined above). Thus, if two identical samples are hybridized to the two channels of an array, one would expect that, after biases are removed, all points should be close to the line $M = 0$ in the M versus A plot. Typically, however, plots of raw data (i.e., prior to bias removal) do not look like this. For example, the Cy3 dye can show a stronger signal, and this effect can be intensity (A) dependent.

Typical methods to normalize M values include normalization by a global constant, global loess normalization, print-tip loess normalization, and dye-swap normalization (performed alone or on top of the previous methods, if the experiment contains dye-swaps). Additional scaling adjustments are also sometimes applied. These methods and their assumptions are discussed briefly here; for further details, the reader is referred to Yang et al. (2002b) and Quackenbush (2002).

The first three methods involve two choices: (a) which normalization factors to use to adjust the values at each reporter, and (b) which reporters to use in order to compute the normalization factors. The latter could be all reporters on the array or a suitable subset of these, such as a set of appropriate controls (e.g., reporters representing transcripts known to be expressed at the same level in both samples hybridized to the array).

In what follows, it should be kept in mind that what comes out of the normalization step are normalized (log) ratios, not normalized values for the individual channels.

Normalization by a global constant is a very simplistic approach and is not generally recommended, but is described for the sake of motivation. This normalization is performed

Figure 19.6.2 (at left) (A) Plot of M versus A for a two-channel microarray assay (see text). The dashed horizontal line is the line $M = m$ where m is the median of M over all reporters. The solid curve represents a global loess fit. (B) Plot of M versus A for the data from panel A after normalization by the global constant m . The solid curve represents a global loess fit and illustrates that this normalization did not eliminate intensity-dependent biases. (C) Plot of M versus A for the data from panel A after global loess normalization. All global loess fitting and normalization performed with the Bioconductor marray R package.

by subtracting from the M value at each reporter the same constant m , which is obtained by computing the median or mean of M over a chosen set of reporters as per (b) above. In this case, the normalization amounts to a vertical shift in the M versus A plot (see Fig. 19.6.2B). This method assumes that the biases to be corrected are the same at all reporters. It also assumes that the differentially expressed genes in the two samples being hybridized to the two channels show similar amounts of up and down regulation. If this last condition does not hold, one could normalize out a biological effect and not just the dye bias. For example, if one uses a brain-specific array (i.e., an array representing mostly genes expressed in the brain) and co-hybridizes a brain sample versus a pancreas sample to that array, then normalizing the M values by the constant computed from all reporters on the array would not be a wise choice of normalization, as it is unlikely that the above assumptions are satisfied.

The assumption that the biases are the same at all reporters is a very strong one and typically does not hold. In most cases there is a trend in the M versus A plot which indicates that the biases might depend on A , i.e., on the average (log) intensity in the two channels (as is the case for the data in Fig. 19.6.2A). To address this, the *global loess* (or *lowess*) *normalization* method subtracts from the M value for each reporter a value $m(A)$ that depends on the A value of the reporters. This has the effect of shifting points in the plot up or down by different amounts based on their A value, potentially allowing a greater number to lie near $M = 0$. The value $m(A)$ is computed by fitting a curve to an appropriate subset (possibly all) of the reporters in the M versus A plot, using a “locally weighted polynomial regression” approach termed *lowess* or *loess* depending on the implementation (Cleveland, 1979; Cleveland and Devlin, 1988). For each A , $m(A)$ is taken to be the M value of the corresponding point on this curve. The subset to which the curve is fit needs to be chosen so that for any range of A values, the differentially expressed genes in the two samples being hybridized to the two channels show similar amounts of up and down regulation. Loess curves are somewhat robust to outliers, so if there is only a relatively small amount of differential expression then this assumption can be violated to some extent; however, the more differential expression there is between the two groups, the more this assumption matters. Figure 19.6.2C illus-

trates the results of performing global loess normalization on the data from panel A. On the one hand, global loess normalization addresses a more general type of bias (intensity dependent) than normalization by a constant; on the other hand, it requires the samples and arrays to satisfy stronger assumptions, as similar assumptions must now hold not just overall, but at every intensity level. In general, normalization methods that correct for a larger variety of biases also typically need to make more assumptions on the samples and arrays. This underscores the importance of keeping normalization issues in mind from the start of an experiment, i.e., during the experimental design phase.

When an array has been printed using multiple printing tips, there might be systematic differences between printing tips that also need to be corrected. Figure 19.6.3A shows curves fit for each print-tip, where each curve is generated by fitting it to those points in the M versus A plot corresponding to reporters in the same print-tip. In this case, it appears that different print-tips have different trends. The *print-tip loess* (or *lowess*) method is aimed at correcting both intensity-dependent and print-tip-dependent biases by performing a separate loess correction for each of the print-tips. This is done by subtracting from M at each reporter a value $m(p,A)$ which depends on A at that reporter as well as on the print-tip p to which the reporter belongs. This value, for each A , is obtained by fitting a loess curve for each print-tip to an appropriate subset (possibly all) of the reporters on that print-tip in the M versus A plot (see Fig. 19.6.3A). For each print-tip, the subset to which the curve is fitted needs to be chosen so that one can make the following assumption on the corresponding reporters: for any small range of A values and any print-tip, the differentially expressed genes in the two samples being hybridized to the two channels show similar amounts of up and down regulation. Figure 19.6.3B illustrates the results of performing print-tip lowess normalization on the data from panel A. If, due to the nature of the samples and the reporters on the array, one does not have such a subset available for all print-tips, then this normalization should not be applied. Note that the print-tip loess method is basically analogous to the global loess except that the data are first stratified (by print-tip) and loess is applied within each stratum instead of globally. In the same spirit as print-tip loess normalization, one can address similarly other kinds of bias that might be

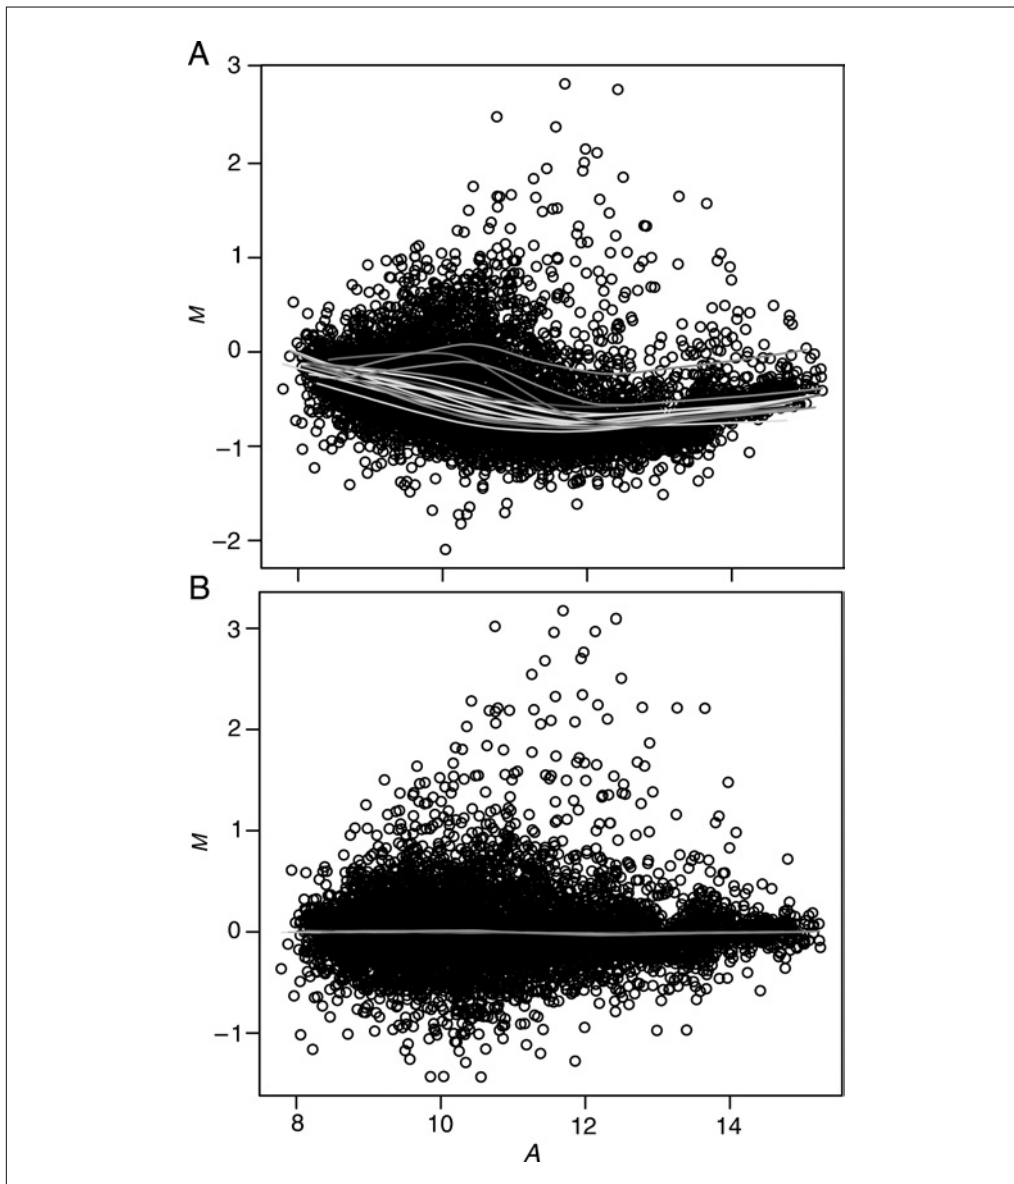

Figure 19.6.3 (A) Plot of M versus A for a two-channel microarray assay. Each curve represents a loess fit to one of the print-tips. Data generated with the Bioconductor *sma* R package, using the *MouseArray* dataset provided therein. (B) Plot of M versus A for the data from panel A after print-tip loess normalization (performed with the Bioconductor *sma* R package). For color version of this figure see <http://www.currentprotocols.com>.

uncovered from diagnostic plots, e.g., plate biases, or spatial biases other than print-tip groups.

In addition to the adjustments described above for a given “stratum” (e.g., print-tip) loess normalization, some methods additionally perform a scale adjustment across strata within a slide. Essentially, the stratum loess normalization will transform the data so that the M values will be centered around 0 for each stratum across all intensities. A *scale adjustment* is aimed at adjusting the spreads of these values, making them equal over all strata. This adjustment makes the further assumption that

the spreads of the M values should be the same over the different strata.

Each of the methods described above is applied within each assay in an experiment with the goal of putting the two channels on equal footing. Often, when multiple assays are to be compared, after normalizing each assay with one of the above methods, it is possible to proceed to the comparisons. In some cases if, after normalizing the M values on each assay, one sees too much variation between their spread across all assays and it is assumed that the samples at hand should roughly have the same kind of variation of M values for the

reporters represented on the array, additional scale adjustments could be performed that will render these spreads roughly the same across all the assays. However, the authors have found global and print-tip loess effective (whenever applicable) and typically refrain from making scale adjustments both within and across assays.

As mentioned in the section on Experimental Design, technical dye-swaps are performed in some experimental designs. For this situation, dye-swap normalization might be applicable. This consists, for each reporter, in taking the average of the M value of one assay with the negative of the M value on the other assay. This is usually referred to as *dye-swap normalization* or *self-normalization*. The assumption made by this method is that the channel biases are very similar in the two assays. As long as this assumption can be made, when dye-swaps are available, this method can be a viable alternative if the assumptions of the previously described normalization methods are not satisfied. Even in cases when one of the previous methods is applicable, dye-swap normalization can be applied following normalization by one of these methods, to combine technical dye-swaps replicates. Moreover, there might be occasional reporter-specific dye incorporation biases which dye-swap normalization can help suppress. Note, however, that application of dye-swap normalization could exaggerate intensity-dependent biases if the assumption that channel biases are similar in two dye-swap assays is not satisfied.

A few comments should be made regarding the typical subset of reporters on an array used to compute the normalization function in the constant or loess normalization methods. This needs to be determined based on the biological assumptions that appear reasonable for the samples at hand and the genes represented on the array. If these assumptions are not valid for the set of all reporters on the array, there might be alternative choices that will still work. For example, if there is set of genes represented on the array which are known to be expressed at roughly the same level in the two samples and which (for intensity dependent normalizations) span the range of A values, then this set could be used. Typically, however, one does not have this kind of prior knowledge. An alternative type of control that might be used is a spiked control. Spiked controls are control reporters that are printed onto the array, representing exogenous transcripts whose corresponding mRNAs can be added to the labeling reaction along with the experimental RNA. A concern with the latter type of control is that

they are not useful for normalization in situations when the quality/quantity of the RNA in the two samples of interest is different. However, spikes are very useful as they can provide an internal quality control for labeling reactions, and can allow rapid identification of problems in terms of mRNA quality along with any potential issues that may have arisen due to an error in the labeling experimental procedure.

The two-channel normalization methods described above are implemented in many freeware and commercial software packages. For example, within the Bioconductor project, one can find implementations both in the *array* and in the *limma* packages. Similarly, the MIDAS component of TM4 implements loess normalization.

Besides the methods described above, other approaches have been developed for two-channel data. Among these, one that is also available from Bioconductor is the *variance stabilizing normalization* (Huber et al., 2002) implemented in the *vsn* package. This method consists of first applying, separately to each channel, a calibration to standardize the data, combined with a variance-stabilizing transformation aimed at rendering the resulting variance for each reporter approximately independent of its mean intensity. (As such, this method could be employed to normalize one-channel data. Moreover, like loess, this can be applied in a stratified fashion.) The difference of the resulting values in each channel is then taken for each reporter, generating the so-called *generalized log-ratios*, which can be employed instead of the traditional M . For two-channel data, however, the authors feel it is best to work solely with ratios without separating the two channels, and thus prefer to utilize approaches which operate directly on the M values, like the loess methods utilizing M versus A plots.

One-channel assays

Affymetrix probe set level data are similar to one-channel data on other platforms in that, for each assay, there is only one value (corresponding to the unique channel) attached to each reporter. Therefore, normalization methods applicable to Affymetrix probe set data are generally also applicable to other one-channel platform data and vice versa. In addition, for Affymetrix data, one could proceed to normalization at the probe cell instead of the probe set level, and some packages implement this.

One very common method of putting different assays on equal footing is to transform the intensities so that their average (or their

median) over an appropriately chosen subset S of the reporters is the same, say T (as target), for all assays. The correction might be additive or multiplicative depending on whether or not the data are in log scale. The assumptions made by this type of normalization are that the biases are the same for all reporters on the assay and that the samples hybridized to the different assays have the same average (median) RNA abundance over the transcripts corresponding to the reporters in S .

A more sophisticated method is the *quantile normalization* method (Bolstad et al., 2003), which makes the assumption that the samples hybridized to the different assays have roughly the same distribution of RNA abundance over the transcripts represented on the array. This method transforms the intensities so that the bulk of the intensity distribution is the same for all assays in an experiment, typically with some differences in the distribution tails (which might reflect actual biological differences). For Affymetrix data, this method is usually applied at the probe cell level. To assess whether or not possible intensity-dependent biases are removed by this kind of processing, one can look at M versus A plots for pairs of one-channel assays. Generally quantile normalization helps remove this type of bias. There are other methods geared at dealing with intensity-dependent biases and specifically based on the M versus A plot idea. The complication is that here one does not have two channels per assay. To deal with this, some of these methods select one of the assays as a baseline and form ratios relative to this for each of the remaining assays. Others (e.g., *cyclic loess* and *contrast-based normalization*) avoid selection of a baseline and use different strategies to overcome this issue. A review and comparison of the above methods can be found in Bolstad et al. (2003). Based on these comparisons, those authors recommend quantile normalization as the preferred choice. The authors of this unit also preferentially utilize this method (applied at the probe cell level in the case of Affymetrix). Quantile normalization is available in many free and commercial packages, including the Bioconductor *affy* and *gcrma* packages.

EXPRESSION AND DIFFERENTIAL EXPRESSION

Expression

Perhaps the most basic question that can be asked is which genes are expressed in the sample being assayed. Unfortunately, most mi-

croarrays are not designed to answer this question. Further, no microarray can determine that a gene is not expressed, because the gene might simply be expressed below the background level of the sensitivity of the array. On the other hand, the signal of a truly nonexpressed gene can be quite high, so in order to have any chance at making a reliable call one needs some kind of control elements on the array. This is provided on probe set arrays that have mismatch probe cells (e.g., Affymetrix arrays) which are used by some quantification software to make presence calls. For example, in the MAS 5.0 software, a statistical test to assess whether the mismatch probes are significantly dimmer than the match probes is typically performed and a p -value is computed. By default, if this p -value is .04 or less, then the software reports a *Present* call (P), if it is 0.6 or higher it reports an *Absent* call (A), and if it is between 0.4 and .06 it reports a *Marginal* call (M). The A call must be interpreted as insufficient *evidence* of expression, and not the absence of expression itself. Furthermore, the P calls are not multiple testing corrected (a correction needed when performing many hypothesis tests simultaneously, see below), so one should expect 4% of the array to be called present even if there are no expressed genes at all.

For arrays that do not have mismatch elements, often genes that are expected to not be expressed are incorporated into the arrays as controls. With enough controls one can get a distribution of nonexpressed elements, and can use some percentile cutoff as a criterion for expression. Since it is often hard to know what should be unexpressed, sequences from highly unrelated species are often used. As such, they might not represent the true null case, so this is subject to a very large margin of error and must be used as only a very crude measure. Often studies use blank spots to generate the “unexpressed” distributions; this is an even rougher estimate and should always be considered as such in any downstream analysis.

Differential Expression

Differential expression analysis involves using microarray data to find genes that are expressed at different levels between two experimental conditions. It should be kept in mind that what is measured for any given transcript is its percentage of the total labeled RNA. Therefore, the differences measured for a given gene are affected both by copy number per cell and by total RNA amount per cell.

Differential expression analysis is more complicated than might be expected and often requires difficult judgment calls. An in-depth look at the problem can be found in Ewens and Grant (2005) as well as Ge et al. (2003). Indeed, every differential expression protocol suffers from a trade-off between advantages and disadvantages, many of which cannot be determined ahead of time. The first issue to be aware of is that of multiple testing. This refers to the phenomenon that, when multiple tests are run in parallel, what might be unlikely to be observed in the data for one test becomes more likely to be observed in at least one of the parallel tests. When thousands of tests are run, what is very unlikely can become very likely. Therefore, any p -values that could be derived from tests on the individual reporters should be very carefully interpreted in the context of many reporters (typically thousands) being tested simultaneously. Usually p -values are modified in order to have sensible error rate control for all of the tests in parallel. The problem is complicated by the large number of tests (typically thousands or tens of thousands) and the small number of replicates available (typically fewer than 10). This renders the traditional and straightforward multiple testing corrections, such as Bonferroni corrections (Ewens and Grant, 2005), virtually useless.

In what follows, it is assumed that all data have been fully preprocessed and, for simplicity, genes are referred to instead of reporters, but often the analyses are performed using the individual reporter values without combining them into genes. Both in the case of one-channel data and in the case of two-channel reference design data, for each gene there is a value in each replicate of the two conditions to be compared (i.e., two sets of replicate values, one for each condition). For reference design data, each of these numeric values represents the (log) ratio of experimental to reference channel intensities, but since the reference should be constant for all samples, one can proceed with differential expression analysis using these values the same way one-channel intensities are used. Thus, the two cases (reference design and one channel) are handled together. In the case of two-channel direct comparison data, there is one set of replicate values, where each such value is a (log) ratio of the intensities in the two conditions being compared, giving the relative abundance between these two conditions (no reference condition). Since the channels are never separated, special considerations of this case will be made along the way.

The popular approaches to differential expression include different schools of thought: e.g., Family-Wise Error Rate methods (FWER), False Discovery Rate methods (FDR), ANOVA-based methods (e.g., Kerr et al., 2000), and Bayesian approaches. There are also nonstatistical methods that could be sufficient for some purposes, e.g., simply creating ranked lists. Each of these approaches has subcategories; for example, the FDR methods divide into Benjamini and Hochberg based methods and permutation estimation methods. The authors are particularly partial to the FDR permutation estimation methods, which will be the focus here, although the FWER methods will be examined in some detail as well.

Consider the scenario of one-channel assays or two-channel reference design assays. If conducting a single test for the equality of means of a gene's expression level in two different conditions, then the null hypothesis is straightforward. H_0 is set to be the hypothesis that the means in both conditions are equal, and a statistical test of this null hypothesis is performed. It is important to keep in mind an asymmetry in this argument. While some genes can be identified as differentially expressed using this approach, that is *not* to say that genes failing to be included in this category are *not* differentially expressed. More technically, statistical measures of confidence are generally ascribed to the rejection of H_0 , while confidence is not ascribed to the nonrejection. From nonrejection of H_0 , one can only conclude that there is insufficient evidence to reject H_0 , not that there is evidence that H_0 is actually true. Therefore, it is never concluded from the nonrejection of H_0 that a gene is not differentially expressed.

The main issue in the single gene case is in determining an appropriate test. The standard T -test will generally not be appropriate, because of the (often severe) violation of the necessary assumption that the gene's intensity is normally distributed in each condition. Instead a permutation based T -test is generally more appropriate. The downside to a permutation-based approach is the need for sufficient replication. For example, with only three replicates per condition, there are only 20 permutations and so the smallest p -value obtainable would be 0.05, and 5% of the genes on the array will achieve this level, on average, regardless of their differential expression. A general algorithm for computing permutation p -values for the T -statistic is as follows. Suppose there are n and m replicates in the two conditions, respectively. A permutation consists of taking

any n of the $n+m$ values and forming a new group 1, and taking the remaining m as a new group 2. Suppose there are N such permutations (including the trivial permutation which keeps the groups unpermuted). Let T_0 be the value of the T -statistic on the unpermuted data. For any permutation b , let T_b be the value of the T -statistic for that permutation of the data. Suppose that $T_0 \geq T_b$ for M of the N permutations b . Then the permutation p -value is defined to be M/N . This tests for whether the gene is up-regulated in the second condition as compared to the first. If one is interested in down-regulation, one would run the test switching the roles of the conditions. If one is interested in differential expression irrespective of direction, then one should work with the absolute value of the T -statistic instead of the T -statistic itself. In the case of the two-channel direct comparison scenario, for one individual gene the investigator would be testing whether or not the mean log ratio is >0 for up-regulation (and <0 for down-regulation). For this, the one-sample T -statistic is used with the appropriate modifications. For example, given n replicate log ratios, a permutation approach would consist, for each permutation b , in selecting a subset of these values and changing their sign, prior to evaluating the value of the statistic for that permutation.

If extending the single-gene procedure to conduct many tests simultaneously, it is not straightforward to set up an appropriate statistical framework. If it is desired to control the probability of making no mistaken calls at all, then this is called controlling the *Family-Wise Error Rate* (FWER). A popular and powerful algorithm for doing this with microarray data is the *Westfall and Young step-down method* (Westfall and Young, 1993; Ge et al., 2003), which assigns an adjusted p -value to each gene, so that choosing all genes with adjusted p -value less than or equal to α guarantees no false positives with probability of error α . There are two variations of the Westfall and Young step-down method, one called minP and one called maxT. The maxT is preferable when there are very few replicates (less than seven or eight per condition). Specific efficient algorithms for the minP and maxT methods can be found in Ge et al. (2003). Implementations of these algorithms can be found in the *multtest* Bioconductor package.

The FWER is generally too strong of an error control for most investigators' purposes, and the authors use it only when it is necessary to be sure there are no mistakes at all

on the resulting gene list. Most of the time, the investigator is not willing to give up the power necessary to assure no false positives and is willing to tolerate some false calls in order not to miss others. For example, suppose there are 10,000 genes on an array. If an investigator would rather be given a set of 150 genes and be told that 75% of them are likely to be true positives than be given a list of 30 genes and be told that they are all true positives, then the FWER is probably too conservative for that investigator's purposes, and this is why the False Discovery Rate (FDR) was introduced. The FDR measures the (expected) *proportion* of false positives among the set of all predictions. The FDR is not this proportion itself, since the methods available only control the *expected value* of this proportion. Intuitively, the FDR is the (expected) proportion of false differential expression calls in the set of all differential expression calls, but there are a number of ways to define the FDR in order to make this rigorous and practical. The original definition of Benjamini and Hochberg (1995) is the expected value of V/R given that $R > 0$, where V is the number of false calls and R is the total number of calls. The 1995 publication introduced the FDR concept and gave a first method for controlling it, which will be described below. The FDR is generally the most natural and useful method for error rate control; however, the endeavor to control it rigorously has been problematic. Strong heuristic assumptions are always relied upon and come in two forms. The first type are assumptions made about the data. The second are assumptions made about the reliability of estimations and other computational heuristics. Given the landscape of available methods, the authors have come to prefer those that make fewer assumptions about the data. The industry that has derived from the original Benjamini and Hochberg method tends to rely on very strong regularity assumptions about the data, e.g., identically and independently distributed t -statistics or, even worse, normally distributed intensities. These methods also tend to be very conservative and start with gene-by-gene p -values which themselves cannot generally be expected to be reliable, particularly when there are few replicates per condition. As a result, the authors rarely, if ever, use Benjamini and Hochberg based methods. More precisely, to apply Benjamini and Hochberg methods for controlling the FDR, one must first generate gene-by-gene p -values. Unless one has a fair number of replicates (at least 8 to 10),

one should not try to generate permutation p -values, as there will not be enough permutations to produce sufficiently small p -values. In the case of insufficient replicates, the best one can do is to apply some flavor of parametric test, typically a two-sample T -test to test for equality of means or, in the case of direct comparison data, a one-sample T -test to test whether the log ratios have means equal to one. Once gene-by-gene p -values are created, the Benjamini and Hochberg correction is applied as follows. Let P_i be the i -th smallest p -value, so that $P_1 \leq P_2 \leq P_3 \leq \dots$. Let $q_i = \alpha i/g$ where g is the total number of genes and α is the desired false discovery rate. Let k be the maximum i such that $P_i < q_i$. If no such k exists, then all null hypotheses are accepted (e.g., one predicts nothing as differentially expressed). If $k > 1$, then one rejects hypotheses H_1 through H_k , predicting those genes to be differentially expressed. It can be proven, in the case that the p -values for all of the genes are independent, that this set of genes has a false discovery rate no greater than α . Note that this says nothing about the actual proportion of false positives in the predicted set; it only says something about the expected value of this proportion. In any given case the actual value could be very different from the expected value. What is outlined above is the most basic version of the Benjamini and Hochberg algorithm. There has been a lot of work to extend the methods to require less strong assumptions about the data (for example, Yekutieli and Benjamini, 1999; Ge et al., 2003; Storey, 2003).

A totally different approach to the FDR has been taken by SAM (Tusher et al., 2001) and PaGE (Grant et al., 2005; see Internet Resources). These algorithms use permutation distributions to estimate certain quantities, so these methods are referred to as *permutation estimation* methods. There is only heuristic theory to support doing these estimations; however, these methods make far fewer assumptions about the data than Benjamini and Hochberg methods, and are thus more reliable and less conservative. It is important to keep in mind that an FDR is quite different from a p -value. As a result, one is often interested in setting the FDR quite high; even 50% FDR gives meaningful results since it produces (on average) a set of genes highly enriched for differentially expressed genes, while on the array 99.9% of the genes might not be differentially expressed. For the purpose of producing sets of genes highly enriched for differential expression, nobody is too concerned about second decimal place accuracy in the FDR. In fact, if

one sets it to 40% but realizes only 50%, the investigator is almost always more than happy with the outcome. Of course one does not want it to be wildly inaccurate. In the authors' experience, SAM and PaGE achieve a practical level of power and accuracy, but any differential expression result set must be carefully interpreted. Often results do not make sense, for example, if every gene on the array is down-regulated. When this happens, the algorithms show that there is such an effect in the data, but it might be due to poorly normalized or poorly generated data.

The PaGE algorithm is based on using a cutoff C for some statistic S (e.g., the T -statistic) and making differential expression calls for each gene based on whether its statistic exceeds C . Suppose there are R such genes. PaGE then estimates the number of nondifferentially expressed genes that are expected to exceed this cutoff, say V . The ratio V/R is then an estimate for the false discovery rate. The quantity V is estimated using permutations. A permutation of the data means the experiments are randomly assigned to conditions. In most permutations no genes should be differentially expressed, so for any such permutation, any gene with T -statistic greater than C should be a false positive, thus giving an estimate of V . To the extent that some genes will be differentially expressed for some permutations, this should only lead to overestimating V and therefore being conservative. By taking many permutations (all of them, if possible) and computing for each the number of statistics that exceed C , a permutation distribution is obtained for V , from which the expected value of V is estimated. This is repeated for a sequence of values of C , and each gene is assigned the lowest FDR realized for any value of C . These gene-by-gene measures are called q -values in the literature. In this way, taking the set of genes with q -value at most α gives a set of genes with FDR estimated to be no more than α . SAM does something similar, and both SAM and PaGE use a modified form of the T -statistic as statistic. Both SAM and PaGE have a multi-class mode. SAM's multi-class mode tests whether the gene has equal distributions in all conditions. PaGE's multi-class mode compares every condition to one fixed reference condition and produces patterns across the conditions for easy visualization of the results. Both methods have a mode for analyzing direct comparison data. SAM also offers a block permutation mode in case of a block design where a block is defined by a factor (see Experimental

Design). In this mode, only permutations that keep samples in the same block are used, which increases power if there is a significant block effect.

CLASSIFICATION

A very popular use of microarray experiments has been in the area of classification problems. Here it is necessary to distinguish between two main scenarios. In both cases the input consists of a two-dimensional matrix of data, representing the preprocessed results of a microarray experiment monitoring the genes represented on a particular array over a set of assays. These are typically one-channel assays or two-channel reference design assays, so that each assay represents one main sample of interest (in a two-channel reference design assay, this would be the nonreference sample). The matrix has as many rows as there are genes on the array (here for simplicity the authors refer to genes, but in reality one might just work at the reporter or at the transcript level), say m , and as many columns as there are samples of interest, say n . The value in the i -th row and j -th column of this matrix represents the preprocessed signal for gene i in sample j (this would be a relative abundance in a two-channel reference design). For each gene a profile exists consisting of the signals for that gene over all the samples (one row of the data matrix); similarly, for each sample a profile exists consisting of the signals for that sample over all the genes (one column of the data matrix). Thus, both genes and samples can be represented by vectors (the profiles) of values where the vector has length n for a gene and m for a sample. In *UNIT 22.5*, the components of such a vector are termed parameters or dimensions; here they are also referred to as features. In some circumstances it might happen that a gene has missing values in some of the assays (e.g., due to filtering of poor-quality spots in an assay). Methods have been proposed to “impute” these values (e.g., Troyanskaya et al., 2001). A classification problem can refer to classification of genes or classification of samples; in both cases the problem reduces to classification of profiles. There are two types of classification problems: *class discovery* and *class prediction*. The former represents an unsupervised classification, because the classes are not known beforehand, whereas the latter represents a supervised one, because relevant classes are known a priori.

In class discovery, the object is to classify the profiles into groups based on their similarity, therefore “discovering” such groups.

For example, class discovery methods could be employed to determine a molecular classification of samples which are otherwise indistinguishable; to determine groups of genes which are expressed similarly in the samples examined and which therefore might share the same type of function or the same regulatory mechanisms; or to reduce the dimensionality of the collection of gene profiles by first grouping them and then studying only a representative profile per group (e.g., the average gene profile in that group). Class discovery methods could also be used for quality control purposes as illustrated further below.

In class prediction, typically the given profiles are already known to belong to certain classes, which are used as a training set to build a classifier to classify novel profiles into one of these known classes. For example, one might have gene expression profiles for a collection of samples partitioned into patients that do and do not respond well to a given treatment. A predictor will be used for a new patient to decide which of the two treatments is likely to perform well, based on his/her expression profile.

The case of time series data, when one seeks a classification of the gene profiles, is somewhat distinguished as there is additional structure in the data (an ordering) that can be exploited. This is discussed separately below.

There are a variety of free and commercial software packages (including Bioconductor) with implementations of some of the classification methods described below. A rich workbench for data mining, comprising implementations of many classification methods, is WEKA (Frank et al., 2004; Witten and Frank, 2005; see also Internet Resources).

Class Discovery

This is probably the area which has seen the greatest number of publications in the microarray literature, especially in the early days of the technology. If one believes there might be interesting subtypes of samples or genes that are not known ahead of time but can be revealed by their expression signatures, then a class discovery analysis is appropriate. Typically, clustering approaches are utilized for class discovery. Existing clustering techniques have been borrowed and applied to microarray data analysis, and variants, refinements, and new approaches have been proposed. Clustering has played and will continue to play an important role in the microarray field as long as it is used when the question of interest is indeed that of class discovery. It is important, however, not to abuse the method (as has often

been done in the literature) when the question at hand is of a different sort and other types of analyses are more appropriate. In clustering, the degree of similarity between profiles is measured and profiles that are most alike are then put into groups (clusters). These clusters can be well defined, as with a definite partition of the profiles, or they can be loosely defined, as represented by the leaves of a hierarchical tree.

There is a vast literature on clustering applied to microarrays and this topic is also addressed in *UNIT 22.5*. It is difficult to impossible to systematically sort out the landscape of methods, as there are no good benchmarks and there is such a variety of methods that one cannot even put them on equal footing. The best one can hope to do is to settle on a few methods that seem to work. This unit summarizes some of the most commonly used approaches, with the criteria that they are well established, readily available, and relatively convenient, and that they have worked reasonably well for the authors.

There are three main choices to make when doing clustering analyses: (1) what features to use, (2) what similarity measure to use (for similarity-based methods), and (3) what clustering method to use. The first consists in determining which components (features) of the profile vector to use. When clustering genes, all features (samples) are often used. When clustering samples, the full profiles have a very high dimension, as there are typically thousands of genes represented on an array. Therefore, one might use only a portion of them, e.g., those that vary the most across the samples or those that are expressed above background level in at least one of the samples. The idea is to remove those features that are not adding information. In other situations, there might be precise subsets of the genes that one wants to focus on, e.g., based on some prior biological knowledge, and only those are used as features. The results will vary depending on what genes one chooses to cluster on, and in each case a different facet of the relationships in the samples might be brought to light. Liu (2005) provides a survey on feature selection for classification problems. Finally, it should be noted that some subsets should never be used for classification. For example, any subset of genes identified from a differential expression analysis will completely bias any classification algorithm, as those genes will naturally distinguish between the two conditions being compared. In this way, any division of the data could be found by using just those

genes that are most different between the two groups.

The second choice when performing clustering analyses using a similarity-based method, like hierarchical clustering or partitioning (described in detail below), has to do with similarity measures—that is, what criterion to use to decide the degree of similarity between two profiles. The most commonly used measures are the Euclidean distance and the Pearson correlation coefficient (refer to *UNIT 22.5* for further discussion). Results can vary tremendously according to the similarity measure chosen. The authors have found that Euclidean distance is more sensitive to artifacts in the data and generally use standard Pearson Correlation, both to cluster genes and samples, also because they are typically more interested in similarity in shape than in magnitude. Often there is a choice between centered and uncentered correlation. Centered is just standard Pearson Correlation, which is what the authors typically use. Another reasonable measure is Spearman's rank correlation, which first ranks the data in order of intensity, and then applies standard correlation to the profiles of the ranks. This can help put data on equal footing. Typically, as the similarity measure and the subset of genes used in the analysis are varied, a number of different results are obtained. One should avoid trying too many combinations so as to find whatever one is looking for. One will inevitably try several ways and should only believe results which are clear and strong effects.

Regarding the third choice, several clustering methods were available prior to the advent of microarrays (e.g., Hartigan, 1975) and have been utilized for this purpose. Microarray technology has also spurred the development of new methods, e.g., CAST (Ben-Dor et al., 1999), PLAID (Lazzeroni and Owen, 2002), and Gene Shaving (Hastie et al., 2003). The two most frequently used approaches in the microarray literature are hierarchical clustering and partitioning approaches, which are described in more detail below.

Hierarchical clustering, borrowed from phylogeny, is based on building a tree with the profiles at the leaves (see Fig. 19.6.4). This tree is a rigid structure representing varying degrees of similarity. Clusters are not well defined, and for any node in the tree one gets a cluster consisting of the leaves below that node. There are many variations found in the available implementations. For example, bottom-up (agglomerative) implementations (e.g., Eisen et al., 1998) start with each profile alone in a group by itself. Similar groups

Figure 19.6.4 Result of hierarchical clustering of both genes and samples for twelve one-channel assays, using centered Pearson correlation and the Eisen's TreeView software (<http://rana.lbl.gov/EisenSoftware.htm>). The sample tree is along the top and the gene tree is along the side. Brighter green represents higher signal intensity. For color version of this figure see <http://www.currentprotocols.com>.

are then gradually merged until all profiles are in one group. Agglomerative hierarchical clustering is discussed in *UNIT 22.5*. Top-down (divisive) implementations (e.g., Alon et al., 1999) start with a single group including all profiles. This is split into two groups, which are in turn split, and so on. In either case, the

output of these methods is a tree with the profiles at the leaves.

Partitioning clustering methods (like *k*-means) do not produce trees; instead they are based on the idea of partitioning the profiles into a *prespecified* number of mutually exclusive and exhaustive clusters, then iteratively

reallocating the profiles to clusters until some criterion is met, e.g., sufficiently high within-cluster similarity. Self Organizing Map (SOM; UNIT 22.5) also leads to a partition of the profiles into a prespecified number of clusters, but it imposes a partial structure on the data in that clusters are represented by nodes in some space (typically a plane), and close nodes correspond to “similar clusters.” However this is much less rigid than the structure imposed by hierarchical clustering. An application of SOM to microarray data can be found in Tamayo et al. (1999). Another useful method is Principal Components Analysis (UNIT 22.5), which can be used to project the data into the two or three most important dimensions for easy visualization, which helps reveal the relationships between the profiles.

The literature on this topic is so large that it is impossible to reference all the relevant papers and surveys. The reader is referred to Fasulo (1999), D’haeseleer et al. (2000), and Handl et al. (2005) for surveys on recent work on clustering.

Besides the typical use of clustering to aid in the discovery of novel classes of profiles, another useful application is that of quality control (Coombes et al., 2002, 2003; Grant et al., 2003; Stivers et al., 2003). For an experiment with replicate assays for each of a collection of experimental conditions, upon clustering, profiles of samples from the same experimental condition should be closer to each other than they are to profiles of samples from the other conditions. When this does not occur, it could be a sign of a problem with the experimental procedure or the data annotation. An application of this is illustrated in Coombes et al. (2003), where quality control clustering revealed a problem that was eventually traced back to mis-annotation of the reporters on the array.

One of the biggest issues with clustering is that results can vary significantly when any of the three main choices—feature, similarity measure, and clustering method—is changed. According to the questions and the data at hand, some approaches might be more suitable than others, and this needs to be determined on a case-by-case basis. When the best route to take is not clear, a typical approach is to try a variety of routes and look for those clusters that are consistently picked up, taking the robustness of these as a possible sign of biological relevance. If one has run a number of tree-based methods, it is possible to combine them into a consensus tree which represents the divisions that are found consistently. There

has also been formal work specifically aimed at cluster validation analysis. A survey of this, with a special focus on post-genomic data, can be found in Handl et al. (2005).

Class Prediction

In this type of problem the input is a training set of profiles with a known classification and the goal is to generate a predictor (a.k.a. classifier) to be used to classify novel profiles. A variety of machine learning approaches to build classifiers were in existence prior to the advent of microarrays and have proven useful in the microarray context. Reviews of some these methods as applied to microarray data can be found in Dudoit et al. (2002), Speed (2003), and Statnikov et al. (2005). The issue of feature selection, mentioned in the clustering section, becomes particularly important in this context. Generally, once a predictor is built, one needs an independent data set to validate the predictor. If this is not available, cross-validation techniques are typically used. These consist in iteratively using only a portion of the training set to build a predictor and testing its classification error rate on the rest of the training set.

One of the simplest classifier techniques is *k-nearest neighbors*. This is based on predicting the class of a novel profile by looking at its *k* most similar profiles in the training set and assigning the novel profile to the class to which the majority of these belong. This method requires the choice of a similarity measure. As for the choice of *k*, the typical approach is to try a range of (integer) values and to select that which yields the smallest cross-validation error rate. That is, for each choice of *k* in this range, each profile in the training set is classified using the majority class among its *k* closest profiles, excluding itself. This classification is then compared to the true known class label for that profile, and the error rate for that choice of *k* is computed by looking at the number of profiles which are mis-classified using this approach.

Nearest centroid methods are also fairly intuitive. The simplest application consists in computing the centroid (average profile) for each class in the training set, and then classifying each novel profile into the class whose centroid it is closest to. More sophisticated modifications of the nearest centroid idea include Linear Discriminant Analysis (LDA) methods (e.g., Dabney and Storey, 2005), where the covariance matrices for each class are taken into account. Various proposals have been put forward to deal with the feature

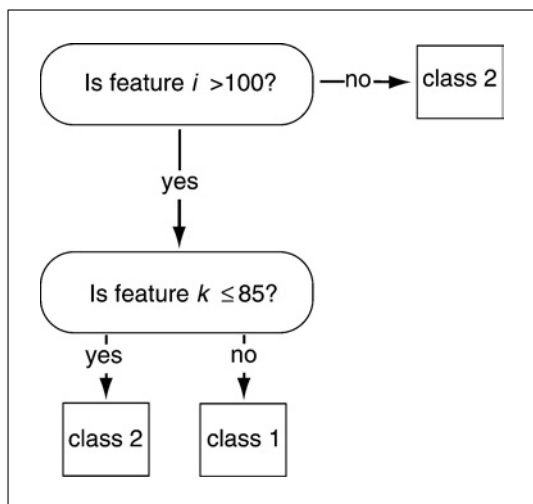

Figure 19.6.5 Simple example of a decision tree.

selection issue for the application of this type of method to microarray experiments where the training sets consist of sample (rather than gene) profiles that have a large number of features (number of genes). One approach in the nearest centroid spirit is Prediction Analysis of Microarray (PAM; Tibshirani et al. 2002, 2003; also see Internet Resources). This uses “shrunk centroids,” which represent a “denoised” version of centroids, down-weighting the contribution of noisy genes to the classifier. Dabney and Storey (2005) propose a different approach which employs a “greedy” algorithm to estimate an optimal subset of features. Greedy algorithms are often used in bioinformatics, when the space of all possible solutions (in this case, subsets of features) to explore is prohibitively large for an exhaustive search. A greedy algorithm does not explore all possible solutions, but always takes the best immediate (local) solution at each step of the search, which can occasionally lead it to miss the optimal global solution.

A very different approach to the construction of a classifier that is frequently utilized in microarray applications is that of Support Vector Machines (SVM; Vapnik, 1998). In its simplest form, SVM has been used for binary classifications (two classes). The idea is to consider each profile as a point in m -dimensional space (where m is the number of features), to map the training profiles into a higher-dimensional space, and then to find a hyperplane in the latter that separates the points corresponding to the two different classes. A novel profile is then classified according to which side of this hyperplane it maps to in this higher-dimensional space. For a review of various extensions of SVMs that have been developed for the case of more than two classes,

see Statnikov et al. (2005). Furlanello et al. (2003) further investigate the issue of feature selection (and feature selection bias) for this type of approach.

Classification trees (Breiman et al., 1984) represent yet another approach to building predictors. The main idea is to build a tree with a rule at every node, typically expressed as a condition on some component(s) of the profile. The leaves of the tree are labeled with class labels. This tree is built using the training set. For a novel profile, one then starts at the root of this tree and moves down. At every node, according to how the condition is satisfied by the appropriate component(s) of the profile, one goes down one branch or another, until a leaf is reached. The label at that leaf corresponds to the classification for that profile (see Fig. 19.6.5). The appeal of this type of class prediction method is that it provides some explicit rules that lead to the classification in each of the classes, thus helping to interpret the class distinctions.

One problem that can occur with decision trees as well as with other machine learning approaches is that the resulting predictors might be unstable, i.e., small perturbations of the training set might lead to very different predictors. This is a sign of *overfitting*, which occurs when the model built for the predictor starts fitting the noise in the training set, thereby leading to a predictor that might perform extremely well on the training set but not as well on the general population of profiles it is supposed to represent. There are various approaches to deal with this within a given machine learning method (for example pruning of decision trees), but an approach that can be applied more generally to any method is to use ensembles of classifiers. The main idea is

to start with the training set and then build a collection of training sets obtained by perturbing the original one, e.g., by resampling. Then a predictor is built using each of these training sets, and the classification of each novel profile is obtained by evaluating it with each predictor and assigning it to the class predicted by majority “vote.” In the case of decision trees, this leads to Random Forests (Breiman, 2001; see also Breiman and Cutler Random Forest Web site in Internet Resources). In this approach, a tree is constructed for each resampling of the original training set (either sampling N profiles with replacement or sampling without replacement about one-third of the profiles each time), yielding a “forest” of decision trees. Each new profile is evaluated according to each of the trees in the forest, and each tree gives a classification, representing a vote for that class. The final classification is the one having the most votes.

As for clustering, there are so many different approaches to class prediction that only some can be illustrated here. The methods presented appear frequently in the microarray literature. The review references cited in this unit contain more pointers and information on other methods.

Time Series

The situation when the experiment consists of a time series, i.e., the samples correspond to different time points (e.g., duration of a certain compound treatment, or different developmental time points in an organism) involves some special considerations as compared to the case of unordered data. In this case, typically one is interested in gene profiles. All of the clustering techniques mentioned above are still applicable to this situation, but one might want to take further advantage of the inherent ordering of the samples according to time and there are approaches that have been designed to this end. Moreover, in many instances one already has in mind some a priori temporal pattern of interest and wants to identify which gene profiles follow those patterns. Another way to take advantage of the temporal component in time series data is to smooth the data across time to eliminate outliers that might be artifacts. A sufficient number of time-points is required to make smoothing reasonable; certainly three or four is not sufficient, while ten or twenty generally is. Smoothing can most easily be done using a local least squares fit to a moving window along the data.

A simple intuitive approach to microarray time series analysis is to first define templates,

e.g., representing an induction or reduction over time or oscillations. Each gene profile is then compared to each of the templates to assess whether or not there is sufficient similarity. As usual, a similarity criterion needs to be established first. An example of an application of this approach can be found in Scearce et al. (2002).

Schliep et al. (2003) propose a more complex approach which utilizes hidden Markov models (HMMs; Rabiner, 1989; Durbin et al., 1999) in a model-based clustering approach. The idea is to start with a seed collection of HMMs, e.g., each representing a prototypical time course pattern. The gene profiles are iteratively assigned to these HMMs and used to refine these HMMs. If at any step an HMM has too few members, it is eliminated; if it has too many members, it is split into two. Thus, the number of clusters is learned from the data. A noise HMM is also used to define a cluster aimed at picking up the noise.

Another example of a model-based approach to time series clustering is that described in Ramoni et al. (2002) and implemented by Cluster Analysis of Gene Expression Dynamics (CAGED; see Internet Resources). This employs a Bayesian approach to determine the number and members of the clusters. In Spellman et al. (1998), time-series microarray experiments are employed to identify cell cycle-regulated genes via a method that combines Fourier transforms with a scaling factor obtained via comparison to gene profiles of genes already known to be regulated by the cell cycle. For a more thorough review of the challenges and techniques geared at analyzing microarray time series data, the reader is referred to Bar-Joseph et al. (2004).

LOOKING AT GENE SETS

One of the advantages of microarray technology is the ability to look in parallel at many transcripts. This enables an investigator to examine sets of genes simultaneously rather than just individual genes. In this respect, it is necessary to distinguish between two kinds of scenarios. The first scenario is that a microarray experiment is conducted in order to discover potentially interesting sets of genes, which has been the focus of the previous section (e.g., genes differentially expressed across two or more conditions or genes that form clusters based on their expression profiles). These sets are typically generated using the analysis methods described in the preceding sections. Once any such potentially interesting set is determined, one typically wants to investigate

its genes further to assess whether or not they share any biologically relevant property such as common pathways, biological processes, or regulators. The second scenario is that an investigator already has in mind particular sets of genes of interest (e.g., genes linked by a particular biological property like a pathway, process, or regulatory mechanism which will define a gene set) or has a set of interesting genes derived from a previous experiment of some sort. In this case, utilizing a microarray study might lead to a better understanding of the molecular profiles of the genes in the set and enable the discovery of any common characteristics of their transcripts with respect to conditions of interest (i.e., the transcriptional profile of each gene set as a whole).

Summarizing, in the first scenario, the starting point is a microarray experiment and the goal is to elucidate common biological trends in gene sets constructed by analyzing that experiment. In what follows, this scenario is referred to as the *a posteriori gene set scenario*, since the gene sets are derived from the microarray experiment. In the second scenario, the starting point is one or more predefined gene sets and the goal is to evaluate their transcriptional behavior utilizing a microarray experiment. This scenario is referred to as the *a priori gene set scenario*, since the gene sets are defined independently of the microarray experiment. Some approaches that have been utilized in each of these scenarios are described below.

A Posteriori Gene Set Scenario

Given a gene set resulting from analyses carried out on a microarray experiment, a typical question of interest is whether or not this set shows enrichment in a predefined biological property. For example, one might be interested in finding whether or not there is a particular biological process or pathway that is common to a large proportion of the genes in the set. Rephrased more rigorously, this question becomes: is there statistical evidence that the proportion of genes in this set having the specified biological property is larger than expected if the set had been chosen at random from the gene population? One of the most popular and powerful associations used for this purpose are Gene Ontology terms. The Gene Ontology (GO) Project (see Internet Resources) provides structured controlled vocabularies for three categories describing gene products: biological processes, cellular components, and molecular functions. Moreover, annotation of genes with terms from these on-

tologies (“Mappings to GO”) is also provided. Given the array used in the microarray study from which a gene set has been derived, and given a GO term of interest (in one of the three GO categories), typical approaches take the genes monitored on the array as a surrogate of the genome and use the GO mapping to determine the fraction that are annotated with that GO term. Then they compare to the latter the fraction of genes in the selected gene set which map to that term, using the hypergeometric distribution (e.g., see section 2.7.3 of Tamhane and Dunlop, 2000) to identify whether or not that GO term is overrepresented in the gene set. Since, for a given gene set of interest, this statistical test is repeated for each GO term for a biological process, it is then necessary to adjust the individual *p*-value obtained from each test for multiple testing (see Expression and Differential Expression for a discussion of multiple testing issues). Of course, if the biological theme of interest is from another category (e.g., KEGG pathways; see Internet Resources), the same approach is applicable. The Expression Analysis Systematic Explorer (EASE), available at the DAVID Web site (see Internet Resources) from the NIAID, is an example of software implementing this kind of analysis.

Although the idea behind this kind of approach is simple, there are some complicating issues. Namely, the *p*-values derived from a hypergeometric distribution make the assumption that the observations are independent, but genes are not independent of each other. Moreover, a set derived from a microarray experiment typically consists of reporters which represent genes, but a given gene might be represented more than once on the array. The latter problem is easier to deal with. For example, EASE does not simply use the identifiers (typically GenBank accessions; see Internet Resources) supplied by the user, but collapses multiple representatives of the same Entrez Gene (see Internet Resources) to avoid the situation in which a gene with multiple accessions receives more than one vote in the overrepresentation analysis. However, the problem of gene dependencies still remains.

Besides EASE, there are several other tools that address the same kind of question, many of them implementing an analogous approach. A summary of tools specifically geared to the biological theme of GO categories as it pertains to an *a posteriori* gene set from microarray experiments, as well as links to the respective Web sites, is available from the Gene Ontology Project Web site (GO tools, microarray).

Another type of biological theme that one might be interested in discovering for a gene set derived from microarray analysis is that of regulatory modules. Namely, given a set of genes that a microarray study indicates might share common regulators (e.g., because they are all differentially expressed under certain conditions or because they have similar expression profiles across multiple conditions), can one identify combinations of regulatory elements (e.g., transcription factor binding sites, TFBS) which appear to be enriched in the promoter regions of these genes? Given the sequences of interest, one might either look for occurrences of known TFBSs (e.g., from TRANSFAC or JASPAR; see Internet Resources) or one might try to find possibly novel motifs. Tools aimed at motif discovery in a group of sequences include MEME (Bailey and Elkan, 1994), AlignAce, Weeder, and the ELPH Gibbs Sampler (see Internet Resources for the corresponding Web sites), which use different algorithmic approaches. There are also approaches that simultaneously combine the discovery of relevant gene sets and of their regulatory modules (e.g., Segal et al., 2003). These citations are not comprehensive as there is a large amount of literature and ongoing research in the area of gene regulation which leverages on the integration of gene expression microarray data with sequence data, as well as other data types (e.g., ChIP-chip data).

A Priori Gene Set Scenario

In this scenario, the starting point consists of a collection of predefined gene sets and a microarray experiment, and the goal is to overlay each such set over the expression data to further characterize these sets in terms of their expression profile as *a whole set*. Here each gene set might be defined based on an ontology (e.g., all genes mapping to a given GO term), a pathway (e.g., all genes in a given KEGG pathway), or on an investigator's prior knowledge and/or experiments.

A first kind of analysis in this scenario is that provided by the public software GenMAPP (see Internet Resources). A MAPP is a grouping of genes defined by some organizing principle. Quoting from <http://www.genmapp.org/GenMAPPHelp2/GenMAPP.htm>:

“Examples of the types of MAPPs that can be represented in GenMAPP are metabolic pathways, signal transduction cascades, sub cellular locations, gene families, or lists of genes associated with Gene Ontology categories. Each MAPP contains gene objects,

which represent biological genes or gene products.”

One of the features of GenMAPP is that of enabling a user to color-code genes within a MAPP according to user-selected criteria on their expression in a microarray experiment, thus providing the means to identify interesting expression trends in that MAPP.

The Gene Set Enrichment Analysis (GSEA; see Internet Resources), first presented in Mootha et al. (2003), is an approach aimed at identifying which gene sets from a given collection show enrichment in genes which are at the top (or bottom) of a ranked list, e.g., where the ranking is based on differential expression between conditions. This method utilizes a score based on the Kolmogorov-Smirnov statistic (see, e.g., Hollander and Wolfe, 1999) and incorporates multiple testing corrections. Details on the algorithm are available in the documentation at the GSEA Web site. Also available at this Web site is MSigDB, a Molecular Signature Database of gene sets.

The general philosophy behind the approaches outlined above is that power can be gained when looking at sets of genes rather than at individual genes. The reason for this is that some characteristics of individual genes might be too weak to overcome noise and to be detected by a statistical analysis if the gene is treated as an individual, but might be identified when the gene is considered as member of a group of genes sharing a common biological theme, since its signal, compounded with those of other genes, might lead to an overall signal whose significance is detectable.

DATABASES

Microarray data are sufficiently large and complex that a database is often required for data management. The bulk of the data will be the intensity values associated with reporters on the array and annotation of the sequences represented by those reporters. Just as important are annotations describing the experimental plan, materials, and protocols used. If the microarray study is to be part of a publication, many journals require that the study be deposited at a public repository adhering to established standards. Topics to be covered in this section are choosing a database system, annotation of microarray data, and submission of data to microarray repositories.

Choosing a Database System

Database systems consist of a schema describing how the data are organized and

software for loading data as well as retrieving data for generating files, reports, or viewing online. Many database systems are currently available covering a wide range of needs. These include freely available systems as well as commercial ones. To help choose a database system, a comparison of microarray databases was published by Gardiner-Garden and Littlejohn (2001) and used as the basis for an online table at the Stanford Microarray Database (SMD; see Internet Resources). Sherlock and Ball (2005) have published a more recent comparison on a few selected freely available systems. Issues to consider include cost (including support), features, and coverage of required information. A database requires a database management system and the most popular ones are relational database management systems (RDMS) such as Oracle, Sybase, Windows SQLServer, IBM DB-2, PostgreSQL, or MySQL. Commercial systems such as Oracle require licenses which can be expensive (although some academic institutions have licenses that cover everyone). These have the advantage of being very powerful, well supported, and well tested. Free RDMSs such as PostgreSQL and MySQL (see Internet Resources) are generally simpler and easier to manage but may not work with the chosen microarray database system. Part of the cost to consider is the staff needed to maintain the database as well as the hardware needed to install it. Generally speaking, choices will be driven by the amount of data anticipated and the expertise available as well as which RDMS is supported by the schema chosen. Any schema used should be *MIAME-compliant*, which means that all the types of information on the MIAME checklist accessible from the MGED Society Web site (see Internet Resources) can be captured in the chosen schema. Schemas vary from those that simply focus on manipulating and viewing microarray results (e.g., SMD), to those that cover the steps required to make a microarray (i.e., include laboratory information management system or LIMS information, e.g., BASE; see Internet Resources), to those covering additional areas outside of microarrays (i.e., include genomics and other functional genomics areas, e.g., RAD as part of GUS; see Internet Resources). Indeed, the reason for the availability of different microarray database systems is that these have been built to address the different needs of groups. Features to consider are tools to load microarray data, annotate the experiments, enable analysis, and export data in a standard format such as MAGE-ML. A

MAGE software tool kit (MAGEstk) to generate MAGE-ML is available through the MAGE working group page at the MGED Society Web site.

Annotation and Data Loading

The intensity values obtained in a microarray experiment are context-dependent; therefore, to interpret the meaning of the intensity value one must know the state of the cells from which the nucleic acid was obtained as well as how the nucleic acid was labeled, hybridized, and so on. While there are many factors both biological and technical that can influence those values, a minimum information about a microarray experiment (MIAME) standard has been established to cover the basics (Brazma et al., 2001). Microarray experiments need to be planned carefully from beginning to end. Although this is true for any experiment, it is perhaps more important here due to the time and cost involved in performing microarray experiments. The MIAME checklist covers experimental design, samples, measurements, normalization controls, and array design. These topics should be considered prior to starting a series of experiments rather than just used to describe what was done at the end. For example, the choice of experimental design will depend on the available samples and, together with normalization controls, determine what kinds of analysis will be most effective.

Capturing the annotation in a structured way for storage in a database is usually done with Web-based tools packaged with the microarray database system employed or custom built for a particular project (or institutional core). For example, the RAD Study Annotator (Manduchi et al., 2004) provides a Web-based tool to annotate biomaterials, protocols, experimental designs and factors, and other MIAME-related information. Array designs and data are loaded using software written for RAD. Wherever possible, the MGED Ontology is used primarily in the form of drop-down menus to choose terms for annotation. This same approach is taken by a number of other microarray database systems, several of which are listed in a recent paper on the MGED Ontology (Whetzel et al., 2006). The use of common terminology by different groups facilitates data retrieval, sharing, and analysis by making it clear when experimental factors and sample characteristics are comparable. It should be noted that for many projects the MIAME checklist does not go far enough to provide sufficient annotation for certain types of

experiments such as those for toxicogenomics. Extension of MIAME have been developed that can be used as guides, and these can be found at the MIAME working group page on the MGED Society Web site.

Submission of Data to Microarray Repositories

Public repositories for microarray data have been established. The primary repositories are ArrayExpress, developed and maintained by the European Bioinformatics Institute, and the Gene Expression Omnibus (GEO), developed and maintained by the National Center for Biotechnology Information (see Internet Resources). Both ArrayExpress and GEO are able to accept submissions in the standard MAGE-ML format and therefore having a database system that generates MAGE-ML addresses this step. Use of MAGE-ML is not mandatory. GEO also has established its own format, Simple Omnibus Format in Text (SOFT). ArrayExpress provides a tool, MIAMExpress, that allows direct submissions. MIAMExpress provides a Web-based tool for annotating experiments using the MGED Ontology as described above. Both repositories do request that submission meet the MIAME standard.

Despite the tools and standards available, it is still possible to submit poorly annotated microarray experiments. The consequences of poor annotation are the failure to live up to the spirit of providing sufficient information to clearly understand the data and the diminished chances of the experimental results being of further use. Therefore, every reasonable effort should be made to fully annotate submissions.

CONCLUSIONS

The landscape of microarray platforms and analysis methods might be overwhelming, but there is no need to master every platform and every method of analysis. Generally a laboratory will use one platform and will assemble a set of protocols that works for them. Optimally, this should be done with the aid of a bioinformatics/statistics consultant. This being said, a lot of mileage can be obtained from just a few tools. For example, a major portion of the information that is desired can be obtained, for two-channel assays, using loess normalization, SAM, or PaGE for differential expression analysis and hierarchical clustering for identifying the major patterns. Analogously, one can use Affymetrix arrays pro-

cessed with gcRMA and then analyzed with SAM or PaGE and via clustering.

To conclude, the following steps are recommended as a general approach for using microarrays (Fig. 19.6.1):

1. Consult a statistician and/or bioinformaticist when designing your experiment. Usually, microarray cores can provide this service or at least recommend someone who can.

- a. Determine what kinds of analysis will be performed and then decide on the number and types of replicates needed to do the experiment.

- b. Make sure that confounding factors like date of hybridization are addressed (i.e., don't process all the controls one day and all the experimental samples another day).

2. Perform the experiment and start collecting information required for the MIAME checklist.

- a. Get the quantified data files (e.g., CEL files for Affymetrix).

- b. Get other files that have MIAME information (e.g., EXP for Affymetrix that provide hybridization date, protocol, array).

3. Preprocess and normalize the data (e.g., use gcRMA for Affymetrix, loess for two-channel assays).

- a. Assess the assays by inspecting images and generating diagnostic plots.

- b. Perform quality control analysis looking for hybridizations that are outliers among replicates in terms of how much they need to be adjusted for normalization and number of signals above background (e.g., P calls for Affymetrix).

- c. Apply quality control clustering to see whether replicates cluster together as expected.

- d. Filter out reporters to be discarded and normalize.

4. Analyze the data (e.g., SAM or PaGE for differential expression, hierarchical clustering).

- a. Look for shared characteristics of differentially expressed genes and genes in a cluster (e.g., look for overenrichment of GO terms using EASE).

- b. Validate differences seen (e.g., qRT-PCR for key genes identified as differentially expressed).

5. Load the data and experiment (MIAME) annotation into a database.

6. Publish your study and submit your microarray data and annotation to ArrayExpress or GEO.

CHAPTER 20

Analysis of Protein Interactions

INTRODUCTION

Most of the work of living organisms is performed by proteins. Proteins do their work by acting on other macromolecules: nucleic acids, carbohydrates, lipids, and, especially, other proteins. Inside cells, protein-protein interactions are instrumental in enzymatic actions upon protein substrates and in the fleeting and lasting protein assemblies that govern signal transduction, cell division, DNA replication, and transcription initiation. Outside cells, protein interactions allow cells to talk with each other: ligands expressed on the cell surface often bind protein receptors expressed on adjacent cells, and secreted protein ligands bind receptors on distant cells. Techniques to detect and study protein-protein interactions have become steadily more easy to use in recent years. This chapter lays them out.

BASIC CONCEPTS

Most of the work of living organisms is performed by proteins. Proteins do their work by acting on other macromolecules: nucleic acids, carbohydrates, lipids, and, especially, other proteins. Inside cells, protein-protein interactions are instrumental in enzymatic actions upon protein substrates and in the fleeting and lasting protein assemblies that govern signal transduction, cell division, DNA replication, and transcription initiation. Outside cells, protein interactions allow cells to talk with each other: ligands expressed on the cell surface often bind protein receptors expressed on adjacent cells, and secreted protein ligands bind receptors on distant cells. Techniques to detect and study protein-protein interactions have become steadily more easy to use in recent years. This unit, and those that follow, lay them out.

Qualitative statements about protein-protein interactions inform much of the current biological literature. This unit presents the basics for understanding such qualitative statements—i.e., the quantitative concepts by which these can be evaluated. Colloquially, protein interactions are often referred to as either **stable** or **transient**. The statement that a certain interaction is **stable** is typically used when the interacting proteins form a complex. Membership in a protein complex is most commonly defined operationally—based on detection of the protein after its coprecipitation with a reagent specific for another member of the complex—but is sometimes defined based on a strong and biologically plausible interaction in a two-hybrid experiment. Proteins that form such complexes with one another are often referred to as **partners**. By contrast, the term **transient** is used to denote, e.g., interactions between an enzyme and a protein substrate.

As the preceding example suggests, there is no particular correlation between the stability of a protein interaction and its biological significance. It is also worth noting that there are exceptions to commonly held assumptions about stable and transient interactions: some interactions observed in coprecipitation experiments have no biological validity, whereas some enzyme-substrate interactions last for minutes. For these reasons, it is often useful to think of protein interactions in more formal terms. The strength, or **affinity**, of an interaction between two proteins is described by **equilibrium parameters**. The speed at which an interaction occurs, and at which interacting proteins come apart, is given by **kinetic parameters**.

Table 20.0.1 Dissociation Constants for Some Biologically Significant Interactions

Interaction	K_d
Streptavidin-biotin binding	10^{-14} M
Antibody-antigen interaction with good antibody	10^{-8} to 10^{-10} M
DNA binding protein with specific site	10^{-8} to 10^{-10} M
Antibody-antigen interaction with weak antibody	10^{-6} M
Enzyme-substrate interactions	10^{-4} to 10^{-10} M
Cooperative interaction between DNA-bound phage repressors	10^{-4} M
Cooperative interaction between phage repressor and <i>E. coli</i> RNA polymerase	10^{-2} M

EQUILIBRIUM PARAMETERS

The strength of an interaction can be given as the **equilibrium dissociation constant**, K_d , or by its reciprocal, K_a (discussed below). When two proteins A and B associate, the K_d is given by

$$K_d = \frac{[A][B]}{[AB]}$$

where $[AB]$ is the concentration of the complexed species and $[A]$ and $[B]$ are the concentrations of the noncomplexed species. Concentrations are given in molar terms, as is the K_d .

There are two useful special cases to keep in mind. First, when A and B are present in equal concentration, the concentration at which half of each protein is present in the form of AB complex is the K_d . Second, when the concentration of A vastly exceeds the concentration of B (say, by 100-fold)—typically indicated $[A] \gg [B]$ —the concentration of A at which half of the B is found in the AB complex approximates K_d .

Typical K_d values for biologically significant interactions are given in Table 20.0.1. Note that many significant interactions are weak.

Alternatively, affinity may be given as an **equilibrium association constant**, K_a . The K_a is simply

$$K_a = \frac{[AB]}{[A][B]}$$

In other words, it is the reciprocal of the equilibrium dissociation constant: $K_a = 1/K_d$. Association constants are used less often than K_d , but do appear in the literature of some subfields—for example, in descriptions of antibody-antigen interactions.

The strength of an interaction is directly proportional to the change in Gibbs free energy (ΔG) when A and B interact, which is given by

$$\Delta G = \Delta H - T\Delta S$$

where T is the temperature in degrees Kelvin, ΔS is the change in entropy (S), and ΔH is the change in enthalpy (H). ΔG is given in units of kilocalories/mole (kcal mol^{-1}). An

increase in the free energy of an interaction by 1 kcal decreases the K_d by a factor of ~7. Note that the temperature affects the entropy term of the equation. As the temperature decreases, reactions driven by enthalpy are less affected by losses in entropy, and are usually favored. By contrast, reactions whose free energy is derived largely from favorable changes in entropy are disfavored at lower temperatures. This means that the dependence of a protein association on temperature can often provide a clue to which term predominately contributes to the free energy change involved in that association.

The relationship between K_a and ΔG is defined as follows:

$$\Delta G^0 = -RT \ln \frac{[AB]}{[A][B]}$$

$$\Delta G^0 = -RT \ln K_a = -RT \ln \left(\frac{1}{K_d} \right) = -RT \ln K_d$$

where ΔG^0 is the free energy change under standard conditions (25°C); R is the universal gas constant (1.9872 calmol⁻¹K⁻¹); and T is the temperature in degrees Kelvin (25°C is 289.1 K). Therefore,

$$\Delta G^0 = 0.588 \ln K_d$$

and, since $\ln x = 2.303 \log_{10} x$, $\Delta G^0 = 1.36 \log_{10} K_d$. For example:

- (a) $K_d = 1 \times 10^{-14}$, then $\Delta G^0 = -19.04 \text{ kcal mol}^{-1}$
- (b) $K_d = 1 \times 10^{-2}$, then $\Delta G^0 = -2.72 \text{ kcal mol}^{-1}$

The streptavidin-biotin reaction (a) is intrinsically more favorable in the direction of binding, [AB] formation, than the low-affinity interaction (b) involving phage repressor (see Table 20.0.1). It should be pointed out that the DG values calculated above assume that the molar ratio of reactants [A] [B] and product [AB] is 1 M (standard state).

Many (but by no means all) biologically important protein interactions seem to be largely driven by ΔH , or changes in enthalpy. That is fortunate, in that changes in entropy on binding are very hard to quantitate, or even think about precisely. For example, proteins in solution are surrounded by water molecules that form hydrogen bonds with surface residues. When two proteins interact, the ordered arrangement of the water molecules that surrounded the interacting surfaces of the proteins is often disrupted, and this loss of order provides an entropically favorable term to the free energy of the interaction. Such changes in the free energy due to entropy are very hard to predict. By contrast, enthalpic changes are easier to understand. If formation of one hydrogen bond liberates about -1 kcal M^{-1} , and formation of a particular ionic contact liberates about -2 kcal M^{-1} , then the energies of these changes are additive such that the formation of both bonds usually liberates -3 kcal M^{-1} —which means that the K_d is decreased >100-fold by the enthalpic changes.

Kinetic Parameters

The above descriptions of protein interactions make no reference to the speed at which association or dissociation occurs. These speeds are given by **kinetic parameters**.

The **dissociation rate constant**, k_{dissoc} , gives the speed at which the AB complex dissociates into A and B ($AB \rightarrow A + B$). k_{dissoc} is a first-order rate constant—i.e., one that

is dependent on the concentration of one species, in this case the AB complex—and is given by the rate of decrease in the concentration of AB:

$$k_{\text{dissoc}}[A][B] = \frac{-d[AB]}{dt}$$

Its units are those of reciprocal time (t in the equation), usually given in sec^{-1} . For example, a dissociation rate constant of 10^{-4}sec^{-1} means that one in 10^4 of the AB complexes present comes apart each second.

Similarly, the **association rate constant**, k_{assoc} , gives the speed at which A and B associate to form an AB complex ($A + B \rightarrow AB$). This is a second-order reaction—i.e., its speed depends on the concentrations of both A and B—and its rate constant is given by

$$k_{\text{assoc}}[A][B] = \frac{+d[AB]}{dt}$$

Its units are those of reciprocal concentration \times reciprocal time, typically given in $\text{M}^{-1} \text{sec}^{-1}$.

For example, suppose that protein A is present at a concentration of 10^{-6}M in a cell, that protein B is injected to a nuclear concentration of 10^{-5}M , and that the rate constant for this antibody-antigen association is $10^{-4} \text{M}^{-1} \text{sec}^{-1}$. After injection, the concentration of AB will be

$$\begin{aligned} [AB] &= [A] \times [B] \times K_{\text{assoc}} \\ &= (10^{-6} \text{M})(10^{-5} \text{M})(10^{-4} \text{M}) \\ &= 10^{-7} \text{M sec}^{-1} \end{aligned}$$

That is, in the first second after mixing, 10^{-7}M of AB complex will form. Every 10-fold increase in the concentration of either reactant increases the rate of product formation 10-fold.

Note that, at equilibrium, by definition,

$$\frac{d[AB]}{dt} = 0$$

and, therefore, for the AB interaction,

$$K_{\text{d}} = \frac{k_{\text{dissoc}}}{k_{\text{assoc}}}$$

The fact that the strength of equilibrium interactions reflects the speed of associations and dissociations has important consequences. To understand this, imagine two pairs of proteins that interact with the same K_{d} . Proteins A and B come together slowly, but, once the AB complex forms, it takes a long time to come apart. By contrast, proteins C and D come together rapidly, and the CD complex dissociates rapidly. There are two common cases in which these kinetic differences in the AB and CD associations would be significant.

One is in measurement. Many techniques, such as the “pulldown” and immunological coprecipitation techniques described in this chapter, rely on the fact that proteins remain associated during some sequence of steps, while they are being separated from other proteins in a mixture and while the isolated complex is being rinsed. No matter how tightly the proteins associate, if they come apart before their complex can be separated and rinsed, the complex will not be detected. Moreover, if the AB and CD interactions

have the same K_d , but CD comes apart more rapidly, then a coprecipitation experiment can falsely suggest that the CD association is weaker.

The second case concerns the biological effects. Many biological phenomena, such as the transcription phenotypes resulting from protein-protein interactions in two-hybrid experiments (*UNIT 19.3*), seem to be well-described by consideration of equilibrium measurements. However, it is worth keeping in mind that any biological process that results from the association of two proteins requires a minimum time to occur. For some enzyme-substrate interactions, the minimum time may be on the order of microseconds, but for others, such as the initiation of DNA replication, it may be measured in seconds. If the complex dissociates faster than the minimum time, then, no matter how tight the interaction, the process will not occur. If AB and CD have the same K_d , but CD dissociates faster, the association may not produce a biological effect.

WHAT THIS CHAPTER DESCRIBES

To a contemporary biologist, the phrase “analysis of protein interactions” encompasses both the identification of interacting proteins and the measurement of the strength and rates of their interactions. This chapter covers both. It does not a number of classical biochemical techniques, including those that separate bound species from free species on chromatographic media, in velocity gradients, or by equilibrium dialysis. It has been designed to present most of the techniques currently used for identification and the most widely used techniques for measurement.

This chapter features several units that provide quite different approaches for identifying interacting proteins. The first approach, described in *UNIT 20.1*, presents recent developments in two-hybrid methods. These approaches allow detection of proteins that interact with a DNA-bound “bait” protein, and isolation of the genes that encode them, based on their biological effect on transcription of reporter genes in yeast.

This chapter also adds a second method (*UNIT 20.6*) for detecting interacting proteins. This method (called the “far-Western”) depends on proteins in a liquid phase (e.g., a cell extract interacting with “bait” proteins separated electrophoretically on a gel). Proteins that interact and whose interaction persists through the washing steps are detected by antibodies against them. This method favors detection of protein interactions with long-off rates.

A third procedure, detailed in *UNIT 20.2*, provides a biochemical method for detecting associations between a GST-fused bait protein and a mixture of proteins that may contain an interacting partner. In this coprecipitation or “pulldown” approach, interacting proteins are identified and can be purified using standard affinity methods for GST-containing proteins.

In the related technique of co-immunoprecipitation (*UNIT 20.5*), cell-free extracts are incubated with an antibody to a desired protein (or to an epitope tag) in order to coprecipitate associated proteins. This approach is used to isolate multiprotein complexes that presumably were present in the intact cell.

Another molecular biological approach that directly yields a clone encoding the interacting protein is described in *UNIT 20.3*. Interaction cloning (also known as expression cloning) is a technique to identify and clone genes which encode proteins that interact with a protein of interest, or “bait” protein. Phage-based interaction cloning requires a gene encoding the bait protein and an appropriate expression library constructed in a bacteriophage expression vector, such as λ gt11.

An in vitro technique called surface plasmon resonance (SPR) can simultaneously detect interactions between unmodified proteins and measure kinetic parameters of the interaction. The availability of user-friendly instruments has facilitated the use of SPR as a means of studying macromolecular interactions. This technology is presented in *UNIT 20.4*.

Roger Brent

Interaction Trap/Two-Hybrid System to Identify Interacting Proteins

To understand the function of a particular protein, it is often useful to identify other proteins with which it associates. This can be done by a selection or screen in which novel proteins that specifically interact with a target protein of interest are isolated from a library. One particularly useful approach to detect novel interacting proteins—the two-hybrid system or interaction trap (see Figs. 20.1.1 and 20.1.2)—uses yeast as a “test tube” and transcriptional activation of a reporter system to identify associating proteins (see Background Information). This approach can also be used specifically to test complex formation between two proteins for which there is a prior reason to expect an interaction.

In the basic version of this method (see Fig. 20.1.2), the plasmid pEG202 or a related vector (see Fig. 20.1.3 and Table 20.1.1) is used to express the probe or “bait” protein as a fusion to the heterologous DNA-binding protein LexA. Many proteins, including transcription factors, kinases, and phosphatases, have been successfully used as bait proteins. The major requirements for the bait protein are that it should not be actively excluded from the yeast nucleus, and it should not possess an intrinsic ability to strongly activate transcription. The plasmid expressing the LexA-fused bait protein (see Table 20.1.1) is used to transform yeast possessing a dual reporter system responsive to transcriptional activation through the LexA operator. In one such example, the yeast strain EGY48 (see Table 20.1.2) contains the reporter plasmid pSH18-34. In this case, binding sites for LexA are located upstream of two reporter genes. In the EGY48 strain, the upstream activating sequences of the chromosomal *LEU2* gene—required in the biosynthetic pathway for leucine (Leu)—are replaced with LexA operators (DNA binding sites). pSH18-34 contains a LexA operator–*lacZ* fusion gene. These two reporters allow selection for transcriptional activation by permitting selection for viability when cells are plated on medium lacking Leu, and discrimination based on color when the yeast is grown on medium containing Xgal (UNIT 13.6).

In Basic Protocol 1, EGY48/pSH18-34 transformed with a bait is characterized for its ability to express protein (Support Protocol 1), growth on medium lacking Leu, and for the level of transcriptional activation of *lacZ* (see Fig. 20.1.2A). A number of alternative strains, plasmids, and strategies are presented which can be employed if a bait proves to have an unacceptably high level of background transcriptional activation.

In an interactor hunt (Basic Protocol 2), the strain EGY48/pSH18-34 containing the bait expression plasmid is transformed (along with carrier DNA made as described in Support Protocol 2) with a conditionally expressed library made in the vector pJG4-5 (see Fig. 20.1.6 and Table 20.1.3). This library uses the inducible yeast *GAL1* promoter to express proteins as fusions to an acidic domain (“acid blob”) that functions as a portable transcriptional activation motif (act) and to other useful moieties. Expression of library-encoded proteins is induced by plating transformants on medium containing galactose (Gal), so yeast cells containing library proteins that do not interact specifically with the bait protein will fail to grow in the absence of Leu (see Fig. 20.1.2B). Yeast cells containing library proteins that interact with the bait protein will form colonies within 2 to 5 days, and the colonies will turn blue when the cells are streaked on medium containing Xgal (see Fig. 20.1.2C). The DNA from interaction trap positive colonies can be analyzed by polymerase chain reaction (PCR) to streamline screening and detect redundant clones in cases where many positives are obtained in screening (see Alternate Protocol 1). The plasmids are isolated and characterized by a series of tests to confirm specificity of the interaction with the initial bait protein (Support Protocols 3 to 5). Those found to be specific are ready for further analysis (e.g., sequencing).

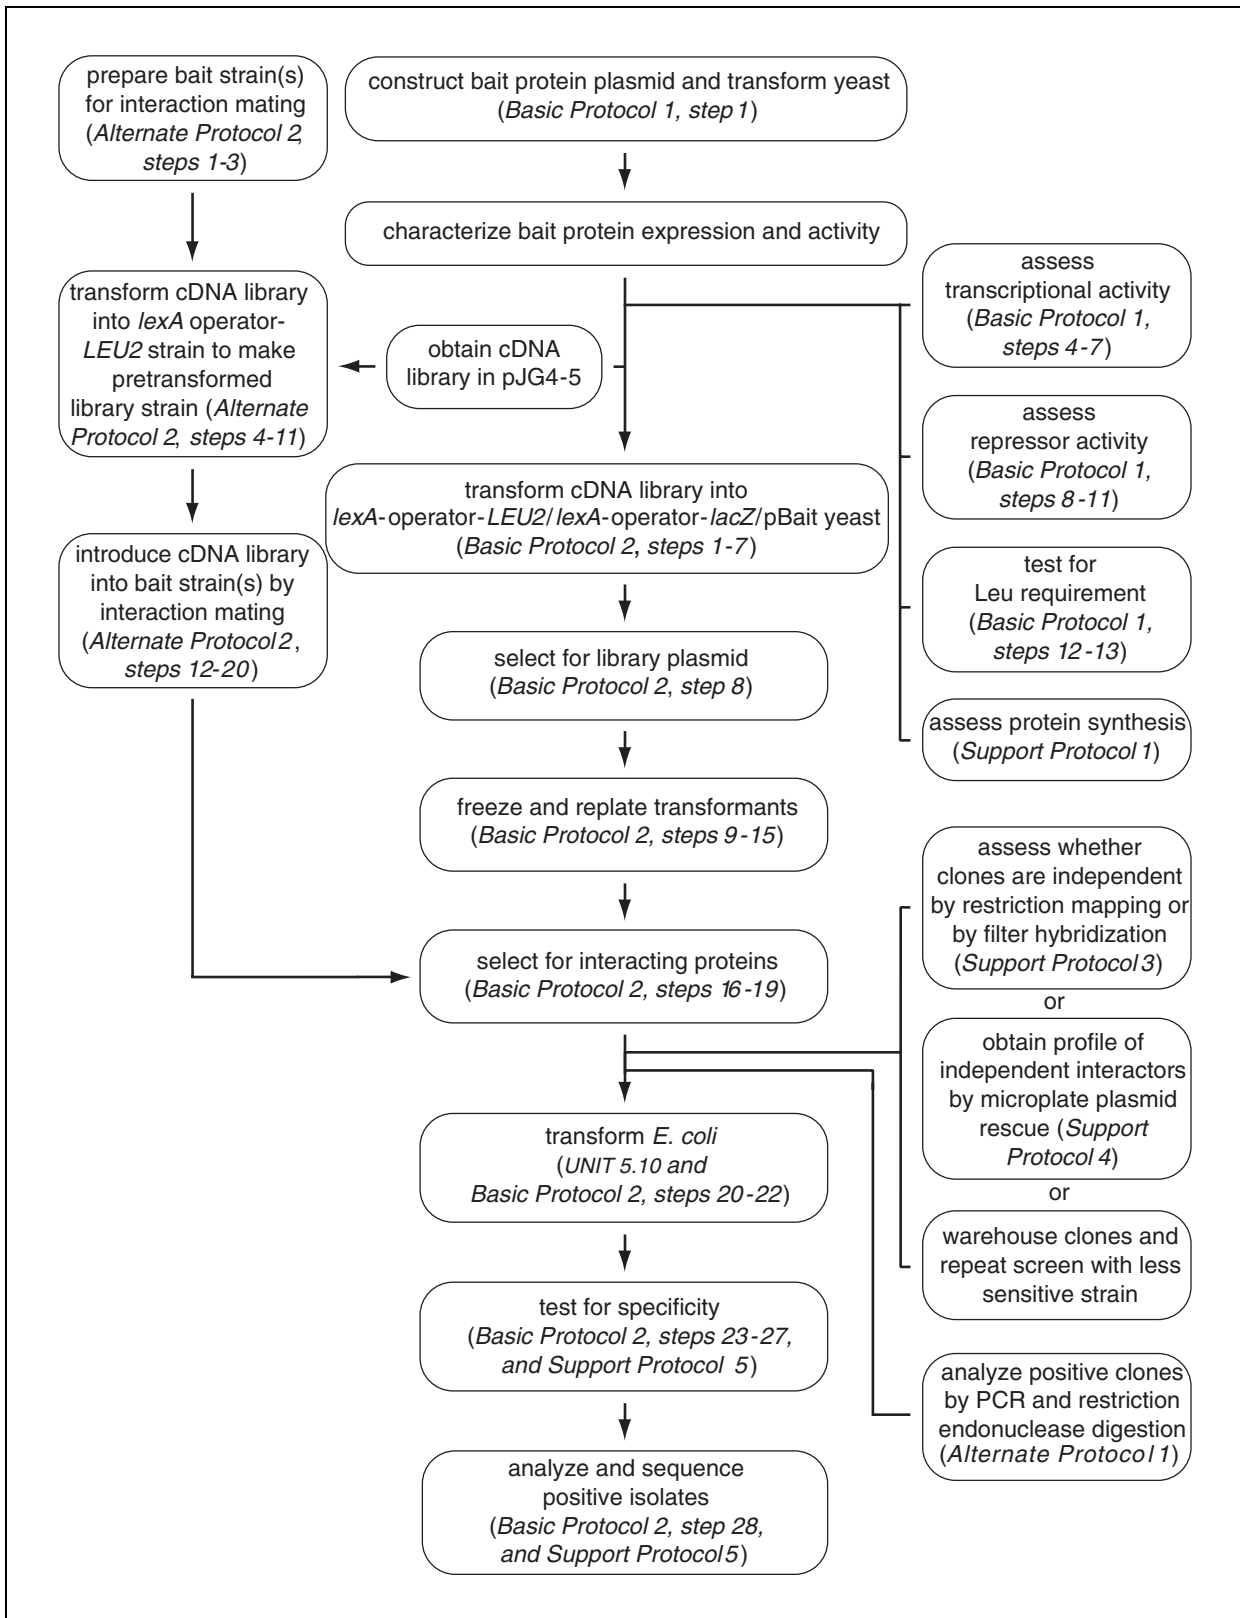

Figure 20.1.1 Flow chart for performing an interaction trap.

20.1.2

Figure 20.1.2 The interaction trap. **(A)** An EGY48 yeast cell containing two LexA operator–responsive reporters, one a chromosomally integrated copy of the *LEU2* gene (required for growth on –Leu medium), the second a plasmid bearing a *GAL1* promoter–*lacZ* fusion gene (causing yeast to turn blue on medium containing Xgal). The cell also contains a constitutively expressed chimeric protein, consisting of the DNA-binding domain of LexA fused to the probe or bait protein, shown as being unable to activate either of the two reporters. **(B)** and **(C)**, EGY48/pSH18-34/pbait-containing yeast have been additionally transformed with an activation domain (act)–fused cDNA library in pJG4-5, and the library has been induced. In **(B)**, the encoded protein does not interact specifically with the bait protein and the two reporters are not activated. In **(C)**, a positive interaction is shown in which the library-encoded protein interacts with bait protein, resulting in activation of the two reporters (arrow), thus causing growth on medium lacking Leu and blue color on medium containing Xgal. Symbols: black rectangle, LexA operator sequence; open circle, LexA protein; open pentagon, bait protein; open rectangle, library protein; shaded box, activator protein (acid blob in Fig. 20.1.6).

When more than one bait will be used to screen a single library, significant time and resources can be saved by performing the interactor hunt by interaction mating (see Alternate Protocol 2). In this protocol, EGY48 is transformed with library DNA and the transformants are collected and frozen in aliquots. For each interactor hunt, an aliquot of the pretransformed EGY48/library strain is thawed and mixed with an aliquot of a bait strain transformed with the bait expression plasmid and pSH18-34. Overnight incubation of the mixture on a YPD plate results in fusion of the two strains to form diploids. The diploids are then exposed to galactose to induce expression of the library-encoded proteins, and interactors are selected in the same manner as in Basic Protocol 2. The advantage to this approach is that it requires only one high-efficiency library transformation for multiple hunts with different baits. It is also useful for bait proteins that are somewhat toxic to yeast; yeast expressing toxic baits can be difficult to transform with the library DNA.

CHARACTERIZING A BAIT PROTEIN

The first step in an interactor hunt is to construct a plasmid that expresses LexA fused to the protein of interest. This construct is transformed into reporter yeast strains containing *LEU2* and *lacZ* reporter genes, and a series of control experiments is performed to establish whether the construct is suitable as is or must be modified, and whether alternative yeast reporter conditions should be used. These controls establish that the bait protein is made as a stable protein in yeast, that it is capable of entering the nucleus and binding LexA operator sites, and that it does not appreciably activate transcription of the LexA operator–based reporter genes. This last is the most important constraint on use of this system. The LexA-fused bait protein must not activate transcription of either re-

Table 20.1.1 Interaction Trap Components^{a,b}

Plasmid name/source	Selection		Comment/description
	In yeast	In <i>E. coli</i>	
<i>LexA fusion plasmids</i>			
pEG202 ^{c,d,e}	<i>HIS3</i>	Ap ^r	Contains an <i>ADH</i> promoter that expresses LexA followed by polylinker
pJK202	<i>HIS3</i>	Ap ^r	Like pEG202, but incorporates nuclear localization sequences between LexA and polylinker; used to enhance translocation of bait to nucleus
pNLexA ^e	<i>HIS3</i>	Ap ^r	Contains an <i>ADH</i> promoter that expresses polylinker followed by LexA; for use with baits where amino-terminal residues must remain unblocked
pGilda ^d	<i>HIS3</i>	Ap ^r	Contains a <i>GAL1</i> promoter that expresses same LexA and polylinker cassette as pEG202; for use with baits whose continuous presence is toxic to yeast
pEE202I	<i>HIS3</i>	Ap ^r	An integrating form of pEG202 that can be targeted into <i>HIS3</i> following digestion with <i>KpnI</i> ; for use where physiological screen requires lower levels of bait to be expressed
pRFHM1 ^{e,f} (control)	<i>HIS3</i>	Ap ^r	Contains an <i>ADH</i> promoter that expresses LexA fused to the homeodomain of bicoid to produce nonactivating fusion; used as positive control for repression assay, negative control for activation and interaction assays
pSH17-4 ^{e,f} (control)	<i>HIS3</i>	Ap ^r	<i>ADH</i> promoter expresses LexA fused to GAL4 activation domain; used as a positive control for transcriptional activation
pMW101 ^f	<i>HIS3</i>	Cm ^r	Same as pEG202, but with altered antibiotic resistance markers; basic plasmid used for cloning bait
pMW103 ^f	<i>HIS3</i>	Km ^r	Same as pEG202, but with altered antibiotic resistance markers; basic plasmid used for cloning bait
pHybLex/Zeo ^{f,g}	Zeo ^r	Zeo ^r	Bait cloning vector compatible with interaction trap and all other two-hybrid systems; minimal <i>ADH</i> promoter expresses LexA followed by extended polylinker
<i>Activation domain fusion plasmids</i>			
pJG4-5 ^{c,d,e,f}	<i>TRP1</i>	Ap ^r	Contains a <i>GAL1</i> promoter that expresses nuclear localization domain, transcriptional activation domain, HA epitope tag, cloning sites; used to express cDNA libraries
pJG4-5I	<i>TRP1</i>	Ap ^r	An integrating form of pJG4-5 that can be targeted into <i>TRP1</i> by digestion with <i>Bsu36I</i> (New England Biolabs); to be used with pEE202I to study interactions that occur physiologically at low protein concentrations
pYESTrp ^g	<i>TRP1</i>	Ap ^r	Contains a <i>GAL1</i> promoter that expresses nuclear localization domain, transcriptional activation domain, V5 epitope tag, multiple cloning sites; contains f1 ori and T7 promoter/flanking site; used to express cDNA libraries (Invitrogen)
pMW102 ^f	<i>TRP1</i>	Km ^r	Same as pJG4-5, but with altered antibiotic resistance markers; no libraries yet available
pMW104 ^f	<i>TRP1</i>	Cm ^r	Same as pJG4-5, but with altered antibiotic resistance markers; no libraries yet available
<i>LacZ reporter plasmids</i>			
pSH18-34 ^{d,e,f}	<i>URA3</i>	Ap ^r	Contains 8 <i>LexA</i> operators that direct transcription of the <i>lacZ</i> gene; one of the most sensitive indicator plasmids for transcriptional activation
pJK103 ^e	<i>URA3</i>	Ap ^r	Contains two <i>LexA</i> operators that direct transcription of the <i>lacZ</i> gene; an intermediate reporter plasmid for transcriptional activation
pRB1840 ^e	<i>URA3</i>	Ap ^r	Contains 1 <i>LexA</i> operator that directs transcription of the <i>lacZ</i> gene; one of the most stringent reporters for transcriptional activation
pMW112 ^f	<i>URA3</i>	Km ^r	Same as pSH18-34, but with altered antibiotic resistance marker
pMW109 ^f	<i>URA3</i>	Km ^r	Same as pJK103, but with altered antibiotic resistance marker

Plasmid name/source	Selection		Comment/description
	In yeast	In <i>E. coli</i>	
pMW111 ^f	<i>URA3</i>	Km ^r	Same as pRB1840, but with altered antibiotic resistance marker
pMW107 ^f	<i>URA3</i>	Cm ^r	Same as pSH18-34, but with altered antibiotic resistance marker
pMW108 ^f	<i>URA3</i>	Cm ^r	Same as pJK103, but with altered antibiotic resistance marker
pMW110 ^f	<i>URA3</i>	Cm ^r	Same as pRB1840, but with altered antibiotic resistance marker
pJK101 ^{e,f} (control)	<i>URA3</i>	Ap ^r	Contains a <i>GAL1</i> upstream activating sequence followed by two <i>lexA</i> operators followed by <i>lacZ</i> gene; used in repression assay to assess bait binding to operator sequences

^aAll plasmids contain a 2 μ m origin for maintenance in yeast, as well as a bacterial origin of replication, except where noted (pEE202I, pJG4.5I).

^bInteraction Trap reagents represent the work of many contributors: the original basic reagents were developed in the Brent laboratory (Gyuris et al., 1993). Plasmids with altered antibiotic resistance markers (all pMW plasmids) were constructed at Glaxo in Research Triangle Park, N.C. (Watson et al., 1996). Plasmids and strains for specialized applications have been developed by the following individuals: E. Golemis, Fox Chase Cancer Center, Philadelphia, Pa. (pEG202); J. Kamens, BASF, Worcester, Mass. (pJK202); cumulative efforts of I. York, Dana-Farber Cancer Center, Boston, Mass. and M. Sainz and S. Nottwehr, U. Oregon (pNLexA); D.A. Shaywitz, MIT Center for Cancer Research, Cambridge, Mass. (pGilda); R. Buckholz, Glaxo, Research Triangle Park, N.C. (pEE202I, pJG4-5I); J. Gyuris, Mitotix, Cambridge, Mass. (pJG4-5); S. Hanes, Wadsworth Institute, Albany, N.Y. (pSH17-4); R.L. Finley, Wayne State University School of Medicine, Detroit, Mich. (pRFHM1); S. Hanes, Wadsworth Institute, Albany, N.Y. (pSH18-34); J. Kamens, BASF, Worcester, Mass. (pJK101, pJK103); R. Brent, The Molecular Sciences Institute, Berkeley, Calif. (pRB1840). Specialized plasmids not yet commercially available can be obtained by contacting the Brent laboratory at (510) 647-0690 or brent@molsci.org, or the Golemis laboratory, (215) 728-2860 or EA_Golemis@fcc.edu.

^cSequence data are available for pEG202 (pLexA) accession number pending.

^dPlasmids commercially available from Clontech and OriGene; for Clontech pEG202 is listed as pLexA, pJG4-5 as pB42AD, and pSH18-34 as p8op-LacZ.

^ePlasmids and strains available from OriGene.

^fIn pMW plasmids the ampicillin resistance gene (Ap^r) is replaced with the chloramphenicol resistance gene (Cm^r) and the kanamycin resistance gene (Km^r) from pBC SK(+) and pBK-CMV (Stratagene), respectively. The choice between Km^r and Cm^r or Ap^r plasmids is a matter of personal taste; use of basic Ap^r plasmids is described in the basic protocols. Use of the more recently developed reagents would facilitate the purification of library plasmid in later steps by eliminating the need for passage through KC8 bacteria, with substantial saving of time and effort. Ap^r has been maintained as marker of choice for the library plasmid because of the existence of multiple libraries already possessing this marker. These plasmids are the basic set of plasmids recommended for use.

^gPlasmids commercially available from Invitrogen as components of a Hybrid Hunter kit; this kit also includes all necessary positive and negative controls (not listed in this table). See Background Information for further details on commercially available reagents.

porter—the EGY48 strain (or related strain EGY191) that expresses the LexA fusion protein should not grow on medium lacking Leu, and the colonies should be white on medium containing Xgal. The characterized bait protein plasmid is used for Basic Protocol 2 to screen a library for interacting proteins.

Materials

DNA encoding the protein of interest

Plasmids (see Table 20.1.1): pEG202 (see Fig. 20.1.3), pSH18-34 (see Fig. 20.1.4), pSH17-4, pRFHM1, and pJK101 for basic characterization; other plasmids for specific circumstances as described (Clontech, Invitrogen, OriGene, or R. Brent)

Yeast strain EGY48 (*ura3 trp1 his3 3LexA-operator-LEU2*), or EGY191 (*ura3 trp1 his3 1LexA-operator-LEU2*; Table 20.1.2)

Complete minimal (CM) medium dropout plates (*UNIT 13.1*), supplemented with 2% (w/v) of the indicated sugars (glucose or galactose), in 100-mm plates:

Glu/CM, –Ura, –His

Gal/CM, –Ura, –His

Gal/CM, –Ura, –His, –Leu

20.1.5

Figure 20.1.3 LexA-fusion plasmids: pEG202. The strong constitutive *ADH* promoter is used to express bait proteins as fusions to the DNA-binding protein LexA. Restriction sites shown in this map are based on recently compiled pEG202 sequence data and include selected sites suitable for diagnostic restriction endonuclease digests. A number of restriction sites are available for insertion of coding sequences to produce protein fusions with LexA; the polylinker sequence and reading frame relative to LexA are shown below the map with unique sites marked in bold type. The sequence 5'-CGT CAG CAG AGC TTC ACC ATT G-3' can be used to design a primer to confirm correct reading frame for LexA fusions. Plasmids contain the *HIS3* selectable marker and the 2μm origin of replication to allow propagation in yeast, and the *Ap^r* antibiotic resistance gene and the pBR origin of replication to allow propagation in *E. coli*. In the recently developed LexA-expression plasmids pMW101 and pMW103, the ampicillin resistance gene (*Ap^r*) has been replaced with the chloramphenicol resistance gene (*Cm^r*) and the kanamycin resistance gene (*Km^r*), respectively (see Table 19.2.1 for details).

Gal/CM dropout liquid medium (*UNIT 13.1*) supplemented with 2% Gal
 Antibody to LexA or fusion domain: monoclonal antibody to LexA (Clontech,
 Invitrogen) or polyclonal antibody to LexA (available by request from R. Brent
 or E. Golemis)
 H₂O, sterile
 30°C incubator
 Nylon membrane
 Whatman 3MM filter paper

Additional reagents and equipment for subcloning DNA fragments (*UNIT 3.16*), lithium acetate transformation of yeast (*UNIT 13.7*), liquid assay for β-galactosidase (*UNIT 13.6*), preparation of protein extracts for immunoblot analysis (see Support Protocol 1), and immunoblotting and immunodetection (*UNIT 10.8*)

Figure 20.1.4 LacZ reporter plasmid. pRB1840, pJK103, and pSH18-34 are all derivatives of LR1Δ1 (West et al., 1984) containing eight, two, or one operator for LexA (*LexA_{op}*) binding inserted into the unique *XhoI* site located in the minimal *GAL1* promoter (*GAL1_{pro}*; 0.28 on map). The plasmid contains the *URA3* selectable marker, the 2μm origin to allow propagation in yeast, the ampicillin resistance (*Ap^r*) gene, and the pBR322 origin (*ori*) to allow propagation in *E. coli*. Numbers indicate relative map positions. In the recently developed derivatives, the ampicillin resistance gene (*Ap^r*) has been replaced with the chloramphenicol or kanamycin resistance genes (see Table 19.2.1 for details).

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly.

Transform yeast with the bait protein plasmid

1. Using standard subcloning techniques (*UNIT 3.16*), insert the DNA encoding the protein of interest into the polylinker of pEG202 (see Fig. 20.1.3) or other LexA fusion plasmid to make an in-frame protein fusion.

The LexA fusion protein is expressed from the strong alcohol dehydrogenase (ADH) promoter. pEG202 also contains a HIS3 selectable marker and a 2μm origin for propagation in yeast. pEG202 with the DNA encoding the protein of interest inserted is designated pBait. Uses of alternative LexA fusion plasmids are described in Background Information.

2. Perform three separate lithium acetate transformations (*UNIT 13.7*) of EGY48 using the following combinations of plasmids:

pBait + pSH18-34 (test)
 pSH17-4 + pSH18-34 (positive control for activation)
 pRFHM1 + pSH18-34 (negative control for activation).

Use of the two LexA fusions as positive and negative controls allows a rough assessment of the transcriptional activation profile of LexA bait proteins. pEG202 itself is not a good negative control because the peptide encoded by the uninterrupted polylinker sequences is itself capable of very weakly activating transcription.

Table 20.1.2 Interaction Trap Yeast Selection Strains^a

Strain	Relevant genotype	Number of operators	Comments/description
EGY48 ^{b,c,d}	<i>MATα trp1, his3, ura3, lexAops-LEU2</i>	6	<i>lexA</i> operators direct transcription from the <i>LEU2</i> gene; EGY48 is a basic strain used to select for interacting clones from a cDNA library
EGY191	<i>MATα trp1, his3, ura3, lexAops-LEU2</i>	2	EGY191 provides a more stringent selection than EGY48, producing lower background with baits with intrinsic ability to activate transcription
L40 ^c	<i>MATα trp1, leu2, ade2, GAL4, lexAops-HIS34, lexAops-lacZ8</i>		Expression driven from <i>GAL1</i> promoter is constitutive in L40 (inducible in EGY strains); selection is for <i>HIS</i> prototrophy. Integrated <i>lacZ</i> reporter is considerably less sensitive than pSH18-34 maintained in EGY strains

^aInteraction Trap reagents represent the work of many contributors: the original basic reagents were developed in the Brent laboratory (Gyuris et al., 1993). Strains for specialized applications have been developed by the following individuals: E. Golemis, Fox Chase Cancer Center, Philadelphia, Pa. (EGY48, EGY191); A.B. Vojtek and S.M. Hollenberg, Fred Hutchinson Cancer Research Center, Seattle, Wash. (L40). Specialized strains not yet commercially available can be obtained by contacting the Brent laboratory at The Molecular Sciences Institute, Berkeley, (510) 647-0690 or brent@molsci.org, or the Golemis laboratory, (215) 728-2860 or EA_Golemis@fcc.edu.

^bStrains commercially available from Clontech.

^cStrains commercially available from Invitrogen as components of a Hybrid Hunter kit; the kit also includes all necessary positive and negative controls (not listed in this table). See Background Information for further details on commercially available reagents.

^dStrains commercially available from OriGene.

pSH18-34 contains a 2 μ m origin and a *URA3* selectable marker for maintenance in yeast, as well as a bacterial origin of replication and ampicillin-resistance gene. It is the most sensitive *lacZ* reporter available and will detect any potential ability to activate *lacZ* transcription. *pSH17-4* is a *HIS3* 2 μ m plasmid encoding *LexA* fused to the activation domain of the yeast activator protein *GAL4*. This fusion protein strongly activates transcription. *pRFHM1* is a *HIS3* 2 μ m plasmid encoding *LexA* fused to the N-terminus of the *Drosophila* protein *bicoid*. This fusion protein has no ability to activate transcription.

3. Plate each transformation mixture on Glu/CM –Ura, –His dropout plates. Incubate 2 days at 30°C to select for yeast that contain both plasmids.

Colonies obtained can be used simultaneously in tests for the activation of lacZ (steps 4 to 7) and LEU2 (steps 12 to 13) reporters.

Assay *lacZ* gene activation by β -galactosidase assay

4. Streak a Glu/CM –Ura, –His master dropout plate with at least five or six independent colonies obtained from each of the three transformations in step 3 (test, positive control, and negative control) and incubate overnight at 30°C.

The filter assay described in Steps 5a to 7a (based on Breeden and Nasmyth, 1985) provides a rapid assay for β -galactosidase transcription. Alternatively, a liquid assay (UNIT 13.6) or a plate assay (described in Steps 5b to 7b) may be used.

Perform filter assay for β -galactosidase activity:

- 5a. Lift colonies by gently placing a nylon membrane on the yeast plate and allowing it to become wet through. Remove the membrane and air dry 5 min. Chill the membrane, colony side up, 10 min at –70°C.

Whatman 3MM filters can be cut to the size of the yeast plate as a more economical alternative to nylon membranes for performing lifts. In addition, two or three 5-min temperature cycles (–70°C to room temperature) can be used instead of a single cycle to promote better lysis; this may be worth doing if there is difficulty visualizing blue color.

- 6a. Cut a piece of Whatman 3MM filter paper slightly larger than the colony membrane and soak it in Z buffer containing 1 mg/ml Xgal. Place colony membrane, colony side up, on Whatman 3MM paper, or float it in the lid of a petri dish containing ~2 ml Z buffer with 1 mg/ml Xgal.

Acceptable results may be obtained using as little as 300 µg/ml Xgal.

- 7a. Incubate at 30°C and monitor for color changes.

It is generally useful to check the membrane after 20 min, and again after 2 to 3 hr. Strong activators will produce a blue color in 5 to 10 min, and a bait protein (LexA fusion protein) that does so is unsuitable for use in an interactor hunt using this lacZ reporter plasmid. Weak activators will produce a blue color in 1 to 6 hr (compare versus negative control pRFHMI which will itself produce a faint blue color with time) and may or may not be suitable. Weak activators should be tested using the repressor assay described in steps 8 to 11.

Perform Xgal plate assay for lacZ activation:

- 5b. Prepare Z buffer Xgal plates as described in UNIT 13.1.

For activation assays, plates should be prepared with glucose as a sugar source. For repression assays (steps 8 to 11), galactose should be used as a sugar source. In our experience, when patching from a master plate to Xgal plates, sufficient yeast are transferred that plasmid loss is not a major problem even in the absence of selection; this is balanced by the desire to assay sets of constructs on the same plate to eliminate batch variation in Xgal potency. Hence, plates should be made either with complete minimal amino acid mix, or by dropping out only uracil (-Ura), to make the plates universally useful.

Figure 20.1.5 Repression assay for DNA binding. **(A)** The plasmid JK101 contains the upstream activating sequence (UAS) from the *GAL1* gene followed by *LexA* operators upstream of the *lacZ* coding sequence. Thus, yeast containing pJK101 will have significant β-galactosidase activity when grown on medium in which galactose is the sole carbon source because of binding of endogenous yeast GAL4 to the GAL_{UAS}. **(B)** LexA-fused proteins (P1-LexA) that are made, enter the nucleus, and bind the LexA operator sequences (ops) will block activation from the GAL_{UAS}, repressing β-galactosidase activity (+) 3- to 5-fold. On glucose/Xgal medium, yeast containing pJK101 should be white because GAL_{UAS} transcription is repressed.

6b. Streak yeast from master plate to Xgal plate and incubate at 30°C.

7b. Examine plates for color development at intervals over the next 2 to 3 days.

Strongly activating fusions should be visibly blue on the plate within 12 to 24 hr; moderate activators will be visibly blue after ~2 days.

When a bait protein appreciably activates transcription under these conditions, there are several recourses. The first and simplest is to switch to a less sensitive lacZ reporter plasmid; use of pJK103 and pRB1840 may be sufficient to reduce background to manageable levels. If this fails to work, it is frequently possible to generate a truncated LexA fusion that does not activate transcription.

Confirm fusion-protein synthesis by repression assay

For LexA fusions that do not activate transcription, confirm by performing a repression assay (Brent and Ptashne, 1984) that the LexA fusion protein is being synthesized in yeast (some proteins are not) and that it is capable of binding LexA operator sequences (Fig. 20.1.5). The following steps can be performed concurrently with the activation assay.

8. Transform EGY48 yeast with the following combinations of plasmids (three transformations):

pBait + pJK101 (test)

pRFHM1 + pJK101 (positive control for repression)

pJK101 alone (negative control for repression).

9. Plate each transformation mix on Glu/CM–Ura, –His dropout plates or Glu/CM–Ura dropout plates as appropriate to select yeast cells that contain the indicated plasmids. Incubate 2 to 3 days at 30°C until colonies appear.

10. Streak colonies to a Glu/CM–Ura, –His or Glu/CM–Ura dropout master plate and incubate overnight at 30°C.

11. Assay β -galactosidase activity of the three transformed strains (test, positive control, and negative control) by liquid assay (using Gal/CM dropout liquid medium), filter assay (steps 5a to 7a, first restreaking to Gal/CM plates to grow overnight), or plate assay (steps 5b to 7b, using Gal/CM–Ura XGal plates).

This assay should not be run for more than 1 to 2 hr for membranes, or 36 hr for Xgal plates, as the high basal lacZ activity will make differential activation of pJK101 impossible to see with longer incubations. Use of Xgal plates, and inspection 12 to 24 hr after streaking, is generally most effective.

The plasmid pJK101 contains the galactose upstream activating sequence (UAS) followed by LexA operators upstream of the lacZ coding sequence. Thus, yeast containing pJK101 will have significant β -galactosidase activity when grown on medium in which galactose is the sole carbon source because of binding of endogenous yeast GAL4 to the GAL_{UAS}. LexA-fused proteins that are made, enter the nucleus, and bind the LexA operator sequences block activation from the GAL_{UAS}, repressing β -galactosidase activity 3- to 20-fold. Note that on Glu/Xgal medium, yeast containing pJK101 should be white, because GAL_{UAS} transcription is repressed.

12. If a bait protein neither activates nor represses transcription, perform immunoblot analysis by probing an immunoblot of a crude lysate with antibodies against LexA or the fusion domain to test for protein synthesis (see Support Protocol 1).

Even if a bait protein represses transcription, it is generally a good idea to assay for the production of full-length LexA fusions, as occasionally some fusion proteins will be proteolytically cleaved by endogenous yeast proteases. If the protein is made but does not repress, it may be necessary to clone the sequence into a LexA fusion vector that contains a nuclear localization motif, e.g., pJK202 (see Table 20.1.1), or to modify or truncate the fusion domain to remove motifs that target it to other cellular compartments (e.g., myristoylation signals).

Test for *Leu* requirement

These steps can be performed concurrently with the *lacZ* activation and repression assays.

13. Disperse a colony of EGY48 containing pBait and pSH18-34 reporter plasmids into 500 μ l sterile water. Dilute 100 μ l of suspension into 1 ml sterile water. Make a series of 1/10 dilutions in sterile water to cover a 1000-fold concentration range.
14. Plate 100 μ l from each tube (undiluted, 1/10, 1/100, and 1/1000) on Gal/CM –Ura, –His dropout plates and on Gal/CM –Ura, –His, –Leu dropout plates. Incubate overnight at 30°C.

There will be a total of eight plates. Gal/CM –Ura, –His dropout plates should show a concentration range from 10 to 10,000 colonies and Gal/CM –Ura, –His, –Leu dropout plates should have no colonies.

Actual selection in the interactor hunt is based on the ability of the bait protein and acid-fusion pair, but not the bait protein alone, to activate transcription of the LexA operator-LEU2 gene and allow growth on medium lacking Leu. Thus, the test for the Leu requirement is the most important test of whether the bait protein is likely to have an unworkably high background. The LEU2 reporter in EGY48 is more sensitive than the pSH18-34 reporter for some baits, so it is possible that a bait protein that gives little or no signal in a β -galactosidase assay would nevertheless permit some level of growth on –Leu medium. If this occurs, there are several options for proceeding, the most immediate of which is to substitute EGY191 (see Table 20.1.2), a less sensitive screening strain, and repeat the assay.

As outlined in this protocol, the authors recommend the strategy of performing the initial screening using the most sensitive reporters and then, if activation is detected, screening with increasingly less sensitive reporters (see Critical Parameters for further discussion).

PERFORMING AN INTERACTOR HUNT

An interactor hunt involves two successive large platings of yeast containing LexA-fused probes and reporters and libraries in pJG4-5 (Fig. 20.1.6, Table 20.1.3) with a cDNA expression cassette under control of the *GAL* promoter. In the first plating, yeast are plated on complete minimal (CM) medium –Ura, –His, –Trp dropout plates with glucose (Glu) as a sugar source to select for the library plasmid. In the second plating, which selects for yeast that contain interacting proteins, a slurry of primary transformants is plated on CM –Ura, –His, –Trp, –Leu dropout plates with galactose/raffinose (Gal/Raff) as the sugar source. This two-step selection is encouraged for two reasons. First, a number of interesting cDNA-encoded proteins may be deleterious to the growth of yeast that bear them; these would be competed out in an initial mass plating. Second, it seems likely that immediately after simultaneous transformation and Gal induction, yeast bearing particular interacting proteins may not be able to initially express sufficient levels of these proteins to support growth on medium lacking Leu. Library plasmids from colonies identified in the second plating are purified by bacterial transformation and used to transform yeast cells for the final specificity screen.

A list of libraries currently available for use with this system is provided in Table 20.1.3. The protocol outlined below describes the steps used to perform a single-step screen that should saturate a library derived from a mammalian cell. For screens with libraries derived from lower eukaryotes with less complex genomes, fewer plates will be required.

Occasionally, baits that seemed well-behaved during preliminary tests produce unworkably high backgrounds of “positives” during an actual screen (see Background Information and Critical Parameters). To forestall the waste of time and materials performing a screen with such a bait would entail, an alternative approach is to perform a scaled-back

screen when working with a new bait (e.g., 5 rather than 30 plates of primary transformants). The results can be assessed before doing a full screen; it is then possible to switch to lower-sensitivity reporter strains and plasmids, if appropriate. Although individual baits will vary, the authors' current default preference is to use the *lacZ* reporter pJK103 in conjunction with either EGY48 or EGY191. Polymerase chain reaction (PCR) can also be used in a rapid screening approach that may be preferable if a large number of positions are obtained in a library screen (see Alternate Protocol 1).

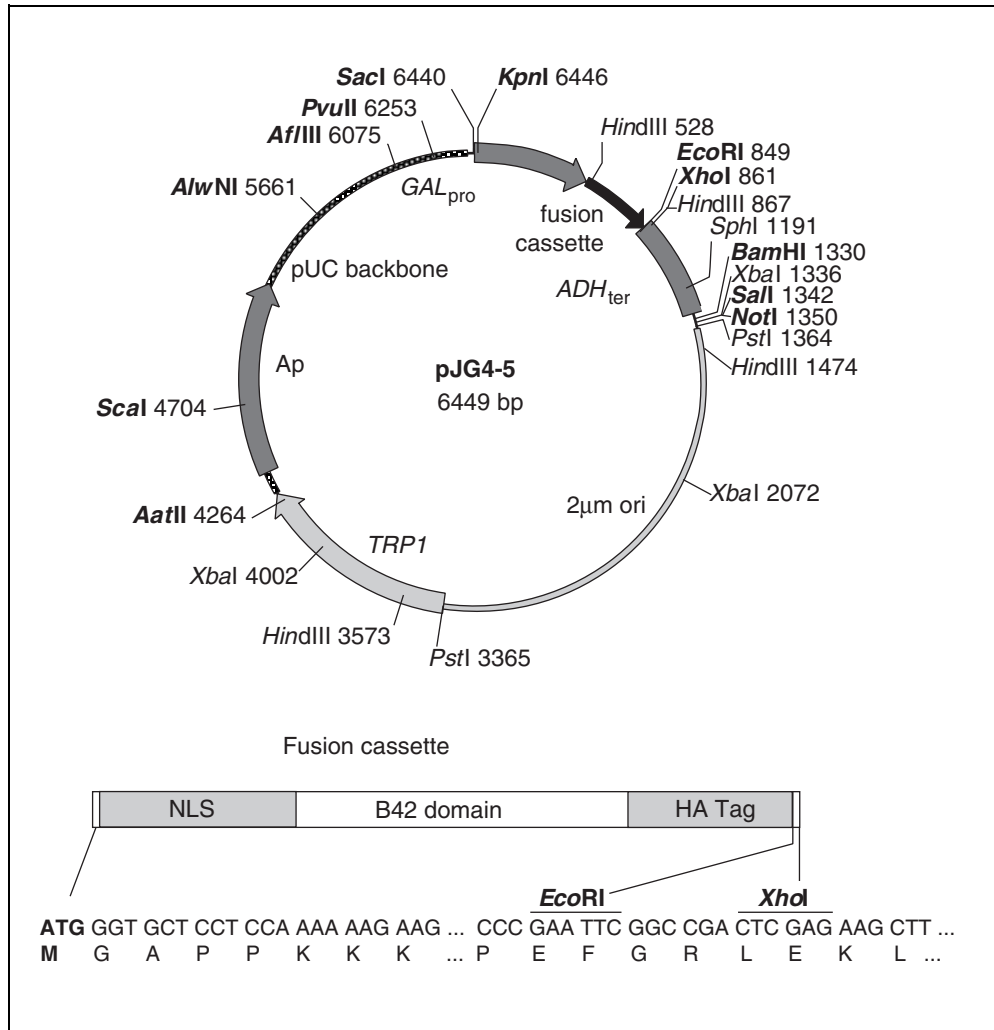

Figure 20.1.6 Library plasmids: pJG4-5. Library plasmids express cDNAs or other coding sequences inserted into unique *EcoRI* and *XhoI* sites as a translational fusion to a cassette consisting of the SV40 nuclear localization sequence (NLS; PPKKKRKVA), the acid blob B42 domain (Ruden et al, 1991), and the hemagglutinin (HA) epitope tag (YPYDVPDYA). Expression of cassette sequences is under the control of the *GAL1* galactose-inducible promoter. This map is based on the sequence data available for pJG4-5, and includes selected sites suitable for diagnostic restriction digests (shown in bold). The sequence 5'-CTG AGT GGA GAT GCC TCC-3' can be used as a primer to identify inserts or to confirm correct reading frame. The pJG4-5 plasmid contains the *TRP1* selectable marker and the 2µm origin to allow propagation in yeast, and the antibiotic resistance gene and the pUC origin to allow propagation in *E. coli*. In the recently developed pJG4-5 derivative plasmids pMW104 and pMW102, the ampicillin resistance gene (*Ap*^r) has been replaced with the chloramphenicol resistance gene (*Cm*^r) and the kanamycin resistance gene (*Km*^r), respectively (see Table 19.2.2 for details). Currently existing libraries are all made in the pJG4-5 plasmid (Gyuris et al., 1993) shown on this figure. Unique sites are marked in bold type.

Materials

Yeast containing appropriate combinations of plasmids (see Table 20.1.1 and Table 20.1.2):

EGY48 containing *LexA*-operator-*lacZ* reporter and pBait (see Basic Protocol 1)

EGY48 containing *LexA*-operator-*lacZ* reporter and pRFHM-1

EGY48 containing *LexA*-operator-*lacZ* reporter and any nonspecific bait

Complete minimal (CM) dropout liquid medium (UNIT 13.1) supplemented with sugars (glucose, galactose, and/or raffinose) as indicated [2% (w/v) Glu, or 2% (w/v) Gal + 1% (w/v) Raff]:

Glu/CM –Ura, –His

Glu/CM –Trp

Gal/Raff/CM –Ura, –His, –Trp

H₂O, sterile

TE buffer (pH 7.5; APPENDIX 2)/0.1 M lithium acetate

Library DNA in pJG4-5 (Table 20.1.3 and Fig. 20.1.6)

High-quality sheared salmon sperm DNA (see Support Protocol 2)

40% (w/v) polyethylene glycol 4000 (PEG 4000; filter sterilized)/0.1 M lithium acetate/TE buffer (pH 7.5)

Dimethyl sulfoxide (DMSO)

Complete minimal (CM) medium dropout plates (UNIT 13.1) supplemented with sugars and Xgal (20 µg/ml) as indicated [2% (w/v) Glu, and 2% (w/v) Gal + 1% (w/v) Raff]:

Glu/CM –Ura, –His, –Trp, 24 × 24-cm (Nunc) and 100-mm

Gal/Raff/CM –Ura, –His, –Trp, 100-mm

Gal/Raff/CM –Ura, –His, –Trp, –Leu, 100-mm

Glu/Xgal/CM –Ura, –His, –Trp, 100-mm

Gal/Raff/Xgal/CM –Ura, –His, –Trp, 100-mm

Glu/CM –Ura, –His, –Trp, –Leu, 100-mm

Glu/CM –Ura, –His, 100-mm

Gal/CM –Ura, –His, –Trp, –Leu, 100-mm

TE buffer (pH 7.5), sterile (optional)

Glycerol solution (see recipe)

E. coli KC8 (*pyrF leuB600 trpC hisB463*; constructed by K. Struhl and available from R. Brent)

LB/ampicillin plates (UNIT 1.1)

E. coli DH5α or other strain suitable for preparation of DNA for sequencing

Bacterial defined minimal A medium plates: 1× A medium plates containing 0.5 µg/ml vitamin B1 (UNIT 1.1) and supplemented with 40 µg/ml each Ura, His, and Leu

30°C incubator, with and without shaking

Low-speed centrifuge and rotor

50-ml conical tubes, sterile

1.5-ml microcentrifuge tubes, sterile

42°C heating block

Glass microscope slides, sterile

Additional reagents and equipment for rapid miniprep isolation of yeast DNA

(UNIT 13.11), transformation of bacteria by electroporation (UNIT 1.8), miniprep isolation of bacterial DNA (UNIT 1.6), restriction endonuclease digestion (UNIT 3.1; optional), and agarose gel electrophoresis (UNIT 2.5A; optional)

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly.

^aMost libraries are constructed in either the pJG4-5 vector or the pYESTrp vector (JG or Y in the Vector column); the peptide aptamer library is made in the pJM-1 vector. Libraries available from the public domain were constructed by the following individuals: (1) J. Gyuris; (3) C. Sardet and J. Gyuris; (4) W. Kolanus, J. Gyuris, and B. Seed; (39) D. Krainc; (50-52) R. Finley; (55) P. Watt; (54) P. Colas, B. Cohen, T. Jessen, I. Grishina, J. McCoy, and R. Brent (Colas et al., 1996). All libraries mentioned above were constructed in conjunction with and are available from the laboratory of Roger Brent, (510) 647-0690 or brent@molsci.org. The following individual investigators must be contacted directly: (18) J. Pugh, Fox Chase Cancer Center, Philadelphia, Pa.; (8,9) Vinyaka Prasad, Albert Einstein Medical Center New York, N.Y.; (57, 58) Gregory B. Martin, gmartin@dept.agry.purdue.edu; (11) Huifeng Niu, hn34@columbia.edu; (16) Christer Hoog, christer.hoog@cmb.ki.se; (12) Kurt Gustin, kgus@umich.edu; (6) Stephan Witte, Stephan.Witte@nimbus.rz.uni-konstanz.de.

^bInsert size ranges for pJG4-5 based libraries originally constructed in the Brent laboratory, which are now commercially available from Clontech, were reestimated by the company.

Transform the library

- Grow an ~20-ml culture of EGY48 or EGY191 containing a *LexA*-operator-*lacZ* reporter plasmid and pBait in Glu/CM –Ura, –His liquid dropout medium overnight at 30°C.
For best results, the pBait and lacZ reporter plasmids should have been transformed into the yeast within ~7 to 10 days of commencing a screen.
- In the morning, dilute culture into 300 ml Glu/CM –Ura, –His liquid dropout medium to 2 × 10⁶ cell/ml (OD₆₀₀ = ~0.10). Incubate at 30°C until the culture contains ~1 × 10⁷ cells/ml (OD₆₀₀ = ~0.50).
- Centrifuge 5 min at 1000 to 1500 × g in a low-speed centrifuge at room temperature to harvest cells. Resuspend in 30 ml sterile water and transfer to 50-ml conical tube.
- Centrifuge 5 min at 1000 to 1500 × g. Decant supernatant and resuspend cells in 1.5 ml TE buffer/0.1 M lithium acetate.
- Add 1 μg library DNA in pJG4-5 and 50 μg high-quality sheared salmon sperm carrier DNA to each of 30 sterile 1.5-ml microcentrifuge tubes. Add 50 μl of the resuspended yeast solution from step 4 to each tube.

The total volume of library and salmon sperm DNA added should be <20 μl and preferably <10 μl.

A typical library transformation will result in 2 to 3 × 10⁶ primary transformants. Assuming a transformation efficiency of 10⁵/μg library DNA, this transformation requires a total of 20 to 30 μg library DNA and 1 to 2 mg carrier DNA. Doing transformations in small aliquots helps reduce the likelihood of contamination, and for reasons that are not clear, provides significantly better transformation efficiency than scaled-up versions.

Do not use excess transforming library DNA per aliquot of competent yeast cells because each competent cell may take up multiple library plasmids, complicating subsequent analysis.

6. Add 300 μ l of sterile 40% PEG 4000/0.1 M lithium acetate/TE buffer, pH 7.5, and invert to mix thoroughly. Incubate 30 min at 30°C.
7. Add DMSO to 10% (~40 μ l per tube) and invert to mix. Heat shock 10 min in 42°C heating block.
- 8a. *For 28 tubes:* Plate the complete contents of one tube per 24 \times 24-cm Glu/CM –Ura, –His, –Trp dropout plate and incubate at 30°C.
- 8b. *For two remaining tubes:* Plate 360 μ l of each tube on 24 \times 24-cm Glu/CM –Ura, –His, –Trp dropout plate. Use the remaining 40 μ l from each tube to make a series of 1/10 dilutions in sterile water. Plate dilutions on 100-mm Glu/CM –Ura, –His, –Trp dropout plates. Incubate all plates 2 to 3 days at 30°C until colonies appear.

The dilution series gives an idea of the transformation efficiency and allows an accurate estimation of the number of transformants obtained.

Collect primary transformant cells

Conventional replica plating (UNIT 13.3) does not work well in the selection process because so many cells are transferred to new plates that very high background levels inevitably occur. Instead, the procedure described below creates a slurry in which cells derived from $>10^6$ primary transformants are homogeneously dispersed. A precalculated number of these cells is plated for each primary transformant.

9. Cool all of the 24 \times 24-cm plates containing transformants for several hours at 4°C to harden agar.
10. Wearing gloves and using a sterile glass microscope slide, gently scrape yeast cells off the plate. Pool cells from the 30 plates into one or two sterile 50-ml conical tubes.

This is the step where contamination is most likely to occur. Be careful.

11. Wash cells by adding a volume of sterile TE buffer or water at least equal to the volume of the transferred cells. Centrifuge ~5 min at 1000 to 1500 \times g, room temperature, and discard supernatant. Repeat wash.

After the second wash, pellet volume should be ~25 ml cells derived from 1.5×10^6 transformants.

12. Resuspend pellet in 1 vol glycerol solution, mix well, and store up to 1 year in 1-ml aliquots at –70°C.

Determine replating efficiency

13. Remove an aliquot of frozen transformed yeast and dilute 1/10 with Gal/Raff/CM –Ura, –His, –Trp dropout medium. Incubate with shaking 4 hr at 30°C to induce the GAL promoter on the library.

Raffinose (Raff) aids in growth without diminishing transcription from the GAL1 promoter.

14. Make serial dilutions of the yeast cells using the Gal/Raff/CM –Ura, –His, –Trp dropout medium. Plate on 100-mm Gal/Raff/CM –Ura, –His, –Trp dropout plates and incubate 2 to 3 days at 30°C until colonies are visible.
15. Count colonies and determine the number of colony-forming units (cfu) per aliquot of transformed yeast.

In calculating yeast concentrations, it is useful to remember that 1 OD₆₀₀ unit = $\sim 2.0 \times 10^7$ yeast cells. In general, if the harvest is done carefully, viability will be greater than 90%. Some intrepid investigators perform this step simultaneously with plating out on Leu selective medium (steps 16 and 17).

Screen for interacting proteins

16. Thaw the appropriate quantity of transformed yeast based on the plating efficiency, dilute, and incubate as in step 13. Dilute cultures in Gal/Raff/CM –Ura, –His, –Trp, –Leu medium as necessary to obtain a concentration of 10^7 cells/ml ($OD_{600} = \sim 0.5$), and plate 100 μ l on each of as many 100-mm Gal/Raff/CM –Ura, –His, –Trp, –Leu dropout plates as are necessary for full representation of transformants. Incubate 2 to 3 days at 30°C until colonies appear.

Because not all cells that contain interacting proteins plate at 100% efficiency on –Leu medium (Estojak et al., 1995), it is desirable that for actual selection, each primary colony obtained from the transformation be represented on the selection plate by three to ten individual yeast cells. This will in some cases lead to multiple isolations of the same cDNA; however, because the slurry is not perfectly homogenous, it will increase the likelihood that all primary transformants are represented by at least one cell on the selective plate.

It is easiest to visually scan for Leu^+ colonies using cells plated at $\sim 10^6$ cfu per 100-mm plate. Plating at higher density can contribute to cross-feeding between yeast, resulting in spurious background growth. Thus, for a transformation in which 3×10^6 colonies are obtained, plate $\sim 2 \times 10^7$ cells on a total of 20 selective plates.

17. Carefully pick appropriate colonies to a new Gal/Raff/CM –Ura, –His, –Trp, –Leu master dropout plate. Incubate 2 to 7 days at 30°C until colonies appear.

A good strategy is to pick a master plate with colonies obtained on day 2, a second master plate (or set of plates) with colonies obtained on day 3, and a third with colonies obtained on day 4. Colonies from day 2 and 3 master plates should generally be characterized further. If many apparent positives are obtained, it may be worth making master plates of the much larger number of colonies likely to be obtained at day 4 (and after). See Critical Parameters and annotation to step 19 for additional information about appropriate colony selection for the master plate.

If no colonies appear within a week, those arising at later time points are likely to be artifactual. Contamination that has occurred at an earlier step (e.g., during plate scraping) is generally reflected by the growth of a very large number of colonies (>500 /plate) within 24 to 48 hr after plating on selective medium.

Some investigators omit use of a Gal/Raff/CM –Ura, –His, –Trp, –Leu master plate, restreaking directly to a Glu/CM –Ura, –His, –Trp master plate as in step 19.

Test for Gal dependence

The following steps test for Gal dependence of the Leu^+ insert and lacZ phenotypes to confirm that they are attributable to expression of the library-encoded proteins. The *GALI* promoter is turned off and –Leu selection eliminated before reinducing.

18. Restreak from the Gal/Raff/CM –Ura, –His, –Trp, –Leu master dropout plate to a 100-mm Glu/CM –Ura, –His, –Trp master dropout plate. Incubate overnight at 30°C until colonies form.
19. Restreak or replica plate from this plate to the following plates:

Glu/Xgal/CM –Ura, –His, –Trp
Gal/Raff/Xgal/CM –Ura, –His, –Trp
Glu/CM –Ura, –His, –Trp, –Leu
Gal/Raff/CM –Ura, –His, –Trp, –Leu.

At this juncture, colonies and the library plasmids they contain are tentatively considered positive if they are blue on Gal/Raff/Xgal plates but not blue or only faintly blue on Glu/Xgal plates, and if they grow on Gal/Raff/CM –Leu plates but not on Glu/CM –Leu plates.

The number of positives obtained will vary drastically from bait to bait. How they are processed subsequently will depend on the number initially obtained and on the preference

of the individual investigator. If none are obtained using EGY48 as reporter strain, it may be worth attempting to screen a library from an additional tissue source. If a relatively small number (≤ 30) are obtained, proceed to step 20. However, sometimes searches will yield large numbers of colonies (>30 to 300, or more). In this case, there are several options. The first option is to warehouse the majority of the positives and work up the first 30 that arise; those growing fastest are frequently the strongest interactors. These can be checked for specificity, and restriction digests can be used to establish whether they are all independent cDNAs or represent multiple isolates of the same, or a small number, of cDNAs. If the former is true, it may be advisable to repeat the screen in a less sensitive strain background, as obtaining many different interactors can be a sign of low-affinity nonspecific background. Alternatively, if initial indications are that a few cDNAs are dominating the positives obtained, it may be useful to perform a filter hybridization with yeast (see Support Protocol 3) using these cDNAs as a probe to establish the frequency of their identification and exclude future reisolation of these plasmids. The second major option is to work up large numbers of positives to get a complete profile of isolated interactors (see Support Protocol 4). A third option is to temporarily warehouse the entire results of this first screen, and repeat the screen with a less sensitive strain such as EGY191, on the theory that it is most important to get stronger interactors first and a complete profile of interactors later. Finally, some investigators prefer to work up the entire set of positives initially obtained, even if such positives number in the hundreds. Particularly in this latter case, it is most effective to use Alternate Protocol 1 as a means to identify unique versus common positives.

Isolate plasmid from positive colonies by transfer into *E. coli*

- 20a. Transfer yeast plasmids directly into *E. coli* by following the protocol for direct electroporation (UNIT 1.8, Alternate Protocol 2). Proceed to step 22.
- 20b. Isolate plasmid DNA from yeast by the rapid miniprep protocol (UNIT 13.11) with the following alteration: after obtaining aqueous phase, precipitate by adding sodium acetate to 0.3 M final and 2 vol ethanol, incubate 20 min on ice, microcentrifuge 15 min at maximum speed, wash pellet with 70% ethanol, dry, and resuspend in 5 μ l TE buffer.

Cultures can be grown prior to the miniprep using Glu/CM –Trp to select only for the library plasmid; this may increase the proportion of bacterial colonies that contain the desired plasmid.

21. Use 1 μ l DNA to electroporate (UNIT 1.8) into competent KC8 bacteria, and plate on LB/ampicillin plates. Incubate overnight at 37°C.

Electroporation must be used to obtain transformants with KC8 because the strain is generally refractory to transformation.

22. Restreak or replica plate colonies arising on LB/ampicillin plates to bacterial defined minimal A medium plates containing vitamin B1 and supplemented with Ura, His, and Leu but lacking Trp. Incubate overnight at 37°C.

Colonies that grow under these conditions contain the library plasmid.

The yeast TRP1 gene can successfully complement the bacterial trpC-9830 mutation, allowing the library plasmid to be easily distinguished from the other two plasmids contained in the yeast. It is helpful to first plate transformations on LB/ampicillin plates, which provides a less stringent selection, followed by restreaking to bacterial minimal medium to maximize the number of colonies obtained (E.G., unpub. observ.).

23. Purify library-containing plasmids using a bacterial miniprep procedure (UNIT 1.6).

Some investigators are tempted to immediately sequence DNAs obtained at this stage. At this point, it is still possible that none of the isolated clones will express bona fide interactors, and it is suggested that the following specificity tests be completed before committing the effort to sequencing (also see annotation to step 28).

Because multiple 2 μ m plasmids with the same marker can be simultaneously tolerated in yeast, it sometimes happens that a single yeast will contain two or more different library plasmids, only one of which encodes an interacting protein. The frequency of this occurrence varies in the hands of different investigators and may in some cases account for disappearing positives if the wrong cDNA is picked. When choosing colonies to miniprep, it is generally useful to work up at least two individual bacterial transformants for each yeast positive. These minipreps can then be restriction digested (UNIT 3.1) with EcoRI + XhoI to release cDNA inserts, and the size of inserts determined on an agarose minigel (UNIT 2.5A) to confirm that both plasmids contain the same insert. An additional benefit of analyzing insert size is that it may provide some indication as to whether repeated isolation of the same cDNA is occurring, generally a good indication concerning the biological relevance of the interactor. See Background Information for further discussion.

Assess positive colonies with specificity tests

Much spurious background will have been removed by the previous series of controls. Other classes of false positives can be eliminated by retransforming purified plasmids into “virgin” LexA-operator-LEU2/LexA-operator-lacZ/pBait-containing strains that have not been subjected to Leu selection and verifying that interaction-dependent phenotypes are still observed. Such false positives could include mutations in the initial EGY48 yeast that favor growth on Gal medium, library-encoded cDNAs that interact with the LexA DNA-binding domain, or proteins that are sticky and interact with multiple biologically unrelated fusion domains.

24. In separate transformations, use purified plasmids from step 23 to transform yeast that already contain the following plasmids and are growing on Glu/CM –Ura, –His plates:

EGY48 containing pSH18-34 and pBait
EGY48 containing pSH18-34 and pRFHM-1
EGY48 containing pSH18-34 and a nonspecific bait (optional).

25. Plate each transformation mix on Glu/CM –Ura, –His, –Trp dropout plates and incubate 2 to 3 days at 30°C until colonies appear.
26. Create a Glu/CM –Ura, –His, –Trp master dropout plate for each library plasmid being tested. Streak adjacently five or six independent colonies derived from each of the transformation plates. Incubate overnight at 30°C.
27. Restreak or replica plate from this master dropout plate to the same series of test plates used for the actual screen:

Glu/Xgal/CM –Ura, –His, –Trp
Gal/Raff/Xgal/CM –Ura, –His, –Trp
Glu/CM –Ura, –His, –Trp, –Leu
Gal/CM –Ura, –His, –Trp, –Leu.

True positive cDNAs should make cells blue on Gal/Raff/Xgal but not on Glu/Xgal plates, and should make them grow on Gal/Raff/CM –Leu but not Glu/CM –Leu dropout plates only if the cells contain LexA-bait. cDNAs that meet such criteria are ready to be sequenced (see legend to Fig. 20.1.3 for primer sequence) or otherwise characterized. Those cDNAs that also encode proteins that interact with either RFHM-1 or another nonspecific bait should be discarded.

It may be helpful to cross-check the isolated cDNAs with a database of cDNAs thought to be false positives. This database is available on the World Wide Web as a work in progress at <http://www.fccc.edu:80/research/labs/golemis/InteractionTrapInWork.html>. cDNAs reported to this database are generally those isolated only once in a screen in which obviously true interactive partners were isolated multiple times, cDNAs that may interact with more than one bait, or cDNAs for which the interaction does not appear to make biological sense

in the context of the starting bait. Although some proteins in this database may ultimately turn out in fact to associate with the bait that isolated them, they are by default unlikely to possess a unique and interesting function in the context of that bait if they are well represented in the database.

28. If appropriate, conduct additional specificity tests (see Support Protocol 5). Analyze and sequence positive isolates.

The primer sequence for use with pJG4-5 is provided in the legend to Figure 20.1.4.

DNA prepared from KC8 is generally unsuitable for dideoxy or automated sequencing even after use of Qiagen columns and/or cesium chloride gradients. Library plasmids to be sequenced should be retransformed from the KC8 miniprep stock (step 23) to a more amenable strain, such as DH5 α , before sequencing is attempted.

RAPID SCREEN FOR INTERACTION TRAP POSITIVES

Under some circumstances, it may be desirable to attempt the analysis of a large number of positives resulting from a two-hybrid screen. One such hypothetical example would be a bait with a leucine zipper or coiled coil known to dimerize with partner “A” that is highly expressed. In order to identify the rare novel partner “B”, it is necessary to work through the high background of “A” reisolates. This protocol uses the polymerase chain reaction (PCR) in a strategy to sort positives into redundant (multiple isolates) and unique classes prior to plasmid rescue from yeast, thus greatly reducing the number of plasmid isolations that must be performed. An additional benefit is that this protocol preidentifies positive clones containing one or multiple library plasmids; for those containing only one library plasmid, only a single colony needs to be prepared through KC8/DH5 α .

Additional Materials (also see Basic Protocol 2)

Yeast plated on Glu/CM –Ura, –His, –Trp master plate (see Basic Protocol 2, step 19)

Lysis solution (see recipe)

10 μ M forward primer (FP1): 5'-CGT AGT GGA GAT GCC TCC-3'

10 μ M reverse primer (FP2): 5'-CTG GCA AGG TAG ACA AGC CG-3'

Toothpicks or bacterial inoculating loops (UNIT 1.1), sterile

96-well microtiter plate

Sealing tape, e.g., wide transparent tape

150- to 212- μ m glass beads, acid-washed (UNIT 13.13)

Vortexer with flat plate

Additional reagents and equipment for performing an interactor hunt (see Basic Protocol 2), PCR amplification of DNA (UNIT 15.1), agarose gel electrophoresis (UNITS 2.5A & 2.6), restriction endonuclease digestion (UNIT 3.1), electroporation (UNIT 1.8), and miniprep isolation of bacterial DNA (UNIT 1.6)

1. Perform an interactor hunt (see Basic Protocol 2, steps 1 to 19).
2. Use a sterile toothpick or bacterial inoculating loop to transfer yeast from the Glu/CM, –Ura, –His, –Trp master plate into 25 μ l lysis solution in a 96-well microtiter plate. Seal the wells of the microtiter plate with sealing tape and incubate 1.5 to 3.5 hr at 37°C with shaking.

The volume of yeast transferred should not exceed ~2 to 3 μ l of packed pellet; larger quantities of yeast will reduce quality of the DNA. DNA can be efficiently recovered from master plates that have been stored up to 1 week at 4°C. If yeast have been previously gridded on master plates, transfer to microtiter plates can be facilitated by using a multicolony replicator.

ALTERNATE PROTOCOL 1

Analysis of Protein Interactions

20.1.21

3. Remove tape from the plate, add ~25 μ l acid-washed glass beads to each well, and reseal with the same tape. Firmly attach the microtiter plate to a flat-top vortexer, and vortex 5 min at medium-high power.

The microtiter plate can be attached to the vortexer using 0.25-in (0.64-cm) rubber bands.

4. Remove the tape and add ~100 μ l sterile water to each well. Swirl gently to mix, then remove sample for step 5. Press the tape back firmly to seal the microtiter plate and place in the freezer at -20°C for storage.
5. Amplify 0.8 to 2.0 μ l of sample by standard PCR (UNIT 15.1) in a ~30- μ l volume using 3 μ l each of the forward primer FP1 and the reverse primer FP2. Perform PCR using the following cycles:

Initial step:	2 min	94 $^{\circ}\text{C}$
31 cycles:	45 sec	94 $^{\circ}\text{C}$
	45 sec	56 $^{\circ}\text{C}$
	45 sec	72 $^{\circ}\text{C}$.

These conditions have been used successfully to amplify fragments up to 1.8 kb in length; some modifications, such as extension of elongation time, are also effective.

6. Load 20 μ l of the PCR reaction product on a 0.7% low melting temperature agarose gel (UNIT 2.6) to resolve PCR products. Based on insert sizes, group the obtained interactors in families, i.e., potential multiple independent isolates of identical cDNAs. Reserve gel until results of step 7 are obtained.

*No special precautions are needed for storing the gel. Since *HaeIII* digests typically yield rather small DNA fragments, running the second gel does not take a lot of time. Usually, the delay does not exceed 45 to 60 min, during which time the first gel may be stored in a gel box at room temperature or wrapped in plastic wrap at 4 $^{\circ}\text{C}$.*

7. While the gel is running, use the remaining 10 μ l of PCR reaction product for a restriction endonuclease digestion with *HaeIII* in a digestion volume of ~20 μ l (UNIT 3.1). Based on analysis of the sizes of undigested PCR products in the gel (step 6), rearrange the tubes with *HaeIII* digest samples so that those thought to represent a family are side by side. Resolve the digests on a 2% to 2.5% agarose gel (UNIT 2.5A).

Most restriction fragments will be in the 200-bp to 1.0-kb size range so using a long gel run is advisable. This analysis should produce a distinct fingerprint of insert sizes and allow definition of library cDNAs as unique isolates or related groups.

A single positive yeast will sometimes contain multiple library plasmids. An advantage of this protocol is the ready detection of multiple library plasmids in PCR reactions; thus, following subsequent bacterial transformations, only a single TRP1 colony would need to be analyzed unless multiple plasmids were already known to be present.

8. Isolate DNA fragments from the low melting temperature agarose gel (step 6).

If inspection of the banding pattern on the two gels suggests that a great many reisolates of a small number of cDNAs are present, it may be worthwhile to immediately sequence PCR products representative of these clusters, but it is generally still advisable to continue through specificity tests before doing so. If the PCR products are sequenced, the FP1 forward primer works well in automated sequencing of PCR fragments, but the FP2 primer is only effective in sequencing from purified plasmid.

In general, priming from the AT-rich ADH terminator downstream of the polylinker/cDNA in library plasmid is less efficient than from upstream of the cDNA, and it is hard to design effective primers in this region.

9. Remove the microtiter plate of lysates from the freezer, thaw it, and remove 2 to 4 μ l of lysed yeast for each desired positive. Electroporate DNA into either DH5 α or KC8 *E. coli* as appropriate, depending on the choice of bait and reporter plasmids (see

Table 20.1.1 and see Background Information for further information). Refreeze the plate as a DNA reserve in case bacteria fail to transform on the first pass.

KC8 E. coli should be used for electroporation when the original reagents pEG202/pJG4-5/pJK101 are used for the interaction trap.

An additional strength of this protocol is that it identifies redundant clones before transfer of plasmids to bacteria, thus reducing the amount of work required in cases where plasmid identity can be unambiguously assigned. However, although restriction endonuclease digestion and PCR analysis are generally highly predictive, they are not 100% certain methods for estimating cDNA identity. Thus, if there is any doubt about whether two cDNAs are the same, investigators are urged to err on the side of caution.

10. Prepare a miniprep of plasmid DNA from the transformed bacteria (*UNIT 1.6*) and perform yeast transformation and specificity assessment (see Basic Protocol 2, steps 24 to 28).

PERFORMING A HUNT BY INTERACTION MATING

An alternative way of conducting an interactor hunt is to mate a strain that expresses the bait protein with a strain that has been pretransformed with the library DNA, and screen the resulting diploid cells for interactors (Bendixen et al., 1994; Finley and Brent, 1994). This “interaction mating” approach can be used for any interactor hunt, and is particularly useful in three special cases. The first case is when more than one bait will be used to screen a single library. Interaction mating allows several interactor hunts with different baits to be conducted using a single high-efficiency yeast transformation with library DNA. This can be a considerable savings, since the library transformation is one of the most challenging tasks in an interactor hunt. The second case is when a constitutively expressed bait interferes with yeast viability. For such baits, performing a hunt by interaction mating avoids the difficulty associated with achieving a high-efficiency library transformation of a strain expressing a toxic bait. Moreover, the actual selection for interactors will be conducted in diploid yeast, which are more vigorous than haploid yeast and can better tolerate expression of toxic proteins. The third case is when a bait cannot be used in a traditional interactor hunt using haploid yeast strains (see Basic Protocol 2) because it activates transcription of even the least sensitive reporters. In diploids the reporters are less sensitive to transcription activation than they are in haploids. Thus, the interaction mating hunt provides an additional method to reduce background from transactivating baits.

In the protocol described below, the library DNA is used to transform a strain with a *LEU2* reporter (e.g., EGY48). This pretransformed library strain is then frozen in many aliquots, which can be thawed and used for individual interactor hunts. The bait is expressed in a strain of mating type opposite to that of the pretransformed library strain, and also bearing the *lacZ* reporter. A hunt is conducted by mixing the pretransformed library strain with the bait strain and allowing diploids to form on YPD medium overnight. The diploids are then induced for expression of the library-encoded proteins and screened for interactors as in Basic Protocol 2.

NOTE: Strain combinations other than those described below can also be used in an interaction-mating hunt. The key to choosing the strains is to ensure that the bait and prey strains are of opposite mating types and that both have auxotrophies to allow selection for the appropriate plasmids and reporter genes. Also, once the bait plasmid and *lacZ* reporter plasmid have been introduced into the bait strain, and the library plasmids have been introduced into the library strain, the resulting bait strain and library strain must each have auxotrophies that can be complemented by the other, so that diploids can be selected.

ALTERNATE PROTOCOL 2

Additional Materials (also see *Basic Protocols 1 and 2*)

Yeast strains: either RFY206 (Finley and Brent, 1994), YPH499 (Sikorski and Hieter, 1989; ATCC #6625), or an equivalent *MATa* strain with auxotrophic markers *ura3*, *trp1*, *his3*, and *leu2*

YPD liquid medium (*UNIT 13.1*)

Glu/CM –Trp plates: CM dropout plates –Trp (*UNIT 13.1*) supplemented with 2% glucose

pJG4-5 library vector (Fig. 20.1.6), empty

100-mm YPD plates (*UNIT 13.1*)

Additional reagents and equipment for lithium acetate transformation of yeast (*UNIT 13.7*)

Construct the bait strain

The bait strain will be a *MATa* yeast strain (mating type opposite of EGY48) containing a *lacZ* reporter plasmid like pSH18-34 and the bait-expressing plasmid, pBait.

1. Perform construction of the bait plasmid (pBait; see Basic Protocol 1, step 1).
2. Cotransform the *MATa* yeast strain (e.g., either RFY206 or YPH499) with pBait and pSH18-34 using the lithium acetate method (*UNIT 13.7*). Select transformants on Glu/CM –Ura,–His plates by incubating plates at 30°C for 3 to 4 days until colonies form. Combine 3 colonies for all future tests and for the mating hunt.

The bait strain (RFY206/pSH18-34/pBait or YPH499/pSH18-34/pBait) can be tested by immunoblotting to ensure that the bait protein is expressed (see Support Protocol 1). Synthesis and nuclear localization of the bait protein can also be tested by the repression assay (see Basic Protocol 1, steps 8 to 12).

3. *Optional:* Assay *lacZ* gene activation in the bait strain (see Basic Protocol 1, steps 4 to 7).

If the bait activates the lacZ reporter, a less sensitive lacZ reporter plasmid (Table 20.1.1), or an integrated version of the lacZ reporter should be tried. A bait that strongly activates the lacZ reporters usually cannot be used in a hunt based on selection of interactors with the LEU2 reporter, because the LEU2 reporters are more sensitive than the lacZ reporters. However, both reporters are less sensitive to activation by a bait in diploid cells, as compared to haploid cells. Thus, a more important test of the transactivation potential of a bait is to test the leucine requirement of diploid cells expressing it, as described in steps 6 to 20, below.

Prepare the pretransformed library strain (EGY48 + library plasmids)

4. Perform a large-scale transformation of EGY48 with library DNA using the lithium acetate method (see Basic Protocol 2, steps 1 to 8, except start with EGY48 bearing no other plasmids). To prepare for transformation, grow EGY48 in YPD liquid medium. Select library transformants on Glu/CM –Trp plates by incubating 3 days at 30°C.
5. Collect primary transformants by scraping plates, washing yeast, and resuspending in 1 pellet vol glycerol solution (see Basic Protocol 2, steps 9 to 12). Freeze 0.2 to 1.0 ml aliquots at –70° to –80°C.

The cells will be stable for at least 1 year. Refreezing a thawed aliquot will result in loss of viability. Thus, many frozen aliquots should be made, so that each thawed aliquot can be discarded after use.

Prepare the pretransformed control strain (EGY48 + pJG4-5)

6. Transform EGY48 grown in YPD liquid medium with the empty library vector, pJG4-5, using the lithium acetate method (UNIT 13.7). Select transformants on Glu/CM –Trp plates by incubating 3 days at 30°C.
7. Pick and combine three transformant colonies and use them to inoculate 30 ml of Glu/CM –Trp medium. Incubate 15 to 24 hr at 30°C (to $OD_{600} > 3$).
8. Centrifuge 5 min at 1000 to 1500 $\times g$, room temperature, and remove supernatant. Resuspend in 10 ml sterile water to wash cells.
9. Centrifuge 5 min at 1000 to 1500 $\times g$, room temperature, and remove supernatant. Resuspend in 1 pellet vol glycerol solution and freeze 100- μ l aliquots at –70° to –80°C.

Determine plating efficiency of pretransformed library and pretransformed control strains

10. After freezing (at least 1 hr) thaw an aliquot of each pretransformed strain (from step 5 and step 9) at room temperature. Make several serial dilutions in sterile water, including aliquots diluted 10⁵-fold, 10⁶-fold, and 10⁷-fold. Plate 100 μ l of each dilution on 100-mm Glu/CM –Trp plates and incubate 2 to 3 days at 30°C.
11. Count the colonies and determine the number of colony-forming units (cfu) per aliquot of transformed yeast.

The plating efficiency for a typical library transformation and for the control strain will be $\sim 1 \times 10^8$ cfu per 100 μ l.

Mate the bait strain with the pretransformed library strain and the pretransformed control strain

In steps 12 through 20, an interactor hunt is conducted concurrently with testing *LEU2* reporter activation by the bait itself. For most baits, this approach will be the quickest way to isolate interactors. However, for some baits, such as those that have a high transactivation potential, or those that affect yeast mating or growth, steps 12 through 20 will serve as a pilot experiment to determine the optimal parameters for a subsequent hunt.

12. Grow a 30-ml culture of the bait strain in Glu/CM –Ura, –His liquid dropout medium to mid to late log phase ($OD_{600} = 1.0$ to 2.0, or 2 to 4 $\times 10^7$ cells/ml).

A convenient way to grow the bait strain is to inoculate a 5-ml culture with approximately three colonies from a plate and grow it overnight at 30°C with shaking. In the morning, measure the OD_{600} , dilute into a 30-ml culture to a final $OD_{600} = 0.2$, and grow at 30°C with shaking. The culture should reach mid to late log phase before the end of the day.

13. Centrifuge the culture 5 min at 1000 to 1500 $\times g$, room temperature, to harvest cells. Resuspend the cell pellet in sterile water to make a final volume of 1 ml.

This should correspond to $\sim 1 \times 10^9$ cells/ml.

14. Set up two matings. In one sterile microcentrifuge tube mix 200 μ l of the bait strain with 200 μ l of a thawed aliquot of the pretransformed control strain from step 9. In a second microcentrifuge tube mix 200 μ l of the bait strain with $\sim 1 \times 10^8$ cfu (~ 0.1 to 1 ml) of the pretransformed library strain from step 5.

The library mating should be set up so that it contains a ~ 2 -fold excess of bait strain cfu over pretransformed library strain cfu. Because the bait strain was harvested in log phase, most of the cells will be viable (i.e., cells/ml = \sim cfu/ml), and the number of cfu can be sufficiently estimated from optical density (1 $OD_{600} = \sim 2 \times 10^7$ cells/ml). Under these conditions, $\sim 10\%$ of the cfu in the pretransformed library strain will mate with the bait

strain. Thus, a complete screen of 10^7 library transformants will require a single mating with at least 10^8 cfu of the pretransformed library strain and at least 2×10^8 cfu of the bait strain.

To screen more library transformants, set up additional matings. The number of pretransformed library transformants to screen depends on the size of the library and the number of primary transformants obtained in step 5. If the size of the library is larger than the number of transformants obtained in step 5, the goal will be to screen all of the yeast transformants. In this case, complete screening of the library will require additional transformations of EGY48 and additional interactor hunts. If the size of the library is smaller than the number of transformants obtained in step 5, the goal will be to screen at least a number of transformants equivalent to the size of the library.

15. Centrifuge each cell mixture for 5 min at 1000 to $1500 \times g$, pour off medium, and resuspend cells in 200 μ l YPD medium. Plate each suspension on a 100-mm YPD plate. Incubate 12 to 15 hr at 30°C.
16. Add ~1 ml of Gal/Raff/CM –Ura, –His, –Trp to the lawns of mated yeast on each plate. Mix the cells into the medium using a sterile applicator stick.
17. Transfer each slurry of mated cells to a 500-ml flask containing 100 ml of Gal/Raff/CM –Ura, –His, –Trp dropout medium. Incubate with shaking 6 hr at room temperature to induce the *GAL1* promoter, which drives expression of the cDNA library.
18. Centrifuge the cell suspensions 5 min at 1000 to $1500 \times g$, room temperature, to harvest the cells. Wash by resuspending in 30 ml of sterile water and centrifuging again. Resuspend each pellet in 5 ml sterile water. Measure OD₆₀₀ and, if necessary, dilute to a final concentration of $\sim 1 \times 10^8$ cells/ml.

This is a mixture consisting of haploid cells that have not mated and diploid cells. Under a microscope, the two cell types can be distinguished by size (diploids are $\sim 1.7\times$ bigger than haploids) and shape (diploids are slightly oblong and haploids are spherical). Because diploids grow faster than haploids, this mixture will contain $\sim 10\%$ to 50% diploid cells. The actual number of diploids will be determined by plating dilutions on –Ura, –His, –Trp medium, which will not support the growth of the parental haploids.

19. For each mating make a series of $1/10$ dilutions in sterile water, at least 200 μ l each, to cover a 10^6 -fold concentration range. Plate 100 μ l from each tube (undiluted, 10^{-1} , 10^{-2} , 10^{-3} , 10^{-4} , 10^{-5} , and 10^{-6} dilution) on 100-mm Gal/Raff/CM –Ura, –His, –Trp, –Leu plates. Plate 100 μ l from the 10^{-4} , 10^{-5} , and 10^{-6} tubes on 100-mm Gal/Raff/CM –Ura, –His, –Trp plates. Incubate plates at 30°C. Count the colonies on each plate after 2 to 5 days.
20. For the mating with the pretransformed library, prepare an additional 3 ml of a 10^{-1} dilution. Plate 100 μ l of the 10^{-1} dilution on each of 20 100-mm Gal/Raff/CM –Ura, –His, –Trp, –Leu plates. Also plate 100 μ l of the undiluted cells on each of 20 100-mm Gal/Raff/CM –Ura, –His, –Trp, –Leu plates. Incubate at 30°C. Pick Leu⁺ colonies after 2 to 5 days and characterize them beginning with step 17 of Basic Protocol 2.

The number of Leu⁺ colonies to pick to ensure that all of the pretransformed library has been screened depends on the transactivation potential of the bait protein itself. The transactivation potential is expressed as the number of Leu⁺ colonies that grow per cfu (Leu⁺/cfu) of the bait strain mated with the control strain, as determined in step 19 of this protocol. It can be calculated as the ratio of the number of colonies that grow on Gal/Raff/CM –Ura, –His, –Trp, –Leu to the number of colonies that grow on Gal/Raff/CM –Ura, –His, –Trp for a given dilution of the mating between the bait strain and the control strain. A bait with essentially no transactivation potential will produce less than 10^{-6} Leu⁺/cfu. For a bait to be useful in an interactor hunt it should not transactivate more than 10^{-4} Leu⁺/cfu.

To screen all of the pretransformed library, it will be necessary to pick a sufficient number of Leu^+ colonies in addition to background colonies produced by the transactivation potential of the bait itself. Thus, the minimum number of Leu^+ colonies that should be picked in step 20 of this protocol is given by:

$$(\text{transactivation potential, } Leu^+/\text{cfu}) \times (\# \text{ library transformants screened}).$$

For example, if 10^7 library transformants were obtained in step 2 (and at least 10^8 cfu of these transformants were mated with the bait strain in step 14, since only ~10% will form diploids), and the transactivation potential of the bait is 10^{-4} Leu^+ /cfu, then at least 1000 Leu^+ colonies must be picked and characterized. In other words, if the rarest interactor is present in the pretransformed library at a frequency of 10^{-7} , to find it one needs to screen through at least 10^7 diploids from a mating of the library strain. However, at least 1000 of these 10^7 diploids would be expected to be Leu^+ due to the bait background if the transactivation potential of the bait is 10^{-4} . The true positives will be distinguished from the bait background in the next step by the galactose dependence of their Leu^+ and $lacZ^+$ phenotypes.

PREPARATION OF PROTEIN EXTRACTS FOR IMMUNOBLOT ANALYSIS

To confirm that the bait fusion protein constructed in Basic Protocol 1 is synthesized properly, a crude lysate is prepared for SDS-PAGE and immunoblot analysis (UNITS 10.2 & 10.8). The presence of the target protein is detected by antibody to LexA or the fusion domain.

Materials

Master plates with pBait-containing positive and control yeast on Glu/CM –Ura, –His dropout medium (see Basic Protocol 1, step 4)

Glu/CM –Ura, –His dropout liquid medium: CM dropout plates –Ura, –His (UNIT 13.1) supplemented with 2% glucose

2× Laemmli sample buffer (see recipe)

Antibody to fusion domain or LexA: monoclonal antibody to LexA (Clontech, Invitrogen) or polyclonal antibody to LexA (available by request from R. Brent or E. Golemis)

30°C incubator

100°C water bath

Additional reagents and equipment for SDS-PAGE (UNIT 10.2) and immunoblotting and immunodetection (UNIT 10.8)

1. From the master plates, start a 5-ml culture in Glu/CM –Ura, –His liquid medium for each bait being tested and for a positive control for protein expression (i.e., RFHMI or SH17-4). Incubate overnight at 30°C.

For each construct assayed, it is a good idea to grow colonies from at least two primary transformants, as levels of bait expression are sometimes heterogenous.

2. From each overnight culture, start a fresh 5-ml culture in Glu/CM –Ura, –His at $OD_{600} = \sim 0.15$. Incubate again at 30°C.
3. When the culture has reached $OD_{600} = 0.45$ to 0.7 (~4 to 6 hr), remove 1.5 ml to a microcentrifuge tube.

For some LexA fusion proteins, levels of the protein drop off rapidly in cultures approaching stationary phase. This is due to a combination of the diminishing activity of the ADHI promoter in late growth phases and the relative instability of particular fusion domains. Thus, it is not a good idea to let cultures become saturated in the hopes of obtaining a higher yield of protein.

SUPPORT PROTOCOL 1

Analysis of Protein Interactions

20.1.27

4. Microcentrifuge cells 3 min at $13,000 \times g$, room temperature. When the pellet is visible, remove the supernatant.

Inspection of the tube should reveal a pellet ~1 to 3 μ l in volume. If the pellet is not visible, microcentrifuge another 3 min.

5. Working rapidly, add 50 μ l of $2\times$ Laemmli sample buffer to the visible pellet in the tube, vortex, and place the tube on dry ice.

Samples may be frozen at -70°C .

6. Transfer frozen sample directly to a boiling water bath or a PCR machine set to cycle at 100°C . Boil 5 min.

7. Microcentrifuge 5 sec at maximum speed to pellet large cellular debris.

8. Perform SDS-PAGE (UNIT 10.2) using 20 to 50 μ l sample per lane.

9. To detect the protein, immunoblot and analyze (UNIT 10.8) using antibody to the fusion domain or LexA.

SUPPORT PROTOCOL 2

PREPARATION OF SHEARED SALMON SPERM CARRIER DNA

This protocol generates high-quality sheared salmon sperm DNA (sssDNA) for use as carrier in transformation (Basic Protocol 2). This DNA is also suitable for other applications where high-quality carrier DNA is needed (e.g., hybridization). This protocol is based on Schiestl and Gietz (1989). For more details of phenol extraction or other DNA purification methods, consult UNIT 2.1A.

Materials

High-quality salmon sperm DNA (e.g., sodium salt from salmon testes, Sigma or Boehringer Mannheim), desiccated
TE buffer, pH 7.5 (APPENDIX 2), sterile
TE-saturated buffered phenol (UNIT 2.1A)
1:1 (v/v) buffered phenol/chloroform
Chloroform
3 M sodium acetate, pH 5.2 (APPENDIX 2)
100% and 70% ethanol, ice cold
Magnetic stirring apparatus and stir-bar, 4°C
Sonicator with probe
50-ml conical centrifuge tube
High-speed centrifuge and appropriate tube
 100°C and ice-water baths

1. Dissolve desiccated high-quality salmon sperm DNA in TE buffer, pH 7.5, at a concentration of 5 to 10 mg/ml by pipetting up and down in a 10-ml glass pipet. Place in a beaker with a stir-bar and stir overnight at 4°C to obtain a homogenous viscous solution.

It is important to use high-quality salmon sperm DNA. Sigma Type III sodium salt from salmon testes has worked well, as has a comparable grade from Boehringer Mannheim. Generally it is convenient to prepare 20- to 40-ml batches at a time.

2. Shear the DNA by sonicating briefly using a large probe inserted into the beaker.

The goal of this step is to generate sheared salmon sperm DNA (sssDNA) with an average size of 7 kb, but ranging from 2 to 15 kb. Oversonication (such that the average size is closer to 2 kb) drastically decreases the efficacy of carrier in enhancing transformation. The original version of this protocol (Schiestl and Gietz, 1989) called for two 30-sec pulses at

Table 20.1.4 Two-hybrid System Variants^a

System	DNA-binding domain	Activation domain	Selection	Reference
Two-hybrid	<i>GAL4</i>	<i>GAL4</i>	Activation of <i>lacZ</i> , <i>HIS3</i>	Chien et al., 1991
Interaction trap	<i>LexA</i>	<i>B42</i>	Activation of <i>LEU2</i> , <i>lacZ</i>	Gyuris et al., 1993
“Improved two-hybrid”	<i>GAL4</i>	<i>GAL4</i>	Activation of <i>HIS3</i> , <i>lacZ</i>	Durfee et al., 1993
Modified two-hybrid	<i>LexA</i>	VP16	Activation of <i>HIS3</i> , <i>lacZ</i>	Vojtek et al., 1993
KISS	<i>GAL4</i>	VP16	Activation of <i>CAT</i> , <i>hyg^r</i>	Fearon et al., 1992
Contingent replication	<i>GAL4</i>	VP16	Activation of T-Ag, replication of plasmids	Vasavada et al., 1991

^aAbbreviations: *CAT*, chloramphenicol transferase gene; *hyg^r*, hygromycin resistance gene; T-Ag, viral large T antigen.

three-quarter power, but optimal conditions vary between sonicators. The first time this protocol is performed, it is worthwhile to sonicate briefly, then test the size of the DNA by running out a small aliquot alongside molecular weight markers on an agarose gel containing ethidium bromide. The DNA can be sonicated further if needed.

- Once DNA of the appropriate size range has been obtained, extract the sssDNA solution with an equal volume of TE-saturated buffered phenol in a 50-ml conical tube, shaking vigorously to mix.
- Centrifuge 5 to 10 min at 3000 × g, room temperature, or until clear separation of phases is obtained. Transfer the upper phase containing the DNA to a clean tube.
- Repeat extraction using 1:1 (v/v) buffered phenol/chloroform, then chloroform alone. Transfer the DNA into a tube suitable for high-speed centrifugation.
- Precipitate the DNA by adding 1/10 vol of 3 M sodium acetate and 2.5 vol of ice-cold 100% ethanol. Mix by inversion. Centrifuge 15 min at ~12,000 × g, room temperature.
- Wash the pellet with 70% ethanol. Briefly dry either by air drying, or by covering one end of the tube with Parafilm with a few holes poked in and placing the tube under vacuum. Resuspend the DNA in sterile TE buffer at 5 to 10 mg/ml.

Do not overdry the pellet or it will be very difficult to resuspend.

- Denature the DNA by boiling 20 min in a 100°C water bath. Then immediately transfer the tube to an ice-water bath.
- Place aliquots of the DNA in microcentrifuge tubes and store frozen at –20°C. Thaw as needed.

DNA should be boiled again briefly (5 min) immediately before addition to transformations.

Before using a new batch of sssDNA in a large-scale library transformation, it is a good idea to perform a small-scale transformation using suitable plasmids to determine the transformation efficiency. Optimally, use of sssDNA prepared in the manner described will yield transformation frequencies of >10⁵ colonies/μg input plasmid DNA.

YEAST COLONY HYBRIDIZATION

This protocol is adapted from a modification of the classic protocol of Grunstein and Hogness (1975; Kaiser et al., 1994). It is primarily useful when a large number of putative interactors has been obtained, and initial minipreps and restriction digests have indicated that many of them derive from a small number of cDNAs; these cDNAs can then be used as probes to screen and eliminate identical cDNAs from the pool.

Materials

Glu/CM –Trp plates: CM dropout plates –Trp (*UNIT 13.1*) supplemental with 2% glucose

Master dropout plate of yeast positive for Gal dependence (see Basic Protocol 2, step 18)

1 M sorbitol/20 mM EDTA/50 mM DTT (prepare fresh)

1 M sorbitol/20 mM EDTA

0.5 M NaOH

0.5 M Tris·Cl (pH 7.5)/6× SSC (*APPENDIX 2*)

2× SSC (*APPENDIX 2*)

100,000 U/ml β-glucuronidase (type HP-2 crude solution from *Helix pomatia*; Sigma)

82-mm circular nylon membrane, sterile

Whatman 3MM paper

80°C vacuum oven *or* UV cross-linker

Additional reagents and equipment for bacterial filter hybridization (*UNITS 6.3 & 6.4*)

1. Place a sterile nylon membrane onto a Glu/CM –Trp dropout plate. From the master dropout plate of Gal-dependent positives, gently restreak positives to be screened onto the membrane and mark the membrane to facilitate future identification of hybridizing colonies. Grow overnight (~12 hr) at 30°C.

Growth for extended periods of time (i.e., 24 hr) may result in difficulty in obtaining good lysis. It is a good idea to streak positive and negative controls for the cDNAs to be hybridized on the membrane.

2. Remove membrane from plate. Air dry briefly. Incubate ~30 min on a sheet of Whatman 3MM paper saturated with 1 M sorbitol/20 mM EDTA/50 mM DTT.

Optionally, before commencing chemical lysis, membranes can be placed at –70°C for 5 min, then thawed at room temperature for one or more cycles to enhance cell wall breakage.

3. Cut a piece of Whatman 3MM paper to fit inside a 100-mm petri dish. Place the paper disc in the dish and saturate with 100,000 U/ml β-glucuronidase diluted 1:500 in 1 M sorbitol/20 mM EDTA (2 μl glucuronidase per ml of sorbitol/EDTA to give 200 U/ml final). Layer nylon membrane on dish, cover dish, and incubate up to 6 hr at 37°C until >80% of the cells lack a cell wall.

The extent of cell wall removal can be determined by removing a small quantity of cells from the filter to a drop of 1 M sorbitol/20 mM EDTA on a microscope slide and observing directly with a phase-contrast microscope at ≥60× magnification. Cells lacking cell wall are nonrefractile.

4. Place membrane on Whatman 3MM paper saturated with 0.5 M NaOH for ~8 to 10 min.
5. Place membrane on Whatman 3MM paper saturated with 0.5 M Tris·Cl (pH 7.5)/6× SSC for 5 min. Repeat with a second sheet of Whatman 3MM paper.

6. Place membrane on Whatman 3MM paper saturated with 2× SSC for 5 min. Then place membrane on dry Whatman paper to air dry for 10 min.
7. Bake membrane 90 min at 80°C in vacuum oven or UV cross-link.
8. Process as for bacterial filter hybridization (UNITS 6.3 & 6.4), hybridizing the membrane with probes complementary to previously isolated cDNAs.

When selecting probes, either random-primed cDNAs or oligonucleotides complementary to the cDNA sequence may be used. If the cDNA is a member of a protein family, it may be advantageous to use oligonucleotides to avoid inadvertently excluding genes related but not identical to those initially obtained.

MICROPLATE PLASMID RESCUE

In some cases, it is desirable to isolate plasmids from a large number of positive colonies (Basic Protocol 2, steps 18 and 19). The protocol described below is a batch DNA preparation protocol developed by Steve Kron (University of Chicago, Chicago, Ill.) as a scale-up of a basic method developed by Manuel Claros (Laboratoire de Génétique Moleculaire, Paris, France).

Materials

- 2× Glu/CM –Trp liquid medium: 2× CM –Trp liquid medium (UNIT 13.1) supplemented with 4% glucose
- Master plate of Gal-dependent yeast colonies (see Basic Protocol 2, step 18)
- Rescue buffer: 50 mM Tris·Cl (pH 7.5)/10 mM EDTA/0.3% (v/v) 2-mercaptoethanol (prepare fresh)
- Lysis solution: 2 to 5 mg/ml Zymolyase 100T/rescue buffer *or* 100,000 U/ml β-glucuronidase (type HP-2 crude solution from *Helix pomatia*; Sigma) diluted 1:50 in rescue buffer
- 10% (w/v) SDS
- 7.5 M ammonium acetate (APPENDIX 2)
- Isopropanol
- 70% ethanol
- TE buffer, pH 8.0 (APPENDIX 2)
- 24-well microtiter plates
- Centrifuge with microplate holders, refrigerated
- Repeating micropipettor
- 37°C rotary shaker

Grow yeast cultures

1. Aliquot 2 ml of 2× Glu/CM –Trp medium into each well of a 24-well microtiter plate. Into each well, pick a putative positive colony. Grow overnight with shaking at 30°C.

The 2× minimal medium is used to maximize the yield of yeast. Four plates can generally be handled conveniently at once, based on the number that can be centrifuged simultaneously.

2. Centrifuge 5 min at 1500 × g, 4°C. Shake off supernatant with a snap and return the plate to upright.
3. Swirl or lightly vortex the plate to resuspend cell pellets in remaining liquid. Add 1 ml water to each well and swirl lightly.

Cell pellets can most easily be resuspended in residual liquid before adding new solutions. Addition of liquid can be accomplished using a repeating pipettor.

SUPPORT PROTOCOL 4

Analysis of Protein Interactions

20.1.31

4. Centrifuge 5 min at $1500 \times g$, 4°C . Shake off supernatant and resuspend pellet. Add 1 ml rescue buffer.
5. Centrifuge 5 min at $1500 \times g$, 4°C . Shake off supernatant and resuspend pellet in the small volume of liquid remaining in the plate.

Lyse cells

6. To each well, add 25 μl lysis solution. Swirl or vortex to mix. Incubate (with cover on) on a rotary shaker ~ 1 hr at 37°C .

Lysis solution need not be completely dissolved before use. By 1 hr, lysis should be obvious as coagulation of yeast into a white precipitate.

Susceptibility of yeast strains to lytic enzymes varies. If lysis occurs rapidly, then less lytic enzyme should be used. If the lysis step is allowed to go too far, too much of the partially dissolved cell wall may contaminate the final material. Lysis can be judged by examining cells with a phase-contrast microscope. Living cells are white with a dark halo and dead cells are uniformly gray. Lysis leads to release of granular cell contents into the medium. Once cells are mostly gray and many are disrupted, much of the plasmid should have been released.

7. To each well, add 25 μl of 10% SDS. Mix gently by swirling to completely disperse the precipitates. Allow plates to sit 1 min at room temperature.

At this point, the wells should contain a clear, somewhat viscous solution.

Purify plasmid

8. To each well, add 100 μl of 7.5 M ammonium acetate. Swirl gently, then incubate 15 min at -70°C or -20°C until frozen.

*Addition of acetate should result in the formation of a massive white precipitate of cell debris and SDS. The freezing step appears to improve removal of inhibitors of *E. coli* transformation.*

9. Remove plate from freezer. Once it begins to thaw, centrifuge 15 min at $3000 \times g$, 4°C . Transfer 100 to 150 μl of the resulting clear supernatants to clean 24-well plates.

In general, some contamination of the supernatant with pelleted material cannot be avoided. However, it is better to sacrifice yield in order to maintain purity.

10. To each well, add ~ 0.7 vol isopropanol. Mix by swirling and allow to precipitate 2 min at room temperature.

A cloudy fine precipitate should form immediately after isopropanol is added.

11. Centrifuge 15 min at $3000 \times g$, 4°C . Shake off supernatant with a snap.
12. To each well, add ~ 1 ml cold 70% ethanol. Mix by swirling, centrifuge 5 min at $3000 \times g$, 4°C . Shake off supernatant with a snap, invert plates and blot well onto paper towel. Allow plates to air dry.
13. To each well, add 100 μl TE buffer. Swirl well and allow to rest on bench several minutes, until the pellets appear fully dissolved. Transfer preps to microcentrifuge tubes or 96-well plates for storage at -20°C .

*One to five microliters of each of the resulting preparations can be used to transform competent *E. coli*: for KC8, electroporation should be used (see Basic Protocol 2, step 21). Sometimes, the yield of transformants is low if *E. coli* carrying plasmids are not permitted time to increase the plasmid copy number above a critical threshold before the cells are placed on selective medium. Allow plenty of time for cells to express antibiotic resistance or the TRP1 gene before plating.*

If insufficient numbers of colonies are obtained by this approach, the final plasmid preparation can be resuspended in 20 μl instead of 100 μl TE buffer to concentrate the DNA stock.

ADDITIONAL SPECIFICITY SCREENING

The three test plasmids outlined (pSH18-34, pRFHM1, and pEG202; see Basic Protocol 2, step 24) represent a minimal test series. If other LexA-bait proteins that are related to the bait protein used in the initial library screen are available, substantial amounts of information can be gathered by additional specificity tests. For example, if the initial bait protein was LexA fused to the leucine zipper of c-Fos, specificity screening of interactor-hunt positives against the leucine zippers of c-Jun or GCN4 in addition to that of c-Fos might allow discrimination between proteins that are specific for fos versus those that generically associate with leucine zippers.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Glycerol solution

- 65% (v/v) glycerol, sterile
- 0.1 M MgSO₄
- 25 mM Tris·Cl, pH 8.0 (APPENDIX 2)
- Store up to 1 year at room temperature

Laemmli sample buffer, 2×

- 10% (v/v) 2-mercaptoethanol (2-ME)
- 6% (w/v) SDS
- 20% (v/v) glycerol
- 0.2 mg/ml bromphenol blue
- 0.025× Laemmli stacking buffer (see recipe; optional)
- Store up to 2 months at room temperature

This reagent can conveniently be prepared 10 ml at a time.

Laemmli stacking buffer, 2.5×

- 0.3 M Tris·Cl, pH 6.8
- 0.25% (w/v) SDS
- Store up to 1 month at 4°C

Lysis solution

- 50 mM Tris·Cl, pH 7.5 (APPENDIX 2)
- 10 mM EDTA
- 0.3% (v/v) 2-mercaptoethanol (2-ME), added just before use
- 2% (v/v) β-glucuronidase from *Helix pomatia* (Type HP-2; Sigma), added just before use

COMMENTARY

Background Information

Interaction-based cloning is derived from three experimental observations. In the first, Brent and Ptashne (1985) demonstrated that it was possible to assemble a novel, functional transcriptional activator by fusing the DNA-binding domain from one protein, LexA, to the activation domain from a second protein, GAL4. This allowed the use of a single reporter system containing a single DNA-binding motif, the LexA operator, to study transcriptional ac-

tivation by any protein of interest. In the second, Ma and Ptashne (1988) built on this work to demonstrate that the activation domain could be brought to DNA by interaction with a DNA-binding domain. In the third, Fields and Song (1989), working independently of Ma and Ptashne, used two yeast proteins, SNF1 and SNF4, to make an SNF1 fusion to the DNA-binding domain of GAL4 and an SNF4 fusion to the GAL4 activation domain. They demonstrated that the strength of the SNF1-SNF4

interaction was sufficient to allow activation through a GAL4 DNA-binding site. From this, they suggested the feasibility of selecting interacting proteins by performing screens of cDNA libraries made so that library-encoded proteins carried activating domains.

Several groups have developed cDNA library strategies along these lines, with some systems using LexA and others using GAL4 as the DNA-binding domain (Table 20.1.4). LexA and GAL4 each have different properties that should be considered when selecting a system. LexA is derived from a heterologous organism, has no known effect on the growth of yeast, possesses no residual transcriptional activity, can be used in GAL4⁺ yeast, and can be used with a Gal-inducible promoter. Because GAL4 is an important yeast transcriptional activator, it has the disadvantage that experiments must be performed in gal4⁻ yeast strains to avoid background due to activation of the reporter system by endogenous GAL4. Such gal4⁻ strains are frequently less healthy and more difficult to transform than wild-type strains, and either libraries must be constitutively expressed or alternate inducible systems must be used. By contrast, the GAL4 DNA-binding domain may be more efficiently localized to the nucleus and may be preferred for some proteins (for a review of GAL4-based systems, see Bartel et al., 1993). Whichever system is used, it is important to remember that the bait protein constitutes a novel fusion protein whose properties may not exactly parallel those of the original unfused protein of interest. Although systems using the two-hybrid paradigm have been developed in mammalian cells (see Table 20.1.4), these have not been used effectively in library screens. It seems likely that the organism of choice for two-hybrid identification of novel partner proteins will remain yeast.

cDNAs that pass specificity tests are referred to as positives, or “true positives.” In interactor hunts conducted to date, anywhere from zero to practically all isolated plasmids passed the final specificity test. If no positives are obtained, the tissue source for the library originally used may not be appropriate, and a different library may produce better results. However, there are some proteins for which no positives are found. Various explanations for this are provided below. Conversely, some library-encoded proteins are known to be isolated repeatedly using a series of unrelated baits, and these proteins demonstrate at least some specificity. One of these, heat shock protein 70, might be explained by positing that it

assists the folding of some LexA-fused bait proteins, or alternatively, that these bait proteins are not normally folded. This example illustrates the point that the physiological relevance of even quite specific interactions may sometimes be obscure.

Because the screen involves plating multiple cells to Gal/CM –Ura, –His, –Trp, –Leu drop-out medium for each primary transformant obtained, multiple reisolates of true positive cDNAs are frequently obtained. If a large number of specific positives are obtained, it is generally a good idea to attempt to sort them into classes—for example, digesting minipreps of positives with *EcoRI*, *XhoI*, and *HaeIII* will generate a fingerprint of sufficient resolution to determine whether multiple reisolates of a small number of clones or single isolates of many different clones have been obtained. The former situation is a good indication that the system is working well.

An important issue that arises in an interactor hunt is the question of how biologically relevant interacting proteins that are isolated are likely to be. This leads directly to the question of what K_d of association two molecules must have to be detected by an interactor hunt. In fact, this is not at all a simple issue. For the system described here, most fusion proteins appear to be expressed at levels ranging from 50 nM to 1 μ M (Golemis and Brent, 1992). Given the strength of the *GAL* promoter, it is likely that many library-encoded proteins are expressed at similarly high levels, $\geq 1 \mu$ M in the nucleus (Golemis and Brent, 1992). At this concentration, which is in considerable excess over the nuclear concentration of operator-bound bait protein, a cDNA library-encoded protein should half-maximally occupy the DNA-bound bait protein if it possesses a K_d of 10^{-6} M, making it theoretically possible that very-low-affinity interactions could be detected. Such interactions have been observed in some cases. In contrast, some interactions that have been previously established using other methods and are predicted by known K_d to be easily detected by these means, either are not detected or are detected only weakly (Finley and Brent, 1994; Estojak et al., 1995). Because of the conservation of many proteins between lower and higher eukaryotes, one explanation for this observation is that either one or both of the partners being tested is being sequestered from the desired interaction by fortuitous association with an endogenous yeast protein. A reasonably complete investigation of the degree of correlation between in vitro determina-

tions of interaction affinity and apparent strength of interaction in the interaction trap is included in Estojak et al. (1995). The result of this investigation suggests it is important to measure the affinity of detected interactions under different conditions, using a second assay system, rather than to draw conclusions about affinity based on detection in the interaction trap.

A number of different plasmids can be used for conducting an interactor hunt. Their properties are summarized in Tables 20.1.1 and 20.1.2. Because of the generous and open scientific exchange between investigators using the system, the number of available plasmids and other components has greatly expanded since the appearance of the initial two-hybrid reagents, facilitating the study of proteins inaccessible by the original system.

The original parent plasmid for generating LexA fusions, pEG202 is a derivative of 202 + PL (Ruden et al., 1991; see Fig. 20.1.3) that contains an expanded polylinker region. The available cloning sites in pEG202 include *EcoRI*, *BamHI*, *SalI*, *NcoI*, *NotI*, and *XhoI*, with the reading frame as described in the legend to Figure 20.1.3. Since the original presentation of this system, a number of groups have developed variants of this plasmid that address specialized research needs. Those currently available, as well as purposes for which they are suited, are listed in Table 20.1.1. pGilda, created by David A. Shaywitz, places the LexA-fusion cassette under the control of the inducible *GAL1* promoter, allowing expression of the bait protein for limited times during library screening, reducing the exposure of yeast to toxic baits. pJK202, created by Joanne Kamens, adds nuclear localization sequences to pEG202, facilitating assay of the function of proteins lacking internal nuclear localization sequences. pNLexA, created by Ian York, places LexA carboxy-terminal in the fusion domain, allowing assay of interactions that require an unblocked amino-terminus on the bait protein. pEE202I, created by Mike Watson and Rich Buckholz, allows chromosomal integration of a pEG202-like bait, thus reducing expression levels so they are more physiological for bait proteins normally present at low levels intracellularly. All of these have been extensively tested by numerous researchers. pGilda, pJK202, and pEE202I work with complete reliability. pNLexA works effectively with ~50% of the fusion domains tried, but synthesizes only very low levels of protein (relative to expression of the same fusion domain as a

pEG202 fusion) with the remaining 50%. Attachment of fusion domains amino-terminal either to *LexA* or *GAL4* has been generally problematic in the hands of many investigators; it may be that appending additional protein sequences to the amino termini of these proteins is destabilizing, although the problem has not been rigorously investigated.

A series of *lacZ* reporters of differing sensitivity to transcriptional activation can be used to detect interactions of varying affinity (see Table 20.1.2). These plasmids are *LexA* operator-containing derivatives of the plasmid LR1Δ1 (West et al., 1984). In LR1Δ1, a minimal *GAL1* promoter lacking the *GAL1* upstream activating sequences (*GAL_{UAS}*) is located upstream of the bacterial *lacZ* gene. In pSH18-34, eight *LexA* operators have been cloned into an *XhoI* site located 167 bp upstream of the *lacZ* gene (S. Hanes, unpub. observ.). pJK103 and pRB1840 contain two and one operator, respectively.

pJK101 is similar to pSH18-34, except that it contains the *GAL1* upstream activating sequences (*GAL_{UAS}*) upstream of two *LexA* operator sites. A derivative of del20B (West et al., 1984), it is used in the repression assay (Brent and Ptashne, 1984; see Fig. 20.1.5) to assess LexA fusion binding to operator.

pSH17-4 is a *HIS3* 2μm plasmid that encodes LexA fused to the activation domain of the yeast activator GAL4. EGY48 cells bearing this plasmid will produce colonies in overnight growth on medium lacking Leu, and yeast that additionally contain pSH18-34 will turn deep blue on plates containing Xgal. This plasmid serves as a positive control for the activation of transcription.

pRFHM1 is a *HIS3* 2μm plasmid that encodes LexA fused to the N-terminus of the *Drosophila* protein bicoid. The plasmid has no ability to activate transcription, so EGY48 cells that contain pRFHM1 and pSH18-34 do not grow on -Leu medium and remain white on plates containing Xgal. pRFHM1 is a good control for specificity testing, because it has been demonstrated to be sticky—that is, to associate with a number of library-encoded proteins that are clearly nonphysiological interactors (R. Finley, Wayne State University, Detroit, Mich., unpub. observ.).

This protocol uses interaction libraries (Table 20.1.3) made in pJG4-5 or its derivatives (see Fig. 20.1.6). pJG4-5 was developed to facilitate isolation and characterization of novel proteins in interactor hunts (Gyuris et al., 1993). The pJG4-5 cDNA library expression

cassette is under control of the *GAL1* promoter, so library proteins are expressed in the presence of galactose (Gal) but not glucose (Glu). This conditional expression has a number of advantages, the most important of which is that many false-positives obtained in screens can be easily eliminated because they do not demonstrate a Gal-dependent phenotype. The expression cassette consists of an ATG to start translation, a nuclear localization signal to extend the interaction trap's range to include proteins that are normally predominantly localized in the cytoplasm, an activation domain (acid blob; Ma and Ptashne, 1987), the hemagglutinin epitope tag to permit rapid assessment of the size of encoded proteins, *EcoRI-XhoI* sites designed to receive directionally synthesized cDNAs, and the alcohol dehydrogenase (*ADH*) termination sequences to enhance the production of high levels of library protein. The plasmid also contains the *TRP1* auxotrophy marker and 2 μ m origin for propagation in yeast. A derivative plasmid, pJG4-5I, was created by Mike Watson and Richard Buckholz to facilitate chromosomal integration of the activation domain fusion expression plasmid.

A series of recently developed derivatives of pEG202, pJG4-5, and *lacZ* reporter plasmids (MW101 to MW112) alter the antibiotic resistance markers on these plasmids from ampicillin (Ap^r) to either kanamycin (Km^r) or chloramphenicol (Cm^r ; Watson et al., 1996). Judiciously mixing and matching these plasmids in conjunction with Ap^r libraries would considerably reduce work subsequent to library screening, because the KC8 transformation, which involves *trpC* complementation in bacteria, could be omitted.

EGY48 and EGY191 (see Table 20.1.2) are both derivatives of the strain U457 (a gift of Rodney Rothstein, Columbia University, New York, N.Y.) in which the endogenous *LEU2* gene has been replaced by homologous recombination with *LEU2* reporters carrying varying numbers of *LexA* operators, using a procedure detailed in Estojak et al. (1995).

Interaction Trap-compatible reagents have recently become commercially available; Clontech and Invitrogen were the first to market such reagents and have recently been joined by OriGene. All suppliers use systems with the most sensitive reporters (EGY48 and pSH18-34), and provide their own positive and negative controls for testing activation or interaction between defined proteins. For expression of bait and library proteins, the Clontech Matchmaker LexA two-hybrid system and the

OriGene Duplex-A system use some of the basic set of plasmids described here (see Table 20.1.1 for availability). Forward sequencing primers for bait and library plasmids are included in the Clontech kit, and Insert Screening Amplimer Sets for both plasmids can be acquired separately. Additional related products from Clontech include KC8 competent cells, anti-LexA monoclonal antibodies, a yeast transformation system, a yeast plasmid isolation kit, and an EGY48 partner strain for yeast mating to facilitate the analysis of interaction specificity. OriGene has a generally similar product line to Clontech. In contrast, Invitrogen has substantially modified the Interaction Trap core reagents to develop its own bait and library plasmids. pHybLex/Zeo, a novel bait plasmid, is ~50% smaller than the original pEG202 (making it easier to clone into), and it has an enriched polylinker. Significantly, it replaces both the *Ap^r* and *HIS3* genes with a novel gene that confers resistance to the antibiotic Zeocin (supplied with the kit), which provides selection in both bacteria and yeast. This elimination of auxotrophic selection for the bait plasmid renders the LexA-fusion construct usable with libraries and strains from all existing two-hybrid systems and additionally facilitates the direct selection of library plasmid in strains other than KC8. Some changes, which are designed to make the vector easier to use, have also been introduced in the library vector pYESTrp (e.g., it uses a V5 epitope tag for protein detection). The Invitrogen kit, termed Hybrid Hunter, includes the bait/library/reporter plasmids and EGY48 yeast strain as noted, and additionally includes primer sets for bait and library plasmids and the L40 yeast strain, should an investigator wish to use a *HIS3* auxotrophy selection. Additional related products from Invitrogen include antibodies for detection of bait and prey fusion proteins (anti-LexA and anti-V5), pJG4-5 library vector primers, and a Transformation Kit.

A significant advantage of the entry of commercial entities into the Interaction Trap field is the rapid increase in the number of compatible cDNA libraries. A list of currently available premade libraries available from these companies is presented in Table 20.1.3, and custom-made libraries are also available upon request. Because new libraries and other related reagents are being constantly added to the line of two-hybrid related products, it is advisable to contact the companies or visit their Web sites (www.clontech.com, www.invitrogen.com, and www.origene.com) for the latest information.

Finally, over the last several years, a number of groups have adapted basic two-hybrid strategies to more specialized applications, and they have devised strategies to broaden their basic functionality. Interaction Mating (Finley and Brent, 1994) has been used to establish extended networks of targeted protein-protein interaction. In this approach, a panel of LexA-fused proteins are transformed into a *MAT α* haploid selective strain (such as RFY206), a panel of activation-domain fused proteins are transformed into a suitable *MAT α* haploid (such as EG448), and the two panels are cross-gridded against each other for mating. Selected diploids are then screened by replica plating to selective medium. This approach complements library screening in large-scale applications, such as proposed definition of interaction maps for entire genomes (Bartel et al., 1996).

Interaction mating has also provided the basis for an alternative two-hybrid hunt protocol (see Alternate Protocol 2), useful in cases when a single library will be screened with different baits. In this approach (Bendixen et al., 1994; Finley and Brent, 1994; Kolonin and Finley, 1998), a library is introduced into a single strain, like EGY48, and aliquots are stored frozen. To conduct a hunt, an aliquot is thawed and mated with a strain expressing a bait. This allows one to avoid repeated high-efficiency transformations, since a single library transformation can provide enough pretransformed yeast to conduct dozens of interactor hunts. Moreover, some yeast strains pretransformed with libraries are becoming commercially available, which may eliminate altogether the need to conduct a high-efficiency library transformation for some researchers.

Two-hybrid approaches have been shown to be effective in identifying small peptides with biological activities on selected baits (Yang et al., 1995; Colas et al., 1996), which may prove to be useful as a guide to targeted drug design. Rapid screening protocols have been devised using custom-synthesized libraries expressing sheared plasmid DNA to facilitate rapid mapping of interaction interfaces (Stagljar et al., 1996). Osborne and coworkers have demonstrated the effectiveness of a tribrid (or tri-hybrid) approach, in which an additional plasmid expresses a tyrosine kinase to specifically modify a bait protein, allowing detection of SH2-domain-containing partner proteins that recognize specific phosphotyrosine residues (Osborne et al., 1995). A variety of more elaborate tribrid approaches, in which a DNA-binding domain fused protein is used to present an

intermediate nonprotein compound for interaction with a library, have been developed and proven effective. These approaches have allowed the identification of proteins binding specific drug ligands (Chiu et al., 1994; Licitra and Liu, 1996), as well as the identification of proteins binding to RNA sequences (SenGupta et al., 1996; Wang et al., 1996). It is expected that the range of utility of these systems will continue to expand.

Critical Parameters and Troubleshooting

To maximize chances of a successful interactor hunt, a number of parameters should be taken into account. Before attempting a screen, bait proteins should be carefully tested to ensure that they have little or no intrinsic ability to activate transcription. Bait proteins must be expressed at reasonably high levels and must be able to enter the yeast nucleus and bind DNA (as confirmed by the repression assay). Optimally, integrity and levels of bait proteins should be confirmed by immunoblot analysis, using an antibody to either LexA or the fused domain. In particular, at this time, bait proteins that have extensive transmembrane domains or are normally excluded from the nucleus are not likely to be productively used in a library screen. Proteins that are moderate to strong activators will need to be truncated to remove activating domains before they can be used.

If a protein neither activates nor represses, the most likely reason is that it is not being made. This can be determined by immunoblot analysis of a crude lysate protein extract of EGY48 (*UNIT 10.8*; Samson et al., 1989) containing the plasmid, using anti-LexA antibodies as primary antiserum. If the full protein is not made, it may be possible to express truncated derivatives of the protein. If the protein is made, but still does not repress, it may not enter the yeast nucleus effectively, although this appears to be a relatively rare problem. In this case, introducing the coding sequence for the fused moiety into a LexA fusion vector containing a nuclear localization motif (e.g., pJK202; J. Kamens, BASF, Worcester, Mass., unpub. observ.) may solve the problem.

The test for the leucine (Leu) requirement is extremely important to determine whether the bait protein is likely to yield an unworkably high background. The *LEU2* reporter in EGY48 is more sensitive than the pSH18-34 reporter for some baits (Estojak et al., 1995). Therefore, it is possible that a bait protein demonstrating little or no signal in a β -galac-

tosidase assay may nevertheless permit some growth on –Leu medium. If this occurs, there are several options. First, a less sensitive strain can be used, as described in the text. Second, background can sometimes be reduced further by making the EGY strain diploid (e.g., D. Krainc, Harvard Medical School, Boston, Mass.; R. Finley and R. Brent, unpub. observ.) or by performing the hunt by interaction mating as described in Alternate Protocol 2. A third option is to attempt to truncate the bait protein to remove activating function. In general, it is useful to extrapolate from the number of cells that grow on –Leu medium to the number that would be obtained in an actual library screen, and determine if this is a background level that can be tolerated. For example, if two colonies arise from 100,000 plated cells on –Leu medium, 200 to 400 would be expected in an actual screen of 10^6 cDNAs. Although this is a high initial number of positives, the vast majority should be eliminated immediately through easily performed controls. This is a judgment call. Finally, very rarely it happens that a bait that appears to be well behaved and negative for transcriptional activation through all characterization steps will suddenly develop a very high background of transcriptional activation following library transformation. The reason for this is currently obscure, and no means of addressing this problem has as yet been found: such baits are hence inappropriate for use in screens.

The protocols described in this unit use initial screening with the most sensitive reporters followed by substitution with less sensitive reporters if activation is detected. An obvious question is, why not start out working with extremely stringent reporters and know immediately whether the system is workable? In fact, some researchers routinely use a combination of pJK103 or pRB1840 with EGY191, and obtain proteins that to date appear to be biologically relevant partners from library screens. However, extensive comparison studies using interactors of defined *in vitro* affinity with different combinations of *LacZ* and *LEU2* reporters (Estojak et al., 1995) have indicated that although the most sensitive reporters (pSH18-34) may in some cases be prone to background problems, the most stringent reporters (EGY191, pRB1840) may miss some interactions that certainly are biologically relevant and occur inside cells. In the end, the choice of reporters devolves to the preference of individual investigators: the bias of the authors is to cast a broad net in the early stages of a screen,

and hence to use more sensitive reporters when practicable.

It is important to move expeditiously through characterization steps and to handle yeast transformed with bait plasmids with care. In cases where yeasts have been maintained on plates for extended periods (e.g., 4 days at room temperature or >2 to 3 weeks at 4°C), unexpected problems may crop up in subsequent library screens.

The transformation protocol is a version of the lithium acetate transformation protocol described by Schiestl and Gietz (1989) and Gietz et al. (1992; see UNIT 13.7) that maximizes transformation efficiency in *Saccharomyces cerevisiae* and produces up to 10^5 colonies/ μ g plasmid DNA. In contrast to *Escherichia coli*, the maximum efficiency of transformation for *S. cerevisiae* is $\sim 10^4$ to 10^5 / μ g input DNA. It is extremely important to optimize transformation conditions before attempting an interactor hunt. Perform small-scale pilot transformations to ensure this efficiency is attained and to avoid having to use prohibitive quantities of library DNA. In addition, as for any effort of this type, it is a good idea to obtain or construct a library from a tissue source in which the bait protein is known to be biologically relevant.

In practice, the majority of proteins isolated by interaction with a LexA fusion turn out to be specific for the fused domain; a smaller number are nonspecifically sticky, and to date there appears to have been only one isolation from a eukaryotic library of a protein specific for LexA. However, it is generally informative to retest positive clones on more than one LexA bait protein; ideally, library-derived clones should be tested against the LexA fusion used for their isolation, several LexA fusions to proteins that are clearly unrelated to the original fusion, and if possible, several LexA fusions that there is reason to believe are related to the initial protein (e.g., if the initial probe was LexA-Fos, a good related set would include LexA-Jun and LexA-GCN4).

Colony selection for master plate production is one of the more variable parts of the procedure. For strong interactors, colonies will grow up in 2 days. However, if plates are left at 30°C, new colonies will continue to appear every day. Those that appear rapidly are most likely to reflect interactors that are biologically relevant to the bait protein. Those that appear later may or may not be relevant. However, many parameters can delay the time of colony formation of cells that contain valid interactions, including the strength of the interaction

and the level of expression of the library-encoded protein.

Anticipated Results

Depending on the protein used as bait, anywhere from zero to hundreds of specific interactors will be obtained from 10⁶ primary transformants.

Time Considerations

If all goes well, once the required constructions have been made it will take ~1 week to perform yeast transformations, obtain colonies, and determine whether bait proteins are appropriate. It will take a second week to perform library transformations, replat to selective medium, and obtain putative positives. A third week will be required to rescue the plasmid from the yeast, passage it through *E. coli*, transform fresh yeast, and confirm specificity.

Affinity Purification of Proteins Binding to GST Fusion Proteins

This unit describes the use of proteins fused to glutathione-*S*-transferase (GST fusion proteins) to affinity purify other proteins, a technique also known as GST pulldown purification. The GST fusion protein is first purified on glutathione-agarose beads as described in UNIT 16.7. The bead-bound fusion protein is then used as “bait” to test for binding to a known or suspected “test” protein which may be either purified or labeled by *in vitro* translation (UNIT 10.17). Beads with bound protein are washed, and the amount of test protein retained is determined by elution with glutathione or salt or simply by applying the beads and bound proteins to an SDS-polyacrylamide gel (UNIT 10.2; Fig. 20.2.1). The bead-bound fusion protein can also be incubated with a complex mixture of proteins. If performed on a large scale, this technique can be used to purify known or unknown proteins that interact directly or indirectly with the bait protein (Fig. 20.2.2). When a method (e.g., antibody binding) exists for detecting a particular protein, it is possible to determine if a test protein is retained from a complex mixture of proteins such as a crude cellular lysate. This GST pulldown technique can complement other methods for assessing protein-protein interactions—in *in vitro* assays such as electrophoretic mobility shift assays (EMSA; see UNIT 12.2) or coimmunoprecipitation (see UNIT 10.16), or *in vivo* assays such as the two-hybrid interaction trap (UNIT 20.1) or ubiquitin-based split-protein sensor (Johnsson and Varshavsky, 1994). The GST pulldown affinity technique is simple to perform and quite powerful. However, it is prone to artifacts due to mass-action effects, and some care should be used in interpreting positive results.

The Basic Protocol describes a strategy that can be used to isolate proteins that display affinity for (bind to) proteins fused to GST. GST fusion protein bound to agarose affinity beads is used to assay the binding of a specific test protein that has been labeled with [³⁵S]methionine by *in vitro* translation (UNIT 10.17). However, this method can be adapted for use with other types of fusion proteins—for example, His₆ (UNIT 10.11B), biotin tags, or maltose-binding protein fusions (MBP; UNIT 16.6), and these may offer particular advantages. A Support Protocol describes preparation of an *Escherichia coli* extract that is added to the reaction mixture with purified test protein to reduce nonspecific binding.

STRATEGIC PLANNING

There are three choices to be made in planning a GST fusion protein affinity purification: the selection and design of the affinity fusion to the bait protein, the assay used to detect the test protein(s), and the controls used to check for specificity.

A GST fusion protein serves well for most applications; the features of this fusion and the methods involved are described in UNIT 16.7. If either glutathione-*S*-transferase or the agarose matrix retains an interfering contaminating protein, changing either the affinity moiety (e.g., nickel, maltose, or streptavidin) or the matrix (e.g., Streptavidin Dynabeads, Dynal) may avoid the problem. If the purpose of the experiment is to determine if the bait and test proteins multimerize, it may be better to use monomeric MBP or His₆ to construct the fusion protein because GST is known to form dimers. Each system has its own advantages and disadvantages. One advantage of GST or MBP fusions is that they can increase the solubility of certain insoluble or semi-soluble proteins. A second advantage is that peptides are more readily fused to a protein (GST, MBP) than to His₆. A third advantage is the low background compared to His₆/Ni agarose. One disadvantage, however, is that the capacity of glutathione agarose beads for GST fusion proteins falls steeply with increasing size of the fusion.

Figure 20.2.1 Schematic representation of GST pull-down purification of proteins.

The two methods commonly used to detect binding of the test protein are immunoblotting with a protein-specific antibody (UNIT 10.8) or measuring bound radioactivity of an in vitro–translated test protein (UNIT 10.17) that has been labeled with [³⁵S]methionine. Radioactive detection is preferable because it is possible to accurately quantitate the protein by phosphorimaging or scanning densitometry, and confers greater sensitivity of detection. Furthermore, after labeled proteins are separated on SDS-PAGE analytical gels, the gels can be fixed, stained for protein, and scanned as a control for loss of beads and bait protein during washing steps. With immunoblotting, accurate quantitation of the signal on a sheet of film (for chemiluminescent detection) or membrane (for the insoluble dye method) is difficult. In addition, the relatively large amount of GST fusion protein bait may exhibit nonspecific cross-reactivity with the antibodies employed, making detection difficult if the GST-bait and test proteins are similar in size. This problem can be circumvented by constructing a GST fusion protein having a protease site at the junction between GST and the bait protein sequence (see UNIT 16.4B). After binding and washing, the bait protein and any bound test protein can be released from the beads by treatment with the appropriate protease. Should nonspecific binding of the test protein to the agarose beads be a problem, protease or glutathione can be employed to elute only that portion of the test protein that is specifically bound to the bait protein or to glutathione, as opposed to the matrix.

A third method to detect binding of the target protein to the bait protein is an activity assay of the washed beads after the binding reaction. When employing an activity assay, however, it may be advantageous to elute the bait/target protein complex first. This will allow the protein to be assayed in a soluble form in the buffer of choice.

Glutathione-agarose beads with bound GST alone are often used as a negative control for nonspecific retention. Two better controls, however, are competition with a large excess of cold target protein or use of a variant of the bait protein which is known not to bind the test protein in vivo (Fig. 20.2.3). When using His₆ or biotin tags on the bait protein, a negative control with an unrelated protein may be used, but, again, it is best to use a nonbinding variant of the bait protein. It should be noted, however, that a number of naturally biotinylated proteins occur in cells—one in *E. coli* (Agarana et al., 1986), four or five in *Saccharomyces cerevisiae*, depending on growth conditions (Lim et al., 1987), and four in mammalian cells (Chandler and Ballard, 1988) and in plants (Nikolau et al., 1985). These may cause high background by binding to streptavidin beads used to immobilize biotinylated bait protein and give nonspecific bands.

GST FUSION PROTEIN–AFFINITY PURIFICATION

Bait protein fused to GST and bound to glutathione-agarose beads is incubated with radiolabeled test protein in the presence of an *Escherichia coli* protein extract. The beads and associated protein complexes are removed from the incubation mixture, washed, eluted in loading buffer, and analyzed on an SDS-PAGE gel. The resulting gel is quantitated using scanning densitometry or phosphorimaging.

Materials

- E. coli* extract in bead binding buffer (see Support Protocol)
- Test protein labeled with [³⁵S]methionine (UNIT 10.17)
- 100 to 250 μg/ml GST and GST fusion protein bound to agarose beads (UNIT 16.7), freshly prepared
- 1× SDS sample buffer (UNIT 10.2)
- Gel fixative: 10% (v/v) glacial acetic acid/45% (v/v) methanol
- Centrifuge and Beckman TLA-100 rotor or equivalent

BASIC PROTOCOL

Analysis of Protein Interactions

20.2.3

Microcentrifuge, 4°C
X-ray film *or* Storage Phosphor screen (Molecular Dynamics)
Scanning densitometer *or* phosphorimager

Additional reagents and equipment for SDS-PAGE (UNIT 10.2), Coomassie blue staining (UNIT 10.6; optional), and autoradiography (APPENDIX 3)

Prepare the extract

1. Thaw soluble *E. coli* protein extract on ice.
2. For each reaction, centrifuge 500 µl thawed extract 30 min at $175,000 \times g$ (70,000 rpm in a Beckman TLA-100 rotor), 4°C

Centrifugation removes any insoluble protein aggregates that form during storage or thawing.

3. Remove the supernatant (≥ 400 µl). Transfer 200 µl supernatant into each of two tubes, and store on ice.

Prepare test protein

4. Add 1 to 5 µl [³⁵S]methionine-labeled test protein to one tube containing 200 µl of the supernatant from step 3. Incubate 15 min on ice.

The specific activity of the [³⁵S]methionine-labeled test protein should be high enough to permit detection within a reasonable amount of time.

5. Microcentrifuge 15 min at maximum speed, 4°C.

This step removes insoluble protein aggregates from the in vitro translation mix.

6. Transfer 200 µl of the supernatant (containing labeled test protein + extract) to a clean microcentrifuge tube.

Prepare the bait protein

7. Add 20 µl GST or GST fusion protein (bait) bound to agarose beads to the other tube containing 200 µl of supernatant from the *E. coli* extract (step 3) and mix thoroughly.

From 2 to 5 µg GST bait protein is required for each reaction. It is best to include ~20 µl beads in each reaction so the bead pellet will be visible during the washes. However, if 20 µl of beads would add more than 2 to 5 µg protein, add unbound glutathione beads to provide the necessary volume. It may be necessary to minimize the amount of bait protein to decrease nonspecific interactions.

Glutathione beads bound with GST alone may be stored a number of months in PBS at 4°C, but fusion proteins are likely to be less stable and preparations should be checked for degradation before use. Excessive degradation will alter the concentration of the bait protein (see Critical Parameters), and released protein fragments may bind test protein and may not be retained on the glutathione beads during the washes, thus interfering with subsequent analysis. Although such degradation usually results in complete loss of the bait component of the fusion protein, partial degradation may leave N-terminal fragments that may or may not bind test protein. SDS-PAGE can be used to check for degradation. Proteolysis may be limited by including protease inhibitors (UNIT 10.11B) in all buffers. Unless a specific GST fusion protein is known to be stable, the binding assay should use freshly prepared beads bound with purified full-length fusion protein. Stored beads should be washed to remove any degradation products.

Perform binding assay

8. Add 200 µl well-mixed bead + extract suspension (step 7) to the tube containing test protein + extract (step 6). Incubate 1 to 2 hr at 4°C with gentle mixing.

9. Microcentrifuge the reaction 1 min at maximum speed, 4°C, to pellet the beads.
10. Remove supernatant and wash the beads three times with 1 ml bead binding buffer each time. Microcentrifuge 1 min at maximum speed, 4°C, between washes.
11. After the final wash, carefully remove all liquid.

It is important to remove all liquid to ensure that equal volumes are loaded on the analytical SDS-PAGE gel. A twisted Kimwipe or a very thin gel-loading pipet tip is useful for removing the final few microliters.

12. Add 25 µl of 1× SDS sample buffer directly to each tube and boil 5 min.

A reduction in background and an increase in the specificity of the reaction can be obtained by eluting only the GST-bait protein and any complexed target from the beads with either glutathione or protease. The eluted material is then mixed with SDS sample buffer and analyzed. Elution may be particularly advantageous when monitoring binding of the target protein by an activity assay. Bait/target complexes can be eluted into the buffer of choice and assayed away from potential interfering activities nonspecifically bound to the beads. One disadvantage of elution, however, is that elution is rarely 100% efficient, which makes quantitation of binding difficult.

Run and analyze an analytical gel

13. Run an analytical SDS-PAGE gel (see UNIT 10.2).

The amount of sample required varies with different bait/target protein pairs and the manner of detection. Loading all the sample avoids the question of loading volumes because there is no uncertainty about the ratio of loaded to unloaded sample.

14. *Optional:* Stain the gel for protein with Coomassie blue (UNIT 10.6).

The stained gel provides a visual confirmation that beads and the bait protein complexes were not lost during the washes and that all reactions contain equivalent amounts of bait protein. To verify that no material was lost during the washes, a parallel gel loaded with one-tenth the sample can be run and stained for protein to more accurately compare the GST fusion protein bands. Also, degradation of the fusion protein may lead to a decrease in the amount of bait protein, especially when using crude extracts (see Fig. 20.2.1) instead of purified labeled test protein. Such degradation must be taken into account in quantifying bound test protein.

15. Fix the gel in gel fixative 30 min at room temperature with gentle shaking.
16. Dry the gel and autoradiograph it or place it on a Storage Phosphor screen.
17. Quantitate the film using a scanning densitometer or phosphorimager.

PREPARATION OF *E. COLI* EXTRACT

It is necessary to perform the binding reactions in the presence of a complex competitor to reduce nonspecific background binding. This is best done by preparing a soluble protein extract from *Escherichia coli* in the buffer that will be used in the GST fusion protein binding reaction (see Basic Protocol).

Materials

E. coli overnight culture grown in LB medium (UNIT 1.1)
Bead binding buffer (see recipe) with and without Triton X-100 and glycerol, 4°C
Tween 20
Glycerol
Sonicator with microprobe
Centrifuge and Sorvall SS-34 rotor or equivalent

SUPPORT PROTOCOL

Analysis of Protein Interactions

20.2.5

Additional reagents and equipment for growing *E. coli* (UNIT 1.2) and quantitating proteins in solution (UNIT 10.1)

1. Harvest an overnight culture of *E. coli* grown in LB medium. Wash the cells in cold bead binding buffer.

If proteolysis of either the target or the GST-bait fusion protein proves to be a problem during the incubation period, a protease-deficient strain of E. coli may be used to prepare the complex competitor extract. However, it should be noted that such strains are often fragile and may not grow well when they contain the pLysS plasmid described in the annotation to step 3. Additional protease inhibitors also may be added to the bead binding buffer. If proteolysis continues to be a problem, alternative blocking/competing reagents—such as BLOTTO or UNI-BLOCK (Analytical Genetic Testing Center)—may be tried.

The size of the culture is dictated by the amount of extract required for the binding assays. A 1-liter culture will yield at least 10 ml of a 10 mg/ml extract.

2. Pellet the cells. Resuspend the pellet in 10 ml per liter of culture of cold bead binding buffer *without* Triton X-100 and glycerol.

Glycerol and Triton X-100 tend to cause foaming during sonication, thus reducing its effectiveness.

3. Sonicate five times, 1 min each, with a 2-min pause on ice between each cycle.

If a sonicator is unavailable, use E. coli strain BL21 (DE3) containing the pLysS plasmid (Novagen), harvest as in steps 1 and 2 but include 1% (v/v) Triton X-100, and subject the resuspended pellet to a single freeze-thaw cycle, which is sufficient to lyse the cells of this strain. DNaseI treatment in the presence of 10 mM Mg²⁺ can be used to reduce the viscosity caused by released DNA.

4. Centrifuge the sonicate 30 min at $47,800 \times g_{\text{avg}}$ (20,000 rpm in a Sorvall SS-34 rotor), 4°C.

5. Remove the supernatant and store on ice.

6. Add Triton X-100 to 1% (v/v) and glycerol to 10% (v/v) and mix thoroughly.

7. Assay the protein concentration (UNIT 10.1). Dilute the extract with cold bead binding buffer to give a final concentration of 10 mg/ml protein and use.

Undiluted extracts may also be stored in 5-ml (10 reactions) or 10-ml (20 reactions) aliquots at -80° or -20°C at least three months. After the aliquot is thawed, repeat step 4 before assaying the protein concentration and diluting to 10 mg/ml.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Bead binding buffer

50 mM potassium phosphate, pH 7.5

150 mM KCl

1 mM MgCl₂

10% (v/v) glycerol

1% (v/v) Triton X-100

Protease inhibitors (UNIT 10.11B or Protease Cocktail, Boehringer Mannheim)

Store buffer at room temperature and add protease inhibitors just before use

Also, prepare the buffer without Triton X-100 and glycerol to be used for resuspending extracts for sonication.

COMMENTARY

Background Information

The glutathione-*S*-transferase (GST) fusion–affinity purification is a simple method to present a native bait protein (as a GST fusion protein) to a test protein or complex of proteins. The assay does not involve denaturing either bait or test proteins, nor does it rely on the more restrictive assay of coimmunoprecipitation with an antibody. It is faster than using the *in vivo* two-hybrid interaction trap system (*UNIT 20.1*) to detect protein–protein interaction and can be performed in a defined medium. It is also quite sensitive—capable of detecting interactions with K_d s in the micromolar range.

The GST pulldown assay has usually been used for qualitative assessment of whether two proteins interact, but demonstration of binding *in vitro* does not necessarily indicate that the binding has *in vivo* biological relevance. Once a binding reaction is identified, variations on the basic assay can be used to further characterize the reaction. The actual bait sequence sufficient for interaction with the test protein can be identified by constructing GST fusions to different regions or fragments of the bait protein and testing them in the binding assay. If it is possible to quantitate the amount of bait protein, the binding constant can then be determined. The half-life of the binding reaction can be determined by binding the labeled test protein in an excess of bait protein: after equilibrium is reached, a large excess of cold test protein is added, and the amount of labeled test protein retained on the beads is assayed at various time points. Because it is not generally feasible to produce large amounts of labeled protein by *in vitro* translation, the test protein can alternatively be labeled with ^{32}P *in vitro* by incorporating a five-amino-acid recognition element for the catalytic domain of heart muscle kinase into the amino-terminal sequence of the protein (Blanan and Rutter, 1992). Competition assays can indicate whether two proteins use exclusive binding sites. With a limiting amount of bait protein, equimolar amounts of two test proteins are added, and the relative amounts of these proteins bound to the bait protein at equilibrium are assayed. The system can also be used to construct a binding pathway for a complex. For example, it may be determined that test protein A may only bind the bait in the presence of test protein B, whereas protein B binds the bait independently of A. This approach has been elegantly used to reconstruct the TFIID complex (Chen et al., 1994).

Many of the potential applications of the pulldown technique rely on accurate quantitation of the reactants and products. However, the sensitivity of this assay rests in the mass-action effects of using high concentrations of bait which allows detection of even weak interactions but also creates the possibility of artifacts. Paying attention to the quantitative features of the pulldown assays leads to an appreciation of both the limitations and powers of this technique.

Critical Parameters

Because of the potential for artifacts, merely showing that a test protein binds the bait protein but not GST is not sufficient to establish that this interaction takes place *in vivo*. Support for a positive binding result can come either from independent assays, such as the two-hybrid interaction trap or immunoprecipitation, or from other control affinity experiments. The most convincing demonstrations are those in which a control variant bait protein that has lost function *in vivo* also does not bind *in vitro* (see Fig. 20.2.3) and those in which the bait–test protein complex reconstitutes an *in vivo* activity.

Quantitation of the amounts of bait and test proteins relative to the question being posed is critical. If the bait is present at a high concentration, nonspecific interactions can be enhanced. If the test protein is in excess, no estimate of relative binding to the bait protein can be made. If substantially more test protein binds to the beads than to bait protein, this probably indicates a nonspecific interaction with the beads; however, test proteins may, in some cases, exhibit a genuine interaction in molar excess over bait (Fig. 20.2.2).

For quantitative purification of a test protein, however, the bait should be in a large excess and the amount of bait bound to the beads should be directly determined. Some GST fusion proteins are prone to degradation, so the beads will contain partial fragments in addition to full-length fusions. Usually, proteolysis leaves an intact GST with little or no bait protein attached, and the amount of GST versus GST-fusion protein can be directly estimated by Coomassie stain on an SDS gel. However, some fusion proteins are prone to small C-terminal deletions, and if estimation of the amount of full-length protein is critical, it should be done carefully. Degradation can result in the accumulation of N-terminal bait fragments on

Figure 20.2.2 Purification of an interacting test protein from a crude *E. coli* extract (-80)/(+80). Crude *E. coli* extracts from control cells (-80) or cells expressing the yeast negative regulator Gal80p (+80) were incubated with a GST fusion protein containing a 34-amino-acid fragment that included the activation domain of the yeast transactivator Gal4p (GST-34). After extensive washing, the beads were boiled in 2× SDS sample buffer and analyzed by SDS-PAGE. Proteins were visualized by Coomassie blue staining. This gel shows that the retained fraction includes GST that has lost the 34-mer bait protein. Gal80p binds to GST-34 as a dimer, hence the molar excess seen in the +80 retained fraction. Photograph provided by Karsten Melcher.

the agarose beads, because these are still able to bind via the GST moiety. If the point of fusion between GST and the bait protein is attacked, GST alone is bound to the agarose beads. If GST is degraded, the fusion protein is unable to bind to the beads. If there are a substantial number of GST fusions with N-terminal bait protein fragments, quantitation of active protein will require limiting proteolysis or purifying the full-length fusion protein.

Troubleshooting

If an interaction occurs between two proteins *in vivo*, a GST pulldown assay will usually detect it. If it is suspected that two proteins interact *in vivo* but the interaction is not detected in the pulldown assay, there are two possible explanations. One is that there is no interaction. The other is that something is suboptimal or missing in the assay. The bait protein may be sterically inhibited as a fusion protein. In this case, the bait protein can be switched to the N-terminus of GST or con-

structed using another affinity tag. Another possibility is that the bait protein is not properly modified when produced as a fusion protein in *E. coli*. In this case, the fusion protein can be produced in yeast (Higgins, 1995; Romanos et al., 1995; Strausberg and Strausberg, 1995), baculovirus (see *UNITS 16.9, 16.10 & 16.11*), or mammalian cells (see *UNITS 16.12, 16.13 & 16.14*). However, if one of these alternative systems is chosen, it is better to use an affinity tag other than GST (such as maltose or biotin) because the level of glutathione in eukaryotic cells can inhibit binding to the agarose beads. Finally, the binding reaction may require one or more additional factors. Investigating this possibility will require binding the test protein out of a cellular extract or adding cellular extract to the labeled, *in vitro*-translated test protein.

If the test protein is specifically retained on the bait protein agarose but not on the GST or negative control agarose, it does not necessarily mean that the bait and test proteins interact *in vivo*. Artifacts may result from mass-action

Figure 20.2.3 Replication in vitro of in vivo Gal4p/Gal80p interactions. In the presence of 10 to 20 μg bait protein and in the absence of complex competitor protein, Gal80p binds to all the mutant Gal4p activation domains tested, even those it does not repress in vivo (data not shown). However, this figure shows that when the amount of bait protein is reduced to 4 μg and 4 mg complex competitor is included, the in vitro pull-down assay parallels the in vivo interaction seen between Gal80p and several different Gal4p activation domain mutants. Lane 1, GST alone; Lane 2, GST + wild-type Gal4p activation domain; Lanes 3 to 7, GST + mutant Gal4p activation domains. A + indicates mutants with a positive in vivo Gal4p/Gal80p interaction; a – indicates mutants with negative in vivo Gal4p/Gal80p interaction; and \pm indicates mutants with low-level in vivo Gal4p/Gal80p interaction. Abbreviation: GST, glutathione-S-transferase. Photograph provided by Karsten Melcher.

effects of large amounts of bait or target protein that drive nonphysiological interactions. Artifacts may also be the consequence of taking a protein out of its normal context. A protein that normally exists in a complex may, when expressed as a GST fusion protein, expose many surfaces that are not normally exposed in the cell. These surfaces may be “sticky” and lead to a general affinity for other proteins. Artifacts can be minimized by reducing the amount of bait protein. Initial GST pull-down assays used tens or even hundreds of micrograms of bait protein. Such high concentrations can produce mass-action effects that drive any interactions with the test protein. While developing conditions to replicate in vitro the known in vivo interactions between the activation domain of the yeast transactivator Gal4p and its repressor Gal80p (Fig. 20.2.3), the authors found that the amount of bait protein needed to be reduced to 1 to 5 μg per reaction.

Inclusion of a complex protein competitor, such as an extract of soluble *E. coli* proteins, in the reaction mix also reduces artifactual interactions. This is very important for the reduction of nonspecific binding, for which a complex competitor is much more effective than a single competing protein like BSA. In the standard assay, the complex protein competitor is pre-

sent in ≥ 100 -fold excess over the GST fusion protein.

Anticipated Results

In the protocol described, with *E. coli* competitor, typically 80% of the input test protein binds to the bait if the affinity is $\leq 10^{-8}$ M. For proteins with binding constants of 10^{-6} to 10^{-8} M, typically 10% to 40% of input test protein is retained. Of course, with large amounts of bait and no competitor even weakly binding proteins can be detected.

If the interaction assay identifies a novel or unknown protein, the system can be scaled up to obtain biochemical amounts of the novel protein for further analysis and identification. After elution with protease or glutathione, the target protein should be highly enriched. Further purification can then be performed following standard protocols (see Chapter 10).

Time Considerations

One of the attractive features of this protocol is how quickly it can be performed. Using the incubation times outlined in the protocol description and labeled test protein, it is easy to determine whether the test protein binds to the GST fusion protein within 1 day. Analysis of the bound test protein by immunoblotting (*UNIT 10.8*) requires an additional day. Construction,

expression, and purification of the GST fusion protein and binding to beads (*UNIT 16.7*) requires additional time.

Phage-Based Expression Cloning to Identify Interacting Proteins

Interaction cloning (also known as expression cloning) is a technique to identify and clone genes which encode proteins that interact with a protein of interest, or “bait” protein. Phage-based interaction cloning requires a gene encoding the bait protein and an appropriate expression library constructed in a bacteriophage expression vector, such as λ gt11. The gene encoding the bait protein is used to produce recombinant fusion protein in *E. coli*. The cDNA is radioactively labeled with ^{32}P . A recognition site for cyclic adenosine 3', 5'-phosphate (cAMP)-dependent protein kinase (protein kinase A; PKA) is introduced into the recombinant fusion protein to allow its enzymatic phosphorylation by PKA and [γ - ^{32}P]ATP. The procedure presented here (see Basic Protocol) involves a fusion protein consisting of bait protein and glutathione-S-transferase (GST) with a PKA site at the junction between them (the protocol can, however, be adapted to use other PKA-containing recombinant proteins). The labeled protein is subsequently used as a probe to screen a λ bacteriophage-derived cDNA expression library, which expresses β -galactosidase fusion proteins that contain in-frame gene fusions. The phages lyse cells, form plaques, and release fusion proteins that are adsorbed onto nitrocellulose membrane filters. The filters are blocked with excess nonspecific protein to eliminate nonspecific binding and probed with the radiolabeled bait protein (see Fig. 20.3.1). This procedure leads directly to the isolation of genes encoding the interacting protein, bypassing the need for purification and microsequencing or for antibody production.

NOTE: Radioactive label is used in this protocol, and appropriate precautions and shielding should be used (*APPENDIX 1F*).

STRATEGIC PLANNING

There are two important choices one must make to begin this procedure: (1) how to design the bait protein and (2) how to construct or acquire an appropriate phage-derived expression library.

Vectors for recombinant fusion protein expression that contain a PKA recognition site can be obtained commercially. Several companies now sell these vectors with various affinity tags such as GST (Pharmacia Biotech), histidine (Novagen), or calmodulin-binding protein (Stratagene). Alternatively, one can engineer the PKA recognition site (the five-amino acid sequence RRASV) into existing vectors by using synthetic DNA that encodes it.

Lambda-derived expression libraries that direct the expression of cDNAs made from many different mRNA sources are widely available. Alternatively, a library may be constructed for a particular experimental purpose; when designing a library to be used in expression cloning, several points should be considered. Libraries made from cDNA synthesized with random primers or an oligo dT-primer during first-strand synthesis (*UNITS 5.5 & 5.6*) can often be advantageous in that multiple clones representing different portions of the same protein can be identified in the screening. Analysis of coding regions present in these multiple clones could provide useful information about what region of the protein is responsible for the observed interaction. Full-length cDNA clones can subsequently be obtained from other available libraries.

Many suitable λ vectors are available for constructing cDNA expression libraries. The most widely used cDNA expression vector has been λ gt11 (Huynh et al., 1985). There are modifications of these λ vectors, however, that facilitate the recovery of the cDNA

inserts by avoiding the necessity of time-consuming λ phage DNA preparations. These modified vectors include those that make use of the *cre-lox* recombination for in vivo conversion of recombinant phages into plasmid DNA in *cre* recombinase-expressing host strains (e.g., λ ZipLox, Life Technologies) as well as those that employ helper phage for in vivo excision of a phagemid vector (e.g., the λ ZAP series of vectors, Stratagene). Most λ vectors available produce fusions of the cDNA inserts to β -galactosidase, because they are cloned into the *lacZ* gene. However, some λ -derived expression vectors (e.g., λ SCREEN-1, Novagen) direct expression of proteins fused to the T7 DNA polymerase promoter (gene *10* under control of the T7 promoter) and may yield higher expression of the library proteins (Margolis et al., 1992).

INTERACTION CLONING

Phage-based interaction expression cloning is a simple, rapid, and powerful technique to identify interacting proteins. A protein of interest is expressed as a recombinant fusion protein and labeled with ^{32}P at a serine residue in an engineered PKA recognition site to facilitate detection. β -galactosidase proteins that are fused in-frame to cDNA inserts in a bacteriophage λ -derived expression library are produced by the phage and adsorbed onto nitrocellulose filters. The filters are then screened with the radiolabeled protein probe to identify phage clones that express an interacting protein.

Figure 20.3.1 Schematic representation of the interaction cloning technique used to identify proteins that associate with a protein of interest (bait protein), and the expected results of a successful screen. **(A)** Expression of β -galactosidase fusion proteins from in-frame cDNA inserts of a λ gt11 *Arabidopsis* library is induced with IPTG-impregnated nitrocellulose membrane filters (indicated by an oval). Filters are probed with GST-bait fusion protein labeled with ^{32}P (•) at the PKA recognition site located at the junction of the fusion. Interacting clones are detected by autoradiography. **(B)** Representative autoradiogram of a tertiary screen of a positive plaque after the control experiment to determine whether the interaction is specific for the bait portion of the probe. The top half of the filter is probed with GST-bait while the bottom half is probed with GST alone as a control.

Materials

cAMP-dependent protein kinase (PKA; e.g., 250-U lots from Sigma)
40 mM DTT, prepared fresh
10× PKA buffer (see recipe)
10 mCi/ml [γ - 32 P]ATP (6000 mCi/mmol)
Purified glutathione-*S*-transferase (GST)-bait protein fusion protein with a PKA recognition site (UNIT 16.7), at ~0.1 to 1 μ g/ μ l concentration
Z'-KCl (see recipe), ice cold
Sephadex G-50 equilibrated in Z'-KCl
E. coli Y1090r⁻ or other appropriate host strain
LB medium containing appropriate selective antibiotic (see UNIT 1.1, APPENDIX 3F, and Table 1.4.1), 10 mM MgSO₄, and 0.2% maltose
10 mM MgSO₄
10 mM IPTG (Table 1.4.2)
150- or 100-mm LB plates (with antibiotic, if necessary; UNIT 1.1)
0.7% top agarose (UNIT 1.1), 47°C
Tris-buffered saline with Triton X-100 (TBS-T; see recipe)
India ink
HEPES blocking buffer (HBB; see recipe)
Binding buffer (BB; see recipe)
Suspension medium (SM; UNIT 6.12)
Chloroform
3-ml disposable plastic columns *or* disposable syringe and glass wool
Scintillation counter and fluid
Tabletop centrifuge or equivalent
Nitrocellulose membrane filters (137- and 82-mm disks)
22-G needle
Additional reagents and equipment for preparation and purification of recombinant glutathione-*S*-transferase fusion protein (UNIT 16.7), SDS-PAGE (optional; UNIT 10.2), autoradiography (APPENDIX 3A), titering and plating λ phage to generate plaques (UNIT 1.11 & UNIT 6.1), and purification of bacteriophage clones (UNIT 6.5)

Prepare the 32 P-labeled protein probe

1. Resuspend 250 U PKA in 25 μ l freshly prepared 40 mM DTT. Let the reconstituted enzyme stand at room temperature ~10 min before use.

It is important to use freshly prepared 40 mM DTT. PKA is extremely unstable after reconstitution; the enzyme stock solution can be stored temporarily at 4°C but retains activity for only 2 to 3 days.

2. Prepare a phosphorylation reaction mixture containing:

1 μ l 10 U/ μ l PKA (from step 1)
3 μ l 10× PKA buffer
5 μ l 10 mCi/ml (6000 mCi/mmol) [γ - 32 P]ATP
1 to 10 μ l (~1 μ g) purified GST-bait fusion protein
H₂O to 30 μ l.

Incubate 1 hr at room temperature.

A fusion protein unrelated to the bait protein, but containing the PKA recognition site, should also be expressed for use as a control to determine whether the observed interaction is specific for the bait moiety. Due to the instability of PKA, it is advisable to label both the bait protein and the unrelated control fusion protein simultaneously (in separate reactions).

3. Add 170 μ l ice-cold Z'-KCl (to stop reaction) and store on ice until use.
4. Prepare a gel filtration column by pouring Sephadex G-50 equilibrated in Z'-KCl into a 3-ml disposable plastic column (or a 3-ml syringe with a glass wool plug) for a final bed volume of \sim 3 ml. Allow the column to drain until the level of the buffer is at the top of the column bed.

The Sephadex G-50 can be swelled in water or buffer and stored at 4°C for months. In this case, five to ten column volumes of Z'-KCl can be used to equilibrate the column after it is poured.

5. Load the entire phosphorylation reaction (from step 3) onto the column and collect the effluent in a 1.5-ml microcentrifuge tube. Place a second tube under the column, add a 200- μ l aliquot of Z'-KCl, and collect the effluent again. Repeat the above loading and collecting steps an additional ten times to collect a total of twelve 200- μ l fractions.
6. Measure the Cerenkov counts with a scintillation counter to identify the fractions with the highest specific activities, and calculate cpm/ μ l.

Typically two peaks of radioactivity are observed. The first peak elutes in fractions five to nine and corresponds to labeled protein. The second peak, usually found in the last few fractions collected, corresponds to unincorporated ATP and should be discarded. The hottest fraction(s), which elute first, should be used. Fractions can be stored at 4°C for several weeks.

7. *Optional:* Analyze a small amount (1 to 2 μ l) of the 32 P-labeled protein probe by SDS-PAGE and autoradiography (UNIT 10.2 & APPENDIX 3A).

Typically two strong signals are observed: one at the predicted size of the GST-bait fusion protein and the other at the predicted molecular weight of the GST alone (28 kDa). This is due to the fusion protein's inherent susceptibility to protease cleavage at the GST-bait protein junction. The presence of labeled GST protein in the probe should not interfere with the screen; a control experiment with labeled GST will be performed at the later stages of screening.

Prepare host strain cells and dilution of bacteriophage cDNA library

8. Using serial dilution as described in UNIT 1.11, determine the titer of the bacteriophage cDNA library.
9. Grow an overnight 50-ml culture of *E. coli* Y1090^r (or other appropriate host strain; UNIT 1.4) in LB medium containing an appropriate selective antibiotic, 10 mM MgSO₄, and 0.2% maltose.
10. Centrifuge cells 10 min at 2000 \times g, room temperature, and resuspend in 25 ml of 10 mM MgSO₄.

The resuspended cells can be stored up to 1 week at 4°C before use.

Prepare the filters to screen the bacteriophage cDNA expression library

11. Soak nitrocellulose filters in 10 mM IPTG for 15 min at room temperature and air dry.

IPTG-impregnated filters can be stored in a petri plate until use.

12. Prepare eight 1.5-ml microcentrifuge tubes each containing 0.6 ml Y1090^r cells (from step 10) and \sim 40,000 pfu bacteriophage (from step 8), and incubate 15 min at 37°C.

13. Add contents of each tube to 7 ml of 0.7% top agarose at 47°C and pour onto 150-mm LB plates (with antibiotic, if necessary). Incubate plates ~3 hr at 42°C, until small plaques are visible.
14. Overlay the plates with IPTG-impregnated filters and incubate an additional 6 to 8 hr at 37°C.

Formation of plaques in the absence of induction of the lacZ gene promoter ensures that any library-encoded proteins that are deleterious to phage growth will not be expressed while the phage are forming a plaque.

Incubation in the presence of IPTG-impregnated filters is usually performed for a 6- to 8-hr period, but can proceed overnight for convenience.

15. Chill plates 15 min (or overnight) at 4°C.
16. Pierce each filter in several locations with a 22-G needle dipped in India ink to mark orientation. Remove filters from plates and wash 15 min in TBS-T at room temperature with shaking.

Screen bacteriophage cDNA expression library

17. Incubate filters 1 to 4 hr with rocking at 4°C in 100 ml HBB.

This blocking step (to reduce nonspecific binding) can also be performed overnight for convenience.

18. Incubate overnight with rocking at 4°C in BB containing $2.5\text{--}5 \times 10^5$ cpm/ml of radiolabeled fusion protein (from step 6).

All eight filters can be placed in one 150-mm plate and probed with 30 to 40 ml of solution. The plate is wrapped in Parafilm and placed in a Plexiglas box for shielding. Alternatively, the filters can be placed with solution in a heat-sealable bag. The probe solution can be stored at 4°C and used for the subsequent secondary and tertiary screenings.

19. Wash membrane filters three times, 10 min each, in 100 ml BB with shaking at room temperature. Air dry and expose to film (see APPENDIX 3).
20. Using the large end of a Pasteur pipet, take an agarose plug at the position of the positive clone. Place into a 1.5-ml microcentrifuge tube and add 1 ml SM and 1 drop of chloroform.

Agarose plugs can be stored at 4°C for months. Therefore, if many putative positive clones are identified in the primary screen, they can all be stored for future analysis if necessary.

21. Determine the titer by serial dilution (UNIT 1.11) and perform successive screening procedures to obtain purified clones as described in UNIT 6.5.

Subsequent screens are performed on 100-mm LB plates with ~2000 pfu/plate for secondary screens and ~300 to 500 pfu/plate for tertiary screens. Before purified clones are obtained (usually during the tertiary screen), a control to eliminate clones that might interact with the GST fusion portion of the probe should be performed. To do this, cut the filters in half and probe one half with the labeled GST fusion to the protein of interest and the other with labeled GST alone or an unrelated control GST fusion protein (see Fig. 20.3.1).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. All solutions should be prepared from sterile, autoclaved stock solutions, except Z'-KCl, which should be filter sterilized. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Binding buffer (BB)

20 mM HEPES·OH, pH 7.4
7.5 mM KCl
0.1 mM EDTA
2.5 mM MgCl₂
1% (w/v) nonfat dry milk

The solution can be prepared without milk and stored indefinitely at room temperature (add milk prior to use).

HEPES blocking buffer (HBB)

20 mM HEPES·OH, pH 7.4
5 mM MgCl₂
1 mM KCl
5% (w/v) nonfat dry milk

The solution can be prepared without milk and stored indefinitely at room temperature (add milk prior to use).

PKA buffer, 10×

200 mM Tris·Cl, pH 7.5
10 mM DTT
1 M NaCl
120 mM MgCl₂
Store up to 6 months at room temperature

Tris-buffered saline with Triton X-100 (TBS-T)

10 mM Tris·Cl, pH 8.0
150 mM NaCl
0.05% (v/v) Triton X-100
Store up to 6 months at room temperature

Z'-KCl

25 mM HEPES·OH, pH 7.4
12.5 mM MgCl₂
20% (w/v) glycerol
100 mM KCl
1 mg/ml BSA
1 mM DTT
Filter sterilize
Store up to 6 months at 4°C

COMMENTARY

Background Information

Historically, interacting proteins have been isolated by biochemical approaches, which required purification of the interacting protein for antibody production or microsequencing before a clone encoding the protein could be identified. Two of the molecular biological approaches described in this chapter, the yeast two-hybrid system (UNIT 20.1) and phage-based

interaction expression cloning (this unit), however, directly yield a clone encoding the interacting protein.

Bacteriophage cDNA expression libraries are commonly screened using antibodies (see UNIT 6.7 and references therein) or radiolabeled DNA probes to identify DNA-binding proteins (see UNIT 12.7 and references therein). Modifications to identify interacting proteins include

screening with the protein of interest (the bait protein) and detecting that protein with antibodies (Chapline et al., 1993). However, by screening with a radiolabeled protein probe, one avoids the additional incubations and washes which are necessary for immunodetection but that increase the likelihood of disrupting weak protein-protein interactions. ¹²⁵I-labeled protein probes have been used successfully to screen for interacting proteins (Hoeffler et al., 1991), although the technique described in this unit avoids the need to label the proteins with ¹²⁵I, and the complications of handling this isotope.

Protein probes autophosphorylated with ³²P were originally used to screen cDNA expression libraries in the isolation of proteins that interact with receptor protein kinases, a technique referred to as CORT (cloning of receptor targets; Skolnik et al., 1991; Lowenstein et al., 1992; Margolis et al., 1992). By introducing a PKA recognition site into the protein probe, the technique was made suitable for proteins that were not themselves protein kinases (Blaner and Rutter, 1992; Kaelin et al., 1992).

Phage-based interaction expression cloning as described in this unit has been used successfully to identify many interacting proteins, but may not be successful for all types of interactions. For example, many related proteins (known as A-kinase anchoring proteins, or AKAPs) have been identified by their ability to interact with the type II cAMP-dependent kinase regulatory subunit, RII (Carr and Scott, 1992). All the AKAPs can bind RII under denaturing conditions (Lester et al., 1996), illustrating that the success of interaction cloning is often dependent on the nature of the interactions and that interactions less dependent on three-dimensional structure may be favored. However, there are many examples of proteins identified by this technique that cannot interact under the denaturing conditions often used to confirm the binding (commonly referred to as overlay assays or Far Western analysis). For example, a protein domain identified by its interaction with a plant receptor-like protein kinase is capable of interacting with a denatured form of the bait protein, but is unable to interact when the interacting protein is denatured (Stone et al., 1994). This fact is consistent with the idea that immobilization on membranes denatures some proteins but not others.

Critical Parameters and Troubleshooting

The success of phage-based interaction expression cloning is inherently dependent on the

quality of the protein probe used and the extent of representation of the bacteriophage cDNA library. GST fusion proteins are often obtained in high quantity in a soluble form, avoiding the necessity of solubilizing and refolding during protein purification from *E. coli* extracts. In most cases the PKA recognition site is readily accessible, and allows production of radiolabeled protein with a high specific activity.

The strength of the protein-protein interaction is also critical. Depending on the nature of the interaction, a filter-binding technique might not be suitable. This technique may not detect weak or transient interactions, such as an enzyme/substrate interaction, and techniques such as the yeast two-hybrid system (*UNIT 20.1*) might be more appropriate.

If no positive clones are identified or if background is high, it may be helpful to add reducing agents or detergents or to alter the salt conditions of the binding and wash solutions (Vinson et al., 1988). Moreover, denaturation and renaturation of the proteins on the filters using 6 M guanidine-HCl, as described in *UNIT 12.7* (Alternate Protocol), may facilitate the recovery of clones expressing interacting proteins, because adsorption of the β -galactosidase fusion proteins to nitrocellulose filters may alter the conformation of the proteins.

For a discussion of common problems with this procedure and their diagnosis and possible solutions, see Table 20.3.1.

Anticipated Results

Depending on the nature of the interaction being sought by this technique, many interacting clones, none, or just a few may be identified. However, the technique is as simple as screening a library by hybridization and often well worth the effort. In any case, observed interactions should be confirmed by other means.

Time Considerations

The interaction cloning technique described in this unit is extremely rapid in comparison with other techniques to identify interacting proteins, such as the yeast two-hybrid system (*UNIT 20.1*). The technique does not require any unusual reagents that would not be readily available in any laboratory routinely engaged in molecular biology, other than the cAMP-dependent protein kinase. Once the appropriate recombinant fusion protein and cDNA expression library are obtained, the primary screen can be completed in a few days. Once the appropriate construct for expression of the GST-bait is obtained, purification of the recom-

Table 20.3.1 General Troubleshooting Guide for Interaction Cloning

Problem	Possible cause	Solution
High background	Insufficient washing	Use more BB wash solution
	Poor choice of nitrocellulose membrane filters	Try a different supplier for membranes
	Insufficient blocking	Block overnight in HBB
No positive plaques	Poor-quality protein probe	Check the probe by SDS-PAGE and autoradiography
	Wash conditions too stringent	Reduce wash times Vary salt and/or detergent concentration
	Poorly folded library fusion proteins	Perform 6 M guanidine-HCl denaturation/renaturation (<i>UNIT 12.7</i>)
Too many positive plaques	Wash and binding conditions insufficiently stringent	Increase salt and/or detergent in BB
	Library biased to proteins that interact with the affinity tag	Include unlabeled affinity tag in blocking, binding, and wash solutions

binant GST-bait protein can be achieved in 1 day. ³²P labeling of the bait protein requires 2 hr (several additional hours if the optional SDS-PAGE and autoradiography are performed). The initial screening of the bacteriophage cDNA library takes 3 days; day 1 to prepare the filters and induce expression of library-encoded proteins, day 2 for blocking and probing overnight with ³²P-labeled bait protein, and day 3 for washing and autoradiography. Subsequent purification of the cDNA clones should only take an additional week. There are a number of steps that can be performed either rapidly or overnight, providing a great deal of convenience and flexibility.

Surface Plasmon Resonance for Measurements of Biological Interest

UNIT 20.4

Genetic manipulations, including gene knockouts and mutant screens, provide an initial hint as to the function of a gene product and indicate possible associated factors. To unravel complicated biological processes that control the development of organisms one must identify the interacting components. Yeast two-hybrid methods (UNIT 20.1; Gyuris et al., 1993; Zervos et al., 1993; Bartel and Fields, 1995) provide an *in vivo* means of identifying species that directly associate with each other. However, many biological systems are notoriously redundant and consist of networks of interacting components. For these and other reasons, it is advisable to verify the *in vivo* observation by an *in vitro* detection method where there are fewer variables and where reaction conditions can be controlled. Few techniques measure equilibrium binding because routine washing steps can cause the dissociation of the interaction under study. Moreover, most *in vitro* techniques used for the detection of intermolecular interactions require the use of antibodies or protein-labeling and subject the interaction under study to harsh and potentially denaturing conditions. These techniques only provide static “snap-shots” of a dynamic process, and kinetic parameters must be inferred from successive experiments.

An *in vitro* technique based on an optical phenomenon, called surface plasmon resonance (SPR; Liedberg et al., 1983; Daniels et al., 1988), can simultaneously detect interactions between unmodified proteins and directly measure kinetic parameters of the interaction. The use of SPR to study macromolecular interactions has recently become popular with the availability of user-friendly instruments. The most popular commercially available SPR device is the BIAcore instrument (BIAcore). This instrument consists of sensing optics, an automated sample delivery system, and a computer for instrument control, data collection, and data processing. Experiments are performed on disposable chips (Löfås and Johnsson, 1990). In practice, a ligand protein is immobilized on the chip while buffer continuously flows over the surface. The buffer flow is interrupted when sample “plugs” containing putative binding partners (analyte or target proteins) are sequentially flowed over the protein surface. The sensing apparatus monitors changes in the angle of minimum reflectance from the interface that result when a target protein associates with the ligand protein. Molecular interactions can be directly visualized (on the computer monitor) in real time as the optical response is plotted against time. This response is measured in resonance units (RUs, where 1000 RUs = 1 ng protein/mm²).

The user handbook with the BIAcore SPR apparatus contains detailed information on the use of the equipment, as well as a number of protocols and information for experimental design. Basic Protocol 1, presented here, is a modification of the standard protocol in the BIAcore user handbook, and is used with the CM-5 BIAcore carboxylated dextran chip. Basic Protocol 2 describes the particular details necessary when using NTA-SAM chips. A detailed discussion on choosing between these two kinds of chips can be found in Critical Parameters and Anticipated Results. The use of SPR provides an accurate measurement of kinetic rate constants for a ligand-target binding reaction. If a ball-park estimate of the range of the equilibrium constants is desired, or if an absolute kinetic rate constant is desired, refer to the discussion in Anticipated Results.

SPR USING BIAcore CHIPS

The following protocol is used when performing an SPR experiment on a BIAcore device with the BIAcore CM-5 chip. This is the most commonly used SPR chip and is made with carboxylated dextran. Two particular deviations from the standard BIAcore protocol are discussed within annotations (steps 3 and 6); both deviations concern ligand binding to the chip, and were designed to avoid artifactual pitfalls that are peculiar to dextran-based chips. For detailed steps in the performance of an SPR experiment, and for additional reagents and equipment information, refer to the BIAcore user handbook.

Materials

- CM-5 dextran chips (BIAcore)
- PBS (*APPENDIX 2*)
- Ligand protein
- Target protein
- Amine-coupling kit (BIAcore), containing:
 - N*-ethyl-*N'*-[(dimethylamino) propyl] carbodiimide hydrochloride (EDC)
 - N*-hydroxysuccinimide (NHS)
 - Sodium acetate buffer, low pH
 - Ethanolamine
- BIAcore SPR equipment
- BIA evaluation point-and-click software

Determine binding conditions

1. Insert a new BIAcore CM-5 dextran chip.
2. Allow the system to equilibrate with PBS as the running buffer in the constant flow system.
3. Experimentally determine buffer conditions and concentrations that minimize non-specific binding of target and ligand proteins to the carboxylated dextran.

With dextran chips, conditions must be determined for the ligand because a ligand which has nonspecifically adsorbed to the highly negatively charged dextran is likely to be denatured and can nonspecifically bind the target protein in solution.

This process can easily use up all four flow channels of two chips.

Determine regeneration conditions

4. Insert new chip.
5. Activate the carboxylates of the dextran support by injecting *N*-ethyl-*N'*-[(dimethylamino) propyl] carbodiimide hydrochloride (EDC) in the presence of *N*-hydroxysuccinimide (NHS).

These reagents are included in an amine-coupling kit from BIAcore.

6. Inject ligand protein in low-pH sodium acetate buffer such that an adequate amount of the protein is presented on the dextran. Perform several parallel experiments in which the density of ligand presented by the dextran is varied.

This can be accomplished by altering contact times and protein concentration. Proceed with steps 7 through 14, and then measure the rates of dissociation of the target protein from each of the ligand densities (step 15). The rate of dissociation should be constant and independent of the concentration of the surface density of the ligand (see Anticipated Results). The ligand density should be optimized to produce a surface presenting enough molecules to elicit a clear binding response yet dilute enough to measure a dissociation rate constant that is constant.

7. Cap any unreacted activated carboxylates by treatment with ethanolamine.
8. Inject a solution containing a known concentration of the putative target protein under buffer conditions and within the concentration range determined in step 3.

Vary the flow rate and the concentration of the analyte to minimize diffusion or “mass transport” effects. The association rate constant for a particular reaction should be just that: constant (see Anticipated Results discussion on Rate and equilibrium constants).
9. Experimentally determine regeneration conditions, i.e., conditions under which the target protein is completely dissociated from the covalently coupled ligand.

One must be careful to determine conditions for the regeneration of the surface that preserve the activity of the immobilized species.

This procedure can easily consume another chip.

Perform experimental measurements

10. Insert new chip, if necessary.
11. Perform steps 2, 5, 6, 7, and 8 (i.e., activate the dextran carboxylates, covalently attach the protein of interest, cap unreacted sites, and introduce a putative binding partner in solution).

Use the optimal buffer conditions and ligand density determined in steps 3 and 6, respectively.
12. Regenerate using reagents determined in step 9.
13. Repeat steps 8 and 12 as necessary to obtain data using a total of at least three different concentrations of the target protein.
14. Using BIA evaluation point-and-click software, measure dissociation and association rate constants. Calculate an equilibrium constant using average values of the association and dissociation rates that resulted from the three different target protein concentrations.

The kinetic parameters measured for the various concentrations of analyte in solution should be within reasonable experimental error limits, similar to the error limits obtained from one “identical” experiment to another.
15. Reverse the experimental configuration: confirm that the same kinetic parameters are measured when the previous analyte is immobilized and the previous ligand is in solution.

SPR USING NTA-SAM CHIPS

The following protocol was developed for SPR experiments using nitrilotri-acetic acid self-assembled monolayer (NTA-SAM; Bamdad et al., 1994; Sigal et al., 1996) chips. This protocol is simpler than Basic Protocol 1, as NTA-SAM chips do not require several of the control measures necessitated by dextran-based chips (see Critical Parameters discussion on NTA-SAM chips). For detailed steps in the performance of an SPR experiment, and for additional reagents and equipment information, refer to the BIAcore user handbook.

Materials

- NTA-SAM chips (3% to 5% NTA relative to an inert ethylene glycol-terminated thiol)
- PBS or HeBS (*APPENDIX 2*)
- 1 mM NaOH
- 1% (w/v) Ni(II)SO₄

**BASIC
PROTOCOL 2**

**Analysis of
Protein
Interactions**

20.4.3

Histidine-tagged ligand protein
Target protein
BIAcore SPR equipment
BIA evaluation point-and-click software

1. Insert an NTA-SAM chip.
2. Use PBS or HeBS as the running buffer.
3. Inject 10 μ l of 1 mM NaOH.
4. Inject 25 μ l of aqueous 1% Ni(II)SO₄.
5. Inject a histidine-tagged ligand protein.
6. Inject a putative target protein.
7. Repeat steps 3 through 6 with a total of at least three concentrations of the target protein.

Histidine-tagged proteins can be removed from the surface by treatment with 200-mM imidazole. Alternatively, a fresh flow cell can be used for each experiment (each chip has four flow cells).

8. Using BIA evaluation point-and-click software, measure dissociation and association rate constants. Calculate an equilibrium constant using average values of the association and dissociation rates that resulted from the three different target protein concentrations.

The kinetic parameters measured for the various concentrations of analyte in solution should be within reasonable experimental error limits, similar to the error limits obtained from one "identical" experiment to another.

COMMENTARY

Background Information

Use of SPR to analyze biomolecular interactions

Optical sensing devices for detecting and kinetically characterizing interactions among biomolecules are now in mainstream use. Complicated, multicomponent interactions can be quickly "dissected" by sequential determination of pair-wise interactions. The BIAcore SPR instrument can tolerate a wide range of buffer conditions. A broad range of affinities are measurable by SPR: from ten millimolar to picomolar. Because binding events are viewed in real time, one can alter experiments immediately in response to initial results. Researchers have eagerly adopted the new methods because they don't require time-consuming and hazardous labeling steps. Perhaps the most important advantage is that because the *mass* of a molecular species is detected by an optical response, no protein labeling is required and only microliter sample volumes are consumed. The microfluidic technology of these devices satisfies a long-standing research need—allow-

ing for both minimal sample consumption and rapid measurements.

The commercial availability of user-friendly optical sensors is a fairly new development. Until recently, the design of the devices has received little input from the bioscientific community. We are now entering a new and exciting phase in the development of this technology that is being driven by the needs of researchers to not only carry out routine experiments faster but to venture into unexplored areas. Derivatized monolayers will play an increasingly important role in state-of-the-art detection devices, as they have demonstrated clear advantages over disordered polymer-based supports (see Critical Parameters discussion on NTA-SAM chips). With optical sensing, it is now possible to design experiments to measure the difference between monovalent and bivalent binding, detect very weak interactions between proteins and protein complexes, and characterize interactions between factors that facilitate the assembly (or catalyze the disruption) of large megadalton complexes. The future evolution of these devices is only limited by the

imagination and needs of researchers in their desire to unravel the complex processes of biological systems.

There is an intrinsic danger in using any instrument as a black box. The fact that many biologists, largely untrained in theoretical physical chemistry, use the instrument to perform kinetic characterization of interactions has led to considerable skepticism among researchers regarding much of the BIAcore-generated data in the literature. An understanding of the physics of the instrument is essential for experimental design and data interpretation. Thus, this commentary treats (1) the theory behind SPR devices, (2) factors that affect the accuracy of an SPR experiment, (3) choice of SPR chips, (4) caveats for experimentation and additional control experiments, and (5) kinetic analysis and higher-order kinetics.

SPR theory

Optical phenomena involving electron oscillations in the surface of a metal have been studied for some time. Electrons move freely through a metal. However, at a metal-medium interface, dipole excitations cause the propagation of electron waves called surface plasma or plasmon waves (SPWs). Because the wave vectors of the SPWs are long, they cannot be excited by simple incident light, so direct coupling of the two waves is not possible. X-rays were originally used to excite SPWs and for this reason interest in the phenomenon was limited to physicists studying how electromagnetic energy behaves at surfaces. A major breakthrough came in the late 1960s, when researchers succeeded in exciting SPWs using simple incident light. Otto (1968a,b) and the team of Kretschmann and Raether (1968), building on the earlier work of Turbadar (1959), exploited the phenomenon of total internal reflection (TIR) to couple incident light to SPWs. This achievement made simple SPR devices possible.

The basic configuration of modern SPR instruments has not deviated significantly from the original experimental setup (see Fig. 20.4.1). Total internal reflection occurs at an interface, when light propagates from a medium of higher refractive index to one of lower refractive index at an angle of incidence greater than the critical angle. The light energy is then totally reflected off of the interface, except for an evanescent field that extends a distance of one wavelength (of the incident light) into the second medium. The magnitude and direction

of the reflected light can be monitored by an array detector. If a very thin layer of a third dielectric material, of lower refractive index than either of the others, is sandwiched between the two different dielectrics within the one wavelength distance, the incident wave will be transmitted through the thin layer and into the second medium by photon tunneling. If the sandwiched material is a metal and the wave vector of the incident light can somehow be increased (achieved by passing it through a prism) to match that of an SPW propagating through the metal, then coupling of the incident light and the SPW will occur. Energy from the incident light will be fed into the SPW and not reflected off the interface. This is important because the coupling of the two waves will produce a minimum or “dip” in the reflected light; the angle at which this occurs is a parameter exquisitely dependent upon the second medium’s dielectric properties (Wahling et al., 1979). Recall that a small portion of incident light extends into the second medium, so that the angle at which the incident wave couples to the SPW is determined by the refractive index of the second medium by Snell’s Law (assuming the first dielectric is held constant). Small changes in the refractive index of the second material cause large shifts in the angle at which coupling and the corresponding dip in reflected light occur.

In the study of protein-protein interactions, increasing the protein concentration of a solution will result in a more dense medium with an altered refractive index. One can infer how the protein content of the second material is changing over time by monitoring the change in the angle of minimum light intensity. If ligand is immobilized at the interface of the thin metal film and the second medium, then subsequent interaction with proteins injected into the second medium will cause a change in the refractive index of the interfacial region, again changing the minimum reflectance angle. It is important to appreciate that the attenuation of the “sensing wave” which projects into the second medium is severe. This allows kinetic information to be extracted from the optical response as a function of time because the sensing wave only detects proteins that are very close to the interface (where the first species is immobilized), as opposed to the total mass of protein in the solution sample. It is assumed that proteins that are so close to the immobilized species are associating.

Critical Parameters

Factors that affect the accuracy of an SPR experiment

The physics of the optical phenomenon of SPR govern the accuracy of the device. Because the sensing wave falls off very rapidly, the change in optical response is only a *linear* function of the net change in protein mass up to a maximum distance of 150 nm from the interfacial region (Stenberg et al., 1991). To reliably measure the kinetics of an interaction, the sensing apparatus should be as inert as possible. Additionally, immobilized ligands should be oriented to provide equal accessibility of binding sites to the binding partners in solution (analytes), and analytes in solution

should have equal access to the immobilized ligands.

Dextran-based chips

Virtually all of the commercially available chips that are suitable for the study of protein-protein interactions using a BIAcore device have a functionalized dextran base that is ~150 nm thick. This presents a problem, as it means that the processes under study are occurring at the very limit of accurate detection. Several other problems arise with the use of dextran-based SPR chips. The most commonly used chip is a carboxylated dextran chip, CM-5, that is available from BIAcore. Proteins are nonspecifically coupled to the carboxylates of the support by standard EDC/NHS chemistry, the

Figure 20.4.1 The physical configuration of modern SPR devices. Light passing through a dense medium (n_1) incident at an angle (Θ_1) greater than the critical angle, to a second medium of lower refractive index (n_2) is totally reflected off the interface, except for an evanescent field that extends into the second medium for a distance of one wavelength. At a certain angle (Θ_2) exquisitely dependent on the refractive index of the second medium, the incident light wave can couple to surface plasmon waves (electron oscillations) propagating through a thin metal film (n_3) sandwiched between the two media. The incident light energy is fed into the surface plasmon wave and a corresponding minimum in reflected light is observed. Proteins immobilized at (or recruited to) the metal-medium interface alter the dielectric of the region, which causes a shift in the angle of minimum reflectivity (Θ_3).

which targets primary amines on the protein surface. The carboxylated dextran carries a high net negative charge (Johnsson et al., 1991); it is thus not inert and may alter the kinetics of the system under study.

The dextran support is also problematic with respect to mutual accessibility of ligand and target proteins. Experiments indicate that very large proteins may be completely prevented from entering the dextran matrix (see Critical Parameters discussion on NTA-SAM chips). The nonspecific coupling of proteins to the support renders the ligand's active site randomly oriented and often inaccessible. Furthermore, flow over the nonuniform dextran polymer is turbulent. A large static layer separates the analyte-containing solution from the ligand-presenting dextran and hinders the diffusion of molecules into the matrix. Increasing the flow rate will help speed diffusion, but if the diffusion rate is slower than the association rate, then the diffusion rate will be the measured parameter. Although analytical methods have been proposed to model the diffusion or "mass transport" factor (Fisher and Fivash, 1994), it would be preferable to eliminate the problem rather than to model its effect into data evaluation software.

NTA-SAM chips

In 1994, a self-assembled monolayer (SAM; Nuzzo et al., 1987; Bain et al., 1989) SPR chip was developed that presents nitrilotri-acetic acid (NTA) ligands for the specific capture of histidine-tagged proteins to overcome the problems intrinsic to the dextran chip (Bamdad et al., 1994; Sigal et al., 1996). The thickness of the monolayer is 2 nm, as opposed to the 150-nm thickness of the dextran chip. It has been possible to detect and characterize interactions on the NTA-SAM that were undetectable on the dextran chip because (1) processes under study are much closer to the emanation of the sensing wave, (2) the active sites are uniformly presented to analytes in solution, (3) noncovalent coupling to the support retains greater protein viability, and (4) flow over the monolayer is near laminar with an insignificant static layer.

The first demonstration of the enhanced sensitivity of the NTA-SAM chip involved the interaction between a mutant form of a yeast holoenzyme component, Gal11p, and an inert DNA-binding domain, Gal4(58 to 100). Although there was considerable genetic evidence that the two proteins were associated, direct detection of the interaction by standard techniques was not demonstrable for a number of

years. The interaction between these two proteins could not be detected by SPR on dextran-based chips, but was easily detected and quantitated using the NTA-SAM chip (Barberis et al., 1995). Subsequently, a fusion protein of Gal11p, which could be prepared at much higher concentrations, was observed to interact with Gal4(58 to 100) using both dextran SPR chips and gel mobility shift assays (Farrell et al., 1996). It is reassuring that the k_d measured on the NTA chip, where protein concentration was low, was virtually the same as that measured on the dextran chip using the fusion protein at a much higher concentration.

The second demonstration of the enhanced sensing capabilities of the NTA-SAM chip was in detecting the interaction of yeast polymerase II with TFIIF (Bushnell et al., 1996), which had not been detectable by SPR with standard dextran chips. A third example of the superiority of monolayer-based SPR chips was the detection of the interaction between TFIIE and polymerase II using the NTA-SAM (Bushnell et al., 1996). The interaction could not be detected using standard dextran chips, presumably because of the size of the protein complexes and related diffusion problems.

To measure the sensitivity of this method, side-by-side experiments were performed comparing dextran chips to NTA-SAMs; a chimeric T-cell receptor (TCR) was probed with two monoclonal antibodies (Sigal et al., 1996). One antibody recognized a particular conformation of the protein; the other recognized a linear epitope. Although six-times more protein was attached to the dextran surface (because of the increased surface area) than to the two-dimensional NTA array, only an effective monolayer of protein on the dextran was accessible to incoming ligand; thus, the total amount of antibody that bound to each surface was identical. The ratio of the conformationally sensitive antibody to the linear epitope-antibody that bound to each TCR-derivatized surface showed that five-times more protein remained in the active conformation when it was attached to the NTA-SAM than when attached to dextran.

In addition to increased sensitivity, NTA-SAMs offer increased experimental simplicity. Because there are a finite and approximately constant number of NTA ligands on every NTA-SAM, the determination of optimal immobilization conditions (e.g., protein pH or concentration) or regeneration conditions is not necessary. For example, maximal NTA occupancy on 5% NTA-SAMs is virtually constant

and is easily achieved by injecting 25 μ l of a 25-kD protein at a concentration of 3 mg/ml; higher injection concentrations will not alter the amount of protein presented. At 3% to 5% NTA, rebinding events are minimal so there is no need to experimentally determine the ligand concentration that will minimize rebinding in order to reflect a true off-rate. It is not necessary to check for artifacts stemming from an attraction to the chip surface by performing reciprocal experiments (reverse configuration) since the NTA-SAM has been shown to be highly resistant to nonspecific binding of all proteins tested including TBP.

An NTA SPR chip for the attachment of histidine-tagged proteins is now commercially available from BIAcore, but importantly the NTA ligands are attached to dextran (Gershon and Khilko, 1995), not incorporated into a monolayer. Noncovalent coupling of the protein of interest to the dextran support is an advantage because the chemical treatment used to promote covalent coupling denatures a significant portion of the protein. However, the chip still suffers from other problems intrinsic to dextran: high background charge, random orientation of the active site relative to analyte flow, and turbulent flow dynamics with a large static layer. Moreover, this chip may introduce a new experimental artifact, which was encountered when this approach was experimented with in 1994 (Bamdad and colleagues; unpub. observ.). The NTA group chelates a Ni(II) atom in a very-high-affinity interaction. However, the disordered nature of the dextran may position two NTA groups such that two ligands simultaneously coordinate one Ni(II) atom, which is much more unstable: subtle changes in pH and protein addition could trigger rearrangements that would act to crosslink the dextran and alter its optical response, thus mimicking protein binding.

Expanded applications with NTA-SAMs

It is likely that monolayer chips will find wide use. This is because biological systems often consist of networks of proteins that interact with each other. For example, it now appears that the active transcription complex may consist of some thirty proteins (Kim et al., 1994; Koleske and Young, 1994). Future research may be increasingly focused on the study of proteins interacting with *complexes* of proteins. The nonuniform surface of dextran can interfere with the entry of large protein complexes into the matrix, whereas monolayers provide near laminar flow dynamics that allow

for the characterization of interactions between large protein complexes. On dextran, the stoichiometry of interactions between a protein in solution and an evolving protein complex assembling on the chip may not be possible, as the interstices of dextran would render variable amounts of the complex accessible at each stage.

Another problem of great interest to biologists is the study of interactions where one or more of the partners is a membrane-associated protein. Plant et al. (1995) reported the development of a lipid bilayer chip for use in SPR instruments. Hydrophobic forces caused the spontaneous attachment of a phospholipid layer to a SAM comprised of hydrophobic alkyl thiolates. The work demonstrated the feasibility of using this approach to study interactions between components that are not water soluble: cell-surface receptor-ligand binding, protein-membrane interactions, and cell-cell associations. Unfortunately, this chip has not yet been made commercially available.

Many protein-protein interactions take place when one or both proteins are bound to DNA. The only method commercially available for the study of these interactions by SPR derivatizes dextran with streptavidin and then attaches it to biotinylated DNA. DNA-binding proteins can then be bound to the presented oligonucleotides for subsequent interaction studies with analytes in solution. These studies are subject to artifacts intrinsic to the dextran-based immobilization methods. A DNA-SAM was recently developed (Bamdad, 1997a) that presents single-stranded DNA above a background of inert alkane thiolates. Double-stranded DNA was hybridized to this surface via a complimentary single stranded "tail". The method was specific for the desired DNA, accepted unmodified bacterially produced DNA, and can easily be extended to present mass arrays of heterogeneous oligonucleotides. The sense strand of the hybridized double-stranded DNA was attached to the surface by an enzyme reaction leaving the antisense strand dissociable by heat treatment. Endonuclease digestion of hybridized DNA would generate a universal acceptor surface for ligation of sample DNA cut with the same enzyme.

Caveats and additional control experiments

Obtaining reliable results from SPR experiments requires careful attention to experimental design. To optimize the veracity of SPR-obtained results, experimental techniques must be designed to minimize systematic artifacts. The

BIAcore handbook is instructive for designing a preliminary set of SPR experiments, but the following additional experiments are well advised.

Once a set of experiments has been analyzed and kinetic rate constants obtained, the user should verify that the calculated rates are approximately correct using some simple experiments. For example, analyte injected at a concentration equal to the BIAcore-calculated k_d should give rise to approximately half-maximal binding, in RUs. Similarly, if the protein in solution (at a concentration capable of eliciting maximal binding) is incubated (competitive inhibition) with ligand at a concentration equal to the calculated k_d , and is then injected over immobilized ligand, approximately half-maximal binding should result. The kinetics of an interaction should be independent of the experimental configuration. To identify artifacts in the *apparent* kinetics of an interaction, a reciprocal experiment should be performed in which the protein in solution (the analyte) is immobilized as the ligand, and the previously immobilized protein becomes the analyte in solution. Performing the experiment in reverse configuration should result in comparable rate measurements. On dextran chips, discrepancies in reciprocal rates may be an indication of an interaction in which diffusion into the dextran, rather than association, is the rate-limiting step. Since diffusion into the dextran matrix is a function of the protein's size and charge, use the rate that is obtained when the smaller or less-charged of the two proteins is used as the analyte. Verification must be done using another method.

If a higher-order interaction is suspected, additional experiments should be designed to directly prove or disprove higher-order binding models, such as dimerization dependence (see Anticipated Results discussion on Kinetics analysis and higher-order kinetics).

It is also useful to repeat binding experiments using genetic variants of one or both of the interacting proteins, particularly variants whose *in vivo* activities are known. Reduced-activity mutants often display differential affinities for functionally relevant target molecules. A panel of mutants possessing a range of *in vivo* activities would provide for excellent control experiments.

Recall that SPR only detects the mass of a species near the interfacial region of the instrument, so the nonspecific binding of a few protein aggregates cannot be distinguished from multiple 1:1 binding events. One must there-

fore be rigorous about protein homogeneity. HPLC purification or centrifugation just prior to the experiment is recommended to rid the preparations of aggregates. Inaccuracies in measured binding constants can arise from discrepancies in the assessment of the *active* concentration of protein components. If the active concentration of one of the binding partners can be adequately assessed, that protein should be used as the analyte, since only the concentration of the analyte enters into the BIAcore kinetic equations. This minimizes problems associated with protein preparation heterogeneity.

Anticipated Results

Rate and equilibrium constants

The measured rate of dissociation should be a constant and independent of the concentration of either the surface density of the ligand or the analyte in solution. A dissociation rate that decreases as the ligand density increases indicates that dissociating molecules are rebinding to nearby sites. The ligand density should be optimized to produce a surface presenting enough molecules to elicit a clear binding response yet dilute enough to measure a dissociation rate constant that is constant. When extracting a dissociation rate from sensorgrams, choose time periods early in the dissociation phase to help eliminate rebinding events.

The measured rate of association for a particular reaction should also be constant. However, if the rate of diffusion into the disordered dextran polymer is slower than the rate of association with the immobilized ligand, then the measurable parameter will be the diffusion rate, not the association rate. Because the diffusion rate is a function of the size of the protein in solution, the flow rate, and the size of the surface irregularities, it may not be possible to measure the true association rate between large analyte proteins (or protein complexes) and ligands immobilized on dextran.

The accuracy of SPR measurements critically hinges on the stringency of the experimental design. For a ball-park estimate of the range of the equilibrium constant, determine the analyte concentrations that give rise to both maximal and minimal binding to a ligand surface. To a first approximation, the equilibrium constant should be the mean of the two concentrations. If an absolute kinetic rate is desired (i.e., one that is comparable to a solution measurement rather than a rank ordering of affinities), obtain an IC_{50} by performing a series of competitive inhibition experiments.

Kinetics analysis and higher-order kinetics

The BIAcore instrument comes with user-friendly kinetic evaluation software (modeled after the analysis described in O'Shannessy et al., 1993) that is now adequate to address simple first-order binding reactions. However, it may not be accurate for higher-order reactions. Others have developed more rigorous software for the kinetic analysis of BIAcore-derived data that uses numerical methods analysis and global fit programs (Fisher et al., 1994; Myszka, 1997). Fisher and Fivash (1994) have done considerable mathematical modeling of higher-order reactions that are then compared to experimental binding curves using a Cray supercomputer and their global fit analysis software. Less rigorous inferences of higher-order reactions based on curve-matching analysis of single experiments is risky. Additionally, over-analyzing data is less reliable than performing experiments designed to test a specific higher-order binding model.

Experimental confirmation of a theorized higher-order binding model was recently accomplished using variable-density NTA-SAMs

with SPR (Bamdad, 1997b). The concentration of NTA-terminated thiol was varied from 3% to 11% relative to an inert alkane thiol (the major component), producing a panel of SPR chips capable of presenting His-tagged peptides in variable-density arrays. It had previously been shown that four or more tandem repeats of an eight-amino acid motif could stimulate transcription *in vivo* and bind to the transcription factor TATA box-binding protein (TBP) *in vitro* (Tanaka, 1996). His-tagged peptides comprised of only two tandem repeats of the same motif were separately immobilized on NTA-SAMs of various density. BIAcore experiments showed that the peptides immobilized on low-density monolayers (3.8% NTA) were not able to bind TBP from solution. However, when the average distance between the peptides was decreased by immobilization on higher-density monolayers (5.7% NTA), a high-affinity interaction (20 nM) resulted (see Fig. 20.4.2). The complete study indicated that this observation resulted from the significant kinetic difference between monovalent and bivalent binding of the target protein, TBP. Com-

Figure 20.4.2 BIAcore sensorgram showing that binding of hTBP_c in solution to peptide motif surfaces is dependent upon density of ligand immobilization. The BIAcore SPR instrument plots changes in the angle of minimum reflectance in resonance units (RUs) as a function of time. The “square waves” represent injections of protein “plugs” that interrupt the constant buffer flow. The net change in measured RUs following a protein plug injection (arrows) indicates binding and can be correlated to a mass of protein recruited to the surface. An association constant can be derived from analysis of the initial phase of the injection, and a dissociation rate can be extracted from analysis of the system as it returns to buffer flow. Histidine-tagged fusion proteins terminated with the desired recognition motif were separately immobilized on NTA-SAMs presenting 3.8% (dashed line) or 5.7% NTA (solid line). hTBP_c in solution was injected over the surfaces in two separate experiments. An overlay of the two resultant SPR sensorgrams shows that hTBP_c cannot bind ($\Delta 5$ RUs; arrowhead) to the repeats when they are immobilized at low density (3.8% NTA; average distance = 29 Å), but bind very tightly ($\Delta 550$ RUs; arrowhead) when the peptides are positioned closer together at a higher density (5.7% NTA; average distance = 23 Å).

petitive inhibition experiments involving peptides either two or four repeats long demonstrated that there was a 250-fold difference in affinity between the two binding modes. The average distance between peptides on the chip surface, which presumably represents the distance between binding sites on TBP, was extrapolated from a statistical analysis of the lowest peptide density that elicited a large increase in target affinity. This analysis enabled the discrimination between three possible mechanistic models describing how reiterated repeats could synergistically effect the general transcription factor.

Despite the advantages presented by the ability to perform SPR experiments on a monolayer surface, it is still possible that experiments on these surfaces reflect interactions that differ significantly from those in solution due to local concentration effects and/or differences between two- and three-dimensional diffusion. A solution measurement, the IC_{50} , can be generated from a series of competitive inhibition experiments where the analyte is preincubated with varying concentrations of the ligand prior to injection of the mix over ligand-immobilized surfaces. In the above experiments, such an analysis revealed that the surface interaction was 20 times tighter than the comparable solution interaction.

Time Considerations

The major time factor in performing SPR experiments is in working out the appropriate conditions and experimental design, which can take weeks or even months. A single binding assay can be carried out in 5 to 10 min per injection. Using NTA-SAM chips, a set of experiments using three protein concentrations can be performed in 2 to 3 hr. However, to perform the same experiments with a dextran chip, it is likely to take several days to work out parameters such as the appropriate binding conditions and regeneration conditions.

Detection of Protein-Protein Interactions by Coprecipitation

Coprecipitation of proteins from whole-cell extracts is a valuable approach to test for physical interactions between proteins of interest. When a precipitating antibody is used, this method is referred to as co-immunoprecipitation. Coprecipitation can be used to study interactions between known proteins under a variety of conditions and as a means of identifying components of a complex. Coprecipitation may be the single method of choice, or may be used in combination with other methods that detect protein-protein interactions, such as two-hybrid analysis and copurification schemes (UNIT 20.1), and tests of physical associations using purified proteins.

This unit describes basic approaches to immunoprecipitating tagged proteins from whole-cell extracts. The approaches described can be adapted for other systems. In a typical experiment, as described here, cells are lysed and a whole-cell extract is prepared under nondenaturing conditions (see Strategic Planning). The protein is precipitated from the lysate with a solid-phase affinity matrix, and the precipitate is tested for the presence of a second specifically associated protein (see Basic Protocol and Alternate Protocol). The approach can be used for native or epitope-tagged proteins for which antibodies are available, or for recombinant proteins that have been engineered to bind with high affinity to a molecule that can be coupled to a solid-phase matrix (see Strategic Planning). The presence of an associated protein is detected by separating the precipitated proteins by SDS-PAGE (UNIT 10.2A) and then immunoblotting (UNIT 10.8) with a second antibody that recognizes the putative associated protein. Controls to test specificity of interaction are crucial (see Strategic Planning).

For additional background reading, the user should consult UNIT 10.16 for a theoretical discussion of immunoprecipitation; see Chapter 11 for principles of antibody production and immunoassays; see UNITS 10.15, 20.2 & 20.3 for approaches to tagging proteins; and see Chapter 13 for transformation and propagation of *S. cerevisiae*. For an in-depth review of immunoprecipitation techniques, see Harlow and Lane (1988). For an in-depth review of coprecipitation and other approaches to detect protein-protein interactions, see Phizicky and Fields (1995), Toby and Golemis (2001), Auerbach et al. (2002), and Gavin and Superti-Ferga (2003).

STRATEGIC PLANNING

Detecting the Proteins in Question

The first step is to generate reagents that detect the two proteins in the coprecipitate under nondenaturing conditions. If antibodies are available that can immunoprecipitate the proteins under nondenaturing conditions, then they can be used. Alternatively, the proteins can be differentially tagged in a variety of ways to allow their detection with commercially available antibodies or other affinity reagents. The tagged proteins are then introduced into the host organism using expression vectors. All tagged proteins must be assessed for function in vivo.

A frequently used option is to add a short peptide or epitope that is recognized by a commercially available high-affinity monoclonal antibody (mAb; UNIT 10.15). The epitope is typically added at the amino or carboxyl terminus, although internal positions that do not disrupt function can also be used. Two frequently used epitopes are derived from influenza hemagglutinin protein (HA) and human c-Myc and are recognized by

high-affinity mAbs (12CA5 and 9E10, respectively; Kolodziej and Young, 1991). Others such as FLAG, the leader peptide of the gene 10 product of bacteriophage T7 (Knappik and Pluckthun, 1994; Witzgall et al., 1994), are also available. The choice of epitope may be dictated by its amino acid composition. It is often useful to insert tandem copies of the epitope in order to increase sensitivity. The number of additional tandem copies can range widely from one (Field et al., 1988) to several (e.g., three; Tyers et al., 1993) to many (e.g., nine; Feng et al., 1998).

Proteins can also be fused to small proteins or peptides that have high affinity to small molecules that can be attached to a solid support. This is a particularly valuable approach when the protein to be precipitated comigrates with immunoglobulin heavy or light chains in an SDS-polyacrylamide gel. Such alternative tagging methods include fusion to glutathione-*S*-transferase (to allow purification by a glutathione affinity matrix; UNIT 16.7), maltose-binding protein (to allow purification by a maltose affinity matrix; UNIT 16.6), polyhistidine (to allow purification by nickel affinity matrix; Bornhorst and Falke, 2000), or strep-tag (to allow purification by streptavidin matrix; Skerra and Schmidt, 2005). Tandem affinity protein (TAP) tags made of two IgG-binding domains of *Staphylococcus aureus* protein A and a calmodulin-binding peptide separated by a TEV protease cleavage site (Puig et al., 2001) have also been successfully used to copurify proteins, especially in yeast (Gavin and Superti-Furga, 2003). Other TAP tags have been described, including a TAP tag of three tandem FLAG epitopes and six histidines that may be more efficient in some organisms (Yang et al., 2006). A reference for identifying sources of commercially available antibodies and vectors encoding various tags can be found in the BioSupplyNet Source Book (2005). See Chapter 11 and Harlow and Lane (1998) for the generation and purification of specific antibodies. The American Type Culture Collection (ATCC) and European Collection of Animal Cell Cultures can be sources for hybridoma cell lines. Numerous genomic coprecipitation and two-hybrid studies have been done in a variety of organisms, so it is wise to check available databases for the current repertoire of interactions for a particular protein (e.g., Gavin and Superti-Furga, 2003, lists a number of such studies). Useful summaries of protein-protein interactions along with references can be found at Proteome Bioknowledge Library (Biobase Biological Databases, <http://www.biobase.de>; formerly Proteome, Inc., a subsidiary of Incyte), which is available by institutional or individual subscription.

Preparing Whole-Cell Extracts

The second step in a successful coprecipitation is generating whole-cell extracts that optimize the yield and activity of the proteins to be analyzed, using lysis buffer conditions that permit recognition of the proteins by the affinity matrix. The yield of total protein in a whole-cell extract is not always a reliable indicator of the relative yield and activity of specific proteins, so it is wise to verify both parameters at the onset of an experiment before proceeding with the coprecipitation. Yield and activity can be affected by a number of factors (see Chapter 10; see Harlow and Lane, 1988). Small variations in the relative amounts of salt and detergents in the lysis buffer can have large effects on yield and activity, as can the speed and efficiency of cell breakage. Both factors are particularly important for less soluble proteins that associate with macromolecular structures such as membranes or cytoskeleton. In addition, global inhibition of proteolysis through the inclusion of multiple classes of protease inhibitors may be essential.

Methods for preparing whole-cell extracts from yeast (UNIT 13.13), *E. coli* (UNITS 16.1-16.8), insect cells (UNIT 16.11), and mammalian cells (UNITS 16.12-16.18) can be found elsewhere in this manual, and specifics will not be discussed here. In general, the lysis buffer conditions are not very different from the coprecipitation conditions. It is recommended that the investigator begin by comparing small-scale extract preparations that vary the

amount of salt and nonionic detergent. As a starting point, a basic lysis buffer might contain the following components.

Basic components. Basic components include a buffering agent (such as 50 mM Tris-Cl, pH 7.5), a small amount of nonionic detergent (such as 0.1% [v/v] Triton X-100), salt (such as 100 mM NaCl), a reducing agent (such as 1 mM DTT), and 10% (v/v) glycerol as stabilizer.

Protease inhibitors. Protease inhibitor cocktails are described in *UNIT 13.13* and are also commercially available. A reasonable starting point would be to include 5 $\mu\text{g/ml}$ each chymostatin, pepstatin A, leupeptin, and antipain, as well as 1 mM phenylmethanesulfonyl fluoride and 1 mM benzamide.

Chelating agents. EGTA (~ 15 mM) is commonly included to chelate divalent metal ions that are essential for metalloprotease activity. Because EGTA also inhibits other metal-dependent enzymes, it may be omitted, combined with the addition of a needed metal ion, and/or substituted with EDTA.

Phosphatase inhibitors. If the phosphorylation state of the proteins in question is important, a mixture of phosphatase inhibitors should also be included in the lysis buffer. A starting mixture could contain 2.5 mM each meta- and ortho-vanadate, 10 mM NaF, and 10 mM β -glycerol phosphate.

Simple modifications of this initial buffer include varying the amount of NaCl (from 0 to 500 mM) and of Triton X-100 (from 0% to 1%). The investigator may choose to compare different means of breaking the cells (for example, glass-bead breakage versus liquid nitrogen/grinding methods for yeast cells; *UNIT 13.13*).

Total protein concentration in the whole-cell extract is generally assayed by using the Bio-Rad protein assay and calculating protein concentration (*UNIT 10.1A*). Extracts should be tested for the amount of each specific protein by immunoblot analysis (*UNIT 10.8*), analyzing 25 to 75 μg of total protein. In general, it is best to test for the presence of a second established protein (such as a housekeeping enzyme, cytoskeletal or ribosomal protein, or a previously defined component in the pathway being studied) as an internal control for normalization and as a positive control for the immunoblot. The amount of specific protein in the whole-cell extract is compared to the amount that is recovered by precipitation with an affinity matrix.

Control Tests for Specificity of Interaction

Controls are essential to verify that the antibodies and protein-protein interactions are specific. Proper controls are simplest to set up when the proteins are differentially tagged. In this instance, two parallel extracts are prepared from strains that contain each protein lacking the tag in the presence of the second tagged protein. An example is shown in the idealized gel in Figure 20.5.1, which includes lanes containing untagged protein 1 + tagged protein 2 and tagged protein 1 + untagged protein 2. If the antibodies are specific, untagged protein 1 will not immunoprecipitate. The presence of untagged protein 1 in the immunoprecipitate will indicate that it binds the affinity matrix nonspecifically. If the interaction between proteins 1 and 2 is specific, then tagged protein 2 will be present in the immunoprecipitate of tagged protein 1, but not in its absence.

If antibodies to native proteins are used, it is necessary to compare extracts made from strains harboring deletions of the proteins in question to test for the specificity of the antibody and the interaction. However, this is obviously possible only if the deletions do not cause inviability. If deletion mutations cannot be used, a common approach is to show that the preimmune serum or an antibody not known to be specific to either of

the proteins in question does not coprecipitate them in a parallel experiment. However, the latter two controls do not rule out the possibility that the antibody is precipitating the protein in question through an indirect association.

It is also essential to compare the amount of coprecipitated protein with the amounts of the two proteins in question in the whole-cell extract. This allows one to determine whether apparent differences in the ability of the two proteins to coprecipitate are a secondary consequence of the relative abundance of the proteins. This control is particularly important when an interaction has been established and the investigator wishes to search for regulatory changes in association apart from changes in abundance.

Figure 20.5.1 Flowchart for the coprecipitation of two proteins that have been differentially tagged and introduced into the host organism. Ig h and Ig l, immunoglobulin heavy and light chains; NT, no tag.

COPRECIPITATING PROTEINS WITH PROTEIN A/G–SEPHAROSE

Once the conditions of extract preparation have been established (see Strategic Planning), the next step is to test for coprecipitation of the specific proteins. This protocol describes a standard coprecipitation procedure that uses an antibody coupled to protein A–Sepharose or protein G–Sepharose. An alternative coprecipitation method that uses GST coupled to glutathione-agarose is also provided (see Alternate Protocol). It is essential to keep all buffers and tubes cold by using an ice bath and a refrigerated centrifuge. The conditions of coprecipitation match the conditions of the lysis buffer described above.

Materials

Whole-cell extract (see Strategic Planning)
Antibody against protein or epitope of interest
5 M NaCl
Co-immunoprecipitation buffer (see recipe)
Protein A/G–Sepharose slurry (see recipe)
2× sample buffer for SDS-PAGE (UNIT 10.2A)
Test tube rotator
20-ml syringe and 18-G needle
Hamilton syringe
Additional reagents and equipment for SDS-PAGE (UNIT 10.2A) and immunoblotting (UNIT 10.8)

1. Prepare duplicate samples in microcentrifuge tubes on ice:

0.5 to 1 mg whole-cell extract
1 μg antibody
5 M NaCl to equalize at 100 mM NaCl
Co-immunoprecipitation buffer to 0.5 ml final volume.

Adjust buffer by adding a divalent cation if necessary for activity of the protein in question (see Strategic Planning).

2. Invert tube gently several times and incubate on ice for 90 min with occasional tube inversion.

It is recommended that the investigator begin with a 90-min incubation. However, this incubation step can be shortened or lengthened.

3. Microcentrifuge 10 min at maximum speed, 4°C, to pellet nonspecific aggregates. Transfer supernatant to a new microcentrifuge tube.**4. Add 50 μl of protein A– or protein G–Sepharose slurry (25 to 30 μl bead volume). Be sure to evenly suspend the slurry before distributing it to the samples.**

Protein A has been used more frequently for historical reasons; however, protein G binds a broader range of Ig subtypes at higher efficiency. See UNIT 11.11 for a description of their relative binding capacities.

5. Rotate tube gently at 4°C for 30 to 60 min.

Rocking is much less efficient and should be avoided.

6. Gently pellet protein A/G–Sepharose by centrifuging 30 sec at 1000 rpm in a tabletop centrifuge, 4°C.

7. Wash pellet three times with 1 ml co-immunoprecipitation buffer. For each wash, gently invert tube three times before pelleting. After each pelleting, use a 20-ml syringe with an 18-G needle to aspirate and remove supernatant.

It may be possible to omit the costly protease inhibitors from the buffer at this stage.

8. Aspirate as much liquid as possible from the final without touching the beads and add 25 μ l of 2 \times sample buffer.

If desired, samples containing sample buffer can be frozen up to several months at -80°C prior to SDS-PAGE. In this case the buffer should be prepared with sterile stock solutions and made with 1 mM sodium azide included.

9. Prepare for SDS-PAGE analysis by boiling for 5 min, vortexing, and microcentrifuging briefly to pellet beads. Use a Hamilton syringe to load eluates onto an SDS-polyacrylamide gel, arranging duplicate samples to allow preparation of duplicate blots. Separate by electrophoresis (UNIT 10.2A).

A Hamilton syringe works well to remove the eluate from the beads during loading.

10. Immunoblot duplicate samples separately with antibodies for each of the two proteins (UNIT 10.8). Be sure to include aliquots of the whole-cell extract for comparison and as a positive control for the immunoblot.

Each immunoblot can be reprobed with the antibody to the other protein.

ALTERNATE PROTOCOL

COPRECIPTATING A GST FUSION PROTEIN

GST fusion proteins may be coprecipitated by following the co-immunoprecipitation procedure (see Basic Protocol) with the modifications outlined below. This procedure might be used when the protein in question comigrates with immunoglobulin heavy or light chain in an SDS-PAGE gel or if the antibodies being used precipitate too many cross-reacting proteins, such as the protein being tested for association. Furthermore, it is possible to dissociate the purified GST fusion from the solid-state glutathione resin under gentle conditions through the use of imidazole. The approach is also useful in that it will increase the size of the protein sufficiently that this size increase can be used as a diagnostic feature in analyzing complexes.

Additional Materials (also see Basic Protocol)

Glutathione-agarose or glutathione-Sepharose slurry (see recipe)

1. Prepare duplicate samples as described for protein A/G-Sepharose (see Basic Protocol, step 1), omitting antibody.
2. Microcentrifuge 10 min at maximum speed, 4°C , to pellet nonspecific aggregates. Transfer supernatant to new microcentrifuge tube.
3. Add 30 μ l glutathione-agarose or glutathione-Sepharose slurry (25- to 30- μ l bead volume). Be sure to evenly suspend the slurry before distributing it to the samples.
4. Rotate the sample, pellet and wash glutathione-agarose/Sepharose, and perform SDS-PAGE and immunoblot analysis (see Basic Protocol, steps 5 to 10).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Co-immunoprecipitation buffer

50 mM Tris·Cl, pH 7.5 (APPENDIX 2)

15 mM EGTA

100 mM NaCl

0.1% (w/v) Triton X-100

Store at 4°C

Immediately before use add:

1× protease inhibitor mix (see recipe)

1 mM dithiothreitol (DTT)

1 mM phenylmethylsulfonyl fluoride (PMSF; from fresh 250 mM solution in 95% ethanol)

If necessary for activity of the protein of interest, a divalent cation may need to be included in the buffer and EGTA omitted (as for extraction buffer; see Strategic Planning).

The protease inhibitor mix, PMSF, and DTT should be added fresh at the time of experimentation. The mixture without those components can be stored for months at 4°C with the addition of 1 mM sodium azide. PMSF is labile in aqueous buffer and should be added at the last minute. Protease inhibitor cocktails are also commercially available.

Since many protein-protein interactions are dependent upon phosphorylation, it may be necessary to include phosphatase inhibitors in the whole-cell extracts and the co-immunoprecipitation buffer phosphatase inhibitor solutions. A starting mix is 0.5 mM vanadate (0.25 mM each meta- and ortho-vanadate or 0.5 mM sodium vanadate, pH 7.4), 10 mM sodium fluoride (NaF), and 10 mM β-glycerol phosphate.

Glutathione-agarose or glutathione-Sepharose slurry

Swell 1.5 g glutathione-agarose or glutathione-Sepharose beads (e.g., Pierce, Sigma) in 30 ml of 50 mM Tris·Cl, pH 7.5 (APPENDIX 2), for 1 to 2 hr on ice. Pellet beads by gravity or very gentle centrifugation (1 min at 1000 rpm in a tabletop centrifuge) and then wash four times with co-immunoprecipitation buffer (see recipe) that lacks protease inhibitor mix and contains 1 mM sodium azide. Resuspend beads in 15 ml of this buffer to yield a final slurry concentration of ~100 mg/ml. Store at 4°C (stable for months).

This recipe can be scaled up or down.

Protease inhibitor mix, 1000×

Dissolve in DMSO:

5 mg/ml chymostatin

5 mg/ml pepstatin A

5 mg/ml leupeptin

5 mg/ml antipain

Store in aliquots up to 1 year at –20°C

Protein A/G–Sepharose slurry

Swell 1.5 g protein A– or protein G–Sepharose beads (e.g., Pierce, Sigma) in 30 ml of 50 mM Tris·Cl, pH 7.5 (APPENDIX 2), for 1 to 2 hr on ice. Pellet beads by gravity or very gentle centrifugation (1 min at 1000 rpm in a tabletop centrifuge) and then wash four times with co-immunoprecipitation buffer (see recipe) that lacks protease inhibitor mix and contains 1 mM sodium azide. Resuspend beads in 15 ml of this buffer to yield a final slurry concentration of ~100 mg/ml. Store at 4°C (stable for months).

This recipe can be scaled up or down.

COMMENTARY

Background Information

Coprecipitation is a powerful and simple approach to test for a physical interaction between proteins. There are many reasons to incorporate coprecipitation into a study. First, as a form of protein affinity chromatography, the method may be sensitive enough to detect weak associations that do not withstand the rigors of standard purification methods involving substantial dilution of the initial cell extract. Second, coprecipitation tests for associations between proteins within the milieu of a whole-cell extract, where the proteins are present at native concentration in a complex mixture of other cellular components. This feature makes it an important partner to two-hybrid methods and direct tests of interactions using purified proteins, because it provides a way to verify that a positive interaction reflects a true *in vivo* association. For example, nonphysiological interactions can be detected when purified proteins are present at too elevated a concentration. A falsely positive interaction between two proteins can also arise in a two-hybrid test when protein domains are inappropriately exposed due to altered folding. In addition, not all proteins are amenable to two-hybrid analysis; a negative result may mask a true association.

Nevertheless, a word of caution is in order. The ability to coprecipitate two proteins from a cellular extract is not proof that a particular interaction normally takes place *in vivo*. Additional experiments are needed to argue that a given interaction is not the result of mixing cell contents during extract preparation. Such evidence could include colocalization of the proteins or demonstration of functional relatedness.

When performing coprecipitation, it is important to precipitate from both directions (i.e., individually precipitating protein 1 and protein 2, and testing for the presence of protein 2 and protein 1, respectively). This is important in that it can provide further verification of an interaction between the proteins. It is also important because it is possible the interaction will only be detected in one direction. An inability to detect an interaction in one direction could be due to a variety of factors including obstruction of an interaction by the binding of the antibody or other affinity agent, or differences in pool size representation of each protein. For example, protein 1 may bind to many proteins besides protein 2, while most of protein 2 binds to protein 1. In this sce-

nario, it would be anticipated that detection of their association will be most efficient when protein 2 is precipitated.

Critical Parameters and Troubleshooting

Two important factors in determining how well an immunoprecipitation will work are the affinity of the antibody for the antigenic site on the protein (or the affinity of the protein tag for the affinity matrix) and the yield of the relevant proteins in the extract. For efficient immunoprecipitation, the antibody should have an affinity to the antigen in the range of 10^7 to 10^9 M^{-1} (Harlow and Lane, 1998). The easiest way to enhance detection of the immune complex is to increase the concentration of antibody and the protein being immunoprecipitated, as long as the concentration of antibody is not already saturating. This can be determined empirically. A starting point is 1 μ g antibody (Harlow and Lane, 1998), which is typically 0.5 to 1 μ l of a polyclonal antiserum, \sim 50 μ l of a hybridoma culture supernatant, or \sim 0.5 ml of ascites fluid. The reaction volume of the immunoprecipitation can be reduced to increase the concentration of the protein along with optimization of the extracts (see below). With protein tagging, it is possible to increase the number of copies of the moiety being bound by affinity matrix as a means of improving detection.

It is important to vary conditions of both the extract preparation and the coprecipitation to determine the optimal conditions. When starting from scratch, it is most prudent to use a range of lysis and precipitation conditions ranging from less to more stringent in terms of the amount of salt and non-ionic detergent to determine which conditions give the best yield of the desired proteins. When no interaction is detected, it is worthwhile to use less stringent conditions (reduced salt and nonionic detergent). In addition, it may be necessary to avoid any dilution of the whole-cell extract. This can be done by adding the protein A/G–Sepharose directly to the extract after an initial clarification centrifugation and by using smaller wash volumes. Depending on the strength and nature of the interaction, the precipitation can be performed in the presence of a mixture of detergents that includes ionic detergents (for example, 1% Triton X-100, 0.5% deoxycholate, 0.1% SDS).

In addition, it may be necessary to increase the expression levels of the proteins in question

in order to detect them readily by coprecipitation. A range of expression levels is recommended, because a level that is too high can lead to unregulated interactions (Feng et al., 1998). One can scale up the coprecipitation to at least 2 mg of whole-cell extract in the described assay (Wang et al., 2005); a starting point is 0.25 to 1 mg. Here, the limiting factor is the concentration of the extracts, which must be high enough to allow the volume of the coprecipitation mixture to remain low. Larger-scale extract preparations may be necessary to generate more concentrated extracts. Finally, in cases of failure due to low abundance of the proteins in the host organism, one can overexpress a tagged version of one of the two proteins in the same or another host (such as *E. coli*), concentrate this protein by pre-immobilization on an appropriate affinity matrix, and then incubate the affixed protein with extracts from the host organism.

The most important objective in these experiments is to generate as great a signal-to-noise ratio as possible and avoid problems of background. A variety of parameters can be changed to enhance the co-immunoprecipitation. Optimization of the precipitating antibody is one possibility. Protein A–Sepharose and protein G–Sepharose should give results comparable to anti-Ig serum. However, direct coupling of the antibody to Sepharose may lead to reduced background and more quantitative precipitation. In addition, varying the ratio of antibody to whole-cell extract and the total amount of whole-cell extract is strongly suggested to determine the optimal amount of antibody that gives the most precipitation with the least amount of background. Affinity purification of the antibody may be necessary if the antibody immunoprecipitates additional cross-reacting proteins.

Additional approaches can be taken to minimize background. First, better clarification of the cell extract can be achieved by precentrifugation at $100,000 \times g$. These extracts can be directly used for coprecipitation without an intervening freezing step, which can increase the amount of protein precipitation. Second, both the lysis buffer and the coprecipitation buffer can be supplemented with 1% BSA to reduce nonspecific binding to the affinity matrix. Third, the whole-cell extract can be preincubated with protein A/G–Sepharose to remove nonspecific proteins that bind to the solid support. Fourth, the amount of salt and detergent can be increased in both the coprecipitation and the washes to reduce nonspecific binding. Fifth, increasing the number of

washes may also help, although it may reduce the amount of specific protein that remains associated. Sixth, the expression levels of the proteins in question can be increased to generate a stronger signal that is above background binding. Alternatively, it may be possible to produce a whole-cell extract that is enriched for the proteins in question (e.g., by preparing a nuclear extract if the proteins are known to be in the nucleus). In instances where one of the proteins binds nonspecifically to Sepharose, the substitution of an agarose-based affinity matrix may help solve the problem. Finally, it may be necessary to generate a different set of reagents to precipitate the proteins in question (i.e., different antibodies and/or protein tag).

Anticipated Results

Provided suitable antibodies are available to the proteins in question and the physical interaction is stable under the coprecipitation conditions, it should be possible to detect an interaction between two proteins. This method can be scaled up to coprecipitate sufficient protein to allow detection in a polyacrylamide gel either by silver stain (~ 1 to 10 ng/band) or Coomassie blue stain (~ 0.1 to 1 mg/band), with subsequent excision of the band from the gel and identification by mass spectrometry.

Time Considerations

Once the extracts are prepared, coprecipitation can be done within 3 to 4 hr, yielding samples ready to load on a gel for SDS-PAGE and immunoblot analysis. It is possible to freeze the prepared extracts and thaw them on ice prior to setting up the coprecipitation, but higher yields may be obtained with samples that have not been frozen.

Identification of Protein Interactions by Far Western Analysis

UNIT 20.6

This unit describes far western blotting, a method of identifying protein-protein interactions. In a far western blot, one protein of interest is immobilized on a solid support membrane, then probed with a non-antibody protein. Far western blots can be used to identify specific interacting proteins in a complex mixture of proteins (see Basic Protocol). They are particularly useful for examining interactions between proteins that are difficult to analyze by other methods due to solubility problems or because they are difficult to express in cells. This method is performed totally *in vitro*, and the proteins of interest can be prepared in a variety of ways. Peptides can be used to determine the effects of specific residues or post-translational modifications on protein-protein interactions (see Alternate Protocol 2). In addition, many different detection techniques, either radioactive or nonradioactive, can be used. For example, the protein probe may be detected indirectly with an antibody, rather than being labeled radioactively (see Alternate Protocol 1). Thus, techniques and reagents already in hand can frequently be adapted for use with this assay.

CAUTION: Appropriate safety precautions must be taken when working with radioactive materials. Information on proper handling and disposal of radioactive compounds can be found in *APPENDIX 3A* and may be obtained from local radiation safety officials. Specific information on handling ^{35}S -labeled compounds can be found in *UNIT 10.18*.

FAR WESTERN ANALYSIS OF A PROTEIN MIXTURE

The following is a basic method for detecting protein-protein interactions by far western blotting when one protein is contained within a simple or complex mixture of proteins. First, the protein sample is fractionated on an SDS-PAGE gel (*UNIT 10.2A*). After electrophoresis, the proteins are transferred from the gels onto a solid support membrane by electroblotting (*UNIT 10.8*). Transferred membranes may be stained with Ponceau S to facilitate location and identification of specific proteins. Nonspecific sites on the membranes are blocked with standard blocking reagents, and the membranes are then incubated with a radiolabeled non-antibody protein probe. After washing, proteins that bind to the probe are detected by autoradiography (*APPENDIX 3A*).

Materials

- Samples to be analyzed
- 1× SDS sample buffer (*UNIT 10.2A*)
- Ponceau S staining solution (see recipe)
- Blocking buffer I: 0.05% (w/v) Tween 20 in 1× PBS (see recipe for PBS); prepare fresh
- Blocking buffer II: dissolve 1 g bovine serum albumin (BSA; fraction V) in 100 ml 1× PBS (see recipe for PBS); prepare fresh
- Phosphate-buffered saline (PBS; see recipe), pH 7.9
- cDNA encoding protein of interest cloned into an *in vitro* expression vector
- In vitro* transcription/translation kit (Promega)
- 10 mCi/ml ^{35}S -methionine (1000 Ci/mmol)
- Probe purification buffer (see recipe)
- Probe dilution buffer (see recipe)

**BASIC
PROTOCOL**

**Analysis of
Protein
Interactions**

20.6.1

Polyvinylidene difluoride (PVDF) or nitrocellulose membrane for protein transfer
Microfiltration centrifuge columns (e.g., Gelman Nanosep, Pall Filtron, or
Millipore Microcon)

Additional reagents and equipment for SDS-PAGE (UNIT 10.2A), electrophoretic
transfer of proteins to a support membrane (UNIT 10.8), in vitro translation (UNIT
10.17), and autoradiography (APPENDIX 3A)

NOTE: Always handle support membranes with gloves or membrane forceps.

Prepare protein blot

1. Prepare the protein sample to be analyzed by resuspending it in 1× SDS sample buffer.

UNIT 10.2A gives instructions on preparation of samples and amount of samples to load. In general, ~50 to 100 μg can be loaded in each lane for a complex mixture of proteins. A smaller amount, i.e., 10 to 20 μg, is loaded for less complex protein samples. The amount loaded may also need to be adjusted for the size of gel. (Usually 30 μg/mm² loading surface can be resolved without smearing.)

2. Separate the samples on an SDS-polyacrylamide gel (UNIT 10.2A).
3. Transfer the proteins from the gel to a solid support membrane (e.g., PVDF or nitrocellulose) by semidry electroblotting (UNIT 10.8).

Either nitrocellulose or PVDF membranes can be used with good results. PVDF membranes are easier to handle and tend to give a slightly higher signal-to-noise ratio, probably due to increased protein retention by the membrane.

Stain with Ponceau S

4. After transfer, stain the membrane for 5 min in ~100 ml freshly diluted 1× Ponceau S staining solution. Stain the membrane in a plastic container large enough to hold the blot and use sufficient Ponceau S to cover the membrane completely.

This step is optional. When the protein samples consist of a few proteins, or when there are clearly visible bands that facilitate orientation of the blot, staining with Ponceau S can provide helpful landmarks. One can unequivocally identify interacting bands, mark the position of molecular weight standards, and trim away excess membrane more exactly.

5. Destain the membrane washing in several changes of deionized water until the proteins are clearly visible. Place light pencil marks adjacent to important protein bands to mark them for future reference. Trim away excess membrane.

The stain fades quickly so the marks must be placed immediately.

6. Destain an additional 5 min in water until the red staining fades.

Block membrane

7. Block blot for 2 hr in 200 ml blocking buffer I at room temperature with gentle agitation.
8. Decant and add 200 ml blocking buffer II. Incubate as in step 7.
9. Decant blocking buffer II and rinse the membrane briefly in 100 ml of 1× PBS.

At this point, the blot may be probed immediately or may be wrapped in plastic wrap and stored for up to 2 weeks at 4°C.

Prepare the probe

10. Following manufacturer's procedures, prepare a radiolabeled in vitro–translated probe of the protein of interest using ^{35}S methionine (also see UNIT 10.18).

The probe can be conveniently prepared during the blocking steps.

The authors routinely use the Promega TnT quick-coupled transcription/translation system for producing probes. For a small blot (e.g., $\leq 9 \times 9\text{-cm}$), one half of a standard in vitro transcription/translation reaction (i.e., 25 μl) is sufficient for the probe. For larger blots, an entire 50- μl reaction may be used. In the authors' laboratory it is considered essential that the transcription/translation lysate not be repeatedly frozen and thawed.

11. After translation, dilute the probe with 500 μl probe purification buffer, and purify by microcentrifuging 15 to 30 min at $10,000 \times g$, room temperature, in a microfiltration column. Save aliquots of the purified probe for analysis by SDS-PAGE (i.e., 2 μl), and for scintillation counting (i.e., 2 to 5 μl).

Check microfiltration column manufacturer's procedure for exact centrifugation times required by different columns. In practice, it is not always necessary to purify the probe through a microfiltration column; many probes give good signals without purification. However, if signal-to-noise ratio is low, probe purification may improve results. In addition, it is possible to quantitate the proportion of probe bound if the probe has been purified.

Bind probe

12. Preincubate blot for 10 min in 50 ml of $1\times$ probe dilution buffer (without probe) by gently agitating at room temperature.
13. Dilute the translated probe with $1\times$ probe dilution buffer in a volume sufficient to cover the membrane to be probed (typically 3 ml).

For small blots, i.e., $\leq 9 \times 9\text{-cm}$, a 50-ml conical tube makes a convenient incubation chamber. A volume of 3 ml is enough solution to cover the blot and tubes can be rotated on a mechanical rotator. In addition, the conical tube makes the radiolabeled probe easy to contain and dispose of. Larger blots can be incubated on a Nutator or orbital shaker in a heat-sealable bag, or rotated in a hybridization oven adjusted to room temperature.

14. Add the probe to the membrane and incubate 2 hr at room temperature. Rotate the tubes or agitate bags throughout the binding reaction.

Wash the membrane

15. Transfer the membrane to a plastic dish and wash the membrane with 200 ml $1\times$ PBS for 5 min, room temperature. Repeat for a total of four washes.

Background is generally quite low and extended washing does not substantially reduce background.

16. Air dry the membrane and expose to X-ray film (autoradiography) or phosphor imager screen (see APPENDIX 3A for both techniques).

Do not cover the blots with plastic wrap as this will quench the ^{35}S signal. Overnight exposure to X-ray film is usually sufficient to detect positive interactions.

DETECTING INTERACTING PROTEINS BY IMMUNOBLOTTING

In vitro–translated probes have the advantages of being quickly produced, easily detected, and quantitated to give an estimate of relative binding. In addition, mutations in the protein probe can be generated by simple cloning procedures and can provide information on binding domains and their critical residues. A disadvantage of in vitro–translated probes is the need for multiple methionine or cysteine residues to obtain a well labeled probe. For the same reasons, small peptide fragments are often not suitable for use as in

ALTERNATE PROTOCOL 1

Analysis of Protein Interactions

20.6.3

vitro–translated probes. [¹⁴C]leucine and [³H]leucine can also be used for in vitro translation of proteins; however, in the authors' laboratory [¹⁴C]leucine has not yielded probes suitable for use as far western probes.

There are many other ways to generate probes for far western blots. The protein probe may be labeled in vitro with ¹²⁵I (Schumacher and Tsomides, 1995) or enzymatically with ³²P (Kimball, 1998). Biotin-labeled probes may be detected with streptavidin-biotin detection schemes (Luna, 1996; Grulich-Henn et al., 1998; Kimball et al., 1998). Protein binding may be detected indirectly as well. If an antibody to the interacting protein is available, then an unlabeled protein probe can be bound to the blots as usual and then detected by western (immunoblot) analysis. This is especially useful when a tagged recombinant protein and antibody to the tag are available. The following procedure describes detection of an unlabeled protein probe with specific antibody. Many variations of immunoblotting exist; additional information and procedures may be found in *UNIT 10.8*.

Additional Materials (also see *Basic Protocol*)

- Recombinant protein or unlabeled in vitro translated–protein for probe
- 5% (w/v) non-fat instant dry milk in 1× TBST (see recipe for TBST)
- Primary antibody specific for protein probe
- TBST (see recipe)
- Alkaline phosphatase (AP)–conjugated secondary antibody against Ig of species from which specific antibody was obtained
- Alkaline phosphatase buffer (see recipe)
- Developing solution (see recipe)
- 100 mM EDTA, pH 8.0 (*APPENDIX 2*)

Prepare blot and probe

1. Prepare and block the blot (see *Basic Protocol*, steps 1 to 9).
2. Prepare the probe protein by diluting in vitro–translated or recombinant protein in 3 ml of 1× probe dilution buffer.

The amount of recombinant protein must be empirically determined for each protein. Various researchers have used from 0.5 to 20 μg recombinant protein/ml of probe dilution buffer.

Expose blot to probe

3. Bind the probe to blot and wash (see *Basic Protocol*, steps 12 and 14 to 15). Do not dry the membrane after washing.
4. Incubate blot in 200 ml of 5% non-fat milk in 1× TBST for 1 hr, room temperature, with gentle rotation on an orbital shaker.

Expose to antibodies

5. Dilute the primary antibody in 5% milk in 1× TBST. Incubate blot in 5 to 10 ml diluted antibody at room temperature with gentle agitation to ensure blot is evenly covered with the antibody solution.

Incubations are usually carried out in heat-sealed plastic bags or hybridization bottles to minimize the volume necessary to completely cover the blot. A volume of 5 to 10 ml of diluted antibody is sufficient to cover most blots. Appropriate antibody concentrations vary for each antibody and must be determined empirically.

6. Wash for 10 min in ≥200 ml 1× TBST by agitating on an orbital shaker. Repeat an additional two times.

7. Dilute the AP-conjugated secondary antibody in 5 to 10 ml of 5% milk in 1× TBST and incubate blot for 1 hr as in step 4.

Suppliers generally provide an estimate of appropriate dilution for the secondary antibody.

8. Wash blot six times for 5 min each in ≥200 ml TBST, with agitation.

Detect antibodies

9. Briefly, rinse blot in 50 ml alkaline phosphatase buffer.
10. Incubate blot in 20 ml developing solution for 1 to 15 min and rinse blot with 100 ml water.
11. Wash blot for 5 min with 100 ml of 100 mM EDTA, pH 8.0, to stop the development reaction. Rinse with 100 ml water, dry, and photograph.

*An example of a far western blot of proteins is shown in Figure 20.6.1. Lane 1 shows a Coomassie blue stain of a protein sample enriched for histone proteins separated on a 22% SDS-PAGE gel. Lane 2 shows a far western autoradiogram of a parallel lane probed with the yeast *Tup1* protein according to this protocol. Lane 3 shows a parallel lane probed with an unlabeled *Tup1* protein and detected with antibody specific to *Tup1* as in Alternate Protocol 2. Both protocols yield the same result—*Tup1p* interacts with H3 and H4 but not with H2A or H2B. Lanes 4 and 5 show immunoblots of parallel lanes using anti-H3 and anti-H4 antibodies to identify histones H3 and H4 unequivocally.*

Figure 20.6.1 Far western of blotted SDS-PAGE gel. Lane 1, Coomassie blue-stained gel showing locations of histone bands. Lane 2, far western of a parallel lane using radiolabeled *in vitro*-translated probe. Lane 3, far western using unlabeled probe detected with probe-specific antibody. Lane 4, western blot using anti-histone H3 specific antibody. Lane 5, western blot using anti-histone H4 specific antibody.

**USING PEPTIDES TO IDENTIFY SPECIFIC INTERACTING SEQUENCES
IN A FAR WESTERN BLOT**

Synthetic peptides can also be used in far western analyses. The use of peptides enables the identification of specific interacting sequences. Specific post-translational modifications can be examined for their effect on protein-protein interactions. Peptides as small as 11 amino acids have been used successfully as far western targets.

Peptide far westerns differ from other far westerns only in the preparation of the blots. Peptide dilutions are prepared, then dot or slot blotted onto the support membrane. Blocking and probing of peptide blots are identical to procedures used for traditional far westerns. Duplicate blots are stained to verify that comparable quantities of different peptides have been loaded. Because Ponceau S staining is temporary, staining of duplicate blots with India ink is used to provide a permanent record for peptide blots.

In the authors' experience, only peptides that have been synthesized on MAP resins have worked well for peptide blots. MAP resins consist of branched lysine chains whose chemically active groups have been blocked. Although peptides prepared in other ways do give reproducible results, the peptide concentrations required are several orders of magnitude higher than those required for MAP peptides, making these blots very costly to perform. The reason why increased peptide is needed is unclear, but perhaps the MAP resin "presents" the peptide in such a way that it is more accessible for interaction.

Additional Materials (also see *Basic Protocol*)

Peptides

0.4% Tween 20/PBS (see recipe)

India ink solution (see recipe)

Slot or dot blot apparatus (e.g., Bio-Rad Bio-Dot SF or Schleicher & Schuell Minifold II)

1. Make dilutions of peptides between 5 ng and 5 μ g in a final volume of 100 to 200 μ l of distilled water.
2. Prepare slot or dot blotter and support membrane (PVDF or nitrocellulose) as described by the manufacturer. Load the peptide dilutions into wells. Prepare duplicate blots, one for far western and one for India ink staining. After all samples are loaded, apply vacuum to draw the peptide samples through the manifold device and onto the support membrane.
3. Block, bind, wash, and autoradiograph one blot for far western (see Basic Protocol, steps 7 to 16).
4. Incubate the second blot in 100 ml of 0.4% Tween 20/PBS for 5 min at room temperature with gentle agitation. Repeat incubation.
5. Stain blot by incubating 15 min to overnight with 100 ml India ink solution at room temperature.
6. Wash the filter for 2 hr in 4 changes of 1 \times PBS. Dry and store the membrane.

This stain is permanent.

Figure 20.6.2 shows an example of results from this alternate protocol, using peptides as a substrate for a far western. The right-hand panel is a blot stained with India ink verifying that comparable quantities of peptide were loaded on the blot. The left-hand panel is a far western of a duplicate blot demonstrating the effect of acetylation of lysine residues of histone peptides on Tup1p/histone interaction.

Figure 20.6.2 Far western blot of peptides (**A**) dot blotted onto PVDF membrane and (**B**) stained with India ink. Figure reproduced with permission of Cold Spring Harbor Laboratory Press.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Alkaline phosphatase buffer

- 100 ml 1 M Tris-Cl, pH 9.5 (APPENDIX 2)
- 20 ml 5 M NaCl (APPENDIX 2)
- 5 ml 1 M MgCl₂ (APPENDIX 2)
- Add H₂O to 1 liter
- Store up to 1 year at room temperature

5-Bromo-4-chloro-3-indolyl phosphate (BCIP) stock solution

Dissolve 0.5 g of BCIP in 10 ml of 100% dimethylformamide. Store at 4°C or in small aliquots at -20°C. Discard when solution turns color.

Developing solution

Add 66 µl of NBT stock (see recipe) to 10 ml of alkaline phosphatase buffer (see recipe). Mix well. Add 33 µl of BCIP stock solution (see recipe) and mix again. Prepare fresh.

India ink solution

Add 100 µl India ink (Pelikan or Higgins) to 100 ml 0.4% Tween 20/PBS (see recipe). Prepare fresh.

Nitroblue tetrazolium chloride (NBT) stock solution

Dissolve 0.5 g of NBT in 10 ml of 70% dimethylformamide. Store at 4°C or in small aliquots up to 6 months at -20°C.

Phosphate-buffered saline (PBS), 10×

- 80 g NaCl
- 2.2 g KCl
- 9.9 g Na₂HPO₄
- 2.0 g K₂HPO₄
- Add H₂O to 1 liter

continued

Adjust pH to 7.4
Store indefinitely at room temperature
Prior to use, dilute to 1× by mixing 1 part 10× PBS with 9 parts water
Leftover 1× PBS should be stored at 4°C to discourage bacterial growth.

Ponceau S staining solution, 10×

2 g Ponceau S
30 g trichloroacetic acid
30 g sulfosalicylic acid
Add H₂O to 100 ml
Store indefinitely at room temperature
Just prior to use dilute to 1× by mixing 1 part 10× Ponceau S with 9 parts water

Probe dilution buffer, 10×

3.0 g bovine serum albumin (BSA)
10 ml normal goat serum
10 ml 10× PBS (see recipe)
H₂O to 100 ml
Store indefinitely at -20°C
Just prior to use, dilute to 1× by mixing 1 part 10× stock with 9 parts 1× PBS

Probe purification buffer

400 μl 1 M HEPES, pH 7.4,
400 μl 1 M dithiothreitol (DTT)
9.2 ml H₂O
Prepare fresh

TBST, 10×

90 g NaCl
100 ml 1 M Tris·Cl, pH 7.5 (*APPENDIX 2*)
10 g Tween 20
Add H₂O to 1 liter
For 1× TBST dilute 1 part 10× TBST with 9 parts water prior to use
Store indefinitely at room temperature

Tween 20/PBS, 0.4% (w/v)

Dissolve 0.4 g Tween 20 in 100 ml 1× PBS (see recipe). Store up to 1 week at room temperature.

COMMENTARY

Background Information

The far western blot (also called a west western and a ligand blot) has been widely used to examine the interactions of many diverse proteins. For example, it has been used to examine the interactions between the subunits of eukaryotic initiation factors (Kimball et al., 1998), to look at interactions between basic helix-loop-helix DNA-binding proteins (Chaudhary et al., 1997), and to examine the interactions of keratin intermediate filaments with desmosomal proteins (Kouklis et al., 1994). Far westerns have been particularly useful in examining interactions of histones with regulatory proteins. Far westerns have been

used to look at interactions of WD repeat proteins with histones (Edmondson et al., 1996; Palaparti et al., 1997), the interaction of Epstein-Barr virus nuclear antigen 2 with histone H1 (Grasser et al., 1993), and the interaction of histones with the *Xenopus* oocyte protein N1 (Kleinschmidt and Seiter, 1988). In addition, far westerns have been used to study receptor-ligand interactions and to screen libraries for interacting proteins (Grulich-Henn et al., 1998; Hsiao and Chang, 1999).

Sometimes, the nature of the proteins being examined is such that standard methods of studying protein-protein interactions are not possible. For example, some proteins are diffi-

cult to solubilize or to extract from cells except under conditions that disrupt protein-protein interactions and therefore, are difficult to assay by immunoprecipitation. Other proteins cannot be expressed in bacteria or yeast due to toxicity problems, thus making the production of recombinant proteins or the use of two-hybrid assays impossible. Far westerns are particularly useful in such cases. Since far westerns are performed totally *in vitro*, they circumvent these types of problems.

Another advantage of the far western blot is its flexibility. Proteins prepared in a variety of ways can be used for the assay. Cell extracts, recombinant proteins, and peptides can all be used as both probe and target proteins. For example, Palaparti et al. (1997) used cell extracts to probe a semipurified histone sample and detected bound proteins of interest with antibodies. Hsiao and Chang (1999) used phage-expressed proteins immobilized on filter lifts for a far western library screen. Unpurified *E. coli* extracts containing recombinant protein have been successfully used as probes (Fischer et al., 1997).

In addition, many different detection techniques, either radioactive or nonradioactive, can be used. Kimball and co-workers used recombinant protein probes that were labeled radioactively with kinases and recombinant proteins labeled with biotin and subsequently detected with a streptavidin-biotin detection scheme (Grulich-Henn et al., 1998; Kimball et al., 1998). Thus, techniques and reagents already in hand can frequently be adapted for use with this assay.

Finally, the far western can be modified to define the protein domains and amino acid residues that are important in protein-protein interactions. Mutagenized clones can be used to produce variants of protein probes. A single SDS-PAGE gel can be run with identical lanes and cut into strips, and a different *in vitro*-translated probe can be used for each strip. In this way, multiple variants of a protein can be tested simultaneously for their ability to interact with a target protein.

Non-SDS polyacrylamide gels can also be used to separate proteins for far westerns. For example, acid urea gels, which separate on the basis of both size and charge, have been successfully employed. Finally, peptides corresponding to specific interacting sequences can be synthesized with specific post-translational modifications to test their effects on protein-protein interactions.

Critical Parameters

Blocking nonspecific binding sites on the membranes is critical to achieving good results with far westerns. Too little blocking results in high background, while extended time in blocking solutions results in weakened or lost signal. The reason for the diminished signal is unclear, but protein renaturation apparently takes place during the blocking step, so an optimal renaturation may require limited blocking. The best time may well be different for each protein and require empirical optimization. In addition, different lots of BSA appear to result in diminished signal. Therefore, it is important to purchase high-quality BSA from a reputable manufacturer.

An important consideration is the inclusion of appropriate controls to rule out nonspecific interactions that might result in false positives. Suitable controls should be furnished for both the target proteins and the protein probe. When using a complex mixture of proteins, such as cell extracts, as target, “negative” control proteins are already present. However, when using a mixture of only a few proteins, it is important to provide a protein that does not interact to serve as a negative control for nonspecific binding. The ideal negative control should be similar to the protein of interest in charge and size. Appropriate controls should be subjected to SDS-PAGE and blotted in parallel with the samples of interest. Another important control is the use of an unprogrammed translation lysate as a probe. Translation of an unrelated protein as a control probe is also often helpful.

Troubleshooting

Precise conditions for far westerns vary from procedure to procedure and probably reflect the nature of the individual proteins being examined. Optimal conditions for each protein may need to be determined empirically. If background staining is too high, there are several possible remedies. The probe may be diluted or the sample concentration lowered. Other “blocking” reagents may be tested. The blocking reagent, nonfat dry milk, ranging in concentration from 1% to 5%, has been used successfully. Other detergents such as NP-40 and Triton X-100 are commonly employed for this procedure and may help to decrease background. Also, increasing the length of the blocking step may aid in background reduction. Most procedures that call for extended blocking times suggest incubation at 4°C.

If no specific staining is observed, confirm the quality of the radiolabeled probe by SDS-PAGE and autoradiography. Make sure the reticulocyte lysate has not been repeatedly frozen and thawed. If using a recombinant protein/antibody scheme, confirm the affinity of that interaction by immunoblotting.

Sometimes a decrease in blocking time or use of a different blocking reagent will increase signal. Some proteins may interact more readily following a denaturation/renaturation cycle. In this case, the membrane is incubated for 1 hr in PBS-buffered 7 M guanidine or 8 M urea and renatured overnight. Renature in blocking buffer I (see Basic Protocol) without agitation at 4°C with several changes of buffer. Finally, the length of the binding reaction can be increased.

Anticipated Results

Sensitivity of the far western blot is dependent on the affinity of the protein-protein interactions being investigated and on the quality of the probe. Thus, extra attention given to the preparation of a high-quality probe is almost invariably worthwhile. When using a radiolabeled probe, a positive interaction can typically be visualized after overnight exposure to X-ray film.

Time Considerations

The basic protocol can be performed in 2 days. An SDS-PAGE gel can be set up and run in 4 to 6 hr. The rest of the procedure can be performed in 8 to 10 hr. It is often convenient to set up the SDS-PAGE gels on one day and run them slowly overnight. The rest of the basic protocol can then be performed the next day. Semidry transfer requires ~2 hr, the blocking steps take ~4 hr, binding of the probe takes ~2 hr, washing, drying, and setting up the autoradiography cassette takes ~1 hr. Detection of interactions using antibodies to detect the probe protein requires an additional day. Peptide blots can be performed in one day.

It is possible to store the blots after the blocking steps for up to 2 weeks at 4°C. The blots should be stored in airtight containers or wrappings so they do not dry out. In addition, in vitro-translated probes may be produced ahead of time and stored unpurified at -20°C, although the efficiency may be reduced for some probes.

Two-Hybrid Dual Bait System

In characterizing a given protein's function, it is frequently desirable to identify other proteins with which it interacts. The yeast two-hybrid system, or interaction trap, is one of the most versatile methods available with which to identify/establish protein-protein interactions. This system relies on the modular nature of many transcription factors, wherein different domains (e.g., DNA binding, transcription activating) function independently. The two-hybrid system takes advantage of this functional independence of transcription factor domains by expressing the DNA binding domain and transcription activation domain as components of separate fusion proteins, which can be coalesced via noncovalent interactions to reconstitute a functional transcription factor. For example, in the two-hybrid system, a protein of interest (the bait) may be expressed as a fusion protein with a DNA binding domain. In parallel, the interacting protein (the prey) is expressed as a fusion protein with a transcription activation domain. Co-expression of the bait and prey fusion proteins in the appropriate yeast strain reconstitutes transcription activity through noncovalent bait-prey interactions.

The yeast two-hybrid system was conceived to determine the affinity of single pair protein-protein interactions (Fields and Song, 1989), but rapidly evolved into an efficient means to identify interacting protein binding pairs in both directed and nondirected screens. The latter feature enables the use of the two-hybrid system to screen a bait library against a prey library to identify interacting protein binding pairs. The two-hybrid system, therefore, lends itself to genomic and proteomic level screens. While the two-hybrid system is well suited to high-throughput screening methodology, it is an ideal system for such broad-based screening projects. More recently, the basic system has evolved to encompass a variety of adaptations, which enhance the versatility of the system by including modifying/accessory proteins and compatibility with peptide libraries and RNA-protein screens (reviewed in Serebriiskii et al., 2001).

The dual bait system (Serebriiskii et al., 1999), which is one such adaptation of the classic two-hybrid system, is the focus of this unit. The dual bait system facilitates the simultaneous comparison of two distinct baits with one prey. Briefly, in the dual bait system one protein of interest is expressed as a fusion to the DNA binding protein LexA (bait 1), while a second protein of interest is expressed as a fusion to the DNA binding protein cI (bait 2). Strains of yeast engineered for screening of these dual baits possess four separate reporter genes: *GusA* and *LYS2*, which are transcriptionally responsive to a *cI* operator (*cIop*); and *LacZ* and *LEU2*, which are transcriptionally responsive to a *LexA* operator (*lexop*). A plasmid expressing an activation domain-fused protein (prey), which can be either a defined protein interactor or a cDNA library, is also expressed to allow dual hybrid-mediated transcriptional activation. Selective interaction of the prey with one of the two baits is scored by observing transcriptional activation of either the *LexA* operator-responsive reporters or the *cI* operator-driven reporter genes—e.g., if the prey preferentially interacts with bait 1 (as shown in Fig. 20.7.1), then *LacZ* and *LEU2* will be more activated than *LYS2* and *GusA*. This selective activation can be detected by comparing yeast growth on plates lacking leucine or lysine, and by comparing quantitative results of *LacZ* and *GusA*, respectively.

By facilitating the simultaneous assay of one prey with multiple baits, the dual bait system overcomes two major problems inherent to the two-hybrid approach. First, since many proteins are members of large protein families which share considerable sequence similarity, the degree to which two-hybrid systems can differentiate between specific partners (e.g., individual members of a protein family) and less specific or nonspecific

Figure 20.7.1 Outline of the dual bait system and the key control points. An activation domain (AD)-fused prey interacts with Bait1 (LexA-fused) to drive transcription of *lexA-op*-responsive reporters (*LEU2* and *LacZ*), but does not interact with Bait2 (cl-fused) and thus does not turn on transcription of *cl-op*-responsive reporters (*LYS2* and *GusA*). As shown in this figure, the cl-Bait represents a negative control for prey binding; the system can also be configured so prey interacts with only cl-bait or both baits. To maximize the utility of the system, one can adjust experimental parameters affecting expression of baits and reporter readouts. Points of flexibility in the dual bait-hybrid system are indicated in the figure by circled numbers and include: (1) varying expression level of baits, (2) varying cellular localization of baits, (3) varying sensitivity of reporters, (4) diversifying plasmid markers to broaden compatibility with different yeast two-hybrid systems and to facilitate isolation of library plasmid in *E. coli*, (5) enriching polylinkers and choice of reading frames to facilitate cloning of baits, and (6) development of robust yeast strains suitable both for bait testing and interaction mating.

partners (e.g., all of the members of the protein family) for a given bait can be an issue. This notion is of paramount importance since multiple members of a protein family are frequently co-expressed in a single cell type and assigning a single physiological interactor with a particular function can be challenging. Second, the majority of two-hybrid library screens yield one or more nonspecific interactors (see <http://www.fccc.edu/research/labs/golemis/InteractionTrapInWork.html>). These false positives are proteins with broad interaction capabilities that result in nonspecific protein binding. Sorting out the physiologically meaningful interactors from the false positives can be time consuming. The dual bait system, therefore, provides a number of significant advantages, including the ability to readily distinguish interactions specific for individual members of related protein families and specific from nonspecific protein-protein interactions.

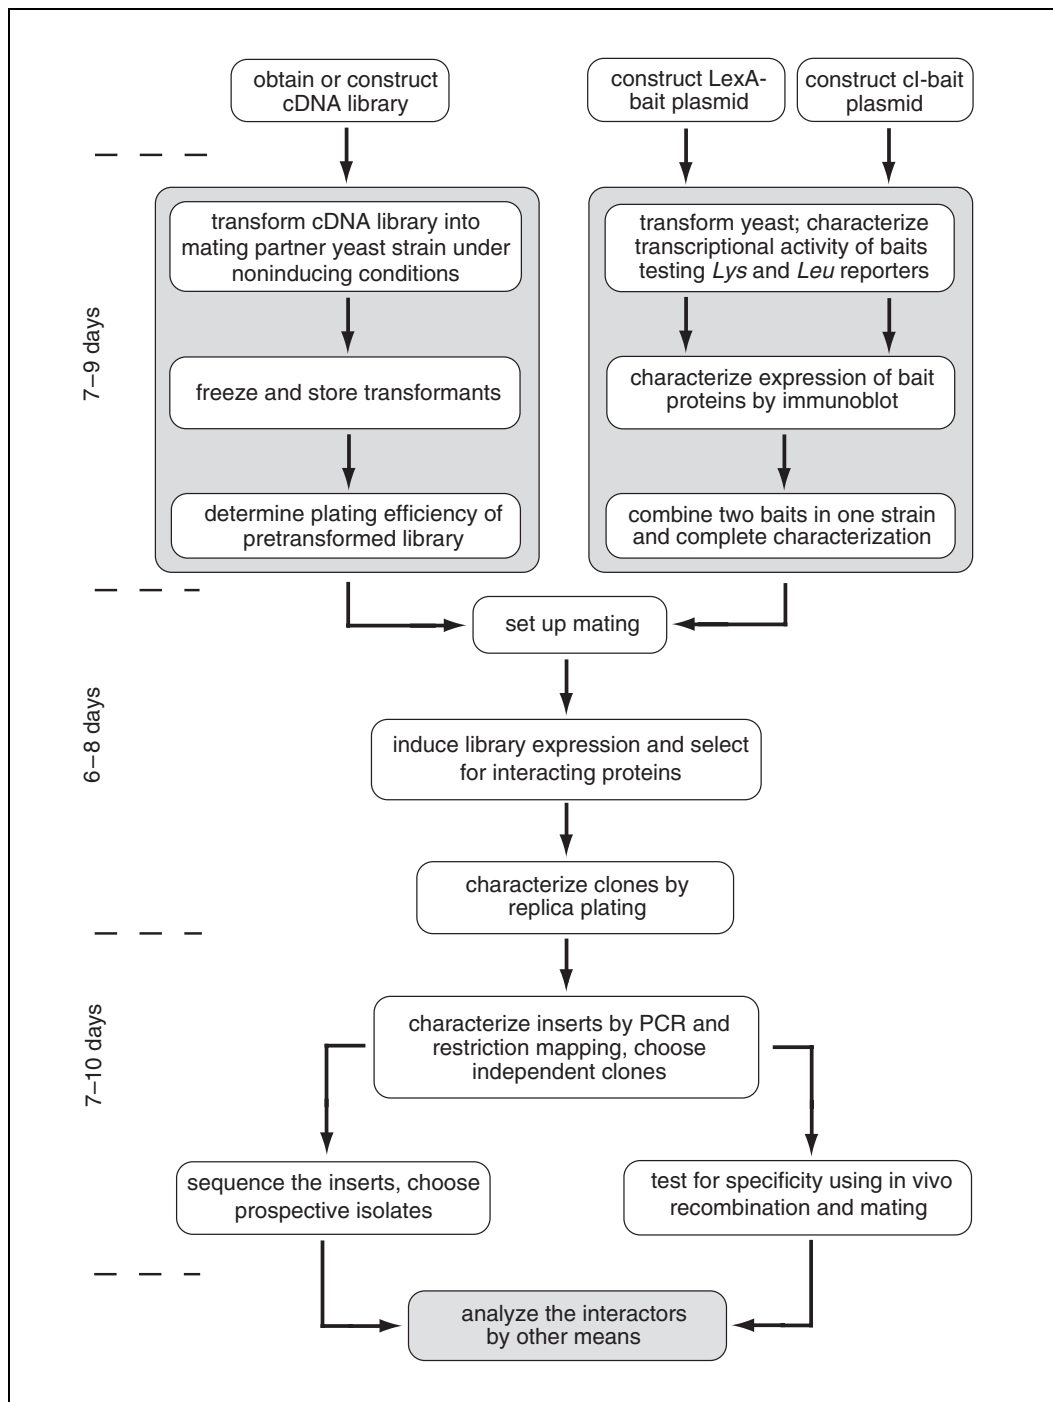

Figure 20.7.2 Flow chart of the two-hybrid screen done by interaction mating. The third stage allows some flexibility, reflected in the availability of different protocols (see Basic Protocol 4 and Alternate Protocol).

The following protocols can be used to investigate questions related to specific protein interactions that are difficult to clarify by other means. This method is a derivation of the classical interaction trap/two-hybrid system and readers are referred to Chapters 1 to 3, 10, and 13 for a more detailed description of the basic methodology related to the execution of the two-hybrid technique (e.g., preparation of yeast medium, immunoblotting). It is recommended that an investigator who is attempting to perform a dual bait screen as a first effort in the field of yeast interaction trap screens consult a basic protocol manual describing the interaction trap system (*UNIT 20.1*).

The outline of the protocol is presented in Figure 20.7.2. In the first protocol (see Basic Protocol 1), baits are transformed into the yeast reporter strains and characterized for protein expression and transcriptional activation. In parallel, a library is introduced into a yeast strain of the opposite mating type, to enable mating (see Basic Protocol 2). In the next method (see Basic Protocol 3), the bait-expressing yeast strain is mated to the library-bearing strain. Expression of library-encoded proteins is induced by growing the diploids in galactose-containing medium, and yeast containing interacting pairs of proteins are identified on the selection plates. Primary candidates are analyzed for their ability to activate the correct set of reporters selected for further study. In the final protocol (see Basic Protocol 4), selected primary candidates are further analyzed by PCR to detect redundant clones, and then the library inserts are isolated and characterized to confirm the specific interaction with the bait protein(s). Clones which satisfy the user's criteria are ready for further analysis.

Three additional protocols are provided as support material. The first (see Support Protocol 1) outlines the Xgal or Xgluc overlay technique, which provides a convenient and sensitive assay to assess β -galactosidase or β -glucuronidase activity of yeast. The second (see Support Protocol 2) describes the detection of bait protein from growth of yeast through immunoblot analysis. Establishing both the expression level and proteolytic status for each novel bait construct is critical for a meaningful interpretation of bait-prey interactions. In the last (see Support Protocol 3) a method to assess the quality of digested library plasmid is described. This protocol is recommended in order to assure minimal background in the testing specificity of interaction using homologous recombination. Together with the basic protocols, these support protocols provide the necessary steps for performing and interpreting the two-hybrid dual bait system.

BASIC PROTOCOL 1

PREPARATION OF BAITS AND LIBRARY: CHARACTERIZING BAIT PROTEINS

To utilize the dual bait system, constructs encoding fusion proteins of independent DNA-binding domains (either LexA or cI) and the two baits must be prepared. A protein to be used as a primary bait should be fused to LexA, since more options exist to optimize LexA bait performance.

Materials

- DNA encoding the proteins of interest
- LexA-fusion plasmids and controls (Table 20.7.1): pMW103 (Figs. 20.7.3 and 20.7.4), pEG202-hsRPB7 (control), pSH17-4, and pEG202-Ras (control)
- cI-fusion plasmids and controls (Table 20.7.2): pGBS10 (Figs. 20.7.4 and 20.7.5), pGBS10-Krit (control), and pGBS10-Krev (control)
- Yeast strains (Table 20.7.3): SKY191 and SKY48
- YPD plates and liquid media (*UNIT 13.1*) with and without 200 μ g/ml geneticin (G418; *APPENDIX 1K*)
- pLacGus (Fig. 20.7.6)

Table 20.7.1 LexA-Fusion Plasmids and Controls

Plasmid name	Yeast selection	<i>E. coli</i> selection	Comment/description	Contact information
<i>LexA Fusion plasmids</i>				
pMW101	<i>HIS3</i>	Cm ^R	Basic plasmids to clone bait as fusion with <i>LexA</i> . Expression is driven by the <i>ADHI</i> promoter.	RB ^a
pMW103	<i>HIS3</i>	Km ^R	Basic plasmids to clone bait as fusion with <i>LexA</i> . Expression is driven by the <i>ADHI</i> promoter.	RB ^a
pEG202	<i>HIS3</i>	Ap ^R	Basic plasmids to clone bait as fusion with <i>LexA</i> . Expression is driven by the <i>ADHI</i> promoter.	Origene ^b , MoBiTec ^c
pJK202	<i>HIS3</i>	Ap ^R	pEG202 derivative, incorporating nuclear localization sequences between <i>LexA</i> and polylinker (enhanced ability to translocate bait to nucleus)	Origene ^b
pNLexA	<i>HIS3</i>	Ap ^R	Polylinker is upstream of <i>LexA</i> , which allows fusion of <i>LexA</i> to C terminus of bait, leaving amino-terminal residues of bait unblocked	Origene ^b
pEG202I	<i>HIS3</i>	Ap ^R	pEG202 derivative (see above), which can be integrated into yeast <i>HIS3</i> gene after digestion with <i>KpnI</i> . Ensures lower levels of bait expression.	RB ^a
pGilda	<i>HIS3</i>	Ap ^R	<i>GALI</i> promoter and CEN-ARS backbone facilitate a tightly controlled, galactose-inducible bait expression; should be used if continuous presence of the bait is toxic to yeast	Origene ^b
pDD	<i>HIS3</i>	Km ^R	<i>GALI</i> promoter and CEN-ARS backbone facilitate a tightly controlled, galactose-inducible bait expression; should be used if continuous presence of the bait is toxic to yeast	R. Hopkins ^d
pHybLex/Zeo	Zeo ^R	Zeo ^R	Bait cloning vector, compatible with IT and all other two-hybrid systems. Minimal <i>ADHI</i> promoter expresses <i>LexA</i> followed by extended polylinker.	Invitrogen ^e
pCGLex/p2GLex	Zeo ^R	Zeo ^R	Gal-inducible bait vector, compatible with IT and all other two-hybrid systems. <i>GALI</i> promoter expresses <i>LexA</i> followed by extended polylinker. Both high and low copy number versions available.	J. Huang ^f
<i>Control LexA-fused baits</i>				
pEG202-Ras	<i>HIS3</i>	Ap ^R	A negative control for activation and positive control for interaction with Raf1 and RalGDS	I. Serebriiskii ^g
pEG202-hsRBP7	<i>HIS3</i>	Ap ^R	A weak positive control for activation	I. Serebriiskii ^g
pEG202-Krit1	<i>HIS3</i>	Ap ^R	A moderate positive control for activation	I. Serebriiskii ^g
pRFHM1 (control)	<i>HIS3</i>	Ap ^R	The homeodomain of bicoid cloned into pEG202 backbone (see above); the resulting nonactivating fusion is recommended as a negative control for activation and interaction assays, and as a positive control for repression assay.	Origene ^b
pSH17-4 (control)	<i>HIS3</i>	Ap ^R	<i>GAL4</i> activation domain cloned into pEG202 backbone (see above) is recommended as a positive control for transcriptional activation.	Origene ^b

Figure 20.7.3 Plasmid map of the 10101-nt basic dual bait vector pMW103. This plasmid, a derivative of pEG202, uses the strong constitutive *ADH1* promoter to express bait proteins as fusions to the DNA binding protein LexA. The plasmid contains the *HIS3* selectable marker and the 2 μ origin of replication to allow selection and propagation in yeast, the kanamycin resistance gene and the pBR origin of replication to allow selection and propagation in *E. coli*. A detailed map of the LexA-fusion polylinker is given in Figure 20.7.4. More maps and sequences are available on the Web at <http://www.fccc.edu/research/labs/golemis/InteractionTrapInWork.html>.

90- or 100-mm complete minimal (CM) medium dropout plates (*UNIT 13.1*) with and without 350 μ g/ml G418 lacking the following nutrients and supplemented with 2% (w/v) glucose (glu) or 2% (w/v) galactose (gal) and 1% raffinose (raff):
 Glu minus uracil and histidine (Glu/CM –Ura –His)
 Glu minus lysine (Glu/CM –Lys)
 Gal and raff minus lysine (Gal-Raff/CM –Lys)
 Gal and raff minus uracil, histidine, and leucine (Gal-Raff/CM –Ura –His –Leu)
 Gal and raff minus uracil and histidine (Gal-Raff/CM –Ura –His)
 Gal and raff minus uracil, histidine, and lysine (Gal-Raff/CM –Ura –His –Lys)
 Glu minus tryptophan (Glu/CM –Trp; also in 24 \times 24-cm plates)

Two-Hybrid Dual Bait System

20.7.8

Figure 20.7.5 Plasmid map of the 5310-nt basic dual bait vector pGBS10. This plasmid uses the strong constitutive *ADH1* promoter to express bait proteins as fusions to the DNA binding protein *cI*. The plasmid contains the 2 μ origin of replication to allow propagation in yeast and the ColE1 origin of replication to allow propagation in *E. coli*. The same Tn903-encoded gene confers kanamycin resistance in *E. coli* and geneticin (G418) resistance in yeast. More maps and sequences are available on the Web at <http://www.fccc.edu/research/labs/golemis/InteractionTrapInWork.html>.

Table 20.7.3 *LEU2/LYS2* Selection Strains

Name	Genotype	No. operators	Comment/description	Contact information
SKY48	<i>MATα, trp1, his3, ura3, lexAop-LEU2, cIop-Lys2</i>	6 <i>lexA</i> , 3 <i>cI</i>	Provides a more stringent selection for interaction partners of <i>cI</i> -fused baits, and more sensitive LexA-responsive <i>LEU2</i> reporter than the one in SKY191	I. Serebriiskii ^a
SKY191	<i>MATα, trp1, his3, ura3, lexAop-LEU2, cIop-Lys2</i>	2 <i>lexA</i> , 3 <i>cI</i>	Provides a more stringent LexA-responsive <i>LEU2</i> reporter, and more sensitive <i>cI</i> -responsive <i>LYS2</i> reporter than the one in SKY48.	I. Serebriiskii ^a
SKY473	<i>MATα, his3, leu2, trp1, ura3, lexAop-LEU2, cIop-LYS2</i>	4 <i>lexA</i> , 3 <i>cI</i>	Mating partner for SKY strains; can be also used as a reporter strain itself. Sensitivity of <i>LEU2</i> reporter is intermediate between sensitivity of <i>LEU2</i> in SKY48 and SKY191. Sensitivity of <i>LYS2</i> reporter is the same as sensitivity of <i>LYS2</i> in SKY191.	I. Serebriiskii ^a

^aE-mail at IG_Serebriiskii@fccc.edu.

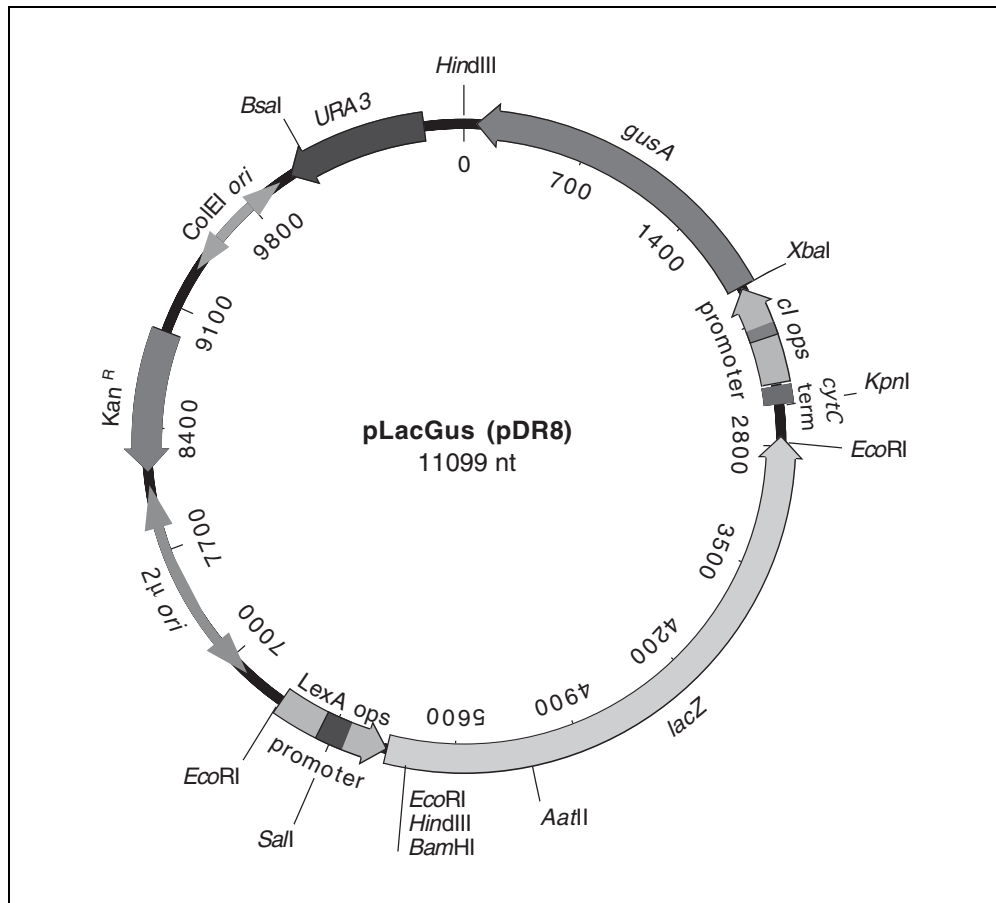

Figure 20.7.6 Plasmid map of the 11099-nt basic dual bait vector pLacGus, which is also known as pDR8. pLacGus is a dual reporter plasmid. Eight *LexA* operators upstream of the *lacZ* reporter make it the most sensitive of the *lexA*-responsive *lacZ* reporters. The *cI*-responsive *gusA* reporter (three *cI* operators) has a comparable sensitivity range. These two cassettes are separated by *cytC* terminator. The plasmid contains the *URA3* selectable marker and the 2 μ origin of replication to allow selection and propagation in yeast, and the kanamycin resistance gene and the pUC origin of replication to allow selection and propagation in *E. coli*. More maps and sequences are available on the Web at <http://www.fccc.edu/research/labs/golemis/InteractionTrapInWork.html>.

Additional reagents and equipment for subcloning DNA fragments (UNIT 3.16) or alternative cloning strategies (e.g., *in vivo* recombination; Ma et al., 1987), lithium acetate transformation of yeast (UNIT 13.7), gal overlay assay (see Support Protocol 1), and immunoblotting and immunodetection (see Support Protocol 2)

1. Using standard techniques for subcloning DNA fragments (UNIT 3.16) or alternative cloning strategies (e.g., *in vivo* recombination), insert the DNA encoding one of the two proteins of interest into the polylinker of the *LexA*-fusion plasmid pMW103 (Figs. 20.7.3 and 20.7.4A) to make an *in-frame* protein fusion to *LexA*. Call this plasmid pMW103-Bait1.

A number of modified versions of the plasmid exist which contain additional sites, altered reading frame, alternate antibiotic resistance markers, or include an in-frame nuclear-localization motif between the LexA protein and the polylinker (see Background Information in the Commentary and Table 20.7.1).

2. Similarly, clone the DNA encoding the second protein of interest into the polylinker of the *cI*-fusion plasmid pGBS10 (Figs. 20.7.4B and 20.7.5) to enable synthesis of an *in-frame* protein fusion to *cI*. Call this plasmid pGBS10-Bait2.

3. Lithium acetate transform yeast strain SKY191 (UNIT 13.7) using the following plasmids:

- pGBS10-Bait2 (step 2)
- pGBS10-Krit (positive control for activation)
- pGBS10-Krev (negative control for activation).

Plate each transformation mixture on YPD plates containing 200 µg/ml geneticin (YPD G418), and incubate two days at 30°C to select for yeast colonies containing transformed plasmid.

Incubating yeast in YPD liquid medium 6 hr to overnight at 30°C prior to plating significantly increases plating efficiency.

4. Transform SKY48 (UNIT 13.7) using the following combinations of LexA-fusion and *lexAop-LacZ* (pLacGus) plasmids:

- pMW103-Bait1 (step 1) + pLacGus
- pEG202-hsRPB7 + pLacGus (weak positive control for activation)
- pSH17-4 + pLacGus (strong positive control for activation)
- pEG202-Ras + pLacGus (negative control for activation).

Transfer the transformations to 90- to 100-mm Glu/CM –Ura –His plates without G418 to select for yeast that contain both plasmids, and incubate 2 to 3 days at 30°C.

If bait transformants either grow noticeably slower or in reduced number (compared to the controls), the bait protein is likely toxic to the yeast (see Critical Parameters and Troubleshooting, Table 20.7.11 and Table 20.7.12 for recommended modifications). Increased heterogeneity of yeast colonies compared to controls (e.g., a mix of large and small colonies) is also suggestive of bait toxicity.

If only a small number of colonies are obtained even in controls, or colonies are not apparent within three to four days, the transformation efficiency is low. (While the transformation efficiency at this particular step is not paramount, it will be critical for the library transformation). In this case, all solutions, media, and conditions must be double-checked or prepared fresh, and the transformation repeated. An efficient transformation should yield $\sim 1 \times 10^4$ transformants per microgram DNA (when two plasmids are being simultaneously transformed), and up to 1×10^5 for transformation with a single plasmid.

5. Replica plate to assess activation of *cI*- and LexA-fused baits:

- a. Add 50 to 75 µl sterile water to each well of one-half (6 × 8 wells) of a 96-well microtiter plate. Place an insert grid from a rack of 200-µl micropipet tips over the top of the microtiter plate and attach with tape.

The grid should be elevated ~1 cm from the plate and the holes in the insert grid should be aligned with the wells of the microtiter plate, as this will keep the tips in the upright position in the plate and allow their simultaneous removal. A convenient pipet-tip brand which accomplishes this is the Rainin RT series.

- b. Pick six 1- to 2-mm-diameter yeast colonies from each of the transformation plates (steps 3 and 4) using a different sterile plastic 200-µl micropipet tip for each colony. Leave the tips supported in a near-vertical position by the insert grid until all the colonies have been picked.
- c. Swirl the plate gently to ensure the yeast are mixed into suspension. Remove the sealing tape and lift the insert grid along with all of the tips.
- d. Use a metal frogger or plastic replicator to plate yeast suspensions (each spoke leaves an ~3-µl drop) on the following plates, marked for orientation:

YPD containing 200 µg/ml G418 (master plate for cI-fused baits)
Glu/CM –Lys
Gal-Raff/CM –Lys
Glu/CM –Ura –His (master plate for LexA-fused baits)
Gal-Raff/CM –Ura –His –Leu
Gal-Raff/CM –Ura –His (for Xgal overlay assay).

- e. Incubate the plates up to 4 days at 30°C, and save the YPD G418 and Glu/CM –Ura –His master plates at 4°C.

Yeast containing cI-fused bait and controls should grow on YPD G418 plates, but should not grow on any –Ura –His plates. On Glu/CM –Lys and Gal-Raff/CM –Lys plates, yeast containing the positive control (pGBS10-Krit) should exhibit growth within 4 days, while yeast containing the negative control (pGBS-Krev) should not grow.

Yeast containing LexA-fused bait and controls should not grow on either YPD G418 or CM –Lys plates, and should grow on Glu/CM –Ura –His plates. On Gal-Raff/CM –Ura –His –Leu plates, the strong positive control (pSH17-4 + pLacGus) should show detectable growth in 1 to 2 days, the weak positive control (pEG202-hsRBP7 + pLacGus) should be growing within 4 days, and the negative control (pEG202-Ras + pLacGus) should not grow. If the yeast containing the bait under test (pMW103-Bait1 + pLacGus) shows no growth in this period, it should be suitable for library screening. If it activates LEU2 reporter similar to the transformants from the pEG202-hsRBP7 reaction, it may be suitable, but is likely to have a high background in library screening (which may be slightly reduced by the use of a less sensitive strain). If it is similar to the pSH17-4 + pLacGus transformants, it must be modified before screening.

6. Approximately 24 to 30 hr after the plating, overlay the Gal-Raff/CM –Ura –His with Xgal agarose as described (see Support Protocol 1). Assess the ability of LexA-fused bait to activate transcription of *LEU2* and *LacZ* reporters.

In assessing the control transformants (step 4), strongly activating baits will be detectable as dark blue colonies in 20 to 60 min, while negative controls should be faint blue or white; an optimal bait would be either as white as the negative control or only a faint blue color.

At this step, the ability of LexA-fused bait to activate transcription is tested on both LEU2 and LacZ reporters, while potential cI self-activation is only tested for LYS2 reporters. Auxotrophic reporters are, however, the most important for the library screening, because they allow the direct selection for interaction phenotype. In addition, there is normally a good correlation between activation of the two reporters, so it is very unlikely that the bait which is not activating LYS2 will significantly activate GusA. Therefore, if no activation is detected on –Lys plates, one should proceed further; if bait causes growth on –Lys plates, it should be modified. The ability of the cI-fused bait to activate GusA reporter will be tested in step 9 below.

7. Select from the master plate at least two primary transformants for each novel bait construct and perform immunoblot analysis as described (see Support Protocol 2).

Establishing protein expression levels by immunoblot analysis is critical for several reasons. Proteins expressed at low levels, and apparently inactive in transcriptional activation assays, can be up-regulated to much higher levels under the auxotrophic selection and unexpectedly demonstrate a high background of transcriptional activation. Moreover, where proteins are proteolytically clipped, screens might inadvertently be performed with LexA fused only to the amino-terminal end of the larger intended bait.

Adding positive controls for protein expression such as pGBS10-Krev (step 3) and pEG202-Ras (step 4) is helpful.

8. Note which cI-bait colonies on the master plate express bait appropriately, and use two of these colonies to introduce LexA-fused bait and reporter plasmids. Use standard transformation procedure (UNIT 13.7), except grow the yeast in YPD liquid medium containing 200 µg/ml G418.

This transformation should combine in a single strain both of the baits and a double reporter plasmid—i.e., pMW103-Bait1 + pLacGus + pGBS10-Bait2 (clones 1 and 2).

In parallel, transform SKY191 expressing pGBS10-Krit and pGBS10-Krev to obtain pEG202-Ras + pLacGus + pGBS10-Krev and pEG202-hsRPB7 + pLacGus + pGBS10-Krit.

9. Plate each transformation mixture on Glu/CM –Ura –His G418 dropout plates, and maintain at 30°C for 2 to 4 days to select for yeast colonies containing desired plasmid combinations.
10. Replica-plate (step 5) twelve colonies of each transformant on the following set of plates:

Glu/CM –Ura –His G418 (new master plate)
Gal-Raff/CM –Ura –His G418 (Xgal overlay assay)
Gal-Raff/CM –Ura –His G418 (Xgluc overlay assay)
Gal-Raff/CM –Ura –His –Leu
Gal-Raff/CM –Ura –His –Lys

Incubate the plates up to 4 days at 30°C, and save the Glu/CM –Ura –His G418 master plate at 4°C.

11. Overlay with Xgal and Xgluc agarose as described (see Support Protocol 1) and analyze the results.

Self-activation abilities are expected to be the same as in the characterization of separate baits.

12. Reconfirm expression of the baits by immunoblot (see Support Protocol 2).

An investigator who is proficient in yeast transformations may wish to cotransform all baits and reporter plasmids into a single strain simultaneously. If the resultant strain behaves favorably, this single transformation can save time. It should be cautioned, however, that simultaneous transformation with three plasmids can be problematic and the authors recommend the step-wise strain construction and verification.

PREPARATION OF BAITS AND LIBRARY: TRANSFORMING AND CHARACTERIZING THE LIBRARY

A list of some of the libraries currently available for use with the Dual Bait system can be found at <http://www.fccc.edu/research/labs/golemis/InteractionTrapInWork.html>. Currently, the most convenient source of libraries suitable for the interaction trap is commercial, and can be viewed at the companies' web-sites.

The protocol outlined below describes the steps used to perform a screen that should saturate a cDNA library derived from a genome of mammalian complexity. Fewer plates will be required for screens with libraries derived from organisms with less complex genomes; therefore, the protocol should be scaled back accordingly.

Currently, mating the library-pretransformed strain with the desired bait strain is recommended as the most convenient strategy. The main advantage of this approach is that if the investigator wishes to use the same library to screen multiple baits, only a single large-scale transformation is required, followed by relatively easy mating steps. This approach is also useful when analyzing a toxic bait, as yeast-expressing toxic proteins can be difficult to transform with high efficiency. Finally, direct transformation in the bait strain requires media not only selective for the library plasmid, but also maintaining selective pressure to keep both baits and reporter. Large-scale transformation plating on G-418 medium will make screening much more expensive.

BASIC PROTOCOL 2

Analysis of Protein Interactions

20.7.13

As outlined in Figure 20.7.7, it is recommended to perform the large-scale library transformation (plated on multiple 24 × 24-cm plates) in parallel with several small-scale control transformations (each plated on a single 90-mm plate). These small-scale controls are critical in calculating the frequency of false positives and will be useful as positive and negative controls during interactor characterization.

Materials

Yeast strains (Table 20.7.3), fresh: SKY473
YPD liquid media (UNIT 13.1) without G418 (APPENDIX 1K)
H₂O, sterile
TE buffer (APPENDIX 2)/0.1 M lithium acetate
Library DNA in pJG4-5 (Fig. 20.7.8) or pYesTrp (Table 20.7.4)
Carrier DNA, freshly denatured
Negative control plasmids (Table 20.7.4; optional): pJG4-5 or pYesTrp2, pJG4-5-Raf1, pJG4-5-Krit, and pYesTrp2-RalGDS
40% (w/v) PEG 4000/0.1 M lithium acetate/TE buffer, pH 7.5
Dimethyl sulfoxide (DMSO)
90-mm and 24 × 24-cm Glu/CM –Trp plates (UNIT 13.1)
TE buffer (APPENDIX 2), sterile (optional)
Glycerol solution: 65% (w/v) sterile glycerol/0.1 M MgSO₄/25 mM Tris·Cl, pH 8.0 (APPENDIX 2)
Orbital shaker, 30°C
50-ml conical tubes, sterile
42°C heat block
3- to 4-mm glass balls, sterile (Thomas Scientific or Fisher)
Additional reagents and equipment for lithium acetate transformation of yeast (UNIT 13.7)

Prepare competent yeast

1. Inoculate a colony of SKY473 in ~20 ml liquid YPD medium and grow overnight on an orbital shaker at 30°C.

It is important to use fresh yeast (i.e., thawed from –70°C and streaked to a single colony less than ~7 days previously) and maintain sterile conditions throughout all subsequent procedures.

2. Dilute the overnight culture into ~300 ml YPD liquid medium such that the diluted culture has an OD₆₀₀ of ~0.15. Incubate at 30°C on an orbital shaker until the culture has reached an OD₆₀₀ of ~0.50 to 0.7.
3. Transfer the culture to six sterile 50-ml conical tubes, and centrifuge 5 min at 1000 to 1500 × g, room temperature. Gently resuspend the pellets in ~5 ml sterile water each, and combine all slurries into one of the conical tubes. Add sterile water to 50 ml and mix.

Perform transformations

4. Centrifuge cells again 5 min at 1000 to 1500 × g, room temperature. Decant water and resuspend yeast in 1.5 ml TE buffer/0.1 M lithium acetate (UNIT 13.7).
5. Mix 30 μg library DNA in pJG4-5 or pYesTrp with 1.5 mg freshly denatured carrier DNA in a microcentrifuge tube and add this mixture to the yeast. Mix gently and aliquot ~60 μl DNA/yeast suspension into each of 30 microcentrifuge tubes.
6. *Optional:* Use aliquots of competent yeast from step 4 to transform control plasmids—i.e., empty library plasmid (pJG4-5 or pYesTrp2), pJG4-5-Raf1, pJG4-5-

Figure 20.7.7 Detailed library screening flow chart. See Basic Protocols 2 and 3 for details.

Figure 20.7.8 Plasmid map of the basic dual bait vector pJG4-5. This plasmid expresses cDNAs or other coding sequences inserted into the unique *EcoRI* and *XhoI* sites as translational fusion to a cassette consisting of the SV40 nuclear localization sequence, the acid blob B42, and the hemagglutinin (HA) epitope tag. Expression of sequences is under the control of the *GAL1* galactose-inducible promoter. The plasmid contains the *TRP1* selectable marker and the 2 μ origin of replication to allow selection and propagation in yeast, and the ampicillin resistance gene and pUC origin of replication to allow selection and propagation in *E. coli*. The fusion cassette is shown at the bottom. A detailed map of the AD-fusion polylinker is given in Figure 20.7.7. More maps and sequences are available on the Web at <http://www.fccc.edu/research/labs/golemis/InteractionTrapInWork.html>.

Krit1, and pYesTrp2-RalGDS—into SKY473. Transfer to a 100-mm Glu/CM – Trp plate and collect the transformed cells as for the library. The control strain with an empty library plasmid can be safely reamplified in liquid medium.

When using a new bait strain, it is recommended to set up a parallel mating with negative and positive controls as outlined in Figure 20.7.7. The negative control strain is the same strain used for the library (e.g., SKY473), but containing the library vector with no cDNA insert. Positive control strains are also very helpful and will be later used in mating with a positive control bait strain (e.g., pEG202-Ras + pLacGus + pGBS10-Krev).

Table 20.7.4 Activation Domain Fusion Plasmids and Controls

Plasmid name	Yeast selection	<i>E. coli</i> selection	Comment/description	Contact information
pJG4-5	<i>TRP1</i>	Ap ^R	Library construction plasmid; <i>GAL1</i> promoter provides efficient expression of a gene fused to a cassette consisting of nuclear localization sequence, transcriptional activation domain, and HA epitope tag	Origene ^a , MoBiTec ^b
pJLo	<i>TRP1</i>	Ap ^R	A derivative of pJG4-5 that has a lower copy number (CEN/ARS <i>ori</i>)	R. Hopkins ^c
pJG4-5I	<i>TRP1</i>	Ap ^R	A derivative of pJG4-5 that can be integrated into yeast <i>TRP1</i> gene after digestion with Bsu36I; designed to study interactions that occur physiologically at low protein concentrations (in combination with pEE202I)	RB ^d
pYesTrp	<i>TRP1</i>	Ap ^R	<i>GAL1</i> promoter expresses nuclear localization domain, transcriptional activation domain, V5 epitope tag, multiple cloning sites; contains <i>f1 ori</i> and T7 promoter/flanking site. Used to express cDNA libraries	Invitrogen ^e
pNB42 series	<i>TRP1</i>	Ap ^R	Allow fusion to the N terminus of an AD, leaving N-terminal residues of Prey unblocked; various multiple cloning sites. No libraries yet available	M. Brown ^f
pMW102	<i>TRP1</i>	Km ^R	Same as pJG4-5, but with altered antibiotic resistance markers; no libraries yet available	RB ^d
pMW104	<i>TRP1</i>	Cm ^R	Same as pJG4-5, but with altered antibiotic resistance markers; no libraries yet available	RB ^d
pCGB42/p2GB42	G418 ^R	Km ^R	The same Tn903-encoded gene confers kanamycin resistance in <i>E. coli</i> and geneticin (G418) resistance in yeast; both high- and low copy number versions available. Multiple cloning site.	J. Huang ^g
<i>Control activation domain-fusions</i>				
pJG4-5-Raf	<i>TRP1</i>	Ap ^R	A positive control for interaction with Ras	I. Serebriiskii ^h
pYesTrp-RalGDS	<i>TRP1</i>	Ap ^R	A positive control for interaction with Ras and Krev	I. Serebriiskii ^h
pJG4-5-Krit	<i>TRP1</i>	Ap ^R	A positive control for interaction with Krev	I. Serebriiskii ^h

7. To each tube (steps 5 and 6), add 300 μ l sterile 40% (w/v) PEG 4000/0.1 M lithium acetate/TE buffer pH, 7.5. Gently invert the tubes several times (do not vortex) and incubate 30 to 60 min at 30°C.
8. To each tube, add 40 μ l DMSO and mix by inversion. Place tubes in a 42°C heat block for 10 min.
9. Evenly spread the contents of each tube onto a 24 \times 24-cm Glu/CM –Trp plate, using sterile 3- to 4-mm glass balls. Invert plates and incubate at 30°C until colonies appear (usually 2 to 4 days).

It is acceptable and efficient to keep the glass balls on the lids while incubating the plates; they will be needed to harvest the library transformants (see below). One to two dozen glass balls is sufficient.

10. Select a couple of representative transformation plates and draw a 23 \times 23-mm square (1% of plate bottom surface) over an average density spot. Count colonies in each grid section and recalculate for the whole transformation.

An efficient transformation done by this protocol should yield ~20,000 to 40,000 colonies per large plate, and represent $\sim 1 \times 10^5$ transformants per microgram library DNA.

Doing transformations in small aliquots helps reduce the likelihood of contamination, and for reasons that are not clear, provides significantly better transformation efficiency than scaled-up versions. Note, it is not recommended to use excess transforming library DNA per aliquot competent yeast cells, as each competent cell may take up multiple library plasmids, complicating subsequent analysis. Under the conditions described here, <10% of yeast will contain two or more library plasmids.

Harvest transformants

11. Inspect all transformation plates. If visible molds or other contaminants (e.g., colonies of unusual color, shape) are observed on the plates, carefully excise them and a region around them using a sterile scalpel prior to harvesting the library's transformants.
12. Pour 10 to 15 ml sterile water on each of five 24 \times 24-cm plates containing transformants. Add 3- to 4-mm sterile glass balls. Stack five of the plates on top of each other. Holding on tightly, shake the stack horizontally until all colonies are resuspended (1 to 2 min). Using a sterile pipet, tilt each plate to collect 5 ml yeast slurry and pool into sterile 50-ml conical tubes. Proceed to the next five plates, resulting in a total volume of up to 150 ml liquid spread across three 50-ml tubes.
13. Adjust the volume of each conical tube containing yeast to 50 ml with sterile TE or water, and vortex/invert to suspend cells. Centrifuge tubes ~5 min at 1000 to 1500 \times g, room temperature, and discard the supernatant. Wash cells by adding sterile water, resuspending, and centrifuging ~5 min at 1000 to 1500 \times g, room temperature. Discard the supernatant.
14. Resuspend each pellet in a small volume of sterile water and combine all slurries into one tube. Add water to 50 ml, and repeat wash (step 13). After the second wash, the cumulative pellet volume should be ~25 ml cells derived from 1.5×10^6 transformants.
15. Resuspend pellet in 1 vol glycerol solution. Freeze in 1-ml aliquots at –70°C.

The frozen aliquots are stable at least 1 year. If the intent is to proceed directly with mating, leave one aliquot unfrozen and assume viability of the culture is 100%.

SELECTING AN INTERACTOR

After the bait strain has been characterized (see Basic Protocol 1) and the library strain has been transformed and frozen in aliquots (see Basic Protocol 2), the next step is to mate the two strains. To mate the two strains, the bait strain is grown in liquid culture and then mixed with a thawed aliquot of the pretransformed library strain. The mixture is then plated on YPD medium and incubated overnight. During this time individual cells of the bait strain will fuse with individual cells of the library strain to form diploid cells. The mixture of diploids and unmated haploids is then collected, and an aliquot plated on media to select for interactors. In practice the diploid/haploid mixture is generally frozen in a few aliquots to allow titering and repeated platings at various cell densities.

The authors recommend mating any new bait strain with a control strain (see Basic Protocol 2). Mating with the control strain (containing the library vector with no cDNA insert) can be performed at the same time as the library mating, and both matings can be treated identically in the next step, selecting interactors. This control will provide a clear estimate of the frequency of cDNA-independent false positives, a frequency that is important to know when deciding how many positives to pick and characterize.

In the second part of this procedure, interactors will be selected by plating the mated cells onto selection plates lacking leucine and/or lysine. It will be important to know how many viable diploids were plated on these selection plates to gain a sense of how much of the library has been screened and to determine the false-positive frequency (see Basic Protocol 4 for discussion). To save time, the titering can be done at the same time as the selection for interactors in the protocol below. Since the titer of diploids will likely be within an order of magnitude of 1×10^8 cfu/ml, one could plate two or three different dilutions onto the selection plates to select for interactors, while at the same time plating dilutions to determine the exact titer of diploids.

Finally, the protocol describes testing for galactose-inducible transcriptional activation of both the auxotrophic and colorimetric reporters. Simultaneous activation of both reporters in a galactose-specific manner generally indicates that the transcriptional phenotype is attributable to expression of library-encoded proteins, rather than derived from mutation of the yeast.

Materials

Complete minimal (CM) medium dropout plates (or medium; *UNIT 13.1*) with and without 350 μ g/ml G418 (as necessary) lacking the following nutrients and supplemented with 2% (w/v) glucose (glu) or 2% (w/v) galactose (gal) and 1% raffinose (raff):

- Glu/CM –Ura –His
- Gal-Raff/CM –Ura –His –Trp
- Glu/CM –Ura –His –Trp
- Gal-Raff/CM –Ura –His –Trp –Leu
- Glu/CM –Ura –His –Trp –Leu
- Gal-Raff/CM –Ura –His –Trp –Lys
- Glu/CM –Ura –His –Trp –Lys
- Gal-Raff/CM –Ura –His –Trp
- Gal-Raff/CM –Lys
- Glu/CM –Ura –His
- Glu/CM –Leu (optional)
- Glu /CM –Lys (optional)
- Gal-Raff/CM –Leu (optional)
- Gal-Raff/CM –Lys (optional)
- Gal-Raff/CM –Ura –His –Trp –Lys –Leu (optional)

Bait strains containing appropriate combinations of plasmids (i.e., pMW103-Bait1 + pLacGus + pGBS10-Bait2) on Glu/CM –Ura –His G418 (see Basic Protocol 1)

Pretransformed library strain (see Basic Protocol 2)

H₂O, sterile

90- or 100-mm-diameter YPD plates (UNIT 3.1)

Glycerol solution: 65% (w/v) sterile glycerol/0.1 M MgSO₄/25 mM Tris·Cl, pH 8.0

30°C incubator with and without shaker

1.5-ml microcentrifuge tube, sterile

3- to 4-mm sterile glass balls (Thomas Scientific or Fisher)

Markers or wax pencils of different colors

Insert grid from a rack of 200- μ l pipet tips

Metal frogger (e.g., Dankar Scientific) or plastic replicator (i.e., Bel-Blotter; Bel-Art Products or Fisher)

96-well microtiter plate

Additional reagents and equipment for lithium acetate transformation of yeast (UNIT 13.7) and Support Protocol 1

Mate the bait strain and the pretransformed library

1. Inoculate 30 ml Glu/CM –Ura –His containing 350 μ g/ml G418 with the bait strain containing appropriate combinations of plasmids (i.e., pMW103-Bait1 + pLacGus + pGBS10-Bait2) from the Glu/CM –Ura –His G418 master plate. Grow in a 30°C incubator with shaking to mid- to late-log phase (i.e., OD₆₀₀ = 1.0 to 2.0).

Note that controls are to be grown in parallel with the bait strain (see step 7).

2. Collect the cells by centrifuging 5 min at 1000 \times g, room temperature. Resuspend the cell pellet in 1 ml sterile water and transfer to a sterile 1.5-ml microcentrifuge tube.

This will yield a yeast suspension of $\sim 1 \times 10^9$ cells/ml.

3. Thaw an aliquot of the pretransformed library strain at room temperature. Mix $\sim 2 \times 10^8$ cells of the bait strain (~ 200 μ l) with $\sim 1 \times 10^8$ colony-forming units (CFU) of the pretransformed library strain on a single 100-mm-diameter YPD plate and incubate at 30°C overnight. Optionally, in parallel, perform mating under the same conditions with the strain carrying the empty library plasmid (see Basic Protocol 2, step 6).
4. Add 1.5 to 2.0 ml sterile water to the surface of the YPD plate and resuspend the cells using 3- to 4-mm sterile glass balls. Transfer the suspension to a sterile tube and vortex gently 2 min. Collect the cells by centrifuging 5 min at 1000 \times g, room temperature.

5. Resuspend in 1 vol sterile glycerol solution. Distribute into 200- μ l aliquots and freeze at –80°C.

As with the frozen pretransformed library strain, the mated yeast should not be thawed and refrozen. Since only one or a few of the aliquots will be needed to represent the library, thawed aliquots can be discarded after use.

6. Titer the mated cells by plating serial dilutions on Glu/CM –Ura –His –Trp plates (unmated haploids will not grow on this medium). Count the colonies that grow after 2 to 3 days, and determine the titer of the frozen mated cells.

Titering can be performed in parallel with the selection step and is necessary to estimate how successful the mating was and therefore how many plates are needed to get full representation of the library. For full representation, it is desirable to have each primary library clone represented on the selection plate by 3 to 10 diploid yeast cells (see

explanation below). For example, if the library comprises 1×10^6 clones then a total of $\sim 5 \times 10^6$ diploid cells is to be plated on selection plates. Assuming that the titer of diploids is 5×10^7 cfu/ml, then ~ 100 μ l slurry has to be plated. However, the total number of cells plated will be much higher, since the efficiency of mating is typically 1% to 10%. An approximate titer can be estimated from the OD reading. Most likely, the same volume of the mating slurry which contains 5×10^6 cfu/ml of diploids, would contain about 1×10^8 cells. To avoid cross-feeding, only 1×10^6 – 10^7 cells can be put on one 100-mm plate. Therefore, to screen the library exhaustively, 10 to 100 plates would be needed (see Basic Protocol 4).

The authors recommend plating three to ten times more diploids than the number of colonies obtained from the transformation, based on the assumption that not all cells that contain interacting proteins plate at 100% efficiency on selective medium (Estojak et al., 1995), and because the created slurry may not be completely homogenous. While this approach may lead to multiple isolations of the same cDNA, it will increase the likelihood that all primary transformants are represented by at least one diploid on the selective plate. In fact, re-isolation of an identical cDNA among a relatively small set of “positives” can be taken as one sign of a specific interaction.

7. *Optional:* In parallel with steps 1 to 5 above, grow an overnight culture of the bait strain containing pEG202-Ras + pLacGus + pGBS10-Krev (control) in a final volume ~ 1.5 ml each. Make three spots of control bait strain by dropping ~ 5 μ l liquid culture on a YPD plate. Without waiting for the liquid to soak in, add 5 μ l of one of the three control prey strains (i.e., pJG4-5-Raf1, pJG4-5-Krit1, or pYesTrp2-RafGDS) to the same spots. Incubate overnight at 30°C and then streak all three matings onto Glu/CM –Ura –His –Trp plates containing G418.

See Figure 20.7.7 for an outline.

Screen for interacting proteins

8. Thaw an aliquot of the mated yeast (step 5). Dilute 100 μ l into 10 ml Gal-Raff/CM –Ura –His –Trp G418 liquid dropout medium and incubate 5 hr with shaking at 30°C. If the frozen culture was not previously titered, plate serial dilutions onto Glu/CM –Ura –His –Trp G418 plates. In parallel, do the same to an aliquot of the yeast mated to the control strain (step 3).
9. On the assumption that a culture at an OD₆₀₀ of 1.0 contains $\sim 1 \times 10^7$ cells/ml, plate 1×10^6 cells on ten 100-mm plates with the appropriate auxotrophic selection medium. In parallel, plate 1×10^7 cells on each of the ten additional plates with the same medium. Similarly, plate 1×10^6 cells control mating on one plate and at 1×10^7 cells/plate on another.

Plating 1×10^7 cells/plate allows screening more diploids on fewer number plates, but may result in higher levels of background growth (see below).

10. Incubate up to 6 days at 30°C. Compare selection plates seeded with lower and higher densities, which should be roughly proportional to seeding. Discard sets of plates in which disproportionately more colonies appear on the more densely seeded plates (especially sitting on the thin lawn), as this is probably background due to cross-feeding. Calculate how many plates at 1×10^6 cells per plate is needed for full representation of the calculated number of diploids. Repeat induction and plating using another frozen mating aliquot.

Depending upon the individual bait used, good candidates for positive interactors will generally produce LEU⁺ colonies during this time, with the most common appearance of colonies at 2 to 4 days. LYS⁺ colonies typically form at 3 to 5 days.

11. Inspect the plates on a daily basis. Each day, mark appearing colonies with different colors of ink or wax. At day 4 or 5, pick colonies in a microtiter plate format onto a

Glu/CM –Ura –His –Trp G418 master plate, in which colonies are grouped by day of appearance. If many apparent positives appear, pick separate master plates for colonies arising on days 2, 3, and 4, respectively.

If contamination has occurred at an earlier step, this is generally reflected by the growth of a very large number of colonies (more than 500/plate) within 24 to 48 hr after plating on selective medium. Compare the smell of the plates and morphology of the colonies to that on the titer plates. A low-power microscope can be helpful for this purpose. In the case of bacterial contamination, screening can be rescued by recreating the selective plates with 15 µg/ml tetracycline, and repeating library induction and plating.

Colonies arising later than within a week are likely to be artifactual.

12. Include positive control colonies—i.e., from matings of SKY191 bearing pEG202-Ras + pLacGus + pGBS10-Krev with SKY473 bearing pJG4-5-Raf1, pJG4-5-Krit1, and pYesTrp2-RalGDS (step 7)—on each of the master plates. Also, include a few colonies from the titer plate (step 8 above). If any colonies appeared on the control mating, include two or three representatives on one of the master plates.

Since they contain randomly chosen library plasmids, the phenotype of the colonies from the titer plates will almost certainly be negative.

The number of colonies to pick and characterize should be based on the frequency of cDNA-independent false positives that arise on the auxotrophic plates for the control mating with empty library vector. (The frequencies of true/false positives should be calculated as number of colonies per 1×10^6 diploids.) The higher the false positive frequency, the more colonies one will need to screen in order to find rare true positives. For example, if the cDNA-independent false positive frequency is one colony in 1×10^4 cfu plated and a true positive exists at a frequency of 1 in 1×10^6 cfu, then it will be necessary to pick at least 100 colonies to find this rare true positive clone.

13. Incubate the master plates at 30°C until patches/colonies form.

Confirm positive interactions

14. Invert a metal frogger or plastic replicator on a flat surface and place a master plate upside down on the spokes, making sure that the spokes and colonies are properly aligned. Remove the plate and insert the frogger or replicator into a microtiter plate containing 50 µl sterile water in each well. Let the plate sit for 5 to 10 min, shaking from time to time to resuspend the cells left on the spokes. When all yeast are resuspended, test for activation of the following genes by printing on the following plates:

Glu/CM –Ura –His –Trp G418 (master plate)
Gal-Raff/CM –Ura –His –Trp –Leu (*LEU2* growth assay)
Glu/CM –Ura –His –Trp –Leu (*LEU2* growth assay)
Gal-Raff/CM –Ura –His –Trp –Lys (*LYS2* growth assay)
Glu/CM –Ura –His –Trp –Lys (*LYS2* growth assay)
2× Glu/CM –Ura –His –Trp G418 (Xgal and Xgluc overlay assays)
2× Gal-Raff /CM –Ura –His –Trp G418 (Xgal and Xgluc overlay assays)

Repeat for each master plate.

The authors omit antibiotic for the plates used to characterize binding to LexA-fused baits, or when an alternative selection is available to maintain pressure on positive interactors for cI-fusions (as on the Lys-medium, which provides selection for growth). This antibiotic omission both accelerates the yeast growth and reduces the cost of the screen. In general, test plates for auxotrophic reporter characterization lacking only leucine or lysine would automatically keep selective pressure for the presence of the prey and the corresponding bait plasmids. Using plates with fewer dropped-out components would slightly accelerate

Table 20.7.5 Interpretation of Interaction Phenotype for Each Bait

Observed phenotype				Interpretation		Recommendation
Auxotrophic reporter		Colorimetric reporter		Traditional	Optimistic	
Glu	Gal	Glu	Gal			
–	+	–	+	Very good sign	Very good sign	Work with those clones first
(+)	+	(+)	+	Bait is mutated or its expression is up-regulated to a high background of transcriptional activation.	<i>GAL1</i> promoter is slightly leaky, both proteins are very stable, and/or interaction occurs with high affinity	Take one clone for confirmation of interaction and store the rest
–	+	–	–	Yeast mutation occurred that favors growth or transcriptional activation on galactose medium	Some bait-interactor combinations are known to preferentially activate one reporter versus another	If all other candidates winnow out, check these clones
All other phenotypes				Contamination, plasmid rearrangement, and/or mutations	Something really new	Trash

Table 20.7.6 Expected Phenotype for Control Set of Interactions^a

Bait	Prey	<i>LEU2</i>	<i>lacZ</i>	<i>LYS2</i>	<i>gusA</i>	Explanation
cI-Krev + LexA-Ras	Raf1	+	+	–	–	Interaction with LexA-fused bait only
cI-Krev + LexA-Ras	RalGDS	+	+	+	+	Interaction with both baits
cI-Krev + LexA-Ras	Krit	–	–	+	+	Interaction with cI-fused bait only
LexA-bait1 + cI-bait2	random	–	–	–	–	No interaction with any bait

^aEach feature marked as positive should be also Gal-dependent, as in Table 20.7.5, top row. Comparing the phenotype of the clones of interest to this set of controls should help to assess whether the isolated prey interacts with one or both baits.

the growth, and the potential loss of other plasmids would not influence the results of the assay on these plates. Thus, –Ura –His –Trp –Lys and –Ura –His –Trp –Leu plates can be substituted at the investigators discretion for –Lys and –Leu, respectively.

15. Incubate the plates 3 to 4 days at 30°C. After 20 to 30 hr of incubation, take out all –Ura –His –Trp plates. Retain one Glu/CM –Ura –His –Trp G418 plate as a fresh master plate, and overlay the remaining two sets with Xgal or Xgluc agarose as described in Support Protocol 1.

16. Assess growth on the –Leu and –Lys plates 48 to 72 hr after plating.

For interpretation of the results, see Table 20.7.5 and Table 20.7.6.

ANALYSIS OF PRIMARY INTERACTORS

Positives obtained during the selection step must next be evaluated for reproducible phenotype and specificity of interaction with the bait used to select them. Two strategies for analyzing positives are summarized in the flow chart in Figure 20.7.9. The rapid screen (PCR) approach is provided here, while the plasmid isolation approach is given elsewhere in the unit (see Alternate Protocol). The choice between strategies is a judgment call, and depends on whether the individual investigator prefers spending time and money doing bulk PCR (this protocol) or bulk yeast plasmid recovery (see Alternate Protocol). This protocol is generally 1 to 3 days faster.

BASIC PROTOCOL 4

Analysis of Protein Interactions

20.7.23

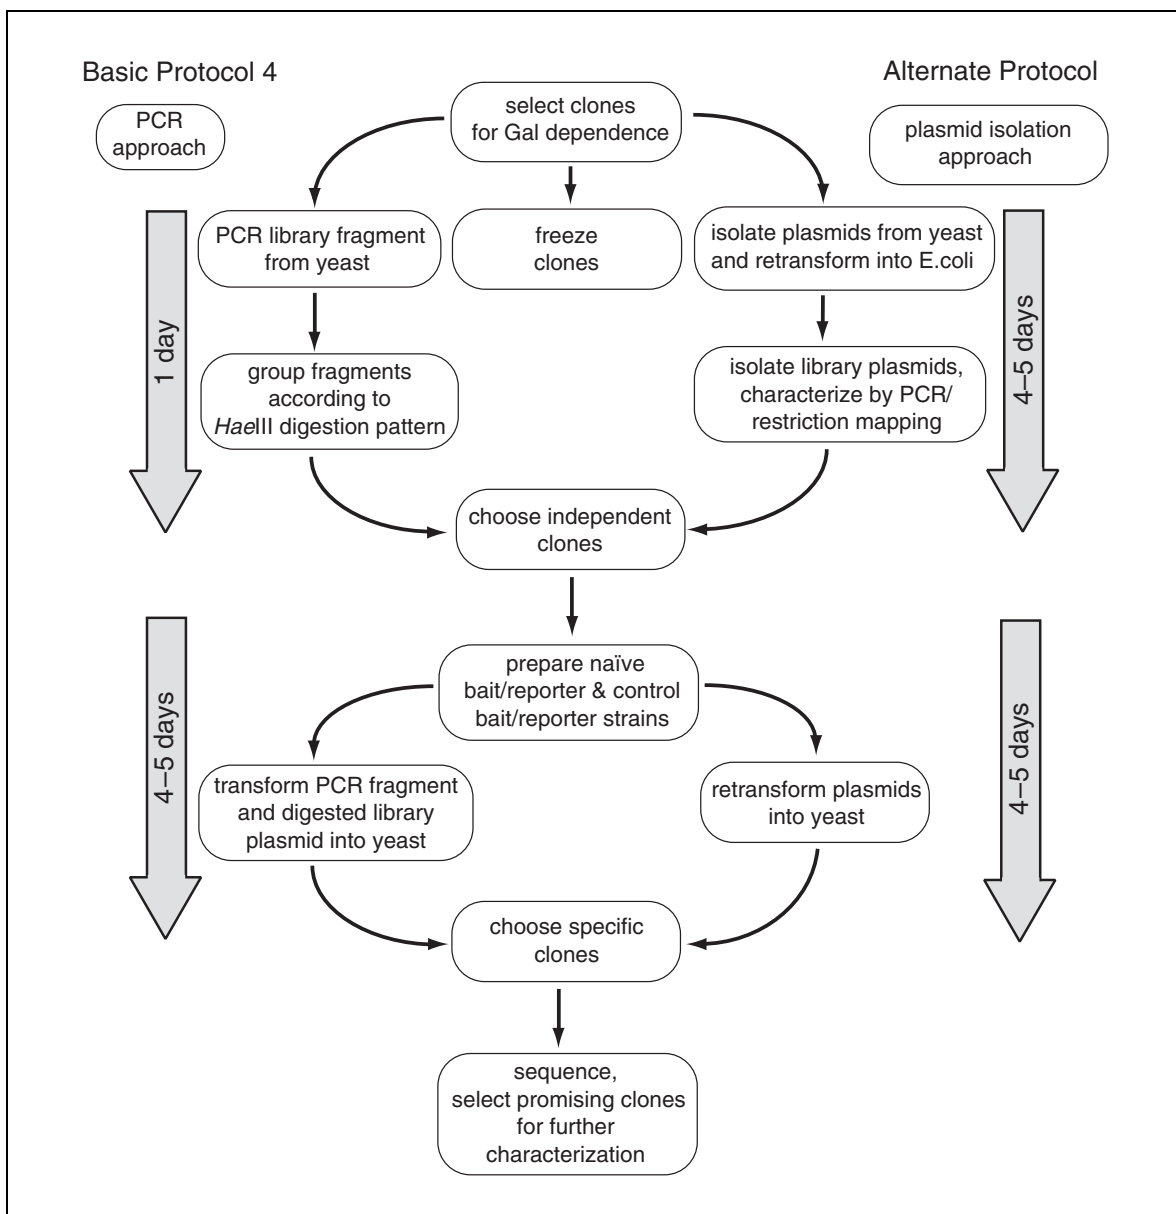

Figure 20.7.9 Detailed flow chart for characterization and second confirmation of primary positives. See Basic Protocol 4 and Alternate Protocol for details.

The next step is to determine whether isolated cDNAs will reproduce an interaction phenotype upon introduction into a fresh bait strain. This reconfirmation step eliminates a variety of false positives, including library-encoded cDNAs that interact with LexA (instead of the bait), “sticky” proteins that interact with the pBait in a nonspecific manner, and clones isolated because of mutations in the yeast strain that render nonbait mediated growth and transcriptional activation. This can be done using a PCR-recombination approach (derived from Petermann et al., 1998) in a single step, in which PCR-amplified cDNA fragments from the primary isolates and the digested library plasmid will be transformed together into a naïve bait strain. In yeast, they will undergo homologous recombination *in vivo* in up to 97% of the transformants that acquired both vector and insert. This is due to the identity between the cDNA PCR fragment and the plasmid at the sites flanking the polylinker. Colonies obtained in this protocol should be tested for

interaction phenotype. After this step, confirmed specific positive clones can be worked up through conventional plasmid purification.

To use the second step of this protocol, there must be ~0.5 to 1 µg of PCR product from the yeast colonies obtained in the first step (reamplify if necessary). Empty library plasmid should be digested with two enzymes producing incompatible ends in the polylinker region (see Support Protocol 3). Together, they will be transformed into the naïve bait strain SKY191 containing pMW103-Bait1 + pLacGus + pGBS10-Bait3 (see Basic Protocol 1, steps 8 to 12). An optional transformation in a control bait strain—SKY191 containing pEG202-Ras + pLacGus + pGBS10-Krev (see Basic Protocol 1, steps 8 to 12)—will provide additional specificity controls. Including in this transformation set Raf1 PCR fragment (from Support Protocol 3) will make the control side of this experiment impeccable.

Bait-expressing strains (see Basic Protocol 1) can only be used if they are >10 days old. Otherwise, these yeast must be replated or the whole transformation process repeated. In any case, single colonies from the fresh bait strains have to be characterized by immunoblotting to confirm the expression of bait proteins.

A major strength of this protocol is that it will identify redundant clones prior to plasmid isolation and bacterial transformation, which in some cases greatly reduces the amount of work required. However, accurate records should be maintained as to how many of each class of cDNA are obtained; and if any ambiguity is present as to whether a particular cDNA is part of a set or unique, investigators should err on the side of caution.

Materials

Glu/CM –Ura –His –Trp G418 master plate (see Basic Protocol 3)

β-glucuronidase solution: dilute crude β-glucuronidase type HP-2 from *H. pomatia* (Sigma) 1:50 in 50 mM Tris-Cl, pH 7.5 (APPENDIX 2)/10 mM EDTA; prepare fresh

Library plasmid specific primers—e.g., for JG4-5:

Forward primer (FP1): 5'-CTG AGT GGA GAT GCC TCC

Reverse primer (FP2): 5' CTG GCA AGG TAG ACA AGC CG

*Hae*III (UNIT 3.1)

SKY191 containing pMW103-Bait1 + pLacGus + pGBS10-Bait2 (see Basic Protocol 1, steps 8 to 12)

SKY 191 containing pEG202-Ras + pLacGus + pGBS10-Krev (see Basic Protocol 1, steps 8 to 12; optional)

Raf1 and Krit1 PCR fragment (see Support Protocol; optional)

Glu/CM –Ura –His –Trp G418 dropout plates (UNIT 13.1)

Metal frogger (e.g., Dankar Scientific) or plastic replicator (i.e., Bel-Blotter; Bel-Art Products or Fisher)

96-well microtiter plate

Horizontal shaker, 37°C

Tape

150- to 212-µm glass beads (e.g., Sigma G-1145)

Vortex with flat-top surface

Additional reagents and equipment for PCR (UNIT 15.1), restriction endonuclease digestion (UNIT 3.1), agarose gel electrophoresis (UNIT 2.5A), purification of DNA fragments (UNIT 2.6), lithium acetate transformation of yeast (UNIT 3.17), sequencing (Chapter 7), rapid miniprep isolation of yeast DNA (UNIT 3.6), and miniprep isolation of bacterial DNA (UNIT 1.6).

Rapid screen for interaction trap positives

1. Starting from a Glu/CM –Ura –His –Trp G418 master plate, use a metal frogger or plastic replicator to resuspend yeast in 25 μ l β -glucuronidase solution in a 96-well microtiter plate (also see Basic Protocol 3, step 14). Seal the wells using tape, and incubate 1.5 to 3.5 hr on a horizontal shaker at 37°C.

Alternatively, pipet tips can be used to transfer yeast in the wells (similar to replica plating; see Basic Protocol 1, step 5). This option is especially useful when the initial set of candidates was spread over a few master plates, and only a fraction of them has to be tested further. Do not take more than approximately the volume of one middle-sized yeast colony; otherwise, quality of isolated DNA may suffer. The master plate does not need to be absolutely fresh: plates that have been stored for a week at 4°C have been successfully used.

2. Remove the tape, add ~25 μ l (i.e., a small scoop) of 150- to 212- μ m glass balls to each well, and seal again. Attach the microtiter plate to a vortex with a flat top surface (e.g., using rubber bands) and mix vigorously for 5 min.
3. Add 100 μ l sterile water to each well. Take 1 to 2 μ l as a template for each PCR reaction. Reseal the plate with tape and keep the remainder frozen at –70°C.

*In many cases, PCR products can be obtained directly from the yeast colonies even without enzymatic treatment (e.g., by introducing a 10-min 94°C step at the beginning of the PCR program). However, the crude yeast lysate obtained in this protocol (step 2) can also be used as a source of plasmid DNA (use 1 to 2 μ l for electroporation into *E. coli*), making it worth preparing this simple lysate.*

4. Prepare master mix (25 to 30 μ l/reaction) as described in UNIT 15.1 using library-specific primers.

For example, use primer FP1 and FP2 for the JG4-5-based library or commercially available primers (Invitrogen) for pYesTrp2-based libraries.

5. Perform a PCR amplification (UNIT 15.1) in 25 to 30 μ l using the following program:

Initial step:	2 min	94°C	(denaturation)
35 cycles:	45 sec	94°C	(denaturation)
	45 sec	56°C	(annealing)
	5 sec	72°C	(extension).

Modified versions of this protocol with extended elongation times were also found to work. The variant given above has been shown to amplify 1.8-kb fragments well.

To interpret the results of the PCR, it is helpful to have the following ~1 ng control templates: empty library plasmid, yeast from the positive control colonies treated in parallel with experimental clones, and the same amounts of library plasmid and positive control yeast, mixed together. Interpretation of possible PCR outcomes is summarized in Table 20.7.7.

If the library being screened is based on JG4-5 plasmid, only clones containing Raf1 and Krit plasmids would produce products. For a pYesTrp-based library, use a RalGDS clone as positive control.

6. Load 2/3 (~20 μ l) of the PCR reaction onto a 0.7% agarose gel (UNIT 2.5A). Identify fragments which appear to be of the same size. Based on insert sizes, group obtained interactors in families (i.e., identify potential multiple isolates of the same cDNAs). Store gel in the refrigerator until ready to isolate fragments.
7. While the gel with the uncut PCR products is running, perform a restriction digest of the remainder (~10 μ l) of the PCR product with 15 U *Hae*III in a total volume of 20 μ l. Based on classification of undigested PCR products (step 6), rearrange the loading

Table 20.7.7 Analysis of PCR Reaction

Empty library plasmid	Template			Possible cause	Solution
	Control yeast	Empty library + control yeast	Clone of interest		
–	–	–	–	Bad master mix, wrong settings, or a faulty amplifier were used	Double check reaction and repeat
+	–	+	–	Not enough template	Add more template/improved
+	–	–	–	Lysed yeast inhibited PCR	Add less template
+	±	±	±	Uneven template load/digestion	Adjust template, PCR from obtained bands again

order of *HaeIII*-digested samples in such a way that the digests of the PCR products thought to be identical are run side-by-side. Load the *HaeIII* digestion products on a 1.0% agarose gel (UNIT 2.5A) and electrophoresis to optimize resolution of DNA products in the 200 to 1000 bp range.

HaeIII is recommended only because it tolerates the presence of PCR buffer well. If the PCR product is purified, any four-base cutter can be used.

This technique will generally yield distinctive and unambiguous groups of inserts, confirming whether multiple isolates of a small number of cDNAs have been obtained. As mentioned above, sometimes a single yeast will contain two or more different library plasmids. If this happens it is typically revealed by PCR. Thus, after bacterial transformation, and increased number of clones should be checked to avoid the loss of the “real” interactor.

- Purify undigested fragments from the agarose gel using standard techniques (UNIT 2.6).

In cases where a very large number of isolates have been obtained from a small number of cDNAs, the investigator may choose to sequence the PCR product directly.

PCR products obtained from this step will also be used for reconfirmation of an interaction. To get enough PCR products, reamplify if necessary.

Only the forward primer, FP1, works reliably in sequencing PCR fragments, while the reverse primer will only work in sequencing from purified plasmid (Chapter 7). In general, the TA-rich nature of the ADH terminator sequences downstream of the polylinker in the pJG4-5 vector makes it difficult to design high quality primers in this region.

Perform specificity testing

- Lithium acetate transform (UNIT 3.17) combinations of digested library plasmid and selected PCR products (optionally including Raf1 and Krit1; see Support Protocol 3) into the naïve bait strain SKY191 (pMW103-Bait1 + pLacGus + pGBS10-Bait2). Optionally, transform the same combinations in parallel into the control bait strain SKY191 (pEG202-Ras + pLacGus + pGBS1-Krev).
- Plate each transformation mix on Glu/CM –Ura –His –Trp G418 dropout plates and incubate at 30°C until colonies grow (2 to 3 days).
- Prepare a master plate for each library plasmid being tested. Each plate should contain at least ten colonies of the transformed PCR-insert/digested plasmid into each of the bait strains.

12. Test for the activity of colorimetric and auxotrophic reporters as described (see Basic Protocol 3, steps 14 and 15). At least ten to twelve colonies from each transformation should be tested.

True positives should show a LEU⁺ LacZ⁺ phenotype with pMW103-Bait1 + pLacGus + pGBS10-Bait2, but not with pEG202-Ras + pLacGus + pGBS10-Krev. Clones transformed with Raf control PCR will provide both positive and negative controls: pMW103-Bait1 + pLacGus + pGBS10-Bait2 should be negative while pEG202-Ras + pLacGus + pGBS10-Krev should be positive when assayed for β -galactosidase and growth on –Leu plates, but negative for β -glucuronidase activity and growth on –Lys plates. Vice versa, clones of pEG202-Ras + pLacGus + pGBS10-Krev transformed with Krit1 control PCR products should be blue on Xgluc, but not Xgal, and grow on –Lys, but not on –Leu dropout plates. Again, pMW103-Bait1 + pLacGus + pGBS10-Bait2 should be completely negative. The fraction of the correct clones in positive controls is indicative of the efficiency of recombination in this particular experiment. Normally, it should be between 85% and 95%.

13. Proceed with sequencing (Chapter 7) and biological characterization.

14. If recovery of yeast plasmids for archival purposes is desired, isolate yeast plasmids using traditional phenol-chloroform technique (UNIT 3.6) or a commercially available kit. Transform selected positives into *E. coli*, using 1 to 2 μ l β -glucuronidase-treated frozen yeast (see Basic Protocol 3).

Use of electroporation is highly recommended.

*An alternative protocol can be used in case PCR technology is not readily available, or in case of failure to obtain a specific PCR product using the library vector primers. It is based on plasmid isolation, its amplification in *E. coli*, and then transformation back into yeast (see Alternate Protocol).*

A database of common false positives has been compiled and made available on the World Wide Web, at <http://www.fccc.edu/research/labs/golemis/interactiontrapinwork.html>. Particularly for cDNAs only isolated a single time, or which do not appear to make biological sense in the context of the starting bait, it may be helpful to consult the database to make sure the clone has not been reported by multiple additional groups.

ALTERNATE PROTOCOL

SCREENING FOR INTERACTION TRAP POSITIVES BY YEAST PLASMID RECOVERY

This protocol can be used instead of the rapid PCR screen (see Basic Protocol 4). See outline in Figure 20.7.9 for additional details. For materials see Basic Protocol 4. Also see UNIT 1.6 for additional reagents and equipment for preparation of plasmid DNA.

1. Isolate plasmid DNA from selected yeast clones (see Basic Protocol 4, steps 1 and 2) and transform into *E. coli*.

*A transformation protocol described in UNIT 13.11 can be used. Alternatively, a number of kits for yeast minipreps are commercially available (e.g., from Clontech and others). Some companies (e.g., Qbiogene; <http://www.qbiogene.com/services/two-hybrid.html>) will isolate plasmid from the yeast cells, transform, and amplify the plasmid in *E. coli* to produce a sequencing template.*

2. Select at least two bacterial clones for each yeast clone, and prepare a small quantity of plasmid DNA (UNIT 1.6) from each bacterial clone.

*If using a specialized Ap^R LexA-fusion bait plasmid in combination with Ap^R library plasmid, it will be necessary to select specifically for transformants containing a library plasmid by the ability of the yeast TRP1 gene to complement the *E. coli* trpC mutation in a KC8 strain (see UNIT 20.1).*

3. Analyze the isolated plasmids by restriction digest (*UNIT 3.1*), to identify redundant clones and to confirm that both isolates from the same yeast clone are identical.
4. Follow the instructions given above (see Basic Protocol 4, steps 9 to 14) as described, except transform with purified library plasmids, instead of a mixture of PCR product and digested library vector.

COLORIMETRIC ASSAY OF β -GALACTOSIDASE AND β -GLUCURONIDASE ACTIVITY BY AGAROSE OVERLAY

SUPPORT PROTOCOL 1

There are a variety of the standard assays used to assess β -galactosidase and β -glucuronidase activity in yeast, including colony overlay, colony lift (filter) assays, and growth on plates containing Xgal or Xgluc. Although popular, assays in which yeast are grown in the presence of substrate yield sometimes erratic results. One of the reasons for this is that expression of some combinations of bait and prey may result in greater permeability of yeast cells, reflected by the increased degree of uptake of Xgal from the surrounding media (yeast seed density may also play a role). In addition, Xgal plates are buffered to approach pH 7.0 (optimal for β -galactosidase activity), while yeast grow optimally on media of pH 5.5. Thus, yeast grow suboptimally under these conditions.

Overlay and colony lift (filter) assays avoid these issues since yeast are first grown under optimal conditions and then exposed to substrates following permeabilization of yeast. Of these techniques, the overlay technique provides the most consistent results in the hands of the authors, in part because of the avoidance of issues such as the sometimes uneven transfer of colonies to filters. Xgal and Xgluc overlay plates are quick and extremely sensitive, and normally will give a strong signal within an hour.

Materials

Plates containing spotted yeast colonies to be assayed

Chloroform

Xgal agarose: prepare 1% low-melting agarose in 100 mM KHPO₄, pH 7.0, and heat to boil; cool to ~60°C and add Xgal to 0.25 mg/ml; prepare fresh

Xgluc agarose: prepare as described for Xgal agarose, except replace Xgal with Xgluc

1. Gently overlay each plate containing spotted yeast colonies to be assayed with a minimal amount of chloroform (CHCl₃), pipetting slowly in from the side so as not to smear colonies. Leave colonies completely submerged for 5 min, but do not cover the dish with the lid.

CAUTION: CHCl₃ is quite toxic and should neither be inhaled nor come into contact with skin. Wear gloves and work in a chemical hood. Try to minimize the amount of CHCl₃ used, just enough to cover the colonies. Try to avoid contact with the walls of the plate, as the plastic will melt.

2. *Optional:* Briefly rinse the plates with another ~5 ml chloroform, drain, and allow to dry uncovered for another 5 min at 37°C or for 10 min in a hood.
3. Overlay the plate with ~10 ml Xgal or Xgluc agarose, making sure that all yeast spots are completely covered.

Plates will be chilled after CHCl₃ evaporation, so it will be difficult to spread <7 ml of top agarose.

4. Incubate plates at 30°C and monitor for color changes. It is generally useful to check the plates after 20 minutes, and again after 1 to 3 hours.

DETECTION OF BAIT PROTEIN EXPRESSION

The technique described here works well for the vast majority of baits. If it is not clear, however, whether the degradation of the protein occurs in the cell or in the test tube. A number of more rigorous (and time-consuming) protocols are available, where yeast lysates are prepared first (*UNIT 13.13*).

Materials

Master plates containing primary transformants of each bait (see Basic Protocol 1) and positive control

Selective medium (*UNIT 13.1*)

2× Laemmli sample buffer (*UNIT 20.1*)

Antibodies to LexA and cI (Invitrogen)

Additional reagents and equipment for minigel electrophoresis (*UNIT 2.5A*)

1. Transfer colonies from the master plate containing two primary transformants of each bait into the appropriate selective liquid media using sterile technique. Grow overnight cultures at 30°C with aeration. The next morning, dilute saturated cultures into fresh tubes containing 3 to 5 ml selective medium to a starting density of OD₆₀₀ ~0.15 and grow at 30°C with aeration.
2. When the culture reaches an OD₆₀₀ of ~0.45 to 0.7 (4 to 6 hr), transfer to a 1.5-ml microcentrifuge tube and microcentrifuge 3 to 5 min at full speed. Aspirate supernatant and resuspend pellet in 50 µl of 2× Laemmli sample buffer. Vortex and then boil samples for five min.
Such samples may be analyzed immediately or stably frozen at -70°C. Alternatively, the unboiled samples can be frozen at -70°C (stable for at least 4 to 6 months), and boiled before use.
3. Pulse centrifuge to pellet debris and chill on ice. Load 5 to 15 µl per well of a minigel (*UNIT 2.5A*) and analyze by immunoblotting following standard protocols. Bait should be visualized using antibody to LexA or cI which allows comparison of expression levels of the Bait protein under test with other standard bait proteins.

PREPARATION OF HIGH-QUALITY DIGESTED LIBRARY PLASMID

This control experiment is an indicator of the degree of digestion of the library plasmid. The background level of colonies transformed with digested empty library plasmid should be minimal. If the background is high, digestion of the empty library plasmid should be improved—e.g., by adding more enzyme(s) and/or increasing the digestion time. If transformation efficiency with digested library plasmid plus Raf1 PCR product with latone is better than with the digested empty plasmid alone by 5- to 20-fold, proceed to the next steps. Uncut library plasmid is a positive control for the transformation.

Additional Materials (also see *Basic Protocol 4*)

Empty library plasmid: pJG4-5

Restriction enzymes (e.g., *EcoRI* and *XhoI*; *UNIT 3.1*)

pJG4-5-Raf1 (Table 20.7.4)

pJG4-5-Krit1 (Table 20.7.4)

SKY 48 (Table 20.7.3)

Glu/CM -Trp dropout plates (*UNIT 13.1*)

1. Digest an empty library plasmid with two enzymes producing incompatible ends in the polylinker region (e.g., *EcoRI* and *XhoI*).

Purification is not necessary.

2. PCR amplify (*UNIT 15.1*) *Raf1* and *Krit1* sequences from pJG4-5-*Raf1* and pJG4-5-*Krit1* plasmids using the FP1 and FP2 primers. Analyze and purify the PCR product if necessary. PCR products from the control reactions above can be also reused in this step.
3. Transform SKY48 with the following:
 - 50 to 100 ng digested library plasmid
 - 50 to 100 ng digested library plasmid and 0.5 to 1 μ g *Raf1* control
 - PCR product
 - 50 to 100 ng uncut library plasmid

Save the digested library plasmid and the *Raf1* and *Krit1* PCR products.
4. Plate the transformations on Glu/CM –Trp dropout plates and incubate at 30°C until colonies grow (2 to 3 days). Store at 4°C.

COMMENTARY

Background Information

The dual bait reagents are built upon the interaction trap form of the two-hybrid system (*UNIT 20.1*; Gyuris et al., 1993) and allow the expression of two independent baits in one yeast cell. This system, therefore, facilitates the efficient isolation of proteins that interact with either one or both of the two bait proteins. Using this system, one can make a direct comparison of the binding partners within a family of proteins or dissect similarities/differences in binding partners of wild-type and mutant forms of a protein.

This system offers important advantages in mutagenesis and small molecule studies. For example, the products from random mutagenesis of a protein can be screened for the persistence of an interaction with one binding partner and the simultaneous disruption of an interaction with a second binding partner. This allows identification of a mutant protein that specifically disrupts binding of discrete partners while preserving other interactions, thus selecting against mutations that cause global conformational disruptions of the mutagenized protein. Similarly, this system should provide a powerful tool for studying the promotion or disruption of protein–protein interactions using peptide or small-molecule libraries. It may be possible to identify compounds that affect the interaction of a (disease-related) mutant form of a protein with a binding partner, but not a wild-type form of the protein with the same binding partner. The authors believe this system is well suited for discovery of specific interactors with individual members of families of related proteins as well as for high-throughput studies of factors affecting protein–protein associations.

In the dual bait system (Fig. 20.7.1, top), a LexA-fused bait interacts with a galactose-inducible activation domain-fused partner to induce the expression of two reporter genes under transcriptional control of LexA operator (*lexAop*) sites: plasmid-borne *LacZ* and integrated *LEU2*. Three additional components include a *cI*-fused alternate bait, a plasmid-borne *GusA* (β -glucuronidase) reporter gene cassette, and an integrated reporter gene, in which *cI* operators direct the expression of the *LYS2* gene. Since *cI* and LexA are similar in size (237 versus 202 amino acids) and structure, and use related amino-terminal helix-turn-helix domains to bind palindromic operator sites with similar K_M 's (reviewed in Serebriiskii et al., 1999), these two systems are well matched.

A key to fully utilizing the power of these systems is the development of reagents that extend their use to as many proteins as possible, while minimizing potential false or otherwise artifactual results positive (Serebriiskii et al., 2000; <http://www.fccc.edu/research/labs/golemis/InteractionTrapInWork.html>). Based on prior experience optimizing and characterizing functionality of the interaction trap (*UNIT 20.1*; Gyuris et al., 1993; Estojak et al., 1995), several points can be noted at which it is desirable to have flexibility. These include control of bait(s) expression level, inducible expression of bait(s), and range of reporter sensitivity (Fig. 20.7.1). In addition, convenience of use is improved by the availability of bait expression variants with diverse polylinkers, plasmids with alternative *E. coli* selectable markers to aid plasmid recovery from yeast, and antibodies allowing bait detection. A whole array of reagents has been developed that should allow modulation of these

properties for the dual bait. These reagents, and compatible interaction trap reagents, are summarized in Table 20.7.1, Table 20.7.2, Table 20.7.8, and Table 20.7.9. Further details of plasmid construction and composition are available at the authors' Web-site (<http://www.fccc.edu/research/labs/golemis/InteractionTrapInWork.html>).

Selection markers

A limited number of convenient selectable auxotrophic markers are available for use in *S. cerevisiae*. Of the recently described dual bait strategies (Jiang and Carlson, 1996; Inouye et al., 1997; Xu et al., 1997), most achieve the use of two distinct baits by sacrificing one of the standard bait-responsive reporters (see Table 20.7.10). It has been well documented that the most artifact-free usage of two-hybrid systems requires the use of at least two-independent

reporters for each bait. As outlined above, an optimal dual bait strategy requires introduction of a significant number of expression or reporter components into yeast (e.g., two bait-expressing elements, an activation-domain expressing element, and four reporters). In the system presented here, the amino acid biosynthetic genes *LEU2* and *LYS2* are utilized as reporters, while *TRP1* is used to select for an activation-domain fusion plasmid. The remaining convenient markers are *HIS3*, *URA3*, and a drug resistance gene, typically either Zeo^R (conferring resistance to zeocin) or G418^R (conferring resistance to G418 or neomycin). In the original design of the system, the Zeo^R pGKS8 plasmid expressed both a cI-fused bait, and a *cIop-GusA* reporter, while *HIS3* was used to express a LexA-fused protein, and *URA3* for a *lexAop-LacZ* reporter (Serebriiskii et al., 1999). The advantage of this approach is that it

^aAbbreviations: D: interaction within defined set of proteins; M: mutational analysis; A: working with aptamer/peptides; L: library screening; P: pharmacological applications.

creates a single *cI*-bait/reporter unit on a marker that can be used with any two-hybrid system (e.g., GAL4-based; Fields and Song, 1989). A disadvantage is that one must reclon a bait to a new plasmid backbone in order to modulate sensitivity of response, (e.g., by utilizing a reporter with different numbers of operators). Recent modifications, therefore, provide an option in which each bait is expressed independently on separate plasmids, while *LacZ* and *GusA* reporters are present on a common backbone. The recommended set in this protocol includes G418^R vectors for *cI*-fusion expression to be used in combination with classic *HIS3* vectors suitable for expressing *LexA*-fused bait. At user's discretion, equivalent Zeo^R vectors can be used in place of G418^R. For use with Invitrogen's Hybrid Hunter system (which utilizes Zeo^R vectors for *LexA*-bait expression) a number of *HIS3 cI*-bait vectors are available.

Note, while it is formally possible to combine Zeo^R *LexA*-baits and G418^R *cI*-baits (Huang and Schreiber, 1997), the inherent exposure to multiple antibiotics may result in the reduced yeast viability.

Bait vectors

To date, a series of vectors suitable for expressing *LexA*-fusions have been developed allowing expression of proteins at high or low levels, or inducibly following induction by galactose (reviewed in UNIT 20.1). The authors have now developed a comparable series for *cI*-fusions (Table 20.7.3; Fig. 20.7.2; Serebriiskii et al., 2002). pGKS6 (Zeo^R) and pGBS9 (G418^R) utilize the same *ADHI* promoter as in GKS8 to express moderate levels of fusion proteins. In pGKS7 (Zeo^R) and pGBS10 (G418^R), the *ADHI* promoter has been modified to enhance levels of bait expression ap-

proximately five-fold. In pGMS11 (Zeo^R) and pGMS12 (G418^R), the *ADHI* promoter has been replaced with a *GALI* promoter, allowing inducible expression. These vectors, therefore, allow the use of the dual bait system with baits whose continuous expression is toxic to yeast.

Most of the cI-fusion vectors exist in versions with polylinkers of multiple reading frames, to accommodate convenient insertion of cDNAs to synthesize fusion proteins (Table 20.7.2).

Colorimetric reporter constructs

Variation of reporter sensitivity in two-hybrid reagents is most conveniently achieved by varying the number of cognate operator sites for the DBD-fusion protein (Estojak et al., 1995). A series of *cIop-GusA* reporters containing 1, 2, 3, or 4 *cI* operators was created and evaluated for activity in parallel with a comparable series of *lexAop-LacZ* reporters with 1, 2, or 8 operators (Serebriiskii et al., 2002). These reporters demonstrate a graded response based on operator number to the cognate bait-fusion construct, while failing to respond to the negative control bait. For *lexAop-LacZ* reporters, sensitivity increases incrementally with each addition of operator (Estojak et al., 1995). For *cIop-GusA* reporters, however, constructs containing a single operator are clearly least sensitive, while constructs with 2, 3, or 4 operators display similar sensitivity. This difference may reflect differences in properties of cooperative binding between the *LexA* and *cI* proteins. Significantly, *cIop-GusA* reporters with more than one operator displayed a weak background level of *GusA* activation, while quantitation of the *cIop-GusA* reporter activation with *cI-TA* versus negative control *LexA-TA* constructs indicated that the degree of amplification was >50-fold over background, indicating a suitable dynamic range of signal for most applications. The pLacGus plasmid is an example of a plasmid which combines both colorimetric reporters on a single backbone. It utilizes eight *lexA* operators to direct *LacZ* and three *cI* operators to direct *GusA*, and provides a well balanced readout for many general applications. Other plasmids, combining *LacZ* and *GusA* reporters of various sensitivity, can be easily constructed.

Auxotrophic reporter strains

Ideally, an auxotrophic reporter yeast strain will be suitable for genomic level applications (e.g., compatible with interaction mating) and possess modulated sensitivity (e.g., variable

operator number). To date, three strains with an expanded range of response for *lexAop-LEU2* are available. These strains demonstrate high (SKY48), moderate (SKY473), or low (SKY191) sensitivity to a *LexA*-fused activator, based on the number of *lexA* operators present. Although all three strains contain the same number of *cI* operators, SKY473 and SKY191 are fortuitously more sensitive to activation by a cI-fusion. Of these strains, SKY473 has the best balance of sensitivity to both *LexA*- and *cI*-fusions. It has the mating type opposite to that of other strains, and thus can be used in combination with them to set up interaction mating.

The dual bait system has been extensively tested in a variety of applications (see Table 20.7.10), and proved to be robust and versatile (Serebriiskii et al., 2002). It was first validated in analysis of the selective interactions of Raf, Ral-GDS, and Krit1 (AD-fused components) with related Ras family GTPases—i.e., Ras (cI-fused Bait 2) and Krev (*LexA*-fused Bait 1). Raf interacts preferentially with Ras, Krit1 with Krev, and RalGDS with both. The dual bait system successfully identifies correct interactions among these proteins, and these reagents are now used as a set of controls in the described protocol. The authors have also documented the ability of the system to sort high-affinity interactors for either *LexA*- or cI-fused baits from a pool of low-affinity interactors, and to identify mutants in an activation domain-fused prey that selectively alter affinity for discrete *LexA*- versus cI-fused partners (Serebriiskii et al., 1999; Reeder et al., 2001). The new reagents described here have been used effectively to study interactions between known sets of proteins (E. Benevolenskaya and W.Kaelin, pers. comm.), and have been utilized in a number of library screening applications. In these library screens, the two baits used to screen either a bait of interest and a nonspecific control (E. Kotova, pers. comm.), or a wild-type and a mutated form of the same bait (Serebriiskii et al., 2002). Both approaches yielded specific interactive partners that were either known to be biological or have been validated (by GST pulldown or co-immunoprecipitation). Baits used in these studies range from cytoplasmic serine/threonine regulatory kinases, morphoregulatory GTPases (e.g., Cdc42, Rac), or cell cycle regulators (e.g., Cdc6, wild-type/mutant RB protein). Screens have been performed by direct library transformation, mating, or both. Significantly, substan-

Table 20.7.11 Possible Modifications to Enhance LexA-Fused Bait Performance in Specific Applications

Response ^b	Problem ^a					
	Strongly activating	Weakly activating	Not transported to the nucleus or low expression level	Continuous expression of LexA-fusion is toxic to yeast	Bait protein requires unblocked amino-terminal end for function	Bait protein expressed at high levels, unstable or interacts promiscuously
Truncate/modify bait ^c	+	+	–	+	–	+?
Use more stringent strain/reporter combination ^d	–	+	–	–	–	–
Fuse to nuclear localization sequence pJK202	–	–	+	–	–	–
Put LexA-fused protein under GAL1-inducible promoter pGilda ^e	–	–	–	+	–	+?
Fuse LexA to the carboxy terminus of the bait pNLexA ^f	–	+?	–	+?	+	+?
Integrate bait, reduce concentration pEG202I ^g	–	+?	–	+?	–	+

^aPlus sign (+) indicates the response usually helps; plus sign followed by question mark (+?) indicates the response may help, and a minus sign (–) indicates the response will not help.

^bAll of the alternative LexA bait expression vectors remain on an Amp^R selection for bacteria. If using them as is, the investigator may need to use KC8 bacteria to isolate the library plasmid after a library screen.

^cIt may be necessary to subdivide bait into two or three overlapping constructs, each of which must be tested independently.

^dUse of very stringent interaction strains may eliminate detection of biologically relevant interactions.

^eCan no longer use GAL-dependence of reporter phenotype to indicate cDNA-dependent interaction.

^fGenerally, LexA poorly tolerates attachment of the N-terminal fusion domain. Only ~60% of constructs are expressed correctly.

^gReduced bait protein concentration may lead to reduced assay sensitivity.

tially overlapping sets of interactors have been obtained both through transformation and interaction mating (B. Spodik and T. Coleman, pers. comm.), supporting the comparable nature of these approaches. Other work has indicated that these reagents will be useful in pharmaceutical screening applications, as the presence of two baits provides a significant shield against artifactual results based on potential global dysregulation of transcription (Serebriiskii et al., 2002). As with other new technologies, and particularly gene discovery screens, it will be several years until the identified interactors and general use of the system will be completely established. However, at present, the assembled reagents appear to offer an efficient, manipulable set of tools to analyze specific protein-protein interactions.

Critical Parameters and Troubleshooting

To make an ideal bait, a protein of interest should satisfy the following four criteria:

1. It should have little or no intrinsic ability to activate transcription.
2. It should be expressed at reasonably high levels.
3. It should be nontoxic for yeast.
4. It must be able to enter the yeast nucleus and bind DNA.

The first three properties are analyzed in the first protocol (see Basic Protocol 1), so that problems can be identified and potentially corrected before screening. Suggested modifications are summarized in Table 20.7.11 and Table 20.7.12. Currently, there are more options to enhance the performance of LexA-fused baits, than the cI-fused. Therefore, a pro-

Table 20.7.12 Possible Modifications to Enhance cI-fused bait Performance in Specific Applications

Response	Problem ^a

Put cI-fused protein under GAL1-inducible promoter pGMS12 ^d	–	–	+	+?
Use low-level expression vector pGBS9 ^e	–	–	+?	+

^aPlus sign (+) indicates the response usually helps, plus sign followed by question mark (+?) indicates the response may help, and a minus sign (–) indicates the response will not help.

^bIt may be necessary to subdivide bait into two or three overlapping constructs, each of which must be tested independently.

^cUse of very stringent interaction strains may eliminate detection of biologically relevant interactions.

^dCan no longer use GAL-dependence of reporter phenotype to indicate cDNA-dependent interaction.

^eReduced bait protein concentration may lead to reduced assay sensitivity.

tein to be used as a primary bait should be fused to LexA.

The inability of the bait to go to the nucleus cannot be detected as reliably as its activation properties. Although the repression assay (described in *UNIT20.1*) was developed to assess this property, the current trend is to proceed with the screening even if the results of this assay are negative. In addition, this assay is not available for cI-fused baits, and therefore it is omitted in this protocol. However, a researcher should be aware of this possibility, and avoid (or truncate) proteins that have extensive transmembrane domains.

In screening the library, it is very important to obtain it for the tissue source in which the bait protein(s) are known to be biologically relevant. A second prerequisite is to screen a sufficient number of clones to fully represent the library. This latter goal is achieved in two steps. First, it requires an efficient transformation of the library in *S. cerevisiae*. In contrast to *E. coli*, the maximum efficiency of transformation for yeast is up to 1×10^5 cfu/ μ g DNA, so it is extremely important to optimize the transformation procedure prior to attempting library transformation. At least 1×10^6 clones should be obtained for a cDNA library derived from a genome of mammalian complexity. A second step requires an efficient mating of the pretransformed library strain with the bait strain. The number of diploids to obtain depends on the number of clones in the library and the number of primary yeast transformants. The objective is to screen a number of transfor-

ants at least equivalent to the size of the library; if the size of the library was larger than the number of transformants, then all of the yeast transformants should be screened. Under the optimal conditions, ~10% of the library strain cells will mate with the bait cells, forming diploids. Thus, a complete screen of 1×10^7 library transformants requires a single mating with about 1×10^8 cfu pretransformed library strain (and twice as much bait strain).

Colony formation on the selection plates is one of the most variable parts of the screening. For strong interactors, colonies will grow up in 2 days on –Leu plates or 3 days on –Lys plates. However, new colonies will continue to appear for up to one week if the plates are left in the incubator. Growth speed depends on many factors, including the expression levels of the library-encoded protein and the strength of interaction, so not necessarily the most rapidly growing colonies are more biologically relevant to the bait protein.

Dual bait provides a “built-in” control for the specificity of interaction. In addition, second confirmation of positives described in this protocol will test the isolated preys against two more unrelated baits. However, it is generally informative to retest positive clones on more than one bait protein. If possible, library-derived clones should be tested against a set of proteins ranging from almost identical to the original bait to clearly unrelated proteins. If the bait used in the screen showed weak transcriptional activity, it is expected to have greater difficulties with false positive background. In

this case it is advisable to choose a nonspecific control bait that can weakly activate transcription on its own in order to match the background level of transcription activation.

Anticipated Results

Depending on the properties of the bait protein(s) and the type of selection applied, screening a library of $\sim 1 \times 10^6$ primary transformants may yield from zero to hundreds of specific interactors.

Time Considerations

In general, it is good practice to move quickly through the steps of the described protocol. While plasmids will be retained in yeast for a long time, expressed protein levels will gradually drop, making the outcome of the whole screening less predictable. Under the favorable conditions, it will take about 3 weeks to complete the screening, as is outlined in Figure 20.7.2.

Interaction Trap/Two-Hybrid System to Identify Loss-of-Interaction Mutant Proteins

UNIT 20.8

To understand how a specific protein functions, it can be useful to identify mutants that no longer interact with a known partner. This is especially useful for proteins that interact with multiple partners, because it allows dissection of the importance of specific protein-protein interactions. By taking advantage of the ease of the interaction trap/two-hybrid system (UNIT 20.1; Gyuris et al., 1993) and of PCR mutagenesis (UNIT 8.3; Cadwell and Joyce, 1992), it becomes possible to rapidly make and identify proteins that no longer bind to a specific partner protein. These mutants usually result from a single missense mutation, which can easily be identified.

IDENTIFYING LOSS-OF-INTERACTION MUTANT PROTEINS

BASIC
PROTOCOL

In this protocol, two-hybrid analysis in *S. cerevisiae* is used to confirm interaction of a bait, a cDNA encoding a protein of interest fused to a DNA binding domain, with a prey, a cDNA encoding an interacting protein fused to a transcription activation domain (see UNIT 20.1 for more details). The open reading frame (ORF) from the cDNA encoding the prey protein is PCR-amplified with primers designed to remove its termination codon to prepare it for fusion with green fluorescent protein (GFP; Fig. 20.8.1, top left). The ORF is mutagenized by Mn-doped PCR—also known as error-prone (EP)-PCR—to introduce an average of one mutation per DNA molecule (Fig. 20.8.1, middle left), and then PCR-ligated at its 3' end to DNA encoding GFP (Fig. 20.8.1, top right and middle). GFP expression is used as a reporter to ensure that the mutagenesis has not introduced a stop codon into the ORF. The resulting construct is then introduced back into a two-hybrid prey plasmid (pJG4-5) by recombination in *S. cerevisiae* (Fig. 20.8.1, bottom) or by standard cloning techniques (see Alternate Protocol). This mutagenized prey minilibrary is then screened for preys that do not interact with their former partner protein expressed as bait. Colonies of cells which fluoresce green and that carry missense mutant proteins that do not interact with a specific bait protein in plasmid pEG202, as shown by two-hybrid analysis, are chosen for further study. DNA derived from these colonies is sequenced and corresponding single-point mutations are introduced into the original prey plasmid by directed PCR mutagenesis. The noninteracting phenotype is then confirmed by two-hybrid analysis.

Materials

- Genes for proteins of interest
- Two-hybrid interaction trap plasmids (Table 20.1.1):
 - Prey plasmid pJG4-5
 - Bait plasmid pEG202
 - LacZ reporter plasmid pSH18-34
- Two-hybrid interaction trap yeast strain EGY48 (UNIT 20.1)
- CM dropout plates (UNIT 13.1) substituted with 2% glucose (Glc), 2% galactose (Gal), and/or 1% raffinose (Raff) as indicated:
 - Glc/CM –Ura
 - Glc/CM –Ura –His
 - Glc/CM –Ura –His, –Trp
 - Glc/CM/Xgal –Ura –His –Trp
 - Gal/Raff/CM/20 µg/ml Xgal in Z buffer –Ura, –His, –Trp: prepare as described for CM plates (UNIT 13.1) using a 1 mg/ml Xgal stock (20 µg/ml final) in Z buffer (UNIT 13.6)

Analysis of
Protein
Interactions

20.8.1

Figure 20.8.1 Interaction trap/two-hybrid system loss-of-interaction mutant proteins. Circled numbers indicate primers (see Basic Protocol). The asterisk (*) on primer 2 indicates that the stop codon has been deleted from the ORF.

- 2.5 mM (each) dNTP stock solution (UNIT 15.1)
- 2.5 U/μl high-fidelity PCR-compatible DNA polymerase (e.g., *Pfu*Turbo, Kod) and 10× buffer
- 1 U/μl *Taq* DNA polymerase (UNIT 3.5) and 10× Mg²⁺-free reaction buffer
- 2.5 mM MgCl₂
- 50 mM MnCl₂
- Plasmid carrying *EGFP* (e.g., pEGFP; BD Biosciences)
- CM –Trp liquid medium (UNIT 13.1)
- TrpC *E. coli* strain KC8 (*hsdR*, *leuB600*, *trpC9830*, *pyrF::Tn5*, *hisB463*, *lacΔX74*, *strA*, *galU*, *galK*) (UNIT 20.1; constructed by K. Struhl and available from R. Brent), competent
- M9 minimal plates (UNIT 1.1) containing 100 μg/ml amp, 40 μg/ml Leu, 40 μg/ml His, and 40 μg/ml Ura
- Commercial miniprep kit (e.g., Qiagen; optional)
- 30°C incubator
- Long-wavelength UV lamp, or fluorescence microscope equipped with fluorescein or GFP filter set
- Additional reagents and equipment for subcloning into plasmid vectors (UNIT 3.16), lithium acetate transformation (UNIT 13.7), PCR (UNIT 15.1), agarose gel electrophoresis (UNIT 2.5A), restriction digestion (UNIT 3.1), replica plating using velvet filters (UNITS 1.3 & 13.2), interaction trap (UNIT 20.1), purification of DNA by glass beads (UNIT 3.11), DNA minipreps (UNIT 2.1; optional), bacterial transformation (UNIT 1.8), sequencing DNA by dideoxy chain termination (UNIT 7.4), and site-directed PCR mutagenesis (UNIT 8.5)

Confirm interaction of bait protein with prey protein by two-hybrid analysis

Once interaction has been confirmed, the experiment can be started with step 7.

1. Insert the gene (*UNIT 3.16*) for the first protein of interest into the prey plasmid pJG4-5.

This protein will later be mutagenized (see step 10) so that it no longer interacts with its protein partner.

2. Insert the gene (*UNIT 3.16*) for the protein partner into bait plasmid pEG202.
3. Transform EGY48 with ~1 µg lacZ reporter plasmid pSH18-34 by the lithium acetate yeast protocol (*UNIT 13.7*) and select for yeast that grow on CM –Ura dropout medium.
4. Transform 1 µg of both plasmids simultaneously into interaction-trap strain EGY48 carrying pSH18-34. Select for yeast carrying all three plasmids by growing on Glc/CM –Ura –His –Trp triple dropout plates.

Selection for pSH18-34 is achieved by omitting uracil (–Ura), pEG202-derived bait plasmid by omitting histidine (–His), and pJG4-5-derived prey plasmid by omitting tryptophan (–Trp).

5. As a negative control, transform EGY48/pSH18-34 (step 3) with prey vector pJG4-5 and bait vector pEG202 and select colonies on Glc/CM –Ura –His –Trp triple dropout plates.
6. Pick colonies and replica plate onto the following fresh plates:

Glc/CM –Ura –His –Trp
Glc/CM/Xgal –Ura –His –Trp
Gal/Raff/CM/Xgal –Ura –His –Trp.

Colonies carrying interacting bait and prey should appear blue on Xgal/Gal/Raff plates and white on Xgal/Glc plates. Compare with the pJG4-5/pEG202 negative control in which colonies should appear white on all plates.

If the interaction is very strong or if the bait self-activates transcription to some extent (see Critical Parameters and Troubleshooting), the colonies may appear somewhat blue on the control Xgal/Glc plates. If the amount of blue on Xgal/Glc plates is substantial and similar to that seen on Xgal/Raff plates, it may not be possible to use this particular bait in this protocol. However, there are several ways to reduce interaction. For example, one way to reduce background is to use a less sensitive lacZ reporter plasmid, such as pJK103 (see Table 20.1.1). For a detailed discussion on how to reduce background from the bait self-activating the lacZ reporter, see UNIT 20.1, Commentary.

Remove the termination codon from the prey ORF

7. Synthesize the following PCR primers (Fig. 20.8.1) to remove the 3' translation termination codon from the prey by directed PCR mutagenesis:

- a. *Primer 1*: Design to contain 5' sequence homologous to the B42 region of pJG4-5 (for later homologous recombination) fused to ~21 bp of the prey ORF beginning at the initiation codon (ATG).

An example sequence is 5'-GATTATGCCTCTCCCGAATTC-ATG-ORF-3', where the ORF is 21 bp directly downstream of the ORFs initiation codon (ATG).

It is also possible to design an alternate primer 1 for later conventional cloning by including an appropriate restriction site such as EcoRI instead of sequence homologous to the B42 region of pJG4-5 (e.g., CTCTCTCTCTCTGAATTC-ORF-3') where the ORF is 21 bp directly downstream of the ORFs ATG.

- b. *Primer 2*: Design to contain 5' sequence homologous to the reverse complement of the sequence homologous to the 5' end of *EGFP* fused to the reverse complement of the 3' end of the ORF just upstream of, but not including, the termination codon.

An example sequence is 5'-CTCCTCGCCCTTGCTCACCAT-ORF-3', where ORF is the reverse complement of the sequence 21 bp upstream of the termination codon.

8. Set up the termination-codon-removal PCR reaction:

1 ng prey plasmid carrying ORF
0.2 μ M primer 1
0.2 μ M primer 2
2 μ l 10 \times (2.5 mM) dNTPs
2.5 μ l 10 \times polymerase buffer
1 μ l 2.5 units/ μ l high-fidelity PCR-compatible DNA polymerase (e.g., *Pfu-Turbo*; add last).

Use distilled water to bring the final reaction volume to 25 μ l.

9. Perform PCR (*UNIT 15.1*) using the following cycling conditions:

Initial step:	30 sec	94°C
20 cycles:	30 sec	94°C
	60 sec	56°C
	60 sec	72°C
Final step:	10 min	72°C.

10. Check for appropriate-sized PCR fragment on a 1% agarose gel with TBE as the buffer (*UNIT 2.5A*).

Mutagenize the prey ORF

11. Synthesize the following primers for mutagenesis of the prey ORF, with termination codon removed, by Mn-doped PCR (Fig. 20.8.1):

- a. *Primer 3*: Design to contain sequences homologous to the 5' part of primer 1 (step 7; i.e., homologous to the B42 region of pJG4-5), but without any sequence homologous to the prey ORF.

This primer is designed to extend the homology with pJG4-5 to 40 bp for later homologous recombination (see below)—e.g., 5'-CTACCCTTATGATGTGCCAGATTATGCCTCTCCCGAATTC-3'.

If the minilibrary (see below) is to be made by conventional cloning, primer 3 can be designed to be homologous only to the 5' region of alternate primer 1 (step 7), such that it does not contain any sequence homologous to the ORF (e.g., 5'-CTCTCTCTCTCTGAATTC-3').

- b. *Primer 4*: Design to be identical to the 3' section of primer 2—i.e., homologous to the reverse complement of the 5' end of the *EGFP* gene (step 7; e.g., 5'-CTCCTCGCCCTTGCTCACCAT-3').

If the region of interaction is known and defined by a contiguous region on the prey protein, then it may be useful to restrict the mutagenesis to this region by appropriate primer design.

Mn-doped PCR mutagenesis has been described by Lin-Goerke et al. (1997), and Cadwell and Joyce (1992).

12. Set up the Mn-doped PCR reaction as follows:

- 16 μ l 2.5 mM (each) dNTPs
- 2 μ l primer 3 (5 μ M final concentration)
- 2 μ l primer 4 (5 μ M final concentration)
- 5 μ l 10 \times Mg²⁺-free *Taq* reaction buffer
- 5 μ l 2.5 mM MgCl₂
- 2.5 μ l 50 mM MnCl₂
- 1 μ l 10 ng of 1.3-kb DNA fragment (step 10)
- 1 μ l 1 U/ μ l *Taq* DNA polymerase
- 15.5 μ l H₂O.

Mutagenesis occurs by increasing the misincorporation rate of Taq DNA polymerase; it is often referred to as error-prone PCR (see UNIT 8.3 for a more in depth discussion of this methodology).

13. Perform PCR (UNIT 15.1) using the following cycling conditions:

- | | | |
|---------------|--------|-------|
| Initial step: | 2 min | 94°C |
| 36 cycles: | 30 sec | 94°C |
| | 1 min | 55°C |
| | 1 min | 72°C |
| Final step: | 10 min | 72°C. |

Mn-doped PCR mutagenesis needs to be optimized in order to obtain an average of one mutation per DNA molecule. Optimization can be performed by varying the concentration of Mn²⁺ and Mg²⁺ in the protocol. It should be noted that even mutagenesis that results in as many as ten mutations per DNA molecule can be successfully used in this protocol, as the key mutation can be identified by sequencing followed by individually introducing mutations into the prey ORF and checking whether the resulting prey does not interact with the bait.

While it can be useful to vary the both the Mn²⁺ and Mg²⁺ concentrations, the authors have had some success varying just the Mg²⁺ concentration from 1 mM to 7 mM. It is suggested that several reactions be performed in parallel using various Mg²⁺ concentrations. Efficiency of mutagenesis can be later determined by sequencing resulting clones from a minilibrary (see below).

Fuse prey ORF with GFP

14. Synthesize the following primers (Fig. 20.8.1) for amplifying the full-length *EGFP* gene:

- a. *Primer 5*: Design to contain a sequence homologous to the 5' end of the *EGFP* gene.

An example sequence is 5'-ATGGTGAGCAAGGGCGAGGAG-3'

- b. *Primer 6*: Design a sequence where the 5' end is homologous to the reverse complement of the polylinker region of pJG4-5 fused to the reverse complement of the 3' end of the *EGFP* gene.

The 5' end is prepared in this fashion in order to facilitate homologous recombination (see below). An example sequence is 5'-TTGACCAAACCTCTGGCGAAGAAGTCCAAAGCT-TCTCGAGTTACTTGTACAGCTCGTCCATG-3'.

*An alternate primer 6 for conventional cloning (see Alternate Protocol) would consist of sequence creating a compatible site for cloning—e.g., *Xho*I fused to the reverse complement of the 3' end of the *EGFP* gene (5'-CTCTCTCTCTCGAGTTACTTGTACAGCTCGTCCATG-3').*

15. Set up the reaction to amplify *EGFP*:

1 ng plasmid carrying *EGFP* (e.g., pEGFP)
1 μ l primer 5 (1 μ M final)
1 μ l primer 6 (1 μ M final)
2 μ l 2.5 mM dNTPs
2.5 μ l 10 \times high-fidelity PCR-compatible DNA polymerase buffer
1 μ l 2.5 U/ μ l high-fidelity PCR-compatible DNA polymerase (e.g., *Pfu*-
Turbo; add last).
H₂O to 25 μ l.

16. Perform PCR (*UNIT 15.1*) using the following cycling conditions:

Initial step:	2 min	94°C
19 cycles:	30 sec	94°C
	1 min	56°C
	1 min	72°C
Final step:	10 min	72°C.

17. Set up PCR reaction to fuse mutated prey ORF with *EGFP*:

1 ng plasmid carrying *EGFP* (e.g., pEGFP)
1 ng mutated prey ORF DNA (step 13)
1 μ M primer 3
1 μ M primer 6
2 μ l 10 \times (2.5 mM) dNTPs
2.5 μ l 10 \times *Pfu*Turbo buffer
1 μ l *Pfu*Turbo (2.5 units/ μ l; add last)
H₂O to 50 μ l.

This reaction can be scaled up if necessary.

Primers 2 and 4 have previously been used to introduce sequence into the prey ORF such that the mutated ORF and GFP now overlap. This allows fusion of the two pieces of DNA by PCR amplification using primers that are homologous to 5' end of the mutated ORF DNA (primer 3) and the 3' end of the EGFP gene (primer 6; see Fig. 20.8.1, middle).

18. Perform PCR (*UNIT 15.1*) using the following cycling conditions:

Initial step:	2 min	94°C
19 cycles:	30 sec	94°C
	1 min	56°C
	1 min	72°C
Final step:	10 min	72°C.

At least 1 μ g DNA is needed for the minilibrary construction if using the yeast recombination method, or 100 ng DNA if using conventional cloning (see Alternate Protocol). The number of cycles or volume of the reaction should be adjusted accordingly. The yield can be checked by samples removed for gel electrophoresis or by real-time PCR.

Create prey minilibrary by recombination in yeast

See Alternate Protocol if constructing minilibrary by conventional means.

19. Make competent EGY48 carrying pSH18-34 and appropriate bait in pEG202 using the lithium acetate method (*UNIT 13.7*).

20. Plate and select on Glc/CM –Ura –His.

21. Add 1 µg mutated ORF-EGFP DNA (step 18) and 1 µg pJG4-5 linearized with *EcoRI* (UNIT 3.1) to 200 µl competent yeast (step 19).
22. Incubate 30 min at 30°C.
23. Heat shock 2 min at 37°C.
24. Plate on Glc/CM –Ura –His –Trp plates, as appropriate.
25. Determine the total number of independent transformants by counting colonies.

At least 1000 independent transformants will be needed for a successful screen. A lesser amount may be satisfactory if the library contains multiple mutations per DNA molecule.

Screen library for loss-of-interaction prey mutants

26. Replica plate the yeast transformed with the prey minilibrary onto Gal/Raff/CM/Xgal –Ura –His –Trp and Glc/CM/Xgal –Ura –His –Trp using velvet filters (UNIT 1.3 & 13.2), or by patching colonies onto the Xgal-containing plates (UNIT 20.1).
27. Incubate 24 to 48 hr at 30°C.
28. Screen the library for the following two features at the same time:
 - a. Search for mutant preys that no longer interact with the original bait by looking for white colonies on Gal/Raff/CM/Xgal –Ura –His –Trp plates.
 - b. Hunt for clones with uninterrupted ORFs by looking for colonies that remain green when viewed under a long-wavelength UV lamp or, more desirably, a fluorescence microscope equipped with a fluorescein or GFP filter set.

Green fluorescent or white colonies represent candidate loss-of-interaction mutants and should be picked for further analysis.

Identify resulting candidate mutations by sequencing

29. Grow candidate colony overnight in 5 ml CM –Trp medium.
30. Microcentrifuge yeast 20 sec to pellet.
31. Use the glass bead method (UNIT 13.11) to isolate DNA from candidates.
32. Transform *E. coli* trp⁻ strain KC8 (*hsdR*, *leuB600*, *trpC9830*, *pyrF::Tn5*, *hisB463*, *lacΔX74*, *strA*, *galU*, *galK*) with DNA (UNIT 1.8) and plate on M9 minimal plates containing 100 µg/ml amp, 40 µg/ml Leu, 40 µg/ml His, and 40 µg/ml Ura.

This works because there is enough expression of the TRP1 gene in E. coli to complement the trpC mutation in KC8.
33. Perform DNA minipreps (UNITS 1.7 or 2.1B) or use a commercial kit (e.g., Qiagen miniprep).
34. Sequence DNA by dideoxy chain termination method (UNIT 7.4).

Confirm candidate mutations by directed PCR mutagenesis and two-hybrid analysis

35. Analyze the results of sequencing the candidate DNAs:
 - a. *For single mutation:* If a candidate clone has only one missense mutation, that mutation must have resulted in the loss-of-interaction phenotype (i.e., no further analysis is necessary).
 - b. *For multiple mutations:* If a candidate clone has multiple mutations, introduce these mutations into the prey individually to determine which one actually causes the loss-of-interaction phenotype (see below).

**ALTERNATE
PROTOCOL**

36. Use site-directed PCR mutagenesis (*UNIT 8.5*) to introduce single specific mutations into the original prey ORF.
37. Individually transform preys into EGY48 carrying pSH18-34 and the original bait cloned into pEG202 (steps 19 and 20).
38. Replica-plate colonies and screen candidates for loss-of-interaction prey mutants as described above (steps 21 to 32).

CREATE PREY MINILIBRARY BY CONVENTIONAL CLONING

The following steps describe preparing minilibraries by conventional cloning. These steps are used in place of the minilibrary construction procedure described above (see Basic Protocol, steps 19 to 25).

Additional Materials (*also see Basic Protocol*)

T4 DNA ligase (*UNIT 3.14*)

LB medium and plates containing amp (*UNITS 1.1 & 1.4*)

Additional reagents and equipment for gel purification of DNA fragments (*UNIT 2.6*), multiple endonuclease digestion (*UNIT 3.2*), DNA ligation (*UNITS 3.14 & 3.16*)

19. Gel purify both cut fragments (*UNIT 2.6*). Digest mutated ORF-EGFP DNA (see Basic Protocol, step 18) and prey plasmid pJG4-5 with *EcoRI* and *XhoI* (see *UNITS 3.1 & 3.2*).

This presumes that there are no internal EcoRI and XhoI sites in the prey ORF. If these sites are present in the ORF, then alternates must be chosen that are compatible with the unique sites in the polylinker of pJG4-5.

20. Gel purify both cut fragments (*UNIT 2.6*). Ligate 100 ng cut DNA using T4 DNA ligase (*UNIT 3.14 & 3.16*).
21. Transform *E. coli* with library DNA (*UNIT 1.8*). Plate serial 1:10 dilutions of *E. coli* transformed with the library DNA onto LB plates containing amp to determine the number of independent transformants.
22. Amplify library by diluting an aliquot 1:10 into 100 ml LB medium containing amp and growing overnight at 37°C.
23. Make high-quality prey DNA from culture using a maxiprep method (*UNIT 1.7*) or commercial kit.
24. Transform competent EGY48 carrying pSH18-34 and appropriate bait in pEG202 (see Basic Protocol, step 19) with prey DNA by lithium acetate method (*UNIT 13.7*). Plate on Glc/CM –Ura –His –Trp plates, as appropriate.
25. Determine the total number of independent transformants by counting colonies.

At least 1000 independent transformants will be needed for a successful screen. A lesser amount may be satisfactory if the library contains multiple mutations per DNA molecule.

COMMENTARY

Background Information

The methodology described in this unit was used to isolate mutants of caspase 2 that no longer interacted with cyclin D3 (Mendelsohn et al., 2002). The basic techniques involved, the two-hybrid system (*UNIT 20.1*), and PCR mu-

tagenesis (*UNITS 8.3 & 8.5*) are established techniques and are easy to perform. The basic advantage of this methodology is the addition of EGFP as a reporter to identify clones that have not been truncated by termination codons introduced by PCR mutagenesis. EGFP also

serves to eliminate mutants that destabilize the prey protein in yeast.

Critical Parameters and Troubleshooting

There are two critical parameters that must be considered to use this methodology successfully. The first is that the interacting proteins must be well-behaved in the interaction trap/two-hybrid system. If the bait is self-activating, or if the interaction is so strong as to activate the lacZ reporter on the glucose plates that should greatly repress the synthesis of the prey, then steps must be taken to reduce the sensitivity of the assay. *UNIT 20.1* discusses this in more depth. The bottom line is that some proteins are not amenable to being used as baits in the two-hybrid system. Therefore, perhaps the simplest way to resolve the problem of a self-activating bait is to switch the bait and prey proteins. It is quite possible that when the prey protein is used as a bait, it will not self-activate transcription.

The second critical parameter is the condition of the *in vitro* mutagenesis. Given a specific rate of mutagenesis, the length of the ORF to be mutated is an important consideration. The same rate of mutagenesis that would cause an average of one mutation in a 100-bp ORF will cause an average of ten mutations in a 1000-bp ORF. Critically, there can be great variation from published ideal conditions for error-prone (EP)-PCR. It is strongly recommended that the magnesium and/or manganese concentration(s) be titrated to obtain the desired rate of mutagenesis on the specific template chosen. Another factor to consider is that Mn^{2+} ions may associate with the DNA and interfere with subsequent DNA manipulations. After the completion of the reaction, it may be useful to add a large excess of Mg^{2+} ions to compete out the Mn^{2+} ions, or EDTA to bind up the Mn^{2+} ions, or to subsequently purify DNA by glass-powder isolation from an agarose gel.

One factor to consider is that the screen described here for intact ORFs could be made into a selection by substituting an auxotrophic yeast marker such as *Lys2* for *EGFP* in the PCR fusion step and then transforming a *Lys2* auxotrophic mutant derived from EGY48. In this case, selection could be made on CM dropout –Ura –His –Trp –Lys plates. The absence of lysine would select for the intact ORF. Protein interaction itself is still probably best measured by screening for white colonies on plates containing Xgal, galactose, and raffinose.

Another factor to think about is that it may prove valuable to test the mutated prey against a battery of known interacting proteins as baits in the two-hybrid system. This may be especially useful if the mutated proteins are to be characterized functionally in their native biological context. Any change of phenotype would likely be the result of the loss of a specific protein-protein interaction. The proteins that no longer interact would thus represent potential key players in causing the observed phenotype. In this regard, it is important to note that it may not be the loss of the specific protein interaction selected in this procedure that has true functional significance, but rather the simultaneous loss of interaction of the mutated protein with another interacting protein that would be critical.

Furthermore, an interesting extension of this technology would be to perform a series of experiments to prove the relevance of a particular protein-protein interaction by (1) isolating a loss-of-function version of the prey protein, (2) associating this mutant with a change of phenotype, (3) isolating a mutant version of the partner protein that does interact with the initial mutant, and then (4) showing that the presence of both mutant proteins restores the original phenotype. The methodology described here could easily be modified to this task by the following modification. After isolating the loss-of-function prey mutant, insert it into the pEG202 bait vector, then insert the original bait into the pJG4-5 prey vector and follow the procedure described, but screen for blue colonies that fluoresce green. In other words, look for full-length mutant proteins that interact with the original mutant protein. After identifying such proteins, if simultaneous expression of both mutant proteins in the original biological system restores the original phenotype, then the specific protein-protein interaction between the nonmutated versions of these proteins must be critical for the function associated with the mutant phenotype.

Anticipated Results

Between one and several hundred loss-of-function mutants should be obtained from successful application of this methodology.

Time Considerations

Altogether, this methodology should require ~2 weeks to obtain and characterize loss-of-function mutants, if the cDNAs for the interacting protein pair are available and behave well in the two-hybrid system.

CHAPTER 21

Chromatin Assembly and Analysis

INTRODUCTION

Many nuclear processes require that DNA be recognized by sequence-specific DNA binding proteins. The packaging of DNA into chromatin inhibits DNA binding by most proteins, and also influences the efficiency of events such as transcription, replication, recombination, and DNA repair. These considerations have led to an increased interest in characterizing chromatin structure in general and the precise structural changes that can occur over specific chromosomal domains.

The basic unit of chromatin is the nucleosome, composed of DNA and histones (small basic proteins that are highly conserved in all eukaryotes). Each nucleosome consists of two copies each of histones H2A, H2B, H3, and H4, arranged into an octamer that organizes 146 bp of DNA. The DNA is wrapped 1.65 times around the histones, and so is severely bent compared to DNA in solution. Each histone has an N-terminal “tail” that extends outside the DNA, and these tails are the sites of numerous covalent modifications that contribute significantly to the regulation of chromatin structure. The most extensively studied of these modifications is acetylation, which occurs on lysine residues.

Chromatin structure can be changed by covalently modifying the nucleosome tails or by noncovalently “remodeling” nucleosome structure. Remodeling is an ATP-dependent process that can alter nucleosome mobility and increase the access of DNA binding proteins and nucleases to the nucleosome. Both remodeling and covalent modification of nucleosomes can lead to local changes in chromatin structure that have been associated with activation or repression of transcription. These structural changes can be studied by characterizing the specific chromatin structure over a defined region of the chromosome *in vivo*, and by recapitulating chromatin structure on DNA fragments *in vitro*.

This chapter presents techniques for analyzing chromatin structure. *UNIT 21.1* describes the use of micrococcal nuclease (MNase), an important reagent for chromatin research, in characterizing nucleosome structure across any specific gene in intact cells. Because MNase cleaves preferentially in the linker DNA that lies between individual nucleosomes, MNase cleavage can be used to map the boundaries of nucleosomes and determine their spacing.

To perform a detailed analysis of chromatin structure, it is frequently necessary to assess whether the nucleosomes in a chromosomal domain are covalently modified, and to determine which other DNA binding proteins are bound nearby. The most commonly studied histone modification is the acetylation of lysine residues. Many cellular enzymes are capable of catalyzing this modification, and several of these have been implicated in transcriptional activation. To separate the differentially acetylated histone species, it is necessary to use a specialized gel system (*UNIT 21.2*). This technique can be used to quantify the amount of each acetylated species in a mixture of histones, either a crude histone fraction prepared from cells or a mixture of histones modified *in vitro*. To determine the location of covalently modified histones, or to localize any other DNA binding protein, immunoprecipitations of cross-linked chromatin can be performed (*UNIT 21.3*). This widely used technique, called Chromatin Immunoprecipitation (or ChIP), can determine

**Chromatin
Assembly and
Analysis**

21.0.1

Supplement 68

the relative concentrations of any protein epitope across a region of chromatin, provided a good antisera is available. This technique has been used to analyze relative levels of covalently modified histones across broad regions of chromatin using antisera that recognize specific histone modifications, to localize sequence-specific DNA binding factors, and to analyze components of the general transcription and replication machinery.

Analysis of the precise position and structure of nucleosomes both *in vitro* and *in vivo* can be accomplished using either enzymatic cleavage reagents, such as DNase, or chemical cleavage reagents (*UNIT 21.4*). These agents produce specific patterns of cleavage that reflect the location of DNA on the surface of the histone octamer, and thus give more precise information than MNase cleavage. While these procedures are most frequently used to analyze nucleosomes formed *in vitro* (see *UNIT 21.5-21.7*), they have also been combined with PCR-based technologies to analyze detailed nucleosome structure in intact cells (as in *UNIT 21.1*).

To characterize the functional roles of chromatin structure in nuclear processes, it is necessary to use *in vitro* systems and templates that have been assembled into appropriate chromatin structure. In order to form chromatin *in vitro*, it is first necessary to have a source for core histones (*UNIT 21.5*). Either isolated histones or nucleosomal DNA can be used to transfer histones onto a specific template, although isolated histones can be used in a wider variety of protocols. *UNIT 21.5* also provides methods for isolating intact polynucleosomes from cells, which have a wide variety of uses *in vitro*.

Templates can be assembled into nucleosomes *in vitro* using either salt dialysis (*UNIT 21.6*) or an enzymatic chromatin assembly system (*UNIT 21.7*). Salt dialysis offers the advantage that no specialized proteins are needed, and the final nucleosome preparation is not contaminated by additional factors that might influence further mechanistic studies. It has the significant disadvantage that appropriate nucleosomal spacing on natural templates or on arrays of nucleosomes will not be achieved unless very specialized templates (such as 5S arrays, see *UNIT 21.6*) are used. Enzymatic assembly of nucleosomal arrays (*UNIT 21.7*) will achieve physiological spacing of nucleosomes on virtually any template, and thus is considerably more flexible than salt dialysis. Care must be taken, however, to either purify the template away from the assembly factors following assembly, or to carefully consider the potential role of the assembly factors in any process that is under study.

Many nuclear processes involve the concerted action of several different DNA binding factors. Factors might bind either sequentially or simultaneously to a given regulatory element. To determine whether factors are bound simultaneously, sequential chromatin immunoprecipitation (*UNIT 21.8*) can be used. Antisera to one factor is used to isolate DNA sequences bound by that factor and then a second immunoprecipitation is used with antisera specific to a second factor. Quantification of the amounts of specific DNA sequences that are immunoprecipitated in each step allows a determination of whether two factors can simultaneously occupy the same sequence.

The techniques described above can be used to define the proteins that bind to a specific gene of interest, but sometimes the starting point is a specific factor and the goal is to identify all of the genes that the factor interacts with. Microarray technology (see Chapter 22) can be combined with chromatin immunoprecipitation to identify target sites for a factor from a collection of a large number of DNA sequences. DNA is immunoprecipitated with antisera specific to a regulatory factor and the precipitated DNA is hybridized to a microarray (*UNIT 21.9*). In this way, binding sites for a factor can be identified on any collection of DNA sequences for which a microarray is available.

Robert E. Kingston

Micrococcal Nuclease Analysis of Chromatin Structure

Micrococcal nuclease (MNase) assays of chromatin are relatively simple procedures for obtaining information about the locations of nucleosomes along DNA strands. When nuclei or permeabilized cells are exposed to MNase in the presence of a divalent cation, the enzyme makes double-stranded cuts between nucleosome particles (see *UNIT 3.12*). Treatment of chromatin substrates with very high concentrations of MNase gives rise mostly to mononucleosome-length DNA, whereas low concentrations of the enzyme will produce one double-stranded cut every 10 to 50 nucleosomes (depending on the exact concentration). MNase can also make single-stranded DNA cuts on the histone octamer, and thus experiments to map the positions of nucleosomes are usually performed with native double-stranded DNA.

In this unit, Basic Protocols 1 and 2 describe how to permeabilize cells or prepare nuclei from tissues, respectively, and then perform MNase digestion. Basic Protocol 3 describes how to perform MNase digests of purified genomic DNA, which will serve as a control for the inherent MNase cleavage pattern over a sequence of interest. Support Protocol 1 describes the purification of DNA from chromatin digests in a manner suitable for subsequent analysis. Support Protocol 2 describes different ways of analyzing the purified DNA at the Southern blot level of resolution, and Support Protocol 3 describes a modification of ligation-mediated PCR (LM-PCR; also see *UNIT 15.3*) to map genomic, double-stranded MNase cleavages at the nucleotide level of resolution.

STRATEGIC PLANNING

In an experiment to probe chromatin structure, the chromatin is made accessible to MNase, the chromatin is digested with the enzyme for a brief period of time, the reaction is stopped by the addition of detergent and proteinase, and DNA within the chromatin is isolated free from protein. Prior to initiating such an analysis, it is important to consider the following three parameters, which will dictate a specific experimental strategy.

Chromatin Preparation Method

The quality of an MNase analysis is critically dependent upon the integrity of the chromatin substrate. Isolated nuclei are most commonly used, but there is clear evidence that chromatin components are perturbed during the nuclear isolation procedure. Permeabilized cells retain chromatin components that can be lost during nuclear isolation, and therefore permeabilization is preferable to nuclear isolation (Pfeifer and Riggs, 1991). The method of preparing a chromatin substrate is generally dictated by the source of cells: tissues must usually be disrupted mechanically, and therefore nuclear isolation is required, whereas cell suspensions or cells on tissue culture plates are uniformly accessible and therefore are suitable for cell permeabilization. The latter protocol is also far faster and simpler. The two procedures are described in Basic Protocols 1 and 2.

Type of Information Desired

The extent of MNase digestion of the sample determines the kind of inferences that can be made about the chromatin structure of the genomic region of interest. An extensive MNase digestion, which yields predominantly mononucleosomal-sized DNA fragments, can indicate the frequency with which a DNA sequence is nucleosomal among a population of templates in the reaction. A partial MNase digestion, which yields lengthy

polynucleosomal-sized DNA fragments, can indicate the positions of nucleosomes with respect to a defined point in the DNA, such as a restriction site. Each of these approaches employs a different Southern blotting or LM-PCR strategy to map MNase cleavages, described in Support Protocols 2 and 3, respectively. It is essential to plan a cleavage mapping strategy in order to determine the controls needed for the MNase digestion reactions.

Controls

Several controls are critical for the strategic planning of any MNase study. First, it is essential to analyze an MNase digestion of protein-free DNA, as described in Basic Protocol 3, because MNase cleaves DNA in a highly nonrandom manner. The range of MNase digestion of free DNA should be comparable to the range of digestion of the target sequence seen in chromatin MNase digests. Only MNase cleavages that are induced or enhanced in chromatin, compared to free DNA, can be presumed to provide conclusive information about the presence of nucleosomes and their positions (see Fig. 21.1.1 in Support Protocol 2). Second, with isolated nuclei or permeabilized cells, it is necessary to include a sample that was incubated in the MNase digestion buffer for the same amount of time and at the same temperature as the MNase-treated samples, but without added enzyme. Cleavages that occur over the genomic region of interest in this control will be due to endogenous nucleases. The Commentary following the protocols describes how to minimize the effects of these enzymes (see Critical Parameters and Troubleshooting).

In summary, a well-controlled MNase assay must include the following, preferably all on the same blot or LM-PCR gel, and in the following order: (1) MNase digestion of free DNA at several enzyme concentrations, including a no-enzyme control; (2) MNase digestion of chromatin at several enzyme concentrations, including a no-enzyme control; (3) MNase digestion of a chromatin sample from a different cell type or physiological condition, to determine the specificity of nucleosomal arrangements observed in the first chromatin sample; and (4) an internal marker lane (see Support Protocol 2).

BASIC PROTOCOL 1

MICROCOCCAL NUCLEASE DIGESTION OF CHROMATIN IN PERMEABILIZED CELLS

In this protocol, chromatin substrates are prepared by permeabilizing cultured cells using the detergent lysolecithin (either *in situ* for cells adherent on plates, or in suspension for suspension cultures). The chromatin is then digested with micrococcal nuclease, and the DNA purified so that it is suitable for Southern blot (see Support Protocol 2) or LM-PCR analysis (see Support Protocol 3). Before proceeding with the full-scale experiment, optimal conditions should be determined by performing a preliminary set of trials, both to determine the appropriate lysolecithin incubation conditions and to select a workable range of MNase that yields the desired level of digestion.

Materials

- Cells cultured on 100-mm petri dishes *or* cells in suspension
- Permeabilization solution 1, room temperature and 37°C (see recipe)
- 1 mg/ml lysolecithin (Sigma) in permeabilization solution 1 (mix fresh before use)
- Permeabilization solution 2 (see recipe), with and without MNase (see step 4 below; mix fresh before use)
- 2× TNE SK solution (see recipe)
- Lysis dilution buffer: 150 mM NaCl/5 mM EDTA
- Phase-contrast microscope
- 12-ml conical polypropylene tubes with caps (e.g., Sarstedt)

NOTE: All solutions, pipets, and pipet tips should be at room temperature so that the permeabilization reaction proceeds rapidly.

Carry out cell permeabilization

- 1a. *Adherent cells (per 100-mm plate)*: Working at room temperature (e.g., in a tissue culture hood), aspirate the medium from the cells and add 5 ml room temperature permeabilization solution 1. Do not remove cells from the plates.

Use a separate plate of cells for each MNase digestion condition, remembering to include a zero-enzyme condition (see Strategic Planning). Try to harvest cells at 70% to 90% confluence.

- 1b. *Suspension cultures*: Pellet by centrifugation under conditions appropriate for cell type and resuspend cell pellet in 5 ml permeabilization solution 1.

The remainder of the procedure is the same for suspension cells as for adherent cells, except that centrifugation is required to change solutions.

2. Aspirate medium from each plate, then treat with lysolecithin (diluted from 1 mg/ml stock in 37°C permeabilization solution 1 to 2.8 ml total volume) at room temperature as follows: either use 0.025% lysolecithin and incubate 2 min, or use 0.05% lysolecithin and incubate 1 min.

Lysolecithin has been the preferred reagent for permeabilizing cells (Zhang and Gralla, 1990; Pfeifer and Riggs, 1991), although other reagents have not been explored in depth for this purpose.

Different cell lines or the same cell line cultured under different conditions may require different concentrations of lysolecithin, or different times or temperatures (30° or 37° C instead of room temperature) for the detergent incubation (see Critical Parameters and Troubleshooting).

3. Aspirate solution from plate, then add 5 ml room temperature permeabilization solution 1 (without lysolecithin). Examine the cells by phase-contrast microscopy to be sure that cell lysis has not occurred. If it has, repeat the assay with a lower concentration of lysolecithin.

Carry out MNase digestion of permeabilized cells

4. Aspirate solution from plate, then add 2.8 ml of room temperature permeabilization solution 2 containing either 0, 7.5, 15, or 30 U MNase for a partial digestion assay, or 0, 50, 100, or 200 U MNase for an extensive digestion assay. Incubate 5 min at room temperature.

Dilute the MNase into aliquots of permeabilization solution 2 just prior to use.

5. Aspirate solution from plate, then add 2.8 ml 2× TNESK solution. Swirl around plate to complete cell lysis.

If the benchtop is not level, occasionally tilt the plate during the MNase digestion.

6. Add 2.8 ml lysis dilution buffer. Swirl around plate to complete mixing, then transfer mixture to a 12-ml conical polypropylene tube. Cap tube and incubate overnight at 37°C.

7. Proceed to purification and characterization of the DNA (see Support Protocol 1).

MICROCOCCAL NUCLEASE DIGESTION OF CHROMATIN IN ISOLATED NUCLEI

In this protocol, chromatin substrates are prepared by isolating cell nuclei, the chromatin within the nuclei is digested with micrococcal nuclease, and the DNA is purified so that it is suitable for Southern blot (UNIT 2.9A) or LM-PCR analysis (UNIT 15.3). Different nuclear isolation conditions are described for liver, kidney, and spleen, each of which exhibit different characteristics during homogenization and thus should serve as examples for a wide variety of tissue types.

BASIC PROTOCOL 2

Chromatin Assembly and Analysis

21.1.3

Materials

Animal tissues (e.g., liver, kidney, and/or spleen) from sacrificed animal(s) or biopsy
Nuclear buffers A, B, and C (see recipe)
Calcium- and magnesium-free (CMF) PBS (e.g., APPENDIX 2)
1 M NaOH
2× TNESK solution (see recipe)
0.1 M CaCl₂
Micrococcal nuclease (MNase) stock solution (see recipe)
Razor blades or scalpels
100-mm petri dishes on ice
10- and/or 15-ml tissue homogenizers with Teflon-coated pestles
Tissue grinder motor and chuck
Phase-contrast microscope
Cheesecloth
15- and 30-ml glass centrifuge tubes (e.g., Corex)
Refrigerated high-speed centrifuge with fixed-angle rotor
Ultracentrifuge with SW50.1 rotor and 1/2 × 2-in. Ultraclear tubes
Ultraviolet light spectrophotometer

NOTE: All solutions, test tubes, pipets, and pipet tips should be ice cold.

Carry out nuclear isolation

1. Immediately after sacrificing animal or obtaining biopsy, rinse isolated tissues in 25 ml nuclear buffer A in a 100-ml glass beaker on ice.

For mice, combine tissues from four mice >1 month old.

Do not freeze tissue or nuclei.

2. Transfer tissues to 100-mm plastic petri dishes on ice containing the following amounts of nuclear buffer A: liver, 8 ml buffer A; kidney, 5 ml; spleen, 4 ml. Mince tissues into chunks several millimeters in size using razor blades or scalpels in a scissors-like motion.
3. Decant each minced preparation into a separate homogenizer. For the aforementioned amounts of tissue, use a 15-ml apparatus for liver or kidney and a 10-ml apparatus for spleen. Let spleen fragments settle on ice ~10 min before decanting, allowing red blood cells to remain in the supernatant. For liver and kidney fragments, decant supernatants immediately.
4. Add 5 ml fresh nuclear buffer A to all samples. Mix, decant supernatants again, and resuspend the tissue fragments into 5 ml fresh nuclear buffer A.

IMPORTANT NOTE: *From this point on, perform all manipulations in the cold room.*

5. Homogenize tissues with five to ten strokes of a motor-driven tissue grinder, followed by an additional five sharp strokes by hand. Dilute a small portion of the homogenate into CMF PBS and view under a phase-contrast microscope. Nuclei appear as grey, evenly round blobs. If intact tissue or cells remain, perform an additional five strokes or so with the homogenizer and check once again for quantitative cell breakage.

Some tissues, such as spleen, require considerably less effort to disrupt than liver. Do not proceed until the cells are quantitatively broken.

6. Filter each homogenate through eight layers of folded cheesecloth that has been prewet with nuclear buffer A into a 30-ml Corex tube on ice. Wearing gloves, twist the cheesecloth to elute most of the liquid.

7. Layer homogenates onto cushions of 1:1 nuclear buffer A/nuclear buffer B in 15-ml Corex tubes, using the following volumes of the buffer A + B mixture: liver, 1.4 ml; kidney, 1 ml; spleen, 0.6 ml.
8. Centrifuge 15 min at $12,000 \times g$, 4°C , in a fixed-angle rotor (e.g., 10,000 rpm in 55-34 rotor).

The liver and kidney pellet should be large, with a bright red center surrounded by brown. The spleen pellet should be small and brown.
9. Discard supernatants and resuspend pellets into the following volumes of nuclear buffer B: liver and kidney, 11 ml; spleen, 3.6 ml. First add ~ 2 ml to each pellet and gently resuspend into a thick slurry, then add remaining nuclear buffer B.
10. Layer 3.6 ml of each suspension over 1.2-ml cushions of nuclear buffer B in $\frac{1}{2} \times 2$ -in. Ultraclear SW50.1 centrifuge tubes (liver and kidney in three tubes; spleen in one).
11. Spin 90 min at $120,000 \times g$ (e.g., 37,000 rpm in SW50.1 rotor) 4°C .
12. Decant by inverting tube and blotting rim on a Kimwipe tissue. Gently resuspend each pellet into the following volumes of nuclear buffer C: liver and kidney, 0.2 ml; spleen, 0.25 ml. Combine suspensions from a single tissue type into a single tube and keep on ice.
13. Dilute 5 μl of each nuclear suspension into 2 ml of 1 M NaOH and measure the OD_{260} by spectrophotometry. Dilute the nuclear suspensions with nuclear buffer C to obtain the following diluted OD_{260} values: liver, $\text{OD}_{260} = 0.25$; kidney and spleen, $\text{OD}_{260} = 0.085$.

Carry out MNase digestion of isolated nuclei

14. Remove one-fifth of each nuclear suspension and mix with an equal volume of $2 \times$ TNESK solution. Mix very well. Incubate overnight at 37°C .

This sample serves as a “quench” control for the extent of nuclear digestion prior to warming up the nuclei.
15. Divide remaining volume into the following number of reaction tubes on ice: liver and kidney, up to six; spleen, about three. Be sure to agitate samples frequently to prevent clumping.

Each reaction tube will be used for a different concentration of MNase.
16. Add 0.1 M CaCl_2 to the first tube to a final concentration of 3 mM, incubate tube 3 min at 37°C , then add equal volume of $2 \times$ TNESK solution and incubate overnight at 37°C .

This sample serves as an essential control to assess the level of endogenous nuclease. Swish the tube around in the 37°C water bath to facilitate warming.
17. Add 0.1 M CaCl_2 to the next tube to a final concentration of 3 mM and incubate tube 1.5 min at 37°C to warm nuclei.
18. Add the desired amount of MNase to each tube. For partial MNase digestions, try the following ranges: liver and kidney, 0.1 U MNase per ml reaction, 0.2 $\mu\text{g}/\text{ml}$, 0.5 $\mu\text{g}/\text{ml}$, 1 $\mu\text{g}/\text{ml}$, and 2 $\mu\text{g}/\text{ml}$; spleen, 0.5 $\mu\text{g}/\text{ml}$ and 1 $\mu\text{g}/\text{ml}$. For extensive MNase digestions, try a range of 10 to 100 U/ml. Mix, then incubate tube 1.5 min at 37°C .
19. Terminate reactions by adding an equal volume of $2 \times$ TNESK solution and shaking the tube sharply a few times to mix, then incubate overnight at 37°C .

20. Repeat steps 17 to 19 in succession for each MNase concentration to be used.

Do not add the CaCl₂ to all tubes at the same time. Do each CaCl₂ addition and MNase digestion separately.

21. Proceed to purification and characterization of DNA (see Support Protocol 1).

MICROCOCAL NUCLEASE DIGESTION OF PURIFIED GENOMIC DNA

The enzyme MNase has a nonrandom sequence preference for cleaving DNA. It is therefore essential to compare the MNase cleavage pattern of chromatin with that for free genomic DNA in order to determine how the inherently nonrandom pattern is influenced by nuclear proteins such as the histones. MNase-digested free DNA, digested to the same relative extent as DNA from a chromatin digest, should be analyzed side-by-side in the cleavage mapping studies described in Support Protocols 2 and 3 below.

Materials

0.5 to 1 mg purified genomic DNA (see Support Protocol 1)

Nuclear buffer C (see recipe)

0.5 M CaCl₂

Micrococcal nuclease (MNase)

0.25 M EGTA

Chloroform

Heating block set to 68°C

Bucket of ice

Additional reagents and equipment for agarose minigel electrophoresis (*UNIT 2.5A*)

1. Dilute 100- μ g aliquots of genomic DNA into a final volume of 300 μ l nuclear buffer C at room temperature. Set up four or five such aliquots.

IMPORTANT NOTE: *For each aliquot, carry out reaction through step 4 before starting the next.*

The reaction is carried out at room temperature, rather than 37°C, to provide better control over the digestion conditions.

2. Add CaCl₂ to 3 mM final concentration.
3. Add MNase to 0.5, 1, 2, or 3 U/ml. Mix sharply to distribute the enzyme evenly (the solution may be viscous). Incubate 3 min.
4. Aspirate solution with a micropipettor and transfer to a tube containing 50 μ l of 0.25 M EGTA, all prewarmed at 68°C. Keep tube in heat block for 10 min.
5. Transfer tube to ice bucket.
6. Electrophorese 200-ng samples on a 1.2% agarose minigel to check the extent of digestion.

It is useful to run these MNase digestion products alongside chromatin DNA samples (see Support Protocol 1), so that the ranges of digestion are similar.

7. Extract the samples of interest once with 1 vol chloroform.
8. Proceed to precipitation, quantitation, and assessment of the DNA (see Support Protocol 1, step 7 onward).

PURIFICATION AND CHARACTERIZATION OF DNA FROM CHROMATIN DIGESTIONS

This protocol has been optimized to maximize the recovery of small amounts of DNA from chromatin digests, and so that the resulting DNA is suitable for direct analysis and should not require further concentration. The protocol begins with a cell or nuclear lysate in an SDS solution that has been incubated with proteinase K for several hours or overnight (this can be used for any small-scale DNA preparation; e.g., see Basic Protocols 1 and 2).

Materials

MNase-digested cell or nuclear lysate (see Basic Protocols 1, 2, and 3)
TE buffer, pH 7.9 (APPENDIX 2)
Neutralized phenol (see recipe)
Chloroform
Ether (for permeabilized cell preparations)
5 mg/ml RNase A (for permeabilized cell preparations)
3 M sodium acetate
95% and 70% ethanol, room temperature
10- or 12-ml polypropylene tubes with tight caps (e.g., 12-ml Sarstedt tubes)
Shaker or rocking device
6-in. Pasteur pipets
30-ml Corex tubes, silanized (APPENDIX 3B; for permeabilized cell preparations)
6000- to 8000-MWCO dialysis tubing (for permeabilized cell preparations)
1- to 5- μ l glass capillary pipets
Glass capillary pipettor
Plastic wrap (e.g., Saran Wrap)
Ultraviolet light spectrophotometer
Additional reagents and equipment for dialysis (APPENDIX 3C) and agarose minigel electrophoresis (UNIT 2.5A)

Carry out organic extractions of MNase-digested DNA

1. Dilute the cell or nuclear lysate with 1 vol TE buffer, pH 7.9. If the resulting volume is ≤ 0.5 ml, perform the following steps in a 1.5-ml microcentrifuge tube; if the volume is ≥ 0.5 ml, transfer to 12-ml polypropylene tube(s).

Diluting the material will make the solution less viscous and reduce loss of DNA during the subsequent manipulations. A marked decrease in viscosity of the MNase-treated samples should be evident at this step, and indicates successful cleavage.

2. In a fume hood, add 1 vol neutralized phenol. Invert tube sharply several times, then place on a gentle shaker or rocking device for 10 to 20 min.
3. Centrifuge the samples 30 sec in a microcentrifuge for those in 1.5-ml tubes, or 5 min at $500 \times g$ (2000 rpm in 55-34 rotor) for those in 12-ml tubes. Using a 6-in. Pasteur pipet, remove the upper aqueous layer and transfer to a fresh tube.

There is little worry about shearing the DNA here, as it should be significantly digested by the MNase and the "0 MNase" samples will be digested with restriction enzymes during analysis.

4. Add 1 vol chloroform. Invert tube sharply several times, then gently shake for 10 to 20 min. Spin and obtain upper aqueous phase as in step 3. Leave the interface behind.

5. Repeat chloroform extractions for a total of two to four extractions, until the interface between the organic and aqueous phases is clear.

For samples that were treated with MNase, two or three chloroform extractions should be sufficient; for samples that did not receive MNase, the aqueous phase should be very viscous and may not clear completely even after four extractions.

For MNase digestions of isolated nuclei and purified DNA, proceed directly to step 7 of this protocol. For MNase digestions of permeabilized cells, proceed to step 6 below.

6. *For permeabilized cell preparations:* Add 1 vol ether, then invert tube sharply several times, burp the tube, and gently shake or rock for 10 to 20 min. Heat uncapped for 10 to 15 min in a 65°C water bath, shaking periodically to help evaporate the ether, then dialyze overnight in 6000- to 8000-MWCO dialysis tubing against two changes of 100 vol TE buffer, pH 7.9, at 4°C. Transfer the dialysate, which will have increased in volume by $\geq 50\%$, to a 30-ml silanized Corex tube and add RNase to 25 $\mu\text{g/ml}$. Incubate 1 hr at room temperature.

The dialysis procedure alleviates the problem of lysolecithin (which can inhibit restriction enzymes) precipitating with the DNA in later steps, and the RNase treatment digests the cytoplasmic RNA present in the permeabilized cell lysates.

7. Add $\frac{1}{10}$ vol of 3 M sodium acetate. Mix well by inversion.

Precipitate, spool, and resuspend DNA precipitate

IMPORTANT NOTE: For each sample, perform steps 8 to 12 in succession without stopping.

8. Add 2.5 vol of 95% ethanol. Invert gently 10 to 30 times, until the Schlieren patterns in the liquid are completely gone, and assess the solution to determine how to proceed.
 - a. If the DNA has not been extensively digested with MNase, a stringy white precipitate should be visible; continue with steps 9 to 13 (and omit steps 14 to 17).
 - b. If the DNA has been extensively digested with MNase, a precipitate may not be visible; proceed directly to step 14 (beginning with overnight incubation at -20°C).
 - c. With a moderate amount of MNase digestion, there may be a small stringy precipitate; spool this out by following steps 9 to 13, and proceed directly to step 14 (beginning with overnight incubation at -20°C) to recapture DNA from the remaining solution.

The DNA from MNase-digested permeabilized cells will probably be too dilute to form the stringy precipitate, in which case proceed directly to step 14.

9. Use a 1- to 5- μl glass microcapillary tube to spool out the DNA precipitate from a single tube. Use a microcapillary pipettor to expel liquid that rises into the capillary while touching the DNA to the inside of the tube to remove excess liquid.

Do this step over a sheet of plastic wrap spread on the laboratory bench. If the spooled DNA falls off the microcapillary, simply use the microcapillary to pick it up from the plastic wrap and carry on.

10. Immediately dip the DNA in a 1.5-ml microcentrifuge tube containing 70% ethanol. Swish around for a few seconds, then again blow out liquid from the tube while removing excess liquid from the DNA.

Work quickly; do not allow the DNA to dry out or it will be impossible to resuspend.

11. Blot the DNA on the inside of an empty 1.5-ml tube. Air dry for ~5 sec.
12. Place the DNA in a 1.5-ml tube containing 75 to 300 μ l TE buffer (depending on the amount of DNA spooled) for isolated nuclei or free DNA experiments, or 400 μ l TE for permeabilized cells. Discard the capillary tube.

Remember to go on to the next sample, starting at step 8. Do not add ethanol to multiple samples at the same time; if the DNA is kept as a stringy precipitate for too long it will be very difficult to resuspend.

13. Let DNA dissolve overnight at room temperature. Vortex lightly a few times, then store at 4°C. Do not freeze.

The DNA is stable for years at 4°C.

Precipitate dilute DNA remaining in solution

14. If the DNA does not precipitate at step 8, or if only a small precipitate can be spooled out, incubate the remaining mixture at -20°C overnight.
15. If using 12-ml polypropylene or 30-ml Corex tubes, centrifuge 10 min at $10,000 \times g$ in a fixed-angle rotor (e.g., 9000 rpm in 55-34 rotor); if using 1.5-ml tubes, spin 5 min in a microcentrifuge. Decant supernatant. Add 0.5 ml of 70% ethanol and gently invert the tube once. Repeat centrifuge spin for 1 min.
16. Decant supernatant. Vacuum dry pellet for 5 min. For experiments with isolated nuclei or free DNA, resuspend in 75 to 300 μ l TE buffer (depending on the size of the pellet and anticipated amount of DNA); for experiments with permeabilized cells, resuspend the DNA in 400 μ l TE. If some DNA from the sample was spooled out and resuspended in TE, use this solution to resuspend the DNA pellet, so the portions are pooled and kept concentrated. Allow solution to dissolve overnight at room temperature and then store at 4°C, as in step 13.
17. *For DNA prepared from permeabilized cells:* Repeat the precipitation starting at step 7 and resuspend the final precipitate in 75 to 150 μ l TE buffer, so that the DNA is sufficiently concentrated for subsequent analysis.

Quantitate and assess DNA

18. Dilute 4 μ l DNA solution in 400 μ l (total) TE buffer and read the OD_{260} . Calculate DNA concentration and total yield, assuming that an OD_{260} reading of 1 equals 50 $\mu\text{g/ml}$ of DNA.

If DNA is very viscous, take up 4 μ l of water in pipet tip and mark the meniscus with a felt tip pen; expel and then use marked tip to take up 4 μ l of the DNA solution.

19. Apply 0.5- μg samples of each DNA to a 1.2% agarose minigel and assess the level of endogenous nuclease and MNase cleavage of the chromatin.

A ladder of bands consistent with the nucleosomal repeat length should be evident.

NUCLEASE CLEAVAGE MAPPING STRATEGIES

Very different approaches are taken to map extensive versus partial MNase digestions, and it is important to know what patterns to look for in the final data, as described below. The methodology for running the DNA samples on agarose gels, blotting to filters, and hybridizing to radiolabeled probes involves well-established technology described in *UNITS 2.5A, 2.9A, & 2.10*, respectively. Mapping MNase cleavages at the nucleotide level of resolution requires special modifications of existing protocols and is described in Support Protocol 3.

SUPPORT PROTOCOL 2

Chromatin Assembly and Analysis

21.1.9

Cleavage Mapping of an Extensive MNase Digest

DNA from a chromatin sample that was extensively digested with MNase is typically assessed by performing gel electrophoresis (e.g., 1.2% to 1.5% agarose or 5% polyacrylamide) to resolve mononucleosomal fragments, blotting to a nylon filter, and then hybridizing to an oligonucleotide or short DNA probe corresponding to the DNA region of interest. Visualization of a mononucleosome-sized hybridization band is evidence that some fraction of the templates in the chromatin population was nucleosomal during the MNase digestion. If an oligonucleotide probe from a different part of the genome is hybridized to another portion of the original chromatin digest, then the signals from the two probes can provide information about the relative frequencies with which the two DNA sequences were nucleosomal in the original population of chromatin templates. The specific activities of the oligonucleotide probes must be comparable or accounted for. Very highly labeled probes are required to observe mononucleosome-sized bands from single-copy higher-eukaryotic gene sequences.

Cleavage Mapping of a Partial MNase Digest by Indirect End Labeling

DNA that is isolated from a chromatin sample that was only partially digested with MNase is typically assessed by an indirect end-labeling experiment (Wu, 1980; see Fig. 21.1.1). The indirect end-labeling approach is designed to map, at the Southern blot level of resolution, the positions of frequent cleavage by MNase at DNA sites in a population of chromatin templates. If multiple MNase cleavage sites occur 160 to 200 bp apart, then nucleosomes may be positioned over the sequence of interest. The variation in the nucleosome repeat length depends upon the organism and other parameters, such as the presence of linker histone in the local chromatin domain. It is also possible to map double-stranded MNase cleavages at the nucleotide level of resolution, using a modification of the LM-PCR technique (see Support Protocol 3).

For indirect end-labeling, the MNase-treated, purified DNA is digested with one or more restriction enzyme(s) that cut(s) at least 1 kb away on both sides of the region of interest (Fig. 21.1.1; see example for *EcoRI*). The genomic DNA is then electrophoresed, blotted to nylon or nitrocellulose membrane, and then hybridized to a purified DNA fragment probe that is 0.5 to 1 kb in length and that abuts one restriction-cut end of the genomic DNA target sequence (Fig. 21.1.1; *EcoRI-HindIII* fragment). Autoradiographic or phosphorimager exposures should reveal the “parent” restriction fragment from control chromatin samples that were not treated with MNase, and the presence of sub-bands in MNase-treated samples. Discrete sub-bands will appear if MNase cleaves at the same position(s) on most of the substrates in the population (Fig. 21.1.1; chromatin sample 2). The positions of cleavages can be determined by the distance in kilobases from the restriction enzyme site abutted by the probe fragment (Fig. 21.1.1, Mapping strategy). If a ladder of sub-bands is evident with the aforementioned spacing, it suggests the presence of a positioned nucleosome or a nucleosome array (Fig. 21.1.1, ovals in diagram in Mapping Strategy).

Inclusion of an internal marker control allows for a definitive mapping of the position of MNase cleavage in an indirect end-label assay. An aliquot of uncut genomic DNA (designated the internal marker control), equal to or less than the amount of the chromatin samples to be loaded onto the gel for Southern blotting, is digested to completion with the restriction enzyme(s) used for the chromatin samples. The internal marker control sample is then digested partially with restriction enzyme(s) that cleave in the vicinity of the region of interest: i.e., where nucleosome phasing is being investigated (Fig. 21.1.1; *HindIII* partial digest). The marker control sample is then loaded onto the same gel as the chromatin samples. It should yield hybridization sub-bands due to the partial restriction enzyme cleavages. These sub-bands provide the ideal standard for the mobility of

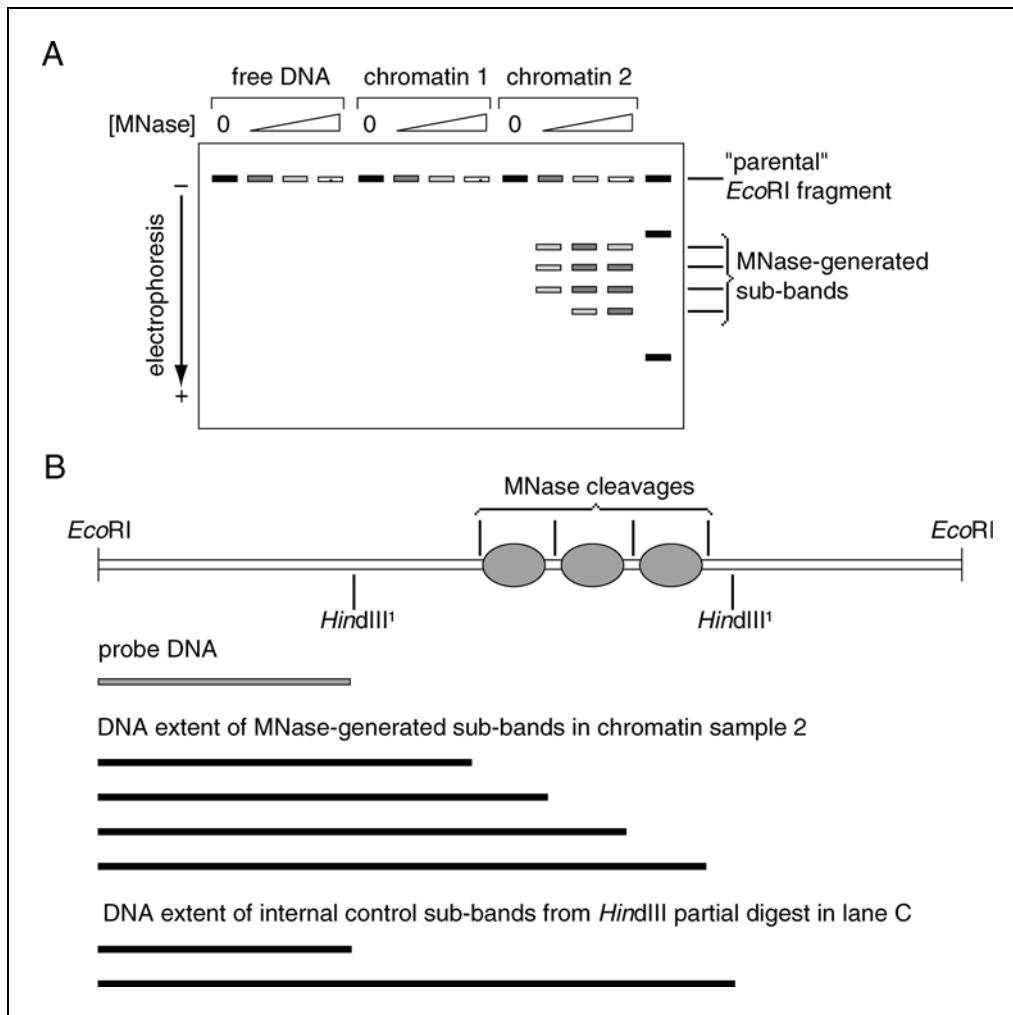

Figure 21.1.1 (A) Hypothetical Southern blot of indirect end-label analysis of MNase-treated chromatin. Expected variation in band intensities are shown with increasing MNase digestion. Lack of sub-bands in free DNA is due to lack of intrinsic MNase hypersensitivity, and lack of sub-bands in chromatin sample 1 is due to lack of nucleosome phasing in the region probed. (B) Mapping strategy and interpretation of bands depicting a positioned nucleosome array.

sub-bands in the MNase digested samples, and allow accurate mapping of the MNase cleavage sites with respect to the positions of the restriction sites from the partial digest (see Liu et al., 1988; McPherson et al., 1993).

Regarding technical details: 12 μg of genomic DNA per lane are sufficient for the Southern blots; large (e.g., 25-cm) 1.2% agarose gels run overnight at 40 to 50 V give the best resolution; and DNA probes should be labeled with ^{32}P to a specific activity of at least 0.5×10^9 cpm per microgram of DNA, preferably in the range of 10^9 cpm/ μg .

USING A MODIFIED LM-PCR PROCEDURE TO MAP DOUBLE-STRANDED MNase CLEAVAGES AT THE NUCLEOTIDE LEVEL OF RESOLUTION

The ligation-mediated PCR (LM-PCR; UNIT 15.3) procedure is used for genomic footprinting and therefore can be used to map MNase cleavages at the nucleotide level of resolution. However, conventional LM-PCR detects single-stranded genomic cleavages, whereas MNase makes single-stranded DNA cleavages on nucleosomes. In order to selectively map these double-stranded intranucleosomal MNase cleavages, modifications to the LM-PCR procedure have been developed (McPherson et al., 1993), as described

SUPPORT PROTOCOL 3

Chromatin Assembly and Analysis

21.1.11

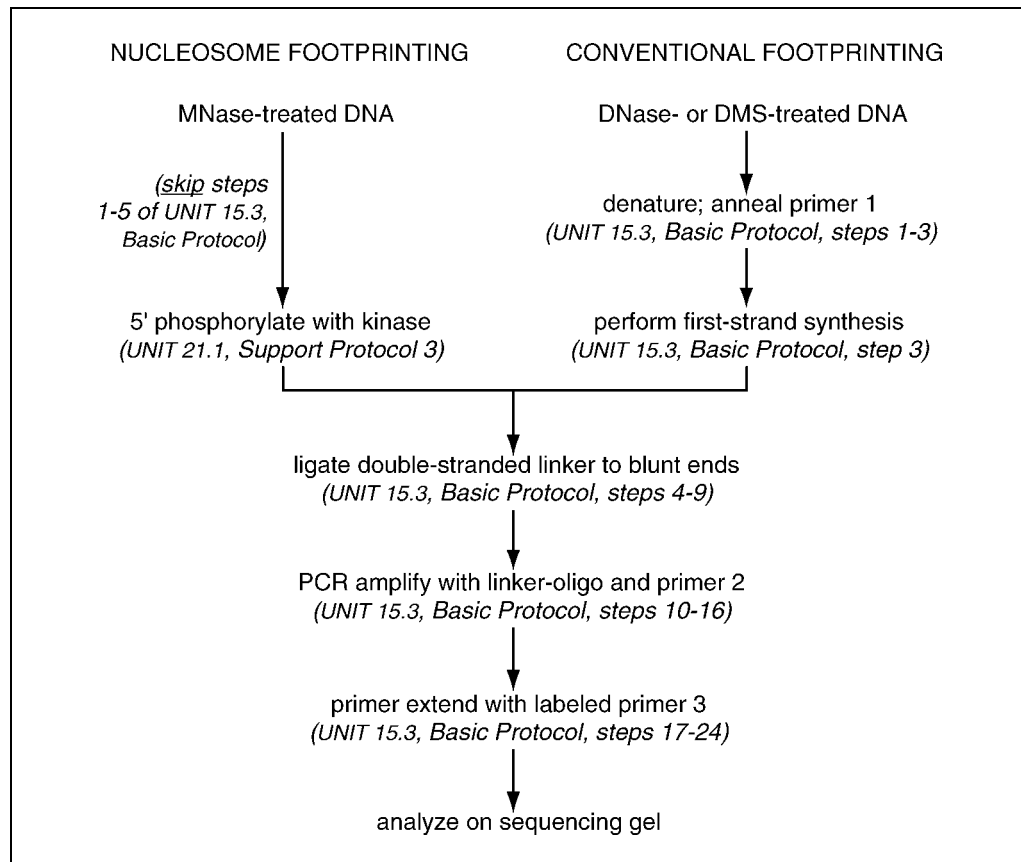

Figure 21.1.2 Nucleosome (MNase; left) versus conventional footprinting (right) by ligation-mediated PCR.

here. See Figure 21.1.2 for a comparison of nucleosome and conventional LM-PCR footprinting.

The essential change that is made in the LM-PCR protocol is to eliminate the initial primer extension step of LM-PCR and directly ligate the asymmetric linker to the MNase-cleaved double-stranded DNA. But because MNase cleavage leaves a 5' hydroxyl, it is necessary to first phosphorylate the cleaved double-stranded substrate so that the long linker strand can be ligated to it (see Fig. 15.5.3). Note that a DMS cleavage pattern with genomic DNA, generated by conventional LM-PCR and run on the same gel as the final MNase LM-PCR products, is necessary to determine the positions of MNase cleavages along the sequence.

Materials

- DNA from MNase digest of chromatin (e.g., see Basic Protocols 1 and 2; see Support Protocol 1 for purification procedure)
- DNA from MNase digest of purified genomic DNA (e.g., see Basic Protocol 3)
- 10 U/μl T4 polynucleotide kinase (e.g., New England Biolabs) and 10× buffer (supplied with enzyme)
- 10 mM ATP
- 0.5 M EDTA, pH 8 (APPENDIX 2)
- 3 M sodium acetate
- 95% and 70% ethanol, room temperature

1. Set up phosphorylation reactions as follows in 1.5-ml microcentrifuge tubes—one for each MNase enzyme digestion point, as well as for no-enzyme and MNase-treated, purified DNA controls:

5 μ l 10 \times kinase buffer
0.5 μ l 10 mM ATP
H₂ O to give 50 μ l final volume
5 μ g MNase-cleaved, purified genomic DNA.

2. Add 1 μ l of 10 U/ μ l T4 polynucleotide kinase (10 U) and incubate 1 hr at 37°C.
3. Add 1 μ l of 0.5 M EDTA and incubate 20 min at 68°C.
4. Add 5 μ l of 3 M sodium acetate, mix, then add 125 μ l of 95% ethanol, mix, and incubate 30 min at –20°C to precipitate DNA.
5. Spin tube 5 min in a microcentrifuge, decant supernatant, add 125 μ l of 70% ethanol, and gently invert once. Spin 2 min, decant supernatant, and dry briefly under vacuum.
6. Suspend the DNA in the tube in water at 0.1 to 0.2 μ g/ μ l and store at –20°C until use.

This DNA can be used directly for LM-PCR; proceed directly to the linker ligation step (step 4 in the Basic Protocol of UNIT 15.3). Use several more cycles of the PCR reaction (e.g., 22 cycles instead of 20) than would be used for conventional LM-PCR.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

MNase stock solution

Dissolve 50 activity units MNase (Worthington Biochemicals) per microliter in 5 mM Tris·Cl (pH 7.5; APPENDIX 2)/0.01 mM CaCl₂. Divide into aliquots in 0.5-ml tubes and store at –20°C.

One activity unit of MNase = 85 OD A₂₆₀ units.

Neutralized phenol

Combine 20 ml phenol with 20 ml of 100 mM Tris·Cl (pH 7.5) in a 50-ml tube. Mix by inversion. After the phases separate, the lower, organic phase will contain neutralized phenol.

Nuclear buffer A

15 mM HEPES, pH 7.5
60 mM KCl
15 mM NaCl
2 mM EDTA
0.5 mM EGTA
0.34 M sucrose
0.15 mM 2-mercaptoethanol (add just before use)
0.15 mM spermine (add just before use)
0.5 mM spermidine (add just before use)

The above was designed for homogenizing liver tissue (Hewish and Burgoyne, 1973; Kornberg et al., 1989). For other tissues, add 0.5% nonfat dry milk (e.g., Carnation).

Nuclear buffer B

15 mM HEPES, pH 7.5
60 mM KCl
15 mM NaCl
0.1 mM EDTA
0.1 mM EGTA
2.1 M sucrose
0.15 mM 2-mercaptoethanol (add just before use)
0.15 mM spermine (add just before use)
0.5 mM spermidine (add just before use)

Nuclear buffer C

15 mM HEPES, pH 7.5
60 mM KCl
15 mM NaCl
10 mM NaHSO₃
0.34 M sucrose
0.15 mM 2-mercaptoethanol (add just before use)
0.15 mM spermine (add just before use)
0.5 mM spermidine (add just before use)

Permeabilization solution 1

150 mM sucrose
80 mM KCl
35 mM HEPES, pH 7.4
5 mM K₂HPO₄
5 mM MgCl₂
0.5 mM CaCl₂

Permeabilization solution 2

150 mM sucrose
50 mM Tris·Cl, pH 7.5 (*APPENDIX 2*)
50 mM NaCl
2 mM CaCl₂

TNESK, 2×

20 mM Tris·Cl, pH 7.4 (*APPENDIX 2*)
0.2 M NaCl
2 mM EDTA
2% SDS
0.2 mg/ml proteinase K (add just before use)

COMMENTARY

Background Information

It is increasingly appreciated that chromatin structure is integral to the mechanisms of transcriptional regulation, DNA replication, and DNA repair (van Holde, 1989; Felsenfeld, 1992). The basic repeating unit of chromatin is the nucleosome core particle, which consists of an octamer of two each of the four core histone proteins, along with ~146 bp of DNA. The addition of linker histone to

the core particle creates the nucleosome and increases the amount of associated DNA by ~20 bp. Nucleosomes and nucleosome cores occur in extensive arrays that span the eukaryotic genome and elicit higher levels of chromatin compaction. Since the histone octamers may span DNA sequences that are important for transcription factors, polymerases, and DNA modification enzymes, understanding precisely where the nucleosomes occur

can provide insight into the role of chromatin structure during physiological conditions of interest.

With the modifications to standard DNA footprinting procedures described in Support Protocol 3, it is now possible to map double-stranded genomic MNase cleavages at the nucleotide level of resolution. This is useful for comparing the apparent positions of nucleosome boundaries to the positions of regulatory-protein binding sites and other genetic landmarks (see McPherson et al., 1993). This method can also be used to compare nucleosome boundaries *in vivo* with those obtained from *in vitro* chromatin reconstitution reactions (Shim et al., 1998).

Critical Parameters and Troubleshooting

For the cell permeabilization in Basic Protocol 1, which is essentially the procedure described by Pfeifer and Riggs (1991), it is best to start with trials to determine the optimal lyssolecithin concentration and incubation temperature and select a workable range of MNase that yields the desired level of digestion. The cells must be checked at various stages of the experiment to be sure that they have not lysed. If cell lysis has occurred, repeat the experiment with a lower concentration of lyssolecithin or at a lower temperature. Lyssolecithin seems to be more potent when fresh than after it has been stored for several months. Conversely, if agarose gel analysis of the bulk chromatin samples reveals a weak ladder of MNase-generated bands and a considerable amount of undigested genomic DNA, it is likely that an insufficient fraction of the cells were permeabilized, and a higher lyssolecithin concentration, longer incubation, or higher incubation temperature may be needed.

Endogenous nucleases can be a major problem when isolating nuclei from certain tissues and cell lines using Basic Protocol 2. A simple way to reduce their effect is to work quickly during the nuclear isolation and chromatin digestion procedures and keep the chromatin on ice as much as possible. It is also helpful to minimize the time taken to warm the sample for the MNase digestion and to use a sufficient concentration of enzyme that the desired amount of digestion is complete within a few minutes. The nuclear isolation buffer contains EDTA to chelate divalent cations that activate endogenous nucleases; spermine and spermidine are included to provide counter-ions that stabilize the chromatin.

To make the nuclear isolation in Basic Protocol 2 readily adaptable for formaldehyde cross-linking experiments, the original protocols of Hewish and Burgoyne (1973) and Kornberg et al. (1989) have been modified here with a Hepes buffer system instead of Tris, because formaldehyde reacts with primary amines in the latter. Spermine and spermidine must be avoided for the same reason, so for formaldehyde-based cross-linking, the cell lysis and nuclear isolations buffers should contain 2 mM MgCl₂ to stabilize the chromatin and lack both EDTA and molecules with primary amines.

For partial MNase digestion studies with indirect end-label probes, as in Support Protocol 2, sub-bands are best seen when ~25% to 75% of the parent restriction fragment is cleaved (i.e., depleted) by MNase. It will be necessary to empirically determine the appropriate concentration of MNase by varying enzyme levels in two-fold steps over the suggested range. Excessive MNase digestion can lead to the artifactual appearance of a positioned nucleosome array because short oligonucleosome fragments bounded by MNase cleavages on both sides can hybridize to the indirect end-label probe.

Note that the activity of MNase is highly dependent upon the concentration of enzyme; a two-fold difference in concentration can yield a marked difference in the average size of double-stranded DNA cleavage product.

Another important parameter is the activity state of the genetic region of interest. Silent chromatin is often highly compacted and may require a ≥ 10 -fold enzyme concentration to cleave a specific genomic sequence to the same extent as when the region is "open" or expressed. Thus, it may require a large difference in bulk chromatin MNase digestion in Basic Protocols 1 and 2 for two samples to exhibit the same extent of cleavage of a specific target gene.

For LM-PCR mapping of nucleosome boundaries, it is critical to first define the general region to be analyzed by mapping MNase cleavages at the Southern blot level of resolution. Chromatin digest samples that just begin to exhibit a laddering band pattern on a Southern blot (see Fig. 21.1.1A, first lane or two of chromatin sample 2) serve as the best substrates for the modified LM-PCR protocol; i.e., under-digested DNA rather than over-digested.

Once a set of genomic DNA samples is obtained where the extents of bulk chromatin

cleavage by MNase are known to give interesting, chromatin-specific results, it is convenient to use these samples as standards for subsequent experiments. That is, 0.5- μ g aliquots of the MNase digested chromatin samples from the known experiment can be run on a 1.2% agarose minigel alongside DNA aliquots from a new chromatin experiment from cells under similar physiological conditions. The gel can be stained with ethidium bromide and samples in the new chromatin experiment which exhibit the same extent of bulk genomic digestion, or laddering, can often be assumed to be worthy of further analysis by the aforementioned hybridization approaches.

Anticipated Results

For an extensive MNase digest, it is critical to compare the intensity of mononucleosome-sized bands hybridizing to DNA probes from different parts of the genome. For two probes of comparable specific activity, if the hybridizing bands are of similar intensity, it indicates that the same fraction of target sequences in the population were nucleosomal. Alternatively, if the hybridizing band is markedly more intense for one probe than for another, then more gene copies in the population hybridizing to the first probe were nucleosomal than in the population hybridizing to the second probe.

It is important to note that nucleosomes do not have to be phased, or positioned, over a DNA sequence in chromatin in order to give clear hybridization signals indicating that the sequence is nucleosomal. Nucleosomes that are randomly positioned over the region spanned by an oligonucleotide will, on average, yield a nucleosomal-sized band upon hybridization to extensively digested chromatin. Thus, if indirect end-labeling analysis indicates a lack of nucleosome phasing over a region, it is inappropriate to conclude that the region is free of nucleosomes. The extensive MNase digestion assay can address this issue.

For a partial MNase digest and indirect end-labeling analysis, it is critical that each sub-band generated by MNase treatment has one end resulting from restriction enzyme cleavage. If the chromatin sample generates a ladder of hybridizing sub-bands that differ in size by \sim 180 to 200 bp, it suggests the presence of a phased nucleosome array. In this case, the size of a sub-band indicates the distance between the restriction enzyme cleavage site and the position of double-stranded MNase cleavage. The hybridizing ladder of bands should not be smaller than the indirect end-labeled probe; if

it is, the band sizes are probably not generated by restriction enzyme cleavage on one side and thus fragment endpoints cannot be predicted. Ideally, internal marker controls are chosen so that the marker bands occur in the region of MNase-generated sub-bands, so that the positions of MNase cleavage can be determined with accuracy. A high level of accuracy in mapping MNase cleavage sites in chromatin, by this method, is useful for planning a primer probe strategy for LM-PCR analysis.

The clusters of MNase cleavages that define apparent linker regions between nucleosomes, by indirect end-labeling, should be evident in the LM-PCR analysis. That is, what appears as a single sub-band on a Southern blot should appear as a cluster of bands on an LM-PCR sequencing gel at about the positions that are predicted by the internal control marker on the Southern blot. Additional bands will probably be seen in the LM-PCR analysis, but if they do not occur in a cluster they may be insufficient to generate a sub-band on the Southern blot. It is worth noting that further evidence, such as may be provided by protein-DNA cross-linking experiments, should be obtained before concluding that an apparent "nucleosomal" ladder of MNase-generated bands is indeed caused by histone octamers on the DNA.

Time Considerations

Cell permeabilization (Basic Protocol 1) is much easier and quicker to perform than nuclear isolation (Basic Protocol 2). The entire cell permeabilization and MNase digestion procedure should take <1 hr. By contrast, for nuclear isolation, it can take several hours to prepare the solutions, and the procedure itself will take ≥ 4 hr, depending upon the number of tissues assayed and the difficulty encountered in releasing nuclei from the cells. One should plan an entire day for Basic Protocol 2. MNase digestion of purified genomic DNA (Basic Protocol 3) should take <1 hr to set up and perform.

When purifying DNA from chromatin digestions (Support Protocol 1), patience is a virtue. The organic extractions are time consuming and careful handling of the material is critical to prevent DNA loss. It may take 30 to 60 min just to precipitate, spool out, and resuspend the DNA; thus, this protocol could take at least several hours on the first day. After that the DNA must be allowed to dissolve overnight, and then quantitated and run on a minigel to assess quality (an additional several hours) on the second day.

When analyzing nuclease cleavages by Southern blot hybridization, any restriction digests that are done (as for a partial MNase digest) should be begun in the morning. After allowing the digests to incubate all day, the gel can be loaded and run overnight. If no restriction digests required (as with an extensive MNase digest), the gel can simply be loaded late in the day and run overnight for agarose, or run several hours, as appropriate, for polyacrylamide. On the second day, the gel should be stained with ethidium bromide, photographed, prepared for blotting, and then blotted overnight. On the third day, the blot should be baked or UV-cross-linked and pre-hybridized in the morning, the probe labeled in the afternoon, and hybridization performed overnight. On the fourth day, the blot should be washed and exposed to a phosphorimager overnight, and finally exposed to X-ray film for 2 to 10 days, depending upon the signal strength.

With nucleosome mapping by LM-PCR, eliminating steps 1 to 3 of the conventional protocol (*UNIT 15.3*) makes the procedure considerably simpler (see Fig. 20.1.2). The phosphorylation reaction and subsequent preparative work in Support Protocol 3 should take a few hours.

Separation of Histone Variants and Post-Translationally Modified Isoforms by Triton/Acetic Acid/Urea Polyacrylamide Gel Electrophoresis

Due to their similarities in size and charge, complete resolution of histones by electrophoresis poses a considerable challenge. The addition of nonionic detergents to the traditional acetic acid/urea (AU) polyacrylamide gel electrophoresis (PAGE) system has afforded an excellent method to separate not only the different modified forms of histones, but also the primary sequence variant subtypes of selected histone species; it is widely used to separate histones with varying levels of acetylation. This unit describes the use of gels containing the nonionic detergent Triton X-100 (Triton is a registered trademark of Rohm and Haas), referred to as Triton/acetic acid/urea (TAU) polyacrylamide gels, for analysis of histones (see Basic Protocol). Also included are support protocols detailing several accessory techniques: assembly of gel plates for the TAU gel (see Support Protocol 1), preparation of histones from isolated nuclei in a solubilized form amenable to electrophoresis (see Support Protocol 2), and electrophoretic transfer of proteins from these gels to PVDF membranes (see Support Protocol 3).

TRITON/ACETIC ACID/UREA (TAU) POLYACRYLAMIDE GEL ELECTROPHORESIS FOR ANALYSIS OF HISTONES

BASIC PROTOCOL

The basic protocol describes the preparation and electrophoresis of one 16 × 22-cm (~60 ml) TAU-polyacrylamide gel (15% acrylamide/0.37% Triton X-100/6 M urea/0.9 M acetic acid; final solution volume 70 ml). The gel polymerizes overnight and is preelectrophoresed during the following day. Histones are resolved overnight and proteins can be visualized through a variety of methods (see Support Protocol 3 and *UNIT 10.6*).

Materials

- Glacial acetic acid (17.4 M)
- TEMED (*N,N,N',N'*-tetramethylethylenediamine)
- 9.5 M urea (see recipe)
- 10% (w/v) ammonium persulfate (APS; prepare fresh for each gel)
- 10% Triton X-100 (protein grade; Calbiochem)
- 63.5% acrylamide/0.4% bisacrylamide (see recipe)
- Moderately warm water (~45°C) in a beaker
- Running buffer (0.9 M acetic acid; see recipe)
- Scavenger solution (2-mercaptoethylamine; see recipe)
- 1000- and 100-ml sidearm flasks
- Gel-casting assembly (see Support Protocol 1)
- Vertical gel electrophoresis apparatus to accommodate 16 × 22-cm glass plates (see Support Protocol 1)
- Power supply capable of running in constant current mode, with two leads
- 1.5-mm-thick 16-well gel comb
- Disposable syringes with 23-G needles
- Disposable syringe with 18-G needle bent into a U shape
- Hamilton syringe
- Additional reagents and equipment for degassing gel solutions (*UNIT 10.2*)

Chromatin Assembly and Analysis

21.2.1

Prepare TAU gel

1. Combine the following in a 1000-ml sidearm flask:

3.62 ml glacial acetic acid
1.88 ml H₂O
0.329 ml TEMED.

2. Swirl gently to mix, then add:

44.21 ml 9.5 M urea
0.875 ml 10% APS.

3. Degas solution completely (*UNIT 10.2*).

4. Add 2.59 ml of 10% Triton X-100 to the flask and degas a second time.

As the detergent will tend to foam during degassing, do not degas until bubbles are completely gone, only until they are reduced somewhat. If solution is degassed excessively the Triton X-100 will begin to crystallize on the sides of the flask.

5. Place 16.5 ml of 63.5% acrylamide/0.4% bisacrylamide in a 100-ml sidearm flask. Place the flask in a beaker containing moderately warm water (~45°) immediately prior to degassing.

6. Gently degas the acrylamide solution in short bursts, swirling constantly in a warm water bath to prevent precipitation of the acrylamide. Stop when the most vigorous bubbling has ceased (do not degas too long).

7. Pour the degassed Triton X-100/urea into the flask of acrylamide and swirl gently to mix.

8. Immediately pour the gel solution into preset gel assembly set up inside a resealable plastic bag (see Support Protocol 1). Fill gel plates to within 1 to 1.5 cm of the top. Place a 1.5-mm-thick 16-well gel comb between plates and insert it until the gel solution comes halfway up the teeth of the comb.

The authors use a 16-well comb with 6 mm-wide teeth. Observe the gel closely as it polymerizes over the next 30 to 60 min, continually pushing the comb down between the plates to keep the bottom surface of the teeth in contact with the polymerizing wells.

9. Close the resealable plastic bag (with a small amount of distilled water in the bottom to prevent desiccation of the gel) and allow the gel to polymerize overnight.

Gels plates are held together with 5-cm-wide stainless steel binder clips (available from Research Products International). By standing the gel assembly upright on the bottom clips, the gel is raised above the water in the bottom of the plastic bag (see Support Protocol 1).

10. Carefully lift the polymerized gel from the plastic bag, and remove the bottom spacer. Place the assembled plates into the gel electrophoresis apparatus, with the notched plate facing the upper buffer chamber. Fasten the gel assembly to the apparatus using 5-cm-wide binder clips, positioned over the upper chamber gasket to ensure a good seal.

11. Fill both chambers with running buffer. Remove bubbles from the bottom surface of the gel using a syringe with an 18-G needle bent into a U shape. Gently remove the comb from the gel assembly, and carefully straighten any bent well walls with the needle of a disposable syringe (23-G needle). Rinse the wells with the same syringe filled with running buffer.

Electrophorese the gel

12. Connect gel to power supply with the positive (red) electrode placed uppermost. Preelectrophorese the gel at 130 V (constant voltage) in running buffer until the current no longer falls (~4 to 5 hr). During this time, periodically shut off the power supply and rinse the wells of the gel using a disposable syringe (with 23-G needle) filled with running buffer. Also, remove any bubbles that have accumulated at the bottom surface of the gel using a syringe with an 18-G needle bent into a U shape.

Removing bubbles will help to decrease the time required to reach constant current during preelectrophoresis.

13. Remove the running buffer from both chambers of the gel apparatus. Add water to the top chamber and rinse the wells. Pour the water from the chamber and remove excess water from the wells using a disposable syringe with 23-G needle, being careful not to pierce the bottom of the wells with the syringe tip.
14. Distribute scavenger solution evenly throughout the wells using a 1-ml pipettor. Slowly add fresh running buffer to the top chamber, being especially careful when the buffer begins to run into the wells; the running buffer should overlay the scavenger. Fill the lower chamber with buffer and continue electrophoresing the gel at 300 V for 3 hr.

Because the gel is polymerized using an oxidizing agent as a catalyst, the application of a "scavenger," or reducing agent, is required prior to the introduction of the sample. Scavenging the gel after preelectrophoresis inhibits oxidation of proteins during electrophoresis (see Background Information).

15. Repeat step 10.
16. Add fresh running buffer to both chambers and rinse the wells with a syringe filled with running buffer. Load samples (usually 2 to 6 μ l) into wells with a Hamilton syringe, layering the sample directly onto the bottom surface of the well. Rinse each well again with a syringe filled with running buffer immediately before loading each sample, to remove any leaching urea.

Typically ~50 to 75 μ g total histone is loaded per well when gels are to be stained with Coomassie blue. As there is no stacking gel in this system, sample loads should be kept <10 μ l.

It is helpful to load 0.1 to 0.15 ml acetic acid/urea sample buffer (see recipe) into an empty well at the edge of the gel to monitor the migration of the dye front. Often, the volume of the sample is too small for the blue dye front (used in determining when to stop electrophoresis; see below) to remain visible.

17. Electrophorese the gel at 400 V for 15 min. Lower the voltage to 200 V and run until the blue dye component of the methyl green runs off the gel (overnight, or ~15 to 17 hr), or longer (see Critical Parameters and Troubleshooting).
18. Visualize the gel by either Coomassie brilliant blue staining (see UNIT 10.6) or electrophoretic transfer and immunoblotting (see Support Protocol 3 and UNIT 10.8).

ASSEMBLY OF GEL PLATES

This support protocol represents one method of assembling gel plates for a TAU gel. Note that glass plates for TAU gels are longer (22 cm long; 20 cm separating length) than those used in typical SDS-PAGE. This is required to resolve histone primary sequence variants, as well as isoforms modified post-translationally (e.g., by phosphorylation or acetylation). Providing that the length requirement is met, other gel systems (including those that are commercially available) can be substituted.

Materials

- 95% ethanol
- 1% (w/v) agarose, melted
- 16 × 22-cm notched glass plate
- 16 × 22-cm glass plate
- Two 22-cm-long × 1.5-mm-thick Teflon spacers
- 18-cm-long × 1.5-mm-thick Teflon spacer
- Six 5-cm-wide stainless steel binder clips (Research Products International)
- Resealable plastic bag large enough to contain gel-casting assembly

1. Clean surfaces of plates and spacers with 95% ethanol. Use a clean razor blade to remove any possible debris.
2. Place the 18-cm-long spacer (bottom spacer) parallel to the bottom of one glass plate ~0.5 cm in from the edge of the plate.
3. Place the two 22-cm-long spacers (side spacers) parallel to either side of the glass plate ~0.5 cm in from the edge of the plate. Place the bottom edge of each side spacer flush with the top edge of the bottom spacer.
4. Clamp the two gel plates together with binder clips: first place two clips across the bottom of the gel, then two on either side of the gel. If necessary, reposition the spacers so that they are in their proper places. Make sure that the pressure point of the binder clips on the glass plates is directly over the spacers.

It is helpful to assemble the plates with the bottom ~5 cm hanging off the edge of the bench; that way the clips can be placed on the bottom edge of the gel without disturbing the position of the plates. Once the plates are secured with the two bottom clips, they can be picked up without disturbing the position of the plates to attach the final four clips on the sides. Often, the position of the side spacers needs to be adjusted before the side clips are added.

5. Once the clips are on the glass plates, snap the handles over onto the plates so that the gel can be stood up on the base of the binder clips.
6. Seal the sides and bottom of the gel plates with melted 1% agarose to guard against leakage of the gel solution. With a Pasteur pipet, add the agarose to the ~0.5-cm space between the outer edge of the spacers and the edge of the plates.
7. Once the agarose has set, stand the gel assembly upright on its bottom binder clips in a resealable plastic bag with a small amount of water in the bottom to prevent desiccation of the gel. The clips will hold the gel assembly above the surface of the water. Pull the opening of the bag down the sides of the gel to provide access for addition of the gel solution.

HISTONE ISOLATION FROM PREPARED NUCLEI

Histones to be subjected to TAU-PAGE can be extracted from isolated nuclei by a low-concentration acid extraction. The resulting acid-soluble nuclear proteins are then precipitated with TCA and resuspended in acetic acid/urea sample buffer at the desired dilution.

Materials

Isolated nuclei (e.g., see *UNIT 12.1*)
Concentrated sulfuric acid (H₂SO₄; 18 M H₂SO₄) diluted to 0.2 M
100% trichloroacetic acid (TCA)
11.6 M hydrochloric acid (HCl)
100% acetone
Acetic acid/urea sample buffer (see recipe)

1. Resuspend isolated nuclei in 0.2 M H₂SO₄ at a concentration of ~2 mg DNA/ml. Let stand at least several hours, or preferably overnight, at 4°C.
Sonicking the nuclei 1 to 2 sec after suspension in the acid can increase the efficiency of extraction.
2. Microcentrifuge the residual nuclei 10 min at ~12,000 × 4°C, to clarify acid-soluble nuclear proteins (including histones). Transfer supernatant to a clean microcentrifuge tube.
3. Add 1/3 vol of 100% TCA to the acid-soluble nuclear proteins (25% TCA final) and mix well to precipitate the proteins. Let stand 30 min on ice.
4. Microcentrifuge mixture 10 min at ~12,000 × g, 4°C, to pellet proteins.
5. Wash protein pellet in 1 ml of 100% acetone/0.05 M HCl, vortexing to remove any histones from the sides of the tube, and microcentrifuge as in step 4.
6. Repeat wash in step 5, this time in 100% acetone.
7. Dry protein pellet in lyophilizer or Speedvac evaporator.
8. Resuspend protein pellets in acetic acid/urea sample buffer at desired concentration (typically 5 µg total histone/µl) for electrophoresis.

ELECTROPHORETIC TRANSFER OF TAU-POLYACRYLAMIDE GELS

Unlike SDS- and AU-polyacrylamide gels, untreated TAU gels will not directly transfer to a membrane. This support protocol describes an effective method of treating TAU gels for reliable transfer (Delcuve and Davie, 1992).

Materials

Wash buffers I and II (see recipes)
CAPS transfer buffer (see recipe)
100% methanol
Ponceau S stain (Sigma; optional)
Transfer membrane (e.g., Immobilon-P PVDF membrane, Millipore)
Filter paper cut to size of gel

1. Remove gel from plates and place it in a plastic dish large enough for the entire gel to lie flat.
2. Wash the gel twice with rocking for 30 min each in 250 ml wash buffer I.

SUPPORT PROTOCOL 2

SUPPORT PROTOCOL 3

Chromatin Assembly and Analysis

21.2.5

3. Place the dish containing the gel in a fume hood and wash the gel once with rocking for 30 min in 150 ml wash buffer II.

The fume hood is necessary because of the high concentration of 2-mercaptoethanol in wash buffer II.

4. In a small plastic dish, hydrate membrane in 100% methanol for 30 sec, then wash in water for 30 sec. Equilibrate in CAPS transfer buffer.
5. Cut a piece of filter paper to the size of the gel and prewet it with transfer buffer. Assemble gel sandwich on the wet filter paper, with the membrane positioned at the anode side of the gel.
6. Place the gel in a transfer apparatus in CAPS transfer buffer and transfer proteins to membrane at 30 V overnight with cooling to 4°C.

Following transfer, proteins can be visualized by staining the membrane with Ponceau S (Sigma).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Acetic acid, 0.9 M (running buffer)

36.2 ml glacial acetic acid
H₂O to 700 ml

Acetic acid/urea sample buffer

1.8 ml 10 M urea (5.8 M final)
0.160 ml glacial acetic acid (0.9 M final)
1 ml 50% glycerol/0.6% methyl green (see recipe; 16% glycerol/0.2% methyl green final)
0.15 ml 2-mercaptoethanol (4.8% final)

63.5% acrylamide/0.4% bisacrylamide

63.5 g acrylamide
0.4 g bisacrylamide
Dissolve in H₂O to 100 ml

CAPS, pH 10, 500 mM

27.66 g 3-(cyclohexylamino)-1-propanesulfonic acid (CAPS)
Adjust pH with 10 M NaOH
Add H₂O to 250 ml final
Destaining solution
800 ml 100% methanol (20% final)
400 ml glacial acetic acid (10% final)
H₂O to 4 liters

50% (v/v) glycerol/0.6% (w/v) methyl green

0.006 g methyl green (Sigma)
0.5 ml glycerol
0.5 ml H₂O

Scavenger solution

0.326 g 2-mercaptoethylamine (Sigma; 2.12 M final)
0.3 g urea (2.5 M final)
0.1 ml glacial acetic acid (0.87 M final)
1.9 ml H₂O

Transfer buffer

250 ml 500 mM CAPS, pH 10 (see recipe; 25 mM final)

1 liter 100% methanol (20% final)

H₂O to 5 liters

Degas buffer before adding to transfer apparatus.

Urea solutions

9.5 M urea: Dissolve 28.5 g urea in H₂O to 50 ml.

10 M urea: Dissolve 30.03 g urea in H₂O to 50 ml.

Wash buffer I

1.4 ml glacial acetic acid (50 mM final)

2.5 g SDS (0.5% final)

H₂O to 500 ml

Wash buffer II

1.135 g Tris base (Sigma; 62.5 mM Tris final,)

3.45 g SDS (2.3% final)

1.5 ml 14.3 M 2-mercaptoethanol (1% final)

H₂O to 150 ml

Mix all components. Working in fume hood and using a hand-held pH meter, adjust pH to 6.8 with HCl.

COMMENTARY

Background Information

The fundamental repeating unit of chromatin, the nucleosome, contains two molecules each of the core histones (H2A, H2B, H3, H4), along with a single molecule of linker histone (H1, H5, H1^o, etc.). Histones are positively charged, low-molecular-weight proteins that are subject to numerous post-translational modifications, including acetylation, methylation, phosphorylation, poly(ADP-ribosylation), and ubiquitination (van Holde, 1988). Such modifications are thought to play a role in modulating chromatin structure, and have been linked to the regulation of gene activity (Wolffe, 1995; Mizzen and Allis, 1998). In addition, histones are found in a variety of primary sequence variants (e.g., H3.1, H3.2, H3.3), whose patterns of expression are developmentally regulated (van Holde, 1988; Wolffe, 1995). Through sequence variant heterogeneity and selective post-translational modification, an extraordinary degree of variability in nucleosome composition can be generated.

It is possible to resolve the five major histones by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE), but their modified forms cannot be resolved by this method. Acetic acid/urea (AU)–PAGE, as described by Panyim and Chalkley (1969), can separate the post-translationally modified iso-

forms of histones, but the level of detailed resolution of primary sequence variants that can be achieved by this method is limited. The introduction of nonionic detergents such as Triton X-100 to the AU-PAGE system by Zweidler (1978) was an innovative step permitting the simultaneous resolution of histone variants and isoforms modified post-translationally (e.g., by acetylation or phosphorylation; Franklin and Zweidler, 1977).

The separation of histones in these gels is improved by a differential reduction in the electrophoretic mobility that is a direct result of the presence of nonionic detergents. The detergents cause the formation of mixed micelles between the detergent and the hydrophobic regions of the histones, a process that is extremely sensitive to minor differences in the hydrophobicity of each protein (Zweidler, 1978). The urea in the gel acts as a denaturing agent; the acetic acid helps separate histones on the basis of charge. As with the standard acid/urea system, TAU gels can resolve the difference in charge caused by a single functional group (Fig. 21.2.1).

An additional characteristic of this gel technique that contributes to its separation capabilities is the requirement for a “scavenger,” or reducing agent. Because the gels are polymerized using an oxidizing agent as a catalyst, scavenging after preelectrophoresis and prior

Figure 21.2.1 HeLa cells were synchronized with a double thymidine block procedure (2.7 mM thymidine; Peterson and Anderson, 1964; Knehr et al., 1995) and released into S phase for 3 hr. Released cells were then incubated 60 min in the absence (-) or presence (+) of okadaic acid (500 nM; Calbiochem), an inhibitor of cellular phosphatases. Acid-soluble nuclear proteins and isolated histone H1 were subjected to electrophoresis in a TAU gel and analyzed by Coomassie blue staining. Lane M contains hyperphosphorylated H1 (pH1) from cells arrested in M phase by treatment with Colcemid (demecolcine; 0.06 $\mu\text{g}/\text{ml}$). The un- (Ac 0) and monoacetylated (Ac 1) isoforms of histone H4 are indicated.

to the introduction of the sample is required to prevent oxidation of the proteins during electrophoresis, which could change their hydrophobic properties and alter their migration (Zweidler, 1978).

The components of TAU-polyacrylamide gels make electrophoretic transfer of the resolved proteins for immunochemical analysis troublesome. In particular, the presence of a nonionic detergent in the gel impairs the migration of the proteins out of the gel and on to the transfer membrane. The electrophoretic transfer method presented in this unit was developed by Delcuve and Davie (1992) based on the method originally presented for TAU gel transfer by Waterborg and Harrington (1987). First,

this method increases the efficiency of transfer by using an alkaline transfer buffer; alkaline transfer buffer has been found to greatly increase the efficiency of transfer of strongly basic proteins, such as histones (Delcuve and Davie, 1992). Second, this method also alleviates the difficulties presented by the presence of Triton X-100, which interferes with the binding of histones to transfer membranes (probably due to complex formation between histones and Triton; Zweidler, 1978; Waterborg and Harrington, 1987). The transfer method solves this problem by treating the gel with a variety of solutions prior to transfer. These solutions contain SDS, which displaces the Triton X-100 present in the gels and gives the

Figure 21.2.2 HeLa cells were synchronized with a double thymidine block procedure and released into S phase for 4 hr (lane S). Isolated histone H1 was subjected to electrophoresis in a TAU gel; lane M contains hyperphosphorylated H1 from cells arrested in M phase by treatment with Colcemid (demecolcine). The gel was transferred electrophoretically to Immobilon-P membrane (Millipore) and probed with antibodies specific for either phosphorylated H1 (a gift of Dr. C. David Allis) or total H1. Bound antibodies were detected by a secondary alkaline phosphatase color reaction. Bullets indicate the positions of the unphosphorylated forms of H1, as determined by staining the membrane with Ponceau S. The mono- (1), di- (2), tri- (3), and hyperphosphorylated (H) isoforms of H1 are indicated.

histones the negative charge required for transfer (Delcuve and Davie, 1992). Figure 21.2.2 shows immunoblots of histone H1 resolved in a TAU-polyacrylamide gel and transferred by this method.

Critical Parameters and Troubleshooting

Maintaining contact between the bottom surface of the comb and the interface of the gel as it polymerizes is vital to creating wells with sharp, even bottoms. A flat well surface is also important for establishing good sample migration. Because there is no stacking gel present in this system, the migration of the sample is strongly affected by how evenly it lies prior to electrophoresis, and by the sample concentration (i.e., loading volume).

Increased resolution of protein bands can also be achieved by maximizing the distance the proteins migrate through the gel—which obviously will maximize their separation. Histone H4 migrates the fastest of the five histones in a TAU gel; when analyzing other histones that migrate more slowly, it is advantageous to electrophorese the gel for an extended period of time after the blue dye component of methyl green runs off the gel. The extra electrophoresis time is determined on the basis of experience: for example, the modified forms and subtypes of histone H1 seen resolved in Figure 21.2.2 were electrophoresed in a TAU gel for an additional 5 hr after the blue dye front ran off the gel.

Anticipated Results

Electrophoretic separation of histones on a TAU-polyacrylamide gel is a highly versatile method for analyzing histones by polyacrylamide gel electrophoresis. With an appropriate electrophoresis time, this system will provide satisfactory separation of different modified forms of histones (e.g., acetylated isoforms of histone H4 or phosphorylated isoforms of histone H1). TAU gels will also resolve sequence-variant subtypes of selected histones. In Figure 21.2.1, distinct migration of the different subtypes of histone H3 and histone H2A can be observed.

Time Considerations

The time considerations for running a TAU-polyacrylamide gel are as follows: polymerization of the gel takes a minimum of several hours, but it is recommended that the process be allowed to continue overnight. Preelectrophoresis of the gel takes ~4 to 5 hr, and is usually started early in the morning following overnight polymerization. Scavenging of the gel is then allowed to proceed for 3 hr, and samples are electrophoresed overnight for ~15 to 17 hr, until the blue dye migrates off the bottom of the gel. Electrophoresis can be terminated at this time, or allowed to proceed for several hours if additional separation of more slowly migrating histones is desired.

Chromatin Immunoprecipitation for Determining the Association of Proteins with Specific Genomic Sequences In Vivo

Chromatin immunoprecipitation (ChIP) is a powerful and widely applied technique for detecting the association of individual proteins with specific genomic regions in vivo. In this technique, live cells are treated with formaldehyde to generate protein-protein and protein-DNA cross-links between molecules in close proximity on the chromatin template in vivo. A whole-cell extract is prepared, and the cross-linked chromatin is sheared by sonication to reduce average DNA fragment size to ~500 bp. The resulting material is immunoprecipitated with an antibody against a desired protein, modified (e.g., acetylated, phosphorylated, methylated) peptide, or epitope (in situations where the protein of interest is epitope-tagged). DNA sequences that directly or indirectly cross-link with a given protein (or modified variant) are selectively enriched in the immunoprecipitated sample. Thus, the method is not restricted to sequence-specific DNA-binding proteins. Reversal of the formaldehyde cross-linking by heating permits the recovery and quantitative analysis of the immunoprecipitated DNA. The amounts of specific genomic regions in control and immunoprecipitated samples are determined individually by quantitative PCR. The fold enrichment of certain chromosomal sequences (e.g., presumed binding sites) relative to other chromosomal sequences (e.g., presumed nonbinding sites) provides quantitative information about the relative level of association of a given protein with different genomic regions. Protein association with specific genomic regions can be performed under a variety of conditions (e.g., environmental change, cell-cycle status) and/or in wild-type versus mutant strains. Furthermore, as formaldehyde inactivates cellular enzymes essentially immediately upon addition to cells, ChIP provides snapshots of protein-protein and protein-DNA interactions at a particular time point, and hence is useful for kinetic analysis of events occurring on chromosomal sequences in vivo. In addition, ChIP can be combined with microarray technology to identify the location of specific proteins on a genome-wide basis (see Commentary). This unit describes the ChIP protocol for cells of the baker's yeast *Saccharomyces cerevisiae* (see Basic Protocol 1); however, it is also applicable to other organisms, although some organism-specific modifications related to cell lysis and sonication are necessary. The ChIP protocol for mammalian cells (see Basic Protocol 2) is adapted from the yeast procedure. A protocol for eluting immunoprecipitated protein-DNA complexes is also provided (see Alternate Protocol 1). As an alternative to gel electrophoretic analysis of the PCR products, a quantitative PCR analysis in real time with SYBR Green is also provided (see Alternate Protocol 2). Finally, a procedure to map protein binding sites using ChIP and quantitative PCR scanning is provided (see Alternate Protocol 3).

CHROMATIN IMMUNOPRECIPITATION IN YEAST CELLS

In this protocol, *Saccharomyces cerevisiae* cells are cross-linked with formaldehyde, then harvested and sonicated to release the chromatin. The chromatin is then immunoprecipitated and purified, the cross-links to the formaldehyde are reversed, and the resulting DNA is analyzed by PCR and gel electrophoresis. The procedure is summarized in Figure 21.3.1.

Figure 21.3.1 Scheme for chromatin immunoprecipitation from yeast whole-cell extracts.

Materials

- Saccharomyces cerevisiae* cells (Chapter 13) to be studied
- 37% formaldehyde: store up to 1 year at room temperature
- 2.5 M glycine, heat sterilized
- TBS (APPENDIX 2), ice cold
- FA lysis buffer with and without 2 mM PMSF (see recipe), ice cold
- ChIP elution buffer (see recipe)
- 20 mg/ml Pronase (Roche) in TBS; store up to 1 year at -20°C
- TE buffer, pH 7.5 (APPENDIX 2)
- 20 mg/ml DNase-free RNase A (UNIT 3.13)
- 10 \times loading buffer (UNIT 2.5A)
- Primary antibody against protein or epitope of interest
- 50% (v/v) protein A–Sepharose beads (Amersham Pharmacia Biotech) or equivalent in TBS

FA lysis buffer, room temperature
 FA lysis buffer/0.5 M NaCl
 ChIP wash buffer (see recipe)
 Primers (see Critical Parameters and Troubleshooting)
 3000 Ci/mmol [³²P]dATP
 2-ml screw-cap microcentrifuge tubes with (relatively) flat bottoms
 ~0.5-mm-diameter silica-zirconia (BioSpec; preferred) or glass beads
 Mini bead beater (BioSpec; preferred) or individual or multivortexer
 5-ml syringe
 15-ml conical tubes, disposable
 25-G needles
 Sonicator with microtip probe (e.g., Branson Sonifier 250)
 End-over-end rotator
 0.5-ml PCR tube
 Spin-X centrifuge-tube filter (e.g., Corning)
 65°C water bath
 PCR-purification spin column (Qiagen)
 Software for analyzing PCR primers and products
 Additional reagents and equipment for growth of *Saccharomyces cerevisiae* cultures (UNITS 13.1 & 13.2), phenol/chloroform extraction and ethanol precipitation (UNIT 2.1A), PCR (UNITS 15.1 & 15.7), agarose gel electrophoresis (UNIT 2.5A), and nondenaturing acrylamide gel electrophoresis (UNIT 2.7)

Cross-link protein-DNA complexes in vivo

1. For each sample, grow 200 ml *Saccharomyces cerevisiae* to OD₆₀₀ = 0.6 to 0.8 (UNITS 13.1 & 13.2).

CAUTION: Keep cultures covered or work in a fume hood to avoid noxious formaldehyde fumes.

The volumes of culture can be reduced (20 ml is a reasonable minimum) or increased depending on need. Typically, 20 to 40 ml yeast is used for an individual immunoprecipitation, so the 200-ml volume permits multiple immunoprecipitations from the same cells. This is particularly useful for experiments involving the analysis of multiple factors or for carrying out independent immunoprecipitations involving the same factor for data reproducibility.

2. Add 5.5 ml of 37% formaldehyde (1% final). Cross-link 15 to 20 min at room temperature by occasionally swirling flask or shaking slowly on a platform.
3. Add 30 ml heat-sterilized 2.5 M glycine and incubate an additional 5 min at room temperature.

Glycine stops the cross-linking by reacting with formaldehyde.

Harvest cells

4. Centrifuge cells 5 min at 2500 × g, 4°C. Discard supernatant into a chemical waste container and resuspend pellet in 50 to 200 ml ice-cold TBS. Repeat once.
5. Centrifuge cells for a third time 5 min at 2500 × g, 4°C. Discard supernatant and resuspend cells in 10 ml ice-cold FA lysis buffer.
6. Pellet cells by centrifuging in a benchtop centrifuge 5 min at 3000 rpm, 4°C. Discard supernatant.

The cells can remain on ice for a few hours while other samples are being collected so that all samples may be processed as a group from this point onward. Alternatively, the cells may be frozen in liquid nitrogen or a dry ice/ethanol bath and stored up to several months

at -80°C . This is particularly helpful if multiple samples are being generated during a time-course experiment. If cells are frozen, they must be thawed on ice before continuing with the procedure.

Lyse cells and isolate chromatin

For lysis using a mini bead beater (preferred)

- 7a. Resuspend the cell pellet in 1 ml ice-cold FA lysis buffer/2 mM PMSF. Fill three-quarters of a 2-ml flat-bottomed screw-cap microcentrifuge tube with ~ 0.5 -mm-diameter silica-zirconia or glass beads. Add cells, taking care to avoid introduction of bubbles, and screw the cap on tightly. Make sure there are no leaks.

The mini bead beater is recommended, because it is more efficient at breaking cells (multiple samples can be broken simultaneously). Silica-zirconia beads are more efficient at breaking cells than glass beads and are also recommended. To facilitate cell breakage with the mini bead beater, it is important that the final suspension nearly fill the tube. Do not break > 160 OD_{600} units of cells (i.e., $< 5 \times 10^9$ cells) in a single 2-ml tube; for larger cultures, split the cells into multiple tubes.

- 8a. Lyse cells 3 min with a mini bead beater at maximum speed. Remove sample and incubate 1 min in an ice-water bath. Repeat five times for a total breakage time of 18 min.

This step assumes breakage with silica-zirconia beads. The cell breakage time with glass beads may be longer.

For lysis using an individual or multivortexer

- 7b. Resuspend in 250 μl FA lysis buffer/2 mM PMSF. Add 350 μl silica-zirconia or glass beads to a 2-ml microcentrifuge tube with relatively flat bottom. Add cells.

When using a multivortexer (or standard vortexer), it is important to keep the volume small as this improves cell breakage. Do not break > 160 OD_{600} units of cells (i.e., $< 5 \times 10^9$ cells) in a single 2-ml tube; for larger cultures, split the cells into multiple tubes.

- 8b. Vortex continuously on an individual or multivortexer 30 min at full speed, 4°C .

Success and reproducibility of the ChIP procedure is aided by complete (or near-complete) breakage of cells. In this regard, formaldehyde-cross-linked cells are considerably harder to break than untreated cells. The use of 1.5-ml microcentrifuge tubes with conical bottoms should be avoided because the narrow shape constricts bead movement, resulting in unequal lysis among samples. The 2-ml microcentrifuge tubes have a nearly flat bottom that allows the beads to vortex vigorously. The indicated vortexing or bead-beating conditions should be tested if a different device is used.

Isolate lysate

9. Cut a 5-ml syringe ~ 1 cm below the flared opening (i.e., where the plunger is inserted) with a razor. Insert the smaller portion into a 15-ml disposable conical tube so that the flared portion of the truncated syringe rests on top of the conical tube opening, forming a microcentrifuge-tube holder.
10. Invert the sample tube and punch a hole in the bottom with a 25-G needle. Place the sample tube into the syringe/conical tube and punch a hole in the top cover with the same needle.
11. Spin the assembly in a benchtop centrifuge 1 min at 1000 rpm, 4°C . Place the conical tube on ice. Discard the 2-ml centrifuge tube containing the dry beads after confirming the sample has been transferred to the 15-ml tube.

Occasionally, beads will clog the pierced hole and prevent complete transfer of the sample. If this occurs, pierce the tube one or two more times and repeat the step in the same 15-ml tube. No additional buffer should be added.

Shear DNA

12. Transfer the sample to a standard 1.5-ml microcentrifuge tube. Microcentrifuge 15 min at maximum speed, 4°C. Discard the supernatant and add 1 ml ice-cold FA lysis buffer to the pellet.

The pellet contains the cross-linked chromatin, cell debris, and unbroken cells. The purpose of this centrifugation step is to remove soluble protein, most of which is not cross-linked to DNA, as it might contribute to nonspecific background in the subsequent immunoprecipitations step. There is no need to resuspend the pellet at this point.

13. Holding the microtip probe near the bottom of the tube to prevent foaming, sonicate the sample 30 sec at 4°C using a continuous pulse at a power output of 20%. Cool in an ice-water bath >1 min. Repeat two more times.

Take great care that the sample does not get too hot.

If a different sonication device is used, empirically determine the conditions necessary to achieve the desired level of DNA shearing. The shear size is determined as described below (see Critical Parameters and Troubleshooting).

14. Microcentrifuge 30 min at maximum speed, 4°C. Transfer the supernatant to a fresh 15-ml disposable conical tube, add 4 ml ice-cold FA lysis buffer, and gently mix by inversion. Remove 250 µl for checking DNA fragment size and freeze the remaining chromatin solution in 800-µl aliquots in liquid nitrogen.

Upon sonication, the cross-linked chromatin is solubilized and purified away from the pelleted material which contains cell debris and unbroken cells. The resulting chromatin solution constitutes the input sample for the subsequent immunoprecipitation. The frozen aliquots are stable for many months when stored at -70°C and are suitable for immunoprecipitations.

Check chromatin-fragment size

15. Add 250 µl ChIP elution buffer and 20 µl of 20 mg/ml Pronase in TBS to the 250-µl chromatin aliquot. Incubate 2 hr at 42°C, followed by 6 hr at 65°C. Phenol extract and ethanol precipitate sample (UNIT 2.1A).

While it is convenient to perform the reaction in a PCR machine overnight, it could just as easily be done in heat blocks or water baths. The same is true of the incubation described in step 26.

16. Resuspend in 30 µl TE buffer, pH 7.5, add 1 µl of 20 mg/ml DNase-free RNase A, and incubate 15 min at 37°C. Add 3 µl of 10× loading buffer and electrophoretically separate the material on a 1.5% agarose gel (UNIT 2.5A).

Fragments should be between 100 to 1000 bp, with an average length of 400 to 500 bp.

It is important to shear DNA fragments down to an average length of 400 to 500 bp. Longer fragments will increase the background and will decrease the resolution of the region to which the protein associates (see Commentary).

Immunoprecipitate

17. Incubate 800 µl chromatin solution with 10 µl primary antibody against the protein or epitope of interest and 20 µl of 50% (v/v) protein A–Sepharose beads in TBS on an end-over-end rotator 90 min at room temperature.

The actual amount of antibody needed has to be empirically determined and can vary considerably. The idea is to have an excess of antibody to efficiently precipitate at least 50% of the antigen in question. One way to assess the efficiency of antigen immunoprecipitation is to determine the amount of antigen present in the sample before and after the immunoprecipitation. An aliquot of 30 µl chromatin solution, taken before and after immunoprecipitation, is usually sufficient to visualize the protein of interest via immunoblotting and standard chemiluminescent detection (UNIT 10.8); however, the samples

have to be boiled in SDS/PAGE sample buffer for 30 min prior to loading in order to reverse the formaldehyde cross-links. The immunoprecipitation conditions can be varied (e.g., time, temperature, salt concentration, presence of detergents) if necessary.

Protein A–Sepharose beads are used here because they work well with most monoclonal and polyclonal sera derived from mouse and rabbit, respectively. In some cases, the use of other beads (e.g., protein G–Sepharose) may improve binding of some antibodies, including rat IgG.

18. Microcentrifuge beads 1 min at 3000 rpm, room temperature. Transfer 300 μ l supernatant into a 0.5-ml PCR tube labeled “INPUT.” Discard the rest of the liquid.

Wash beads

19. Resuspend beads in 700 μ l FA lysis buffer, room temperature, and transfer mixture into a Spin-X centrifuge-tube filter.

The use of Spin-X filters aids in the recovery of the beads after washes and results in better uniformity between different samples. The procedure is also substantially faster with the filters, particularly when multiple samples are processed simultaneously. Alternatively, one could use conventional microcentrifuge tubes for the washes and aspirate the supernatant with a narrow-bore pipet tip after each spin.

20. Place the filter into a 1.5-ml microcentrifuge tube and mix sample 3 min on an end-over end rotator. Microcentrifuge 2 min at 3000 rpm, room temperature. Discard the flow-through liquid at the bottom of the tube.
21. Add 700 μ l FA lysis buffer, room temperature, to the beads and repeat step 20.

Elute protein from beads

22. Wash beads for 3 min each with 700 μ l FA lysis buffer/0.5 M NaCl, 700 μ l ChIP wash buffer, and finally 700 μ l TE.

For many polyclonal antibodies, the more stringent washes in this step result in a cleaner signal, while gentle washes frequently lead to an unacceptably high background. For some antibodies (e.g., monoclonal against peptide epitopes; see Alternate Protocol 1), repeated washes with FA lysis buffer, which are gentler, might be more appropriate.

23. Place filter unit containing the beads into a new 1.5-ml microcentrifuge tube and add 100 μ l of ChIP elution buffer. Gently pipet up and down two or three times in order to dislodge beads from the filter. Incubate 10 min in a 65°C water bath.

A water bath is used instead of other heating apparatuses in order to improve heat transfer.

24. Microcentrifuge beads 2 min at 3000 rpm, room temperature. Discard filter with beads. Transfer the eluate into a 0.5-ml PCR tube labeled “IP.”

Reverse cross-links and purify DNA

25. Add 80 μ l TE and 20 μ l Pronase in TBS to the IP tube. Combine 20 μ l INPUT material (step 18), 100 μ l ChIP elution buffer, 60 μ l TE, and 20 μ l TBS into a new 0.5-ml PCR tube.

26. To reverse cross-links, place tubes into a PCR machine. Incubate 2 hr at 42°C, followed by 6 hr at 65°C. Store samples at 4°C until use.

The incubation at 42°C allows for Pronase digestion of cross-linked polypeptides, while the 65°C incubation results in a reversal of the formaldehyde cross-links.

27. Purify DNA using a Qiagen PCR-purification spin column as per manufacturer’s instructions.

This will require double loading of the spin column (i.e., 600 μ l spin through and then repeat).

Alternatively, add 20 μl of 4 M LiCl and purify by extracting with 25:24:1 phenol/chloroform/isoamyl alcohol, followed by extraction with chloroform and ethanol precipitation (UNIT 2.1). It is useful to add 2 μl of Pellet Paint (Novagen) prior to the addition of ethanol, as this aids both the ethanol precipitation and visualization of the very small pellet.

28. Resuspend in 300 μl TE and store at -20°C .

DNA pellets stored in this fashion should be stable for years.

Perform quantitative PCR

29. Design primer pairs for the desired genomic regions to be examined.

Success in obtaining high-quality data is critically dependent on good primer design (see Critical Parameters and Troubleshooting). In general, primers should be 20 to 30 bases long with a T_m of 55°C to 60°C . The design of good primers is greatly facilitated by commercially available software packages such as Oligo 6.6 (see <http://www.oligo.net>) or Primer Express 1.5 (see <http://www.appliedbiosystems.com>). Most primers require no purification or special treatment prior to PCR. Amplification products should be 75 to 350 bp; longer products should be avoided, as the amplification efficiency is substantially lower. A final primer concentration of 1 μM works well for most primers, but in some instances, improved product specificity may be obtained by lowering the final primer concentration 5 to 10 fold. Refer to UNIT 15.1 for more information.

30. Dilute INPUT DNA (obtained from step 18) in three separate tubes by a factor of 5, 10, and 20. Set up standard PCR reactions (UNITS 15.1 & 15.7) with 2 μl DNA sample, primers at 1 pmol/ μl , and total reaction volumes of 10 to 50 μl . If PCR products will be detected by radioactivity, add 1 μCi of 3000 Ci/mmol [^{32}P]dATP.

For a typical measurement, the three dilutions of input DNA are tested along with duplicate immunoprecipitated samples (or undiluted and 5-fold diluted immunoprecipitated samples). This permits an assessment of whether the assay is being performed in the linear range as well as of the reproducibility of the PCR reaction. The immunoprecipitated DNA is typically used without dilution, although it is useful to analyze different amounts to ensure that it is also in the linear range.

There are several key parameters for achieving an optimum PCR reaction. For example, it is very important to have a quality repeat pipettor that can reproducibly dispense 2 μl DNA. Pipetting inaccuracies at this stage will lead to greater well-to-well variability and poorer reproducibility among identical samples. Additionally, multiple primer pairs (up to 4 to 5) can be included in the same reaction, provided that the PCR products can be unambiguously resolved from each other by gel electrophoresis. This permits simultaneous and internally controlled analysis of multiple genomic regions in a single reaction. However, it is critical to ensure that there is no competition between the different primer pairs and PCR products. Also, comparable results are obtained when PCR reactions are performed in volumes between 10 to 50 μl ; using smaller volumes reduces the cost and facilitates loading of the reaction products on gels. See Critical Parameters and Troubleshooting for a discussion of primer choice.

Detection of PCR products by [^{32}P]label is recommended over detection by ethidium bromide or SYBR Green staining as it improves the sensitivity and extends the linear range of detection; however, it necessitates using the usual precautions in working with radioactivity.

31. Carry out hot-start PCR using the following thermal cycling parameters.

Initial step:	10 min	95°C	(denaturation)
26 cycles:	30 sec	95°C	(denaturation)
	30 sec	55°C	(annealing)
	1 min	72°C	(extension)
Final step:	4 min	72°C	(final extension).

These conditions are generally appropriate for most situations. The annealing temperature may have to be adjusted if the melting temperatures of the primers is substantially above or below 55°C. The number of cycles might also have to be adjusted in some cases if reactions are not in the linear range. See Critical Parameters and Troubleshooting for more details.

Analyze PCR products

32. Add the appropriate loading buffer to the PCR products, and analyze by electrophoresis on nondenaturing polyacrylamide (UNIT 2.7) or agarose gels (UNIT 2.5A).

The gels should be stained either with ethidium bromide or SYBR Green dyes, or analyzed by autoradiography or PhosphorImager.

33. Quantitate the relative amount of PCR products using appropriate software for the accompanying instrument.
34. Calculate the apparent immunoprecipitation efficiency for a specific fragment by dividing the amount of PCR product obtained with the immunoprecipitated DNA by the amount obtained with the input DNA.

A volume of 2 μ l immunoprecipitated DNA sample (1/150 total immunoprecipitated material) contains \sim 200 times the number of cell equivalents as 2 μ l INPUT sample that has been diluted 5-fold (1/30,000 of the original aliquot that was immunoprecipitated). Thus, if the amount of PCR product in the immunoprecipitated sample is equal to the amount of PCR product in the 5-fold diluted INPUT sample, the apparent immunoprecipitation efficiency is 0.5%. The apparent immunoprecipitation efficiency for the background signal is typically \sim 0.025% to 0.05%, and it should not be higher than 0.1%.

BASIC PROTOCOL 2

CHROMATIN IMMUNOPRECIPITATION IN MAMMALIAN CELLS

ChIP experiments in mammalian cells are performed using a modified version of the procedure developed for yeast cells (Basic Protocol 1). In this alternative procedure, immunoprecipitations are performed on material from 5×10^7 cells, which generates immunoprecipitated DNA for approximately 100 quantitative PCR reactions; this is sufficient for triplicate analysis of 33 genomic loci.

Materials

Mammalian cells growing in culture
Culture medium (see APPENDIX 3F)
37% (v/v) formaldehyde
2.5 M glycine
Tris-buffered saline (TBS; APPENDIX 2), ice cold
MC lysis buffer (see recipe), ice cold and room temperature
Liquid nitrogen
MNase buffer (see recipe), room temperature
100 mM (50 \times) phenylmethylsulfonyl fluoride (PMSF) in ethanol (prepare fresh)
20 \times protease inhibitors: 1 mini complete-EDTA free tablet (Roche) in 500 μ l
MNase buffer (prepare fresh)
Micrococcal nuclease (MNase; USB; optional)
0.2 M EGTA
20% (w/v) sodium dodecyl sulfate (SDS)
Protein A/G–Sepharose beads (Amersham Biosciences)
FA lysis buffer (with 150 mM NaCl; see recipe) with 2 mM (1 \times) PMSF and 1 \times protease inhibitors (added from 20 \times stock; see above)
Platform shaker
Refrigerated centrifuge
2-ml screw-cap microcentrifuge tubes

Probe sonicator (e.g., Branson)

15-ml conical tubes

End-over-end rotator

Additional reagents and equipment for mammalian cell culture (*APPENDIX 3F*) and checking DNA fragment size, immunoprecipitation, reversing cross-links, purification of immunoprecipitated DNA, and quantitative PCR (as for ChIP with yeast; see Basic Protocol 1)

Cross-link protein-DNA complexes in vivo

1. For each sample, grow 2×10^8 cells in appropriate medium (*APPENDIX 3F*). For cells grown in suspension, proceed to step 2. For adherent cells, harvest cells by trypsinization and inactivate trypsin by adding serum-containing medium (*APPENDIX 3F*), then resuspend in 50 ml culture medium.

The number of cells can be reduced or increased depending on need. In the procedure described here, the immunoprecipitation (IP) is performed on cross-linked chromatin from 5×10^7 cells, thereby permitting four immunoprecipitations from the culture of cells grown as described above. The minimum number of cells for a standard ChIP experiment depends on the number of immunoprecipitations to be performed and the number of genomic loci to be investigated by quantitative PCR. In general, 10^7 cells are sufficient for a ChIP experiment involving a single immunoprecipitation, but 10^6 cells are not (See Critical Parameters and Troubleshooting).

2. Add formaldehyde (as 37% solution) to cell suspension for a final concentration of 1% (v/v). Cross-link by incubating 8 min at room temperature in a fume hood, occasionally swirling the flask or shaking slowly on a platform.

The volume of cells can be varied over a wide range, but the final formaldehyde concentration should be 1%.

3. Quench the cross-linking reaction by adding 2.5 M glycine to a final concentration of 0.2 to 0.4 M. Incubate for an additional 5 min, then cool on ice.

Lyse cells and isolate chromatin

4. Centrifuge cells 5 min at $450 \times g$, 4°C , and discard supernatant into chemical waste container. Resuspend pellet in 10 to 50 ml ice-cold TBS. Centrifuge cells 5 min at $450 \times g$, 4°C . Repeat this wash one more time and discard the supernatant.

5. Wash cells three times, each time by adding 10 ml MC lysis buffer, centrifuging 5 min at $200 \times g$, room temperature, and decanting supernatant. After final wash, remove residual buffer and snap-freeze in liquid nitrogen.

MC buffer contains NP-40, a detergent that disrupts mammalian cells and generates a nuclear pellet.

6. Thaw frozen nuclear pellet in cool water, then resuspend in 1 ml MNase buffer. Bring volume to 1.5 ml with MNase buffer.

7. *Optional:* Add 10 to 100 U micrococcal nuclease (MNase) and incubate at 37°C for 10 min.

It is important to optimize the amount of MNase for the cell lines being analyzed by performing control reactions in which the amount of MNase is varied. The resulting MNase-digested DNA is analyzed by agarose gel electrophoresis. The desired DNA fragment size should average 50 to 1000 bp, and a nucleosomal ladder should be apparent, with roughly equal band intensities for DNA fragments ranging from nucleosome monomers to octamers.

Note that while MNase treatment is very useful, it is not essential for the procedure. Sonication of cross-linked chromatin from mammalian cells is often insufficient to both solubilize the chromatin (which is necessary for the subsequent immunoprecipitation)

and reduce DNA fragment size to the desired extent. The decision whether to omit MNase treatment and rely on sonication alone depends on a number of factors, including cell type and number of cells, and is difficult to predict. The combination of MNase treatment and sonication is more reliable for producing cross-linked chromatin suitable for subsequent immunoprecipitations and quantitative PCR analysis. However, MNase treatment has the potential to introduce some bias into the results, given that cleavage does not occur in a manner completely independent of DNA sequence.

- 8a. *If optional MNase reaction was performed:* Stop the MNase reaction by adding the following in the order indicated:

30 μ l 0.2 M EGTA (3 mM final)
40 μ M 100 mM (50 \times) PMSF (1 \times final)
100 μ l 20 \times protease inhibitors (1 \times final)
100 μ l 20% SDS (1% w/v final)
80 μ l 5 M NaCl (200 mM final).

Mix well.

- 8b. *If MNase treatment was not performed (i.e., if step 7 was skipped):* add all of the above components except EGTA to the pellet suspension from step 6 and proceed to step 9.

9. Transfer the sample to a 2-ml screw-cap microcentrifuge tube. Sonicate six times, each time for 1 min (power level 4, 60% duty, pulse, 4°C) with a cooling period of at least 2 min in an ice-water bath between pulses. Take great care that the sample does not get too hot.

Hold the microtip probe of the sonicator near the bottom of the microcentrifuge tube to prevent foaming of the sample. The main purpose of sonication is to solubilize the chromatin, not to reduce the size of the DNA beyond that already achieved by MNase treatment. If MNase treatment was not performed, the sonication step should yield some fragmentation of DNA, depending on the cell line.

10. Microcentrifuge 30 min at maximum speed, 4°C, to remove cellular debris. Carefully transfer the supernatant to a new microcentrifuge tube (this is the solubilized chromatin that represents the input sample for the subsequent immunoprecipitation). Remove 100 μ l, and check DNA fragment size as described for yeast (see Basic Protocol 1, steps 15 and 16). Freeze the remaining chromatin solution in 500- μ l aliquots in liquid nitrogen.

Fragments should be between 100 and 2000 base pairs (average 500 to 1000), and a nucleosomal ladder should be apparent with bands representing monomers to octamers being of approximately equal intensity. The frozen chromatin is stable for many months when stored at -70°C and is suitable for immunoprecipitations. Each 500- μ l aliquot represents material from 5×10^7 cells, a number that is appropriate for a typical immunoprecipitation.

Perform immunoprecipitation

11. Thaw chromatin on ice, and microcentrifuge 10 min at maximum speed, 4°C, to remove any precipitate. Transfer supernatant to a new 15-ml conical tube. Dilute chromatin sample 1:5 by adding 2 ml FA lysis buffer containing 1 \times (2 mM) PMSF and 1 \times protease inhibitors.

If smaller volumes are involved, the sample can be placed in a 1.5-ml microcentrifuge tube.

12. Add 50 to 100 μ l protein A/G–Sepharose beads (equilibrated in FA lysis buffer) and incubate 1 to 4 hr at 4°C on an end-over-end rotator. After this incubation, centrifuge 5 min at 300 \times g, room temperature, and transfer the supernatant to a new tube. Take 10% (250 μ l) of this supernatant (precleared chromatin) and label as INPUT.

Adjust SDS concentration (using 20% SDS stock) to 0.5% (w/v), add Pronase (from 20 mg/ml stock) to a final concentration of 1.5 $\mu\text{g}/\mu\text{l}$, then reverse cross-links as in Basic Protocol 1, steps 25 to 28.

This preclearing step removes any material that nonspecifically associates with the protein A/G–Sepharose beads. If performing multiple immunoprecipitations, it is best to preclear in a single batch and then divide the resulting material into separate aliquots for each immunoprecipitation.

13. To the remaining precleared chromatin from step 12, add $\sim 1 \mu\text{g}$ (optimal amount determined empirically) of primary antibody against the protein or epitope of interest and 50 to 100 μl of protein A/G–Sepharose beads (equilibrated in FA lysis buffer). Incubate overnight at 4°C. After incubation, centrifuge 2 min at $200 \times g$, room temperature, discard supernatant, and proceed with washing and elution steps (see Basic Protocol 1, steps 19 to 24).

As the volume of the immunoprecipitation mixture is $\sim 2.5 \text{ ml}$, the initial incubation and centrifugation are typically performed in 15-ml conical tubes, rather than the 1.5-ml microcentrifuge tubes used for the yeast procedure.

The amount of antibody needs to be empirically determined and can vary considerably. In some cases, the conditions for the immunoprecipitation and washing steps need to be varied to maximize the amount of protein-bound DNA that is immunoprecipitated while minimizing the amount of nonspecific background material that remains after washing.

14. Reverse cross-links and purify immunoprecipitated DNA as described for yeast (see Basic Protocol 1, steps 25 to 28).

Typically, 3 μl of the IP DNA is used for each PCR reaction, thereby permitting one to carry out 100 PCR reactions for each IP sample.

Analyze DNA by quantitative PCR

15. Design primer pairs for the desired genomic regions to be examined.

Success in obtaining high-quality data is critically dependent on good primer design, and obtaining suitable primers for quantitative PCR analysis is more difficult for experiments involving mammalian cells because of the increased genomic complexity. It is extremely useful to perform BLAST analysis (UNIT 19.3) on the designed primers to exclude the possibility of similar sequences elsewhere in the genome. In addition, it is critical to perform control experiments involving a range of concentrations of genomic DNA in order to determine if the primers are suitable for quantitative analysis (see Critical Parameters and Troubleshooting). In general, primers should be 20 to 30 bases long with a T_m of 55°C to 60°C. The design of good primers is greatly facilitated by commercially available software packages such as Oligo 6.6 or Primer Express 1.5. Most primers require no purification or special treatment prior to PCR. Amplification products should be 75 to 350 base pairs; longer products should be avoided, as the amplification efficiency is substantially lower. A final primer concentration of 1 μM works well for most primers, but in some instances, improved product specificity may be obtained by lowering the final primer concentration 5- to 10-fold.

16. Dilute INPUT DNA (obtained from step 12 of this protocol) in three separate tubes by factors of 300, 150, and 75. Use the immunoprecipitated DNA (prepared in steps 13 and 14) without dilution, although it is useful to analyze different amounts to ensure that is also in the linear range. Set up standard PCR reactions (UNITS 15.1 & 15.7) with primers at 1 pmol/ μl and 3 μl DNA sample.

Reactions can be performed in volumes of 10 to 50 μl , and PCR products can be detected by gel electrophoresis or on a machine that permits analysis in real time.

The number of genomic regions to be analyzed is limited by the amount of DNA in the immunoprecipitated sample (the amount of input DNA far exceeds the amount of immunoprecipitated DNA, and hence is not limiting for the PCR analysis). The above procedure is based on immunoprecipitations involving 5×10^7 cells, which generate sufficient immunoprecipitated material for 100 PCR reactions. As analysis of each genomic region requires triplicate PCR reactions, 33 genomic regions can be analyzed using the abovementioned number of cells. If material from fewer cells is used for the immunoprecipitation, this reduces the number of PCR reactions and hence the number of genomic regions that can be analyzed. It is possible to increase the number of genomic regions to be analyzed by using less immunoprecipitated material in the PCR reactions. Such an approach is best employed for genomic regions that are enriched by the immunoprecipitation, because the reproducibility of the PCR reaction is related to the number of molecules. In practice, measurements that involve 30 or more cycles of PCR amplification are more variable and should be avoided if possible.

ALTERNATE PROTOCOL 1

SPECIFIC PEPTIDE ELUTION OF PROTEIN-DNA COMPLEXES IMMUNOPRECIPITATED FROM CROSS-LINKED CHROMATIN

Peptide elution represents an alternative method for removal of immunoprecipitated protein-DNA complexes from beads. In this procedure, beads containing the immunoprecipitated complexes are incubated with high concentrations of a peptide recognized by the antibody used in the immunoprecipitation. The added peptide competes with the protein antigen of interest for binding to the antibody, and specifically liberates the protein-DNA complexes from the beads. The high specificity of peptide elution reduces the nonspecific background (typically by a factor of 2 to 4), which makes it the method of choice, particularly for applications where the expected immunoprecipitation signal is low. Peptide elution is especially useful for chromatin immunoprecipitation experiments involving proteins that are tagged with the HA or myc epitopes (in single or multiple copies); however, it would also be appropriate in cases where the antibody used for the immunoprecipitation was generated against a defined peptide sequence. Peptide elution is slightly more expensive than conventional elution, due to the cost of the peptide. In general, peptide elution should be used in conjunction with gentle washes during the immunoprecipitation procedure described below, which minimizes antigen leaching. Stringent washes, such as those employed in the main method (see Basic Protocol 1), will often result in signals that are several-fold lower, with little or no improvement in background. Finally, peptide elution may vary in quality depending on factors such as the number of epitopes in the antigen and the relative stability of the antibody:antigen interaction.

Additional Materials (also see Basic Protocol 1)

1 mg/ml peptide (e.g., myc, HA) in TBS (see APPENDIX 2 for TBS)

For this protocol, follow steps 1 to 21 of the main method (see Basic Protocol 1), replace steps 22 to 25 with the following, and continue with step 26 onwards.

22. Repeat FA lysis buffer wash (see Basic Protocol 1, steps 20 and 21) three additional times for a total of five washes.

Repeated washes with FA lysis buffer are much more gentle than the single washes with FA lysis buffer/0.5 M NaCl, ChIP wash buffer, and TE used in the Basic Protocol 1 and result in higher signal-to-background ratios.

23. Place the Spin-X centrifuge-tube filter unit containing the beads into a new 1.5-ml microcentrifuge tube and add 100 μ l of 1 mg/ml peptide (typically myc or HA) in TBS. Gently pipet up and down two or three times in order to dislodge beads from the filter. Incubate 30 min at 30°C.

24. Microcentrifuge beads 2 min at 3000, room temperature. Discard filter with beads. Transfer the eluate into a 0.5-ml PCR tube suitable for PCR labeled “IP.”
25. Add 150 μ l TE, pH 7.5, 250 μ l of ChIP elution buffer, and 20 μ l of 20 mg/ml Pronase in TBS.

ANALYSIS OF CHROMATIN IMMUNOPRECIPITATION EXPERIMENTS BY REAL-TIME QUANTITATIVE PCR WITH SYBR GREEN

*ALTERNATE
PROTOCOL 2*

Quantitative PCR (QPCR) analysis in real time with SYBR Green has several advantages over the analysis of PCR reactions by gel electrophoresis (see Basic Protocol 1, step 32). First, the method saves considerable time because no gels are involved and because quantitative values are obtained directly from the data curves and do not require densitometry or phosphor imager analysis. As a consequence, this approach permits very rapid analysis of much larger numbers of chromatin immunoprecipitation samples than can be performed with the Basic Protocol 1. Using standard 96-well instruments, it is a straightforward procedure to analyze 100 to 200 samples/day (in replicates of three) with only 1 to 2 hr of total setup time. With newer 384-well instruments and automated robotics equipment, sample throughput can be further increased to thousands per week. Second, the data generated by this procedure are more accurate and reproducible, because quantitative values are determined from continuous sampling throughout the PCR reaction rather than a single end-point determination. Furthermore, the quality and “linear range” of every PCR reaction are directly visualized. Third, the procedure is significantly safer for the researcher, as no radioactive materials or toxic acrylamide are used. The major disadvantage of this procedure is that the measurements are performed individually and hence are not internally controlled, whereas the Basic Protocol 1 permits the simultaneous analysis of multiple genomic regions in a single PCR reaction (provided the individual primer pairs function independently). As such, the Basic Protocol 1 is more useful for analyzing the same small set of genomic regions under multiple experimental conditions and for simultaneous analysis of electrophoretically distinguishable alleles of a given genomic region.

SYBR Green is a sensitive and highly selective double-stranded DNA (dsDNA)–binding dye that remains associated even at the high temperatures normally used for PCR template extension. Real-time PCR reactions involving SYBR Green are performed with standard oligonucleotide primers, and hence are much less expensive than real-time PCR reactions using fluorophore-conjugated oligonucleotides (e.g., TaqMan or Lux probes). Measurements of SYBR Green fluorescence at the polymerase extension step of PCR, when plotted against PCR cycle number, provide both a qualitative assessment of the progress of the PCR and a way to quantitate the relative amount of DNA template initially present in the reaction. Typical real-time QPCR graphs feature the plot of the \log_{10} (Net fluorescence) on the *y* axis versus the PCR cycle number on the *x* axis, and usually contain three well-defined stages: (1) baseline, (2) linear, and (3) plateau. In the baseline stage, the amount of DNA product formed is still below the sensitivity threshold of SYBR Green, so product formation is undetectable. This part of the curve is typically used as a baseline for SYBR Green signal drift. The linear part of the curve is the most important from the analytical standpoint, because it is at this stage that the rate of PCR product accumulation is both constant on a per-cycle basis and readily detectable by increased SYBR Green fluorescence. Finally, as all of the SYBR Green in the reaction becomes bound to the recently synthesized PCR products, the amount of fluorescence stays constant from cycle to cycle and the reaction reaches a plateau.

In the protocol described below, PCR is performed under special conditions that minimize the inhibitory effects of SYBR Green on *Taq* activity and maximize the linear range of product detection. After amplification is complete, raw data are stripped of outliers and

**Chromatin
Assembly and
Analysis**

21.3.13

exported in a format readable by a spreadsheet program such as Microsoft Excel. Finally, data points from replicate samples are averaged, and mean values are further manipulated and ultimately compared to some internal reference or control.

Materials

Input DNA (see Basic Protocol 1, step 28, and Basic Protocol 2, step 14)
Immunoprecipitated fragments (“IP” sample; see Basic Protocol 1, step 23, and Basic Protocol 2, step 13)
TE buffer, pH 7.5 (APPENDIX 2A)
Primers (see Critical Parameters and Troubleshooting)
2× SYBR Green *Taq* mix (see recipe)
Real-time PCR machine and corresponding software (e.g., ABI)
96-well PCR plates (ABI, cat. no. 4306737) and optical adhesive covers
Centrifuge with swinging-bucket rotor and microtiter plate adapter
Spreadsheet program (e.g., Microsoft Excel)

Set up PCR reactions

1. Dilute input DNA to an approximate equivalent of 1×10^6 cells/ml in TE buffer, pH 7.5.

If immunoprecipitations were performed as described in the Basic Protocol 1 or 2, then a 1:25 dilution of the input sample from step 28 of Basic Protocol 1 or the equivalent step of Basic Protocol 2 will result in 1:1000 overall dilution and will correspond to $\sim 5 \times 10^8$ to 1×10^9 cell equivalents.

2. If necessary, resuspend immunoprecipitated fragments in TE buffer, pH 7.5, so that the approximate cell equivalent is 1×10^9 cells/ml.

Immunoprecipitated DNA derived from the IP sample obtained by Basic Protocol 1, step 23 or the equivalent step of Basic Protocol 2 is appropriately diluted and needs no further treatment.

3. Prepare PCR primer stocks by mixing each primer pair at a final concentration of 3.3 μ M in TE buffer, pH 7.5.

It is critical to test newly obtained primer pairs for amplification specificity and performance under conditions that will be used for real-time PCR with SYBR Green (see Critical Parameters and Troubleshooting). SYBR Green can inhibit PCR reactions, and primer pairs that are appropriate for quantitative PCR analysis in the absence of SYBR Green may not work well in the presence of SYBR Green. High-quality primer pairs should result in ~ 1.9 -fold amplification/cycle (this can be determined from quantitative analysis of raw fluorescence data for each cycle, which is generally available on commercial instruments). Amplified material at the completion of the PCR should contain only one band (as assayed on high-percentage agarose or polyacrylamide gels). Specificity information may also be obtained by running dissociation curves on reactions following the conclusion of the PCR run. Typically, samples are melted for 15 min at 95°C, cooled to 60°C, and then slowly heated back up to 95°C over a period of 20 min. Plotting the first derivative of the fluorescence against the temperature allows for simple visual identification of sample heterogeneity. Some instrument-specific software packages have built-in modules for dissociation curve analysis.

4. Select and label the wells to be used in the run.

In general, individual samples should be run in triplicate. Obvious outliers occur with some frequency, generally at <5%. Triplicate analysis of samples permits removal of those outliers while still allowing for inclusion of two accurate measurements for each sample. While this reduces the number of different samples that can be run at any given time, the resulting data is much more reliable and accurate.

For each primer pair examined, the input DNA samples should be run alongside the immunoprecipitated samples. Amplification efficiencies among different primer pairs vary slightly on a per-cycle basis, but those slight variations in efficiency translate into substantially different amounts of amplified material in the cycle range used for analysis. Precise quantitation of relative binding cannot be accurately performed without primer pair-specific input signal.

Detailed instructions on the use of the real-time PCR machine and general issues, e.g., calibration and camera exposure settings, are addressed in the documentation that accompanies the instruments.

5. Program the real-time PCR machine as follows:

1 cycle:	10 min	95°C	(initial denaturation)
40 cycles:	30 sec	95°C	(denaturation)
	30 sec	53°C	(annealing)
	30 sec	72°C	(extension).

Collect the data only at 72°C.

The annealing temperature may have to be adjusted if the melting temperatures of the primers are substantially above or below 53°C. If the desired amplification product is >500 bp (this is not recommended), the extension time at 72°C should be increased to 1 min. See Critical Parameters and Troubleshooting for more details.

6. Using a small-volume automatic pipettor (20- μ l capacity), place a 2- μ l aliquot of each DNA template into the appropriate wells of a 96-well PCR plate. Gently tap the plate to allow the sample droplets to fall to the bottoms of the wells.

It is very important to have a quality repeating pipettor that can reproducibly dispense small volumes of sample into the wells. Pipetting inaccuracies at this stage will lead to greater well-to-well variability and poorer reproducibility among identical samples.

7. Using a small-volume automatic pipettor (20- μ l capacity), place a 3- μ l aliquot of primer mix (see step 3) into the relevant wells and tap the plate a few times to settle the contents.

On many real-time PCR machines, results from 10- μ l reactions are virtually indistinguishable from those of 25- and 50- μ l reactions in their accuracy and reproducibility. The use of 10- μ l reactions provides substantial savings in reagent costs. On some machines, the minimal reaction volume needed for accurate and reproducible results may be greater.

8. With a larger automatic pipettor (100- μ l capacity), add 5 μ l of 2 \times SYBR Green Taq Mix to every assayed well. Place microtiter plate into appropriate microtiter plate adapter and centrifuge 1 min at 200 \times g, room temperature, in a swinging-bucket rotor.

The 2 \times SYBR Green Taq Mix contains a variety of components that considerably reduce the inhibitory effect of SYBR Green, thereby resulting in more reproducible signals that require fewer amplification cycles. Comparable mixes containing proprietary buffers can be obtained commercially. It is critical that quantitative PCR reactions containing SYBR Green be performed under conditions of efficient amplification (e.g., 1.9-fold amplification/cycle).

9. Seal plate with clear optical adhesive covers, overlay foam compression pad with gold side facing up, and place into the real-time PCR machine. Secure lid.

The details of this step may differ, depending on the machine.

10. Start the PCR protocol (see step 5). After completion, save the run for future analysis.

DATA analysis

11. Open the file containing the real-time data according to the manufacturer's instructions for the instrument.

Although the specific protocol will depend on the software and instrument, the overall logic and approach to the analysis of real-time data is generally applicable.

12. Look at the different curves and set the baseline as needed.

Generally, the baseline should be set from cycle 3 to the cycle just prior to where the curves start increasing in a linear fashion. It is desirable to have at least 10 cycles for the calculation of the baseline, as this results in increased accuracy in the subsequent calculations of the threshold cycle.

13. Change the value in the Threshold box to be about halfway up in the linear range, and apply changes to the data set.

The threshold cycle is defined to be the PCR cycle at which the fluorescence is 10 times (10 is the default multiplier) the standard deviation obtained in the baseline calculation. When the multiplier is set to 10, the fluorescence at the threshold cycle is considered the lowest fluorescence value that is significantly above the background. In practice, this number frequently lies in the nonlinear range of many of the curves. For later calculations, it is easier to manually set the fluorescence value used to calculate the threshold cycles to 0.04. At this value, all the curves should be in the linear range and well above the baseline, allowing for far more accurate comparisons of the threshold cycles. On occasion, however, it will be necessary to adjust this value either up or down to better reflect the linear range of net fluorescence for most of the curves.

14. Manually select one group of triplicates and visually inspect their amplification plots. If curves are essentially superimposable and the threshold cycle (C_T) values are close to each other (maximal and minimal replicates within 1 cycle, preferably within 0.5 cycles), proceed to the next triplicate sample. Otherwise, remove the outlier and continue to the next triplicate.

Decisions regarding the removal of some outliers could either be straightforward or judgment calls, depending on the circumstances. In cases where two out of three curves are superimposable while the third is clearly off by more than a cycle, it is a fairly easy decision to consider the third replicate an outlier. If the curves are closer, the decision on which one to eliminate, if any, becomes much more difficult. As a general guide only, if the spread between the lowest and highest C_T values is less than 0.5, it is probably safe to average all the C_T values (see step 12). If the C_T range is <1 but >0.5 , the data are less reliable and the decision to remove any data points should probably be made on a case-by-case basis. It is highly recommended that the PCR be repeated for samples where the C_T ranges are >1 with no two curves superimposable.

15. Proceed to analyze the data for all triplicates in the manner described above. Save the results in a different file.

16. Export the data to a spreadsheet program such as Microsoft Excel by using built-in filters. The file should not contain omitted wells (see step 14) and should be in a column format containing well positions, descriptors, and C_T values for each selected well.

Final calculations are most easily handled in a spreadsheet, but could also be performed with a scientific calculator.

17. Open the exported file. Proceed to average triplicate measurements for each sample in a new column ($^{\text{AVERAGE}}C_T$).

For some samples, there may be only two measurements left as a result of the removal of outliers in step 14.

18. For each primer pair, subtract the $\text{AVERAGE } C_T \text{ (INPUT)}$ from $\text{AVERAGE } C_T \text{ (IP)}$ in a new column. This number is the $\text{NET } C_T$.

This value represents the difference in cycles between the immunoprecipitated sample and the input DNA.

19. Subtract the $\text{NET } C_T$ of a primer pair that serves as a reference or a control (CTRL) from the $\text{NET } C_T$ of the experimental (EXPT) primer pair in a new column. The resulting value is $\text{NET } C_T^{\text{EXPT}} - \text{CTRL}$. Repeat $\text{NET } C_T$ subtraction of control primer for all other experimental primers.

It is very desirable to have a control primer pair that can be used to assess the relative cross-linking efficiency at promoters of interest. Frequently, the control primer pair could be specific for a DNA region that does not bind to the immunoprecipitated protein of interest. The signal from the control primer pair could then be considered the background, and the binding efficiency of the protein to different promoter regions could be expressed as fold over background binding.

20. Evaluate the expression POWER ([mean primer slope], $-\text{NET } C_T^{\text{EXPT}} - \text{CTRL}$), where the [mean primer slope] is the base and $-\text{NET } C_T^{\text{EXPT}} - \text{CTRL}$ is the exponent. Repeat the process with other primers by using the different $\text{NET } C_T^{\text{EXPT}} - \text{CTRL}$ values calculated in step 19.

The actual value calculated in the POWER expression above is the degree of occupancy of the immunoprecipitated protein at the sequence of interest relative to that of a control (or background) DNA region.

*Perfectly efficient PCR, in which the number of amplified molecules doubles every cycle, has a primer slope of 2. As defined, this value is independent of primer pair sequence, target sequence length, and other variables that under normal circumstances may adversely affect the efficiency of amplification. In practice, however, the mean primer slope is almost always <2 and is slightly variable from primer pair to primer pair, mostly due to differences in primer sequence and other parameters (e.g. GC content and length of amplified sequence). For the majority of primers designed to amplify *S. cerevisiae* promoter sequences, the mean slope is 1.9 ± 0.06 , and this value can be safely used in the calculations above. However, it is still good practice to calculate representative slopes for every newly synthesized primer pair; any substantial deviation from $1.9 (\pm 0.06)$, especially to the downside, should be viewed suspiciously. Frequently, a slope that substantially deviates from the normal range is indicative of problems in the amplification.*

The mean primer slope for a given primer pair is most easily calculated by performing linear regression on the linear portion of the amplification plot (log net fluorescence versus PCR cycle). In order to perform this calculation, it is first necessary (if possible) to export a file containing the fluorescence values for all the wells in use at every PCR cycle (see software manuals for more information). It is then possible to use linear regression to estimate the slope within the linear range (i.e., by using the MS Excel function LINEST). Since it is rather time-consuming to calculate slopes for an entire 96-well plate one-by-one, it may well be worthwhile to write a macro (or a stand-alone program) to automate this process.

MAPPING PROTEIN BINDING SITES IN VIVO USING CHROMATIN IMMUNOPRECIPITATION FOLLOWED BY QUANTITATIVE PCR SCANNING

The chromatin immunoprecipitation procedures described in this unit are typically used to measure the association of a given protein with a general region, e.g., the promoter of a gene of interest. In fact, the technique may also be applied to relatively fine-scale mapping of binding sites by using a series of PCR primers to scan a DNA region. This method has been used to define a narrow zone of peak DNA occupancy by RNA polymerase III transcription factors at a newly described locus (Moqtaderi and Struhl, 2004). Scanning

Chromatin Assembly and Analysis

21.3.17

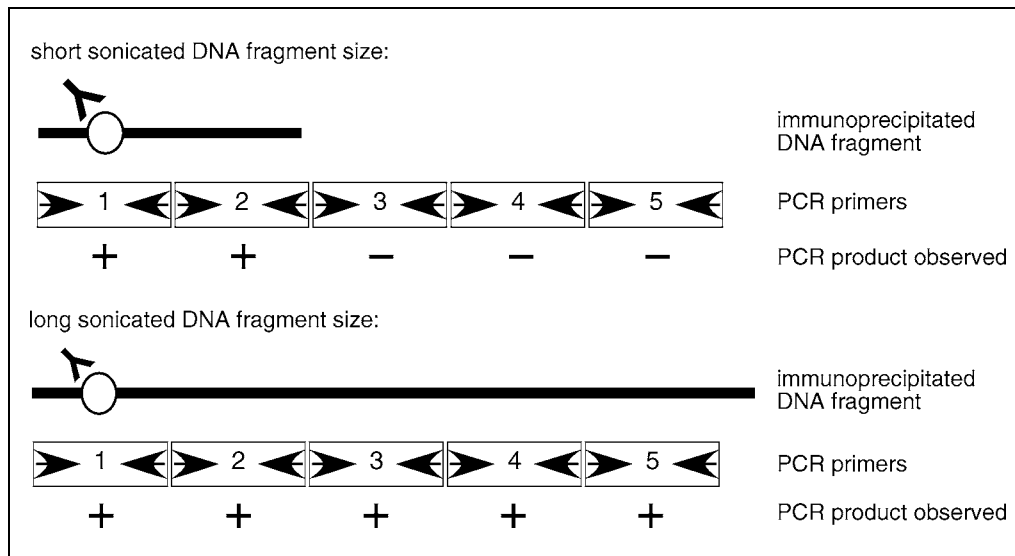

Figure 21.3.2 Effect of immunoprecipitated DNA fragment size on the distance from a binding site from which PCR signal will be observed. As DNA fragment size increases, PCR signal is observed upon amplification with primer pairs further from the binding site.

with closely spaced or even nested PCR products yields peak signal intensity over a very small area (<100 bp) and is especially valuable in distinguishing relative binding position of two proteins with fairly closely spaced recognition sequences. The primary determinants of success in a scanning experiment are the size and spacing of the quantitative PCR products, which define the optimum region of association, and the average DNA fragment size, which determines the apparent spread of the observed association peak.

First, consider the effects of DNA fragment size. Any unbound region of DNA that is contained on the same fragment as a true binding site will be co-immunoprecipitated along with the true target DNA; thus, the longer the average sonicated DNA fragment size, the higher the quantitative PCR signal at points far upstream or downstream of a true target. Figure 21.3.2 illustrates this for immunoprecipitation of a protein bound to its target sequence on either a short or a long DNA fragment. If the average size of the sonicated DNA fragments is small, then the true binding site will only rarely coexist on the same DNA molecule with unbound regions of DNA far away. These distal unbound regions will therefore almost never be co-immunoprecipitated with protein bound to the true target sequence, and they will consequently yield poor signals in the subsequent quantitative PCR. In other words, as the sonicated fragment size decreases, positive signal in a scanning experiment is focused over a narrower region of DNA. Figure 21.3.3 (A and B) shows the relative breadth of signal peaks that would be obtained using the same set of primer pairs on two different hypothetical populations of immunoprecipitated DNA differing only in average fragment size. For simplicity, an idealized population of sonicated fragments of uniform size and unbiased distribution is assumed. Consideration of how far the signal deriving from a point source might be expected to spread has been used to determine the range of histone deacetylation *in vivo* by the Sin3-Rpd3 complex (Kadosh and Struhl, 1998).

Notice that the peak quantitative PCR signal occurs in the same position (primer pair 3 in Fig. 21.3.3) regardless of sonicated fragment size. Although the larger fragment size causes signal to be observed over a wider area, it also means that there are more fragments that will both cover the binding site and be long enough to contain the complete

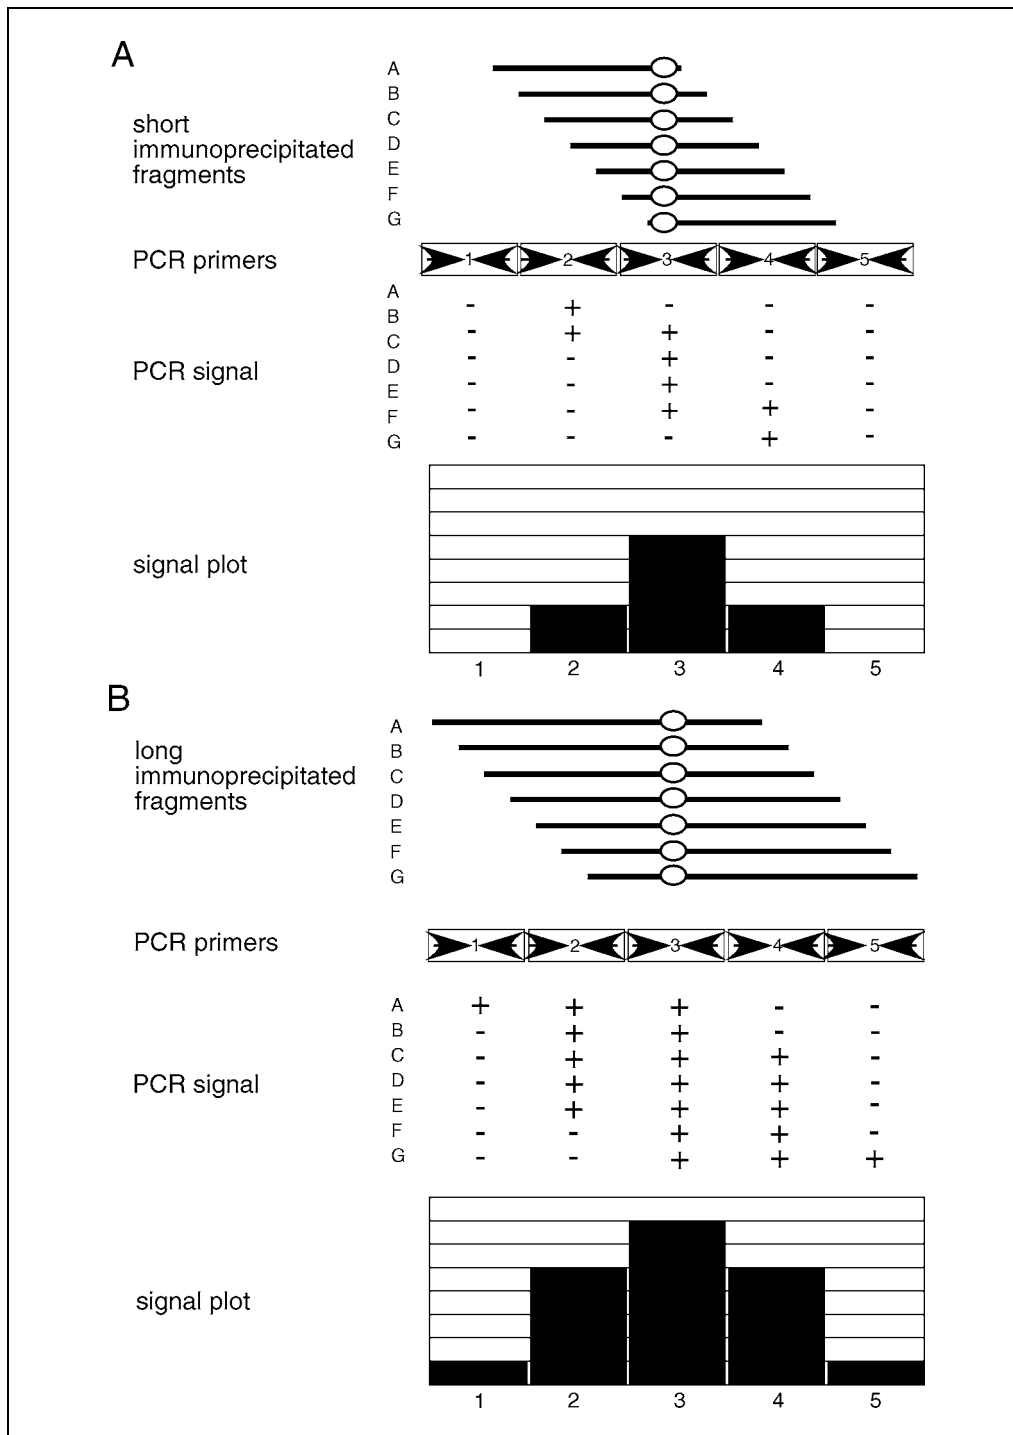

Figure 21.3.3 Distribution of PCR signal observed after ChIP in two idealized DNA populations of different sonicated fragment size. **(A)** When fragment size is short, the distribution of signal around a binding site is fairly narrow. **(B)** With a population of larger DNA fragments, the distribution of PCR signal is broader, though it will be more intense at its peak, since more immunoprecipitated fragments can be amplified by the central primer pair. Peak signal occurs in the same position regardless of fragment size.

target sequence amplified by the peak central primer pair. If, for example, all sonicated fragments are 1000 bp long, then there are 1000 possible unique DNA fragments that cover a hypothetical single-point binding site (assuming again that sonication produces an unbiased distribution of all possible 1-kb fragments). In PCR with one primer 50 bp upstream and one 50 bp downstream of this binding site, amplification can occur only

Figure 21.3.4 With fewer and larger PCR products, information about the position of the binding site within the peak PCR product is limited. Here, all that can be said is that the binding site is contained somewhere within the section of DNA amplified by the central PCR primer pair.

if the sonicated fragment contains a binding site and if this binding site is at least 50 bp from either end; these numbers are obviously approximate, since a PCR primer does not anneal to a single nucleotide. Thus, there are 900 possible fragments in an idealized pool of 1-kb fragments that can be amplified by the central PCR primer pair. If, instead of 1 kb, the fragment size were 500 bp, the number of fragments potentially detectable by the same primer pair would be only 400, yielding a lower peak, but a more focused one. The use of DNA with a smaller fragment size therefore makes it easier to exclude neighboring unbound DNA when attempting to delimit a true region of association.

Secondly, and more critically, the lower limit to the width of the signal peak is determined by the length and spacing of the PCR products. Imagine a hypothetical point-source binding site in the exact center of a 500-bp PCR product. In a series of nonoverlapping 500-bp PCR products, this product will yield the peak signal. However, to a first approximation, the most that can be said is that the binding site lies somewhere within this 500-bp region. If, instead of 500 bp, the length of the PCR products is 250 bp, then the possible position of the binding site is narrowed to a 250-bp region; the neighboring nonoverlapping 250-bp PCR products will yield a lower signal, since in some fraction of the cases the neighboring regions of DNA that they cover will not happen to be included on the same sonicated fragment as the binding site. Figure 21.3.4 shows the same hypothetical sample as in Figure 21.3.3B as it would look with fewer and longer PCR products.

When primer pairs are spaced closely enough, the symmetry of the signal contributed by PCR products adjacent to the peak will yield additional information about the position of the binding site. For example, if a series of primer pairs is designed such that the resultant PCR products overlap, it is possible to narrow the optimum binding region to an area smaller than the length of any one PCR product. This is illustrated in

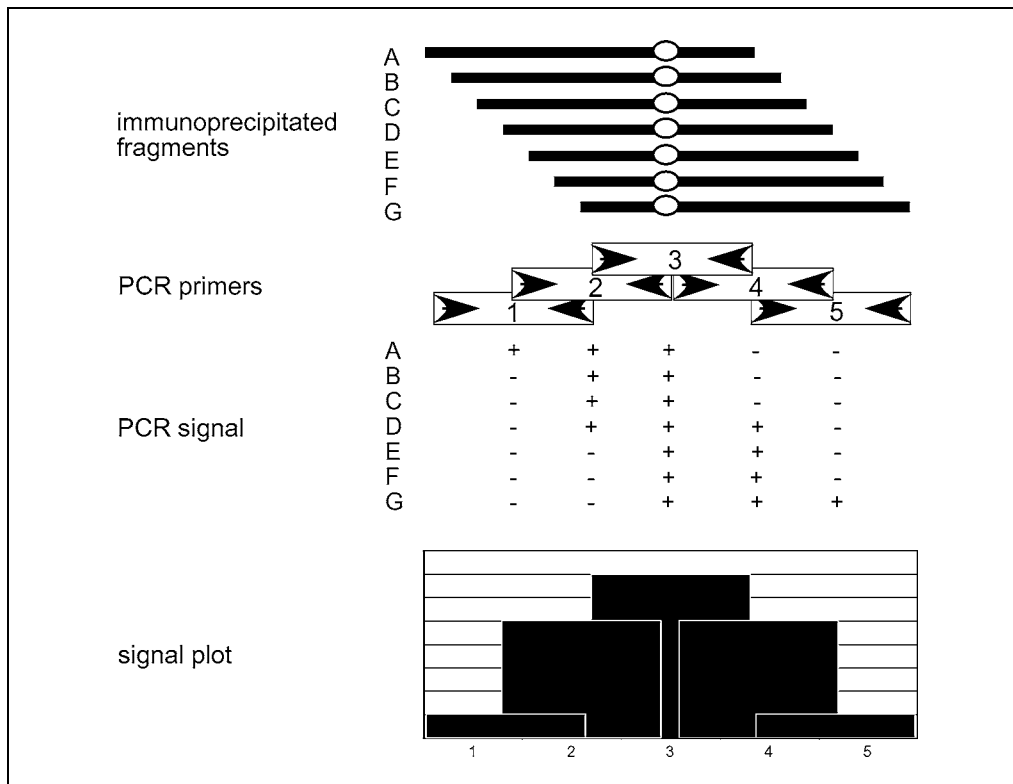

Figure 21.3.5 When the midpoint-to-midpoint distances of the PCR products are more closely spaced, the density of information and the symmetry of the signal plot make it possible to infer that the binding site is in the middle, rather than close to either end, of the DNA amplified by the central primer pair.

Figure 21.3.5 for a binding site at the exact center of PCR product 3. If the binding site is not perfectly centered over any one PCR product, the shape of the distribution will tend to the left or the right, as shown in Figure 21.3.6, panels A and B. The crucial parameter is the density of scanning information, i.e., the relative midpoint-to-midpoint spacing of the PCR products. High scanning density may be achieved with larger, overlapping PCR products or smaller, nonoverlapping PCR products.

When designing oligos for PCR scanning across a genomic region, several parameters should be considered. The size of the PCR products should be kept relatively small; 100 bp is generally a convenient compromise between achieving specificity and maintaining a reasonable limit on the number of nonoverlapping primer pairs needed to scan the whole region. The PCR primers should all produce PCR products of similar size, and the primers should all have approximately the same optimal annealing temperature, so that PCR reactions performed in parallel are equally efficient. This is most easily accomplished by using a primer-design program such as Oligo 6.6, which allows many potential primer sequences to be analyzed relatively quickly. Inevitably, the specific properties of the sequence (repeated sequence, regions of low melting temperature, the potential for primer-dimer formation) constrain the primer design such that perfectly even spacing, similar melting point, and uniform PCR product size are difficult to achieve across an entire series of primer pairs. In such situations, one should strive for well-spaced PCR product midpoints as a first consideration. This allows peak symmetry to be used most effectively in defining a binding site. In addition, for experiments meant to separate two binding sites, if there is any prediction of where the binding sites might be, it is useful to center one primer pair over each, while minimizing overlap with the neighboring binding site.

Figure 21.3.6 When the binding site is much closer to one or the other end of the fragment amplified by the central primer pair, the signal distribution will be skewed toward the neighboring PCR product. In **(A)**, peak binding occurs at the very end of the region amplified by primer pair 3 and slightly off-center with respect to that amplified by primer pair 2. In **(B)** peak binding occurs at the opposite end of the region amplified by primer pair 3 and is slightly off-center with respect to the region amplified by primer pair 4.

REAGENTS AND SOLUTIONS

Use double-distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

ChIP elution buffer

50 mM Tris·Cl, pH 7.5 (APPENDIX 2)
10 mM EDTA
1% SDS
Store up to 1 year at room temperature

ChIP wash buffer

10 mM Tris·Cl pH 8.0 (APPENDIX 2)
0.25 M LiCl
1 mM EDTA
0.5% Nonidet P-40
0.5% sodium deoxycholate
Store up to 1 year at room temperature

FA lysis buffer with and without 2 mM PMSF or 0.5 M NaCl

For FA lysis buffer:
50 mM HEPES: adjust pH to 7.5 with KOH
150 mM NaCl (or 0.5 M; see below)
1 mM EDTA
1% Triton X-100
0.1% sodium deoxycholate
0.1% SDS
Store up to 1 year at room temperature

For FA lysis buffer/2 mM PMSF add 100 mM phenylmethylsulfonyl fluoride (PMSF) in ethanol (store up to 1 year at -80°C) to a final concentration of 2 mM just before use. For FA lysis buffer/0.5 M NaCl, change the amount of NaCl added to 0.5 M. Store up to 1 year at room temperature.

MC lysis buffer

10 mM Tris·Cl pH 7.5 (APPENDIX 2A)
10 mM NaCl
3 mM MgCl_2
0.5% (v/v) NP-40
Store up to 1 year at 4°C

MNase reaction buffer

10 mM Tris·Cl pH 7.5 (APPENDIX 2A)
10 mM NaCl
3 mM MgCl_2
1 mM CaCl_2
4% (v/v) NP-40
Store buffer with above components up to 1 year at room temperature
Immediately before use, add:
1 mM PMSF (from 100 mM stock in ethanol).

SYBR Green Taq mix, 2×

12 mM Tris·Cl, pH 8.3 (*APPENDIX 2*)

50 mM KCl

5 mM MgCl₂

150 mM trehalose (Sigma)

100 mM betaine (Aldrich)

0.2% (v/v) Surfact-Amps 20 (Pierce; active ingredient, Tween 20)

0.2 mg/ml nonacetylated BSA (Sigma, B8667)

1 μM 5(6)-carboxy-X-rhodamine (ROX; Helix Research)

0.133× SYBR Green (Molecular Probes; final dilution 1:75,000)

Store solution with above components indefinitely at -80°C or up to several months at 4°C in the dark

Add the following immediately prior to use

0.5 mM each dATP, dTTP, dCTP, dGTP

0.2 U/μl hot-start *Taq* DNA polymerase (amount may need to be slightly adjusted to account for batch/activity variations among different manufacturers)

COMMENTARY

Background Information

Direct protein-DNA contacts and indirect protein-DNA interactions regulate fundamental chromosomal functions such as DNA replication, gene expression, and chromosome segregation. Thus, knowledge about the distribution of particular proteins on specific chromosomal DNA sequences can provide important insights into the mechanisms that govern chromosomal functions, structure, and organization. *In vivo* footprinting methods provide high-resolution mapping of protein-DNA interactions but cannot directly identify the chromatin-associated protein(s) responsible for the footprint. Chromatin immunoprecipitation, by contrast, is ideally suited for determining the identity of proteins associated with specific DNA sequences *in vivo*, albeit with lower resolution (≤ 1 kbp).

Two groups, Gilmour and Lis, and Solomon and Varshavsky, independently pioneered cross-linking and immunoprecipitation methods for *in vivo* chromatin analysis (Gilmour and Lis, 1984; Solomon and Varshavsky, 1985; Solomon et al., 1988; Gilmour et al., 1991). These methods exploited cross-linking to conserve *in vivo* chromatin structures and permit their isolation under the stringent conditions necessary to isolate soluble chromatin. Cross-linked protein-DNA complexes were purified by cesium chloride centrifugation (a time-consuming step) and subjected to immunoprecipitation. Their methods were distinguished primarily by the cross-linking agent: Gilmour and Lis employed UV irradiation, while Solomon and Varshavsky used formaldehyde. The biochemical characteristics of each method have been discussed ex-

tensively (Gilmour and Lis, 1984; Solomon and Varshavsky, 1985; Orlando et al., 1997, and references therein). In short, UV irradiation cross-links only protein-DNA complexes in direct contact, which limits its use. Formaldehyde reacts with primary amines on amino acids and DNA and RNA bases, reversibly forming a covalent adduct between two primary amines in close proximity to each other (≤ 2 Å). Because protein-protein adducts are formed in addition to protein-DNA adducts, chromatin-associated proteins not directly bound to DNA can be cross-linked to DNA via other proteins such as histones, significantly broadening the applicability of this procedure. Cross-linking with formaldehyde is also more easily accomplished than UV irradiation, especially with larger culture volumes.

Formaldehyde-based chromatin immunoprecipitation was simplified and adapted for use in other experimental systems, including budding yeast, where it was first used to assess the association of differentially acetylated histones with the silent mating-type loci (Dedon et al., 1991; Braunstein et al., 1993). This method involved fractionation of cell extracts to isolate a chromatin fraction before immunoprecipitation. A closely related method was used to assess the composition of the budding yeast centromere (Meluh and Koshland, 1997). The protocol presented here (see Basic Protocol 1; Fig. 21.3.1) is for a simpler procedure derived by Hecht and Grunstein in which immunoprecipitations were performed with whole-cell extracts to assess the spatial distribution of SIR proteins on telomere-proximal DNA regions (Hecht et al., 1996;

Strahl-Bolsinger et al., 1997). Basic Protocol 1 has also been applied to characterize the spatial and temporal associations of DNA replication proteins with chromatin at replication origins (Aparicio et al., 1997; Tanaka et al., 1997), the association of general transcription factors at promoters (Kuras and Struhl, 1999; Li et al., 1999), and the dynamics of DNA-binding proteins and chromatin-modifying activities associated with a cell-cycle and developmentally regulated promoter (Cosma et al., 1999). In each of these latter studies, protein association with relevant DNA sequences was examined using PCR amplification.

ChIP experiments in mammalian cells are performed using a modified version of Basic Protocol 1. The protocol for mammalian cells differs in five significant respects from the yeast protocol. First, intact mammalian cells are easily lysed by detergents, whereas breakage of yeast cells requires harsh mechanical treatment in the presence of glass beads to disrupt the cell wall. Second, formaldehyde-cross-linked chromatin in mammalian cells is generally more insoluble than comparable material from yeast cells. As a consequence, sonication is often insufficient to generate soluble material that is suitable for immunoprecipitation and that contains DNA fragments averaging the desired 500 to 1000 base pairs in length. Thus, in the mammalian cell protocol, cross-linked chromatin suitable for ChIP analysis is generated by a combination of micrococcal nuclease (MNase) treatment and sonication. Third, the immunoprecipitation procedure in the mammalian protocol includes a preclearing step to remove background material that sticks nonspecifically to the beads (this preclearing step is helpful, but not essential, and it can also be used in the yeast basic protocol). Fourth, ChIP experiments in mammalian cells are generally more limited with respect to the number of immunoprecipitations to be performed and/or the number of genomic loci to be investigated by quantitative PCR. For cultures of comparable volumes, there are ~10- to 100-fold fewer mammalian cells than yeast cells, and obtaining large numbers of mammalian cells is often limited by the expense of the growth medium and/or the inability to grow cell lines in suspension. The number of cells, and hence number of DNA molecules for individual genomic regions, is an important consideration in ChIP experiments because the sensitivity and reliability of the quantitative PCR assay is directly related to the number of molecules for a given genomic region. Finally, as mammalian genomes are 100-fold more

complex than yeast genomes, it is more difficult to generate PCR-primer pairs specific to the genomic region of interest and hence suitable for quantitative PCR analysis. It is essential to perform BLAST analyses (*UNIT 19.3*) to minimize possible cross-reactivity of primers with undesired regions of the genome, and to perform control reactions on genomic DNA to evaluate the suitability of PCR primer pairs for quantitative analysis.

ChIP can also be used to specifically follow the genomic association of mutant proteins that are unable to support cell growth (Mencia and Struhl, 2001). This involves a strain containing both an epitope-tagged version of the mutant protein and an untagged version of the wild-type protein, which supports cell growth; ChIP is performed with an antibody against the epitope. Lastly, ChIP can be combined with microarray technology to identify the location of specific proteins on a genome-wide basis (Ren et al., 2000; Iyer et al., 2001). The immunoprecipitated DNA is PCR amplified with linkers, and the resulting material hybridized to microarrays containing the complete set of intergenic regions in *Saccharomyces cerevisiae*. Such “genome-wide location” or “ChIP-chip” is particularly powerful, because it allows one to identify novel regions of protein association, without any previous knowledge.

Critical Parameters and Troubleshooting

Controls

There are two basic types of controls for a standard ChIP experiment. One control is mock immunoprecipitation to determine the specificity of an observed signal. This is accomplished by performing parallel immunoprecipitations of a given cross-linked chromatin sample with the antibody of interest and with an irrelevant antibody (or simply not providing any antibody). Alternatively, when antibodies against epitope-tagged proteins are employed (e.g., anti-HA, anti-myc), a similar comparison can be made with parallel immunoprecipitations (primary antibody included) of chromatin samples from strains expressing epitope-tagged or untagged versions of the protein of interest. However, in such experiments, it is often observed that the apparent immunoprecipitation efficiency for any irrelevant genomic region is about 2- to 3-fold higher in the experimental sample than in the control sample. This probably reflects nonspecific, and perhaps artifactual, association of the protein of interest with chromatin; hence it is not

indicative of specific protein association with the genomic region. For proteins that generally and strongly associate with the entire genome (e.g., histones), the apparent immunoprecipitation efficiency in the experimental sample will be much higher than the control sample.

The second control, which is usually more meaningful, is to examine a given pair of input and immunoprecipitated samples for multiple genomic regions. Control genomic regions (i.e., those not interacting with the protein) should all give the same background level of apparent immunoprecipitation efficiency (typically ~0.025% to 0.05%). Fragments bound by the protein of interest will give higher apparent immunoprecipitation efficiencies, and the difference can be expressed as fold enrichment over the background level. In the best cases, enrichments can be >100-fold, but even a factor of two can be meaningful if the experiment is repeated enough times and the experimentally determined error is sufficiently low. The advantage of this approach is that the identical samples are used to directly determine relative protein association to different genomic regions. Furthermore, differences in fold enrichments for different genomic regions represent relative quantitative measurements of protein association *in vivo*.

Additional controls may be used depending on the specific application. For example, where binding to a putative binding site is being tested, a mutation in the binding site is a critical control (especially if such a mutation previously was shown to eliminate binding *in vitro*). In a related manner, it might be useful to determine the protein association in mutant strains or under particular environmental conditions that are suspected to be important for the protein of interest.

Cross-linking

The extent of formaldehyde cross-linking is an important variable that in principle may be modified by changing the duration of cross-linking, the concentration of formaldehyde, or the temperature at which the cross-linking is performed. The use of 1% (final concentration) formaldehyde for 15 min at temperatures ranging from 12°C to 37°C usually works well; however, at temperatures above 30°C, background sometimes increases. Therefore, when fixation at a higher temperature is required, reducing the duration of cross-linking or the formaldehyde concentration may be helpful. Excessive cross-linking can interfere with cell breakage by bead beating and effective

fragmentation and solubilization of the DNA by sonication (see below). For some applications where protein cross-linking is particularly efficient (e.g., histones), it might be useful to decrease the cross-linking time or formaldehyde concentration. In particular, histone tails have a number of lysine residues that are likely to be modified by formaldehyde, and such modified lysines may interfere with the binding of antibodies against specific peptides corresponding to modified histones (e.g., by acetylation, phosphorylation, methylation).

Cell lysis

Although complete lysis of all cells is not absolutely necessary (and may be difficult to achieve), it is very important that lysis be as efficient as possible. Efficient lysis is important to obtain a reproducible degree of cell breakage among a group of samples to reliably compare results. Significant differences in cell lysis efficiency will result in immunoprecipitations with different ratios of antibody to chromatin, which will possibly alter immunoprecipitation efficiency. Cell breakage by a mini bead beater is generally more efficient than breakage by a multi-vortexing apparatus, although both methods work. In both cases, it is important to use flat-bottomed 2-ml microcentrifuge tubes. When using the mini bead beater, the sample and beads should nearly fill the tube, whereas for vortexing it is important to maintain a small volume. The extent of cell breakage may be monitored microscopically by comparing the number of intact cells (determined by counting on a hemacytometer) in small, diluted aliquots of the sample taken before and after vortexing. In addition, the size of the remaining pellet (unbroken cells and debris) obtained in the first centrifugation following sonication (see Basic Protocol 1, step 14) is a good general indicator of the extent of lysis. The size of this pellet should be routinely checked (by rapid visual inspection) to compare the extent of lysis among samples.

The final yield of genomic DNA in the extract is also an important indicator of the extent of cell breakage, although the DNA yield is also dependent on the solubilization of chromatin by sonication (see below). Poor or variable cell breakage may result from excessive cross-linking that toughens the yeast cell wall and other structures. The procedure for lysis of *Saccharomyces cerevisiae* is appropriate for other yeast species. However, modified procedures are necessary for breaking mammalian cells.

Sonication

Shearing DNA to a small size (~500 bp average) by sonication is the critical factor in achieving resolution between a DNA sequence where a particular protein is bound and a nearby (*cis*-)DNA sequence that does not bind that protein. In addition, fragmentation of the chromatin is essential for its solubilization from the ruptured cells. As indicated above, the ability to fragment and solubilize the chromatin depends on the extent of chromatin cross-linking. In general, more cross-linking results in larger fragment size and lower solubility, resulting in lower yield (Orlando et al., 1997). Because of the importance of this variable, the shear size of the DNA should be assessed to confirm that the desired degree of fragmentation has been achieved, and should be reassessed if fixation conditions are altered. The shear size is determined by electrophoresing DNA from step 16 of the Basic Protocol 1 on a 1.5% to 2.0% agarose gel and visualizing with ethidium bromide (UNIT 2.5A). A smear of DNA should be apparent with an average size of 500 bp and most of the DNA (>90%) should be in the size range of 100 to 1000 bp.

As an alternative to sonication, DNA fragment size can be reduced by treatment of the cross-linked chromatin with micrococcal nuclease (UNIT 3.12). Micrococcal nuclease preferentially cleaves DNA located in the linker regions between nucleosomes. By varying the concentration of micrococcal nuclease, it is possible to generate samples in which average DNA size varies. The minimal useful size is about 150 bp, which corresponds to a mononucleosome. However, cleavage to mononucleosome-sized fragments may also result in a preferential loss of certain genomic regions due to the sequence-specificity of micrococcal nuclease.

Immunoprecipitation

The success of this procedure relies on the use of an antibody that will specifically and tightly bind its target protein in the buffer and wash conditions used. In addition, antibody should be present in excess with respect to its target protein so that differences in the amounts of the protein-DNA complexes of interest will be accurately measured. Perform preliminary experiments to confirm avid immunoprecipitation and determine an approximate amount of antibody to use. Chromatin extracts should be prepared without prior cross-linking of the cells and subjected to immuno-

precipitation with varying concentrations of antibody (20 µg/ml antibody may be a good starting point). The amount of the protein of interest in the extracts before and after immunoprecipitation should be analyzed by immunoblotting (UNIT 10.8) to determine the lowest antibody concentration that depletes >90% of the protein of interest from the extract. This antibody concentration is a good starting point for the full protocol and may later be modified to maximize the signal-to-noise ratio (see Anticipated Results). With cross-linked chromatin, immunodepletion of the target protein is less efficient (~50%), presumably due to masking or modification of the epitopes, and a significant amount of the protein remains refractory to immunoprecipitation even with higher antibody concentrations. Thus, the ideal antibody concentration is ultimately determined empirically to maximize the yield of specific coprecipitated DNA while minimizing precipitation of nonspecific DNA.

Both monoclonal and polyclonal antibodies have been used in this procedure. The monoclonal antibodies 12CA5 (anti-HA), 17D09 (anti-HA), and 9E10 (anti-myc) have been used successfully in different laboratories. In general, triple-HA epitope tags work well (Hecht et al., 1996; Aparicio et al., 1997; Tanaka et al., 1997), and larger multi-myc epitope tags have also been successful (e.g., myc-9, myc-18; Tanaka et al., 1997). Protein G-Sepharose, Protein A-Sepharose, and anti-mouse immunoglobulin-coupled magnetic beads have all been used to precipitate the immune complexes, although it should be noted that certain classes of mouse and rat immunoglobulins are not strongly bound by protein A (Harlow and Lane, 1988).

For optimal results, it is critical to minimize the background level of material that inevitably comes down during the immunoprecipitation. The procedures described here work well with a diverse set of antibodies, but it might be necessary to modify the binding and elution conditions in specific cases. Peptide elution is clearly preferred over heat elution, as it is more specific and results in lower experimental backgrounds and hence higher-fold inductions. However, peptide elution is only possible for experiments using antibodies against peptides (typically for analyzing epitope-tagged proteins, but analysis of native proteins should also be possible). In performing peptide elution, it is important to add enough peptide such that the protein-DNA complexes are efficiently eluted from the beads.

Another consideration is that the epitope of interest in the chromatin-bound protein might be inaccessible to the antibody due to associated proteins or DNA structures. In such a case, one might obtain a false-negative result. Whereas the majority of a given protein may be efficiently immunoprecipitated from the cross-linked cells, the fraction that is actually cross-linked might be undetectable. The use of polyclonal antibodies (which often recognize multiple determinants within a protein) or epitope-tagged proteins (the epitope is unlikely to have a specific interaction with other proteins or DNA sequences, particularly if the epitope does not affect the biological function as determined by genetic complementation) minimizes, but does not eliminate this concern. Because of this caveat, negative results should be interpreted cautiously and alternative methods (e.g., *in vitro* DNA binding or association of the protein with bulk chromatin) should be tried. This concern is particularly relevant when a protein of interest does not appear to interact with any genomic sequence. However, if a protein selectively associates with some genomic sequences, this concern is significantly reduced—i.e., it is unlikely that epitope masking will occur at some loci, but not others.

PCR strategy

The choice of primers depends on the experimental goals. If binding to a specific site is being tested, a primer pair that flanks the site and at least one control primer pair recognizing

a DNA sequence not expected to bind the protein of interest are the minimal requirements (see Fig. 21.3.7). When choosing primers, it is important to remember that resolution between adjacent sequences is limited by the shear size of the DNA. For an average DNA size of 500 bp, a significant fraction of the DNA molecules will be in the 500 to 1000 bp range, and hence DNA sequences 1000 bp distal from the actual protein binding site may be coprecipitated. Therefore, primer pairs used as controls should amplify a region of DNA that is far enough away from the expected binding site (e.g., >1 kbp) that coprecipitation of adjacent DNA is not detected. A good strategy is to design multiple sets of primers at increasing distances from a suspected binding site. Such a strategy has also been used to probe the “spreading” and “movement” of proteins on chromatin (Hecht et al., 1996; Aparicio et al., 1997; Strahl-Bolsinger et al., 1997).

Success in obtaining high-quality quantitative data is critically dependent on good primer design! In general, primers should be 20 to 30 bases long with a T_m of 55° to 60°C. Most primers require no purification or special treatment prior to PCR. Amplification products should be 75 to 300 bp. Longer PCR products should be avoided, because the amplification efficiency is substantially lower, and DNA fragments that do not bind to both primers will not be amplified (this can be a significant problem since the size of DNA fragments in the samples averages ~500 bp and ranges between 100 to 1000 bp). A final primer concentration

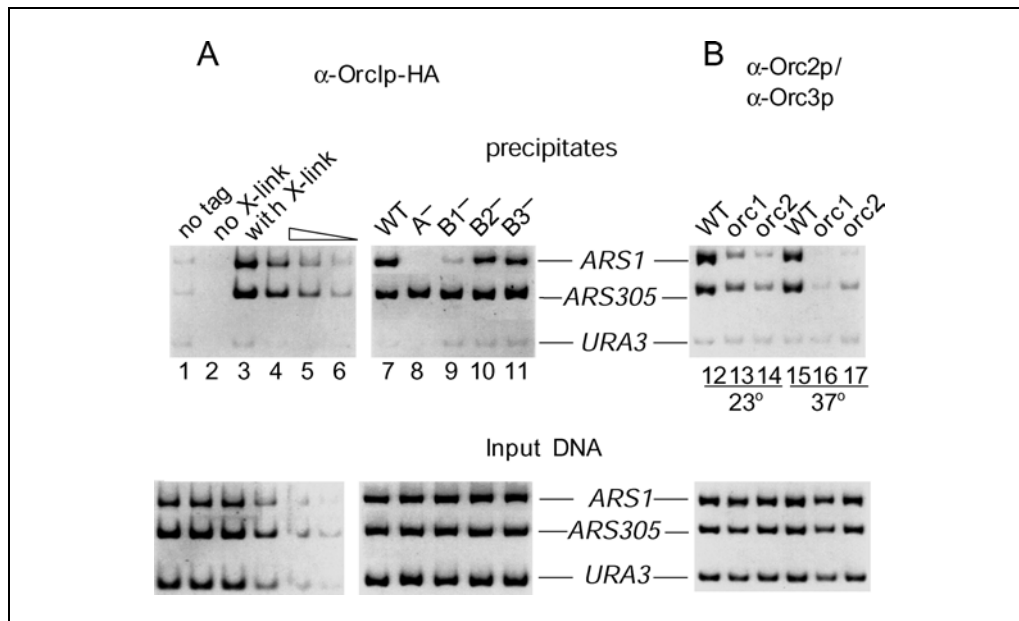

Figure 21.3.7 Anticipated results from chromatin immunoprecipitation analysis of origin recognition complex (ORC) with replication origin and nonorigin DNA sequences.

of 1 μM works well for most primers, but in some instances, improved product specificity may be obtained by lowering the final primer concentration 5 to 10 fold.

The design of good primers is greatly facilitated by commercially available software packages such as Oligo 6.6 or Primer Express 1.5. These packages allow for extensive customization of many different parameters, including T_m , oligonucleotide length, GC content, and more. While the success of each individual primer pair in the specific amplification of its target sequence is dependent on many variables, special care must be taken to minimize primer-dimers and hairpins. Finally, it is a good idea to check primers for hybridization to other genomic sequences through the use of a Web-based program such as BLAST.

Newly obtained primer pairs must be tested for amplification specificity and performance under the conditions that will be used in quantitative PCR. Primer pairs that are suitable for reactions performed by the Basic Protocol 1 might not be suitable for real-time PCR reactions using SYBR Green, because SYBR Green can inhibit *Taq* polymerase. It is particularly informative to analyze input DNA amplification by the primers in question on high-percentage agarose or polyacrylamide gels after completion of the PCR. The presence of multiple product bands indicates poor specificity, and will invariably lead to unreliable results.

For Basic Protocol 1, the best test for quality of a given primer pair is to carry out a standard curve using different dilutions of DNA. For a high-quality primer pair, the amount of PCR product should be directly proportional to the amount of DNA, with an error of less than $\pm 20\%$. The number of PCR cycles is determined empirically. Usually, 25 to 28 cycles is appropriate. More than 28 cycles can result in detection of nonspecifically precipitated sequences and/or lead to variable results due to inactivation of *Taq* polymerase. Multiple primer pairs can be used in combination if the PCR products are separable by gel electrophoresis (as many as five have been used), but some combinations interfere with efficient amplification of one or more products. It is essential to test primer pairs singly and in combination, with titrations of template DNA, to determine if this is a problem. The advantage of using multiple primer pairs is that individual reactions can generate data for multiple genomic regions in an internally controlled manner. In addition, the Basic Protocol 1 can be used to simultaneously analyze two alleles of

a given locus in an internally controlled manner, provided the individual alleles result in different-sized PCR products.

When quantitative PCR will be performed in real time using SYBR Green (see Alternate Protocol 2), high-quality primer pairs should result in ~ 1.9 -fold amplification/cycle. Such amplification efficiency can be determined from quantitative analysis of raw fluorescence data for each cycle. Amplification efficiencies < 1.8 are likely to cause problems, particularly if detection of the PCR product requires 30 cycles or more. Specificity information may also be obtained by running dissociation curves on reactions following the conclusion of the PCR run.

Quantitation

For Basic Protocol 1, PCR products are analyzed by gel electrophoresis and detected by staining with ethidium bromide or SYBR Green or by radioactivity (typically by including a small amount of [^{32}P]dATP in the reactions). DNA staining has the advantage of not having to use radioactivity, but the linear detection range is relatively limited. In this regard, SYBR Green is more sensitive than ethidium bromide and is preferred. Radioactive detection is more sensitive and has a larger linear range than detection by DNA staining. Whatever detection method is employed, it is essential to use a high-quality imager to accurately quantitate the amounts of PCR product in the various reactions.

When quantitative PCR is performed in real time using SYBR Green (Alternate Protocol 2), the linear range is directly visualized and the quality of the reactions can be directly assessed. For reactions involving a given primer, the curves should be superimposable with respect to shape, and should differ only in the number of cycles needed to reach the threshold (C_T). Amplification efficiencies should be ~ 1.9 -fold/cycle. If the curves have different shapes and/or amplification efficiencies are < 1.8 , the reactions are not equivalent and accurate quantitation is impossible.

Data interpretation

In most experiments, it is presumed that the protein of interest associates specifically with certain genomic regions and only associates nonspecifically with other genomic regions. In general, it is very difficult to distinguish true nonspecific association from experimental background of the cross-linking procedure. In this regard, immunoprecipitations with the antibody of interest generally give 2- to 3-fold higher immunoprecipitation efficiencies than

immunoprecipitations with control (or no) antibodies, but it is unclear whether this effect is physiologically meaningful or an experimental artifact.

For this reason, the best way to interpret the data for most experiments is to compare the immunoprecipitation efficiencies for different genomic regions from the same INPUT and IP samples. The immunoprecipitation efficiency is calculated by the amount of PCR product in the IP sample divided by the amount of PCR product in the INPUT sample. A typical background level for DNA fragments that do not associate with the protein of interest is 0.025% to 0.05%. However, background levels can vary, depending on the antibody used and the elution method. In general, monoclonal antibodies give lower background signals than polyclonal antibodies. Peptide elution is preferred over heat elution for the same reason, although this can only be employed for ChIP experiments involving antibodies against defined peptide epitopes. By definition, the background level should be the same for all DNA fragments that do not specifically associate with the protein of interest. In many cases, the choice of suitable negative control regions is based on expectation from other lines of evidence (e.g., the middle of protein-coding regions are unlikely to bind general transcriptional initiation factors). In cases where there is no previous knowledge, the background level can only be based on multiple regions having similar immunoprecipitation efficiencies that are roughly at the level of a typical background immunoprecipitation efficiency. In this regard, it is particularly useful to use proteins tagged with a standard epitope (e.g., HA or myc), as there is considerable information on background levels in such cases.

DNA fragments that display immunoprecipitation efficiencies significantly above the background are indicative of protein association to those genomic regions *in vivo*. Moreover, for a given pair of INPUT and IP samples, the fold enrichment of a given genomic region over the background is directly related to the level of protein association *in vivo*. It is useful to define “relative protein occupancies” for different regions by subtracting the background from the observed immunoprecipitation efficiencies. For example, if the background level is arbitrarily defined as 1 occupancy unit, fragment A that shows 6-fold enrichment over background will have 5 occupancy units, whereas fragment B that shows 21-fold enrichment over background will have 20 occupancy units. Thus, one can conclude

that the protein association with fragment B is 4-fold greater than with fragment A. Without further considerations (see below), this conclusion is only relevant for the particular pair of INPUT and IP samples because absolute immunoprecipitation efficiencies and fold enrichments can vary among repeated trials of the same experiment.

Absolute immunoprecipitation efficiencies and fold enrichments depend on multiple factors. First, the number and physical location of amino acid and nucleotide residues within the interacting protein surfaces that react with formaldehyde vary considerably among protein-protein and protein-DNA interactions. Second, proteins directly interacting with DNA can be cross-linked by a single event, whereas proteins that indirectly associate with DNA need multiple cross-linking events. In this regard, proteins directly binding DNA (e.g., specific DNA binding proteins and general transcription factors) typically give higher fold enrichments than other proteins (e.g., components of chromatin-modifying complexes). Third, some proteins might stably associate with genomic DNA sequences (maximally 100% occupancy), whereas association of other proteins might be transient. Fourth, the absolute immunoprecipitation efficiency depends on the quality of the specific antibody-antigen interaction as well as the antibody concentrations, and the fold enrichment depends on both the absolute immunoprecipitation efficiency and on the background. Thus, absolute immunoprecipitation efficiencies and fold enrichments cannot be used to compare binding characteristics of different proteins. Furthermore, ChIP experiments do not provide absolute measurements of protein occupancy on specific genomic regions or relative stoichiometry of factors on a given sequence. Despite these limitations, ChIP experiments do provide direct quantitative information on the relative levels of protein association on different genomic sequences.

As mentioned above, absolute immunoprecipitation efficiencies and fold enrichments can vary among repeated trials of the same experiment due to potential differences in overall immunoprecipitation efficiency and experimental background. To account for these experimental variations, it is useful to arbitrarily define occupancy units for a specific protein-DNA association. In the example above, one might arbitrarily define fragment A to have 4 occupancy units. In independent experiments, association with fragment A will always be defined as having 4 occupancy units, and

association with other fragments will be defined relative to that of fragment A in the same pair of INPUT and IP samples. In this manner, it is possible to accurately determine the relative level of protein association to multiple genomic regions even though the absolute immunoprecipitation efficiencies and fold enrichments might vary in different repeats of the same experiment. However, in actual practice, differences in absolute immunoprecipitation efficiencies and fold enrichments should not show significant sample-to-sample variation.

A related issue occurs when comparing the level of protein association under different physiological conditions (e.g., different growth conditions or strains). The ideal way to handle this situation is to analyze a “positive control” region that is predicted to be unaffected by the growth condition or genetic constitution. For example, in analyzing association of general transcription factors under a particular environmental condition, it would be useful to examine promoters that are regulated and promoters that are not. In some cases, such a control genomic region is not available, in which case one must rely on simple sample-to-sample reproducibility from independent trials of the same experiment.

ChIP can be used to determine the relative occupancy levels of different proteins at genomic regions (Kuras et al., 2000). Ideally, this is accomplished by performing parallel immunoprecipitations with different antibodies on the same cross-linked chromatin sample. Alternatively, immunoprecipitations can be performed on different samples (this often occurs when using epitope-tagged strains or when multiple proteins are examined). To determine occupancy ratios for two different factors (e.g., X and Y), occupancy units for X and Y are calculated independently as described above. The X:Y occupancy ratios are then calculated for all genomic regions examined. The resulting occupancy ratios are defined in arbitrary units, but the relative occupancy ratios for the different genomic regions are valid. To account for potential sample-to-sample variations among repeats of the same experiment, a given X:Y occupancy ratio should be defined for a specific genomic region and ratios at all other genomic regions calculated in relative terms. Using this rationale, it has been shown that the relative associations of TBP and the general transcription factors TFIIA and TFIIB are essentially constant at all promoters, whereas the TAF:TBP occupancy ratios vary considerably

(Kuras et al., 2000). Importantly, however, occupancy ratios determined from such experiments cannot address whether two proteins co-occupy a given genomic region or mutually compete for the same genomic region.

For some experiments, particularly those involving histone modifications, it is inappropriate to analyze the data in terms of occupancy units and specific versus nonspecific binding sites. Histones associate with essentially all genomic regions, and the level of a particular chromatin modification typically occurs in a continuum. Thus, it is very difficult to determine whether a given region is devoid of a particular modification, although information in this regard can be obtained in control immunoprecipitations using an irrelevant antibody. For these reasons, quantitative analysis of the relative level of a given histone modifications is best presented using simple immunoprecipitation efficiencies. Again, to account for sample-to-sample variations, a specific genomic region should be given an arbitrarily defined value, which is used to determine the relative levels of all other genomic regions.

Anticipated Results

Figure 21.3.7 shows the results of chromatin immunoprecipitation of protein subunits of the origin recognition complex (ORC) and relevant controls (Aparicio et al., 1997). In panel A, immunoprecipitation of Orc1p-HA was shown to specifically coprecipitate the replication origin sequences *ARS1* and *ARS305*, but not the nonorigin DNA sequence *URA3*. Enrichment of *ARS1* and *ARS305* (~0.4% precipitated relative to total) compared to *URA3* (~0.01% precipitated) was ~40-fold and depended on formaldehyde cross-linking and on the epitope-tagged Orc1p (lanes 1 to 3). Mutation of DNA sequences (A and B1) in the *ARS1* replication origin (required in vivo for origin activity and in vitro for binding of ORC to origin DNA) greatly reduced or eliminated association of Orc1p-HA with *ARS1*. The continued association with the wild-type *ARS305* origin served as an additional control (lanes 7 to 9). Analysis of the totals demonstrated that the origin and nonorigin DNA sequences were equally represented in the whole-cell extract (lower panel, “input DNA”). In panel B, origin association of ORC was tested in strains with temperature-sensitive alleles of *ORC1* or *ORC2* demonstrating loss of ORC-origin DNA binding under nonpermissive conditions (lanes 15 to 17). Nevertheless, it should not be assumed that a

mutation in a protein of interest would necessarily result in loss of its chromatin association.

Time Considerations

Basic Protocol 1 may be completed in a 2- or 3-day period. On the first day, cells are fixed with formaldehyde and harvested (1 hr). For convenience, or if preparation of the cells for cross-linking will require an extended period of time beforehand (e.g., induction of expression, cell cycle synchronization), the cells may be frozen and stored at -80°C as described (see Basic Protocol 1, step 6). Preparation of chromatin extracts (2 hr) and immunoprecipitations (primary antibody incubation, ~ 2 hr; incubation with secondary-coupled beads, ~ 1 hr; washing and elution, 2 hr) may be carried out in 1 day, after which the samples are placed at 65°C overnight to reverse the cross-links. If necessary, immunoprecipitation with the primary antibody or bead-coupled secondary antibody may be extended overnight; however, it is most efficient to perform the ≥ 6 hr cross-link reversal step overnight. On the final day, the DNA is purified (< 4 hr, including a 2-hr incubation with proteinase K), PCR amplified (< 3 hr, including 2 hr for the PCR program), and analyzed by gel electrophoresis (< 2 hr, including 1 hr of gel running time).

The entire protocol should take ~ 3 to 4 days.

For Alternate Protocol 2, setup time is < 30 min, thermal cycling takes ~ 2 hr, and data analysis takes < 30 min.

DNase I and Hydroxyl Radical Characterization of Chromatin Complexes

UNIT 21.4

Purified nucleosomes are prepared with radioactively end-labeled DNA from native chromatin or by reconstitution from purified components (Wolffe and Hayes, 1993). The DNA within these complexes is then subjected to DNase I cleavage (see Basic Protocol) or hydroxyl radical cleavage (see Alternate Protocol). Cleavage products are visualized by separation on DNA sequencing gels, followed by autoradiography of the gel. Analysis of the cleavage pattern reveals details of histone-DNA interactions and the extent of nucleosome translational and rotational nucleosome positioning within the chromatin complexes.

NOTE: Radioactive label is used in this unit, and appropriate precautions and shielding should be used (*APPENDIX 1F*).

ANALYSIS OF CHROMATIN COMPLEXES BY DNase I CLEAVAGE

**BASIC
PROTOCOL**

DNase I digestion of purified chromatin complexes can be used to determine what regions of a DNA segment are intimately associated with the core histone proteins and what regions are more like naked DNA (linker DNA within the nucleosomal repeat). DNase I associates with the minor groove of the double helix and cuts DNA endonucleically, leaving a single-stranded nick end (Suck and Oefner, 1986). Thus, cleavage by this enzyme reveals where the minor groove is alternately protected by histone proteins and exposed to bulk solvent on the surface of the nucleosome. For intranucleosomal DNA, this produces a ladder of cleavage products on a sequencing gel in which the bands are spaced by 10 to 11 bp. The protocol below includes the DNase I cleavage reaction and analysis of cleavage products by sequencing gel electrophoresis, as well as an optional nucleoprotein gel electrophoresis fractionation of the nucleosomes. Note that other fractionation procedures such as sucrose gradient sedimentation (*UNIT 5.3*) may also be used.

Materials

- Nucleosome preparation, radiolabeled (see Critical Parameters)
- Nucleosome buffer (see recipe)
- 20 mM MgCl₂
- 2000 U/ml (1 mg/ml) DNase I: purchase 10,000 U lyophilized with glycine (Worthington) and reconstitute with 5 ml H₂O (store in aliquots at -20°C)
- 10× stop solution: 50 mM EDTA/0.2% (w/v) SDS (store up to 6 months at room temperature)
- 3 M and 0.3 M sodium acetate (*APPENDIX 2*)
- 95% and 70% ethanol (-20°C)
- 0.3 M sodium acetate in TE buffer, pH 8.0
- 10 mg/ml Pronase or 10 mg/ml protease K (store up to 1 year at -20°C)
- 2% (w/v) SDS
- 0.1% (w/v) SDS in TE buffer, pH 8.0
- 25:24:1 (v/v/v) phenol/chloroform/isoamyl alcohol made with buffered phenol (*UNIT 2.1A*)
- 25 mM EDTA/50% (v/v) glycerol
- 0.7% preparative agarose gel (*UNIT 2.5A*) in 1× Tris·borate buffer, pH 8.3 (see recipe)
- Running buffer for nucleoprotein gel electrophoresis: 1× Tris borate buffer, pH 8.3 (see recipe)
- TE buffer, pH 8.0

**Chromatin
Assembly and
Analysis**

100% formamide containing 1 mM EDTA and 0.005% tracking dyes

Transfer micropipets

90°C water bath

Additional reagents and equipment for phenol extraction and ethanol precipitation of DNA (UNIT 2.1A), agarose gel electrophoresis (UNIT 2.5A), autoradiography and phosphor imaging (APPENDIX 3A), and sequencing gel electrophoresis (UNIT 7.6)

NOTE: Proper sample preparation is critical for both the DNase I and hydroxyl radical cleavage procedures. See Critical Parameters for guidelines before proceeding with the experiments.

Prepare sample of chromatin complexes

1. Prepare samples containing nucleosomes at 100 to 400 ng/μl and volumes ranging from 10 μl to several hundred μl (although a convenient size is 20 to 40 μl) in nucleosome buffer.

Most nucleosomal complexes are stable under the conditions described for the nucleosome buffer (see Reagents and Solutions) although it is noted that oligonucleosomal templates will exist in a full extended conformation at these ionic strengths (Hansen, 1997). Chromatin complexes such as mononucleosomes can be separated from any naked DNA remaining after the reconstitution by sucrose or glycerol gradient sedimentation (UNIT 5.3) before the digestion. This obviates the need for nucleoprotein gel fractionation of digested complexes (see Fig. 21.4.1).

2. Equilibrate sample at room temperature.

Digestions of very concentrated material may be carried out at 37°; however, digestions usually are more easily carried out at ambient temperature.

3. If necessary, bring the Mg²⁺ concentration to 0.5 to 1.0 mM by adding 1/20 vol of 20 mM MgCl₂ stock solution.

This step is omitted if the Mg²⁺ concentration is already in molar excess over chelation agents such as EDTA (e.g., in cases where Mg²⁺ is present in the transcription buffer). If EDTA or other metal-binding species are present, adjust Mg²⁺ concentration to be 0.5 to 1.0 mM in excess of the chelation agent.

DNase I requires Mg²⁺ as a cofactor. However, note that with some oligonucleosomal complexes addition of Mg²⁺ salts must be done with care—i.e., slowly with rapid mixing—as concentrations in excess of a few mM can cause aggregation and precipitation of oligonucleosome substrates (Schwartz et al., 1996).

Digest with DNase I

4. Add 0.5 to 1 μl of a 1:50 to 1:500 dilution of the 2000 U/ml DNase I stock.

The authors have found 0.1 to 0.2 mg enzyme per mg nucleic acid to be optimal under the experimental conditions used in their laboratory. However, the optimal concentrations of DNase I must be determined empirically, since the extent of nucleolytic activity varies as a function of DNA concentration and ionic strength.

Under optimal conditions approximately 2/3 to 3/4 or more of the original DNA fragment should remain uncut by the enzyme (see Troubleshooting).

5. Incubate the digestion for 1 to 2 min.

Terminate the reaction and purify the DNA digest

The method used to terminate the reaction depends on the subsequent steps to be followed. If nucleosomes are free of contaminating DNA (i.e., have been previously purified by gradient isolation), then the gel step is not necessary. If complexes are to be fractionated by nucleoprotein gel electrophoresis, proceed to step 6c. If the complexes are relatively

pure or have been purified by gradient fractionation the digestion may be stopped and the DNA directly prepared for sequencing gel electrophoresis (step 6a).

For complexes that are relatively pure or that have been purified by gradient fractionation:

6a. Stop the reaction by adding 10× stock of stop solution to a final concentration of 1×.

Preparations of reconstituted nucleosomes containing protein and DNA concentrations <0.1 mg/ml do not require protease treatment and phenol extractions. These may be precipitated directly with ethanol/salt in the presence of SDS. The DNA pellet is then dried and analyzed directly.

7a. Adjust the solution to 0.3 M sodium acetate by adding $\frac{1}{10}$ vol of 3 M sodium acetate. Precipitate the DNA by adding 2 to 2.5 vol of -20°C 95% ethanol. Collect the DNA pellet by microcentrifuging 20 to 30 min at maximum speed, room temperature, and carefully removing the supernatant with a transfer micropipet.

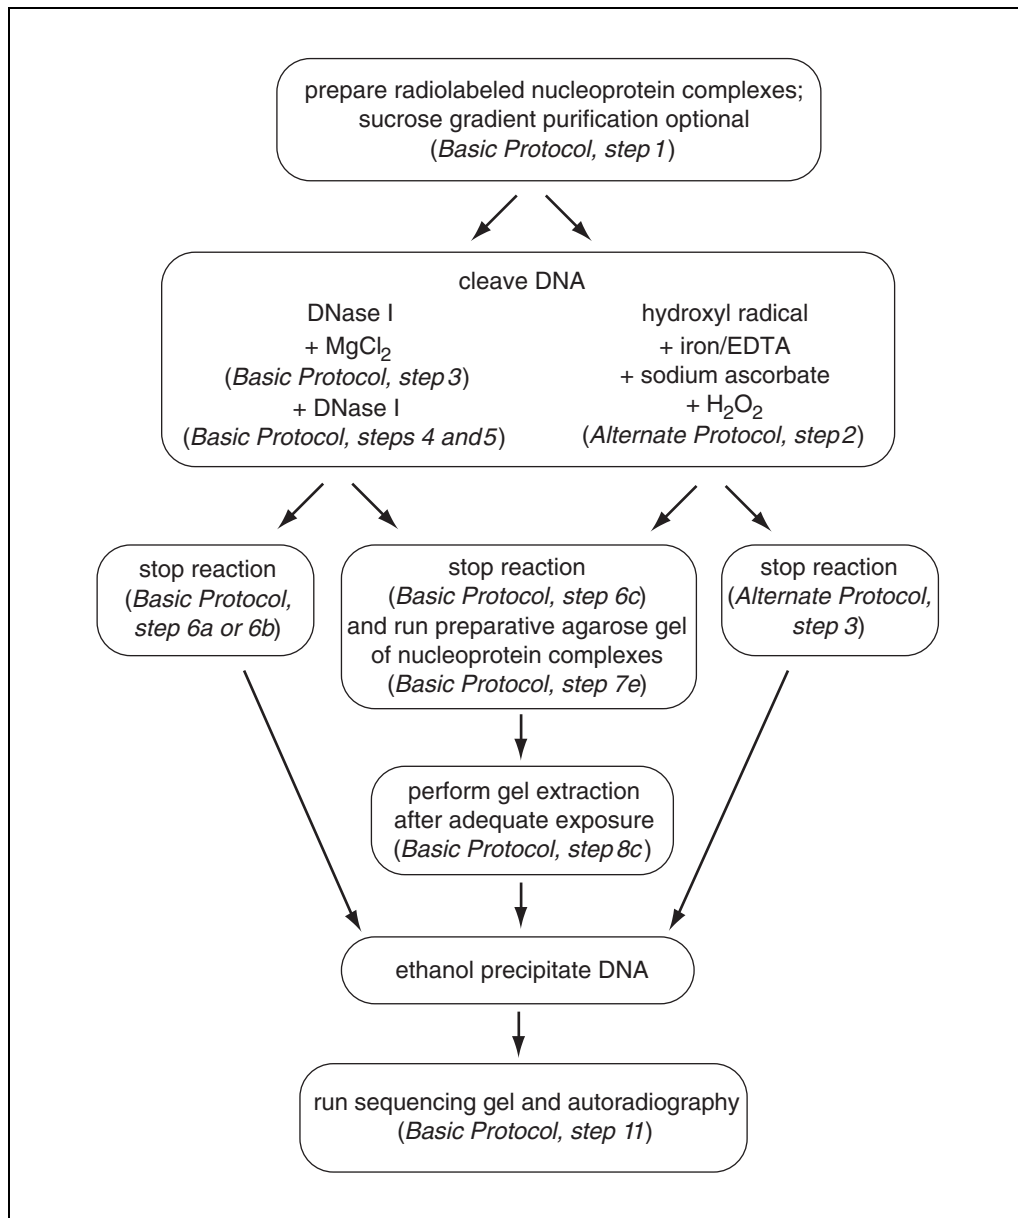

Figure 21.4.1 Flow chart for DNase I and hydroxyl radical cleavage analysis of chromatin complexes.

- 8a. Resuspend the DNA pellet in 0.3 M sodium acetate/TE buffer, pH 8.0, and reprecipitate with ethanol as before to remove additional salt and SDS. Wash the final pellet gently with 400 μ l of ice-cold 70% ethanol.

For complexes containing larger quantities of histone proteins:

- 6b. Add a 10 mg/ml stock solution of Pronase or a 10 mg/ml stock solution of protease K to ~0.25 mg/ml final concentration. Also add 1/10 vol of 2% SDS (0.2% final). Incubate 2 to 3 hr at 37° to 42°C.

Complexes containing histone protein concentrations in excess of 0.1 mg/ml, as is typical with preparations of native chromatin, should be digested with proteinase K and phenol/chloroform extracted before ethanol precipitation.

- 7b. Adjust the sample volume to 180 μ l with 0.1% SDS/TE buffer, pH 8.0. Extract with 1 vol 25:24:1 phenol/chloroform/isoamyl alcohol made with buffered phenol (*UNIT 2.1A*). Adjust the aqueous phase to 0.3 M sodium acetate by adding 20 μ l of 3 M sodium acetate, then precipitate the DNA by adding 550 μ l of -20°C 95% ethanol. Collect the DNA pellet by microcentrifuging 20 to 30 min at maximum speed, room temperature, and carefully removing the supernatant with a transfer micropipet.
- 8b. Resuspend the DNA in 0.3 M sodium acetate/TE buffer, pH 8.0, and reprecipitate with ethanol as before to remove additional salt and SDS, Wash the final pellet gently with 400 μ l of ice-cold 70% ethanol.

To separate digested nucleosomes from naked DNA (nucleoprotein gel electrophoresis):

- 6c. Stop the reaction by adding $\frac{1}{10}$ vol 25 mM EDTA/50% glycerol.
- 7c. Immediately load the sample onto a 0.7% preparative agarose gel and perform electrophoresis in 1 \times Tris-borate buffer, pH 8.3, for 3 hr with an applied voltage of 5 V/cm. When electrophoresis is complete, wrap the gel tightly in plastic wrap and expose to autoradiographic film (*APPENDIX 3A*).

Typically, all visual tracking dyes such as bromophenol blue or xylene cyanol are omitted from nucleosome samples but are loaded in adjacent wells to gauge the progress of the gel. The bromophenol blue dye is typically run approximately $\frac{1}{2}$ to $\frac{2}{3}$ of the way through a standard 10 to 12 cm horizontal agarose gel.

For the autoradiography, the authors have found that the gel must be exposed for 1.5 to 3 hr before sufficiently dark bands are obtained. It is crucial at this point to be able to precisely align the gel with the exposure after developing; typically, phosphorescent markers available from Stratagene are placed directly on the surface of the plastic wrap. Alternatively, one can simply cut one corner from the gel, wrap it in plastic wrap, then carefully trace around the edges of the gel with a marker right on the film. Care must be taken so that the film does not shift position as the gel is prepared for exposure (the gel can be fastened at the corners with transparent adhesive tape). The gel may also be aligned by preparation of radioactive "marker dye." Some old radioactive nucleotides are mixed with concentrated bromophenol blue dye and spotted into the gel with a micropipet. The dye will diffuse slightly; however the original point of placement usually can be visualized on the gel and the autoradiogram. It is also possible to prepare a "radioactive marker pen" by dipping the end of a marker in some old source radioactivity and then writing directly onto the plastic wrap.

- 8c. Cut out the digested nucleosome and naked DNA bands and isolate the radiolabeled DNA (*UNIT 2.7*). Adjust the DNA solution to 0.3 M sodium acetate by adding $\frac{1}{10}$ vol of 3 M sodium acetate. Precipitate the DNA by adding 2 to 2.5 vol of -20°C 95% ethanol. Collect the DNA pellet by microcentrifuging 20 to 30 min at maximum speed, room temperature, and carefully removing the supernatant with a transfer micropipet. Resuspend the DNA pellet in 0.3 M sodium acetate/TE buffer and

reprecipitate with ethanol as before to remove additional salt and SDS. Wash the final pellet gently with 400 μ l of ice-cold 70% ethanol.

The DNA can be recovered from the gel by electroelution of the isolated band (UNIT 2.7) or by standard “freeze and squeeze” procedures using a small filtration unit that fits into the top of a microcentrifuge tube (pore size 0.4 μ m; e.g., March Biomedical). If the latter procedure is used, the authors find it improves recovery to reextract the plug of agarose in the filter with 0.5 ml TE/0.2% SDS solution either overnight at room temperature or for 2 hr at 37°C with constant gentle mixing on a rotator.

Perform sequencing gel electrophoresis

9. Resuspend the DNA pellet from step 8a, b, or c in 10 to 20 μ l of TE buffer, pH 8.0.

The exact volume will depend on how many radioactive counts are to be used in the experiment. The 10 to 20 μ l volume allows all radioactivity to be more easily resuspended by vortexing. Note that, typically, much of the precipitated, dried DNA is stuck to the inner wall of the microcentrifuge tube and care must be taken to resuspend all the radioactive material. This can be done by vigorous vortexing and/or by rubbing the droplet of TE buffer against the inner wall of the tube. The efficiency of resuspension in the formamide dye solution is checked with a benchtop Geiger counter. Virtually all of the counts should be resuspended.

10. Briefly microcentrifuge the resuspended DNA to collect the solution at the bottom of the tube and to bring down any insoluble material from the gel isolation. Pipet approximately equivalent numbers of counts from each sample (minimally 2000 to 5000 cpm) into fresh microcentrifuge tubes (ideally this should be \sim 1/4 of the total resuspended DNA, or \sim 5 μ l). Evaporate to dryness in a Speedvac evaporator.

If all of the solution must be used, attempt to pipet the solution without disturbing the pellet of insoluble material.

11. Resuspend the DNA in \sim 3 μ l of 100% formamide containing 1 mM EDTA and 0.005% tracking dyes, denature at 90°C for 2 to 5 min, place on ice, and load into the well of a sequencing gel (UNIT 7.6). Run the gel and expose to autoradiographic film or a phosphor imager plate (APPENDIX 3A).

FOOTPRINTING WITH HYDROXYL RADICALS

Chemical nucleases such as hydroxyl radicals can be used in place of enzymatic nucleases to probe histone-DNA interactions within nucleosomes. Hydroxyl radicals can be chemically generated in solution and have many advantages over enzymatic nucleases, such as their small size and ability to cleave the DNA backbone at every position without sequence selectivity. For these reasons, much more detailed and precise mapping information can be obtained by footprinting with hydroxyl radicals than with DNase I. However, hydroxyl radical footprinting requires solutions prepared without radical scavengers and chromatin complexes prepared with virtually nick-free DNAs (see Background Information).

Additional Materials (also see Basic Protocol 1)

Glycerol

1 M Tris·Cl, pH 8.0 (APPENDIX 2)

Iron/EDTA working solution (see recipe), freshly prepared

10 mM sodium ascorbate [prepare fresh from 1 M stock stored at -70°C (stable >1 year; e.g., Aldrich)]

0.12% H_2O_2 , prepared fresh by 1:250 dilution from 30% H_2O_2 (stock solution stable up to several years at 4°C if kept free of metal contamination)

ALTERNATE PROTOCOL

Chromatin Assembly and Analysis

21.4.5

1. Add glycerol to the sample to a concentration of $\leq 0.2\%$ (v/v) and 1 M Tris-Cl, pH 8.0 to a concentration of ≤ 10 mM.

Most salts and EDTA may be present at any concentration (Tullius, 1987). Any volume may be used; typically nucleosomes are prepared in $\frac{7}{10}$ of the final reaction volume.

2. Initiate the cutting reaction by placing a drop each of the iron/EDTA working solution ($\frac{1}{10}$ vol), 10 mM sodium ascorbate ($\frac{1}{10}$ vol), and the 0.12% H_2O_2 ($\frac{1}{10}$ vol) on the inner wall of a 1.5-ml microcentrifuge tube which already contains the nucleoprotein sample ($\frac{7}{10}$ vol). Allow the three added reagents to mix briefly. Immediately after the addition of the peroxide solution, using the pipet tip, add the reagents to the nucleoprotein solution, and mix thoroughly by pipetting.

For example, for digestion of a 35 μl solution of nucleosomes 5 μl of each of these reagents would be mixed together on the side of the tube and then rapidly mixed with the sample.

3. Incubate the free radical reaction 1 to 2 min at room temperature, then quench by adding glycerol to 5% (v/v) and transfer the entire reaction volume transferred to a nucleoprotein gel (see Basic Protocol, step 7c).

Alternatively, the reaction may be adjusted to 0.3 M sodium acetate and precipitated with ice-cold ethanol (see Basic Protocol). The presence of ethanol effectively quenches the radical cleavage reaction. If considerable time (minutes) is to elapse between the cleavage reaction and ethanol precipitation, the reaction may be quenched by the adjusting the solution to 50 mM thiourea (Tullius and Dombroski, 1985).

4. Analyze the DNA cleavage products (see Basic Protocol).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Iron/EDTA solution

Stock solution: Prepare a small amount (typically 1 ml) of 100 mM ferrous ammonium sulfate hexahydrate $[\text{Fe}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}]$; e.g., Aldrich] containing 200 mM EDTA in water and store up to 1 year frozen at -70°C .

Working solution: Just before use, dilute stock solution 1:99 with water for a final concentration of 1 mM Fe(II)/2 mM EDTA.

See Troubleshooting for guidelines on stability of this solution.

Nucleosome buffer

10 mM Tris-Cl, pH 8.0 (APPENDIX 2)

<0.1 mM EDTA

0 to 50 mM NaCl

This is an optimal buffer for DNase I digestion of chromatin. A small amount of EDTA protects the DNA from metal-mediated damage. The amount of NaCl will depend on the preparation method and application.

Tris-borate buffer, pH 8.3, 10 \times

108 g Tris base

55 g boric acid

H_2O to ~ 800 ml

Adjust pH to 8.3

Add H_2O to 1 liter

COMMENTARY

Background Information

Analysis of histone-DNA interactions within nucleosomes. The native chromatin complex within most eukaryotic nuclei is very difficult to study by biochemical means. However, as described elsewhere in this chapter, researchers have developed methods for preparation of smaller and experimentally tractable portions or forms of this complex. Often these methods involve reconstitution of the fundamental subunit of the chromatin complex, the nucleosome, from purified components (Wolffe, 1995). Once prepared, the integrity of these complexes can be ascertained by assays for protein composition, hydrodynamic behavior, DNA supercoiling, *trans*-acting factor binding, and a myriad of other biochemical and biophysical approaches (van Holde, 1989). In addition, an important and unique feature of chromatin is the distinct structure adopted by nucleosomal DNA. The DNA is wrapped into $\sim 1\frac{3}{4}$ tight 80 base pair circles on the surface of the histone octamer and contains distinct regions of helical periodicity that differ from the helical period of bare DNA (Hayes et al., 1990, 1991; Luger et al., 1997).

This unit details common but extremely powerful methods to assay DNA structure and accessibility within purified nucleosome complexes. Nucleosome-specific cleavage patterns obtained with DNase I or hydroxyl radicals typically comprise an alternating pattern of cleavage and protection with a frequency of 10 to 11 base pairs. This pattern, often referred to as a “nucleosome ladder,” reflects the helical structure of the DNA backbone, which alternately contacts the histone proteins or is oriented away from the surface of the histone octamer, toward the bulk solvent. Indeed, quantitative analysis of this pattern has been used to precisely measure the helical periodicity of DNA within the nucleosome (Hayes et al., 1990). In addition, the ladder not only indicates the region of DNA in contact with core histones but also the degree of rotational positioning of the DNA on the surface of the nucleosome(s).

DNase I digestion can reveal many details about the location and extent of histone-DNA interactions and can be used in complicated extracts containing nucleosomal complexes. However, the finer details of histone-DNA interactions and DNA structure within these complexes are best characterized by digestion of the DNA with the hydroxyl radical, an efficient chemical nuclease. Because of the small size

and lack of sequence specificity of this diffusible reactive species, very fine details of DNA conformation and protein-DNA contacts can be resolved. These features are reflected in the rates of DNA cleavage at individual nucleotide positions. Cleavage is effected by the (probable) abstraction of a hydrogen atom by a hydroxyl radical from a deoxyribose carbon center in the minor groove of the DNA. This leaves a carbon-centered radical which rapidly disintegrates to leave 5' and 3' monophosphoester termini on either side of a one nucleoside gap. Hydroxyl radicals can be efficiently produced in solution in virtually any salt conditions and in the presence of any soluble protein-DNA assembly via the one-electron reduction of hydrogen peroxide by an iron(II)-EDTA complex to produce $\cdot\text{OH}$ and OH^- :

The oxidation of Fe(II) is readily reversible by mild reducing agents such as sodium ascorbate, thus effectively recycling the iron complex until the peroxide is depleted. See Tullius et al. (1987) for a complete review of hydroxyl radical mediated DNA cleavage. Note that the hydroxyl radical cleavage procedure has the drawback that the complexes must be prepared in relatively pure form and buffer solutions must be free of radical scavengers. Common buffer components such as glycerol, Tris buffer in excess of 10 mM, and carbohydrates must be avoided.

Critical Parameters

Proper sample preparation is critical for the DNase I as well as the hydroxyl radical cleavage method. For DNase I digestions, samples of nucleosomes or other chromatin complexes should be prepared with DNA containing a unique radioactive end label or a label incorporated after the digestion. In addition, the complexes should be in appropriate buffers. A typical sample for digestion of reconstituted nucleosomes contains ~ 50 to 200 ng of cold “carrier” DNA and 2 to 10 ng (2000 to 20,000 cpm) of radioactively end-labeled specific DNA restriction fragment reconstituted with 25 to 100 ng of purified core histone proteins. Note that samples to be treated with DNase I prior to resolving nucleoprotein complexes on preparative 0.7% agarose gels should contain $>20,000$ cpm (see below).

1. DNase reactions generally require buffers lacking metal-chelation agents such as

EDTA or ATP. Alternatively, the concentration of these species should be <1 mM, since free Mg^{2+} is required for activity of the enzyme and must be added in excess of chelators.

2. For DNase I digestions, samples should contain less than ~ 100 to 150 mM ionic strength, since the activity of the enzyme decreases considerably in elevated salt solutions. For radioactively end labeled complexes, it is recommended that each sample contain at least $5,000$ cpm. Samples containing less radioactivity can be used, depending on the losses during sample preparation, but at least 1000 to 2000 cpm should be loaded in each lane of the sequencing gel.

3. For analysis of natural, random-sequence chromatin fragments, similar masses of material may be used. These are typically prepared by micrococcal nuclease digestion, and since this enzyme leaves $5'$ -OH, these complexes are directly end-labeled with T4 polynucleotide kinase and $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ (UNIT 3.10). In some cases it is advantageous to examine the DNase I digestion pattern of specific sequences within the natural chromatin by indirect end labeling via DNA blotting or LM-PCR approaches (UNIT 21.1).

Troubleshooting

This section reviews issues concerning cleavage evaluation, common problems with the hydroxyl radical cleavage reaction, and ways to optimize the cleavage. However, comments concerning background (points 2 and 3, below) and gel effects (point 6) are also relevant to experiments with DNase I.

1. *Evaluation of hydroxyl radical cleavage.* Since the hydroxyl radical yields an even pattern of cleavage at every nucleotide position, the intensity of individual bands on the gel is somewhat less than that obtained with DNase I. Thus, common problems are the lack of observable cleavage on the gel and determining if sufficient cleavage has occurred. The lack of an apparent cleavage pattern on the gel may be due to underexposure of the gel. A simple method to ensure sufficient exposure is to load a mock-treated sample containing the same number of counts in an adjacent lane. The gel is exposed to the point that the “background” within the control lane is barely visible and compared to the signal in the experimental lane.

2. *Determination of background.* The hydroxyl radical cleavage pattern within DNAs containing a high amount of inherent background cleavage may be difficult to see. The amount of background cleavage may be judged

by running a mock-treated sample as described above and directly evaluating the autoradiogram. Alternatively, after a brief exposure, the full-length band may be cut out of the sequencing gel and the total counts within this band determined by scintillation counting. The total counts within this band should be $\geq 95\%$ of the counts loaded in the lane.

3. *Background remediation.* High background may be due to several problems. Note that labeled DNA should be stored in the presence of EDTA, if possible, and at less than $\sim 10,000$ cpm per μl to avoid autoradiolysis. In addition, DNA subjected to treatment with $\text{Fe(II)}\text{-EDTA}$ should never be stored as a precipitate immediately after the digestion; the DNA should be processed at least through the rinse step. Another source of background comes from the use of partially hydrolyzed formamide or excessive heating before loading the sequencing gel. DNA should not be heated in formamide at temperatures greater than 95°C , and the formamide should be stored frozen at -20°C between uses. These problems are usually manifested as elevated background cleavage at purine residues within the DNA.

4. *Buffer components.* A lack of cleavage may be due to the presence of radioprotectants within the nucleosome solutions. Buffer components such as glycerol in excess of $\sim 0.2\%$, Tris in excess of 10 mM, and carbohydrates such as mannitol or dextrose should be avoided.

5. *Reagents.* The efficiency of radical production is greatly reduced in acidic solutions. Thus, it is important to employ sodium ascorbate. Prepare sodium ascorbate solutions from dry crystals that do not appear to have become moist or reddish in color. The authors have found that 1 M solutions of this reagent are stable for >1 year when stored at -70°C and the 10 mM working stocks are stable for >3 months when stored frozen. Likewise the working stocks of the Fe(II)EDTA complex are stable if kept frozen for extended periods. Note that the appearance of a reddish-brown color in these solutions indicates significant oxidation of the iron and formation of insoluble μ -hydroxy iron complexes, and that the stock should be discarded. Although solutions of 30% H_2O_2 are stable for several years if stored properly at 4°C , contamination of this solution with transition metals can cause a loss of peroxide. In addition, the diluted working stock solution of hydrogen peroxide is relatively unstable on the bench top and should be discarded immediately after the reaction.

6. *Band smearing*. “Smearly” bands may be due to several problems. First, a common mistake is to use too much carrier DNA in the preparation of samples. For example, an excess of tRNA added as carrier will cause a smear in the region 120 to 150 bp on the sequencing gel. Most nucleosome samples have sufficient DNA for quantitative precipitation. Another source of “fuzziness” is loading too much of the final sample into the well. This sample typically contains relatively insoluble contaminants from the agarose gel. If these are loaded into the well, the heated sample has a very viscous character and yields a poorly resolved lane. If necessary, remove 20 μ l of the 25 total resuspension in TE after a brief microcentrifuge spin of this material to sediment insoluble contaminants.

Anticipated Results

If the starting material consists of well positioned nucleosomes, the DNase cleavage should yield a pattern with maximal cleavages every 10 bp and minimal cleavages in between. This pattern will not be completely regular because DNase I shows some sequence specificity in its cleavage activity. Hydroxy radical cleavage will produce a much more regular cleavage pattern, with enhanced cleavages every 10 bp, and a gradual decrease, then increase, in between maximal cleavages. If nucleosomes are not well positioned (i.e., if the preparation contains a mixture of different positions), then no 10-bp periodicity will be observed.

Time Considerations

Performing the cleavage reactions requires <1 hr total if all starting materials (including labeled nucleosomes) are available. Preparation of the sample for electrophoresis requires several hours, and electrophoresis itself can be accomplished in several hours. The entire procedure can be completed in a full day. 1- to 2-day exposures should be sufficient to observe the signal.

Isolation of Histones and Nucleosome Cores from Mammalian Cells

UNIT 21.5

In vitro analysis of DNA in chromatin is often important for understanding mechanisms of regulation of transcription and other processes that occur on DNA. The basic unit of chromatin is the nucleosome core, containing two copies each of the core histones H2A, H2B, H3, and H4 to form a histone octamer that wraps ~145 base pairs of DNA in a left-handed superhelix. In vivo, chromatin is associated with linker histones (such as H1), which facilitate the ordered packing of nucleosomes. This linker histone-containing particle is properly termed the nucleosome (or chromatosome), while the linker histone-free particle is the nucleosome core.

Long arrays of nucleosome cores (poly- or oligonucleosome cores) as well as pure populations of mono- and dinucleosome cores can be purified. These purified nucleosomes are useful for a variety of applications; for example, they can act as histone donors for the assembly of nucleosomes on defined-sequence DNA. The core histones can be purified away from chromosomal DNA and from linker histones, as well. These are useful in a variety of procedures for in vitro chromatin assembly. The method here does not denature the histones (as does the acid extraction protocol in UNIT 21.2), and may yield histones that are more active for in vitro assemblies.

Pure polynucleosome cores and histones are useful in the in vitro assembly of chromatin on defined-sequence DNA. These can be readily isolated from mammalian tissue culture cells. In Basic Protocol 1, nuclei are isolated and purified. In Basic Protocol 2, polynucleosomes lacking linker histones are isolated from these nuclei. In Basic Protocol 3, pure populations of mono- and dinucleosome cores are isolated from oligonucleosome fractions from Basic Protocol 2. In Basic Protocol 4, core histones are isolated from purified nuclei.

The large genome size of mammals makes mammalian tissue culture cells abundant sources for chromatin and histones. The core histones are highly evolutionarily conserved, and human histones are frequently used in assembly systems derived from *Drosophila* and for in vitro transcription systems from eukaryotes as simple as yeast. The assumption is that, at the level of simple hypo-acetylated nucleosome cores, histone source matters little. Thus far, this assumption appears to be warranted. However, when histone modifications, linker histones, and other nonhistone chromosomal proteins begin to be considered, the organismal, tissue, and cell-type source become increasingly important.

NOTE: Unless otherwise indicated, keep all solutions and materials on ice or at 4°C.

PREPARATION OF A WASHED NUCLEAR PELLET

The isolation of nucleosomes and free histones requires clean nuclei as starting material. In this protocol, nuclei are released from cultured cells by physical shear forces (homogenization) and nonionic detergent (NP-40; Côté et al., 1995). Several washes with a buffer containing detergent are then used to remove membranes and yield a pellet containing relatively clean nuclei. Subsequent extraction with 0.3 M KCl removes most loosely bound proteins from chromatin. This yields a nuclear pellet and what is, effectively, a nuclear extract (from which several transcription factors can be isolated). However, the NP-40 washes may make the extract less active than nuclear extracts prepared by other means. If both nuclear extract and chromatin are desired, the nuclear extract should be

Supplement 50

prepared as in *UNIT 12.1*, and the “spent” nuclear pellet from this procedure can be used to prepare chromatin (Schnitzler et al., 1998).

Materials

Mammalian tissue cell culture (e.g., HeLa cells)

PBS (*APPENDIX 2*)

Lysis buffer (see recipe)

Buffer B (see recipe)

2 M NaCl

Buffer B/0.6 M KCl/10% (v/v) glycerol

Dounce homogenizer with type B pestle

Light microscope

Additional reagents and equipment for mammalian cell culture (*APPENDIX 3F*) and quantitation of DNA (*APPENDIX 3D*)

1. Grow and harvest 3 liters of mammalian tissue culture cells (e.g., HeLa) at 1×10^6 cells/ml and wash twice in 1 liter PBS.

See APPENDIX 3F for counting cells.

2. Resuspend pellet in 20 pellet vol (~40 ml) lysis buffer, transfer to a Dounce homogenizer, and lyse cells with ~15 strokes of a type B pestle. Monitor lysis by light microscopy.

The cells should be clearly lysed when viewed by light microscopy. The NP-40 in the buffer solubilizes membranes, resulting in a clean (white or light tan) pellet.

Alternatively, the nuclear pellets remaining after nuclear extract preparation (UNIT 12.1) can be resuspended by homogenization in the same buffer. If this is done, wash as described in steps 2 to 4, and then proceed to purification of H1-depleted oligonucleosomes (see Basic Protocol 2).

3. Centrifuge 15 min at $3000 \times g$, 4°C .
4. Repeat resuspension and pelleting twice with lysis buffer and once with buffer B. Just before the final pelleting, estimate the yield of DNA in the nuclei by diluting 10- to 30-fold into 2 M NaCl and measuring A_{260} (*APPENDIX 3D*).

A few strokes with the type B pestle can be used to help resuspend the pellet.

5. Resuspend nuclei in 2 pellet vol buffer B and measure the total volume of the suspension.
6. While gently stirring, add 1 total vol of buffer B/0.6 M KCl/10% glycerol in a dropwise fashion. Continue gentle stirring for 10 min at 4°C . Homogenize gently, if necessary.
7. Pellet nuclei 30 min at $17,500 \times g$, 4°C .

Nuclear pellets can be frozen in liquid nitrogen or dry ice and kept for more than a year at -80°C .

SOLUBILIZATION AND PURIFICATION OF HISTONE H1-DEPLETED OLIGONUCLEOSOMES

BASIC
PROTOCOL 2

Oligonucleosome cores lacking histone H1 are commonly used to assemble labeled, defined-sequence mononucleosomes by the method of octamer transfer at high salt, amongst other applications. The NP-40-washed nuclear pellet is washed at 0.4 M NaCl to remove nonhistone proteins. The pellet is then solubilized in 0.65 M NaCl. At this salt concentration, the linker histones are released from the nuclei, resulting in chromatin decompaction. The resultant nuclei are much less resistant to shear forces, and vigorous homogenization fragments the chromatin to a size that allows their separation from other nuclear fragments. After dialysis to reduce the salt concentration, digestion with the endonuclease micrococcal nuclease releases even smaller fragments. These fragments are size-separated by either gradient centrifugation or gel filtration, and different size distributions are pooled and stored frozen. Size separation is done at salt concentrations (0.6 M NaCl) at which linker histones do not bind, allowing their efficient separation from oligonucleosome cores (Côté et al., 1995; Schnitzler et al., 1998).

Materials

Washed nuclear pellet (see Basic Protocol 1)
MSB (see recipe)
HSB (see recipe)
2 M NaCl
LSB (see recipe)
0.1 M CaCl₂
50 U/μl micrococcal nuclease (see recipe)
0.5 M EGTA, pH 8.0
HSB without sucrose
HSB/glycerol: HSB containing 10% and 40% (v/v) glycerol instead of sucrose
0.5% (w/v) SDS
0.5 mg/ml proteinase K
Dialysis buffer (see recipe)

Dounce homogenizer with type B pestle
6 to 8 kDa MWCO dialysis membrane
~1.6 × 58-cm Sepharose CL-6B column (Amersham Pharmacia Biotech; for gel filtration) and accessories
Refrigerated ultracentrifuge with appropriate rotor and tubes, e.g.,
Beckman SW55 rotor with polyallomer or ultraclear tubes (for gel filtration)
Beckman SW28 rotor with 1 × 3.5-in. (2.5 × 8.9-cm) polyallomer tubes (for centrifugation)
Gradient maker (for centrifugation)
21-G needle (for centrifugation)
Tubing (for centrifugation): e.g., 21-G needle infusion set with 12-in. (30.5-cm) tubing (Abbot Laboratories)
50°C water bath
6 to 8 kDa MWCO dialysis bag

Additional reagents and equipment for quantitation of DNA (APPENDIX 3D), pouring gradients (UNIT 10.10), agarose gel electrophoresis (UNIT 2.5A), and SDS-PAGE (UNIT 10.2A)

Purify oligonucleosome cores

1. Resuspend ~2 ml nuclear pellet with 40 ml MSB. Centrifuge 10 min at 10,000 × g, 4°C (e.g., 9200 rpm in Beckman JA-20 rotor).

Dounce homogenization (a few strokes with type B pestle) can be used to resuspend nuclei.

Chromatin
Assembly and
Analysis

21.5.3

2. Resuspend nuclei in 4 pellet vol of HSB and homogenize in a Dounce homogenizer with 40 to 50 strokes of a type B pestle to release oligonucleosome fragments.
3. Pellet nuclei 20 min at $10,000 \times g$, 4°C , and collect the supernatant. Dilute a sample of this supernatant into 2 M NaCl and measure A_{260} (APPENDIX 3D) to calculate the percent of chromosomal DNA that has been solubilized from the nuclei.

Typically ~3 to 4 mg of oligonucleosome cores can be expected at this point (~50% of the DNA in the nuclei).

4. Dialyze supernatant overnight at 4°C against 4 liters LSB with 6 to 8 kDa MWCO dialysis membrane. When collecting the dialysate, mix the sample (pressing on the sides of the dialysis bag) in order to collect those oligonucleosomes that precipitated during dialysis.
5. Add 0.1 M CaCl_2 to 3 mM (final) and warm the sample for 5 min at 37°C .
6. Add 50 U/ μl micrococcal nuclease to 10 U/ml (final) and incubate 5 min at 37°C .

The solution should become clearer, because digestion will resolubilize precipitated oligonucleosomes.
7. Stop digestion with 0.1 vol of 0.5 M EGTA and chill on ice.
8. While gently vortexing, add 2 M NaCl dropwise to a final concentration of 0.6 M.

For separation by gel filtration:

- 9a. Pour an $\sim 1.6 \times 58\text{-cm}$ Sepharose CL-6B column and equilibrate with several column volumes of HSB without sucrose at 12 to 24 ml/hr.
- 10a. Centrifuge polynucleosome fragments 30 min at $150,000 \times g$, 4°C , (e.g., 40,000 rpm in a Beckman SW55 rotor) to remove insoluble material.
- 11a. Load supernatant onto the column, run the column at 12 ml/hr, and collect 2-ml fractions.

If the load exceeds 10% of the column volume, rerun the column with additional material or use a larger column with proportional dimensions.

For separation by centrifugation:

- 9b. Pour two (or more) 34-ml linear gradients (UNIT 10.10) in $1 \times 3.5\text{-in.}$ polyallomer centrifuge tubes using HSB/glycerol, with 10% at the top to 40% at the bottom.

For this procedure, perform all steps and maintain all buffers at 4°C .

- 10b. Carefully layer 2 ml quenched digestion reaction on top of each gradient and centrifuge 16 hr at $100,000 \times g$, 4°C (e.g., 27,500 rpm in a Beckman SW28 rotor).

A 4-ml load onto a 32-ml gradient also gives good resolution with higher final concentration.

- 11b. Harvest the gradients by piercing the bottom edge (where it bends upward) with a 21-G needle attached to outlet tubing. Hold the needle at an $\sim 30^{\circ}$ angle, with the beveled edge up, to pierce the tube, and then lodge the needle tip near the very bottom of the tube (without puncturing the opposite end of the tube). To start the flow, cover the top with Parafilm and apply gentle pressure. Collect 1- to 1.5-ml fractions.

Analyze and store oligonucleosome cores

12. Determine DNA concentration of fractions by diluting an aliquot 10- to 40-fold into 2 M NaCl and measuring absorbance at 260 nm.

13. Measure DNA lengths of oligonucleosomes by treating aliquots of fractions (≥ 0.5 μg) with 0.5% SDS and 0.5 mg/ml proteinase K for 1 hr at 50°C, and separating by native 1.5% agarose TBE gel electrophoresis (UNIT 2.5A). Stain with 0.1 $\mu\text{g}/\text{ml}$ ethidium bromide.

Ethidium bromide staining should show a smear of overdigested DNA, a band of DNA at ~150 bp (mononucleosomes), and larger bands equal to ~150 bp plus multiples of ~200 bp (di-, tri-, tetranucleosomes and so on). Higher multiples will be nearer the column void or the bottom of the gradient.

CAUTION: Ethidium bromide is a mutagen and should be handled appropriately.

14. Analyze 5 to 20 μl of selected fractions for the presence of all four core histones (H2A, H2B, H3, and H4) and for the absence of H1 on a 15% SDS-PAGE gel (UNIT 10.2A). Stain the gel with Coomassie brilliant blue.

Molecular weights of core histones are 14.1 kDa (H2A), 13.8 kDa (H2B), 15.3 kDa (H3), and 11.3 kDa (H4). H1 (21.5 kDa) should separate from most of the DNA and run at the top of the gradient or at the end of the included volume on the column.

15. Pool fractions that contain mono- and dinucleosomes, short oligonucleosomes (3 to 6 units), and long oligonucleosomes (>6 units) total three pooled fractions). Be careful to avoid fractions where the DNA is <150 bp (overdigested) or that contain H1.

16. If DNA concentration is low (<0.5 mg/ml), concentrate by putting sample in a 6 to 8 kDa MWCO dialysis bag and surrounding with solid sucrose. Once the volume has decreased 2 to 4 fold, rinse off sucrose with water and reclip the dialysis bag to the new volume.

Adjusting the clip prevents samples from swelling back to the original volume in the next step.

17. If step 16 was bypassed, place samples in a 6 to 8 kDa MWCO dialysis bag and dialyze into 100 vol dialysis buffer at 4°C for >4 hr.

Alternatively, or in addition, samples can be concentrated up to 1 mg/ml using Centriprep-10 concentrators (Amicon).

18. Divide into aliquots, freeze on dry ice or in liquid nitrogen, and store for up to 2 years at -80°C .

The nucleosomes are also stable for many weeks at 4°C.

NOTE: When polynucleosome stocks are thawed, some precipitation may be observed. This will not interfere with the use of the polynucleosomes in salt-dilution assembly procedures, as long as they are well mixed before use to ensure proper concentration. Also, material precipitated during freezing appears to come back into solution when the stock is diluted. The addition of 20% (v/v) glycerol and rapid freezing in liquid nitrogen may help to reduce this effect.

PURIFICATION OF MONO- AND DINUCLEOSOMES

The previous protocol rarely yields pure mono- and dinucleosomes, either because fractions don't separate well or because H1 may contaminate these fractions. By redigesting pure oligonucleosomes, however, mono- and dinucleosomes with little cross-contamination can be recovered (Schnitzler et al., 1998).

Materials

Oligonucleosomes: medium or large polynucleosome fractions (see Basic Protocol 2)
100 mM CaCl₂
1 M MgCl₂
50 U/μl micrococcal nuclease (see recipe)
0.5 M EDTA
10% and 30% (v/v) glycerol gradient buffer (see recipe)
30°C water bath
Ultracentrifuge with rotor (e.g., Beckman SW55) and 0.5 × 2.5-in. (1.3 × 6.4-cm) polyallomer tubes
Gradient maker
Additional reagents and equipment for harvesting, analyzing, and concentrating fractions (see Basic Protocol 2) and for nondenaturing acrylamide electrophoresis (*UNIT 10.2B*)

1. Thaw ~1 mg oligonucleosomes (ideally ~1 to 2 mg/ml) and warm to 30°C.
2. Add 100 mM CaCl₂ to 1.5 mM final and 1 M MgCl₂ to 3.5 mM final.
3. Add 50 U/μl micrococcal nuclease to 0.1 U/μg polynucleosomes and allow digestion to proceed for 10 min at 30°C.
4. Stop the reaction by adding 0.5 M EDTA to 15 mM.
5. Pellet insoluble material by microcentrifuging 30 sec at ~10,000 × g, 4°C.
6. Pour a 4.7-ml linear gradient in a 0.5 × 2.5-in. polyallomer ultracentrifuge tube using 10% glycerol gradient buffer at the top and 30% at the bottom.
7. Layer 0.5 ml digestion reaction onto the gradient and centrifuge 18 hr at 100,000 × g, 4°C (e.g., 35,000 rpm in SW55 rotor).
8. Harvest the gradient as described (see Basic Protocol 2, step 11b), taking about twenty four 5-drop fractions.
9. Analyze fractions by agarose gel electrophoresis as described (see Basic Protocol 2, step 13).
10. Pool clean mono- and dinucleosome peaks and concentrate, if desired (see Basic Protocol 2, steps 16 and 17, but perform final dialysis in 10% glycerol gradient buffer; see recipe). Store at 4°C (>1 month) or freeze in liquid nitrogen or on dry ice and store up to 2 years at -80°C.

The integrity of mono- and dinucleosome cores can be checked by nondenaturing electrophoresis on either 5% acrylamide (UNIT 10.2B) or 1.2% agarose gels run at 4°C in 0.5-fold TBE electrophoresis buffer. Intact mononucleosomes will run much slower than the DNA they contain (~700 bp rather than 150 bp for samples treated with SDS and proteinase K).

PURIFICATION OF CORE HISTONES BY HYDROXYLAPATITE CHROMATOGRAPHY

BASIC PROTOCOL 4

A second common method for assembling mononucleosomes or polynucleosomes from defined-sequence, labeled DNA relies on the direct assembly of nucleosomes from free histones and DNA as the salt concentration is decreased from 1 or 2 M. For this and other applications, the four core histones can be readily purified by binding chromatin fragments to hydroxylapatite resin (to which DNA binds very strongly), washing away histone H1 with 0.6 M NaCl, and eluting the histones from the resin-bound DNA at 2.5 M NaCl (Côté et al., 1995; Workman et al., 1991).

Materials

Nuclear pellet (see Basic Protocol 1)

HAP buffer (see recipe), with and without 2.5 M NaCl

BioGel HTP powder (Bio-Rad), with adsorption capacity 0.6 mg DNA per g dry powder

Bio-Rad Protein Assay (optional)

2 × 15-cm column and accessories

Centriprep-10 concentrators (Amicon; optional)

Additional reagents and equipment to determining protein concentration (UNIT 10.1A) and SDS-PAGE (UNIT 10.2A)

1. Resuspend ~2 ml nuclear pellet containing ~6 mg DNA in 25 ml HAP buffer and stir gently for 10 min at 4°C.

A few strokes with a dounce homogenizer and a type B pestle can be used to aid resuspension. To avoid proteolysis, 1 μM pepstatin A and 1 μM leupeptin can be added to HAP buffer.

2. While stirring, add 10 g dry BioGel HTP powder.
3. Add just enough HAP buffer to make a slurry. Pour this into a 2 × 15-cm column and collect the eluant.
4. Wash resin with 10 vol HAP buffer (~300 ml at 30 ml/hr).

The eluant from step 3 and the first 2/3 column volume of wash contain H1, which can be further purified as described (Côté et al., 1995) in order to reconstitute chromatosomes.

5. Elute the core histones with HAP buffer containing 2.5 M NaCl, collecting 8-ml fractions.
6. Determine protein concentration of fractions by A_{230} or A_{280} readings or by protein assay, and pool the peak fractions.

Because histones are small positively charged proteins, many methods for determining protein concentration give differing results. Since nucleosome assembly protocols require careful determination of the molar ratio of histones to DNA, it is essential to use the same method for determining histone concentration as used in the assembly protocol. One reasonably good method is to measure absorbance at 230 nm. The extinction coefficient (calculated for chicken erythrocyte histones, but likely to be similar for mammalian histones) is 4.3 A_{230} units/mg histones/ml. Alternatively, a Bio-Rad or other protein assay (UNIT 10.1A) can be performed with BSA as a standard. The Bio-Rad assay tends to yield concentration estimates that are ~1.6-fold higher than the A_{230} method.

7. Measure the salt concentration of pooled fractions by conductivity readings.

The salt concentration should be ~2 M.

Chromatin Assembly and Analysis

21.5.7

8. Measure the purity of the core histones by SDS-PAGE as described (see Basic Protocol 2, step 14).
9. If necessary, concentrate the core histones to between 2 and 10 mg/ml using Centriprep-10 concentrators.
10. Divide into aliquots, freeze on dry ice, and store up to 4 years at -80°C .

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Buffer B

20 mM HEPES, pH 7.5
3 mM MgCl_2
0.2 mM EGTA
Store up to several weeks at 4°C
Immediately before use add:
3 mM 2-mercaptoethanol
0.4 mM PMSF (see recipe)
1 μM pepstatin A (see recipe)
1 μM leupeptin (see recipe)

Dialysis buffer

20 mM HEPES, pH 7.5
1 mM EDTA
Store up to several weeks at 4°C
Immediately before use add:
1 mM 2-mercaptoethanol
0.5 mM PMSF (see recipe)

Glycerol gradient buffer, 10% and 30% (v/v)

20 mM HEPES, pH 7.9
1 mM EDTA
30 mM KCl
0.1% Nonidet P-40 (NP-40)
10% or 30% (v/v) glycerol
Store up to several weeks at 4°C

This buffer can be adjusted as desired. Virtually any solution with >0.2 mM EDTA, no divalent cations, and salt from 0 to 600 mM will work well as the basis for a glycerol gradient buffer.

High-salt buffer (HSB)

20 mM HEPES, pH 7.5
0.65 M NaCl
1 mM EDTA
0.34 M sucrose
Store up to several weeks at 4°C
Immediately before use add:
1 mM 2-mercaptoethanol
0.5 mM PMSF (see recipe)

Hydroxylapatite (HAP) buffer

50 mM sodium phosphate, pH 6.8
0.6 M NaCl
Store up to several weeks at 4°C
Immediately before use add:
1 mM 2-mercaptoethanol
0.5 mM PMSF (see recipe)

Leupeptin

Prepare a 1 mM aqueous stock solution and store up to 1 year at -20°C.

Low-salt buffer (LSB)

20 mM HEPES, pH 7.5
0.1 M NaCl
1 mM EDTA
Store up to several weeks at 4°C
Immediately before use add:
1 mM 2-mercaptoethanol
0.5 mM PMSF (see recipe)

Lysis buffer

20 mM HEPES, pH 7.5
0.25 M sucrose
3 mM MgCl₂
0.5% (v/v) Nonidet P-40 (NP-40)
Store up to several weeks at 4°C
Immediately before use add:
3 mM 2-mercaptoethanol
0.4 mM PMSF (see recipe)
1 μM pepstatin A (see recipe)
1 μM leupeptin (see recipe)

Medium-salt buffer (MSB)

20 mM HEPES, pH 7.5
0.4 M NaCl
1 mM EDTA
5% (v/v) glycerol
Store up to several weeks at 4°C
Immediately before use add:
1 mM 2-mercaptoethanol
0.5 mM PMSF (see recipe)
1 μM pepstatin A (see recipe)
1 μM leupeptin (see recipe)

Micrococcal nuclease, 50 U/μl

50 U/μl micrococcal nuclease (from solid; Sigma)
50% (v/v) glycerol
50 mM Tris·Cl, pH 8 (APPENDIX 2)
0.05 mM CaCl₂
Store at -20°C (can be stable for >1 year)

Note that different suppliers define units of micrococcal nuclease differently. If Sigma enzyme is not used, be sure that the unit definition is the same, or determine the proper conversion ratio to Sigma units.

Pepstatin A

Prepare a 1 mM stock solution in methanol and store up to 2 years at -20°C .

Phenylmethylsulfonyl fluoride (PMSF)

Prepare a 100 mM stock solution in isopropanol and store up to 4 years at room temperature.

COMMENTARY

Background Information

Use of polynucleosomes and histones in chromatin assembly

A principle use of oligonucleosome cores and core histones is the *in vitro* assembly of nucleosome cores on defined-sequence DNAs. Several templates exist that allow the formation of radiolabeled mononucleosomes. Many of these contain “rotational phasing sequences,” which are essentially DNA sequences that cause the DNA to bend, promoting wrapping around the histone core with one face outwards (a single rotational phase). Frequently used mononucleosome templates are those based on 5S rDNA sequences and those with artificial phasing sequences (e.g., Kwon et al., 1994; Hayes and Lee, 1997; Luger et al., 1997; Schnitzler et al., 1998). Mononucleosomes can be formed by incubating the template DNA with excess polynucleosomes (octamer transfer method; Côté et al., 1995) or with roughly equimolar free histones at 1 or 2 M NaCl (salt assembly; Imbalzano et al., 1996). At this high salt concentration the H2A/H2B dimers dissociate and the H3/H4 tetramers readily transfer from donor polynucleosomes, or begin to assemble *de novo* onto the template DNA. As the salt concentration is reduced, either by dilution or dialysis, the H2A/H2B dimers are added and the complete nucleosome is formed. Polynucleosomes can be formed by salt assembly on any linear DNA template, although the resulting nucleosomes assume somewhat random positions (Stein, 1989). Templates that are made up of a repeated array of 5S rDNA sequences, however, result in arrays of reasonably well-positioned nucleosomes (Carruthers et al., 1999).

Although salt assembly methods are the simplest assembly systems, containing only DNA and the core histones, other systems for chromatin assembly exist. Heat-treated extracts of *Xenopus* oocytes allow assembly of poorly positioned nucleosomes at lower salt concentrations (Workman et al., 1991). Many cellular factors that facilitate such random deposition

are known and can be purified from a variety of sources (Ito et al., 1996, and references therein). Unheated *Xenopus* oocyte and *Drosophila* egg extracts contain ATP-dependent factors that result in uniform spacing of nucleosomes assembled onto templates (Sessa and Ruberti, 1990; Becker et al., 1994). The factors responsible for some of these activities have been identified, and defined *in vitro* reconstitution systems for spaced nucleosomes using pure proteins are now possible (Ito et al., 1997; Varga-Weisz et al., 1997).

Variations for histone and polynucleosome isolation

Polynucleosomes that contain linker histones can be isolated by a protocol that uses micrococcal nuclease to release chromatin fragments from nuclei (Kornberg et al., 1989). Partially purified linker histone H1 is a by-product of the chromatography step in Basic Protocol 4. This can be further purified and used to reconstitute chromatosomes (Côté et al., 1995). Treatment of cultured cells with the histone deacetylase inhibitor butyrate results in hyperacetylation of histone tails (Vettese-Dadey et al., 1995). The acetylation state of the histones can be assayed by Triton/acid/urea gels (UNIT 21.2). Nuclei from these cells can be subjected to the above protocols to yield hyperacetylated oligonucleosome cores or histones. A stepwise elution of histone from hydroxylapatite allows H2A and H2B to be separated from H3 and H4 (Simon and Felsenfeld, 1979). The N- and C-terminal tails of the histones in oligonucleosome cores can be cleaved off by treatment with trypsin. These proteolyzed arrays can be subjected to hydroxylapatite chromatography to yield tailless histones, and both the arrays and histones can be used in nucleosome assembly reactions (Guyon et al., 1999).

Critical Parameters

As with any protein isolation, everything should be kept on ice or at 4°C except where noted. Small amounts of endogenous nucleases

and residual micrococcal nuclease may be present in poly- and mononucleosome samples. To avoid slow hydrolysis during storage, samples should always be stored in buffers containing EDTA, which chelates the divalent cations required for endonuclease action.

Reducing agents (2-mercaptoethanol and DTT) and protease inhibitors (PMSF, pepstatin A, and leupeptin) used in these experiments should all be added to the buffers just before use. Other buffer components can be stored at 4°C for several weeks.

Troubleshooting

It is important to check the integrity and purity of histones in oligonucleosome and histone preparations. Each of the four core histones should stain roughly evenly using Coomassie stain. If one stains much more weakly (often H2A), protease inhibitors should be added at steps where it is an option.

Anticipated Results

The nuclear pellet from 3 liters of HeLa cells should yield 4 to 10 mg of DNA. Of this, ~1 to 2 mg of medium polynucleosomes (Basic Protocol 2) or ~3 to 8 mg of core histones (Basic Protocol 4) should be obtained. The yield of mononucleosomes (Basic Protocol 3) is generally ~20% to 30% of the mass of input polynucleosomes.

Time Considerations

Basic Protocol 1 should take ~3 hours (less if starting with spent nuclear pellet). Basic Protocol 2 will take ≥2 days to complete. The dialysis step can be reduced to ~2 to 3 hr by dialyzing into LSB with only 50 mM salt, taking samples from within the bag and monitoring salt concentration with a conductivity meter. Oligonucleosomes can be collected when the salt concentration is 100 mM. The column washes in the gel filtration method are often conveniently done overnight (washing more slowly or with a greater volume is acceptable). Depending on the experimental needs, the lengthy concentration steps may not be necessary. Be aware that nucleosomes below ~10 ng/μl may not be stable without 0.1% NP-40 or >50 μg/ml BSA as carriers.

Basic Protocol 3 takes a few hours to set up, plus an overnight centrifugation and an hour to collect fractions. Basic Protocol 4 calls for ~10 hr wash time at 0.6 M NaCl to remove all traces of H1. The flow rate during this wash can be increased (up to 60 ml/hr) without creating excessive H1 contamination.

Assembly of Nucleosomal Templates by Salt Dialysis

UNIT 21.6

The assembly of nucleosomal templates through salt dialysis has been a useful tool to generate, conveniently and in a relatively short period of time, large quantities of homogeneous model chromatin complexes containing defined DNA sequences. The first protocol of this unit (see Basic Protocol 1) describes the assembly of mononucleosomes and nucleosomal arrays through step salt dialysis. The assembly through step salt dialysis allows rapid reconstitution of mononucleosomes and nucleosomal arrays by lowering the salt concentration of the original reconstitute by transferring it through a series of buffers. Gradient dialysis is used to reconstitute large amounts of mononucleosomes or nucleosomal arrays. The second protocol (see Basic Protocol 2) describes assembly of mononucleosomes through gradient salt dialysis; an additional basic protocol (see Basic Protocol 3) describes use of gradient dialysis to reconstitute nucleosomal arrays. Gradient dialysis is useful when step dialysis is not an option. In addition to the basic protocols, the support protocols describe methods to isolate the components of the assembly: the histones and the DNA fragment. The purification of histones from native chromatin sources is described in *UNIT 21.5* of this section. Purification of recombinant histones is described in Support Protocol 1. The protocol for preparation of the DNA template for assembly is provided in Support Protocol 2. Support Protocols 5 to 7 describe techniques to analyze the assembled nucleosomal template using gel mobility shift assays.

CAUTION: Radioactive, biological, and chemical substances require special handling; see *APPENDIX 1E* for guidelines.

STRATEGIC PLANNING

A critical aspect of nucleosome assembly is the integrity of the reconstituted nucleosomal template. Since the primary goal in nucleosome assembly by salt dialysis is to produce structurally homogeneous samples, assembly of an optimal nucleosomal template is dependent on the stoichiometry of the histones and DNA and also the positioning of the histone octamer on the DNA template. The total histone mass and DNA mass should be approximately equal to each other to generate a homogeneous population of nucleosomal template. If the histones are not sufficient, inefficient octamer assembly is the result, and, conversely, nonspecific binding and aggregation occur when the amount of DNA is not enough. The ratio between histones and DNA must be empirically adjusted by varying the ratio to yield maximum octamer-DNA complexes. The positioning of the histone octamer is also important because many experiments, such as nuclease mapping, require that the octamer adopt a single position relative to the DNA fragment. This can be accomplished by using DNA templates that carry a strong positioning sequence such as fragments that contain the *Xenopus borealis* 5S rRNA gene which has been shown to strongly direct unique positioning (see Commentary).

ASSEMBLY OF NUCLEOSOMAL TEMPLATES BY STEP SALT DIALYSIS

The method described here for the reconstitution of nucleosomes allows for large quantities of nearly homogeneous core particles in 10 hr (Hayes and Lee, 1997). Virtually any piece of DNA 147 bp or longer can be used. However to obtain nucleosomes with only one translational position, the DNA sequence should contain nucleosome positioning sequences such as that from the *Xenopus borealis* 5S rRNA gene as previously mentioned (Hayes et al., 1990).

**BASIC
PROTOCOL 1**

**Chromatin
Assembly and
Analysis**

21.6.1

Nucleosomal arrays can also be assembled by step dialysis as described in this protocol. The difference is that the relative mass ratio between histone:DNA is 1.2, which is slightly higher than for mononucleosomes. Optimal conditions should be determined empirically. The authors find that gradient dialysis (see Basic Protocol 3) gives better assembled arrays than step dialysis.

Materials

- ~1 to 2 mg/ml sonicated calf thymus DNA (~0.5 to 1 kb; Sigma)
- Radioactively labeled DNA (see Support Protocol 2)
- Purified native core histone protein fractions (Support Protocol 1)
- 5 M NaCl (APPENDIX 2)
- TE buffer, pH 8.0 (APPENDIX 2)
- TE buffer, pH 8.0 (APPENDIX 2), containing 1.2, 1.0, 0.8, and 0.6 M NaCl
- 6000 to 8000 MWCO dialysis tubing (Spectrapor; boil in Milli-Q water for 5 min and store at 4°C)
- Additional reagents and equipment for dialysis (APPENDIX 3C) and purification of nucleosomes by glycerol gradient (UNIT 21.5)

1. Prepare the following reconstitution mixture:

- ~8 µg unlabeled sonicated calf thymus DNA (as carrier DNA; add from ~1 to 2 mg/ml stock)
- 200,000 to 400,000 cpm singly labeled DNA
- 6.4 µg (for 0.8:1 histone:DNA ratio) or 0.8 µg (for 1:1 histone:DNA ratio) purified native core histone protein fractions (H2A/H2B and H3/H4)
- 160 µl 5 M NaCl (2.0 M final)
- TE buffer, pH 8.0, to 400 µl.

The unlabeled competitor DNA is necessary to accurately determine nucleic acid concentration and thereby establish the correct histone:DNA stoichiometry. It is possible to disregard the DNA amount contributed by the labeled DNA if the final unlabeled DNA concentration does not go below 50 ng/µl. The ratio of histone:DNA mass must be empirically adjusted to obtain a maximum of mononucleosomes without detectable dinucleosomes. The usual starting ratio for mononucleosome assembly is 0.8 or 1.0 parts histone to one part DNA by mass.

2. Incubate at room temperature for 30 min.
3. Place the reconstitution mixture into a 6000 to 8000 MWCO dialysis bag (APPENDIX 3C).
4. Dialyze the reconstitution mixture in 1 liter of TE buffer, pH 8.0, containing 1.2 M NaCl, for 2 hr at 4°C (APPENDIX 3C).
5. Dialyze the reconstitution mixture successively, each time for 2 hr at 4°C, against the following freshly prepared dialysis buffers:
 - TE buffer, pH 8.0, containing 1.0 M NaCl
 - TE buffer, pH 8.0, containing 0.8 M NaCl
 - TE buffer, pH 8.0, containing 0.6 M NaCl.
6. Dialyze the reconstitution mixture overnight at 4°C in TE buffer, pH 8.0, without added NaCl.

Nucleosomes at this stage can be used for gel shift experiments where EDTA does not interfere.

7. Analyze the integrity of the nucleosomes by electrophoresis (see Support Protocols 5 and 6).
8. Purify assembled nucleosome cores from naked DNA over a 10% to 30% glycerol gradient (Basic Protocol 3 in *UNIT 21.5*) run for 18.5 hr at $100,000 \times g$.

ASSEMBLY OF HIGH CONCENTRATION OF MONONUCLEOSOMES BY GRADIENT SALT DIALYSIS

**BASIC
PROTOCOL 2**

To obtain high concentrations (~ 0.5 mg/ml) of core particles, gradient dialysis is recommended over step dialysis, as high concentrations of histones and DNA form nonspecific aggregates unless the dialysis is very gradual (Luger et al., 1997a, 1999). The buffer volumes and pump flow rates mentioned below are for a 200 to 1000 μ l reconstitution mixture.

Materials

Unlabeled DNA fragment at high concentration (>2 mg/ml; Support Protocol 3)
 1 M Tris·Cl, pH 7.7 (*APPENDIX 2*)
 1 M dithiothreitol (DTT)
 0.5 M disodium EDTA, pH 8.0 (*APPENDIX 2*)
 2.5 M KCl
 0.5 M benzamidine
 Core histones (purified from HeLa nuclear pellets; *UNIT 21.5*)
 High-salt buffer (see recipe)
 Low-salt Buffer (see recipe)
 Zero-salt buffer (see recipe)
 10% and 30% glycerol gradient buffer (see recipe in *UNIT 21.5*)

Rabbit pump (Rainin) with tubes
 6000 to 8000 MWCO dialysis tubing (Spectrapor, 6.4 mm diameter; boil in Milli-Q water for 5 min and store at 4°C)
 Conductivity meter calibrated for KCl concentration

Additional reagents and equipment for analysis of reconstituted complexes by agarose gel electrophoresis (see Support Protocol 5) or polyacrylamide gel electrophoresis (see Support Protocol 6)

Figure 21.6.1 Setup for gradient salt dialysis (adapted from Luger et al., 1999).

**Chromatin
Assembly and
Analysis**

21.6.3

1. Prepare the following reconstitution mix (adding the histones last):

0.7 mg/ml DNA fragment
20 mM Tris-Cl, pH 7.7 (from 1 M stock)
10 mM DTT (from 1 M stock)
1 mM EDTA, pH 8.0 (from 0.5 M stock)
2 M KCl (from 2.5 M stock)
0.5 mM benzamidine (from 0.5 M stock)
0.63 mg/ml histones.

Put assembly reaction at 4°C for 30 min after mixing components.

The histones can be prediluted in 2 M NaCl to get manageable concentrations. Reconstitutions can be carried out in volumes from 200 μ l up to many milliliters.

2. Set up “rabbit” pump assembly and set flow rate at 205 to 210 μ l/min (Figure 23.6.1).
3. Transfer reaction mixture to 6000 to 8000 kDa dialysis tubing.
4. Put membrane in middle beaker containing high-salt buffer, turn on the pump and keep at 4°C for ~ 50 hr.

The published procedure (Luger et al., 1997a, 1999) is to incubate for 36 hrs so the flow rate from the pump can be adjusted a bit to reduce time. However dialyzing faster than over 36 hrs can give precipitation of histones with DNA, so it is safer to keep the dialysis rate slow.

5. Check conductivity of solution in middle beaker every 5 hr or so.

By 50 hr, should drop from 2 M to ~300 mM.

6. Dialyze into zero-salt buffer (\geq 3 hr)

Nucleosomes can also be stored in the 300 mM salt buffer if the gradient buffer used in step 8 contains KCl.

7. Check assembly on a 0.7% agarose gel (see Support Protocol 5) or a 5% polyacrylamide 0.5 \times TBE gel (see Support Protocol 6).
8. Purify nucleosomes from free DNA over a 10% to 30% glycerol gradient (UNIT 21.5) run for ~18.5 hr at 100,000 \times g.

The fractions can be stored at 4°C for up to 2 months.

BASIC PROTOCOL 3

ASSEMBLY OF NUCLEOSOMAL ARRAYS BY GRADIENT SALT DIALYSIS

The procedure has been optimized with a specific DNA fragment, (G5E4 DNA) but can be used to assemble any 5S array. The DNA used in this assembly (G5E4 DNA) is a 2546 bp fragment that has five 5S rDNA positioning sequences on either side of a ~400 bp sequence containing 5 Gal4 binding sites, the E4 promoter, and several unique restriction sites (Neely et al., 1999). The central 400 bp can accommodate two nucleosomes.

Materials

Unlabeled G5E4 DNA (Dr. Jerry Workman; jlw10@psu.edu)
End-labeled G5E4 DNA (see Support Protocol 2 for labeling)
Bovine serum albumin (BSA)
High-salt buffer (see recipe) with 2 M NaCl in place of KCl
Low-salt buffer (see recipe) with 250 mM NaCl in place of KCl

Additional reagents and equipment for assembly of mononucleosomes by gradient salt dialysis (see Basic Protocol 2) and *EcoRI* digestion to determine extent of array assembly (see Support Protocol 7)

1. Prepare the following reconstitution mix (adding the histones last):

~100 µg/ml of a mixture of 9 parts unlabeled to 1 part end-labeled (molar ratio) G5E4 DNA
20 mM Tris-Cl, pH 7.7
10 mM DTT
1 mM EDTA
2 M NaCl
0.5 mM benzamidine
~100 µg/ml histones
100 µg/ml BSA

Put assembly reaction at 4°C for 30 min after mixing components.

2. Dialyze the reconstitution mix through salt gradient (in this case, NaCl) as for mononucleosomes (see Basic Protocol, steps 2 to 6).

For arrays, final dialysis into zero-salt buffer is preferable. The high-salt and low-salt buffers are the same as above except the KCl is substituted with the same amount of NaCl.

3. Analyze the assembly by *EcoRI* digestion (see Support Protocol 7).

PURIFICATION OF RECOMBINANT CORE HISTONES FROM BACTERIA

Core histones can be purified from a variety of sources but histones obtained from native chromatin provide a simple and abundant source for many different experiments (*UNIT 21.5*). Alternately, recombinant histones that have been overexpressed in bacteria can be isolated. This has the advantage of generating mutant histones which can be used for experiments that require modified histones. e.g., histones with deleted N-terminal domains (Luger et al., 1997a).

Although the ability to obtain recombinant histones from bacteria allows manipulations of these histones for experiments that require its modified forms, a concern regarding recombinant histones is that they are often obtained individually (Luger et al., 1997a). Thus, in addition to total histone mass, the ratio of the core histones must also be adjusted empirically. This can be done by combining purified histone H3 and H4 and purifying them in one mixture and H2A and H2B in another mixture. It has been shown that H3 and H4 can form a H3/H4 complex when combined together, and the same is true for H2A and H2B (Lee et al., 1999). It is also known that these complexes can be purified stoichiometrically on an ion-exchange column (Lee et al., 1999). Once these complexes are isolated, the assembly can be done by forming tetramers of histones H3 and H4, (H3/H4)₂, onto DNA by omitting histones H2A and H2B from the reconstitution (Hayes and Lee, 1997). After identification of the tetramer complexes, several reconstitutions containing increasing amounts of H2A/H2B can be prepared, essentially titrating these proteins into the reconstitution mix until the core histone octamer-DNA complex is completely formed. The advantage of this method is that it is possible to assemble modified forms of the H2A/H2B dimer and H3/H4 tetramer complex.

SUPPORT PROTOCOL 1

Chromatin Assembly and Analysis

21.6.5

Materials

Bacteria overexpressing core histones (BL21; Novagen; Luger et al., 1997a)
Luria broth (LB), sterile
100× (0.2 M) isopropyl D-thiogalactopyranoside (IPTG) stock
TE buffer, pH 8.0 (*APPENDIX 2*) containing 1 mM PMSF (add from saturated PMSF stock in 95% ethanol)
10 mg/ml lysozyme solution
Triton X-100 detergent
Denaturing solution (see recipe)
5 M NaCl (*APPENDIX 2*)
50% (v/v) slurry of Bio-Rex 50-100 mesh chromatography resin (Bio-Rad)
TE buffer, pH 8.0, containing 0.6, 1.0, and 2.0 M NaCl and 1 mM PMSF (add from saturated PMSF stock in 95% ethanol)

Oak Ridge centrifuge tubes
Sonicator
Beckman centrifuge with JA-20 rotor (or equivalent)
6000 to 8000 MWCO dialysis tubing (Spectrapor; boil in Milli-Q water for 5 min and store at 4°C)
10-ml disposable plastic chromatography column (Bio-Rad)
15- and 50-ml conical centrifuge tubes

Additional reagents and equipment for dialysis (*APPENDIX 3C*)

Grow the bacterial culture

1. Grow the culture in Luria broth in the absence of IPTG at 37°C to an optical density of 0.6 at 595 nm wavelength light.

The overexpression of each histone in bacteria is done individually; these are later mixed together.

2. Add IPTG to a final concentration of 0.2 mg/ml and return the culture to 37°C for approximately 2 to 4 hr.
3. After 2 to 4 hr pellet the bacteria by centrifuging 15 min at 4000 × g, 4°C.
4. Decant the supernatant and resuspended the pellet in 5 to 10 ml of TE buffer, pH 8.0.

Lyse the cells and obtain histones

5. Add 10 mg/ml lysozyme to a final concentration of 0.2 mg/ml.
6. Add Triton X-100 to a final concentration of 0.2% (v/v) and incubate for 30 min at room temperature.
7. Transfer the bacteria to Oak Ridge centrifuge tubes on ice.
8. Sonicate the bacterial slurry for 2 min total (two 1-min sonications).
9. Pellet the cell debris by centrifuging 30 min at 10,000 × g, 4°C. Discard supernatant.

The pellet contains the insoluble overexpressed histone in inclusion bodies.

10. Repeat steps 8 and 9 two additional times (total of three sonications/centrifugations).

Solubilize the histone pellet

11. Dissolve pellet in 2 ml of denaturing solution for 30 min at room temperature.

The denaturing step is required to solubilize the pellet, which mainly consists of overexpressed histones in inclusion bodies.

12. Renature the histones by dialyzing away the denaturant against a total of two to three changes (1 liter each) of TE buffer, pH 8.0, at 4°C, over a period of 48 hr (see *APPENDIX 3C* for dialysis procedures), using a 6000 to 8000 MWCO dialysis membrane.

During dialysis, it is likely that there will be a significant amount of precipitation. If precipitation seems excessive (i.e., small amount of protein in supernatant), it will be necessary to purify the denatured histones on a denaturing size exclusion column and purify the histones from chromosomal DNA which is causing the precipitation (Luger et al., 1997a).

13. Spin down any precipitate for 30 min at 8000 × g (10,000 rpm in a JA-20 rotor), 4°C.
14. Collect supernatant and raise NaCl concentration to 0.5 M by adding a sufficient quantity of 5 M NaCl.

Core histone proteins must first be incubated with their partner proteins before they will bind to the chromatography matrix (i.e., H2A with H2B).

Purify histone complexes

15. Incubate 5 ml of supernatant with 1 ml of a 50% suspension of Bio-Rex 50-100 mesh beads for 2 hr at 4°C, with mixing on an end-over-end rotator.

The ratio between supernatant to beads can be raised proportionately if there is more than 5 ml of supernatant.

16. After 4 hr, collect the beads in a plastic 10-ml disposable chromatography column. Collect the flowthrough fraction in a 50-ml conical tube. Freeze at –20°C.
17. Wash the column with 2 to 3 column volumes of TE buffer, pH 8.0, containing 0.6 M NaCl. Collect each wash fraction separately in a 15-ml conical tube. Freeze at –20°C.
18. Elute the bound proteins with two separate single-column-volume elutions of TE buffer, pH 8.0, containing 2.0 M NaCl, into separate 15-ml conical tubes. Freeze at –20°C.
19. Check 10 µl of each fraction for protein content by SDS-PAGE (see Support Protocol 6).

PREPARATION OF SINGLE 5' END-LABELED DNA FOR MONONUCLEOSOME ASSEMBLY

SUPPORT PROTOCOL 2

An important consideration in nucleosome assembly is how the histone octamer positions itself relative to the DNA. In order to generate homogeneous samples with unique positioning, the use of DNA that has a well-defined nucleosome positioning sequence is required. It has been known that DNA fragments which contain 5S RNA gene sequences have been found to strongly direct translational positioning (Rhodes, 1985). DNA fragments that contain these sequences are ideal templates for assembly.

Materials

- Plasmid DNA containing sequence of interest, with two convenient restriction sites that generate a ~150-bp fragment
- Restriction endonuclease suitable for linearizing the plasmid, and corresponding endonuclease buffer
- 3 M sodium acetate (*APPENDIX 2*)
- 95% and 70% ethanol, –20°C
- Alkaline phosphatase (Boehringer Mannheim) and alkaline phosphatase buffer
- 10% (w/v) SDS

Chromatin Assembly and Analysis

21.6.7

TE buffer, pH 8.0 (*APPENDIX 2*)
10,000 U/ml T4 polynucleotide kinase (Promega) and 10× T4 polynucleotide kinase buffer
10 μCi/μl [γ -³²P]dATP (6000 Ci/mmol; NEN Life Science Products)
2.5 M ammonium acetate
Restriction endonuclease appropriate for liberating the end-labeled fragment of interest, and corresponding endonuclease buffer
6% nondenaturing polyacrylamide gel
Pestle homogenizer fitting microcentrifuge tubes (VWR)
SpinX microcentrifuge tubes (Costar)
Additional reagents and equipment for phenol extraction and ethanol precipitation of DNA (*UNIT 2.1A*), polyacrylamide gel electrophoresis of DNA (*UNIT 2.7*), and autoradiography (*APPENDIX 3A*)

Linearize and dephosphorylate the DNA

1. Treat approximately 5 μg of plasmid DNA or ~0.5 μg of a purified DNA fragment with the appropriate restriction endonuclease using the buffer supplied by the manufacturer.
2. Precipitate the DNA by adding 0.1 vol 3 M sodium acetate and 2.5 vol ice-cold 95% ethanol.
3. Microcentrifuge 15 min at maximum speed. Discard supernatant and resuspend the DNA in 20 μl of 1× phosphatase buffer. Treat with 1 U/μl alkaline phosphatase for 1 hr at 37°C.
4. Adjust the solution to 0.1% SDS (by adding 0.01 vol 10% SDS stock), then phenol extract the solution and precipitate the aqueous phase twice with ethanol and sodium acetate (*UNIT 2.1A*).

Label the 5' ends

5. Resuspend the DNA in 10 μl TE buffer, pH 8.0, and add 2.5 μl of 10× T4 polynucleotide kinase buffer.
6. Add 50 μCi of [γ -³²P]dATP and adjust volume to 24 μl with water.
7. Start the reaction by adding 10 U of T4 polynucleotide kinase and incubate for 30 min at 37°C.
8. Stop the kinase reaction by adding 200 μl of 2.5 M ammonium acetate and 700 μl of cold 95% ethanol.
9. Microcentrifuge 30 min at maximum speed, 4°C.
10. Wash the DNA pellet briefly with cold 70% ethanol and dry in a Speedvac evaporator.
11. Dissolve the DNA in 34 μl of TE buffer, pH 8.0.

Obtain specific end-labeled fragment

12. Digest the DNA fragment with a second restriction endonuclease that liberates the fragment of interest and yields fragments that can be easily separated on a gel.
13. Apply the sample to a 6% nondenaturing polyacrylamide gel (*UNIT 2.7*). Perform electrophoretic separation.

The use of chemiluminescent markers allows the alignment of the gel in the following step.

14. After separation, wrap the gel in Saran Wrap and expose to film for 1 min (autoradiography; *APPENDIX 3A*), which is sufficient to detect the specific band containing the labeled fragment.

- Excise the band of interest from the polyacrylamide gel and place into a clean microcentrifuge tube. Crush the acrylamide gel slice with a pestle homogenizer fitting the microcentrifuge tube. Add 700 μ l of TE buffer, pH 8.0.

The labeled fragment will elute overnight with passive diffusion.

- Split the sample equally into two SpinX microcentrifuge filtration devices. Microcentrifuge 30 min at maximum speed.
- Precipitate the DNA and dissolve in TE buffer, pH 8.0, adding enough TE buffer so that the labeled DNA is approximately 1000 cpm/ μ l.

PREPARATION OF DNA FOR ASSEMBLY OF HIGH CONCENTRATION UNLABELED MONONUCLEOSOMES

Large amounts of mononucleosome-length (147 to 155 bp) DNA can be prepared by digestion from a plasmid as described in Support Protocol 2, steps 1 and 2. The DNA fragment can also be made by PCR (UNIT 15.1) from the plasmid, using appropriate primers. Once large amounts of the fragment have been obtained, the fragment can be gel purified as described in the Basic Protocol 1 of UNIT 2.7. The authors find that the crush-soak method described in Basic Protocol 1 of UNIT 2.7 works well, giving > 80% recovery of the DNA.

PREPARATION OF DNA FOR NUCLEOSOMAL ARRAYS

This protocol is described for obtaining the G5E4 DNA but modifications of this protocol can be used for generating other 5S DNA fragments.

Materials

p2085-G5E4 plasmid (Dr. Jerry Workman; *jlw10@psu.edu*) or other 12S array plasmid

40 U/ μ l *Asp718* and *ClaI* restriction endonucleases and buffer B (all from Boehringer-Mannheim)

DdeI restriction endonuclease and buffer 3 (both from New England Biolabs)
65°C water bath

Additional reagents and equipment for phenol/chloroform extraction and ethanol precipitation of DNA (UNIT 2.1A), purification of restriction fragments (UNIT 2.6), and labeling with Klenow fragment (UNIT 3.5)

- Mix ~200 μ g of p2085S-G5E4 plasmid with 200 U each of *Asp718* and *ClaI* in buffer B (Boehringer-Mannheim) and bring up to a total of 160 μ l. Digest at 37°C for 3 hr, then heat for 15 min at 65°C.

High-concentration (40 U/ μ l) stocks of Asp718 and ClaI are used to avoid high glycerol concentrations in the reaction mix.

- Perform a phenol/chloroform extraction followed by a chloroform extraction and ethanol precipitation (UNIT 2.1A).
- Resuspend in ~98 μ l water. Digest with 100 U of *DdeI* using buffer 3 in total of 115 μ l for 1.5 hr at 37°C.

The DdeI digestion digests the backbone of the plasmid making it easier to separate the ~2.5 kb array template from the backbone.

- Purify the ~2.5 kb DNA fragment using the protocols in UNIT 2.6.
- Label the array template at one end using the Klenow protocol in UNIT 3.5. Use a mix of NTPs without dATP and label using [γ -³²P]dATP.

This will label the Asp718 end.

PROTOCOL 4**

**Chromatin
Assembly and
Analysis**

21.6.9

ANALYSIS OF RECONSTITUTED COMPLEXES BY AGAROSE GEL ELECTROPHORESIS

The analysis of nucleosomes after reconstitution is necessary in order to determine the efficiency of nucleosome assembly, and also provides a way to gauge the integrity of the reconstituted nucleosomes. There are a number of techniques to analyze nucleosomes; combined together, they provide a reliable interpretation of the outcome of the assembly.

Materials

- Agarose (Research Genetics)
- 5× TBE buffer (see recipe)
- Labeled or unlabeled nucleosomes (see Basic Protocols 1 and 2)
- 50% (v/v) glycerol
- DNA loading dye (see recipe)
- 0.5 µg/ml ethidium bromide in 0.5× TBE buffer (see recipe for 5× TBE buffer)
- Whatman filter paper
- X-ray film (Kodak)
- Additional reagents and equipment for agarose gel electrophoresis (*UNIT 2.5A*) and autoradiography (*APPENDIX 3A*)

1. Prepare a thin (~0.4 cm × 10 × 13 cm) horizontal 0.7% agarose gel containing 0.5× TBE buffer. Set up the electrophoresis apparatus and begin running the gel at ~10 V/cm.
2. Prepare the sample by mixing 9 µl (2000 cpm of labeled nucleosomes) of the final solution (or an appropriate amount adjusted to this volume) with 1 µl of 50% glycerol and loading onto the gel while the gel is running.

A naked DNA marker containing SDS and typical gel dyes may be run in adjacent lanes without detectable effects on the nucleoprotein complexes.
3. Run the gel at ~10 V/cm at room temperature until the bromophenol blue dye marker has run ~1/2 to 2/3 of the way through the gel.
4. Place the gels onto filter paper, cover with plastic wrap, and dry in gel dryer without heat for 15 min, then with heat set to 55°C for ~1 hr.
- 5a. *For labeled nucleosomes:* Expose the gel to X-ray film (autoradiography; *APPENDIX 3A*) for 1 to 12 hr, depending on the cpm loaded.

Figure 21.6.2 Gel retardation assay of reconstituted nucleosomes.

5b. *For unlabeled nucleosomes:* Stain the gel in 0.5 µg/ml ethidium bromide by gently agitating for ~20 min. Rinse with distilled water and visualize under UV light.

The results of a typical agarose gel are shown in Figure 21.6.2.

ANALYSIS OF RECONSTITUTED COMPLEXES BY POLYACRYLAMIDE GEL ELECTROPHORESIS

**SUPPORT
PROTOCOL 6**

Assembled mononucleosomes can be resolved from naked DNA fragment on 5% acrylamide, 0.5× TBE gel of dimensions ~10 cm × 8 cm × 1 mm.

Materials

40% acrylamide 29:1 (acrylamide:bis) solution (see *UNIT 2.7*)

5× TBE buffer (see recipe)

Labeled or unlabeled nucleosomes (see Basic Protocols 1 and 2)

Naked DNA template used to prepare nucleosomes, as control

50% (v/v) glycerol

DNA loading dye

0.5 µg/ml of ethidium bromide solution in 0.5× TBE buffer (see recipe for 5× TBE buffer)

X-ray film (Kodak)

Additional reagents and equipment for polyacrylamide gel electrophoresis of DNA (*UNIT 2.7*)

1. Prepare a 5% acrylamide, 0.5× TBE gel of dimensions ~10 cm × 8 cm × 1 mm (*UNIT 2.7*) using 40% acrylamide 29:1 (acrylamide:bis) solution and 5× TBE buffer. Set up the electrophoresis apparatus.
2. Load the nucleosomes by mixing 10 µl of the sample with 0.1 vol of 50% glycerol. Add loading dye containing bromophenol blue to a separate lane. As a control, add 10 µl of an appropriate amount of the naked DNA template.

Do not add dye to samples as this can disrupt histone-DNA interactions. Loading can be visualized due to the viscosity of the glycerol.

3. Run the gel at ~100 V at 4°C till the bromophenol dye is close to the bottom of the gel.
- 4a. *For labeled nucleosomes:* Dry the gel on a gel dryer for ~30 min at 80°C and expose to X-ray film (autoradiography; *APPENDIX 3A*).
- 4b. *For unlabeled nucleosomes:* Stain the gel in 0.5 µg/ml of ethidium bromide solution by gently agitating for ~20 min. Rinse with distilled water and visualize using a UV transilluminator.

The nucleosomes run significantly more slowly than the naked DNA. The ethidium fluorescence signal from the nucleosomal bands should be multiplied by 2.5 to correct for histone quenching.

The efficiency of assembly can be determined by quantifying the percentage of DNA incorporated into nucleosomes.

**Chromatin
Assembly and
Analysis**

21.6.11

***Eco*RI DIGESTION TO DETERMINE EXTENT OF G5E4 ARRAY ASSEMBLY**

Estimating the degree of array assembly is often crucial for interpretation of results from experiments using the array (Carruthers et al., 1999). The G5E4 fragment has *Eco*RI sites flanking each 5S positioning sequence but not within the central 400 bp. If all the 5S positioning sequences are saturated with histone octamers, cleavage with *Eco*RI will generate mononucleosomes and no 208-bp-length naked DNA. The central two nucleosomes, if fully assembled, will generate a dinucleosome. The percentage of naked DNA of length 208 and ~400 bp will be indicative of the degree of array assembly. If unlabeled array is being analyzed, the ethidium fluorescence signal from the nucleosomal bands should be multiplied by 2.5 to correct for histone quenching.

Materials

Nucleosomal array (see Basic Protocol 3)

*Eco*RI restriction endonuclease and corresponding buffer

25% (v/v) glycerol/10 mM disodium EDTA, pH 8.0 (see APPENDIX 2 for preparation of the EDTA)

Agarose (Research Genetics)

5× TBE buffer with increased EDTA (see recipe)

0.5 µg/ml ethidium bromide solution in 0.5× TBE buffer with regular EDTA concentration (see recipe for 5× TBE buffer)

Additional reagents and equipment for restriction endonuclease digestion (UNIT 3.1), agarose gel electrophoresis (UNIT 2.5A), and autoradiography (APPENDIX 3A)

1. Digest ~1 µg of nucleosomal array with 10 U of *Eco*RI in 20 to 100 µl for 60 min at room temperature in *Eco*RI digestion buffer.
2. Quench the reaction by adding 1/5 vol of 25% glycerol/10 mM EDTA, pH 8.0.
3. Prepare a 0.8% nondenaturing agarose gel in 0.5× TBE buffer with increased EDTA (UNIT 2.5A). Assemble the gel apparatus, load the samples, and run for 3 hr at 1 V/cm.

Do not add dye to samples as it can disrupt histone-DNA interactions. Add it in a separate lane.

- 4a. *If labeled array is being analyzed:* Place the gels onto filter paper, cover with plastic wrap, and dry in a gel dryer without heat for 15 min, then with heat set to 55°C for ~1 hr. Analyze by autoradiography (APPENDIX 3A) or using a phosphor imager.
- 4b. *If unlabeled array is being analyzed:* Stain the gel in 0.5 µg/ml ethidium bromide by gently agitating for ~20 min. Rinse with distilled water and visualize on a UV transilluminator.

The TBE buffer composition is crucial to obtain well-defined bands on the gel. Use of TAE results in smears.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Denaturing solution

6 M guanidium hydrochloride

20 mM sodium acetate

1 mM DTT

Prepare fresh before use

DNA loading dye

50% (v/v) glycerol
0.1% (w/v) bromophenol blue
0.1% (w/v) xylene cyanol

High-salt buffer

20 mM Tris·Cl, pH 7.7 (*APPENDIX 2*)
2 M KCl (2 M NaCl for nucleosome array assemblies)
1 mM EDTA
1 mM DTT
0.5 mM benzamidine
Store up to several weeks at 4°C without DTT or benzamidine

Low-salt buffer

20 mM Tris·Cl, pH 7.7 (*APPENDIX 2*)
250 mM KCl (250 mM NaCl for nucleosome assemblies)
1 mM EDTA
1 mM DTT
0.5 mM benzamidine
Store up to several weeks at 4°C without DTT or benzamidine

Tris/borate/EDTA (TBE) buffer, 5× (for Support Protocols 5 and 6)

0.45 M Tris·Cl, pH 8.3 (*APPENDIX 2*)
0.45 M boric acid
5.0 mM EDTA
Store up to several weeks at room temperature

Tris/borate/EDTA (TBE) buffer with increased EDTA, 5× (for Support Protocol 7)

0.45 M Tris·Cl, pH 8.3 (*APPENDIX 2*)
0.45 M boric acid
10 mM EDTA
Store up to several weeks at room temperature

Zero-salt buffer

20 mM Tris·Cl, pH 7.7 (*APPENDIX 2*)
1 mM EDTA
1 mM DTT
0.5 mM benzamidine
Store up to several weeks at 4°C without DTT or benzamidine

COMMENTARY**Background Information**

Chromatin is the substrate of virtually all processes within the eukaryotic nucleus that involve DNA. The structure and protein components of chromatin are increasingly being identified as integral components of these processes, which include transcription, replication, and recombination (van Holde, 1989).

The basic building block of the chromatin fiber is a 250-kDa structure known as the nucleosome. This subunit contains about 200 bp of DNA, two copies each of the four core histones, and generally a single molecule of a linker histone. The DNA within this complex

is partially wrapped in two 80-bp turns around a spool formed by the core histones. The core histones and the central 146 bp of DNA in tightest association with these proteins form a structure resistant to micrococcal nuclease digestion, referred to as the nucleosome core. The details of the organization of DNA and the proteins within the nucleosome core have been well-documented (Luger et al., 1997b). The remainder of the DNA within the nucleosome subunit (~40 bp) links nucleosome cores together to form a continuous string of these subunits. Strings of nucleosomes are further coiled or compacted into fibers approximately

Table 21.6.1 General Troubleshooting Guide For Assembly of Nucleosomal Templates by Salt Dialysis

Problem	Possible cause	Solution
Histones precipitate during renaturation dialysis.	Excess DNA present in the preparation.	Purify denatured histones away from DNA on size exclusion column before renaturation (Support Protocol 1).
When run on gel mononucleosome assembly is mainly in the wells.	Weight ratio of histones to DNA is significantly greater than 1 causing nonspecific aggregation.	Repeat assembly with lower amounts of histones and perform a titration with a few different concentrations to obtain the optimal ratio.
Complexes that run more slowly than mononucleosomes are observed on gel.	The higher complexes are likely to have more than one histone octamer per DNA fragment. This can arise from histone:DNA ratios of >1.	If the higher complexes form a significant fraction of assembly, one can perform histone titration as above. If these complexes are not a significant fraction of the total assembly, they can be separated away from standard mononucleosomes on a glycerol gradient (Basic Protocol 2).
Less than 30% of the DNA is incorporated into nucleosomes.	The histone:DNA ratio is significantly less than 1.	Perform a titration with increasing amounts of histones.
Nucleosomes look “smearly” when run on gel.	The gel temperature is high causing dissociation of nucleosomes.	Maintain gel at room temperature for agarose gel and run acrylamide gel in cold room.
<i>Eco</i> RI digestion of array gives smearly bands on agarose gel.	The running and gel buffer composition is different from recipe.	Use 45 mM Tris-borate, 1 mM EDTA buffer (see Support Protocol 7).

30 nm in diameter. Unfortunately, details of this compaction, such as the conformation of the linker DNA within the 30-nm fiber or the packing of nucleosome cores within the fiber, have not been elucidated. These fibers are organized into even higher-order structures to form the metaphase chromosome.

Efforts to recapitulate in vivo the processes which occur within the eukaryotic nucleus require the reconstruction of proper chromatin substrates. Thus, methods for the reconstitution of chromatin complexes have become widely used (Camerini-Otero, 1976). Moreover, reconstitution methods allow the construction of model chromatin complexes containing defined DNA sequences. Salt dialysis reconstitution has been useful in this respect. It is known that at 2 M salt, the histone octamer forms its canonical structure even when not bound to DNA. As the salt concentration falls below 2 M, the histone octamer dissociates into an H3/H4 and two H2A/H2B dimers. The tetramer also starts to bind to DNA at this salt concentration. At ~0.8 M salt, a single H2A/H2B dimer binds to each H3/H4 tetramer and by 0.6 M

nucleosome assembly is complete. Samples of reconstituted chromatin complexes can be prepared that exhibit less structural heterogeneity than preparations of natural chromatin complexes. This homogeneity has allowed detailed investigations of nucleosomal DNA structure and the salt-induced folding properties of nucleosomal arrays (Hayes et al., 1990, Schwarz and Hansen, 1994).

Reconstituted nucleosomes exhibit physical and structural properties identical to native complexes isolated from eukaryotic nuclei. Hydroxyl radical cleavage analysis and micrococcal nuclease digestions have shown that the DNA structure within reconstituted complexes is identical to that found in bulk preparations containing random DNA sequences (Hayes et al., 1990). Cross-linking experiments have demonstrated that the histone protein–DNA contacts within reconstituted nucleosomes are identical to that of native complexes (Lee and Hayes, 1997). Reconstituted oligonucleosomal complexes exhibit the same hydrodynamic shape and folding behavior as native complexes (Schwarz and Hansen, 1994). Further, the

stoichiometry of polypeptides within reconstituted complexes is identical to that found in native chromatin (Camerini-Otero et al., 1976).

A key element in many of these studies is the use of a well-defined nucleosome positioning sequence. Sequence-dependent variations in the B-DNA structure within these fragments cause the fragments to adopt a defined rotational and translational orientation with respect to the surface of the nucleosome core. Since the core histone-DNA contacts occur at specific locations on the surface of the octamer, these two positional variables are related. However, a single preferred rotational orientation may accommodate several translational frames related by approximately $10n$ base pairs. Therefore, reconstitutions with stably curved DNAs will exhibit a strong rotational preference but may yield a population with a heterogeneous distribution of translational frames. DNA fragments that contain 5S RNA gene sequences have been found to strongly direct translational positioning (Rhodes, 1985). A 5S DNA fragment from *Xenopus* exhibits has been found to exhibit exceptional nucleosome positioning properties. When this fragment is reconstituted with purified core histones, approximately 80% of the population of nucleosomes within the sample adopt a unique translational position (Hayes et al., 1990). The molecular basis of this translational positioning effect is not yet understood.

Critical Parameters and Troubleshooting

Critical variables and ways to overcome experimental difficulties are presented in Table 21.6.1.

Anticipated Results

The results obtained from the analysis should reveal the quality of the nucleosomal template (Support Protocol 3). If the purity of the histones and DNA is high and consideration is given to the relative stoichiometry, the assembly should generate suitable template for further experiments. The efficiency of assembly is obtained by quantifying the percentage of naked DNA assembled into nucleosomes as described in Support Protocols 5, 6, and 7. This should be between 30% and 80%.

Time Considerations

Theoretically, step salt dialysis can be completed in 10 hr. Step dialysis has the advantage of being quick and convenient to set up. However, the drawbacks are that it does not always

generate properly assembled nucleosomes when the nucleosome concentration is high (~1 mg) and when nucleosomal arrays are generated. An alternative method is to use the gradient salt dialysis method (see Basic Protocol 2). The assembly through gradient dialysis takes ~50 hr. It is a relatively long procedure but once it is set up, there are no further manipulations until the reconstitution is finished. The purification of histones from native chromatin takes roughly two full days after the necessary equipment is set up. The isolation of recombinant histones from bacteria requires 3 to 4 half days starting from the inoculation to the final chromatography steps. The analysis of the nucleosomes takes about 3 to 4 hr.

Chromatin Assembly Using *Drosophila* Systems

UNIT 21.7

To study chromatin structure and activity *in vitro*, it is necessary to use appropriate methods for the preparation of chromatin substrates. The goal of chromatin assembly procedures is to prepare extended nucleosome arrays from cloned DNA templates (usually plasmid DNA) and purified chromatin proteins (core and linker histones, DNA-binding proteins). The assembled chromatin should be highly defined in its protein content and resemble bulk chromatin isolated from living cell nuclei in terms of periodicity and nucleosome positioning. In this unit we describe two systems that assemble minichromosome templates in an ATP-dependent fashion from circular plasmid DNA and purified core histones. These systems can be used to assemble minichromosomes from linear DNA (plasmid and lambda) and can also incorporate proteins other than core histones (linker histone H1, HMG17, and DNA-binding transcription factors). The products of these chromatin assembly reactions have been used directly (or after purification) in assays to study transcription, DNA replication, recombination, and repair. The first of the two systems employs a *Drosophila* embryonic extract (S-190) as a source of the assembly factors (see Basic Protocols 1 to 3). Well established and easy to troubleshoot, this protocol should be considered the first stop for researchers with limited experience in chromatin analysis. The second system utilizes purified recombinant *Drosophila* chromatin assembly factors (see Basic Protocols 4 to 6 and Alternate Protocol 1). It provides an additional advantage of strictly defined protein content of assembled chromatin. Determining the optimal ratio of core histone to DNA is important for either system; this is presented in Alternate Protocol 2. Chromatin assembly on relaxed circular DNA requires the presence of a topoisomerase activity in the reaction. An example of expression and purification of the core catalytic domain of *Drosophila* topoisomerase I is presented in the Support Protocol.

PREPARATION OF THE *DROSOPHILA* S-190 CHROMATIN ASSEMBLY EXTRACT

BASIC
PROTOCOL 1

This protocol describes the preparation of the S-190 *Drosophila* cell extract. When supplemented with core histones and ATP, the S-190 extract can mediate the *in vitro* assembly of regularly spaced arrays of nucleosomes on a DNA template.

Materials

- 0- to 6-hr *Drosophila* embryos
- Bleach wash: 50% (v/v) household bleach in distilled H₂O
- Embryo wash: 0.7% (w/v) NaCl/0.4% (v/v) Triton X-100, room temperature and 4°C
- Saline wash: 0.7% (w/v) NaCl, 4°C
- Buffer R (see recipe), 4°C
- 1 M MgCl₂ (APPENDIX 2)
- Liquid N₂
- Fine nylon mesh (e.g., Sefar America 03-80/37)
- 800-ml glass beaker
- Glass rod
- Vacuum aspirator
- 40 ml Wheaton Dounce homogenizer with “A” and “B” pestles
- 17 × 100–mm polypropylene tubes (e.g., Falcon 2059)
- Sorvall Superspeed centrifuge with SS-34 rotor (or equivalent)

Chromatin
Assembly and
Analysis

21.7.1

50-ml conical tubes
10-ml plastic syringes and 18.5-G needles
Beckman ultracentrifuge with SW 41 and SW 55 rotors
Thin-walled 14 × 89-mm (for SW 41 rotor) and 13 × 51-mm (for SW 55 rotor)
Beckman ultracentrifuge tubes

Prepare the embryos

1. Secure a fine nylon mesh in a support and place ~100 g of 0- to 6-hr *Drosophila* embryos on the mesh. Wash thoroughly with cold tap water to eliminate yeast and contaminants.

Do not freeze the embryos before extraction.

100 g of the starting material should yield ~50 ml of S-190 extract. S-190 extracts prepared from embryos older than 6 hr are significantly less active. It is important to select an appropriate mesh that is fine enough to retain the embryos but large enough to allow the buffers and yeast to flow through. A coarser mesh placed above the fine mesh can be used to separate adult fly bodies and parts as well as pieces of food agar from the embryos.

2. Soak the embryos 90 sec in 3 liters bleach wash at room temperature. Quickly rinse with 1 liter embryo wash at room temperature. Rinse extensively with distilled water. Transfer embryos to an 800-ml glass beaker on ice.

Bleach wash will remove chorions from the embryos. After this point, all subsequent steps should be carried out on ice or in a cold room, unless otherwise noted.

3. Add 500 ml of embryo wash at 4°C and suspend the embryos by stirring with a glass rod. Allow the embryos to settle to the bottom of the beaker for ~2 min. Aspirate the embryo wash using a vacuum aspirator, avoiding the settled embryos at the bottom of the beaker.

Be sure to aspirate the chorions and other floating non-embryo material at the top of the beaker.

4. Repeat step 3 with an additional 500 ml of 4°C embryo wash.
5. Repeat step 3 twice, each time with 500 ml of 4°C saline wash.

Allow the embryos to settle ~5 min in saline wash. It is important to avoid aspirating the now floating embryos in the beaker.

6. Repeat step 3 twice, each time with 500 ml of 4°C buffer R.

The embryos will require up to 10 min to settle in buffer R. Again, it is important to avoid aspirating floating embryos as much as possible. After the second aspiration, the final volume should be no more than 80 ml. While it may require some loss of the starting material, it is more desirable to have a concentrated extract than a larger volume of the extract.

Prepare the extract

7. Transfer the material to a 40 ml Wheaton Dounce homogenizer on ice. Homogenize with 15 strokes of the “B” pestle and additional 40 strokes of the “A” pestle. Repeat with any remaining material.

Be certain to homogenize with full strokes. It is important to achieve complete homogenization of the embryos. This can be verified by placing a drop of the homogenate on a glass slide and examining for the presence of intact embryos.

8. Transfer the homogenate to 17 × 100-mm polypropylene tubes on ice. Spin 5 min at 7500 × g (8000 rpm in a Sorvall SS-34 rotor), 4°C. Extract the aqueous supernatant from the middle of the tubes and pool in 50-ml conical tube(s).

To avoid the pellet at the bottom and the white lipid layer at the top of the tube, use a 10-ml syringe and an 18.5-G needle inserted through the tube just above the pellet.

- Using 1 M MgCl_2 , adjust the concentration of magnesium to 7 mM.

Note that buffer R contains 1.5 mM MgCl_2 . This step significantly reduces the amount of RNA in the final extract.

- Transfer the supernatant to thin-walled 14×89 -mm ultracentrifuge tubes. Ultracentrifuge for 2.25 hr at $200,000 \times g$ (40,000 rpm in an ultracentrifuge with Beckman SW 41 rotor), 4°C .

For smaller volumes, use 13×51 -mm tubes and spin at $192,000 \times g$ (45,000 rpm in a Beckman SW 55 rotor), 4°C .

- Remove the white upper lipid layer from each tube with a metal spatula and discard. Collect the golden-brown liquid layer and pool in a 50-ml conical tube(s) on ice. Freeze in liquid nitrogen.

It is important to avoid the beige, upper layer of the pellet, which will inhibit the assembly activity. At this point, the extract can be stored at -80°C indefinitely until the final spin. However, freezing of the extract is essential even if you proceed directly to step 12.

Handle the 50-ml polypropylene tubes gently in liquid N_2 to avoid cracking.

- Thaw the extract in a room temperature water bath. Spin 2.25 hr at $192,000 \times g$ (45,000 rpm in an ultracentrifuge with Beckman SW 55 rotor), 4°C .

Note that the SW 55 rotor consistently yields a more active extract than the SW 41 for this spin.

- Remove the white upper lipid layer (if any) and pool the extract in a 50-ml conical tube. Aliquot 1-ml fractions into microcentrifuge tubes and freeze in liquid nitrogen. Store at -80°C .

The S-190 extract will remain active for up to 3 years at -80°C .

PURIFICATION OF CORE HISTONES FROM THE *DROSOPHILA* EMBRYOS

Nuclei are isolated from the *Drosophila* embryos. Chromatin is partially digested with micrococcal nuclease to generate ~ 2000 -bp fragments. The chromatin fragments are isolated, bound to hydroxylapatite resin, and core histones are separated from the DNA by salt elution.

Materials

0- to 12-hr *Drosophila* embryos

Bleach wash: 50% (v/v) household bleach in distilled H_2O

Embryo wash: 0.7% (w/v) NaCl/0.04% (v/v) Triton X-100

Buffer B (see recipe)

Buffer A (see recipe)

1 M NaOH

0.1 M CaCl_2

200 U/ml micrococcal nuclease stock solution (see recipe)

10 mM and 500 mM EDTA

10% (w/v) SDS

5 M NaCl (APPENDIX 2)

24:1 chloroform/isoamyl alcohol

Linear 5% to 30% sucrose gradients (see recipe)

T_{50}E_4 buffer: 50 mM Tris·Cl, pH 7.9 (APPENDIX 2)/4 mM EDTA

Hydroxylapatite resin (e.g., BioGel HT gel; Bio-Rad)

HA chromatography buffer (see recipe) with 0 M, 0.35 M, and 2.5 M NaCl

Core histone storage buffer (see recipe)

BCA assay kit (Pierce)

BASIC PROTOCOL 2

Chromatin Assembly and Analysis

21.7.3

Fine nylon mesh (e.g., Sefar America 03-80/37)
Weigh boats
Yamato LH-21 homogenizer (alternatively, Potter-Elvehjem homogenizer)
500-ml centrifuge bottles for Sorvall GSA rotor (or equivalent)
Mira cloth (Calbiochem-Novabiochem)
Sorvall Superspeed centrifuge with GSA and SS-34 rotors or equivalents
Beckman ultracentrifuge with SW-28 rotor and appropriate tubes
12,000 to 15,000 and 3,500 MWCO dialysis tubing
FPLC apparatus

Additional reagents and equipment for extraction of DNA (*UNIT 2.1A*), agarose gel electrophoresis (*UNIT 2.5A*), SDS-PAGE (*UNIT 10.2*), Coomassie blue staining and destaining of proteins in gels (*UNIT 10.6*), and dialysis (*APPENDIX 3C*)

Prepare the embryos

1. Secure a fine nylon mesh in a support and place ~100 g of 0- to 12-hr *Drosophila* embryos on the mesh. Wash thoroughly with cold tap water to eliminate yeast and contaminants.

The embryos can be frozen in liquid nitrogen and stored up to 1 year at -80°C before processing.

100 g of the starting material should yield between 5 to 10 mg of core histones. See step 1 of Basic Protocol 1 for information on the nylon mesh.

2. Soak the embryos 90 sec in 3 liters bleach wash at room temperature. Quickly rinse with 1 liter of embryo wash at room temperature. Rinse extensively with distilled water. Blot embryos dry through the mesh with paper towels. Transfer to a weigh boat and weigh.

Bleach wash will remove chorions from the embryos. After this point, all subsequent steps should be carried out on ice or in a cold room, unless otherwise noted.

Isolate the nuclei

3. Transfer the embryos to a glass beaker. Resuspend in 3 ml buffer B per 1 g of embryos. Pour the suspension through a Yamato LH-21 homogenizer at 1000 rpm and filter the effluent into GSA bottles through Mira cloth.

If a Yamato homogenizer is not available, the embryos can be disrupted with six to eight strokes in a motorized Potter-Elvehjem homogenizer (serrated Teflon pestle in a glass vessel), followed by several strokes in a Wheaton Dounce homogenizer with the "B" pestle.

4. Wash the original beaker with 1 ml buffer B per 1 g of embryos and pass through the homogenizer and Mira cloth as in step 3. Repeat with 1 ml buffer B per 1 g of embryos. Centrifuge the filtrate 20 min at $10,000 \times g$ (8000 rpm in a GSA rotor), 4°C .

The final volume of the suspension before spinning should be 5 ml buffer B per 1 g of embryos.

5. Discard the supernatant. Resuspend the loose pellet of nuclei in 200 ml buffer A. Centrifuge 10 min at $10,000 \times g$ (8000 rpm in a GSA rotor), 4°C .

Avoid the yellow yolk protein pellet when resuspending the nuclei. A firmer, "yellow" yolk pellet should form at the center of the looser nuclei pellet; it is this pellet that should be avoided. A Pasteur pipet can be used to trace the outline of the yolk pellet, after which gentle resuspension of the nuclear pellet can be carried out with a battery-powered pipetting device (e.g., Pipet-Aid) and buffer A.

6. Discard the supernatant. Resuspend the nuclei in 100 ml buffer A. Centrifuge 10 min at $10,000 \times g$ (8000 rpm in a GSA rotor), 4°C .

Again, avoid the yolk protein, if any remains.

7. Discard the supernatant. Resuspend the nuclear pellet in 30 ml buffer A.

Digest a sample of the chromatin

8. Dilute 10 μl of suspended nuclei with 990 μl of 1 M NaOH. Measure the optical density at 260 nm (OD_{260}). Dilute the suspension of nuclei to 100 OD_{260} units/ml with buffer A.
9. Perform a test micrococcal nuclease digestion as follows:
 - a. In a 1.5 ml microcentrifuge tube, prewarm 1 ml of the nuclear suspension to 37°C .
 - b. Add 10 μl of 0.1 M CaCl_2 and 2 μl of 200 U/ml micrococcal nuclease stock solution.
 - c. Incubate at 37°C . At 1, 2, 4, 6, 8, 10, 15, and 20 min, remove a 100- μl aliquot and stop enzyme activity in the aliquot with 2.5 μl 500 mM EDTA.
10. To each aliquot add 30 μl water and 20 μl 10% SDS. Mix thoroughly and add 40 μl 5 M NaCl. Mix thoroughly. Extract each aliquot with 200 μl of 24:1 chloroform/isoamyl alcohol.

UNIT 2.1A describes general techniques for extraction of DNA.

11. Mix 4 μl of the aqueous phase from each aliquot with agarose gel loading buffer. Run each of the aliquots (representing time points from step 9) in a separate lane of a 1% agarose gel. Stain with ethidium bromide and photograph (see *UNIT 2.5A* for reagents and techniques used in this step).

Use a 1-kb ladder as a reference and select the time point displaying a prevalence of ~2000-bp fragments.

Perform bulk digest of the chromatin

12. Warm the nuclear suspension to 37°C and add 1/100 vol of 0.1 M CaCl_2 . Add 1/500 vol of 200 U/ml micrococcal nuclease and mix by swirling. Incubate at 37°C with occasional swirling for the time determined in steps 8 to 11. Stop digestion by adding of 1/50 vol of 500 mM EDTA and place at 4°C .
13. Centrifuge 10 min at $12,000 \times g$ (10,000 rpm in an SS-34 rotor), 4°C . Discard the supernatant. Resuspend the pellet in 10 mM EDTA for a total volume of 9 ml. Add 1 ml of 5 M NaCl and swirl 5 min.

Upon the addition of NaCl, extensive lysis should be observed and the solution should become more viscous.
14. Centrifuge 5 min at $12,000 \times g$ (10,000 rpm in an SS-34 rotor), 4°C . Save the supernatant. Dilute 10 μl into 990 μl of 1 M NaOH and measure the OD_{260} .
15. Load $\leq 500 \text{OD}_{260}$ units of supernatant onto linear gradients (18 to 20 ml each) of 5% to 30% sucrose in sucrose gradient buffer in SW 28 tubes. Ultracentrifuge 16 hr at $90,000 \times g$ (26,000 rpm in an SW 28 rotor), 4°C .
16. Cut the gradients into 2-ml fractions and run 8 μl per fraction on a 15% SDS-PAGE gel (*UNIT 10.2*). Coomassie stain and destain (*UNIT 10.6*). Pool the peak core histone containing fractions and dialyze in 12,000 to 15,000 MWCO tubing twice, each time for 2 hr against 2 liters T_{50}E_4 buffer (*APPENDIX 3C*) at 4°C .

Like fractions from each gradient tube can be pooled in 50-ml conical tubes. If any debris is suspended in sucrose-containing fractions, it can be spun down after dialysis. The fractionated digested chromatin can be stored for several months at 4°C without loss of core histone integrity. When selecting fractions for further purification, be careful to avoid histone H1-containing fractions.

Purify core histone octamers by hydroxylapatite chromatography

17. Dilute 10 µl dialyzed sample with 990 µl of 1 M NaOH and measure the OD₂₆₀. Calculate the required volume of hydroxylapatite resin as 1 ml column volume per 1.5 mg of DNA.
18. Pack an appropriately sized hydroxylapatite column on an FPLC and equilibrate in 3 column volumes HA chromatography buffer without NaCl.
19. Apply the dialyzed sample to the column and wash with an additional 3 column volumes of HA chromatography buffer without NaCl. Wash with an additional 3 column volumes of HA chromatography buffer containing 0.35 M NaCl.

The 0.35 M NaCl wash elutes DNA-binding proteins, other than histones, off the resin-bound chromatin.

20. Elute the core histones with 2 column volumes of HA chromatography buffer containing 2.5 M NaCl.

Alternatively, the core histones can be eluted with a salt gradient from 0.35 to 2.5 M NaCl in HA chromatography buffer. This separates any residual histone H1 that was collected from the sucrose gradient. A variation of this procedure can also be used to fractionate histone dimers and tetramers.

Additional information on hydroxylapatite chromatography of histones is found in UNIT 21.5.

21. Analyze 2 µl of peak fractions on a 15% SDS-PAGE gel (UNIT 10.2). Coomassie stain and destain (UNIT 10.6). Pool the peak core histone-containing fractions and dialyze in 3,500 MWCO tubing twice, each time for 2 hr against 2 liters core histone storage buffer at 4°C.
22. After dialysis, determine the histone concentration by BCA assay. Aliquot into microcentrifuge tubes and freeze in liquid nitrogen. Store at -80°C.

The core histones can be stored for several years at -80°C.

CHROMATIN ASSEMBLY WITH THE S-190 EXTRACT

The extract (from Basic Protocol 1) and core histones (from Basic Protocol 2) are combined and preincubated at room temperature to facilitate binding of histones and chaperone(s). A DNA template, ATP, and ATP regeneration system are added, and chromatin is assembled at 27°C. Chromatin is analyzed by partial micrococcal nuclease digestion.

Materials

- Buffer R (see recipe)
- S-190 extract (see Basic Protocol 1)
- Core histones (see Basic Protocol 2)
- ATP mix (see recipe)
- 0.1 M MgCl₂
- DNA template (2.5 to 25 kbp circular or linearized plasmid, or λ DNA)
- 0.1 M CaCl₂
- 200 U/ml micrococcal nuclease stock solution (see recipe)

0.5 M EDTA
10 mg/ml RNase A
Glycogen stop buffer (see recipe)
2.5 mg/ml proteinase K
50:49:1 (v/v/v) phenol/chloroform/isoamyl alcohol, equilibrated with 10 mM
Tris-Cl, pH 8.0 (see *UNIT 2.1A* for equilibration technique)
2.5 M ammonium acetate
70% and 100% ethanol
1.2% agarose gel (*UNIT 2.5A*)
TBE buffer (*APPENDIX 2*)
123 bp DNA ladder (Life Technologies)
27° and 37°C water baths

Additional reagents and equipment for extraction of DNA (*UNIT 2.1A*) and agarose gel electrophoresis (*UNIT 2.5A*)

Preincubate core histones with the extract

1. Combine 40 μ l buffer R, 30 μ l S-190 extract, and 400 ng of core histones. Incubate 30 min at room temperature.

A single reaction produces enough chromatin for one micrococcal nuclease digestion analysis (two lanes on an agarose gel). The reaction can be scaled up. Typically, the S-190 extract comprises 25% to 40% of the reaction volume and the core histones are in a 0.8:1 mass ratio with the DNA template (5 ng/ μ l). The final Mg²⁺ concentration is 7 mM.

Add ATP and the DNA template

2. Add 10 μ l ATP mix, 0.1 M MgCl₂ to 7 mM final concentration, and 500 ng DNA template. Incubate 5 hr at 27°C. If necessary, make up to a final volume of 100 μ l with buffer R.

Note that both buffer R and the S-190 extract contain MgCl₂.

Perform partial micrococcal nuclease digestions

3. Add 3 μ l of 0.1 M CaCl₂ to the assembly reaction. Divide the reaction in two equal parts (“a” and “b”). Dilute the micrococcal nuclease (200 U/ml) 1:50 and 1:150 with buffer R.

Prepare the nuclease dilutions within a few minutes before use.

4. In a controlled manner (at certain time intervals, e.g., 15 sec), add 5 μ l of the 1:150 dilution to the “a” tube and 5 μ l of the 1:50 dilution to the “b” tube. Digest 10 min at room temperature.
5. Terminate the reactions with 7 μ l of 0.5 M EDTA. Add 1 μ l of 10 mg/ml RNase A solution and incubate for 10 min at room temperature.

This step eliminates RNA present in the S-190 extract.

Deplete the chromatin samples

6. To each aliquot add 95 μ l glycogen stop buffer and 5 μ l of 2.5 mg/ml proteinase K solution. Incubate 30 min at 37°C.
7. Extract with 200 μ l of 50:49:1 phenol/chloroform/isoamyl alcohol. Precipitate the DNA from 150 μ l of the aqueous phase with 15 μ l of 2.5 M ammonium acetate and 450 μ l of 100% ethanol. Microcentrifuge for 15 min at maximum speed, room temperature. Wash the pellets with 200 μ l of 70% ethanol. Microcentrifuge 5 min at maximum speed, room temperature. Dry by exposing to air for 5 min.

UNIT 2.1A describes general techniques for extraction and precipitation of DNA.

Figure 21.7.1 Chromatin assembly by the S-190 extract. Lanes 1, 2—complete system, as described in Basic Protocol 3; lanes 3, 4—no S-190 extract; lanes 5, 6—no core histones (note residual assembly activity with the endogenous histones of the extract); lanes 7, 8—no ATP; lanes 9, 10—no DNA template.

Analyze micrococcal nuclease ladders

- Resuspend the pellets in 6 μ l gel loading buffer and run on a 1.2% agarose gel in 1 \times TBE buffer. Use 123 bp DNA ladder as a marker. Stain with ethidium bromide (see *UNIT 2.5A* for the reagents and techniques used in this step).

Run the gel at ~5 to 10 V/cm. Running too quickly will cause uneven heating of the gel and tilting of the DNA bands, which will interfere with detection of the bands at the top of the ladder. Running the gel too slowly will cause excessive diffusion of the bands at the bottom of the ladder. The electrophoresis should be terminated when the bromphenol blue dye front reaches the bottom quarter of the gel. Bromphenol blue migrates at ~250 bp DNA size, while the mononucleosome band has a size of ~170 bp. For the best results, stain the gel 15 to 20 min in 2 gel volumes of 0.75 μ g/ml ethidium bromide in distilled water. Do not overstain. Destain the gel for 1 to 3 hr in distilled water with several changes. A ladder of at least 7 to 8 nucleosomal bands, counting from the bottom up, should be apparent. The repeat length should be 165 base pairs or more. An example of the type of results obtained is shown in Figure 21.7.1.

EXPRESSION AND PURIFICATION OF THE RECOMBINANT *DROSOPHILA* ACF

BASIC PROTOCOL 4

Drosophila ACF (ATP-utilizing chromatin assembly and remodeling factor) is prepared by coexpression of carboxyl-terminally FLAG-tagged Acf1 subunit with untagged ISWI subunit in baculovirus. The complex is then purified in one step by FLAG immunoaffinity chromatography and eluted with a buffer containing the FLAG peptide. This procedure typically results in a stoichiometric complex of p185 isoform of Acf1 and ISWI. In a slight alteration of this protocol, it is possible to express and purify the individual FLAG-tagged ISWI subunit.

Materials

High titer Acf1-FLAG and ISWI baculovirus stocks (Orbigen; also see *UNITS 16.9 & 16.10*)

Late log phase Sf9 cells cultured in suspension ($>2 \times 10^6$ cells/ml; also see *UNITS 16.9 & 16.10*)

Phosphate-buffered saline (PBS; *APPENDIX 2*), ice-cold

Lysis buffer F (see recipe)

1:1 (v/v) slurry of FLAG-M2 resin (Sigma-Aldrich), equilibrated in lysis buffer F

Dilution buffer F (see recipe)

Wash buffer F (see recipe)

Elution buffer F (see recipe)

Liquid nitrogen

Bovine serum albumin (BSA) standard, 2 mg/ml (Pierce, Cat. No. 23209)

Clinical centrifuge with swinging-bucket rotor, 4°C

250-ml conical centrifuge bottles appropriate for clinical centrifuge, or 50-ml conical tubes

14- and 50-ml disposable conical centrifuge tubes

15-ml Wheaton dounce homogenizer, "A" pestle

Sorvall Superspeed centrifuge with SS-34 rotor (or equivalent)

15-ml capped polypropylene tubes

Siliconized 1.5-ml polypropylene tubes (e.g., ISC BioExpress, Cat. # C-3302-1)

Additional reagents and equipment for baculovirus culture (*UNITS 16.9 & 16.10*), SDS-PAGE (*UNIT 10.2*), and staining of gels (*UNIT 10.6*)

Infect and harvest Sf9 cells

1. Amplify baculovirus stocks several days before the infection (*UNIT 16.10*).

Viruses are supplied as cell culture supernatants and are to be stored at 4°C. Titers of the original stocks may vary ($1-5 \times 10^8$ pfu per ml; see Orbigen's protocols; <http://www.orbigen.com>). To amplify the viruses, Sf9 cells are plated on 150-mm culture plates at 2×10^7 cells/plate in a total of 25 ml of appropriate serum-containing medium, and infected at multiplicity of infection (MOI) of 0.1 to 0.5 (10 to 20 μ l viral supernatant per plate). To pass a virus stock for storage, allow the infection to proceed for 60 hr and collect the medium supernatant aseptically. For high-titer stock (to be further used for expression infection), the infection is allowed to progress until cell lysis is apparent (~72 hr for His-NAP-1 virus, ~84 hr for ISWI and Acf1-FLAG). This procedure produces viral stocks with titers close to or above 10^9 pfu per ml. The medium is aspirated off the plates aseptically and stored in sterile 50-ml tubes in the dark at 4°C for up to 12 months without significant loss of titer.

2. Grow Sf9 cells (see *UNIT 16.10*) in 150 or 500 ml spinner flasks for 2 to 3 days after seeding at 0.5×10^6 cells/ml. Plate 5 to 25 plates of Sf9 cells at 2.5 to 3×10^7 cells/plate in a total of 25 ml of appropriate insect medium per plate. Allow the cells to settle

for 20 min in the tissue culture hood and infect with recombinant Acf1-FLAG and ISWI baculoviruses at an MOI of 5 to 10 each.

It is not necessary to completely replace the old medium. Typically, equal volumes (0.3 to 0.7 ml) of both high titer virus stocks are used. Occasionally, the ratio of Acf1-FLAG and ISWI viruses has to be adjusted empirically to ensure a proper stoichiometry.

3. At 44 to 46 hr subsequent to infection, aspirate the medium and wash the cells off the plates with 10 ml ice-cold PBS per plate. Centrifuge 5 min at 2000 rpm in a clinical centrifuge in 250-ml conical bottles or 50-ml tubes at 4°C.

Do not exceed the 2-day infection time, since it may result in lower yields and accumulation of complexes with partially degraded Acf1 and ISWI. From this point on, work in a cold room or on ice. Cell pellets can be frozen in liquid nitrogen and stored at -80°C for several weeks before further processing.

4. Resuspend the cell pellet in 8 ml of lysis buffer F and disrupt with a Wheaton Dounce homogenizer ("A" pestle; 3 series of 10 strokes over a 30 min period, on ice).

Cell nuclei are lysed by 500 mM salt. Both nuclei and cytosol are extracted. Cell lysis can be monitored microscopically, if desired. However, the appearance of the cell debris pellet after centrifugation, with distinct yolk and nuclear phases, may serve as an equally good indication of lysis completeness.

Prepare and analyze ACF protein

5. Pellet insoluble material by centrifuging in 14-ml disposable conical tubes 10 min at $14,500 \times g$ (11,000 rpm in an SS-34 rotor), 4°C. Combine the supernatant with 250 μ l of FLAG-M2 resin (as a 1:1 slurry equilibrated in lysis buffer F) and 7 ml dilution buffer F. Mix the slurry on a rocking platform for 3 to 4 hr at 4°C in a 15-ml capped polypropylene tube.

The salt concentration is decreased to allow efficient binding of the FLAG-tag to the M2 antibody.

6. Wash the resin four times, each time with 12 ml wash buffer F by successive cycles of centrifugation for 3 min at 2000 rpm in the clinical centrifuge at 4°C, followed by aspiration and resuspension.

Mix by inverting; avoid vigorous shaking.

7. Elute protein as follows:

- a. Add 100 μ l elution buffer F to resin pellet from step 6 and resuspend.
- b. Transfer resin to a 1.5-ml siliconized microcentrifuge tube.
- c. Incubate on ice 10 min.
- d. Microcentrifuge 30 sec at maximum speed.
- e. Transfer the supernatant to another tube (to be pooled with subsequent elutions).
- f. Continuing in the same siliconized microcentrifuge tube, repeat steps 7a, 7c, 7d, and 7e, three additional times, pooling all of the eluates together.

Insulin is thought to stabilize the recombinant protein at low concentrations.

8. Freeze the protein in liquid nitrogen in small aliquots (20 to 50 μ l) and store at -80°C.

The recombinant ACF is stable for several years and can withstand multiple (5 to 10) freeze-thaw cycles. Prepare and freeze several aliquots of wash buffer F containing 0.4 mg/ml insulin. This solution will be used further as ACF dilution buffer.

9. *Optional*: Estimate protein concentration by SDS-PAGE (UNIT 10.2) along with a range of concentrations of the BSA standard, followed by staining with Coomassie Brilliant Blue R-250 (UNIT 10.6).

Typical yields of ACF are ~5 to 10 µg per 150-mm plate.

EXPRESSION AND PURIFICATION OF THE RECOMBINANT DROSOPHILA NAP-1

**BASIC
PROTOCOL 5**

Sf9 cells are infected with dNAP-1 expressing baculovirus. The chaperone protein is purified by affinity chromatography through a 6-Histidine tag, followed by anion exchange chromatography on Source 15Q resin (Pharmacia).

Materials

Late-log-phase Sf9 cells cultured in suspension ($>2 \times 10^6$ cells/ml; also see UNITS 16.9 & 16.10)

High-titer His-NAP-1 baculovirus stock (Orbigen; also see UNITS 16.9 & 16.10)

Phosphate-buffered saline (PBS; APPENDIX 2), ice-cold

Lysis buffer H (see recipe)

Wash buffer H (see recipe)

Elution buffer H: wash buffer H (see recipe) containing 480 mM imidazole

HEGD buffer containing 0.1 M NaCl (see recipe)

NAP-1 purification buffer (see recipe) containing 0.0, 0.1, and 1.0 M NaCl

Ni-NTA agarose resin (Qiagen)

Bovine serum albumin (BSA) standard, 2 mg/ml (Pierce, Cat. No. 23209)

Source 15Q resin (Amersham Pharmacia Biotech)

20% (v/v) ethanol

8% and 15% SDS-PAGE gels (UNIT 10.2)

Liquid nitrogen

Clinical centrifuge with swinging-bucket rotor, 4°C

250-ml conical centrifuge bottles appropriate for clinical centrifuge

40-ml Wheaton Dounce homogenizer with "A" pestle

Sorvall Superspeed centrifuge with SS34 rotor (or equivalent)

15- and 50-ml conical tubes

End-over-end rotator

12,000 to 15,000 MWCO dialysis tubing

HR-5 or HR-10 FPLC column (Amersham Pharmacia Biotech)

FPLC apparatus

Siliconized 1.5 ml polypropylene tubes (e.g., ISC BioExpress, Cat. # C-3302-1)

Additional reagents and equipment for baculovirus culture and infection (UNITS 16.9-16.11), dialysis (APPENDIX 3C), and SDS-PAGE (UNIT 10.2)

Infect and harvest Sf9 cells

1. Grow Sf9 cells in 500 or 1000 ml spinner flasks to a density $>2.0 \times 10^6$ cells/ml in culture medium (UNIT 16.10). Dilute with the medium to 1.0×10^6 cells/ml. Infect with 25 ml amplified His-NAP-1 virus per 1 liter cell culture.
2. At 72 hr subsequent to infection, collect the cells by spinning 5 min at 2000 rpm in 250 ml conical tubes in a clinical centrifuge at 4°C. Resuspend each pellet in cold PBS (1/10 of the original culture volume). Repeat the centrifugation.

Exercise caution not to discard the cell pellet, which becomes quite loose after washing with PBS. From this point on, all steps should take place on ice or in a cold room, unless otherwise noted. All buffers should be at 4°C unless otherwise noted. Cell pellets can be frozen in liquid nitrogen and stored at -80°C for several weeks before further processing.

**Chromatin
Assembly and
Analysis**

21.7.11

3. Resuspend the cell pellet in lysis buffer H (1/40 original culture volume). Homogenize in a Dounce homogenizer using 40 strokes of the “A” pestle over 30 min. Centrifuge 10 min at $14,500 \times g$ (11,000 rpm in an SS-34 rotor), 4°C. Pool all supernatants in a 50-ml conical tube.

Purify NAP-1 by nickel affinity chromatography

4. Equilibrate 1 ml Ni-NTA agarose resin in lysis buffer H per 500 ml original cell culture volume. Add the cell extract and incubate for 3 to 4 hr on an end-over-end rotator. Pellet the resin by centrifuging 5 min at 2000 rpm in a clinical centrifuge, 4°C. Wash the resin twice with 100 ml lysis buffer H, then twice with 100 ml wash buffer H, resuspending the resin by inverting the tube after each addition of buffer, and pelleting the resin by centrifuging 3 min at 2000 rpm in the clinical centrifuge after each wash.
5. To elute protein, resuspend the resin in 2 ml elution buffer H by gentle vortexing. Incubate on ice for 5 min. Centrifuge 3 min at 2000 rpm in clinical centrifuge, then remove the supernatant to a fresh tube on ice. Repeat this elution cycle three more times, pooling the eluates.
6. Dialyze the eluted NAP-1 twice in 12,000 to 15,000 MWCO tubing, each time for 2 hr against 4 liters HEGD buffer containing 0.1 M NaCl.

General techniques for dialysis are described in APPENDIX 3C. This dialysis step removes phosphate from the buffer.

7. Dialyze for an additional 2 hr against 4 liters NAP-1 purification buffer containing 0.1 M NaCl.

Significant protein precipitation at this step is reduced by complete dialysis in step 6. The dialyzed protein can be frozen in liquid nitrogen and stored at -80°C before further processing.

8. Remove the precipitate by spinning in a 15-ml conical tube at $14,500 \times g$ (11,000 rpm in an SS-34 rotor), 4°C. Analyze the dialyzed NAP-1 by SDS-PAGE (UNIT 10.2) with BSA standard to estimate the amount of protein.

A 14-kDa contaminating Sf9 protein band will be apparent if analyzed on a 15% (or higher) gel. Although dNAP-1 is >95% pure after the affinity chromatography step, the contaminants appear to moderately inhibit chromatin assembly.

Purify NAP-1 to apparent homogeneity by anion-exchange chromatography

9. Using an FPLC, pack Source 15Q resin in an HR-5 or HR-10 column according to the manufacturer’s instructions. Use 1 ml of packed resin per 5 mg of NAP-1 from step 8. Equilibrate the Source 15Q column in 10 column volumes of NAP-1 purification buffer containing 0.1 M NaCl.
10. Load the NAP-1 onto the Source 15Q column. Wash the sample with 10 column volumes of NAP-1 purification buffer containing 0.2 M NaCl. Elute the protein with a 20-column-volume gradient of NAP-1 purification buffer from 0.2 M to 0.5 M NaCl.

NAP-1 should elute in two distinct peaks. The early (lower-salt) peak is inhibitory towards assembly while the later (higher salt) peak is active. The 14-kDa band (see step 8) elutes with the early (inhibitory) peak. Collect fractions of 0.25 to 0.5 column volumes.

11. Run 2 μl of each fraction on 15% SDS-PAGE gel (UNIT 10.2) to identify pure NAP-1-containing fractions. Combine peak fractions and dialyze twice (APPENDIX 3C), each time for 2 hr against 2 liters NAP-1 purification buffer containing 0.1 M NaCl.

A 15% gel will allow visualization of the 14-kDa contaminating band.

- Analyze the dialyzed NAP-1 on an 8% SDS-PAGE gel (UNIT 10.2) along with BSA standard to determine the concentration. Divide the material into 100- to 200- μ l aliquots in 1.5-ml siliconized tubes and freeze in liquid nitrogen. Store at -80°C .

The expected yield of the active NAP-1 fraction is 1 to 3 mg per 1 liter of the cell culture volume.

EXPRESSION AND PURIFICATION OF THE RECOMBINANT *DROSOPHILA* NAP-1 (NTA SUPERFLOW RESIN)

**ALTERNATE
PROTOCOL 1**

If culture volumes are large, it can be helpful to perform the affinity chromatography purification with NTA Superflow resin (Qiagen) on an FPLC, rather than using batch purification on Ni-NTA agarose.

Additional Materials (also see Basic Protocol 5)

NTA Superflow resin (Qiagen)

Superflow chromatography buffer (see recipe) containing 20 mM and 500 mM imidazole

C-10/10 or C-10/20 FPLC column (Amersham Pharmacia Biotech)

- Using an FPLC, pack an NTA Superflow column in 20% ethanol using 1 ml NTA Superflow resin per 500 ml of the original culture volume. Attach column to FPLC apparatus.
- Equilibrate the column with 5 column volumes of Superflow chromatography buffer containing 20 mM imidazole. Load the supernatant from Basic Protocol 5, step 3 onto the column.

If you plan to reuse the column, it may be helpful to briefly spin the extract in an ultracentrifuge 30 min at $80,000 \times g$ (25,000 rpm in an SW-28 rotor), 4°C , in order to reduce the particulate matter being injected on the FPLC column. The injection on the column should be very slow (overnight at 0.05 to 0.1 ml/min). If the flowthrough contains significant amounts of NAP-1, it can be used for an additional round of purification.

- Wash with 5 column volumes of Superflow chromatography buffer containing 20 mM imidazole. Elute the protein with a 10 column volume gradient from 20 mM to 500 mM imidazole in Superflow chromatography buffer.
- Run 5 μ l per fraction on a 15% SDS-PAGE gel (UNIT 10.2) and pool the protein peak. Continue as in Basic Protocol 5, step 6.

A 15% gel will allow visualization of the 14-kDa contaminating band.

CHROMATIN ASSEMBLY WITH PURIFIED RECOMBINANT *DROSOPHILA* FACTORS

**BASIC
PROTOCOL 6**

Core histones are preincubated on ice with NAP-1 to form histone-chaperone complexes. The chromatin assembly reaction is initiated at 27°C by addition of ACF, ATP, and plasmid DNA (circular supercoiled or relaxed, or linear). The extent of chromatin assembly can be monitored by analysis of circular DNA supercoiling, while the “quality” of chromatin is assayed by micrococcal nuclease digest assay.

Materials

HEG buffer (see recipe)

300 mM KCl (store in aliquots of 0.1 to 1 ml at -20°C)

PvOH/PEG solution (see recipe)

2 mg/ml BSA solution (store in aliquots of 0.1 to 1 ml at -20°C)

**Chromatin
Assembly and
Analysis**

21.7.13

0.5 to 4.0 mg/ml recombinant NAP-1 (see Basic Protocol 5)
 0.3 to 2.0 mg/ml purified *Drosophila* core histones, 0.3 to 2.0 mg/ml (see Basic Protocol 2)
 0.5 M ATP (store in aliquots of 0.1 to 1 ml at -20°C)
 0.5 M creatine phosphate (see recipe)
 5 mg/ml creatine kinase (see recipe)
 100 mM MgCl_2 (store in aliquots of 0.1 to 1 ml at -20°C)
 0.3 to 2.0 mg/ml plasmid DNA, double CsCl-purified (*UNIT 1.7*), in TE buffer (*APPENDIX 2*)
 10 \times topoisomerase I buffer (see recipe)
 Recombinant topoisomerase I working solution (see Support Protocol)
 0.002 to 0.2 mg/ml recombinant ACF (see Basic Protocol 4)
 ACF dilution buffer: wash buffer F (see recipe) containing 0.4 mg/ml recombinant human insulin (Roche)
 200 U/ml micrococcal nuclease stock solution (see recipe)
 Buffer R (see recipe)
 10 mM CaCl_2 (store in aliquots of 0.1 to 1 ml at -20°C)
 0.5 M EDTA
 10 mg/ml RNase A
 Glycogen stop buffer (see recipe)
 2.5 mg/ml proteinase K
 50:49:1 (v/v/v) phenol/chloroform/isoamyl alcohol, equilibrated with 10 mM Tris-Cl, pH 8.0 (see *UNIT 2.1A* for equilibration technique)
 2.5 M ammonium acetate
 100% ethanol

 Siliconized 1.5 ml polypropylene tubes (e.g., ISC BioExpress, Cat. # C-3302-1)
 27 $^{\circ}$ and 30 $^{\circ}\text{C}$ water baths

 Additional reagents and equipment for extraction of DNA (*UNIT 2.1A*) and agarose gel electrophoresis (*UNIT 2.5A*)

Prepare master solutions for chromatin assembly

1. Thaw all buffers and proteins.

It is recommended that all buffers be equilibrated to room temperature (for consistent pipetting). Proteins must be quick-thawed (in a room temperature water bath, mixed by tapping or extremely gentle vortexing, and transferred on ice) and quick-frozen (in liquid nitrogen) after use. ACF, NAP-1, core histones, and micrococcal nuclease (but not topoisomerase I or ISWI expressed and purified as an individual polypeptide) can withstand multiple freeze-thaw cycles (up to 10). Small working aliquots of topoisomerase I (which contains 50% glycerol) can be stored for up to 3 months at -20°C without freezing.

2. Prepare the master mix of NAP-1 and core histones (NH) by combining the following in a siliconized 1.5-ml microcentrifuge tube:

172 μl of HEG
 70 μl of 300 mM KCl
 84 μl of PvOH/PEG solution
 4.2 μl of 2 mg/ml BSA
 6.4 μl of 2 mg/ml NAP-1
 3.03 μl of 0.7 mg/ml core histones.

Vortex gently for 2 to 3 sec.

Use siliconized 1.5-ml tubes throughout the protocol. The provided recipe is calculated for six standard reactions, and should be used to perform five or fewer reactions (to allow for imprecise pipetting). A single reaction is calculated to contain 0.353333 μg DNA, 0.353333

μg core histones, 2.12 μg NAP-1, 10 units ACF (0.22 pmol), 1.4 μg BSA in 70 μl of a buffer, containing ~50 mM KCl, 3 mM ATP, and ~5 mM MgCl₂. The final volume of the reaction is made up to 70 μl with HEG. The NAP-1 to core histone mass ratio is 5:1 and should be sufficient to eliminate unbound histones in the reaction. PvOH/PEG and BSA are not obligatory—simply use or do not use them consistently in all assembly experiments. Preparing the master mix for several assembly reactions minimizes pipetting small volumes of core histones. Use a P2 Pipetman (Gilson) to pipet the core histones.

3. Pipet a 56.6-μl aliquot of the NH mix prepared in step 2 (at room temperature) into each of five siliconized 1.5-ml microcentrifuge tubes. Incubate on ice for ≥20 min to allow histone-NAP-1 binding.
4. Prepare the master mix of ATP and Mg²⁺ (AM) by combining 3 μl of 0.5 M ATP with 30 μl of 0.5 M creatine phosphate, 16.5 μl distilled water, and 25 μl 100 mM MgCl₂. Add 0.5 μl 5 mg/ml creatine kinase immediately before use.

The ATP regeneration system (creatine phosphate and creatine kinase) is optional (it is only required for assembly times >2 hr and high ACF concentrations). Keep the mix at room temperature at all times to avoid creatine phosphate precipitation. Discard the thawed aliquots of creatine kinase.

5. Prepare the DNA template by combining:

7.64 μl of plasmid DNA (at 0.42 mg/ml)
2 μl 10× topoisomerase I buffer
2.36 μl recombinant topoisomerase I working solution
8 μl distilled H₂O.

Relax the DNA for 10 min at 30°C; keep at room temperature until ready to use.

Chromatin inhibits DNA relaxation by topoisomerase I. Thus, topoisomerase I in the reaction should be in 5- to 10-fold excess over the amount that is necessary to completely relax the supercoiled plasmid after a 10-min incubation at 30°C. The purified system will efficiently assemble chromatin on linear supercoiled DNA in the absence of the topoisomerase. In the latter case, the template must contain more than 95% supercoiled DNA (achieved by two rounds of CsCl banding).

6. Prepare ACF dilution(s) in ACF dilution buffer (2 to 10 units/μl). Keep on ice.

1 unit of ACF equals 22 fmol of protein.

Assemble chromatin and analyze by micrococcal nuclease assay

7. Start 5 assembly reactions as follows:

- a. To 56.6 μl NH (step 3) add 1 μl ACF (2 to 10 units)
- b. Transfer from ice and equilibrate to room temperature.
- c. Add 10.5 μl AM master mix (step 4) and 2 μl DNA template (relaxed with excess topoisomerase I or supercoiled; step 5). Immediately vortex, gently, for 2 to 3 sec.
- d. Allow the assembly to proceed at 27°C for 1.5 to 2.5 hr.

Mix the reactions by gentle vortexing after adding each component. Microcentrifuge the tubes briefly after vortexing to collect the solution in the bottom of the tube. It is especially important to mix the reactions immediately upon the addition of the DNA template.

8. Immediately before use, prepare two dilutions of micrococcal nuclease in buffer R, 1:500 and 1:1500.

Note the difference in dilution ratios from step 3 of Basic Protocol 3. Micrococcal nuclease digests purified chromatin more efficiently in the absence of inhibitory components within the crude system.

9. Add 17.5 μl 10 mM CaCl_2 to each reaction. Divide each reaction in two equal parts (“a” and “b”). In a controlled manner (at certain time intervals, e.g., 15 sec), add 5 μl of the 1:1500 dilution prepared in step 8 to each “a” tube and 5 μl of the 1:500 dilution to each “b” tube. Allow the digestion to progress for 10 min at room temperature for every tube.

The assembly reaction can also be monitored by the DNA supercoiling assay. Stop one quarter of the 70 μl assembly reaction ($\sim 0.177 \mu\text{g}$ DNA in 17.5 μl) by addition of 3 μl 0.5 M EDTA. Deproteinase and precipitate the DNA as in step 11 below. Run, along with supercoiled and relaxed DNA samples, 1 kbp DNA ladder on a 0.8% agarose, 1 \times TBE gel until the xylene cyanol dye front reaches the bottom third of the gel. Stain and destain with ethidium bromide.

10. Prepare stop solution (ST) by mixing 55 μl of 0.5 M EDTA and 11 μl of 10 mg/ml RNaseA. Stop micrococcal digestions by adding 6 μl ST to each tube and then vortexing. Allow samples to stand 5 min at room temperature to digest contaminating RNA.

From this point on, the reactions do not have to be timed precisely.

11. Prepare proteinase solution (PR) by mixing 1.1 ml glycogen stop buffer and 55 μl of 2.5 mg/ml proteinase K solution. Add 105 μl PR to each tube, then vortex. Digest the histones and soluble proteins at 37°C for ≥ 30 min. Extract with 200 μl of 50:49:1 phenol/chloroform/isoamyl alcohol. Precipitate the DNA with 25 μl of 2.5 M ammonium acetate and 475 μl of 100% ethanol.

Do not wash the pellets with 70% ethanol. UNIT 2.1A describes general techniques for extraction and precipitation of DNA.

12. Perform agarose gel electrophoresis as described (see Basic Protocol 3, step 8, and UNIT 2.5A).

ALTERNATE PROTOCOL 2

TITRATION OF THE RATIO OF CORE HISTONES TO DNA IN THE RECOMBINANT CHROMATIN ASSEMBLY REACTION

For every new plasmid DNA and core histone preparation, the optimal core histone to DNA ratio should be determined experimentally.

For materials, see Basic Protocol 6

1. Proceed as in Basic Protocol 6, steps 1 to 6.

As an approximation for actual concentrations, use the DNA concentration as calculated from A_{260} and the histone concentration as determined by the BCA assay.

2. Start 5 assembly reactions as follows:

- a. To 56.6 μl NH (see Basic Protocol 6, step 3) add 1 μl ACF (2 to 10 units)
- b. Transfer from ice and equilibrate to room temperature.
- c. Add 10.5 μl AM master mix (see Basic Protocol 6, step 4) and 2.5, 2.22, 2.0, 1.82, or 1.67 μl DNA template (relaxed with excess topoisomerase I or supercoiled; see Basic Protocol 6, step 5). Immediately after adding DNA, vortex each tube gently for 2 to 3 sec.
- d. Allow the assembly to proceed at 27°C for 1.5 to 2.5 hr.

The assumed histone to DNA mass ratios in these reactions are 0.8:1, 0.9:1, 1:1, 1.1:1, and 1.2:1, respectively. Use a P2 Pipetman (Gilson) to pipet the DNA solution.

3. Proceed as in steps 8 to 12 of Basic Protocol 6.

Figure 21.7.2 Chromatin assembly in the recombinant system. The reactions were performed as described in Alternate Protocol 2. The core histone to DNA ratios were initially estimated as: lanes 1, 2—0.8:1; lanes 3, 4—0.9:1; lanes 5, 6—1.0:1; lanes 7, 8—1.1:1; lanes 9, 10—1.2:1.

4. From the gel, determine the highest histone-to-DNA mass ratio that still results in an unsmeared ladder (lanes 5, 6 in Fig. 21.7.2, 1.0:1 estimated ratio).

The next lowest ratio (i.e., 0.9:1 as in lanes 3, 4 of Fig. 21.7.2) is postulated to be the optimal ratio for further chromatin assembly experiments. The effective concentration of the core histones is recalculated so that the new calculated optimal ratio is set to 1.0:1.

For instance, for the experiment in Figure 21.7.2, the original (estimated) histone concentration is multiplied 1.111 times. Thus the histone to DNA ratio in lanes 3, 4 calculated from the new (effective) histone concentration is 1.0:1.

EXPRESSION AND PURIFICATION OF THE CORE CATALYTIC DOMAIN OF THE *DROSOPHILA* TOPOISOMERASE I

The smallest active N-terminal truncation (Shaiu and Hsieh, 1998) of the *Drosophila* topoisomerase I was cloned into pET-28a expression vector (Novagen) from a cDNA that was kindly provided by Tao-shih Hsieh at Duke University. The coding sequence was subcloned into *NcoI/XhoI* restriction sites in frame with the C-terminal 6-His tag. The construct is referred to as pET-NDH6; the protein is referred to as ND423.

SUPPORT PROTOCOL

Chromatin Assembly and Analysis

21.7.17

Materials

Competent BL21(DE3) bacteria (Novagen)
PET-NDH6 plasmid (available on request from Dmitry Fyodorov;
fyodorov@ucsd.edu)
LB plates and medium (UNIT 1.1) containing 50 µg/ml kanamycin (add from 10
mg/ml kanamycin stock)
100 mM IPTG
Liquid nitrogen
Lysis buffer T (see recipe)
Ni-NTA resin (Qiagen)
Elution buffer T: lysis buffer T containing 0.5 M imidazole
Dialysis buffer T (see recipe)
Storage buffer T (see recipe)
8% SDS-PAGE gel (UNIT 10.2)
Bovine serum albumin (BSA) standard, 2 mg/ml (Pierce, Cat. No. 23209)
0.8% agarose gel (UNIT 2.5A)
10× topoisomerase I buffer (see recipe)

Sorvall Superspeed centrifuge with GSA and SS-34 rotors (or equivalents)
Microtip sonicator (e.g., Branson Sonifier 450; VWR Scientific)
10-ml polypropylene chromatography column
0.5 to 3.0 ml Slide-A-Lyzer, 10,000 MWCO (Pierce)

Additional reagents and equipment for transformation of bacteria (UNIT 1.8), growth
of bacteria in solid (UNIT 1.3) and liquid (UNIT 1.2) media, SDS-PAGE (UNIT 10.2),
and agarose gel electrophoresis (UNIT 2.5A)

Express ND423 in *E. coli*

1. Transform BL21(DE3) cells with pET-NDH6. Plate on LB plates containing 50 µg/ml kanamycin; incubate overnight at 37°C.

Transformation is performed immediately prior to the expression.

2. Pick one average size colony into 0.5 liter LB medium (containing 50 µg/ml kanamycin) and grow while shaking at 37°C for 6 to 8 hr. At a bacterial density equivalent to $A_{600} \sim 0.5$, induce by adding 100 mM IPTG to a final concentration of 0.42 mM.
3. Incubate while shaking at 30°C for 5 hr. Harvest the cells by centrifugation for 10 min at $8500 \times g$ (7000 rpm in a GSA rotor), 4°C.

Note the temperature change from 37° to 30°C in this incubation.

4. Freeze the cell pellets in liquid nitrogen.

The pellets can be stored at -80°C overnight, if desired.

Extract soluble bacterial proteins and isolate ND423 by affinity chromatography

5. Thaw and resuspend the cell pellets in 10 to 20 ml lysis buffer T (20 to 40 ml per 1 liter of original culture). Freeze again in liquid nitrogen and thaw in a water bath at room temperature.
6. Sonicate on ice with a microtip with 4 burst of 30 sec at a setting of “6.5.” Centrifuge the lysate in 40 ml polycarbonate tubes for 10 min at $19,000 \times g$ (16,000 rpm in an SS-34 rotor), 4°C.
7. Equilibrate 2 ml Ni-NTA resin with the lysis buffer T. Mix and incubate the cell lysate with the resin for 3 hr in the cold room on a rocking platform.

8. Load the resin onto a disposable 10-ml polypropylene column by gravity flow (in a cold room). Wash 3 times with 10 ml of cold lysis buffer T. Elute three times, each time with 1 ml elution buffer, discarding the void volume (the first 350 μ l).
9. Dialyze in a 10,000 MWCO Slide-A-Lyzer against 2 liters dialysis buffer T for 2 hr at 4°C. Dialyze again against 1 liter storage buffer T for 2 hr at 4°C, then freeze in 100- μ l aliquots in liquid nitrogen. Store at -80°C. Determine the concentration by visualizing on an 8% SDS-PAGE gel (UNIT 10.2) along with the BSA mass standard.

The typical yield is 1.5 to 2.0 mg protein in 1.0 to 1.2 ml.

Prepare the working stock of topoisomerase I and assay the enzymatic activity

10. Prepare the working solution by 100-fold dilution in storage buffer T containing 0.2 mg/ml human recombinant insulin (add from 50 mg/ml stock). Upon dilution, store in 100- μ l aliquots at -80°C. Keep one aliquot at -20°C for daily use.
11. Assay the activity of the protein by relaxing 0.5 μ g supercoiled plasmid DNA with different dilutions of the enzyme. Run on a 0.8% agarose gel; stain with ethidium bromide and destain (UNIT 2.5A).

1 μ l of the working stock should completely relax ~10 μ g of 3 kbp plasmid in a 100- μ l reaction in 1 \times topoisomerase buffer after 10 min incubation at 30°C.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

ATP mix

300 mM creatine phosphate
30 mM ATP
10 μ g/ml creatine kinase
Store up to 2 years at -80°C

Buffer A

15 mM Tris-Cl, pH 7.5 (APPENDIX 2)
15 mM NaCl
60 mM KCl
0.34 M sucrose
0.1% (v/v) 2-mercaptoethanol
Store solution with above components up to 24 hr at 4°C
0.5 mM spermidine (add immediately prior to use)
0.15 mM spermine (add immediately prior to use)
0.25 mM PMSF (add immediately prior to use)

Buffer B

To buffer A (see recipe above), add:
2 mM EDTA
0.5 mM EGTA
Store up to 24 hr at 4°C

Buffer R

10 mM potassium HEPES, pH 7.6
10 mM KCl
1.5 mM MgCl₂
0.5 mM EGTA

continued

10% (v/v) glycerol
Store solution with above components up to 24 hr at 4°C
10 mM β -glycerophosphate (add immediately prior to use)
1 mM DTT (add immediately prior to use)
0.2 mM PMSF (add immediately prior to use)
Aliquots of 0.1 to 1 ml can be stored at -20°C for up to 2 years.

Core histone storage buffer

10 mM potassium HEPES, pH 7.6
1 mM EDTA
10 mM KCl
10% (v/v) glycerol
Store solution with above components up to 24 hr at 4°C
1 mM DTT (add immediately prior to use)

Creatine kinase solution

5 mg/ml creatine kinase (Sigma-Aldrich)
10 mM potassium phosphate, pH 7.0 (*APPENDIX 2*)
50 mM NaCl
50% (v/v) glycerol
Store in 5- to 10- μ l aliquots up to 2 years at -80°C

Creatine phosphate, 0.5 M

106 mg/ml creatine phosphate (phosphocreatine)
20 mM potassium HEPES, pH 7.6
Adjust pH to 7.0
Store in aliquots of 0.1 to 1 ml up to 2 years at -20°C

Dialysis buffer T

HEG buffer (see recipe below) containing:
50 mM NaCl
0.01% NP-40
Store solution with above components up to 24 hr at 4°C
0.5 mM DTT (add immediately prior to use)
0.2 mM PMSF (add immediately prior to use)
0.5 mM benzamidine (add immediately prior to use)
5 mM Na₂S₂O₅ (add immediately prior to use)

Dilution buffer F

20 mM Tris-Cl, pH 7.9 (*APPENDIX 2*)
10% (v/v) glycerol
0.02% (v/v) NP-40
Store up to 24 hr at 4°C

Elution buffer F

Wash buffer F (see recipe below) containing:
0.4 mg/ml FLAG peptide (Sigma-Aldrich)
0.4 mg/ml recombinant human insulin (Roche)
Use immediately
Add FLAG peptide from 10 mg/ml stock in STE buffer and add insulin from 50 mg/ml stock in TE buffer (see *APPENDIX 2* for buffers).
Store stock solution of FLAG peptide in 20- μ l aliquots up to 2 years at -80°C. Store insulin stock solution up to 1 year at 4°C.

Glycogen stop buffer

20 mM EDTA
0.2 M NaCl
1% (w/v) SDS
0.25 mg/ml glycogen
Store up to 2 years at room temperature

HA chromatography buffer

40 mM sodium phosphate, pH 6.8 (*APPENDIX 2*)
0, 0.35, or 2.5 M NaCl
Store solution with above components up to 24 hr at 4°C
1 mM DTT (add immediately prior to use)
0.2 mM PMSF (add immediately prior to use)

HEG buffer

25 mM potassium HEPES, pH 7.6
0.1 mM EDTA
10% (v/v) glycerol
Store in aliquots of 0.1 to 1 ml up to 2 years at -20°C

HEGD buffer with 0.1 M NaCl

25 mM potassium HEPES, pH 7.6
1 mM EDTA
10% (v/v) glycerol
0.1 M NaCl
0.01% (v/v) NP-40
Store solution with above components up to 24 hr at 4°C
1 mM DTT (add immediately prior to use)
0.2 mM PMSF (add immediately prior to use)
10 mM β -glycerophosphate (add immediately prior to use)

Lysis buffer F

20 mM Tris-Cl, pH 7.9 (*APPENDIX 2*)
500 mM NaCl
20% (v/v) glycerol
4 mM MgCl₂
0.4 mM EDTA
Store solution with above components up to 24 hr at 4°C
2 mM DTT (add immediately prior to use)
20 mM β -glycerophosphate (add immediately prior to use)
0.4 mM PMSF (add immediately prior to use)
1 mM benzamidine hydrochloride (add immediately prior to use)
4 μ g/ml leupeptin (add immediately prior to use)
2 μ g/ml aprotinin (add immediately prior to use)

Lysis buffer H

50 mM sodium phosphate, pH 7.6 (*APPENDIX 2*)
0.5 M NaCl
15% (v/v) glycerol
20 mM imidazole
0.01% (v/v) NP-40
Store solution with above components up to 24 hr at 4°C
10 mM β -glycerophosphate (add immediately prior to use)
0.2 mM PMSF (add immediately prior to use)
0.5 mM benzamidine (add immediately prior to use)

Lysis buffer T

50 mM sodium phosphate, pH 7.0 (*APPENDIX 2*)
0.5 M NaCl
15% (v/v) glycerol
15 mM imidazole
0.1% (v/v) NP-40
Store solution with above components up to 24 hr at 4°C
0.2 mM PMSF (add immediately prior to use)
0.5 mM benzamidine (add immediately prior to use)
10 mM Na₂S₂O₅ (add immediately prior to use)

Micrococcal nuclease stock solution, 200 U/ml

1.56 mg/ml (200 U/ml) micrococcal nuclease (Sigma-Aldrich)
5 mM sodium phosphate, pH 7.0 (*APPENDIX 2*)
2.5 μM CaCl₂
Store in aliquots of 0.1 to 1 ml up to 1 year at -20°C

NAP-1 purification buffer

Buffer R (see recipe above) containing:
0.0, 0.1, or 1.0 M NaCl (add from 5 M NaCl stock or as solid NaCl)
0.01% NP-40 (add from 10% v/v stock)
Store up to 24 hr at 2°C

PvOH/PEG solution

HEG buffer (see recipe above) containing:
5% polyvinyl alcohol (mol. wt. 10,000, Sigma-Aldrich P-8136)
5% polyethylene glycol (mol. wt. 8,000, Sigma-Aldrich P-2139)
Store in aliquots of 0.1 to 1 ml up to 2 years at -20°C

Storage buffer T

10 mM potassium HEPES, pH 7.6
0.1 mM EDTA
50 mM NaCl
0.01% (v/v) NP-40
50% (v/v) glycerol
Store solution with above components up to 24 hr at 4°C
10 mM β-mercaptoethanol (add immediately prior to use)
0.2 mM PMSF (add immediately prior to use)
1 mM benzamidine (add immediately prior to use)
1 μg/ml leupeptin (add immediately prior to use)

Sucrose gradients, 5% to 30%

10 mM potassium HEPES, pH 7.6
1 mM EDTA
0.5 M NaCl
5% or 30% (w/v) sucrose
0.02% (w/v) NaN₃
Store solution with above components up to 1 year at 4°C
0.2 mM PMSF (add immediately prior to use)
Use a gradient maker to prepare 5% to 30% sucrose gradients in SW 28 ultracentrifuge tubes

Superflow chromatography buffer

50 mM sodium phosphate, pH 7.6 (*APPENDIX 2*)
500 mM NaCl
15% (v/v) glycerol
0.01% (v/v) NP-40
Store solution with above components up to 24 hr at 4°C
10 mM β -glycerophosphate (add immediately prior to use)
0.2 mM PMSF (add immediately prior to use)
0.5 mM benzamidine (add immediately prior to use)
2 μ g/ml leupeptin (add immediately prior to use)
2 μ g/ml aprotinin (add immediately prior to use)

Topoisomerase I buffer, 10 \times

0.5 M Tris·Cl, pH 7.5 (*APPENDIX 2*)
100 mM MgCl₂
1 mM EDTA
0.5 mg/ml BSA
5 mM DTT
Store in aliquots of 0.1 to 1 ml up to 2 years at -20°C

Wash buffer F

20 mM Tris·Cl, pH 7.9 (*APPENDIX 2*)
150 mM NaCl
15% (v/v) glycerol
2 mM MgCl₂
0.2 mM EDTA
0.01% (v/v) NP-40
Store solution with above components up to 24 hr at 4°C
1 mM DTT (add immediately prior to use)
10 mM β -glycerophosphate (add immediately prior to use)
0.2 mM PMSF (add immediately prior to use)
0.5 mM benzamidine-HCl (add immediately prior to use)
2 μ g/ml leupeptin (add immediately prior to use)
1 μ g/ml aprotinin (add immediately prior to use)

Wash buffer H

50 mM sodium phosphate, pH 7.6 (*APPENDIX 2*)
100 mM NaCl
20 mM imidazole
15% glycerol (v/v)
0.01% NP-40 (v/v)
Store solution with above components up to 24 hr at 4°C
10 mM β -glycerophosphate (add immediately prior to use)
0.2 mM PMSF (add immediately prior to use)
0.5 mM benzamidine (add immediately prior to use)

COMMENTARY

Background Information

Several procedures to assemble nucleosome arrays on circular or linear DNA in vitro have been developed (reviewed in Ito et al., 1997a). Some of these procedures employ a histone transfer process with a histone transfer vehicle (histone-binding proteins, polyglutamic acid,

RNA, or high salt concentration; *UNIT 21.6*). They yield well-defined templates, yet the nucleosomes are irregularly distributed and lack the periodicity of bulk native chromatin. The second type of these procedures utilizes crude cell extracts and yields extended periodic arrays of nucleosomes. This reaction was

achieved with cytosolic extracts from *Xenopus* oocytes (Glikin et al., 1984), HeLa cells (Banerjee and Cantor, 1990), or *Drosophila* embryos (Becker and Wu, 1992; Bulger and Kadonaga, 1994). The third type of chromatin assembly procedure is the assembly during viral DNA replication (Stillman, 1986). In this reaction, crude cell extracts (from human 293 cells) are complemented by SV40 T antigen helicase and histone chaperones CAF-1 and RCAF (Tyler et al., 1999) to achieve chromatin assembly of the newly replicated SV40 DNA.

The early realization that chromatin assembly in crude cell extracts is an ATP-dependent process has triggered the quest to purify individual protein factors that could mediate this reaction. Fractionation of *Drosophila* extracts resulted in purification of two essential assembly components, a histone chaperone NAP-1 (Bulger et al., 1995) and a SWI/SNF-like chromatin remodeling factor, ACF (Ito et al., 1997b). This work was supported by the NIH grant GM58272 to James T. Kadonaga at University of California, San Diego. ACF consists of two subunits, a SWI2/SNF2-related ATPase ISWI (p140) and a subunit termed Acf1 (p170 and p185). The chromatin assembly reaction can be reconstituted in a purified recombinant system that contains plasmid DNA, purified native or recombinant histones, recombinant NAP-1, recombinant ACF, and ATP (Ito et al., 1999; Levenstein and Kadonaga, 2002). This system combines the advantages of histone transfer procedures (well-defined reaction products) with the advantages of ATP-dependent crude extract assembly procedures (nucleosome array regularity similar to that of the native bulk chromatin).

The pair of cofactors (an ATP-dependent remodeling factor and a histone chaperone) is likely to represent the minimal required reaction system that assembles physiologically relevant chromatin. The histone chaperone NAP-1 is necessary to prevent rapid nonspecific histone-DNA aggregation and to present histones to ACF. Consistent with its role as a molecular sink that sequesters positively charged histones, NAP-1 has to be present at 1:1 or higher stoichiometry with respect to core histone polypeptides. Although NAP-1 has a higher affinity to H2A/H2B dimers, it also binds to H3/H4 tetramers and can facilitate the assembly of nucleosomes from dimers and tetramers. On the other hand, ACF performs multiple functions: core histone deposition on the DNA, establishing proper histone-DNA contacts in the nucleosome, and spacing nu-

cleosome arrays. All these tasks are carried out catalytically (substoichiometric relative to the core histones) and at the expenditure of ATP hydrolysis by ISWI.

Although histone chaperones (and specifically NAP-1) have been reported to mediate nucleosome assembly with supercoiled plasmid DNA, it is important to note that they do not deposit histones efficiently on relaxed DNA templates. Furthermore, electron microscopy of “chromatin” assembled by NAP-1 alone reveals that it is composed of large histone-DNA particles that are not canonical nucleosomes (Nakagawa et al., 2001). Finally, the replication-dependent chromatin assembly of the SV40 DNA by CAF-1 and RCAF histone chaperones may also be mediated by an ATP-dependent chromatin remodeling complex that is present in the 293 cell extract.

Critical Parameters and Troubleshooting

S-190 extract

A concentrated extract, stemming from a high ratio of embryos to buffer R, tends to be a highly active extract. Aspirating buffers too cautiously to prevent the loss of embryo material may result in a dilute extract. This can lead to low quality of assembly or require the S-190 to assume a significant portion of the reaction volume. Homogenizing embryos in a Dounce homogenizer generates sizeable resistance on down strokes as well as considerable back-pressure on up strokes. Be careful not to lose grip of the pestle during homogenization, or else the vessel may break and the embryos may be lost in the ice bucket. Be certain to use full strokes in order to homogenize all embryos. Between the first and second spins in the ultracentrifuge, the S-190 extract should be frozen in liquid nitrogen and then thawed in a room-temperature water bath. This step presumably precipitates unwanted materials and improves the activity of the assembly extract.

Core histone purification

When isolating the nuclei, the yellow yolk protein is undesirable. It will form a tight pellet at the bottom of the tube. A Pasteur pipet can be used to carefully separate the loose nuclear pellet from the yolk before resuspending. The addition of 5 M NaCl to the nuclear suspension (step 13) may not result in obvious lysis. Continue to the next step under the assumption that the lysis was successful. When selecting fractions from the sucrose gradient, avoid those

containing histone H1. H1 will be a significant band at ~40 kDa. Dialyzing the sucrose gradient fractions will result in significant swelling within the dialysis tubing. Take this into consideration when cutting the tubing size and consider using double clips to avoid mishaps. Hydroxylapatite resin crushes easily and needs to be run on the FPLC at low pressure. If the core histone volume is large, this is a good opportunity to inject the sample overnight at a very slow flow rate (0.1 ml/min or less). As an alternative to crystalline hydroxylapatite, ceramic hydroxylapatite resin is now available from Bio-Rad Laboratories (CHT Type I Ceramic Hydroxylapatite). This resin performs well at higher pressures and yields otherwise equivalent results.

S-190 chromatin assembly

Three key parameters tend to influence assembly with the S-190 extract: (1) the proportion of the extract in the reaction volume, (2) the Mg^{2+} concentration, and (3) the ratio of core histones to DNA. Variations among extracts result in a range of adequate S-190 proportions, typically falling between 25% to 40% of the reaction volume. The most desirable percentage should be determined for each extract. The optimal Mg^{2+} concentration lies between 3.5 and 7 mM. This should also be determined for each extract. The ratio of histones to DNA is affected by the volume of the S-190 used. The S-190 extract contains a residual pool of core histones (in the realm of 20% to 30% required for assembly). Typically, a 0.8:1 mass ratio yields high quality chromatin (as assayed by partial micrococcal nuclease digestion), but this ratio can be examined from 0.6:1 to 1.2:1. If low-quality agarose is used for gel electrophoresis, ladders can appear “smeared.” SeaKem LE agarose (BioWhittaker) is suggested. Complete destaining can significantly improve the appearance of nucleosomal ladders, especially those at the top of the ladder.

Purification of recombinant ACF and NAP-1

Lysing of the Sf9 cells must be thorough and complete. Low yield is likely to be a direct result of incomplete lysis. Sonication can be used in place of homogenization on the Dounce homogenizer to disrupt Sf9 cells (2 to 3 bursts of 30 sec with a microtip, on ice). The resulting extract will be cruder, and thus the affinity resins should be washed more thoroughly after the protein binding step.

Typically, purified ACF will contain equimolar amounts of p185 (Acf1-FLAG) and p140 (ISWI). However, ACF complexes with substoichiometric ISWI will also be suitable for most chromatin assembly applications. Calculate ACF molar concentration based on the concentration of the ISWI subunit. After affinity chromatography, the dNAP-1 protein is often more than 95% pure but performs poorly in assembly reactions. At this stage, it exists as a mixture of pure active NAP-1 multimers and an inhibitory NAP-1 fraction, which is contaminated with a 14-kDa Sf9 protein. It is therefore critical to perform the anion-exchange chromatography to separate active NAP-1 from this inhibitory species.

Recombinant chromatin assembly

The purified system performance is relatively harder to fine-tune than the S-190 based system. While the success in the latter is determined primarily by the quality of the extract, the purified system requires more extensive optimization of reaction parameters to achieve the best performance. The single most critical parameter in the reaction is the ratio of core histones and template DNA. Variations as low as 5% to 10% can inhibit the reaction or result in lower-quality chromatin as evidenced by the micrococcal digest analysis. Standard methods to determine DNA and protein concentrations (spectrophotometric, colorimetric) are almost never accurate enough to establish the correct histone-to-DNA ratio. Thus, it has to be determined experimentally for every pair of DNA and histone preparations. Alternate Protocol 2 provides an idea of such a titration experiment. The range and the step of this titration can be expanded, if necessary. In general, low histone content results in short ladders (2 or 3 apparent nucleosome bands at the bottom) and large nucleosome repeat (180 bp and longer). Excessive histone concentration will completely inhibit the reaction and result in histone-DNA aggregates that will not be efficiently digested by the micrococcal nuclease (see Fig. 21.7.2).

The assembly reaction is much less sensitive to the concentration of NAP-1. It should be noted, however, that it is safer to add an excess of the chaperone. If the mass ratio of NAP-1 to core histones drops below 3.8 to 4, the extra free histones that are present in the solution can form histone-DNA aggregates, which cannot serve as a substrate for ACF. The assembly reaction is tolerant to over an order of magnitude variation in ACF concentration. ACF will

assemble chromatin within a range of concentrations from 0.05 to 1 ACF protomers per 1 kbp DNA. It is recommended that the reaction be first optimized for a short plasmid template (3 kbp or less) before attempting to assemble chromatin on larger templates.

Chromatin may be purified after the assembly by gel filtration or sucrose gradient centrifugation. However, unpurified chromatin templates perform equally well in transcription assays. Several components of the assembly reaction are semi-optional. They include PvOH/PEG, BSA, ATP regeneration system, and topoisomerase I (if the DNA template is predominantly supercoiled). The reactions can be formulated and optimized accordingly (the changes will alter other reaction parameters, such as the optimal histone to DNA and NAP-1 to histone ratios). The suggested reaction conditions and micrococcal dilutions will produce nucleosome ladders with an apparent repeat length of ~165 bp. The nucleosomes can be packed more loosely or more tightly (down to 145 bp repeat length) by varying KCl concentration and the amount of histones in the assembly reaction. Tighter packed nucleosomes will require higher micrococcal concentration to be comparably digested. The purified system appears insensitive to histone modification states: it assembles chromatin equally well with purified native or unmodified bacterially expressed *Drosophila* core histones (Levenstein and Kadonaga, 2002). Moreover, the system does not exhibit specificity towards *Drosophila* core histones and can assemble chromatin with histones purified from other species.

Anticipated Results

Both ATP-dependent chromatin assembly systems described here can provide chromatin substrates for use in studies of chromatin structure, transcription, and DNA metabolism. Micrococcal nuclease analysis of the reaction products should reveal highly periodic nucleosome arrays. A DNA-binding transcription factor, when added to the assembly reaction, can position nucleosomes with respect to its binding sites. The number of negative supercoils in the assembled DNA (for circular plasmid DNA templates) can be estimated by one- or two-dimensional supercoiling analyses and may be used as a measure of the nucleosome content of the assembled minichromosomes. The assembled chromatin should migrate differently and can be separated from the unassembled DNA on sucrose gradients.

Time Considerations

Allow 2 days each for core histone purification and preparation of the S-190 extract. S-190 mediated chromatin assembly is extremely reproducible and does not require extensive troubleshooting. Typically, chromatin is assembled, then digested with micrococcal nuclease (6 to 7 hr) and analyzed by electrophoresis on the next day (3 to 4 hr). Allow 3 to 5 days for baculovirus amplification and 2 to 3 days for infection of Sf9 cells before harvesting. The recombinant ACF prep takes 1 day, and the NAP-1 prep takes 2 days. Recombinant chromatin assembly may require several pilot experiments to optimize concentrations of the components. Many researchers have reported that the quality of chromatin assembly in the recombinant system improves significantly after several trials.

Acknowledgments

The studies of the *Drosophila* chromatin assembly factors were supported by the NIH grant GM58272 to James T. Kadonaga. We thank Dr. Kadonaga for critical reading of the manuscript.

Analysis of Protein Co-Occupancy by Quantitative Sequential Chromatin Immunoprecipitation

UNIT 21.8

**BASIC
PROTOCOL**

Chromatin immunoprecipitation (ChIP; UNIT 21.3) is a widely used and powerful method for assaying individual protein-DNA interactions *in vivo*. As discussed earlier in this chapter (UNIT 21.3), ChIP experiments provide quantitative information about the relative level of binding of a given protein or proteins to different genomic regions. However, what standard ChIP experiments do not address is whether two proteins can simultaneously co-occupy a specific genomic region. For example, with conventional ChIP, the observation that two proteins associate with a given genomic region might reflect co-occupancy, or, alternatively, it might indicate that the two proteins associate with different populations of DNA molecules in a mutually exclusive fashion. There is simply no way to determine the extent to which (either positively or negatively) any two proteins influence one another when it comes to binding to the specific fragment in question via conventional ChIP.

Sequential chromatin immunoprecipitation (SeqChIP), on the other hand, is a powerful tool to address precisely this type of question: do two proteins simultaneously co-occupy a specific DNA region *in vivo*? In SeqChIP, protein-DNA complexes from the first ChIP are subjected to an additional immunoprecipitation with an antibody of a different specificity, typically to a second protein that is tested for its ability to co-occupy with the initially immunoprecipitated protein. The cross-links of these doubly immunoprecipitated protein-DNA complexes are then reversed, and the DNAs are analyzed by quantitative PCR in a manner analogous to conventional ChIP samples (see UNIT 21.3, Alternate Protocol 2). Occupancy values for both single and double immunoprecipitations are first calculated and then compared for any enrichment brought about by the second immunoprecipitation relative to the singly immunoprecipitated sample. While the following protocol has been successfully developed for and used with *Saccharomyces cerevisiae* samples, it is sufficiently general that it should be applicable for other species with minor modifications.

Materials

100 mg/ml bovine serum albumin (BSA, Fraction V; Sigma) in water (store at -20°C)

500 $\mu\text{g/ml}$ λ phage DNA (not sheared; New England Biolabs)

10 mg/ml *E. coli* tRNA in water (store at -20°C)

20 mg/ml glycogen, or Pellet Paint (Novagen) as DNA carrier

Additional reagents and equipment for ChIP (UNIT 21.3, Basic Protocol), growth of *Saccharomyces cerevisiae* (UNITS 13.1 & 13.2), extraction and purification of DNA (UNIT 2.1A), and real-time quantitative PCR (UNIT 21.3, Alternate Protocol 2)

Cross-link protein-DNA complexes *in vivo*

1. For each sample, grow 400 ml *Saccharomyces cerevisiae* to $\text{OD}_{600} = 0.6$ to 0.8 (UNITS 13.1 & 13.2).

It is necessary to use more extract for sequential immunoprecipitations (80 to 100 ml cells) than for conventional samples (20 to 40 ml cells) in order to ensure that enough material remains after the first immunoprecipitation to generate a reproducible signal following the second immunoprecipitation. The actual amount of extract required for this purpose depends on a number of factors, including cross-linking efficiency and protein

**Chromatin
Assembly and
Analysis**

21.8.1

abundance, and may have to be adjusted accordingly. This protocol doubles the culture volume (400 ml) used as compared to the single ChIP protocol (200 ml); consequently, it is helpful to split the cultures into the equivalent of two 200-ml samples for the cell lysis and sonication steps.

2. Add 11 ml of 37% formaldehyde (1% final). Cross-link for 20 min at room temperature by occasionally swirling flask or shaking slowly on a platform.
3. Add 60 ml heat-sterilized 2.5 M glycine and incubate an additional 5 min at room temperature.

Glycine stops the cross-linking by reacting with formaldehyde.

4. Split the cultures into two equal 200-ml samples and harvest cells, isolate chromatin, and shear the DNA fragments exactly as described in UNIT 21.3, Basic Protocol, steps 4 to 13.
5. Microcentrifuge 30 min at maximum speed, 4°C. Transfer the supernatants into a fresh 15-ml disposable conical tube, adjust the total sample volume to ~4.5 ml with ice-cold FA lysis buffer, and gently mix by inversion. Remove 250 µl to check DNA fragment size (see UNIT 21.3, Basic Protocol, steps 15 and 16) and freeze the remaining chromatin solution in 1-ml aliquots in liquid nitrogen up to 1 year.

Perform first immunoprecipitation

6. Incubate 1 ml chromatin solution with 20 µl primary antibody against the protein or epitope of interest and 20 µl of 50% (v/v) protein A–Sepharose beads in TBS, on an end-over-end rotator for 90 min at room temperature.

The amount of antibody used is double that in the Basic Protocol of UNIT 21.3, to reflect the increased amount of protein in the SeqChIP extract. As with conventional ChIP, the optimal amount of antibody will vary with each antigen and has to be empirically determined.

Sequential immunoprecipitations should normally be performed in both the forward and reverse directions to be able to analyze results in a quantitative fashion and to unambiguously determine the extent of co-occupancy between two proteins (see Anticipated Results).

7. Microcentrifuge beads 1 min at 3000 rpm, room temperature. Transfer 100 µl supernatant into a 0.5-ml PCR tube labeled “INPUT.” Discard the rest of the liquid.
8. Resuspend beads by pipetting up and down in 700 µl FA lysis buffer, room temperature, and transfer mixture into a Spin-X centrifuge-tube filter.

The use of Spin-X filters aids in the recovery of the beads after washes and results in better uniformity between different samples. The procedure is also substantially faster with the filters, particularly when multiple samples are processed simultaneously. Alternatively, one could use conventional microcentrifuge tubes for the washes and aspirate the supernatant with a narrow-bore pipet tip after each spin.

9. Place the filter into a 1.5-ml microcentrifuge tube and mix sample 3 min on an end-over-end rotator. Microcentrifuge 2 min at 3000 rpm, room temperature. Discard the flowthrough liquid at the bottom of the tube.
10. Add 700 µl FA lysis buffer, room temperature, to the beads and repeat step 9 two additional times.

Elute protein from beads

11. Wash beads for 3 min each with 700 µl FA lysis buffer/0.5 M NaCl, 700 µl ChIP wash buffer, and finally 700 µl TE buffer.

For many polyclonal antibodies, the more stringent washes in this step result in a cleaner signal, while gentle washes frequently lead to an unacceptably high background. For some

antibodies (e.g., monoclonal against peptide epitopes; see UNIT 21.3, Alternate Protocol 1), repeated washes with FA lysis buffer, which are gentler, might be more appropriate. Consult UNIT 21.3 for more information.

- Place filter unit containing the beads into a new 1.5-ml microcentrifuge tube and add 100 μ l of ChIP elution buffer. Gently pipet up and down two or three times to dislodge beads from the filter. Incubate 10 min in a 65°C water bath.

A water bath is used instead of other heating apparatuses to improve heat transfer.

- Microcentrifuge beads 2 min at 3000 rpm, room temperature. Discard filter with beads. Transfer 9 μ l (out of 100 μ l) of the eluate into a 0.5-ml PCR tube labeled “1st IP.”

Perform second immunoprecipitation

- Add 775 μ l FA lysis buffer (without SDS), 50 μ l of 100 mg/ml BSA, 50 μ l of 500 μ g/ml λ phage DNA, 5 μ l of 10 mg/ml *E. coli* tRNA, 10 to 20 μ l antibody, and 20 μ l of 50% protein A–Sepharose to the remaining 91 μ l of eluate obtained in the step 13. Incubate on an end-over-end rotator for 90 min at room temperature.

*In case peptide elution was performed (see Alternate Protocol 1 in UNIT 21.3), substitute FA lysis buffer containing 0.1% SDS for the non-SDS-containing buffer recommended above. It is important to keep overall SDS concentration to $\leq 0.1\%$. BSA, λ phage DNA, and *E. coli* tRNA are carriers designed to mimic the protein/nucleic acid mixture in chromatin samples and to prevent nonspecific precipitation of cross-linked protein-DNA complexes. They are also necessary for the first and second immunoprecipitations to be experimentally equivalent (see Critical Parameters and Troubleshooting). Finally, as in the case of the first immunoprecipitation, the amount of antibody required to produce optimal signal with the lowest background may have to be empirically determined.*

- Wash beads and elute protein complexes by following steps 8 to 13 (above). Transfer eluate into a 0.5-ml PCR tube labeled “SeqChIP,” taking note of the order of IPs.

For gentle washes (i.e., peptide elution), follow steps of UNIT 21.3, Alternate Protocol 1.

Reverse cross-links and purify DNA

- Add 100 μ l ChIP elution buffer to the tube marked “INPUT” and “1st IP;” add 100 μ l and 91 μ l TE to the tubes marked “SeqChIP” and “1st IP,” respectively, and 20 μ l Pronase in TBS to all three tubes.

If either the first IP and/or second IP was eluted by peptide, add 100 μ l ChIP elution buffer instead of 100 μ l TE to the relevant sample(s).

- To reverse cross-links, place tubes into a PCR machine. Incubate 2 hr at 42°C, followed by 6 hr at 65°C. Store samples at 4°C until used.

The incubation at 42°C allows for Pronase digestion of cross-linked polypeptides, while the 65°C-incubation results in a reversal of the formaldehyde cross-links.

The samples may be stored up to several days at 4°C.

- Transfer samples to new 1.5-ml microcentrifuge tubes, add 20 μ l of 4 M LiCl, and purify by extracting with 25:24:1 phenol/chloroform/isoamyl alcohol, followed by extraction with chloroform (UNIT 2.1A). Add 2 μ l of 20 mg/ml glycogen (or Pellet Paint; Novagen) as carrier, and 2.5 vol ethanol. Vortex briefly and precipitate the DNA for 1 hr at -20°C (see UNIT 2.1A).

- Microcentrifuge 30 min at maximum speed, 4°C. Discard aqueous phase and wash with 1 ml of 70% ethanol, room temperature, by gently inverting samples several times.

- Microcentrifuge 5 min at maximum speed, room temperature. Aspirate supernatant and air dry pellet for ≤ 5 min.

21. Resuspend in 150 μ l TE buffer and store at -20°C .

DNA stored in this fashion should be stable for years.

22. Analyze samples with real-time quantitative PCR (UNIT 21.3).

As signals from sequential immunoprecipitations are considerably weaker than from conventional ChIPs, it is recommended that the total number of amplification cycles be increased from 35 to 40. In some extreme circumstances where the amount of DNA to be amplified is minute, it might be beneficial to go beyond 40 cycles. Other parameters should be identical to those described in UNIT 21.3.

COMMENTARY

Background Information

Sequential chromatin immunoprecipitation, a natural extension of conventional ChIP, arose due to the inability of conventional ChIP to determine whether two different proteins can simultaneously co-occupy a given stretch of DNA *in vivo*. As described in this unit, the technique simply involves an additional immunoprecipitation with antibody to an unrelated protein, with subsequent steps essentially identical to conventional ChIP (UNIT 21.3). The resulting material can then be analyzed by either conventional (UNIT 21.3) or real-time QPCR (UNIT 21.3, Alternate Protocol 2), with real-time QPCR clearly being the preferred method due to its superior linear range, which permits simultaneous analysis of both singly and doubly immunoprecipitated samples.

SeqChIP has been successfully applied in the analysis of wide-ranging biological phenomena in a number of different organisms and cell types. For example, SeqChIP was used to help elucidate the mechanism of PPRE-dependent RXR homodimer signaling (Ijpenberg et al., 2004), to demonstrate TBP binding to nucleosomal DNA (Soutoglou and Talianidis, 2002), to identify the various protein complexes involved in mediating transcriptional activation by the estrogen receptor alpha (Metivier et al., 2003), and to study hyperosmotic stress response at the transcriptional level in yeast (Proft and Struhl, 2002). The procedure outlined in the Basic Protocol, with some modifications, can be readily adapted for use on non-*Saccharomyces cerevisiae* chromatin.

Critical Parameters and Troubleshooting

Sequential IP analysis requires substantially greater quantities of starting material (extract) than normally used for single ChIP experiments. This is due to a number of factors, including low cross-linking efficiencies (typically $<5\%$, depending on both protein and

DNA region) and the necessity to do two IPs instead of one. The problem becomes especially acute if the proteins in question are poorly cross-linked to DNA, are low in abundance, and exhibit no or partial co-occupancy. In the Basic Protocol, the amount of extract (and the corresponding purified DNA) used is four- to five-fold greater than typically used for single IPs, and is likely to be sufficient for most SeqChIP applications in yeast. Additional scale-up may be desirable in some specific instances.

Of special concern is the need to ensure that the second IP behaves identically to the first IP from a quantitative standpoint. The addition of BSA, *E. coli* tRNA, and λ phage DNA to the eluate from the first ChIP serves to ensure that the two IPs behave in a similar manner irrespective of actual order. BSA, *E. coli* tRNA, and λ phage DNA mimic the concentrated cross-linked *S. cerevisiae* chromatin that is present in the sample prior to the first IP, but which is effectively absent from the post-elution complexes. Alternatively, cross-linked chromatin from an unrelated yeast such as *Kluyveromyces lactis*, or even *E. coli* chromatin, can be used as a carrier in place of the combination of BSA/tRNA/ λ DNA. An added benefit of using non-*S. cerevisiae* yeast (or *E. coli*) chromatin is that these organisms can be engineered to serve as internal controls for the efficiency of the second immunoprecipitation. However, the actual strain construction and preparation of cross-linked chromatin from these organisms is time-consuming and provides no appreciable benefit (relative to BSA/tRNA/ λ DNA) when it comes controlling variability between 1st and 2nd IPs.

Anticipated Results

Predicted outcomes of SeqChIP experiments

SeqChIP experiments have three possible outcomes: complete co-occupancy, no co-occupancy, and partial co-occupancy (Fig. 21.8.1). Complete co-occupancy describes the scenario when two proteins, A and B, are

Figure 21.8.1 Schematic depiction of the three possible outcomes of a SeqChIP between proteins A and B: complete co-occupancy (top left), no co-occupancy (top right), and partial co-occupancy (bottom panel). Partial co-occupancy can be further subdivided into two categories: A is required (bottom left) or not required (bottom right) for the binding of B.

always present in unison at any given DNA molecule. No A/B co-occupancy takes place when both A and B bind to the DNA region in question, yet are confined to non-overlapping subsets of molecules and are never found at the DNA fragments at the same time. Partial co-occupancy takes place when some of the DNA molecules are bound by both A and B, while others are bound by only A and/or only B.

Partial co-occupancy can be further subdivided into two distinct subgroups, differentiated by the ability or inability of one protein (B) to bind DNA independently of the other (A) as illustrated in Figure 21.8.1. In one scenario, DNA binding of protein B always occurs in combination with (and is completely dependent of the presence of) protein A, whereas protein A can associate with DNA in the absence of protein B. An example of this factor-

dependent DNA binding can be found in the interactions between the yeast TATA-box binding protein (TBP) and TBP-associated factors (TAFs): promoter binding by TAFs is critically dependent on TBP, yet TBP can be found at many promoters that lack TAFs (Kuras et al., 2000; Li et al., 2000). In the second scenario, A and B can bind independently of one another to a given genomic region, yet the proteins may co-occupy the same stretch of DNA in some (but not all) of the cases. This scenario is likely to be valid for two DNA-binding proteins that do not interact with one another and bind to different target sequences in an enhancer or other regulatory region of a eukaryotic promoter.

Quantitative analysis of SeqChIP results

Fold-enrichment over background for both individual ChIPs and SeqChIPs can be

calculated relative to a control genomic location as described in *UNIT 21.3*. Let A, B, and AB represent the fold-enrichments for the first, second, and sequential IPs, respectively. Then, in cases of complete co-occupancy (e.g., components of the general RNA polymerase II transcription machinery), the fold-enrichment of individual ChIPs should be equal to the product of the fold-enrichment of the individual ChIPs ($A \times B = AB$; Geisberg and Struhl, 2004). In cases of no co-occupancy, no enrichment is seen over that obtained by the first immunoprecipitation ($AB \approx A$). For partial co-occupancy, the fold-enrichment typically lies somewhere in between A (no co-occupancy) and AB (full co-occupancy). Mathematically, efficiency of co-occupancy (C, in percent) can be defined as follows:

$$C = 100(AB - A)/(A \times B - A)$$

In cases of complete co-occupancy, AB typically equals the product of A and B, and C = 100. If the value of $AB = A$, then there is no enrichment over the first immunoprecipitation and C = 0. For cases of partial co-occupancy, typical experimentally obtained C values range between >0 to significantly <100. It is important to note that in order for C values to be meaningful, fold-occupancies for individual ChIPs must be substantially above background (typically greater than two-fold), and SeqChIP enrichment (the ratio AB/A must be reproducibly above background as well ($AB/A > 2$ works well). Of course, the definition of what represents experimental background is somewhat arbitrary and will vary depending on experimental setup, the number of repetitions, as well as other factors.

Order of IPs may influence SeqChIP outcomes

An interesting (and predicted) outcome in some SeqChIP experiments is that the order of sequential IPs makes a difference in cases of partial co-occupancy. In a typical experiment, there are three classes of DNA molecules of interest—those bound to A alone, B alone, or both A and B. If X is defined as the fraction of A-DNA molecules that also contain B, and Y is defined as the fraction of B-DNA that also contain A, then the expected fold-enrichments for the three different classes of molecules are given by:

- (1 - X)A for the A-alone DNA molecules
- (1 - Y)B for the B-alone DNA molecules
- (XA)(YB) for the A + B + DNA molecules

It should be noted that X and Y are independent of one another, as A and B may have different occupancy properties. Using the equations above, it follows that:

when A ChIP is first, the fold-enrichment (AB) for the SeqChIP = $(1 - X)A + (XA)(YB)$

when B ChIP is first, the fold-enrichment (BA) for the SeqChIP = $(1 - Y)B + (XA)(YB)$.

For cases of complete co-occupancy ($X = 1, Y = 1$), the fold-enrichment is the same irrespective of IP order, as the equations above simplify to $AB = BA$. Likewise, the order of IPs makes no difference in cases of no co-occupancy ($X = 0, Y = 0$), as $AB = BA = 0$. By contrast, the order of IPs does make a difference in cases of partial co-occupancy. For example, when $X = 1$ and Y is small (i.e., A always co-occupies with B, but B rarely co-occupies with A), meaningful co-occupancy is likely to be observed in only one direction. In specific terms, if $X = 1, Y = 0.1, A = 10$, and $B = 50$, then the fold-enrichments are 50 when A ChIP is first and 95 when B ChIP is first. Clearly, these two values are not equal ($AB \neq BA$). More importantly, when A ChIP is performed first, the SeqChIP value of 50 represents a five-fold enrichment relative to the value of the single IP, although it is also well below the value for predicted full co-occupancy ($A \times B = 500$). By contrast, when B ChIP is performed first, the SeqChIP value of 95 is less than two-fold greater than the value of the single IP ($B = 50$), and typically falls within the cut-off for experimental error. The theoretically predicted (and experimentally confirmed) IP-order-dependent nature of SeqChIP values requires careful interpretation of so-called negative (no co-occupancy) results: definitive demonstration of lack of co-occupancy between two factors requires that the SeqChIP be performed in both directions with identical results of no co-occupancy. On the other hand, partial (or full) co-occupancy can be effectively demonstrated if observed in one direction.

Time Considerations

Cell growth, formaldehyde cross-linking, and chromatin isolation/purification can be completed in 2 to 3 days. Sequential immunoprecipitation requires a total of 7 to 8 hr: 2 hr for antibody binding, 1 hr for washes, and 30 min for elution for each IP, with 30 min set-up time in between the two immunoprecipitations. Complexes eluted from the first IP can

be conveniently frozen at -20°C and the second immunoprecipitation can be performed at a later time for added convenience. Cross-link reversal takes ≥ 6 hr and is best performed in a thermal cycler programmed to run overnight (see UNIT 21.3, Alternate Protocol 2). DNA purification takes 2 hr and quantitative PCR takes ≤ 2 to 3 hr, depending on instrument and cycling parameters.

Defining In Vivo Targets of Nuclear Proteins by Chromatin Immunoprecipitation and Microarray Analysis

UNIT 21.9

**BASIC
PROTOCOL**

Chromatin immunoprecipitation (ChIP) is an extremely useful method for determining the association of a given protein with potential DNA targets in vivo (UNIT 21.3). To identify novel regions of protein association, ChIP may be combined with microarray technology to identify the location of a specific protein in an unbiased, genome-wide manner, a technique often called “ChIP-chip” or “genome-wide location” analysis. Such an approach is particularly powerful, since it requires no previous knowledge of a protein’s likely targets. The small amount of DNA obtained by ChIP must first be amplified to yield enough material for array hybridization; the methods used are designed to ensure that the relative concentrations of all genomic regions in the original samples are faithfully maintained. Immunoprecipitated and input DNAs from standard ChIP experiments (UNIT 21.3) are subjected to primer extension using a primer with a 5′ tail consisting of a fixed sequence and a random octamer at its 3′ end; the primer-extension products are then amplified by PCR. The resulting amplified material is hybridized to microarrays of DNA fragments representing a large number of genomic regions. As described for transcriptional profiling (UNIT 22.1), DNA on the microarrays may be in the form of PCR products or oligonucleotides. The process of printing microarrays with PCR products is described in UNIT 22.3. Examples of such arrays include (1) the complete set of intergenic regions in the yeast *Saccharomyces cerevisiae*, (2) all nonrepetitive DNA sequences on entire human chromosomes, (3) numerous promoter-proximal regions of expressed mouse genes, and (4) CpG islands. This unit consists of a ChIP-chip protocol derived from experiments involving whole-genome analysis of *Saccharomyces cerevisiae* and using glass microarrays spotted with PCR products. It is applicable to the study of other organisms, although some organism- and array-specific modifications may be necessary.

Materials

- De-cross-linked DNA samples: typically yeast DNA from chromatin immunoprecipitation and input DNA control; (UNIT 21.3)
- 5× Sequenase buffer (USB)
- 80 μM primer A: GTTCCAGTCACGATCNNNNNNNNN (see UNIT 2.11 for oligonucleotide synthesis)
- 10 mg/ml BSA
- 0.1 M DTT
- 10 mM dNTP mix: 10 mM each dATP, dCTP, dGTP, and dTTP (UNIT 3.4)
- 13 U/μl Sequenase (USB) stock: dilute 1/10 immediately before use
- 10× PCR buffer (see recipe)
- Amino-allyl dNTP mix (see recipe)
- 100 μM primer B: GTTCCAGTCACGATC (see UNIT 2.11 for oligonucleotide synthesis)
- 5 U/μl *Taq* DNA polymerase
- 0.1 M sodium bicarbonate, pH 9.0
- Cy3 or Cy5 monoreactive dye (Amersham): resuspend entire tube of Cy5 or Cy3 dye in 45 μl DMSO
- 3 M sodium acetate (APPENDIX 2)
- 10 mg/ml sheared salmon sperm DNA (UNIT 20.1)
- 2.5× array hybridization buffer (see recipe)

**Chromatin
Assembly and
Analysis**

21.9.1

Array prehybridization buffer (see recipe)
 95% ethanol
 Array wash buffer (see recipe)
 0.2× SSC (APPENDIX 2)
 QIAquick PCR purification kit (Qiagen)
 Thermal cycler
 MinElute PCR purification kit (Qiagen)
 Microarrays (UNIT 22.1)
 Coplin jar or petri dish
 Plastic racks for holding microscope slides
 Plastic containers for washing microscope slides in holders
 Tabletop centrifuge with adaptors suitable for holding plastic microscope slide racks (typically the same as the adaptors meant for holding 96-well plates)
 95°C heating block or water bath
 LifterSlip coverslips for microarrays (Erie Scientific Company)
 Rubber cement
 Humidified chamber (see recipe)
 45°C oven
 Platform shaker
 Additional reagents and equipment for PCR amplification (UNIT 15.1) and separation of small DNA fragments by agarose gel electrophoresis (UNIT 2.5A)

Perform primer extension

1. Purify each DNA sample using a QIAquick PCR purification column according to the manufacturer's instructions, eluting with 42 µl water.

Use at least 50% of an immunoprecipitated sample (UNIT 21.3) from 20 ml of yeast cells—this corresponds to 10⁸ cells. For input DNA control, use 1/100 of the original chromatin sample from 20 ml cells.

2. Set up the following primer extension reaction in a 0.5-ml microcentrifuge tube:

40 µl QIAquick-purified DNA (immunoprecipitated or input-DNA control)
 12 µl 5× Sequenase buffer
 2 µl 80 µM primer A.

3. Begin the primer extension in a thermal cycler programmed as follows:

2 cycles:	2 min	94°C
	2 min	10°C
	Ramp slowly to 37°C over an 8-min period	
	8 min	37°C.

If processing many samples, it may be easier to pause the thermal cycler at 10°C long enough to add enzyme mix to each tube (see steps 4 and 5).

4. During the first 10°C step, add the following:

0.5 µl 10 mg/ml BSA
 3 µl 0.1 M DTT
 2 µl 10 mM dNTP mix
 1 µl diluted Sequenase.

It is best to premix the four components. If droplets have collected on the lid of the PCR tube, microcentrifuge briefly at maximum speed to collect the contents before adding the mix.

5. During the second 10°C step, add an additional 1 µl diluted Sequenase.
6. Upon completion of the 2 cycles, purify the DNA on a QIAquick column, eluting with 80 µl water.

Perform PCR

7. Mix the following components in a 0.5-ml microcentrifuge tube:

78 μ l DNA from step 6
10 μ l 10 \times PCR buffer
10 μ l amino-allyl dNTP mix
1 μ l 100 μ M primer B
1 μ l 5 U/ μ l *Taq* DNA polymerase.

8. Perform PCR (also see *UNIT 15.1*) using the following program in a thermal cycler:

35 cycles:	30 sec	92°C
	30 sec	40°C
	30 sec	50°C
	1 min	72°C.

If microarrays require blocking or other processing, it is convenient to do this while the PCR program is being executed.

9. Check 5 μ l of the PCR product on an agarose gel (*UNIT 2.5A*) to determine the success of amplification.

A successful amplification will yield a smear of DNA fragments with an average size of ~300 bp. A faint smear is all that is necessary.

10. Purify the remaining 95 μ l of the PCR reaction with MinElute kit according to the manufacturer's instructions, eluting in 11 μ l of 0.1 M sodium bicarbonate, pH 9.0.

For this procedure, be sure to elute using 0.1 M sodium bicarbonate, pH 9.0, not the elution buffer supplied with the MinElute kit.

Couple samples with dye

11. Mix 10 μ l eluted DNA from step 10 with 10 μ l Cy5 or Cy3 dye in DMSO. Incubate 1 hr at room temperature in darkness.

For a given array, the sample from immunoprecipitation is coupled to one dye, and the total DNA input to the other. If the hybridization will be performed on the same day, it is convenient to prehybridize the arrays (step 13) during this incubation.

12. Add 80 μ l water and 3 μ l of 3 M sodium acetate. Purify on QIAquick PCR clean-up column according to the manufacturer's instructions, washing with PE buffer (provided with QIAquick kit) three times or until all uncoupled dye has been removed and flowthrough runs clear. Elute with 32 μ l water. Store samples at -20°C until ready to perform hybridization.

The eluted dye-coupled product should be visibly pink or blue.

Prehybridize/hybridize samples to arrays

13. Incubate prepared microarrays for 1 hr at 45°C in enough array prehybridization buffer to cover the slides.

For multiple slides, it is convenient to use a Coplin jar, but for one or two slides a petri dish will work equally well.

14. Place prehybridized microarrays in microscope slide racks and briefly dip five times in water, then once in 95% ethanol. Dry by centrifuging 1 min at 800 rpm in a tabletop centrifuge.

15. Prepare hybridization solution by mixing the two dye-coupled samples representing immunoprecipitated and input DNA (30 μ l each) for a given array with 3 μ l of 10 mg/ml salmon sperm DNA and 40 μ l of 2.5 \times array hybridization buffer.

Any excess hybridization solution may be stored at -20°C for future use.

- Denature hybridization mixture at 95°C for 3 min. Transfer immediately to ice. Place a LifterSlip coverslip ridge-side-down onto the prehybridized array. Using a small plastic pipet tip, dab a small dot of rubber cement at each corner of the cover slip to prevent it from moving. Gently pipet the sample-containing hybridization solution (from step 15) onto the array under the LifterSlip coverslip, allowing capillary action to pull the liquid under the coverslip rather than squirting it all in at once.

LifterSlip coverslips have two white ridges along their edges to raise the coverslip slightly above the slide surface, allowing a larger volume of liquid to be injected. Take care not to put pressure on the coverslip when handling the array. About 50 μ l will suffice to fill the space under the cover slip. Store any leftover hybridization mixture at -20°C in case of catastrophe.

- Incubate arrays overnight at 45°C in a humidified chamber (see Reagents and Solutions).
- Remove array slides from humidified chamber, remove coverslips, and place arrays in a slide holder in a plastic wash container. Wash array twice, each time for 3 min in ~ 200 ml array wash buffer. Agitate slides on a platform shaker during washes.
- Wash arrays twice, each time for 3 min in 200 ml 0.2 \times SSC using the same technique as in step 18.

Transfer slides to a fresh rack to minimize SDS carryover between wash steps.

- Dry arrays by centrifuging 1 min at 800 rpm in a tabletop centrifuge.

Proceed quickly with the centrifugation step so as not to allow any residual wash solution to dry unevenly on the slide surface. The slides are now ready for scanning. If there is a high background on scanning, further washes may be performed and the slides re-scanned.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Amino-allyl dNTP mix

5 mM each dATP, dCTP, and dGTP
2 mM dTTP
3 mM amino-allyl dUTP (Ambion)
Store at -20°C

Array hybridization buffer, 2.5 \times

25 μ l formamide
15 μ l 20 \times SSC (APPENDIX 2)
1 μ l 10% (w/v) SDS
Store at -20°C

Array prehybridization buffer

5 \times SSC (APPENDIX 2)
0.1% (w/v) SDS
1% (w/v) BSA
Store at 4°C

Array wash buffer

0.2 \times SSC (APPENDIX 2)
0.1% (w/v) SDS
Store indefinitely at room temperature

Humidified chamber

Remove the sieve-like plastic insert from an empty hinged pipet-tip box. Place a moist paper towel in the bottom of the box and replace the plastic insert. Place arrays on top of the plastic insert, and close the hinged lid of the box before placing the box in the incubator.

The perforated insert allows the circulation of humid air within the chamber without actually allowing the arrays to sit on a wet surface.

PCR buffer, 10×

100 mM Tris·Cl, pH 8.3 (APPENDIX 2)
500 mM KCl
15 mM MgCl₂
Store at −20°C

Sequenase buffer, 5×

200 mM Tris·Cl, pH 7.5 (APPENDIX 2)
100 mM MgCl₂
250 mM NaCl
Store at −20°C

COMMENTARY

Background Information

The combination of chromatin immunoprecipitation (ChIP) and microarray technology represents a powerful approach to identifying the location of specific proteins on a genome-wide basis. ChIP and quantitative PCR (UNIT 21.3) have been used with considerable success to study the association of proteins with individually chosen potential DNA targets (Kuras et al., 1999; Li et al., 1999). In addition, microarrays are widely used for genome-wide expression profiling (DeRisi et al., 1996, 1997; Lockhart et al., 1996), as described in UNIT 22.1. In recent years, ChIP-chip using yeast whole-genome microarrays has allowed the identification of the physiological target sites of numerous DNA-binding proteins, chromatin-modifying activities, and transcription factors in an unbiased and comprehensive manner (Reid et al., 2000; Iyer et al., 2001; Lee et al., 2002; Moqtaderi and Struhl, 2004).

The small amount of DNA obtained from a typical ChIP experiment must be amplified before being hybridized to a microarray. The methods used generally involve adding fixed sequence to the ends of the immunoprecipitated DNA fragments either by ligation or by primer extension using oligonucleotides with a fixed 5' tail and a random 3' end (Bohlander et al., 1992; Eberwine, 1996). The resulting fragments may then be amplified by PCR, in the presence of either dye-coupled nucleotides

or a modified amino-allyl nucleotide that is coupled to dye in a subsequent step. The advantage of the latter method is that it eliminates unequal labeling that results from different efficiencies of incorporation of Cy3- and Cy5-coupled nucleotides during PCR.

Critical Parameters and Troubleshooting

It is important to begin with sufficient immunoprecipitated DNA of high purity. In general, half an immunoprecipitation reaction is enough, and the Qiagen purification before the initial primer extension is sufficient to ensure that the DNA is clean and of high quality. As for any ChIP experiment, be certain that the chromatin sample used in the immunoprecipitation is sufficiently sonicated; smaller fragment sizes (ideally averaging 300 bp) result in higher signal-to-background ratios. This can be especially important when trying to distinguish true occupancy at a locus from apparent occupancy at a neighboring locus on a microarray. In addition, on an array consisting of relatively large spotted PCR products (e.g., ones representing entire intergenic sequences), the true association site of any given factor is likely to be considerably smaller than the size of the spotted fragment. The contribution of the neighboring nonoccupied DNA on the same PCR fragment tends to dampen the overall positive signal of the spot, making the apparent occupancy lower for a given spot

than it would appear with smaller PCR products spanning little sequence other than true target. It is therefore especially important in a microarray experiment of this type to maximize the immunoprecipitation signal; to this end, it is often helpful to use peptide elution (UNIT 21.3, Alternate Protocol) when immunoprecipitating epitope-tagged proteins.

If the scanned array has high background fluorescence, especially background signal that appears patchy, it is often helpful to wash and scan the slide again. It is important not to allow the wash solution to dry unevenly on the glass slide—dry the slides quickly by centrifugation. Be certain to use a fresh slide rack and new plastic wash container for each wash so as to minimize carryover of SDS-containing wash solution, which can appear as a blotchy background signal.

If using a previously untested batch of microarrays, it is often useful to perform a trial hybridization using unimportant material (e.g., amplified total genomic DNA, or even leftover unhybridized material from a previous experiment) to verify the quality of a representative array. The array should consist of distinct, round spots with no unevenness of printing; missed spots or feathering of spot edges are signs of bad quality. Some of these problems may be obvious upon just a brief SYBR Green staining of the array, but occasionally problems with array quality become apparent only after overnight hybridization.

The procedure described here yields approximately twice as large a volume of hybridization mixture as is needed to cover a typical microarray. The excess material may be stored at -20°C in case any unanticipated slide-specific problems occur with the first array.

At least three replicates of an array experiment are usually performed to allow statistical determination of the validity of the results. These replicates should be fully independent, resulting from separately grown cultures and chromatin preparations. Even with multiple replicates, it will be apparent that certain spots emerge reliably as false positives—i.e., statistically meaningful positives which turn out to have no biological merit. Some of these are antibody-dependent and can be easily identified by array hybridization of sample immunoprecipitated with the same antibody, but from an untagged strain.

Anticipated Results

In general, a good yield of amplified material after the PCR step (i.e., 5 μl of the PCR

reaction should produce an easily visible smear when run on an agarose gel) is highly predictive of success in the array hybridization. It is therefore always worthwhile to run a gel to verify the success of the amplification step before continuing. If no smear of amplified DNA is visible, do not continue; any resulting array hybridization signal is likely to be very weak. Additionally, the material eluted from the Qiagen column after the subsequent dye-coupling step should be clearly and unambiguously pink or blue; it is not a good sign if seeing this color requires a great deal of imagination or fiddling about with white pieces of background paper. If a co-worker hesitates when asked to distinguish which of the two samples is the pink one, do not waste an array by proceeding with hybridization.

Time Considerations

The primer extension, amplification, and labeling steps in this procedure can be performed relatively easily in one day, allowing hybridization to be performed overnight. Washing and scanning can then be done on the morning of the second day. If the protein of interest has known DNA targets, it is often worth spending 1 day at the beginning of the procedure to determine the success of the immunoprecipitation (by quantitative PCR of known DNA targets) before embarking on amplification and array hybridization.

If the microarrays require advance preparation such as blocking or UV cross-linking, these steps may be performed during the PCR amplification. It is convenient to prehybridize the arrays during the 1-hr dye-coupling step.

Identifying Chromosomal Targets of DNA-Binding Proteins by Sequence Tag Analysis of Genomic Enrichment (STAGE)

This unit describes a protocol for identifying the target loci of DNA-binding proteins in any genome by sequence tag analysis of genomic enrichment (STAGE). The method is conceptually similar to serial analysis of gene expression (SAGE; UNIT 25B.6), but the template for STAGE consists of DNA fragments enriched by chromatin immunoprecipitation (ChIP; UNIT 21.3). The STAGE procedure generates a library of 21-mer sequences, or tags, that represent the original ChIP sample. High-throughput sequencing of concatamers of tags, and the mapping of these tags to the genome, allows one to identify the direct binding targets of DNA-binding proteins *in vivo*.

STAGE starts with the amplification of ChIP DNA as described in the Basic Protocol. The enrichment of specific target loci by ChIP can be detected by ChIP-PCR (UNIT 21.3). If the enrichment of known target loci relative to nonspecific genomic background is not very high, a large proportion of tag sequences could be derived from this nonspecific background. An optional procedure, Subtraction STAGE (SubSTAGE; see Support Protocol), may be used to obtain better enrichment of target loci for input into the subsequent STAGE procedure.

SEQUENCE TAG ANALYSIS OF GENOMIC ENRICHMENT (STAGE)

A schematic representation of the STAGE procedure is shown in Figure 21.10.1. The steps of the STAGE procedure, in brief, are as follows. (1) ChIP DNA fragments are amplified by PCR using partially degenerate biotinylated primers, and (2) the product is digested with the restriction endonuclease *Nla*III, which cuts at 5'-CATG. (3) Biotinylated fragments are isolated using streptavidin beads and split into two pools. (4) Each pool is ligated to a different linker containing a recognition site for *Mme*I, a type IIS restriction enzyme that cuts away from its recognition site, as well as a specific primer-recognition sequence. (5) Digestion with *Mme*I releases 21-bp tags that are derived from the original ChIP DNA, attached to the linker sequence. (6) The two pools are ligated and amplified by nested PCR using primers complementary to the linkers. (7) The amplified sample is trimmed by *Nla*III digestion to generate ditags. (8) Multiple ditags are concatamerized, cloned, and sequenced. (9) Mapping each tag back to the genome sequence can identify the DNA fragments that were present in the ChIP sample and thus identify the genomic loci that are occupied by DNA-binding protein *in vivo*.

Materials

- 10 ng/ μ l chromatin immunoprecipitated (ChIP) DNA fragments (UNIT 21.3; test enrichment by PCR as described in that unit; if not sufficiently high, perform subtraction as described in Support Protocol to improve enrichment)
- 5 \times Sequenase reaction buffer (USB)
- 40 μ M round A primer (see recipe for PCR primers)
- 10 ng/ μ l sheared genomic DNA generated from the same cells used in the ChIP procedure
- TE buffer, pH 8.0 (APPENDIX 2)
- Round A dNTP mix: 3 mM each dNTP (A, C, G, and T) in TE buffer, pH 8.0
- 0.1 M dithiothreitol (DTT)
- 0.5 mg/ml bovine serum albumin (BSA)

BASIC PROTOCOL

Chromatin Assembly and Analysis

21.10.1

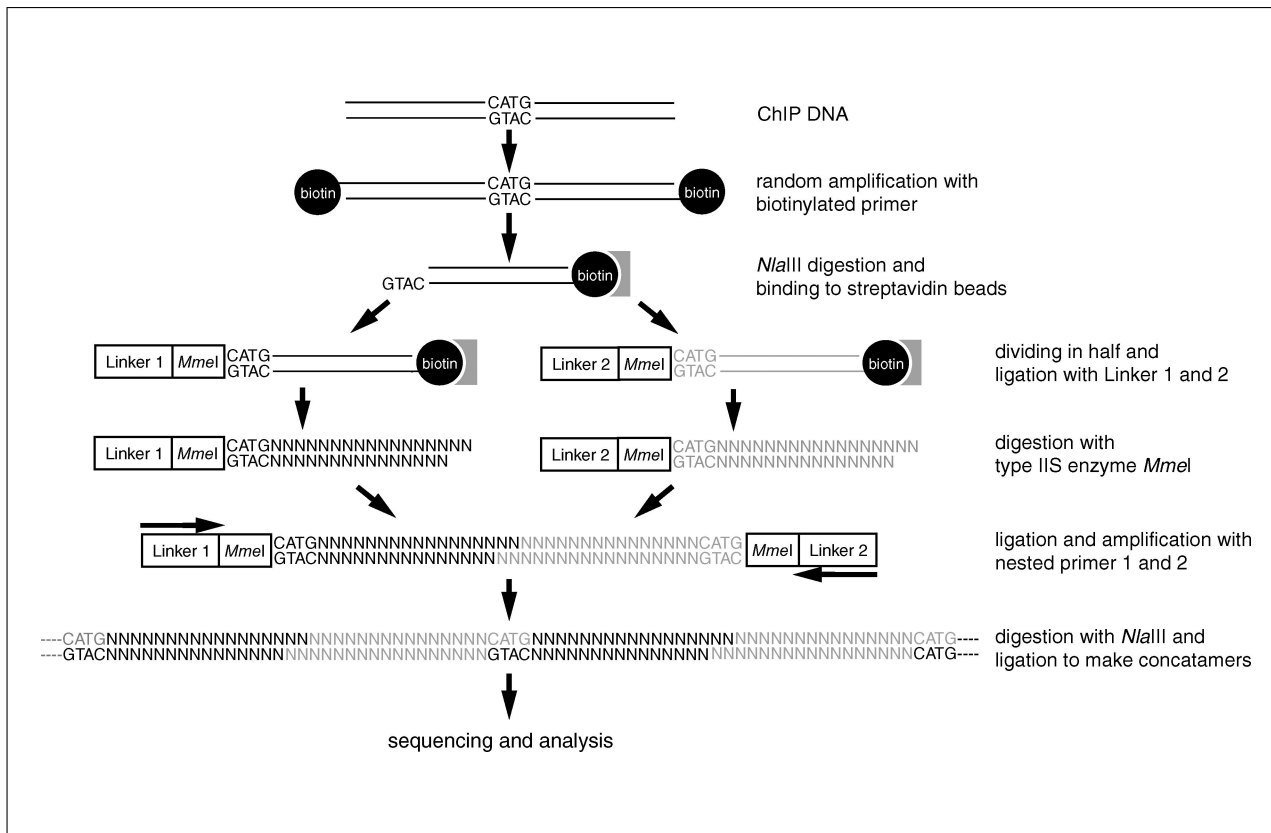

Figure 21.10.1 Scheme for sequence tag analysis of genomic enrichment (STAGE).

- 13 U/μl Sequenase (USB)
- 10× PCR buffer (see recipe)
- 25 mM MgCl₂
- 500 μM biotinylated round B primer (see recipe for PCR primers)
- Standard dNTP mix: 25 mM each dNTP (A, C, G, and T) in TE buffer, pH 8.0
- 5 U/μl *Taq* DNA polymerase
- 1% and 1.5% agarose gels (UNIT 2.5A)
- PC8 (see recipe)
- 20 mg/ml glycogen (Roche Diagnostics)
- 7.5 M ammonium acetate (Sigma)
- 100% and 70% ethanol
- LoTE buffer (see recipe)
- 100× BSA (New England Biolabs)
- 10× Buffer 4 (New England Biolabs)
- Nla*III restriction endonuclease (New England Biolabs; also see UNIT 3.1)
- Dynabeads M-280 Streptavidin slurry (Dynal)
- 1× and 2× BW buffer (see recipe)
- Annealed linkers 1 and 2: linkers 1A, 1B, 2A, and 2B (see recipe), phosphorylated and annealed as in Support Protocol 3 of UNIT 25B.6
- 10× ligase buffer (New England Biolabs)
- T4 DNA ligase (high concentration, 2000 U/μl; New England Biolabs)
- 32 mM *S*-adenosylmethionine (SAM; New England Biolabs)
- Mme*I restriction endonuclease (New England Biolabs)
- Primers 1 and 2 (see recipe for PCR primers)
- 12% (10-well) and 8% nondenaturing polyacrylamide gels prepared in TBE buffer (UNIT 2.7)

**Sequence Tag

Genomic
Enrichment
(STAGE)**

21.10.2

10-bp and 1-kbp DNA ladders
 6× sample loading buffer (see recipe)
 1 μg/μl pZErO-1 plasmid (Invitrogen), linearized
 10× Buffer 2 (New England Biolabs)
SphI restriction endonuclease (New England Biolabs)
 ElectroMAX DH10B electroporation-competent cells (Invitrogen; frozen at
 −80°C)
 SOC medium (see recipe)
 10-cm Zeocin-containing low-salt LB plates (see recipe)
 Dimethyl sulfoxide (DMSO)
 5 μM M13 forward and reverse primers (see recipe for PCR primers)
 0.2-ml thin-walled PCR tubes
 Thermal cycler
 0.5- and 1.5-ml snap-cap and 2-ml screw-cap microcentrifuge tubes
 Magnetic rack for Dynabead separations (Dyna)
 12°, 16°, 37°, 42°, 50°, and 65°C water baths or temperature blocks
 15- and 50-ml conical tubes
 Tabletop centrifuge with swinging-bucket rotor
 25-G needles
 Spin-X centrifuge tube filters (Costar)
 Bio-Rad GenePulser electroporator (or equivalent) and 0.1-mm disposable
 electroporation cuvettes (Bio-Rad)
 Platform shaker
 37° and 30°C incubators
 96-well PCR plate (MJ Research)
 Sterile toothpicks

Additional reagents and equipment for PCR (*UNIT 15.1*), restriction enzyme
 digestion of DNA (*UNIT 3.1*), phenol extraction and ethanol precipitation of DNA
 (*UNIT 2.1A*), agarose gel electrophoresis (*UNIT 2.5A*), nondenaturing polyacrylamide
 gel electrophoresis (*UNIT 2.7*), ligation (*UNIT 3.14*), electroporation of bacteria
 (*UNIT 1.8*), and direct DNA sequencing of PCR products (*UNIT 15.2*)

NOTE: Use aerosol-barrier pipet tips to prevent contamination of PCR reactions; see
APPENDIX 2 for additional precautions with PCR.

Perform primer extension: Round A

1. For each amplification reaction to be performed, prepare the following mixture in
 separate 0.2-ml thin-walled PCR tubes:

7 μl ChIP DNA fragments
 2 μl 5× Sequenase reaction buffer
 1 μl 40 μM round A primer.

For positive control reactions, use 7 μl of 10 ng/μl sheared genomic DNA in place of
 the ChIP DNA. For negative control reactions, use 7 μl TE buffer, pH 8.0, in place
 of the ChIP DNA.

2. Based on the total number of reactions to be performed, add the following ingredients
 to a single tube (total 5.05 μl per reaction):

1 μl 5× Sequenase reaction buffer
 1.5 μl round A dNTP mix (3 mM each dNTP)
 0.75 μl 0.1 M DTT
 1.5 μl 0.5 mg/ml BSA
 0.3 μl 13 U/μl Sequenase.

- Based on the total number of reactions to be performed, add the following ingredients to another tube (total, 1.2 μl per reaction):

0.3 μl 13 U/ μl Sequenase
0.9 μl Sequenase reaction buffer.

- Transfer the tubes from step 1 to a thermal cycler and carry out two rounds of DNA strand extension as follows:

2 cycles: 2 min 94°C
 2 min 8°C
 Ramp to 37°C over 8 min.

During the first 8°C step, add 5.05 μl of the reaction mixture from step 2 to each tube. Quickly mix the sample and reaction mixture by pipetting. During the second 8°C step, add 1.2 μl of the mixture from step 3 to each tube and mix the reaction well by pipetting.

Use the pause option on the instrument, if necessary, to add the reaction buffer and enzyme to each tube and mix.

- Dilute the product to 30 μl with TE buffer, pH 8.0, and use 15 μl of this diluted round A product for each round B reaction.

Perform PCR for biotinylation: Round B

- Mix the following components in each of two 0.2-ml thin-walled PCR tubes:

15 μl round A product
10 μl 10 \times PCR buffer
8 μl 25 mM MgCl₂
1.5 μl 500 μM biotinylated round B primer
2 μl standard dNTP mix (25 mM each dNTP)
62.5 μl H₂O
1 μl 5 U/ μl *Taq* DNA polymerase.

- Transfer the tubes to a thermal cycler and amplify the DNA templates using the following conditions:

1 cycle: 2 min 94°C (denaturation)
25 cycles: 30 sec 94°C (denaturation)
 30 sec 45°C (first annealing)
 30 sec 50°C (second annealing)
 1 min 70°C (extension)
1 cycle: 5 min 70°C (final extension).

- Analyze 5 μl of round B product by electrophoresis on a 1% agarose gel (UNIT 2.5A).

A smear of DNA averaging in size from 300 to 1000 bp should be seen from the amplified ChIP DNA sample and genomic DNA control. No smear should be seen from the amplification of the negative control (TE).

- Combine the two round B reactions (final 200 μl) in one 1.5-ml microcentrifuge tube and extract the sample with an equal volume of PC8 (also see UNIT 2.1A).

10. Precipitate with ethanol by combining the following (also see *UNIT 2.1A*):

200 μ l round B product
2 μ l 20 mg/ml glycogen
150 μ l 7.5 M ammonium acetate
600 μ l 100% ethanol.

Vortex briefly and place at -80°C for 15 min.

11. Microcentrifuge 30 min at maximum speed, room temperature. Wash by adding 500 μ l of 70% ethanol and microcentrifuging 5 min at maximum speed, room temperature. Remove ethanol and resuspend pellet in 20 μ l LoTE buffer.

Digest with *Nla*III and immobilize biotinylated fragments to magnetic beads

12. Mix the following components:

10 μ l round B product (half the total product)
2 μ l 100 \times BSA
20 μ l 10 \times Buffer 4
8 μ l *Nla*III
160 μ l LoTE buffer.

Incubate for 1.5 hr at 37°C .

13. Extract the sample with 200 μ l PC8 and precipitate with ethanol by combining the following:

200 μ l sample
2 μ l 20 mg/ml glycogen
150 μ l 7.5 M ammonium acetate
600 μ l 100% ethanol.

Vortex briefly and place at -80°C for 15 min.

14. Microcentrifuge 30 min at maximum speed, room temperature. Wash by adding 500 μ l of 70% ethanol and microcentrifuging 5 min at maximum speed, room temperature. Remove ethanol and resuspend pellet in 20 μ l LoTE buffer.

15. Place a 100- μ l aliquot of Dynabeads M-280 Streptavidin slurry in each of two microcentrifuge tubes. Immobilize the beads using a magnetic rack according to manufacturer's instructions, and remove the supernatant. Wash beads three times, each time with 500 μ l of 1 \times BW buffer, using the magnetic rack.

16. Add the following to each tube containing the washed Dynabeads:

100 μ l 2 \times BW buffer
90 μ l H_2O
10 μ l DNA sample.

Incubate 20 min at room temperature with gentle mixing.

17. Immobilize the samples in two tubes with the magnetic rack. Wash three times with 500 μ l of 1 \times BW buffer and once with LoTE buffer using the magnetic rack.

Ligate linkers to sample

18. Resuspend the beads in each tube with the following:

- 29 μl LoTE buffer (both tubes)
- 4 μl 10 \times ligase buffer (both tubes)
- 5 μl linker 1 (only in tube 1)
- 5 μl linker 2 (only in tube 2).

Prepare linkers 1 and 2 by phosphorylating linkers 1B and 2B and annealing with linkers 1A and 2A as described in Support Protocol 3 of UNIT 25B.6. Use the four oligonucleotide sequences shown in Reagents and Solutions of this unit (see recipe for linkers).

19. Incubate tubes 2 min at 50°C, then let sit 15 min at room temperature.
20. Add 2 μl high-concentration T4 DNA ligase and incubate 2 hr at 16°C with occasional mixing.
21. Place the tubes on the magnetic rack for 1 min and wash the beads in each tube three times, each time with 500 μl of 1 \times BW buffer.
22. Pool the beads from tubes 1 and 2 in a new tube, then wash once with 500 μl of 1 \times BW buffer and twice with 1 \times Buffer 4 using the magnetic rack.

Release tags by MmeI digestion and ligate tags to form ditags

23. Remove 1 \times Buffer 4 from the tube and resuspend the sample with the following mix:

- 175 μl LoTE buffer
- 20 μl 10 \times Buffer 4
- 0.3 μl 32 mM SAM
- 5 μl *MmeI*.

Incubate for 2 hr at 37°C.

24. Put the sample tube on the magnetic rack for 2 min to immobilize the beads, then transfer the supernatant to a new tube. Repeat this process three times to obtain a supernatant free of beads.
25. Extract with an equal volume of PC8 and then precipitate the sample with ethanol by combining the following:
- 200 μl sample
 - 3 μl 20 mg/ml glycogen
 - 150 μl 7.5 M ammonium acetate
 - 600 μl 100% ethanol.

Vortex briefly and place at -80°C for 15 min.

26. Microcentrifuge 30 min at maximum speed, room temperature. Wash by adding 500 μl of 70% ethanol and microcentrifuging 5 min at maximum speed, room temperature. Remove ethanol and resuspend pellet in 10 μl LoTE buffer.
27. Prepare two tubes of ligation mixture as follows:
- 5 μl sample DNA
 - 1 μl 10 \times ligase buffer
 - 1 μl high-concentration (2000 U/ μl) T4 DNA ligase (or 1 μl H₂O)
 - 3 μl H₂O.

Use ligase in one tube and water in the other as a no-ligase control. Incubate tubes overnight at 16°C.

28. Add 10 μl LoTE buffer to make final 20 μl .

Perform PCR amplification of ditags

29. Prepare 1/100 to 1/600 dilutions of sample to optimize amplification. Prepare the same dilution series for the no-ligase control.
30. Set up a series of PCR reactions using the following components:
 - 5 μ l 10 \times PCR buffer
 - 3 μ l 25 mM MgCl₂
 - 1 μ l 350 mM primer 1
 - 1 μ l 350 mM primer 2
 - 1 μ l ligation product (various dilutions)
 - 0.5 μ l standard dNTP mix (25 mM each dNTP)
 - 1 μ l 5 U/ μ l *Taq* DNA polymerase
 - 37.5 μ l H₂O.

31. Perform PCR amplification in thermal cycler with following parameters:

1 cycle:	2 min	94°C	(denaturation)
26 cycles:	40 sec	94°C	(denaturation)
	1 min	55°C	(annealing)
	1 min	70°C	(extension)
1 cycle:	5 min	70°C	(final extension).

32. Remove a 5- μ l aliquot of PCR product from each dilution and run on a 12% nondeaturing polyacrylamide/TBE gel with a 10-bp DNA ladder (*UNIT 2.7*).

The purpose of testing a dilution series of the ditag ligation is to avoid possible saturation of the PCR amplification. In the series of amplified ditag bands (120 bp in size), the band intensity will likely begin to decrease with one of the dilutions. Use this dilution factor to prepare the master mix and perform large-scale PCR amplifications in three 96-well plates. There should be no amplified ditags from the no-ligase control samples.

33. Perform a large-scale PCR reaction (three 96-well PCR plates with 50- μ l reaction volume per well) to amplify ditags using the optimal dilution and the conditions described in step 31.

Isolate ditags

34. Pool PCR reactions into two 50-ml conical tubes (~7 ml in each tube), extract with an equal volume of PC8, and precipitate by combining the following:

- 7 ml PCR sample
- 100 μ l 20 mg/ml glycogen
- 5 ml 7.5 M ammonium acetate
- 21 ml 100% ethanol.

Vortex briefly and place at -80°C for 15 min.

35. Centrifuge 30 min at 1600 \times g, room temperature, in a tabletop centrifuge with swinging-bucket rotor. Wash by adding 5 ml of 70% ethanol, centrifuging 5 min at 1600 \times g, room temperature, and removing the ethanol. Resuspend each pellet in 150 μ l LoTE buffer.
36. Pool the samples and add 60 μ l of 6 \times sample loading buffer. Load 10 μ l of the sample into each well of four 12% polyacrylamide 10-well gels and run gels at 160 V for ~2.5 hr (*UNIT 2.7*) to separate the 120-bp ditag band from the 100-bp linker-linker dimer band.

Before running all of the samples, run a test gel run using 5 μ l of pooled PCR reaction to get an idea of the maximum separation of the 120-bp ditag band and the 100-bp linker-linker dimer band.

37. Stain gels using SYBR Green or ethidium bromide (UNIT 2.7) and visualize under UV illumination.
38. Cut out only the amplified 120-bp ditag bands from the gels and place the bands in six 0.5-ml microcentrifuge tubes that have a hole pierced through the bottom by a 25-G needle.
39. Place the 0.5-ml tubes inside 2-ml microcentrifuge tubes and microcentrifuge for 3 min at maximum speed to force the gels through the holes and thereby break them up into small fragments. Discard the 0.5-ml tubes.
40. Add 500 μ l of a 5:1 mixture of LoTE buffer and 7.5 M ammonium acetate to each 2-ml tube. Vortex, then incubate 1 hr at 65°C (or overnight at 4°C).
41. Wet twelve Spin-X centrifuge tube filters by adding 5 μ l LoTE buffer and transfer the contents of each 2-ml tube to two Spin-X tubes.
42. Microcentrifuge 5 min at maximum speed and pool all the eluates in a 15-ml tube.
43. Precipitate combined eluate with ethanol by combining the following:
 - 3 ml sample
 - 50 μ l 20 mg/ml glycogen
 - 2 ml 7.5 M ammonium acetate
 - 9 ml 100% ethanol.Vortex briefly and place at -80°C for 15 min.
44. Centrifuge 30 min at $1600 \times g$, room temperature, in a tabletop centrifuge with a swinging-bucket rotor. Wash by adding 5 ml of 70% ethanol, centrifuging 5 min at $1600 \times g$, room temperature, and removing the ethanol. Resuspend sample DNA pellet in 200 μ l LoTE buffer.
45. Prepare two 1.5-ml microcentrifuge tubes as follows:
 - 100 μ l sample
 - 30 μ l 10 \times Buffer 4
 - 3 μ l 100 \times BSA
 - 20 μ l *Nla*III
 - 147 μ l H₂O.Incubate 2 hr at 37°C.
46. Extract with an equal volume of PC8, then precipitate with ethanol by combining the following:
 - 300 μ l sample
 - 5 μ l 20 mg/ml glycogen
 - 200 μ l 7.5 M ammonium acetate
 - 900 μ l 100% ethanol.Vortex briefly and place at -80°C for 15 min.
47. Microcentrifuge 30 min at maximum speed, room temperature. Wash by adding 500 μ l of 70% ethanol, microcentrifuging 5 min at maximum speed, room temperature, and removing the supernatant. Resuspend each pellet in 38 μ l LoTE buffer.

48. Pool the samples in one tube and add 15 μ l of 6 \times sample loading dye.
49. Load 10 μ l of sample into each of nine lanes of a 12% polyacrylamide gel with a 10-bp DNA ladder as a size marker in a separate lane. Run gel at 160 V for \sim 2.5 hr to separate the ditag band (\sim 40 bp) and the linker band (\sim 50 bp).
50. Stain the gel and cut out the 40-bp band from each of the nine lanes under UV illumination. Place into three 0.5-ml tubes with a hole pierced through the bottom by a 25-G needle, and break up the gels as in step 39.
51. Add 300 μ l of 5:1 mixture of LoTE buffer and 7.5 M ammonium acetate to each 2-ml tube. Vortex and incubate tubes for 2 hr at 42°C (or overnight at 4°C).
52. Wet three Spin-X centrifuge tube filters by adding 5 μ l LoTE buffer and transfer contents of each 2-ml tube to a single Spin-X tube. Microcentrifuge 5 min at maximum speed to filter the eluted DNA.
53. Extract with an equal volume of PC8, then precipitate with ethanol as follows:
 - 300 μ l sample
 - 5 μ l 20 mg/ml glycogen
 - 200 μ l 7.5 M ammonium acetate
 - 900 μ l 100% ethanol.Vortex briefly and place at -80°C for 15 min.
54. Microcentrifuge 30 min at maximum speed, room temperature. Wash by adding 500 μ l of 70% ethanol, microcentrifuging 5 min at maximum speed, room temperature, and removing the supernatant. Resuspend each pellet in 2.5 μ l cold LoTE buffer and pool (total 7.5 μ l).

Ligate ditags to form concatamers

55. Prepare the following:
 - 7.5 μ l ditag pool
 - 1 μ l 10 \times ligase buffer
 - 0.5 μ l H₂O
 - 1 μ l high-concentration (2000 U/ μ l) T4 DNA ligase.

Incubate at 16°C for 30 min to get appropriate-size concatamers for sequencing.

Concatamers that are too short will not yield sufficient numbers of tags from one sequencing reaction. Concatamers that are larger than 1.5 kb cannot be entirely sequenced in a single sequencing reaction even if sequenced from both ends. For this reason, concatamers that are 600 bp to 1.5 kb in size are most useful. In the authors' experience, a 30-min incubation is sufficient for obtaining the optimal size of concatamers. The incubation time during the ligation may be adjusted to ensure that the bulk of the concatamers are in this range.

56. After ligation, resolve the concatamers by running the sample in one lane on an 8% polyacrylamide gel, with a 1-kbp DNA ladder in a separate well. Run sample for 45 min at 200 V.
57. Stain the gel to visualize the DNA. From the smear of concatamers, cut out the portion of the gel lane that contains the 600- to 1.5-kbp size range of concatamers.
58. Place gel slices into two 0.5-ml tubes with holes and break up the gel slices by centrifugation.
59. Add 300 μ l of a 5:1 mixture of LoTE buffer and 7.5 M ammonium acetate to each 2-ml tube. Vortex and incubate tubes for 1 hr at 42°C (or overnight at 4°C).

60. Wet two Spin-X centrifuge tube filters by adding 5 μl of LoTE buffer and transfer the contents of each 2 ml tube to a Spin-X tube. Microcentrifuge 5 min at maximum speed to filter the eluted DNA.
61. Extract with an equal volume of PC8, then precipitate with ethanol as follows:
 - 300 μl sample
 - 5 μl 20 mg/ml glycogen
 - 200 7.5 M ammonium acetate
 - 900 μl 100% ethanol.Vortex briefly and place at -80°C for 15 min.
62. Microcentrifuge 30 min at maximum speed, room temperature. Wash by adding 500 μl of 70% ethanol, microcentrifuging 5 min at maximum speed, room temperature, and removing the supernatant. Resuspend each pellet in 3 μl of LoTE buffer (total 6 μl).

Ligate concatamers and vector

63. Prepare linearized plasmid by combining the following:
 - 1 μl 1 $\mu\text{g}/\mu\text{l}$ pZErO-1 vector
 - 1.5 μl 10 \times Buffer 2
 - 1.5 μl *Sph*I
 - 11 μl H₂O.Incubate 25 min at 37 $^{\circ}\text{C}$.

Do not incubate >30 min, as overdigestion will reduce cloning efficiency.
64. Add 185 μl LoTE. Extract with an equal volume of PC8 and precipitate with ethanol by combining the following:
 - 200 μl linearized plasmid
 - 3 μl 20 mg/ml glycogen
 - 150 μl 7.5 M ammonium acetate
 - 600 μl 100% ethanol.Vortex briefly and place at -80°C for 15 min.
65. Centrifuge 30 min in a tabletop centrifuge at maximum speed at room temperature. Wash with 500 μl of 70% ethanol and resuspend the pellet in 10 μl of LoTE buffer.
66. Prepare the following reaction mixture for ligation:
 - 6 μl purified concatamer (or 6 μl H₂O for vector-alone control)
 - 1 μl linearized pZErO-1 vector
 - 1 μl 10 \times ligase buffer
 - 1 μl H₂O
 - 1 μl T4 DNA ligase.Incubate overnight at 12 $^{\circ}\text{C}$.
67. Add 200 μl LoTE buffer. Extract with an equal volume of PC8, then precipitate with ethanol by combining the following:
 - 200 μl sample
 - 3 μl 20 mg/ml glycogen
 - 150 μl 7.5 M ammonium acetate
 - 600 μl 100% ethanol.Vortex briefly and place at -80°C for 15 min.

68. Microcentrifuge 30 min at maximum speed, room temperature. Wash by adding 500 μ l of 70% ethanol, microcentrifuging 5 min at maximum speed, and removing the supernatant. Resuspend pellet in 10 μ l LoTE buffer.

Transform E. coli and check insert sizes

69. Thaw ElectroMAX DH10B electroporation-competent cells on ice. Pipet 40 μ l of the competent cells and 5 μ l DNA into an electroporation cuvette.
70. Perform electroporation with Bio-Rad GenePulser electroporator at 100 Ω , 25 μ F, and 1.8 kV (also see *UNIT 1.8*). Transfer electroporated cells into a 1.5-ml microcentrifuge tube, add 1 ml SOC medium at room temperature, and shake for 20 min at 225 rpm at 37°C.
71. Plate one-fifth of the transformed cells onto each of five 10-cm Zeocin-containing low-salt LB plates. Incubate at 30°C and analyze 14 to 18 hr later.

Save all plates for future use. If insert sizes are appropriate, these may be used for further sequencing.

72. To check insert sizes, set up 50- μ l PCR reactions in a 96-well PCR plate as follows:

5 μ l 10 \times PCR buffer
3 μ l 25 mM MgCl₂
2.5 μ l DMSO
0.7 μ l standard dNTP mix (25 mM each dNTP)
1 μ l 5 μ M M13 forward primer
1 μ l 5 μ M M13 reverse primer
35.8 μ l H₂O
1 μ l 5 U/ μ l *Taq* DNA polymerase.

Use a sterile toothpick to pick each clone and transfer it to a well of the plate.

73. Perform amplification as follows:

1 cycle:	2 min	94°C	(denaturation)
25 cycles:	30 sec	94°C	(denaturation)
	1 min	55°C	(annealing)
	90 sec	72°C	(extension)
1 cycle:	5 min	72°C	(final extension).

74. Run 5 μ l of each PCR reaction on a 1.5% agarose gel and select the clones that have concatamer inserts of the appropriate size for subsequent sequencing reactions.

75. Perform sequencing reactions and analyze the sequencing data (*UNIT 15.2*).

Instead of sequencing the colony PCR product as described here, 96-well cultures can be grown from recombinant clones and frozen as glycerol stocks. These stocks can be used for subsequent PCR reactions or plasmid preparation to generate templates for sequencing.

SUBTRACTION STAGE (SubSTAGE)

Nonspecific genomic DNA carried through in the ChIP sample can also be represented as STAGE tags. Applying a subtraction step to the original ChIP DNA material increases the relative enrichment of target loci, and this increased enrichment can be verified by ChIP-PCR (*UNIT 21.3*). The Subtraction STAGE (SubSTAGE) protocol is used to subtract background from ChIP DNA with an excess of genomic DNA.

**SUPPORT
PROTOCOL**

**Chromatin
Assembly and
Analysis**

21.10.11

Additional Materials (see also *Basic Protocol*)

- Unbiotinylated round B primer (see recipe for PCR primers; omit biotinylation)
- 1 M Tris·Cl, pH 7.5 (*APPENDIX 2*)
- 0.5 M EDTA (*APPENDIX 2*)
- 1 M NaOH (*APPENDIX 2*)
- 72° and 95°C water baths or heating blocks
- Additional reagents and equipment for ChIP-PCR (*UNIT 21.3*)

Anneal ChIP DNA and genomic DNA

1. Amplify ChIP DNA samples as described in the *Basic Protocol*, steps 1 to 11, but use a normal, unbiotinylated round B primer in step 6 and perform 20 amplification cycles in step 7. Use 1 µg of this amplified ChIP DNA as a “tester” in the subtraction step below.

Here, “tester” means the amplified sample ChIP DNA and “driver” means amplified genomic DNA used to remove nonspecific DNA fragments from the tester.

2. Amplify sheared genomic DNA samples (average length, 1 kb) as described in the *Basic Protocol*, steps 1 to 11, using a biotinylated primer B and resuspending the pellet in water rather than LoTE buffer at step 11 of the *Basic Protocol*. Use a 5×, 10×, or 15× excess of this amplified genomic DNA (5 µg, 10 µg, or 15 µg) as a “driver.”

All three “drivers” may be used for subsequent steps. After finishing subtraction, enhancement of enrichment can be tested as described in step 17, below.

3. Incubate driver genomic DNA at 72°C for 15 min in a 200-µl solution containing either 5, 10, or 15 µg genomic DNA, 10 mM Tris·Cl, pH 7.5 (added from 1 M stock), 1.0 mM EDTA, and 100 mM NaOH.

The purpose of this step is to denature dsDNA fragments. Unbiotinylated ssDNA will be removed in subsequent steps.

4. Wash four 100-µl aliquots of Dynabeads M-280 Streptavidin beads three times as described in the *Basic Protocol*, step 15.
5. Add driver genomic DNA to one aliquot of prewashed beads and incubate at room temperature for 20 min with occasional mixing.
6. Immobilize driver genomic DNA using a magnetic rack and remove the supernatant.
7. Wash the beads/driver genomic DNA three times with 1× BW buffer using the magnetic rack.

This step removes unbiotinylated genomic DNA.

8. Dissolve 1 µg tester DNA in 200 µl of 1× BW buffer and add this to the complex of beads and driver genomic DNA.
9. Denature the sample by incubating at 95°C for 5 min and cool slowly to room temperature to form tester-driver heteroduplexes.
10. Add the second aliquot of prewashed beads to the reaction and incubate at room temperature for 20 min with occasional mixing.

Remove heteroduplexes

11. Immobilize the beads with tester-driver heteroduplexes using the magnetic rack and transfer the supernatant to a new tube.
12. Add the third aliquot of prewashed beads to the tube that contains the supernatant, incubate at room temperature for another 20 min, and remove the beads remaining in the supernatant using the magnetic rack. Transfer the supernatant to a new tube.

13. Add the fourth aliquot of prewashed beads, perform a third round of magnetic bead removal, and then transfer the final subtracted DNA fragments to a new tube.

Isolate subtracted DNA

14. Extract sample with an equal volume (200 μ l) of PC8.

15. Precipitate with ethanol by combining the following:

- 200 μ l subtracted ChIP DNA
- 2 μ l 20 mg/ml glycogen
- 150 μ l 7.5 M ammonium acetate
- 600 μ l 100% ethanol.

Vortex briefly and place at -80°C for 15 min.

16. Microcentrifuge 30 min at maximum speed, room temperature. Wash by adding 500 μ l of 70% ethanol, microcentrifuging 5 min at maximum speed, room temperature, and removing the ethanol. Resuspend pellet in 20 μ l LoTE buffer.
17. Test the enrichment of the original ChIP DNA and subtracted ChIP DNA by ChIP-PCR as described in *UNIT 21.3*.
18. Use this subtracted ChIP DNA as the input for STAGE when it shows better enrichment than the original ChIP DNA (see Basic Protocol, step 1).

REAGENTS AND SOLUTIONS

Use autoclaved double-distilled water in all recipes and protocol steps. For common stock solutions, see *APPENDIX 2*; for suppliers, see *APPENDIX 4*.

BW buffer, 1 \times

For 2 \times stock:

10 mM Tris \cdot Cl, pH 7.5 (*APPENDIX 2*)

1 mM EDTA

2.0 M NaCl

Store up to 1 year at room temperature

Dilute to 1 \times with H₂O just before use

Linkers

Linker 1A: 5'-TTTGGATTTGCTGGTGCAGTACAACCTAGGCTTAATATCCGACATG-3'

Linker 1B: 5'-TCGGATATTAAGCCTAGTTGTACTGCACCAGCAAATCC (aminomod C7)-3'

Linker 2A: 5'-TTTCTGCTCGAATTCAAGCTTCTAACGATGTACGTCCGACATG-3'

Linker 2B: 5'-TCGGACGTACATCGTTAGAAGCTTGAATTCGAGCAG (aminomod C7)-3'

In linkers 1B and 2B, "aminomod C7" refers to a 3' amino modification. A primary amine group is attached to the 3' end of a nucleotide through a C7 carbon-chain arm. It blocks a possible ligation reaction at the 3' terminus.

The authors recommend ordering oligonucleotides from Integrated DNA Technologies.

LoTE buffer

3 mM Tris \cdot Cl, pH 7.5 (*APPENDIX 2*)

0.2 mM EDTA, pH 7.5

Store up to 1 year at room temperature

PC8

Combine the following in the order indicated:

480 ml phenol, warmed to 65°C
320 ml 0.5 M Tris·Cl, pH 8.0 (*APPENDIX 2*)
640 ml chloroform

Shake to mix and place at 4°C. After 2 to 3 hr, shake again. After an additional 2 to 3 hr, aspirate aqueous layer. Store up to 1 year in aliquots at -20°C or up to 6 months at 4°C.

Commercially available 1:1 (v/v) phenol:chloroform mix can also be substituted, as long as the pH is preset to 8.0.

PCR buffer, 10×

500 mM KCl
100 mM Tris·Cl, pH 8.3 (*APPENDIX 2*)

PCR primers

Round A primer: 5'-GTTTCCCAGTCACGATCNNNNNNNNN-3'
Round B primer: 5'-Biotin-GTTTCCCAGTCACGATCACGATC-3'
Primer 1: 5'-GTGCTCGTGGGATTTGCTGGTGCAGTACA-3'
Primer 2: 5'-GAGCTCGTGCTGCTCGAATTCAAGCTTCT-3'
M13 forward primer: 5'-GTAAAACGACGGCCAGT-3'
M13 reverse primer: 5'-GGAAACAGCTATGACCATG-3'

The authors recommend ordering oligonucleotides from Integrated DNA Technologies.

Sample loading buffer, 6×

0.25% (w/v) bromphenol blue
0.25% (w/v) xylene cyanol FF
30% (v/v) glycerol

SOC medium

0.5% yeast extract
2% tryptone
10 mM NaCl
2.5 mM KCl
10 mM MgCl₂
10 mM MgSO₄
20 mM glucose
Store at room temperature (stable for years)

Zeocin-containing low-salt LB plates

For 1 liter:
10 g tryptone
5 g yeast extract
5 g NaCl
Adjust pH to 7.5
Add 15 g Bacto agar
Autoclave and allow to cool
Add Zeocin to 100 mg/ml

COMMENTARY

Background Information

DNA-binding proteins such as transcription factors, activators, and repressors control the expression of target genes by binding to specific genomic target loci. Mapping the chromosomal target loci of transcription factors is important for deciphering gene regulatory networks that mediate cellular responses. Conventionally, a small number of target loci of various transcription factors have been determined by chromatin immunoprecipitation (ChIP) and subsequent PCR (UNIT 21.3). More recently, methods combining ChIP and DNA microarrays have allowed researchers to define the direct chromosomal targets of transcription factors *in vivo* on a genome-wide scale (Ren et al., 2000; Iyer et al., 2001; UNIT 21.9). It is not yet feasible, however, to apply this method on a truly comprehensive scale in organisms with large and complex genomes, because whole-genome microarrays are not available for most organisms (Ren et al., 2002; Weinmann et al., 2002). Sequence tag analysis of genomic enrichment (STAGE) is a genome-wide method for identifying the chromosomal targets of DNA-binding proteins in any sequenced genome without using microarrays (Kim et al., 2005). STAGE is conceptually derived from serial analysis of gene expression (SAGE; Velculescu et al., 1995; Saha et al., 2002), but is applied to DNA isolated after ChIP.

STAGE does not rely on any assumptions about the location and distribution of these binding sites in the genome. It is therefore a useful method for identifying functional elements in the genome. The coverage, or comprehensiveness, of this method is limited in principle only by the depth of sequencing, which is a reliable, widely available, automatable, inexpensive, and high-throughput procedure. The fact that sequencing is performed on concatamerized tags makes this a truly genomic method that can be quantitative. By analogy to SAGE, the number of times one observes a given tag within a STAGE pool or library should be directly proportional to the enrichment of that sequence in the original ChIP DNA pool. Since it is not dependent on microarray resources, STAGE is applicable to any sequenced genome.

Critical Parameters and Troubleshooting

For successful STAGE, it is critical to start with high-purity ChIP material that shows high

enrichment of target loci relative to background (UNIT 21.3). The quality of the ChIP DNA material should be tested by conventional ChIP-PCR before starting the STAGE procedure.

Obtaining good separation of bands on gels and identification and isolation of the correct band away from nonspecific bands during all gel-extraction steps are very important to this procedure. In case the isolation of the right band is not successful, a second gel-purification step should be carried out.

It is possible that a proportion of STAGE tags will not match any sequence within the given genome. This can occur because of contaminating DNA in the original ChIP sample or because of PCR or sequencing errors. To minimize contamination from extraneous DNA, use fresh solutions for every step and prepare aliquots for all solutions. Use aerosol-barrier pipet tips throughout the procedure.

Anticipated Results

If the Basic Protocol works without any problems, ~90% of colonies should contain inserts of the appropriate size. The majority of inserts should contain ~25 tags, so ~50,000 STAGE tags will be obtained from 2000 sequencing reactions. The number of STAGE tags that need to be sequenced to achieve complete coverage of the targets of a protein will depend on many factors, including the actual number of targets and the quality of the ChIP reaction.

Time Considerations

Biotinylation of ChIP DNA using the two-round amplification procedure usually takes 3 to 4 hr. From this point to ditag ligation takes ~8 to 10 hr, excluding the overnight ligation step. Optimizing PCR and performing the large-scale amplification takes 6 to 8 hr. Ditag purifications, including the two gel extraction steps, take 6 to 8 hr on 2 days. Concatamer ligation, purification, and subcloning take 6 to 8 hr. Cleanup of ligation products and transformation takes 3 to 4 hr. Colony PCR and gel analysis take 5 to 6 hr. After obtaining the desired number of colonies with appropriate insert sizes, sequencing can be carried out. The laborious step of picking hundreds of *E. coli* transformants and assaying for insert sizes may be circumvented by using an automated colony picker if one is available, or by using commercial services that can carry out this part of the operation.

Mapping Chromatin Interactions by Chromosome Conformation Capture

This unit describes chromosome conformation capture (3C), a PCR-based method to analyze chromosome conformation (Dekker et al., 2002). This methodology is used to detect the frequencies of interactions between chromosomal fragments inside intact cells and is one of only a few techniques that allows for high-resolution analysis of chromosome organization. Specifically, 3C is widely and successfully used for detection of looping interactions between sequence elements, e.g., between gene promoters and distant regulatory elements such as enhancers (Tolhuis et al., 2002; Spilianakis and Flavell, 2004; Vakoc et al., 2005).

In this assay (depicted in Fig. 21.11.1), cells are treated with formaldehyde to induce both protein-protein and protein-DNA cross-links, which can result in covalently linking interacting chromatin segments. Cross-linked chromatin is then solubilized and digested by a restriction enzyme. The digestion is followed by ligation under dilute DNA concentrations, which strongly promotes intramolecular ligation of cross-linked fragments over intermolecular ligation of random fragments. The cross-links are then reversed and DNA is purified. The resulting 3C template contains a large number of ligation products, each representing a specific interaction between two genomic loci. The relative abundance of a particular ligation product reflects the frequency with which the two restriction fragments interact inside the cell nucleus.

Ligation products are detected and quantified by semi-quantitative PCR. A control template must also be generated to contain all possible ligation products in equal amounts. The control template is used to correct for differences in primer efficiencies. A ratio is then determined between the amount of ligation product of the 3C template versus the amount of ligation product of the control template. This value, the interaction frequency, is a measure of how frequently two chromosomal fragments interact inside the nucleus. Once a sufficient number of interaction frequencies have been obtained for a genomic region of interest, its spatial organization can be inferred.

This unit describes the protocols for generating 3C and control templates for both *Saccharomyces cerevisiae* (see Basic Protocols 1 and 2) and mammalian cells (see Basic Protocols 3 and 4). Also included in this unit is a description of how to analyze ligation products by PCR (see Basic Protocol 5).

Figure 21.11.1 Schematic representation of the chromosome conformation capture (3C) technology. Cells are treated with formaldehyde to induce a cross-link resulting in covalent linkage of interacting chromatin segments (indicated by the solid center oval). Cross-linked chromatin is digested and ligated under dilute DNA concentrations. After reversal of cross-links, ligation products can be detected by semi-quantitative PCR (arrows indicate PCR primers).

STRATEGIC PLANNING

The 3C technique has proven to be exceptionally powerful and is now widely used, at least in part because it can be performed in any molecular biology laboratory and does not require any special equipment. The preparation of the assay should involve careful thought and planning. Restriction enzyme selection and primer design play pertinent roles and should be considered before the start of the experiment.

Restriction Enzyme Selection

The restriction enzyme used for digestion can vary. As mentioned previously, 3C can be used to detect looping interactions between sequence elements. It is important that the restriction enzyme cut sites are spaced evenly and frequently throughout the region of interest. For proper analysis, the putative looping elements should each be contained in a restriction fragment no larger than 10 kb and no smaller than 1 kb in size, because very large and very small fragments result in slightly higher and lower interaction frequencies, respectively. Furthermore, there should be multiple restriction fragments between the elements to obtain a high-resolution looped structure. Once a looping interaction is found, a different enzyme should be selected to confirm the results. For initial studies, a restriction enzyme that cuts every 4 kb or so is recommended. Once a looped structure is detected, a more frequently cutting enzyme can be used to obtain a more precise map.

Primer Design

Once a restriction enzyme is chosen, primers must be designed throughout the genomic region of interest. Primers are designed unidirectionally at a site that is ~80 to 150 bp 5' of the restriction enzyme cut site. Head-to-head ligation of two restriction fragments can then be amplified by two primers, resulting in a PCR product that will be 160 to 300 bp long.

Typically, primers are 28 bp in length, have a GC content of ~50%, and ideally have similar melting temperatures. Primer combinations should be tested using a control template (see Basic Protocols 2 and 4), and primer pairs that do not amplify the correct product, that amplify multiple products, that do not yield equal amounts of PCR products when using control template, or that produce high levels of primer dimers should be omitted and redesigned, if so desired. Primers should not be designed on restriction fragments > 10 kb or < 1 kb in size.

GENERATION OF 3C TEMPLATE FROM INTACT YEAST CELLS

This protocol outlines the method to obtain a 3C template from intact *Saccharomyces cerevisiae* cells. In this protocol, intact yeast cells are spheroplasted and the cell wall is digested with zymolyase. These spheroplasts are cross-linked with formaldehyde, and the chromatin is solubilized and digested with a restriction enzyme. After digestion, the cross-linked chromatin is ligated, cross-links are reversed, and DNA is purified. The resulting 3C template consists of a collection of ligation products. The abundance of a given ligation product depends on the distance between the two genomic segments (when they are located on the same chromosome) and, importantly, also depends on any specific looping interactions (see Fig. 21.11.4).

Materials

- Saccharomyces cerevisiae* cells of interest (UNIT 13.2)
- Spheroplasting buffer I (see recipe)
- 20 mg/ml zymolyase 100-T solution (see recipe)
- MES wash buffer (see recipe)
- 37% (v/v) formaldehyde
- 2.5 M glycine

BASIC PROTOCOL 1

Chromosome Conformation Capture

21.11.2

Restriction enzyme and corresponding 10× restriction enzyme buffer
 1% and 10% (w/v) sodium dodecyl sulfate (SDS; *APPENDIX 2*)
 10% (v/v) Triton X-100
 10× ligation buffer (see recipe)
 10 mg/ml bovine serum albumin (BSA)
 100 mM adenosine triphosphate (ATP)
 T4 DNA ligase
 10 mg/ml proteinase K in TE buffer, pH 8.0
 1:1 (v/v) phenol/chloroform (*UNIT 2.1A*)
 3 M sodium acetate, pH 5.2 (*APPENDIX 2*)
 100% ethanol
 TE buffer, pH 8.0 (*APPENDIX 2*)
 10 mg/ml DNase-free RNase A (*UNIT 3.13*)
 15-, 50-, and 250-ml disposable conical tubes
 Roller drum in 30°C incubator
 Refrigerated tabletop centrifuge
 1.7-ml microcentrifuge tubes
 16°, 37°, 42°, and 65°C water baths
 30-ml screw-cap centrifuge tubes

Prepare and cross-link cells

1. Obtain a 200-ml culture of *Saccharomyces cerevisiae* cells at $OD_{600} = 1$ (*UNIT 13.2*).
2. Centrifuge cells in a 250-ml disposable conical tube for 10 min at $1250 \times g$ (2500 rpm), room temperature, and remove supernatant promptly.
3. Resuspend cells in 10 ml spheroplasting buffer I and transfer to a 15-ml disposable conical tube. Add 50 μ l of 20 mg/ml zymolyase 100-T solution and gently mix tube.

The entire concentration of 20 mg/ml zymolyase 100-T will not go into solution. Make up the zymolyase solution at least 1 day prior to use. Before zymolyase is added to the cells, be sure that the solution is mixed well and in a suspension.

4. Incubate in roller drum for 40 min at 30°C.

The efficiency of cell wall digestion should be tested by cell lysis. This can be done by adding water to a small amount of cells on a glass slide while observing under a microscope. Digestion is complete when ~80% of cells burst open and exhibit hypotonic lysis within 1 to 2 min.

5. Centrifuge cells 5 min at $2460 \times g$ (3500 rpm), room temperature, in a refrigerated tabletop centrifuge. Wash cells two times in 10 ml MES wash buffer, centrifuging again after each wash.
6. Dissolve cell pellet in 10 ml MES wash buffer.
7. Add 263 μ l of 37% formaldehyde (1% final), mix thoroughly, and incubate 10 min at room temperature.
8. Add 0.5 ml of 2.5 M glycine and incubate 5 min at room temperature.

Cells can now be stored for up to 1 year at -80°C in 1-ml aliquots or can directly be digested.

Digest cross-linked cells

9. Add 50 μ l of cross-linked cells to 40 individual 1.7-ml microcentrifuge tubes.

Reactions should not be pooled. Typically, tubes containing 50 μ l of cells yield the best results, although the total amount of cells used can vary depending on need. When 40 tubes are used, the obtained 3C template is sufficient to measure ~350 interactions.

10. Wash cells three times with 100 μ l of 1 \times restriction enzyme buffer per tube. For each wash, mix by pipetting up and down, centrifuge 3 min at 18,000 \times g (14,000 rpm), room temperature, and remove the supernatant.

Restriction enzyme buffer should correspond with enzyme of choice, as recommended by the manufacturer.

11. Resuspend pellet thoroughly in 36.2 μ l of 1 \times restriction enzyme buffer per tube, add 3.8 μ l of 1% SDS per tube, and incubate for 10 min at 65°C.

This step proves to be essential in template generation. Care should be taken to ensure proper incubation temperature.

12. Add 4.4 μ l of 10% Triton X-100 per tube. Mix well by pipetting up and down.

Triton X-100 binds to SDS and will thereby effectively remove SDS, which is required for subsequent restriction digestion.

13. Add 60 U restriction enzyme per tube, mix well, and incubate reactions overnight at an appropriate temperature.

The temperature should correspond with enzyme of choice, as recommended by the manufacturer.

14. Add 8.6 μ l of 10% SDS per tube and incubate 20 min at 65°C.

SDS is added at high concentrations to inactivate the restriction enzyme.

Ligate cross-linked cells

15. Add the following to each tube and incubate for 2 hr at 16°C:

74.5 μ l of 10% Triton X-100
74.5 μ l of 10 \times ligation buffer
8 μ l of 10 mg/ml BSA
8 μ l of 100 mM ATP
596 μ l distilled water
800 Weiss units T4 DNA ligase.

Due to the large number of tubes, a master mix of all components is typically made for all ligations and distributed amongst the tubes.

Reverse cross-links and purify 3C template

16. Add 5 μ l of 10 mg/ml proteinase K in TE buffer, pH 8.0, and incubate overnight at 65°C to reverse cross-links.

17. Add an additional 5 μ l of 10 mg/ml proteinase K in TE buffer, pH 8.0, and incubate 2 hr at 42°C.

An additional proteinase K treatment improves DNA purification.

18. Combine ten reactions in 50-ml disposable conical tubes to end up with four larger pooled reactions (if starting with 40 tubes).

Do not pool more than ten reactions, as template quality will decrease.

19. Add an equal volume of 1:1 (v/v) phenol/chloroform to each of the ligation mixtures, vortex for 30 sec, and centrifuge 5 min at 2460 \times g (3500 rpm), room temperature.

At this step in the purification, the aqueous (upper) phase will appear cloudy.

20. Promptly collect the aqueous (upper) phase, taking care not to include any of the interface layer.

21. Repeat phenol/chloroform extraction and transfer aqueous phase to a 30-ml screw-cap centrifuge tube.

At this step, the aqueous phase should be clear. If the aqueous phase is still cloudy, then repeat the phenol/chloroform extraction until the aqueous phase becomes clear.

22. Add 1/10 vol of 3 M sodium acetate, pH 5.2, and vortex briefly. Precipitate DNA by adding 2.5 vol of ice-cold 100% ethanol and mixing gently. Incubate 15 min at -80°C and centrifuge 20 min at $12,000 \times g$ (10,000 rpm), 4°C .

23. Remove supernatant and let pellets dry completely before resuspending each pellet in 50 μl TE buffer, pH 8.0. Pool all four samples to obtain a 200 μl DNA solution (this is the 3C template).

A total volume of 200 μl TE buffer, pH 8.0, should be used to resuspend the pellet when 40 tubes are initially used (in step 9). If fewer tubes are used, the final volume should be adjusted accordingly.

24. Add 2 μl of 10 mg/ml DNase-free RNase A and incubate 15 min at 37°C .

25. Store 3C template up to 2 years at -20°C .

3C templates stored for 2 years at this temperature have retained original quality.

GENERATION OF CONTROL TEMPLATE FROM YEAST GENOMIC DNA

This protocol outlines the method to obtain a control template from *Saccharomyces cerevisiae*. In this protocol, yeast chromosomal DNA is isolated, digested, and randomly ligated. This control template will contain all possible ligation products in equal amounts and serves as an excellent control for primer efficiencies. The control template is used in combination with the 3C template to determine interaction frequencies (see Basic Protocol 5).

Materials

Saccharomyces cerevisiae cells of interest (UNIT 13.2)
Spheroplasting buffer II (see recipe)
Lysing buffer I (see recipe)
20 mg/ml proteinase K in TE buffer, pH 8.0
5 M potassium acetate
80% and 100% ethanol, ice cold
TE buffer, pH 8.0 (APPENDIX 2), containing 10 $\mu\text{g}/\text{ml}$ DNase-free RNase A
1:1 (v/v) phenol/chloroform (UNIT 2.1A)
100% isopropanol
Restriction enzyme and corresponding $10\times$ restriction enzyme buffer
3 M sodium acetate, pH 5.2 (APPENDIX 2)
 $10\times$ ligation buffer (see recipe)
1 mg/ml bovine serum albumin (BSA)
10 mM adenosine triphosphate (ATP)
T4 DNA ligase
0.5 M EDTA, pH 8.0 (APPENDIX 2)
250-ml disposable conical tubes
 16° , 37° , and 65°C water baths
1.7-ml microcentrifuge tubes
Refrigerated microcentrifuge
Additional reagents and equipment for quantifying DNA by absorption spectroscopy (APPENDIX 3D)

BASIC PROTOCOL 2

Chromatin Assembly and Analysis

21.11.5

Isolate yeast chromosomal DNA

1. Obtain a saturated, overnight 200-ml culture of the same *Saccharomyces cerevisiae* strain used in Basic Protocol 1.
2. Centrifuge cells in a 250-ml disposable conical tube for 10 min at $1250 \times g$ (2500 rpm), room temperature, and remove supernatant promptly.
3. Resuspend cells in 20 ml spheroplasting buffer II. Distribute 500 μl of cells to each of 40 individual 1.7-ml microcentrifuge tubes.

Reactions should not be pooled.

4. Incubate 40 min at 37°C .

Solution should appear stringy.

5. Add 100 μl lysing buffer I to each tube.
6. Add 10 μl of 20 mg/ml proteinase K in TE buffer, pH 8.0, to each tube and incubate 30 min at 65°C .

Solution should now appear clearer.

7. Add 100 μl of 5 M potassium acetate to each tube and incubate 10 min in ice water.
8. Centrifuge tubes 20 min at $18,000 \times g$ (14,000 rpm), 4°C .
9. Transfer supernatants to fresh 1.7-ml microcentrifuge tubes containing 500 μl of ice-cold 100% ethanol. Invert tubes five times and centrifuge 10 min at $18,000 \times g$ (14,000 rpm), room temperature.
10. Carefully remove supernatant and let DNA pellet dry completely.
11. Add 500 μl TE buffer, pH 8.0, containing 10 $\mu\text{g/ml}$ DNase-free RNase A and incubate 30 min at 37°C to dissolve DNA. Occasionally tap tubes gently.

Depending on amount of DNA isolated, this step may take >30 min. Incubation should continue until all DNA is dissolved.

12. Add an equal volume of 1:1 (v/v) phenol/chloroform, vortex 30 sec, and centrifuge 5 min at $1100 \times g$ (3500 rpm), room temperature.
13. Transfer aqueous (upper) phase to fresh 1.7-ml microcentrifuge tubes. Precipitate DNA by adding 500 μl of 100% isopropanol and invert tubes five times. Centrifuge 10 min at $18,000 \times g$ (14,000 rpm), room temperature.

DNA should be visible as a string-like ball after isopropanol is added.

14. Wash DNA with 500 μl of 80% ethanol and centrifuge 10 min at $18,000 \times g$ (14,000 rpm), room temperature.
15. Dry DNA pellets, then dissolve each pellet in 100 μl TE buffer, pH 8.0. Pool samples.
16. Determine DNA concentration using absorption spectroscopy (*APPENDIX 3D*).

Digest yeast genomic DNA

17. Add 10 μg genomic DNA to each of 20 individual 1.7-ml microcentrifuge tubes.

Reactions should not be pooled.

18. Digest in 400- μl reactions using 60 U of the same restriction enzyme and $10\times$ restriction enzyme buffer used in Basic Protocol 1. Incubate 3 hr at an appropriate temperature.

Restriction enzyme buffer and incubation temperature should correspond with enzyme of choice, as recommended by the manufacturer.

19. Add an equal volume of 1:1 phenol/chloroform to each reaction, vortex for 30 sec, and centrifuge 5 min at $1100 \times g$ (3500 rpm), room temperature.
20. Transfer aqueous (upper) phase to a fresh 1.7-ml microcentrifuge tube. Add 1/10 vol of 3 M sodium acetate, pH 5.2, and vortex briefly. Precipitate DNA by adding 2.5 vol of ice-cold 100% ethanol and mixing gently. Centrifuge cells for 10 min at $18,000 \times g$ (14,000 rpm), 4°C, and carefully remove supernatant.
21. Resuspend DNA in 0.5 ml of 80% ethanol to wash pellet and centrifuge tubes 10 min at $18,000 \times g$ (14,000 rpm), 4°C. Carefully remove supernatant and let pellet dry completely.
22. Dissolve each DNA pellet in 20 μ l autoclaved water.

Ligate yeast genomic DNA

23. Add the following to each tube and incubate 1 hr at 16°C:

3 μ l of 10 \times ligation buffer
 3 μ l of 1 mg/ml BSA
 3 μ l of 10 mM ATP
 800 Weiss units T4 DNA ligase.

Due to the large number of tubes, a master mix of all components is typically made for all ligations and distributed amongst the tubes.

Purify yeast genomic DNA control template

24. Make two pools of ten reactions each to result in two larger reactions, and stop the reactions by adding 6 μ l of 0.5 M EDTA, pH 8.0.
25. Add an equal volume of 1:1 phenol/chloroform, vortex for 30 sec, and centrifuge 5 min at $1100 \times g$ (3500 rpm), room temperature.
26. Transfer aqueous (upper) phase to a fresh 1.7-ml microcentrifuge tube. Add 1/10 vol of 3 M sodium acetate, pH 5.2, and vortex briefly. Precipitate DNA by adding 2.5 vol of ice-cold 100% ethanol and mixing gently. Centrifuge cells 10 min at $18,000 \times g$ (14,000 rpm), 4°C, and carefully remove supernatant.
27. Resuspend DNA in 0.5 ml of 80% ethanol to wash pellet. Centrifuge samples 10 min at $18,000 \times g$ (14,000 rpm), 4°C. Carefully remove supernatant and let pellet dry completely.
28. Dissolve each pellet in 400 μ l TE buffer, pH 8.0, and pool them to obtain a total volume of 800 μ l (this is the control template).
29. Store control template up to 3 years at -20°C .

Control templates stored for 3 years at this temperature have retained original quality.

GENERATION OF 3C TEMPLATE FROM MAMMALIAN CELLS

3C analyses in mammalian cells are performed using a modified version of the protocol developed for yeast cells (see Basic Protocol 1). In this modified version, intact mammalian cells are cross-linked and lysed. The lysed cells are then digested, ligated under dilute conditions, and the cross-links are reversed.

Materials

Mammalian cells growing in appropriate culture medium (*APPENDIX 3F*)
 37% (v/v) formaldehyde
 2.5 M glycine
 Lysing buffer II (see recipe), ice cold

**BASIC
 PROTOCOL 3**

**Chromatin
 Assembly and
 Analysis**

21.11.7

Protease inhibitor cocktail for use with mammalian cells
 Restriction enzyme and corresponding 10× restriction enzyme buffer
 1% and 10% (w/v) SDS
 10% (v/v) Triton X-100
 10× ligation buffer (see recipe)
 10 mg/ml BSA
 100 mM ATP
 T4 DNA ligase
 10 mg/ml proteinase K in TE buffer, pH 8.0
 Phenol (*UNIT 2.1A*)
 1:1 (v/v) phenol/chloroform (*UNIT 2.1A*)
 3 M sodium acetate, pH 5.2 (*APPENDIX 2*)
 70% and 100% (v/v) ethanol
 TE buffer, pH 8.0 (*APPENDIX 2*)
 Chloroform
 10 mg/ml DNase-free RNase A
 Dounce homogenizer with pestle B
 1.7-ml microcentrifuge tubes
 16°, 37°, 42°, and 65°C water baths
 15- and 50-ml disposable conical tubes
 250-ml screw-cap centrifuge bottles

Prepare and cross-link cells

1. Grow 1×10^8 cells in appropriate culture medium (*APPENDIX 3F*). Centrifuge cells 10 min at $450 \times g$ (1500 rpm), room temperature, remove supernatant, and dissolve pellet in 45 ml fresh culture medium.

The number of cells can be reduced or increased depending on need. In the procedure described here, the obtained template is sufficient to measure ~1000 interactions.

2. Add 1.35 ml of 37% formaldehyde (1% final), mix thoroughly by pipetting up and down, and incubate 10 min at room temperature.
3. Add 2.5 ml of 2.5 M glycine. Mix by pipetting up and down and incubate 5 min at room temperature.
4. Store on ice for at least 15 min.
5. Centrifuge cells 10 min at $800 \times g$ (2000 rpm), room temperature, resuspend pellet in 1 ml ice-cold lysing buffer II supplemented with 0.1 ml protease inhibitor cocktail, and incubate 15 min on ice.
6. Dounce homogenize cells on ice with pestle B by gently stroking 15 times, incubating 1 min on ice, and finally stroking 15 additional times.

Digest cross-linked cells

7. Centrifuge cells 5 min at $2500 \times g$ (5000 rpm), room temperature, in a 1.7-ml microcentrifuge tube, and wash with 0.5 ml of 1× appropriate restriction enzyme buffer. Centrifuge again and resuspend in 0.5 ml of 1× restriction enzyme buffer.
8. Distribute 25 μ l of cells to 20 individual 1.7-ml microcentrifuge tubes (each tube containing 5×10^6 cells).
9. Centrifuge 5 min at $2500 \times g$ (5000 rpm), room temperature, and resuspend each pellet in 362 μ l of 1× restriction enzyme buffer.
10. Add 38 μ l of 1% SDS to each tube and incubate 10 min at 65°C.
11. Add 44 μ l of 10% Triton X-100 to each tube. Mix by pipetting up and down.

12. Add 400 U restriction enzyme per tube. Mix well and incubate overnight at an appropriate temperature (per manufacturer's instructions).
13. Add 86 μl of 10% SDS and incubate 30 min at 65°C.

Ligate cross-linked cells

14. Transfer each reaction to a 15-ml disposable conical tube. Add the following to each tube and incubate 2 hr at 16°C:

745 μl of 10% Triton X-100
745 μl of 10 \times ligation buffer
80 μl of 10 mg/ml BSA
80 μl of 100 mM ATP
5960 μl distilled water
4000 Weiss units T4 DNA ligase.

Due to the large number of tubes, a master mix of all components is typically made for all ligations and distributed amongst the tubes.

Reverse cross-links and purify 3C template

15. Add 50 μl of 10 mg/ml proteinase K in TE buffer, pH 8.0, and incubate overnight at 65°C.
16. Add an additional 50 μl of 10 mg/ml proteinase K in TE buffer, pH 8.0, and incubate 2 hr at 42°C.
17. Transfer solutions to 50-ml disposable conical tubes, add an equal amount of phenol to each of the tubes, vortex for 30 sec, and centrifuge 5 min at 2460 $\times g$ (3500 rpm), room temperature.
18. Remove the aqueous (upper) phase, transfer to fresh 50-ml disposable conical tubes, and repeat the phenol extraction.
19. Add an equal volume of 1:1 (v/v) phenol/chloroform, vortex for 30 sec, and centrifuge 5 min at 2460 $\times g$ (3500 rpm), room temperature.
20. Pool the aqueous (upper) phases from the 20 samples into three 250-ml screw-cap centrifuge bottles. Add 1/10 vol of 3 M sodium acetate, pH 5.2, vortex briefly, and add 2.5 vol of ice-cold 100% ethanol.
21. Incubate 30 min (or overnight) at -80°C and centrifuge 20 min at 12,000 $\times g$ (10,000 rpm), 4°C.
22. Aspirate supernatant and resuspend the pellets in a total volume of 1 ml TE buffer, pH 8.0. Transfer DNA to two fresh 1.7-ml microcentrifuge tubes each containing 500 μl of DNA solution.
23. Perform phenol extraction (step 17), followed by two 1:1 phenol/chloroform extractions (step 19) for each tube.
24. Add an equal volume of chloroform to each tube, vortex for 30 sec, and centrifuge 5 min at 1100 $\times g$ (3500 rpm), room temperature. Remove the aqueous phase and transfer to fresh 1.7-ml microcentrifuge tubes.
25. Add 1/10 vol of 3 M sodium acetate, pH 5.2, and vortex briefly. Precipitate DNA by adding 2.5 vol of ice-cold 100% ethanol and mixing gently. Incubate 15 min at -20°C and centrifuge 20 min at 18,000 $\times g$ (14,000 rpm), 4°C.
26. Wash the pellets five times with 70% ethanol.

These five wash steps are necessary to remove extra salt in the template.

27. Dry the pellets and dissolve in a total volume of 1 ml TE buffer, pH 8.0 (this is the 3C template).
28. Add 1 μ l of 10 mg/ml DNase-free RNase A and incubate 15 min at 37°C.
29. Store 3C template up to 2 years at -20°C.

3C templates stored for 2 years at this temperature have retained original quality.

GENERATION OF CONTROL TEMPLATE FROM MAMMALIAN DNA

This protocol outlines the method to obtain a control template from mammalian genomic DNA. Due to the complexity of the mammalian genome, a control template generated from whole genomic DNA does not contain detectable levels of any specific ligation product. Thus, a control template is generated from the genomic region of interest only. In this protocol, a bacterial artificial chromosome (BAC) clone (*UNIT 5.9*) or set of clones containing the genomic region of interest is purified, digested, and randomly ligated. This procedure generates a control template, i.e., a collection of all possible ligation products that are present in equimolar amounts. This control template is used in combination with the 3C template to determine interaction frequencies (see Basic Protocol 5).

Materials

BAC clones (e.g., Invitrogen and CHORI; <http://bacpac.chori.org>)
TE buffer, pH 8.0 (*APPENDIX 2*)
0.8% agarose/0.5 \times TBE gel (*UNIT 2.5A*)
Molecular weight standard of known concentration
Restriction enzyme and corresponding 10 \times restriction enzyme buffer
10 mg/ml BSA
1:1 (v/v) phenol/chloroform (*UNIT 2.1A*)
3 M sodium acetate, pH 5.2 (*APPENDIX 2*)
70% and 100% (v/v) ethanol, ice cold
10 \times ligation buffer (see recipe)
100 mM ATP
T4 DNA ligase
Chloroform
1.7- and 2-ml microcentrifuge tubes
16°, 37°, and 65°C water baths
Additional reagents and equipment for recovery of DNA from PAC/BAC clones (*UNIT 5.9*), for real-time PCR if applicable (*UNIT 21.3*), and for agarose gel electrophoresis (*UNIT 2.5A*)

Select, amplify, and purify BAC clone(s)

1. Select one or more BAC clones covering the genomic region of interest. If more than one clone is needed, there should be minimal overlap and possibly no gaps between the clones.
2. Purify the BAC DNA from 500-ml overnight cultures by the modified alkaline lysis method as described in *UNIT 5.9*. Resuspend BAC DNA in 1 ml of TE buffer, pH 8.0.
3. Estimate DNA concentration by running 1 μ l of BAC DNA on a 0.8% agarose/0.5 \times TBE gel (*UNIT 2.5A*) beside a molecular weight standard of known concentration.

The concentration of the BAC DNA should be between 50 and 100 ng/ml.

*If more than one BAC clone is required to cover the genomic region of interest, the clones should be mixed in equimolar ratios before digestion. For this, the BAC preparations should be quantified by real-time quantitative PCR with SYBR green (*UNIT 21.3*) using universal primers that amplify part of the BAC vector backbone.*

Digest BAC genomic DNA clones

4. Transfer ~20 μg of BAC DNA to a 2-ml microcentrifuge tube.

If more than one BAC is required, the total amount of BAC DNA should equal 20 μg .

The total DNA volume should represent 10% of the final digestion volume. Do not exceed 200 μl of DNA in the final 2-ml digestion. If the volume is >200 μl , precipitate DNA and resuspend in a more suitable volume.

Reserve 1 μl of undigested material to run on an agarose gel alongside the digested BAC DNA and ligated BAC DNA as a control for digestion efficiency.

5. Add an appropriate amount of water, 10 \times restriction enzyme buffer, and 10 mg/ml BSA (if recommended by the manufacturer) to obtain, after addition of enzyme, a solution containing 1 \times restriction enzyme buffer and 100 ng/ μl BSA.
6. Add 40 U/ μl of restriction enzyme stock corresponding to 8.75% of the final digestion volume.
7. Incubate overnight at an appropriate temperature (per manufacturer's instructions).

BAC DNA is often difficult to digest to completion. This protocol has been optimized and standardized for digestion efficiency.
8. Add an equal volume of 1:1 (v/v) phenol/chloroform, vortex for 30 sec, and centrifuge 5 min at 18,000 $\times g$ (14,000 rpm), room temperature, separating the reaction volume in multiple tubes if necessary.
9. Transfer aqueous (upper) phase to a fresh 1.7-ml microcentrifuge tube.
10. Add 1/10 vol of 3 M sodium acetate, pH 5.2, vortex briefly.
11. Add 2.5 vol of ice-cold 100% ethanol and mix gently. Incubate at least 15 min at -20°C and centrifuge 20 min at 18,000 $\times g$ (14,000 rpm), 4°C .
12. Discard supernatant and wash pellet by resuspending in 1 ml of 70% ethanol. Centrifuge 15 min at 18,000 $\times g$ (14,000 rpm), 4°C .
13. Remove 70% ethanol wash, and briefly air dry.

Do not let the DNA dry completely as it becomes very difficult to resuspend.
14. Resuspend DNA in 161 μl water. Incubate 15 min at 37°C to dissolve the DNA completely.

Reserve a 4- μl aliquot of digested material to run on an agarose gel alongside the undigested BAC DNA and ligated BAC DNA as a control for digestion efficiency.

Ligate BAC DNA

15. Combine the following and incubate overnight at 16°C (adjust to 200 μl final volume if necessary):

157 μl of digested BAC DNA
20 μl of 10 \times ligation buffer
2 μl of 10 mg/ml BSA
2 μl of 100 mM ATP
7600 Weiss units T4 DNA ligase.

Due to the large number of tubes, a master mix of all components is typically made for all ligations and distributed amongst the tubes.

16. Incubate DNA 15 min at 65°C to inactivate the ligase.

Purify BAC genomic DNA control template

17. Add 200 μl of 1:1 phenol/chloroform, vortex for 30 sec, and centrifuge 5 min at $18,000 \times g$ (14,000 rpm), room temperature.
18. Transfer aqueous (upper) phase to a fresh 1.7-ml microcentrifuge tube without touching the interface.
19. Repeat 1:1 phenol/chloroform extraction. Transfer aqueous (upper) phase to a fresh tube.
20. Add 200 μl chloroform, vortex for 30 sec, and centrifuge 5 min at $18,000 \times g$ (14,000 rpm), room temperature.
21. Transfer aqueous (upper) phase to a fresh 1.7-ml microcentrifuge.
22. Add 1/10 vol of 3 M sodium acetate, pH 5.2, and vortex briefly. Add 2.5 vol of ice-cold 100% ethanol and mix gently. Incubate 15 min at -20°C and centrifuge 20 min at $18,000 \times g$ (14,000 rpm), 4°C .
23. Discard supernatant and resuspend the pellet in 1 ml of 70% ethanol. Centrifuge 15 min at $18,000 \times g$ (14,000 rpm), 4°C .
24. Discard supernatant and air dry slightly.
25. Resuspend pellet in TE buffer, pH 8.0, to give a final concentration of $\sim 100 \text{ ng}/\mu\text{l}$.
26. Incubate 15 min at 37°C to completely dissolve DNA (this is the control template).

Reserve 1 μl of ligated material to run on an agarose gel alongside the undigested BAC DNA and digested BAC DNA as a control for ligation efficiency.

27. Run 1 μl of uncut BAC DNA, 4 μl of cut BAC DNA, and 1 μl of ligated BAC DNA side by side on a 0.8% agarose/0.5 \times TBE gel (*UNIT 2.5A*).

There should be a smear after digestion, and part of the smear should disappear after ligation. An example is shown in Figure 21.11.2.

Figure 21.11.2 Gel analysis of BAC DNA during generation of mammalian control template. A 1-kb ladder is shown in lane 1 for size reference. Lane 2 is undigested BAC DNA, which runs on an agarose gel at slightly more than 10 kb. Lane 3 is digested BAC DNA, which is smear-like in appearance. Lane 4 is ligated BAC DNA, which shows the disappearance of most of the smear-like trail. Similar results are obtained for a *Saccharomyces cerevisiae* control template at the corresponding stages.

28. Store control template up to 3 years at -20°C .

Control templates stored up to 3 years at this temperature have retained original quality.

ANALYSIS OF INTERACTION FREQUENCIES USING 3C AND CONTROL TEMPLATES BY QUANTITATIVE PCR

**BASIC
PROTOCOL 5**

After generation of 3C and control templates (see Basic Protocols 1 through 4), it is necessary to roughly determine the amount of template generated. After a rough estimate of DNA concentration is determined, a titration must be performed to determine how much of the templates should be used in a PCR reaction to accurately quantify ligation products.

Materials

DNA templates (see Basic Protocols 1 through 4)
Molecular weight standard of known concentration
10 \times PCR buffer for yeast *or* mammalian templates (see recipes)
100 mM dNTPs
Primers (see Strategic Planning)
Taq DNA polymerase
50 mM MgSO_4
Automated thermal cycler
Gel documentation setup with appropriate software for quantifying PCR products
Additional reagents and equipment for agarose gel electrophoresis (*UNIT 2.5A*) and PCR (*UNITS 15.1 & 15.7*)

1. Determine DNA concentration of templates by agarose gel electrophoresis by running template DNA in parallel with a molecular weight standard (*UNIT 2.5A*).

The template will run as a high-molecular-weight DNA sample. The template appearance may vary between samples and may contain smear-like trails. The appearance of the template may not be an indication of template quality, and only after titration can the quality of the template be accurately determined. Typically, the DNA concentration is ~ 0.8 to $1.4 \mu\text{g}/\mu\text{l}$ for yeast templates and ~ 200 to $250 \text{ ng}/\mu\text{l}$ for mammalian templates. Absorption spectroscopy should not be used to measure DNA concentration due to a high concentration of salt remaining in the templates after purification.

2. Make a two-fold dilution series of template DNA and include a water control.

Typically, eight to ten dilutions are made, with the highest concentrations at $\sim 250 \text{ ng}/\mu\text{l}$ for mammalian templates and $\sim 1 \mu\text{g}/\mu\text{l}$ for yeast templates.

3. Set up PCR reactions for each dilution (*UNITS 15.1 & 15.7*).

- a. For yeast, perform PCR in a 50- μl reaction containing:
 - 2 μl each template dilution (i.e., starting with 2 μg DNA)
 - 1 \times PCR buffer for yeast templates
 - 0.5 mM dNTPs
 - 0.4 μM of each primer
 - 2.5 U *Taq* DNA polymerase.
- b. For mammalian cells, perform PCR in a 25- μl reaction containing:
 - 2 μl each template dilution (i.e., starting with 500 ng DNA)
 - 1 \times PCR buffer for mammalian templates
 - 4 mM MgSO_4
 - 0.2 mM dNTPs
 - 0.4 μM of each primer
 - 1 U *Taq* DNA polymerase.

**Chromatin
Assembly and
Analysis**

21.11.13

Titration experiments are performed with two different primer combinations. Primers to use in titrations should be chosen based on efficiency (i.e., lack of primer dimers). The two primer pairs chosen should also differ in the genomic distance that separates the restriction fragments they recognize. Preferably, one pair of primers should amplify a ligation product that represents an interaction between restriction fragments that are relatively far apart (e.g., 50 to 80 kb) on the genomic map, whereas the other pair should amplify a ligation product that represents an interaction between two fragments that are located close together (i.e., 10 kb).

4. Use the following hot-start PCR parameters to program the thermal cycler:

a. For quantitative results for yeast templates:

1 cycle:	1 min	95°C
32 cycles:	1 min	95°C
	45 sec	60°C
	2 min	72°C
1 cycle:	1 min	95°C
	45 sec	60°C
	8 min	72°C

b. For quantitative results for mammalian templates:

1 cycle:	1 min	95°C
34 cycles:	1 min	95°C
	45 sec	65°C
	2 min	72°C
1 cycle:	1 min	95°C
	45 sec	65°C
	8 min	72°C

5. Analyze PCR products by agarose gel electrophoresis (UNIT 2.5A) on a 1.5% agarose gel containing 0.5× TBE and 0.5 µg/ml ethidium bromide.

An example of a titration experiment is shown in Figure 21.11.3.

A loading buffer without bromophenol blue is recommended, since this dye will run close to the PCR products and interfere with quantification. The use of Ficoll is encouraged.

6. Quantify PCR products using a gel documentation setup equipped with appropriate software and determine amount of PCR product per reaction.

An example of a quantification is shown in Figure 21.11.3.

The recommended amount of template that should be used for quantitative PCR detection of ligation products (and thus chromatin interactions) should be in the linear range of PCR amplification (e.g., as indicated in Fig. 21.11.3). This concentration should be used for all subsequent PCR reactions with template.

7. Use the proper DNA concentration determined by the PCR titration to analyze the genomic region of interest. For each primer pair, set up three reactions using the control template and three reactions using the 3C template. Follow the same PCR conditions and program as described in steps 3 and 4.

The control template and 3C template PCRs for each primer pair should always be performed during the same PCR run.

8. Analyze and quantify the PCR products using the same conditions as described in steps 5 and 6.

PCR products obtained with the 3C and control templates should be run side by side on the same gel, as there is also variation in DNA staining between gels.

Figure 21.11.3 Titration and quantification of *Saccharomyces cerevisiae* 3C and control templates. The panels depict titration and analysis of a control template (left) and 3C template (right) using the same two primer pairs. The PCR products were run on agarose gels, PCR products were quantified, and the amount of PCR product was plotted versus DNA concentration in micrograms for the two primer pairs, one 11 kb apart in genomic distance (closed circles) and one 85 kb apart (open circles). For both primer pairs, the control template yields similar amounts of PCR product. The 3C template yields lower PCR products for the 85-kb primer pair than for the 11-kb primer pair. The linear range for PCR amplification for 3C and control templates is to the left of the dashed line. The DNA concentration for use in subsequent reactions should be in this range, but should also be high enough so that PCR products can be accurately quantified on an agarose gel. Similar results are obtained for a mammalian control template and 3C template.

- Determine the interaction frequency for each primer pair by dividing the amount of PCR product obtained using the 3C template by the amount of PCR product obtained using the control template.

As each primer pair using each template was set up in triplicate, three different values will be obtained. These values are averaged to determine the final interaction frequency for a particular primer pair.

The standard error of the mean of the three values for the interaction frequencies should not be more than 15%.

REAGENTS AND SOLUTIONS

Use deionized, autoclaved water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Ligation buffer, 10×

500 mM Tris·Cl, pH 7.5 (APPENDIX 2)
 100 mM MgCl₂
 100 mM dithiothreitol
 Store up to 1 year at −80°C

Lysing buffer I

0.25 M EDTA, pH 8.0 (*APPENDIX 2*)
0.5 M Tris base
2.5% (v/v) SDS
Make fresh on day of experiment

Lysing buffer II

10 mM Tris·Cl, pH 8.0 (*APPENDIX 2*)
10 mM NaCl
0.2% (v/v) Igepal (NP-40)
Make fresh on day of experiment

MES wash buffer

0.1 M MES
1.2 M sorbitol
1 mM EDTA, pH 8.0 (*APPENDIX 2*)
0.5 mM MgCl₂
Adjust pH to 6.4 with NaOH
Store up to 6 months at 4°C

PCR buffer for mammalian templates, 10×

600 mM Tris, adjust to pH 8.9 with H₂SO₄
180 mM (NH₄)₂SO₄
Store up to 1 year at -80°C

PCR buffer for yeast templates, 10×

100 mM Tris·Cl, pH 8.4 (*APPENDIX 2*)
500 mM KCl
22.5 mM MgCl₂
Store up to 1 year at -80°C

Spheroplasting buffer I

0.4 M sorbitol
0.4 M KCl
40 mM sodium phosphate buffer, pH 7.2 (*APPENDIX 2*)
0.5 mM MgCl₂
Store up to 6 months at 4°C

Spheroplasting buffer II

10 mM sodium phosphate buffer, pH 7.2 (*APPENDIX 2*)
10 mM EDTA, pH 8.0 (*APPENDIX 2*)
1% (v/v) 2-mercaptoethanol
100 µg/ml zymolyase 100-T (US Biological)
Store up to 6 months at 4°C

Zymolyase 100-T solution, 20 mg/ml

20 mg/ml zymolyase 100-T (US Biological)
2% (w/v) glucose
50 mM Tris·Cl, pH 7.5 (*APPENDIX 2*)
Make solution at least 1 day prior to experiment to increase the enzyme efficiency
Store up to 1 month at 4°C

COMMENTARY

Background Information

Chromatin organization has been studied at a very local level, i.e., at the level of one or a few nucleosomes. For instance, crystal structures of single nucleosomes and their constituents have been solved at high resolution (Luger et al., 1997). On the other hand, microscopic techniques have allowed analysis of whole chromosome organization. However, very little is known about chromatin conformation at a scale ranging from a few kilobases to hundreds of kilobases. This intermediate level of chromosome structure is extremely relevant for genome regulation, as it is the scale at which chromatin affects many aspects of gene regulation. The relatively new 3C technology allows for such structural analysis of chromatin, which was not possible with existing techniques (Dekker et al., 2002). 3C makes use of formaldehyde cross-linking to capture chromatin in a particular conformation. As a result, chromatin segments that interact inside of the cell will be covalently linked.

The 3C technique has been used to detect and quantify physical interactions between sequence elements located on the same chromosome or on different chromosomes in *Saccharomyces cerevisiae* (Dekker et al., 2002) as well as in higher eukaryotes (Tolhuis et al., 2002; Dekker, 2003; Spilianakis and Flavell, 2004; Spilianakis et al., 2005; Vakoc et al., 2005). Such chromatin interactions can result in the formation of chromatin loops, as in the case of enhancers and promoters, but they will also reflect more general properties of the chromatin fiber such as chromatin compaction. Together, these types of interactions can directly provide information about the spatial organization of a genomic region, but careful analysis of 3C data is required to arrive at a correct biological interpretation.

Critical Parameters and Troubleshooting

Experimental preparation

Many factors play a role in a successful 3C experiment. A 3C experiment should always involve careful thought and planning. One of the most important factors is the quality of the starting material. *Saccharomyces cerevisiae* cells should be freshly grown on the appropriate medium and a liquid culture should be inoculated from one isolated colony. Mammalian cells should be exponentially growing in the appropriate medium and exhibit healthy growth curves appropriate to the cell type.

It is also critical to start with the appropriate amount of cells indicated in Basic Protocols 1 through 4. Deviations from these conditions may result in poor or very low PCR signals.

As described in Strategic Planning, restriction enzyme selection and primer design are critical. An enzyme should be chosen based on multiple criteria. The enzyme should cut evenly and frequently throughout the region of interest. Once an enzyme is chosen, primers must be designed carefully. Primers should be designed unidirectionally, and should not be designed for large (>10 kb) or small (<1 kb) fragments, as these may result in slightly higher and lower interaction frequencies, respectively. Primers that do not amplify the correct product, amplify multiple products, do not yield equal amounts of PCR products when using control template, or produce high levels of primer dimers should not be included in the analysis. If crucial to the experiment, the primer should be redesigned.

The reagents prepared for use in a 3C experiment should be stored at the appropriate conditions, according to the recipes listed in the Reagents and Solutions section. Among the most important reagents is formaldehyde. The efficiency of cross-linking will directly affect the frequency with which ligation products are formed and will thus impact the reliability of PCR detection. Therefore, the formaldehyde used should be no more than 1 year old.

Template quality

The most commonly encountered problem during 3C is difficulty in identifying the concentration of 3C template that should be used for quantitative PCR detection of ligation products. This problem is apparent when one cannot find a range of template concentrations for which the amount of PCR product obtained is linearly related to the template concentration (see Fig. 21.11.3). If this situation occurs, it is likely due to a high concentration of salt remaining in the template after purification. This remaining salt will severely reduce the quality and intensity of the PCR signal. It is therefore necessary to remove salt from the template preparation. This can be achieved by repeating the ethanol precipitation and ethanol wash steps (as described in Basic Protocol 3), and resuspending in the appropriate volume. This extra wash step should improve template titrations.

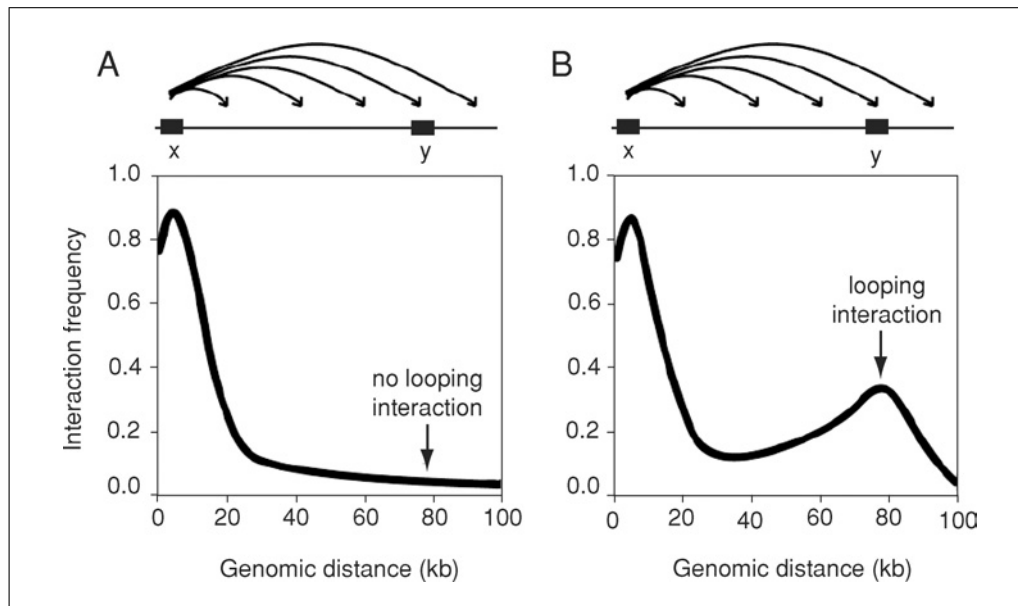

Figure 21.11.4 Hypothetical results for a 3C experiment. **(A)** A 3C dataset with no looping interaction between sequence elements *x* and *y* (black boxes). A number of interactions have been tested between sequence element *x* and sites located further away from it including sequence element *y*. Neighboring sites of *x*, those separated by a small genomic distance, exhibit high interaction frequencies. As genomic distance between sites increases, the interaction frequencies decrease progressively. A low interaction frequency is detected between sequence elements *x* and *y*. The exact shape of the curve is dependent on flexibility and the level of compaction of the chromatin fiber. **(B)** In a 3C dataset with a looping interaction between sequence elements *x* and *y*, a local peak of interaction frequencies is observed. This peak (at ~80 kb) shows that sequence elements *x* and *y* interact more frequently than expected, which is indicative of a looping interaction.

The quality of the control template is also crucial for a successful 3C experiment. As mentioned, a control template should contain equal amounts of all possible ligation products (see Fig. 21.11.3 for an example). If this is not the case, a new control template should be generated, or the reliability of the data obtained will be compromised. When generating a control template for mammalian cells, if the genomic area of interest spans multiple BAC clones, it is important that the BAC clones chosen have minimal overlaps and gaps, as these particular regions will be overrepresented or absent, respectively. If this cannot be avoided, the gap or overlap region should never be directly at a putative looping element as this may skew results.

Finally, as a general rule, sites separated by a small genomic distance (i.e., separated by <10 kb) should exhibit high interaction frequencies. The interaction frequencies should decrease as sites are tested that are further apart in genomic distance (i.e., 50 to 80 kb). If sites separated by small genomic distances do not exhibit high interaction frequencies, a new template should be generated, as something has gone awry during the course of

the experiment. Importantly, the presence of a looping interaction between two distant sequences will be apparent when they interact more frequently than one would expect for two sequences separated by that particular genomic distance (Fig. 21.11.4).

Experimental design and data analysis

The 3C technique has successfully been used to detect looping interactions between sequence elements (Dekker et al., 2002; Tolhuis et al., 2002; Spilianakis and Flavell, 2004; Vakoc et al., 2005); however, experimental design is crucial for correct interpretation of the data. When designing an experiment, it is important that multiple primer pairs are chosen to detect a loop. For example, if two putative looping elements are located 100 kb apart, it will be important to also test interactions of each of the two elements with several sites located in between them. These interactions should be less frequent than the interaction between the two looping elements (see Fig. 21.11.4). In other words, a looping interaction is detected as a local peak in interaction frequencies. Measuring only the interaction frequency between the two putative looping

elements does not allow the detection of such a local peak in interaction frequency and thus is never sufficient to confirm that a chromatin loop is formed.

As mentioned, 3C is a PCR-based method. PCR reactions themselves are a source of noise. Therefore, PCR reactions using the control template and the 3C template should be performed in triplicate as described in Basic Protocol 5. From the abundance of PCR product, three individual interaction frequencies should be determined and the values averaged to obtain one data point. Typically, the standard error of the mean of the three interaction frequencies is 15%. The average interaction frequency is used for compiling datasets. For the control template to be a true control of primer and PCR efficiency, it is imperative that the PCR reactions used to detect ligation products for both the 3C and control templates are performed during the same PCR run. PCR products obtained with the 3C and control templates should be run side by side on the same gel, as there is also variation in DNA staining between gels.

Lastly, if comparing two 3C datasets, e.g., derived from two cell strains/lines or two experimental conditions, it is important that the two datasets are normalized with respect to each other. Normalization will control for non-relevant differences between the two 3C templates, such as differences in DNA concentration. Normalization is achieved by measuring a number of interaction frequencies that are likely to be the same in both cell lines or experimental conditions. Ideally, a set of at least ten to twenty interaction frequencies is measured (relative to the control template) within a genomic region other than the region of interest to serve as an internal control. Once these interaction frequencies are determined, the log ratio between the two cell lines for each interaction is calculated. The average of all log ratios will then serve as a factor to normalize the two 3C datasets.

Anticipated Results

Figure 21.11.4 shows hypothetical results of a typical 3C experiment where interaction frequencies are plotted versus the genomic distance (in kilobases) that separates the interacting restriction fragments. Figure 21.11.4A shows a dataset exhibiting no looping interaction. Sites separated by a relatively small genomic distance exhibit high interaction frequencies. As genomic distance between sites increases, the interaction frequency decreases

progressively. The exact shape of this curve is dependent on the flexibility and level of compaction of the chromatin fiber. However, if a loop is present at a particular genomic region, a local peak of interaction frequencies will be observed, as shown in Figure 21.11.4B. This peak could be several fold higher than predicted for that particular site separation. The height of the peak can indicate the fraction of cells engaged in that particular interaction. For example, a study from Vakoc et al. (2005) observed a loop in the globin locus between the LCR and β -major gene upon GATA-1 activation that is reflected in an interaction frequency that is 3.3-fold higher than expected.

Time Considerations

Preparation of 3C templates from yeast and mammalian cells (Basic Protocols 1 and 3) may be completed in a 3- or 4-day period. Day 1 consists of preparation of cells and cross-linking (~3 hr). At this stage, cross-linked cells can be stored at -80°C or used directly for cell lysis and digestion of chromatin. Day 2 (or end of day 1) consists of a series of wash steps followed by solubilization of chromatin and addition of restriction enzyme (<4 hr). The digestion is allowed to proceed overnight. Inactivation of the restriction enzyme and the ligation reactions (~3 hr) are performed on day 3 (or day 2), followed by reversal of the cross-links, which is performed overnight. Day 4 (or day 3) consists of purification of DNA through a series of phenol/chloroform extractions and ethanol precipitations. Purification of DNA for yeast 3C templates will take up to 5 hr. A full day should be reserved for purification of DNA for mammalian 3C templates.

Preparation of the control yeast template (see Basic Protocol 2) may be completed in 2 days. Isolation of yeast genomic DNA will take 1 full day. Day 2 consists of digestion (~4 hr) followed by ligation (~1 hr) and purification of DNA (~1.5 hr). Preparation of mammalian control templates (see Basic Protocol 4) may be completed in 4 days. Day 1 consists of purification of BAC DNA. Day 2 consists of assembling digestion reactions (<1 hr). The digestion is allowed to proceed overnight. Day 3 consists of purification of digested BAC genomic DNA clones followed by assembling ligation reactions (~2 hr). The ligation is allowed to proceed overnight. Day 4 consists of purification of mammalian control template DNA (~3 hr).

Once all templates are generated, titrations must be performed as described in Basic

Protocol 5. This protocol will take ~5 hr including time for titration setup, the PCR program, and gel electrophoresis. The time needed to analyze an entire genomic region of interest will depend on the number of interactions that need to be measured.

Paired-End diTagging for Transcriptome and Genome Analysis

Paired-End diTagging (PET) is the process of extracting 18-base “signatures” or “tags” from each of the 5′ and 3′ termini of any contiguous DNA sequence, and ligating them into paired-end ditags (PETs) that are concatenated for enhanced sequencing efficiency. Each PET can subsequently be mapped onto the appropriate genome assembly to accurately define the location of the original fragment from which it was derived. Analysis of PETs can be used in transcriptome characterization, genome annotation, and analysis of transcription factor binding sites. There are two main approaches that can be chosen depending on the application.

GIS-PET. The gene identification signature (GIS)-PET analysis method was developed to facilitate high-efficiency transcriptome analysis and genome annotation. It captures the 5′ and 3′ terminal signatures of full-length transcripts in the form of covalently-linked DNA ditags or PETs. Essentially, GIS-PET analysis is a two-part procedure, consisting of the construction of a GIS full-length cDNA (flcDNA) library in a unique cloning vector (pGIS4) using a modified biotinylated CapTrapper approach (see Basic Protocol 1), followed by the construction of a GIS-PET library containing concatenated PETs for DNA sequencing (see Basic Protocol 2). Concatenated PETs in bacterial clones are sequenced, and the PET sequences are extracted and mapped onto assembled genomes for further analysis using a customized software suite (PET-Tool; contact Dr. Yijun Ruan at ruanyj@gis.a-star.edu.sg). For ease of visualization, the PETs are displayed on a genome browser developed in-house called “T2G Browser.” Using GIS-PET, one can verify existing transcripts, validate gene predictions, identify splice variants and novel and/or unusual transcripts, and compare gene expression between different libraries. A major advantage of this procedure is the ready availability of the flcDNA plasmid library, from which transcripts of interest can be readily obtained for downstream functional studies by simple PCR, using primers designed based on the PET sequences. The original published GIS-PET method involved the separate ligation of a 5′ adapter-mix and a 3′ adapter onto full-length cDNA before cloning into vector pGIS1. This current variation replaces pGIS1 with vector pGIS4, which already has the 3′-adapter sequences built into one of its arms, thereby reducing the number of steps required.

ChIP-PET. The same principle of paired-end ditagging can be applied to the efficient mapping of transcription factor binding sites (TFBS) identified by chromatin immunoprecipitation (ChIP). In this method, referred to as ChIP-PET, randomly sheared genomic DNA fragments that are first enriched for the TFBS of interest by ChIP (see UNIT 21.3) are inserted into a specific cloning vector (pGIS3; see Basic Protocol 3) and subjected to the same ditagging approach as in GIS-PET. Genuine TFBS are indicated by the overlapping of multiple distinct PET sequences on defined chromosomal loci.

NOTE: The terms ditag and PET are synonymous in the context of this procedure and are used interchangeably within the text.

CONSTRUCTION OF A GIS FULL-LENGTH cDNA LIBRARY

This procedure is outlined on the left side of Figure 21.12.1. In the first steps, full-length mRNA is converted to first-strand, full-length cDNA (flcDNA). For the generation of flcDNA, we decided to adapt the CapTrapper procedure first developed by Piero

BASIC PROTOCOL 1

Chromatin Assembly and Analysis

21.12.1

Figure 21.12.1 The current GIS-PET procedure, where the use of vector pGIS4 obviates the 3'-adapter ligation.

Carninci (Carninci and Hayashizaki, 1999). Although this procedure is lengthy and requires a significant quantity of mRNA (10 μ g), trials showed that it produces high-quality flcDNA consistently, which is critical for the success of the subsequent ditagging. In the CapTrapper procedure, the diol structures present in the cap and 3' end of mRNA are oxidized, then chemically biotinylated. RNase I digestion of single-stranded mRNA regions not protected by hybridization to the first-strand flcDNA results in the removal of the biotinylated 3' mRNA ends, as well as the biotinylated caps from prematurely terminated first-strand cDNA/mRNA hybrids. The resulting enriched flcDNA/mRNA hybrids containing biotinylated caps are then captured by binding to streptavidin-coated beads for further manipulation. The isolated (–)flcDNA is converted to double-stranded (ds) cDNA by 5'-adapter ligation using a mix of two adapters, GIS-(N)5 and GIS-(N)6, followed by primer extension. *GsuI* is used to remove the residual polyA tail, leaving an AA dinucleotide residue. This is followed by *NotI* digestion to form the 5' cohesive site, resulting in ds flcDNA that can be directionally inserted into the prepared pGIS4 vector.

The original (published) GIS-PET method involved the separate ligation of a 5' adapter-mix and a 3' adapter onto full-length cDNA, before cloning into vector pGIS1 (Ng et al., 2005). This current variation of the protocol replaces pGIS1 with vector pGIS4, which already has the 3' adapter sequences built into one of its arms, thereby reducing the number of steps required. pGIS4 was derived from pGEM-3z (Promega) using site-directed mutagenesis and adapter ligation to eliminate unwanted *MmeI* sites and to facilitate vector purification and usage. It is available upon request from the authors.

Details for oligonucleotide sequences used in GIS-PET are shown in Figure 21.12.2. Although PAGE-purified oligonucleotides are preferred, for reasons of economy, HPLC-purified oligonucleotides are usually used and have worked well.

Materials

2 $\mu\text{g}/\mu\text{l}$ *GsuI*-oligo dT primer
40 U/ μl RNasin-PLUS RNase inhibitor (Promega)
PolyA RNA sample of interest (10 to 20 μg)
Nuclease-free water (Ambion)
2 \times GC-I buffer (Takara; available as part of the LA Taq kit)
Modified 10 mM dNTP (with 5-Me-dCTP instead of dCTP; see recipe)
4.9 M D-sorbitol (Sigma)
200 U/ μl Superscript II reverse transcriptase (RNase H⁻; Invitrogen)
Saturated trehalose (see recipe)
20 mg/ml proteinase K (Ambion)
25:24:1 (v/v/v) phenol/chloroform/IAA, pH 6.6 and 7.9 (Ambion)
Sodium acetate solutions: 3 M at pH 5.2 (APPENDIX 2), 1.1 M at pH 4.5, and 1 M at pH 6.1
Absolute and 70% ethanol
Biotin hydrazide (long arm; Vector Laboratories)
Sodium periodate (NaIO₄; Sigma)
10% SDS (APPENDIX 2)
5 M NaCl
Isopropanol
10 U/ μl RNaseONE ribonuclease and 10 \times RNaseONE buffer (Promega)
10 mg/ml yeast tRNA (Ambion)
M-280 streptavidin Dynabeads (Dyna)
1 \times binding buffer (see recipe)
1 \times blocking buffer (see recipe)
1 \times wash buffer (see recipe)
Alkaline hydrolysis buffer (see recipe), prepare fresh
1 M Tris-Cl, pH 7.5 (APPENDIX 2)
15 mg/ml GlycoBlue (Ambion)
LoTE buffer (optional; see recipe)
EB buffer (10 mM Tris-Cl, pH 8.5; Qiagen)
0.4 $\mu\text{g}/\mu\text{l}$ GIS-(N)5 and 0.4 $\mu\text{g}/\mu\text{l}$ GIS-(N)6 adapters (see Fig. 21.12.2; validated as in Support Protocol 2)
Solutions I (enzyme solution) and II (concatenation buffer) from DNA ligation kit (Takara version 2.1)
5 U/ μl ExTaq polymerase and 10 \times ExTaq buffer with Mg²⁺ (Takara)
2.5 mM dNTP mix (Takara)
10 \times Tango buffer (Fermentas)
32 mM S-adenosyl methionine (SAM; NEB; supplied with *MmeI* enzyme)
10 mg/ml BSA
5 U/ μl *GsuI* (Fermentas)
10 U/ μl *NotI* (NEB)
1 \times TEN buffer (see recipe)
SYBR Green I (Molecular Probes) or GelStar nucleic acid gel stain (Cambrex BioWhittaker), optional
pGIS4 cloning vector cut with *NotI/BseRI* (obtain from authors; see Support Protocol 1)
5 U/ μl T4 DNA ligase and 5 \times T4 DNA ligase buffer with PEG (Invitrogen)
Electrocompetent cells (e.g., OneShot electrocompetent TOP10 cells, Invitrogen)
SOC medium (see recipe)
LB-amp agar plates (UNIT 1.1; use Lennox formulation with 5 g/liter NaCl)
20 μM PMR011 and 20 μM PMR012 PCR primers (Fig. 21.12.2)

0.2- and 1.7-ml thin-walled PCR tubes
 Heat/chill block or thermal cycler
 1.7-ml microcentrifuge tubes
 1.5-ml siliconized microcentrifuge tubes
 1.5-ml DNA LoBind tubes, PCR clean, safe lock (Eppendorf or Sigma), optional
 Magnetic rack for washing Dynabeads (Dyna)
 Benchtop hot/cold shaking incubator (e.g., Eppendorf)
 Benchtop rotator (Grant-bio)
 Phase Lock Gel Light tubes (Eppendorf), optional
 cDNA size fractionation columns (Invitrogen)
 Spectrophotometer with 7- μ l submicro-volume cell (Amersham)
 Electroporator and cuvettes (e.g., BioRad)
 15-ml conical tubes (e.g., Falcon)
 96-well microtiter plates

Additional reagents and equipment for phenol extraction and ethanol precipitation (UNIT 2.1A), ligation (UNITS 3.14 & 3.16), agarose gel electrophoresis (UNIT 2.5A), restriction enzyme digestion (UNIT 3.1), electroporation (UNIT 9.3), PCR (UNIT 15.1), and plasmid purification (UNIT 1.6)

Reverse transcribe polyA RNA

1. Mix the following in a 0.2-ml thin-walled PCR tube:

3.5 μ l 2 μ g/ μ l *Gsu*I-oligo dT primer (7 μ g)
 1 μ l 40 U/ μ l RNasin-PLUS inhibitor
 10 to 20 μ g polyA RNA sample of interest
 Nuclease-free water to 20 μ l.

2. Heat the reaction mixture to 65°C for 10 min and cool to 37°C for 1 min. Hold at 42°C while preparing the other components.

PolyA RNA can be purified using any suitable method. The authors routinely purify polyA RNA from total RNA (extracted using Trizol reagent available from Invitrogen) using the μ MACS mRNA isolation kit (Miltenyi Biotech), as this gives the best combination of throughput and purity.

If necessary, the polyA RNA can be ethanol precipitated (without glycogen) to concentrate it prior to use. Care should be taken to not overdry the RNA pellet, as it will be exceedingly difficult to resuspend.

3. Prepare the reverse transcriptase (RT) mix in a 0.2-ml thin-walled PCR tube on ice (total 121 μ l) as follows:

75 μ l 2 \times GC-I buffer
 1 μ l RNasin-PLUS inhibitor
 4 μ l modified 10 mM dNTP (with 5-Me-dCTP instead of dCTP)
 26 μ l 4.9 M sorbitol
 15 μ l 200 U/ μ l Superscript II reverse transcriptase.

The mix should be kept on ice to ensure no RT activity. RNasin-PLUS inhibitor is preferred because of its wide-spectrum properties and its thermal stability.

4. Place 10 μ l saturated trehalose into another 0.2-ml thin-walled PCR tube and leave warming at 42°C in a thermal cycler.

5. When the oligo-dT/mRNA annealing step is complete, place the RT mix into the 42°C thermal cycler for 2 min to preheat. Add the warm trehalose to the warm RT mix (now 131 μ l), and quickly transfer the entire reaction mix into the tube containing the annealed primer/mRNA (final 151 μ l). Immediately start the incubation as follows:

40 min at 42°C
20 min at 50°C
20 min at 55°C.

6. Add 2 μ l of 20 mg/ml proteinase K to degrade all enzymes and incubate 15 min at 45°C.
7. Perform an extraction with 25:24:1 phenol/chloroform/IAA (using pH 6.6 phenol, not pH 7.9), and then re-extract with 150 μ l nuclease-free water.

Refer to UNIT 2.1A for phenol extraction and ethanol precipitation.

8. Ethanol precipitate the aqueous layer containing RNA and DNA (~300 μ l) by adding 30 μ l of 3 M sodium acetate, pH 5.2, and 825 μ l absolute ethanol. Keep 30 min at -80°C, then microcentrifuge 30 min at maximum speed, 4°C.

Do not add glycogen.

9. Wash with 70% ethanol and resuspend the sizeable white pellet in 44.5 μ l nuclease-free water.

Oxidize diol structures

10. Prepare the following stocks fresh using 1.7-ml microcentrifuge tubes:

10 mM biotin hydrazide (long arm)
100 mM sodium periodate (NaIO₄).

11. Combine the following in a 1.5-ml siliconized tube:

44.5 μ l (-)cDNA/RNA heteroduplex
3 μ l 1.1 M sodium acetate, pH 4.5
2.5 μ l fresh 100 mM NaIO₄.

Incubate on ice 45 min in the dark.

12. Add the following to the 50- μ l reaction to precipitate the (-)cDNA/RNA heteroduplex:

0.5 μ l 10% SDS
11 μ l 5 M NaCl
61 μ l isopropanol.

Keep 30 min at -80°C, then microcentrifuge 30 min at maximum speed, 4°C.

13. Wash with 70% ethanol and resuspend the small white pellet in 50 μ l nuclease-free water.

Biotinylate RNA ends

14. To the 50 μ l oxidized (-)cDNA/RNA, add the following:

5 μ l 1 M sodium acetate, pH 6.1
5 μ l 10% SDS
150 μ l 10 mM fresh biotin hydrazide.

Incubate overnight (12 to 16 hr) at room temperature in the dark.

Perform RNaseONE selection

15. Precipitate the biotinylated (–)cDNA/RNA heteroduplex (210 μ l) by adding:

- 5 μ l 5 M NaCl
- 7 μ l 1 M sodium acetate, pH 6.1
- 750 μ l absolute ethanol.

Keep 30 min at -80°C , then microcentrifuge 30 min at maximum speed, 4°C .

16. Wash one time with 70% ethanol. Resuspend the small white pellet in 170 μ l nuclease-free water.

17. Use ~ 5 U RNaseONE/ μ g starting mRNA:

- 170 μ l biotinylated (–)cDNA/RNA heteroduplex
- 20 μ l $10\times$ RNaseONE buffer
- 4.5 μ l 10 U/ μ l RNaseONE
- 5.5 μ l nuclease-free water.

Incubate 30 min at 37°C .

18. Quench the reaction by adding 4 μ l of 10 mg/ml yeast tRNA and 50 μ l of 5 M NaCl.

Bind biotinylated (–)cDNA/RNA to beads

19. During the selection procedure, wash M-280 streptavidin Dynabeads (200 μ l bead suspension per RNA sample) as follows:

- a. Wash three times with 200 μ l of $1\times$ binding buffer, room temperature.
- b. Add 200 μ l of $1\times$ binding buffer plus 0.25 $\mu\text{g}/\mu\text{l}$ yeast tRNA and incubate 30 min at 4°C on a benchtop hot/cold shaking incubator at 800 rpm. Remove wash.
- c. Wash three times with 200 μ l of $1\times$ binding buffer, room temperature.

Before beginning, be familiar with the use of the magnetic stand for washing and separating beads. Use siliconized or low-binding tubes (e.g., LoBind) for all steps involving M-280 beads.

20. Remove supernatant from beads and add the ~ 254 μ l RNaseONE-treated (–)cDNA/RNA. Rotate 30 min at room temperature on a rotator for binding to occur.

21. Wash heteroduplex-bound beads at room temperature as follows:

- two times with 200 μ l of $1\times$ binding buffer
- one time with 200 μ l of $1\times$ blocking buffer
- one time with 200 μ l of $1\times$ wash buffer
- one time with 200 μ l of 50 $\mu\text{g}/\text{ml}$ yeast tRNA.

Perform hydrolytic degradation to release minus (–) strand flcDNA

22. Remove the supernatant (wash solution) from the beads, and add 50 μ l freshly made alkaline hydrolysis buffer. Shake 10 min at 65°C on a shaker at 1400 rpm.

The alkaline hydrolysis buffer must be made fresh before use.

23. Collect the supernatant containing full-length (–)cDNA (flcDNA) into a tube containing 150 μ l of 1 M Tris·Cl, pH 7.5, for neutralization.

24. Repeat the hydrolysis and collection steps two more times, collecting all fractions into the same tube, for a final volume of 300 μ l.

25. Perform an extraction with 25:24:1 phenol/chloroform/IAA, pH 7.9, then ethanol precipitate as follows to recover the (–) f/cDNA:

300 μ l full-length (–)cDNA
30 μ l 3 M sodium acetate, pH 5.2
4 μ l 15 mg/ml GlycoBlue
800 μ l absolute ethanol.

Keep 30 min at -80°C , then microcentrifuge 30 min at maximum speed, 4°C .

In this and subsequent extractions, the use of Phase Lock Gel Light tubes greatly facilitates the extraction procedure.

26. Wash with 70% ethanol. Resuspend the barely visible pellet in 5 μ l LoTE buffer or 10 mM Tris-Cl, pH 8.5 (EB buffer).

Synthesize double-stranded cDNA for cloning

27. Perform single-stranded linker (SSL) ligation of mixed 5' adapters by combining the following in a 1.7-ml microcentrifuge tube on ice:

5 μ l (–)f/cDNA
4 μ l 0.4 $\mu\text{g}/\mu\text{l}$ GIS-(N)5 adapter
1 μ l 0.4 $\mu\text{g}/\mu\text{l}$ GIS-(N)6 adapter
10 μ l Takara solution II
20 μ l Takara solution I (ligase).

Incubate overnight (12 to 16 hr) at 16°C .

28. Set up the primer extension reaction in a 1.7-ml thin-walled PCR tube on ice:

40 μ l overnight ligation reaction
20 μ l deionized water
8 μ l 10 \times ExTaq buffer with Mg^{2+}
8 μ l 2.5 mM dNTP mix
4 μ l 5 U/ μ l ExTaq polymerase.

29. Move tube straight from the ice to a 65°C preheated thermal cycler and start incubations as follows:

5 min at 65°C
30 min at 68°C
10 min at 72°C
hold at 4°C .

30. Add 2 μ l of 20 mg/ml proteinase K and incubate 15 min at 45°C to remove any remaining DNA polymerase.

31. Adjust volume to 200 μ l with deionized water, perform phenol/chloroform extraction, pH 7.9, and then ethanol precipitate as follows:

200 μ l ds cDNA
20 μ l 3 M sodium acetate, pH 5.2
2 μ l 15 mg/ml GlycoBlue
600 μ l absolute ethanol.

Keep 30 min at -80°C , then microcentrifuge 30 min at maximum speed, 4°C .

32. Wash with 70% ethanol and resuspend ds cDNA pellet in 70 μ l water. Set aside 5 μ l to run on an agarose gel (UNIT 2.5A) to check if ds cDNA synthesis was successful.
33. To remove the polyA tail, set up the following reaction in a 1.7-ml microcentrifuge tube (total 86 μ l):

65 μ l resuspended ds fcdDNA
8.6 μ l 10 \times Tango buffer
8.6 μ l 10 \times SAM (optional, but stimulates *GsuI* activity)
1.0 μ l 10 mg/ml BSA
2 μ l 5 U/ μ l *GsuI*
0.8 μ l water.

Digest 4 hr to overnight at 30°C (not 37°C).

An older buffer formulation, TANGO/Y+, contained BSA. Since the current Tango buffer does not, BSA must be added separately, as it is required by both GsuI and NotI.

The commercially available 32 mM SAM is diluted to a 500 μ M working solution, which is referred to as 10 \times SAM. This should be prepared fresh, as it is unstable.

Incomplete GsuI digestion will lead to problems; colleagues have observed the entire oligo-dT stretch (from the oligo-dT primer used for reverse transcription) ligated to the 3' adapter/vector 3' arm. This is probably due to a combination of failed GsuI digestion (and hence no removal of the polyA tail), A-overhang after ExTaq extension, and degraded TT overhang from the 3' adapter/pGIS4 vector 3' arm. It is critical to dispense the validated, processed pGIS4 cloning vector into aliquots and store them frozen.

34. To form the cohesive 5' terminal site, add the following to the reaction (final 100 μ l):

11.4 μ l 10 \times Tango buffer
2.6 μ l 10 U/ μ l *NotI*.

Incubate 4 hr at 37°C.

*The additional Tango buffer brings the buffer concentration to \sim 2 \times final (high salt). An excess of *NotI* is used because *NotI* is only 20% to 50% active in 2 \times Tango buffer.*

35. Heat inactivate the enzymes 15 min at 65°C and place tube on ice. Proceed directly to cDNA size fractionation.

Alternatively, perform sequential digestions with each enzyme. First digest with GsuI in Buffer B (Fermentas), followed by a spin-purification step to remove enzyme and buffer salts. Then digest with NotI in NEBuffer 3 (NEB). Proceed immediately to cDNA size fractionation.

Size fractionate cDNA

36. During the restriction digest, prepare cDNA size fractionation columns (one per sample) following manufacturer's instructions. Equilibrate column to room temperature. Remove the top cap, then the bottom, and allow to drain. Add 0.8 ml of 1 \times TEN buffer and allow to drain completely. Repeat three times (this process will take 1 hr).
37. Label twenty 1.7-ml microcentrifuge tubes to be used for fraction collection.
38. Add the 100 μ l digestion reaction (adjust volume with TEN buffer) to the prepared column. Collect the entire flowthrough in collection tube 1.
39. Add 100 μ l TEN buffer and collect the flowthrough in tube 2.

40. Add another 100 μl TEN buffer and start collecting single drops, 1 drop ($\sim 35 \mu\text{l}$) per tube, for subsequent tubes 3 to 20. Allow column to drain completely before adding another 100 μl TEN buffer.
41. Measure the absorbance of each fraction, using 10 μl per fraction in a 7- μl submicro-volume cell.

Alternatively, use a Nanodrop instrument, which requires only 1 μl of sample, or use PicoGreen-based fluorimetry (Molecular Probes; see Support Protocol 3).

42. *Optional:* Remove 4 μl from each fraction and run on an agarose gel to assist in determining which fractions are suitable for cloning. Depending on yields and technique, ethidium bromide staining may be sufficient to observe the fractions; otherwise SYBR Green I or GelStar stain can be used.

Fractions 7 through 10 are usually suitable.

43. Pool selected fractions, if desired, and ethanol precipitate (step 31) to concentrate the ds f1cDNA for ligation. Wash pellet with 70% ethanol and resuspend in 6 μl EB buffer.

Ligate f1cDNA to cloning vector pGIS4

44. Set up the following reaction in 1.7-ml microcentrifuge tubes on ice (total 10 μl):

1 μl 40 ng/ μl *NotI/BseRI*-cut pGIS4
6 μl ds f1cDNA fraction(s) (a minimum of 100 ng, but preferably ≥ 200 ng)
2 μl 5 \times ligase buffer with PEG
1 μl 5 U/ μl T4 DNA ligase.

Also set up a vector self-ligation control. Incubate overnight (12 to 16 hr) at 16°C.

45. Adjust volume to 200 μl with deionized water, and perform phenol/chloroform extraction and ethanol precipitation as in step 31. Wash the pellet at least two times with 70% ethanol, and resuspend in 20 μl EB buffer.

This removes salts prior to transformation.

Transform cells

46. Add 1 μl purified ligation reaction to 25 μl electrocompetent cells (e.g., OneShot electrocompetent TOP10 cells) in prechilled 1.7-ml microcentrifuge tubes. Gently stir with the pipet tip (do not pipet up and down). Let cells stand 5 min on ice.
47. Transfer to prechilled electroporation cuvettes (0.1 cm gap) and perform electroporation (*UNIT 9.3*).
48. Add 1 ml room temperature SOC medium within 10 sec of pulsing to maximize efficiency. Transfer cells to 15-ml conical tubes and allow cells to recover 1 hr at 37°C with shaking at 200 rpm.
49. Plate 20 to 50 μl (out of 1 ml) on LB-amp agar plates for quality control (QC) screening and library efficiency calculations. Incubate overnight at 37°C.

Perform QC on f1cDNA library

50. Count the numbers of colonies and determine library efficiency taking into consideration the self-ligation background. Pick colonies (24 to 48 colonies are sufficient and convenient) for screening by PCR (*UNIT 15.1*) using primers PMR011 and PMR012. Analyze PCR products by agarose gel electrophoresis.
51. If PCR shows a satisfactory range of insert sizes, pick one to four 96-well plates of colonies for overnight culture, purify plasmids (*UNIT 1.6*), and sequence to determine

full-length efficiency (by BLAST alignment of sequences against the GenBank nr database).

PCR products typically range from ~200 to >4000 bp. There should not be a predominance of a single-sized band, which would indicate a cloning problem.

The quality of the fcdDNA library can also be assayed using a commercial cDNA Integrity Kit (KPL). This kit contains sets of primers that are designed to amplify a range of inserts from human and rodent species: abundant versus rare and long versus short. It is also important to sequence a sufficient number of clones to have an idea of the full-length success rate in the library; it is critical that the full-length rate be high to successfully perform the next part of the GIS-PET method. Using this approach, the authors consistently obtain full-length efficiencies of >90%, defined as sequences that match known transcripts at both the 5' and 3' termini (including documented splice variants of known genes).

52. Store the library in the form of a purified ligation mix up to 2 years at -20°C (or indefinitely at -80°C) until ready to construct the GIS-PET library (see Basic Protocol 2).

CONSTRUCTION OF A GIS-PET LIBRARY (DITAGGING)

This procedure is outlined on the right side of Figure 21.12.1. The ds fcdDNA clones constructed in Basic Protocol 1 contain one *MmeI* site (TCCGAC) flanking the 5' terminus of the cDNA insert, and another on the minus strand flanking the 3' end of the insert. The *MmeI* restriction enzyme is used to cleave these clones 20 bp/18 bp into the cDNA fragments from both their 5' and 3' ends, thereby forming the 5' and 3' tags. Consequently, despite the variable sizes of the cDNA inserts, the vector-plus-40-bp cDNA signature tags (linear single-PET plasmids) will be of a constant size (~ 2800 bp) that can be easily recognized using agarose gel electrophoresis, and can be purified from the unwanted cDNA fragments that are a byproduct of the *MmeI* digestion. The gel-purified linear single-PET plasmids are then blunt-ended (to remove any incompatible 3' overhangs) and self-ligated to produce "single-PET plasmids" containing the 5' and 3' GIS tags now linked in the form of PETs. The entire pool of these single-ditag plasmids thus represents the GIS single-PET library. In the final steps, plasmid DNA is extracted from the single-PET library and digested with *BamHI* to obtain the actual GIS PETs. These are gel-purified, concatenated, size-fractionated, and ligated to prepared pZErO-1 vector to yield the final GIS-PET library.

Materials

Purified ligation mix (see Basic Protocol 1)
LB medium (*UNIT 1.1*; use Lennox formulation containing 5 g/liter NaCl)
HiSpeed Plasmid Maxi kit (Qiagen) or equivalent
2 U/ μl *MmeI* (NEB) and 32 mM *S*-adenosyl methionine (SAM; supplied with *MmeI*)
10 \times NEBuffer 4 (NEB)
pGIS4 cloning vector (obtain from authors; prepare as in Support Protocol 1)
Qiaquick gel extraction kit (Qiagen)
10 \times Tango buffer (Fermentas)
0.1 M DTT
5 to 10 U/ μl T4 DNA polymerase (Promega)
10 mM dNTP mix (Invitrogen)
25:24:1 (v/v/v) phenol/chloroform/IAA, pH 7.9 (Ambion)
3 M sodium acetate, pH 5.2 (*APPENDIX 2*)
15 mg/ml GlycoBlue (Ambion)
Absolute and 70% ethanol
Solution I (enzyme solution) from DNA ligation kit (Takara version 2.1)

BASIC PROTOCOL 2

Chromatin Assembly and Analysis

21.12.11

EB buffer (10 mM Tris·Cl, pH 8.5; Qiagen)
 Electrocompetent cells (e.g., OneShot electrocompetent TOP10 cells)
 SOC medium (see recipe)
 LB-amp agar plates (*UNIT 1.1*; use Lennox formulation with 5 g/liter NaCl)
 20 U/μl *Bam*HI and 10× unique *Bam*HI buffer (NEB)
 10 mg/ml BSA
 1 M MgCl₂
 LoTE buffer (see recipe)
 Wide-range DNA ladder (50 to 10,000 bp; Takara)
 4% to 20% PAGE minigel (TBE; 1.0-mm, 10 wells; Invitrogen)
 Low DNA mass ladder (Invitrogen)
 25- and 100-bp DNA ladders (Invitrogen)
 29:1 (v/v) acryamide/bis solution (BioRad)
 5× TBE buffer (*APPENDIX 2*)
 TEMED
 10% ammonium persulfate (APS)
 SYBR Green I (Molecular Probes)
 7.5 M ammonium acetate stock solution
 5 U/μl T4 DNA ligase and 10× ligase buffer with spermidine (see recipe for ligase buffer)
 Qiaquick PCR purification kit (Qiagen)
 6× loading dye (Fermentas)
 pZerO-1 cloning vector (Invitrogen)
 5× ligase buffer with PEG (Invitrogen)
 LB agar plates (*UNIT 1.1*; use Lennox formulation with 5 g/liter NaCl) with 25 μg/ml Zeocin (Invitrogen)
 20 μM PMR011 and PMR012 PCR primers (Fig. 21.12.2)
 22 × 22-cm Q-trays (Genetix) or other large agar plates for bacterial plating
 Disposable plastic spreaders (e.g., Lazy L-spreaders, Sigma), optional
 500-ml plastic centrifuge bottles
 Floor-standing ultracentrifuge (e.g., Sorvall with an SLA3000 rotor)
 Phase Lock Gel Light tubes (Eppendorf), optional
 0.6- and 1.7-ml microcentrifuge tubes
 Electroporation cuvettes (0.1-cm gap; BioRad), prechilled
 15-ml conical tubes (e.g., Falcon)
 Hot/cold shaking incubator (Eppendorf)
 Disposable ElutaTubes (Fermentas) or equivalent
 Dark Reader blue-light transilluminator (Clare Chemical)
 21-G needles
 Microspin plastic centrifuge tube filter units (0.45-μm; Costar Spin-X or BioRad Mermaid), sterile
 Nanodrop spectrometer (optional)
 96-well microtiter plates
 Additional reagents and equipment for plasmid preparation (*UNITS 1.6 & 1.7*), restriction enzyme digestion (*UNIT 3.1*), agarose gel electrophoresis (*UNIT 2.5A*), DNA quantitation (see Support Protocol 3 and *APPENDIX 3D*), phenol extraction and ethanol precipitation (*UNIT 2.1A*), ligation (*UNITS 3.14 & 3.16*), electroporation (*UNIT 9.3*), electroelution (*UNIT 2.6*), PAGE (*UNIT 10.2A*), validation of cloning vector (see Support Protocol 1), PCR (*UNIT 15.1*)

Prepare plasmid DNA

1. Transform all of the remaining purified ligation mix and amplify once by plating an appropriate number of clones (60,000 to 100,000 cfu/tray to allow growth of each colony without excessive overcrowding) on large (22 × 22-cm) agar plates

(e.g., Genetix Q-trays). Use a maximum of 700 μl of culture per Q-tray. Incubate overnight at 37°C.

The number of colonies required is determined by the estimated transcriptome size; 1×10^6 cfu can be used as a convenient benchmark. This number is estimated to give a $10\times$ over-coverage of a transcriptome population of 100,000. (The transcriptome size itself is estimated as 100,000 because 35% to 59% of the estimated 30,000 to 40,000 human genes undergo alternative splicing to give an average of three alternative transcripts per gene.) Although only a small fraction of the expected milligram quantities of plasmid DNA obtained is subsequently used for MmeI digestion, it is still critical for the sake of proper representation/complexity to first obtain the benchmark 1×10^6 cfu.

Growth on agar (solid-phase plasmid amplification) is important, as this maintains representation better than growth in liquid culture. This is because, on a solid substrate, each clone can grow without competition from other bacterial clones.

2. Harvest the resulting bacterial colonies by manually scraping into LB medium (20 to 30 ml per Q-tray) and transfer to 500-ml plastic centrifuge bottles. Centrifuge cells 20 min at $\sim 4000 \times g$, 4°C, in a floor-standing ultracentrifuge.

Disposable plastic spreaders (e.g., Lazy L-spreaders, Sigma) are convenient for harvesting cells.

3. Prepare plasmid DNA using the HiSpeed Plasmid Maxi kit or any other preferred method.

Ten Q-trays of bacteria produce ~ 1 mg of plasmid DNA. Therefore, in theory, two Qiagen Maxi tips (per library) should be sufficient. However, to avoid clogging due to the large volumes involved, the authors usually use three to four tips per library. Suggested volumes of buffers to use with bacteria from ten Q-trays are 20 to 50 ml each of P1, P2, and P3 buffers.

Also see UNIT 1.7 for plasmid preparation.

Perform MmeI digestion (tagging)

4. Digest ~ 10 μg plasmid DNA using MmeI according to the manufacturer's recommended conditions, ensuring that the number of units of enzyme is always in less than a four-fold excess to prevent methylation-induced inhibition. Suggested reaction conditions are as follows (total 200 μl):

100 μl (10 μg) plasmid DNA
20 μl 10 \times NEBuffer 4
20 μl 10 \times SAM
12 μl 2 U/ μl MmeI
48 μl deionized water.

Incubate 4 hr to overnight at 37°C.

The 10 \times SAM should be prepared fresh, as it is unstable. The 10 \times concentration should be 500 μM , and the final SAM concentration should be ~ 50 μM .

An overnight digest usually works best. The main band of ~ 2800 bp is the desired linear single-PET plasmid.

5. Purify the entire digestion reaction on a 0.7% agarose gel (UNIT 2.5A), loading the digestion products in as few lanes as possible to facilitate excision. Run controls on the same gel, comprising uncut as well as linearized pGIS4 cloning vector, to ensure that the correct band is excised.

An ~ 2800 -bp band corresponding to linear single-PET plasmid DNA should be the dominant species in the gel. Unwanted digestion products will be present as a faint smear behind the 2800-bp band.

- Excise the 2800-bp linear single-PET plasmid DNA band and purify using a Qiaquick gel extraction kit.

The number of Qiaquick spin columns to use depends on the amount of DNA that was digested. Remember that each column has a maximum capacity of ~10 µg DNA.

- Quantify the amount of DNA recovered from the gel by spectrometry (APPENDIX 3D).

The recovery rate is consistently ~50%.

Perform self-ligation to create circular single-PET plasmids

- Set up the following reaction to create blunt ends:

50 µl (0.5 to 2.0 µg) DNA
6.0 µl 10× Tango buffer
0.3 µl 0.1 M DTT
5 U T4 DNA polymerase/µg DNA
0.6 µl 10 mM dNTP mix
Deionized water to 60.0 µl.

Incubate 5 min at 37°C, then inactivate 10 min at 75°C.

MmeI digestion (TCC(A/G)AC 20/18) results in a random 2-base 3'-overhang at the ends of both 5' and 3' signature tags. These must be removed by end-polishing using T4 DNA polymerase, leaving behind 18-bp blunt-ended tags.

Alternatively, use the Epicentre End-It blunting kit, which does not require any optimization, and works well for up to 5 µg per reaction.

- Adjust to 200 µl with deionized water, extract with 25:24:1 phenol/chloroform/IAA, pH 7.9, and perform ethanol precipitation as follows:

200 µl blunt-ended DNA
20 µl 3 M sodium acetate, pH 5.2
2 µl 15 mg/ml GlycoBlue
600 µl absolute ethanol.

Keep 30 min at –80°C, then microcentrifuge 30 min at maximum speed, 4°C.

Refer to UNIT 2.1A for phenol extraction and ethanol precipitation. The use of Phase Lock Gel Light tubes greatly facilitates the extraction procedure.

- Wash with 70% ethanol. Resuspend the DNA pellet in LoTE or EB buffer. Dilute an aliquot to ~2 ng/µl, assuming an arbitrary 100% recovery.

A very dilute DNA solution is desired (final DNA concentration of 1 to 2 ng/µl) to favor intramolecular ligation.

- Set up the self-ligation (intramolecular recircularization) reaction on ice by combining 50 µl (~100 ng) DNA with 50 µl DNA ligation solution I (from Takara ligation kit version 2.1). Incubate overnight (12 to 16 hr) at 16°C.

Alternatively, use 5× ligation buffer with PEG (Invitrogen) and 5 U T4 DNA ligase. The final DNA concentration should be adjusted to 1 to 2 ng/µl.

- Adjust volume to 200 µl with deionized water, and perform phenol/chloroform extraction and ethanol precipitation as in step 9. Wash the pellet at least two times with 70% ethanol, and resuspend in 20 µl EB buffer.

This removes salts before electroporation.

Transform cells

13. Add 1 μl purified ligation reaction to 25 μl electrocompetent cells (e.g., OneShot electrocompetent TOP10 cells) in prechilled 1.7-ml microcentrifuge tubes. Gently stir with the pipet tip (do not pipet up and down). Let cells stand 5 min on ice.
14. Transfer to prechilled electroporation cuvettes (0.1-cm gap) and perform electroporation (UNIT 9.3).
15. Add 1 ml room temperature SOC medium within 10 sec of pulsing to maximize efficiency. Transfer cells to 15-ml conical tubes and allow cells to recover 1 hr at 37°C with shaking at 200 rpm.
16. Plate 20 to 50 μl (out of 1 ml) on LB-amp agar plates for quality control (QC) screening and library efficiency calculations. Incubate overnight at 37°C.

Perform QC on GIS single-PET library

17. Plate dilutions of 1:100 to 1:1000 in a final 100- μl volume made up in SOC medium. Incubate overnight at 37°C. On the following day, examine the colonies growing on the agar.

Usually, even the 1:1000 plating is almost confluent (i.e., several thousand colonies). It is important that there are many colonies growing at this stage, as this indicates that the self-circularization step was efficient, and that the resulting single-PET library will be of sufficient complexity.

18. For large-scale plating, based on the number of colonies observed, spread enough of the remaining transformed bacterial culture on Q-trays to obtain at least the same number (or greater) of colonies as in the original f1cDNA library. Incubate overnight at 37°C.

This ensures that the library remains representative of the original sample.

Release single PETs using BamHI

19. Harvest bacterial colonies by scraping into LB medium (20 to 30 ml per Q-tray) and centrifuge 20 min at $\sim 4000 \times g$, 4°C, in a floor-standing ultracentrifuge. Prepare plasmid DNA using the HiSpeed Plasmid Maxi kit (or any other preferred method).
20. Digest ~ 100 to 500 μg plasmid DNA using *Bam*HI. Suggested reaction conditions are:

500 μg plasmid DNA ($x \mu\text{l}$)
100 μl 10 \times unique *Bam*HI buffer
10 μl 10 mg/ml BSA
50 μl 20 U/ μl *Bam*HI
Deionized water to 1 ml.

Pipet into 100- μl aliquots for enhanced digestion efficiency and incubate overnight at 37°C.

There is no upper limit to the amount of DNA being cut here. It is advisable to cut as much plasmid DNA as possible to obtain a large quantity of PETs.

*A two-fold excess of *Bam*HI is used. Better downstream results have been obtained using these conditions compared with a five-fold excess of enzyme.*

Purify BamHI-cohesive single PETs

21. To remove buffer salts and reduce volume, extract with 25:24:1 phenol/chloroform/IAA, pH 7.9, and ethanol precipitate as follows:

200 μ l digest
20 μ l 3 M sodium acetate, pH 5.2
4.5 μ l 1 M $MgCl_2$
2 μ l GlycoBlue
600 μ l absolute ethanol.

Keep 30 min at $-80^\circ C$, then microcentrifuge 30 min at maximum speed, $4^\circ C$. Wash with 70% ethanol.

If buffer salts are not removed, they will distort the subsequent gel run (especially for PAGE) and thus affect purification of the 50-bp PETs. The addition of $MgCl_2$ during precipitation enhances recovery of short fragments.

For convenience, PETs are most often run on a 2% agarose gel and then electroeluted (steps 21 to 27a). This is a lower-resolution method and does not purify PETs as efficiently as PAGE, which was used when developing the original procedure (steps 21 to 29b). The effect of these impurities is manifested as damaged sequences that “poison” the concatenation step, leading to shorter concatemers. Nonetheless, agarose gel electrophoresis is easier to set up and faster to run, and suitable if there are no problems with the single-PET library (which enables one to obtain pure PETs). It is critical to examine the quality of agarose-gel-purified PETs (e.g., by running a mini PAGE gel) before concatenation.

For agarose gels

22a. Resuspend the pellets from all the tubes in a total of 100 μ l LoTE buffer or EB buffer.

23a. Load on a 2% agarose gel along with 20 μ l wide-range DNA ladder. Run at 80 V for ~ 1.5 hr and visualize at 365 nm UV to confirm good separation of PETs from other DNA.

It is convenient to run a wide-range DNA ladder for sizing.

24a. Excise the PET band from the agarose gel and electroelute using disposable ElutaTubes (or equivalent). Follow the manufacturer’s instructions for maximum gel size per tube. Perform electroelution for 1 to 1.5 hr at 90 V.

Also see UNIT 2.6 for electroelution from agarose gels.

25a. Precipitate the harvested PETs as in step 21. Resuspend all precipitated PET DNA in 20 μ l LoTE buffer.

26a. Run 0.5 μ l and 1 μ l on a 4% to 20% gradient polyacrylamide minigel (UNIT 10.2A) together with a low DNA mass ladder and a 25-bp DNA ladder to check for purity and to quantify PETs by visual comparison to mass ladders.

27a. *Optional:* Quantify PETs using PicoGreen (see Support Protocol 3). Proceed to step 30.

Some investigators have found that visual estimation of PET DNA quantity results in subjective variability, and hence uncertainty in subsequent enzymatic digestion steps. Although not critical, PicoGreen quantitation (which is not affected by the presence of glycogen/GlycoBlue) can be useful in providing a more accurate quantitation of DNA.

For polyacrylamide gels

22b. Resuspend and pool the DNA pellets in LoTE buffer at ~ 10 μ g per 20 μ l, which is suitable for gel-loading.

23b. Cast a 15 × 15-cm, 1.5-mm thick, 10-well, 10% polyacrylamide gel according to the following recipe:

10 ml 40% acryamide/bis (29:1) solution
8 ml 5× TBE buffer
16 μl TEMED
21.6 ml deionized water
When ready to pour, add 0.4 ml of 10% APS.

Refer to UNIT 10.2A for PAGE.

24b. Load no more than ~10 to 15 μg per well, as excessive DNA loading results in self-quenching of fluorescence. Load 1 μl (1 μg) of 25-bp DNA ladder into one well. Electrophorese at 200 V until the bromphenol blue band almost reaches the bottom of the gel.

25b. Stain the gel with SYBR Green I for 30 min and visualize on a Dark Reader blue-light transilluminator.

It is preferable to use the Dark Reader transilluminator for visualization, as exposure to UV light (especially short-wavelength UV) will damage DNA. If this is not possible, at least ensure that long-wavelength (365-nm) UV light is used.

26b. Excise the 50-bp GIS-PETs and collect gel fragments into 0.6-ml microcentrifuge tubes that have been pierced at the bottom with a 21-G needle. Use DNA from two lanes per tube. Place the pierced tubes inside 1.7-ml microcentrifuge tubes and microcentrifuge 5 min at maximum speed, 4°C.

The gel pieces are conveniently shredded and collected at the bottom of each 1.7-ml microcentrifuge tube. This is known as the gel-crush method.

27b. Add 150 μl of 125:25 (v/v) LoTE buffer/ammonium acetate to each tube and elute overnight (12 to 16 hr) at 4°C and then 30 min to 2 hr at 37°C.

28b. Separate the supernatant (containing eluted 50-bp PETs) from the gel pieces with the aid of microspin plastic centrifuge tube filter units (e.g., SpinX or Mermaid). Using a 1-ml pipet tip, aspirate as much liquid and gel into each column, then microcentrifuge 10 min at maximum speed, 4°C.

29b. Pool the collected supernatant and precipitate as in step 21. Resuspend the pellets from all the tubes in a total of 20 μl LoTE buffer and proceed to quantitation by visual comparison to mass ladders or by PicoGreen fluorimetry (see Support Protocol 3).

A phenol/chloroform extraction prior to precipitation is optional.

The presence of GlycoBlue (or glycogen) at this stage precludes spectrophotometric quantitation.

Concatenate PETs

30. Set up the following ligation reaction:

200 to 1000 ng 50-bp cohesive PETs
1 μl 10× ligase buffer with spermidine
1 μl 5 U/μl T4 DNA ligase
Deionized water to 10 μl (or 20 μl if PETs are too dilute).

Incubate 2 hr to overnight at 16°C.

Addition of spermidine is important for enhancing ligase activity and favoring linear concatenation.

Overnight incubation does not appear to affect the concatenation efficiency of agarose-gel-purified PETs, which is somewhat disconcerting, since over-concatenation would be expected. Apparently there is a limit to concatenation efficiency due to impurities that “poison” the ligation reaction. In the case of PAGE-purified PETs, some optimization must be done with regard to ligation time, as over-concatenation can occur due to the higher purity of the recovered PETs. Over-concatenation will result in excessively high-molecular-weight DNA that is difficult to clone. The authors find that the >2-kb fraction (in step 36) clones poorly (high incidence of empty clones) unless special measures are taken (a much higher insert-to-vector ratio of up to 50:1; incubation of transformed cells for longer periods). Although ligation is done with this high-molecular-weight fraction as a matter of course, it is seldom actually used in the final sequencing, as the clones from the lower-molecular-weight fractions provide sufficient PET data.

31. Purify the concatemer DNA using the Qiaquick PCR purification kit, keeping in mind the 10- μ g DNA capacity of each spin column. Elute DNA with 50 μ l EB buffer. Quantitate DNA by Nanodrop (if available).

If Nanodrop is not available, quantitate using another spectrophotometer.

32. Perform a partial *Bam*HI digest as follows:

50 μ l concatemer DNA
6 μ l 10 \times *Bam*HI buffer
1 U *Bam*HI/ μ g DNA (up to a maximum of 3 U/ μ g DNA)
1 μ l 10 mg/ml BSA
Deionized water to 60 μ l.

Incubate 30 min at 37°C.

Concatenated PETs are partially redigested with BamHI to ensure the presence of cohesive termini suitable for insertion into BamHI-digested pZErO-1 vector. This step is critical to the success of concatemer cloning. A partial digestion apparently ensures the recreation of “correct” BamHI cohesive ends on the concatemer termini. Without this step, a significant fraction of the concatemers fail to insert into the vector in the next step. This BamHI redigestion is performed only on BamHI cohesive-ended concatemers.

Do not exceed the 30-min digestion time as this will destroy the concatemers. It is helpful initially to visualize the digestions at several time points on a polyacrylamide minigel.

33. Quickly add 6 μ l of 6 \times loading dye, heat 15 min at 65°C, and then chill on ice.

This step minimizes nonspecific aggregation/annealing of DNA, which might otherwise give a false picture of concatenation efficiency.

Purify concatenated PETs

34. Load the entire sample (preferably into one well to facilitate recovery) on a 4% to 20% gradient polyacrylamide minigel, flanked by suitable DNA ladders to allow sizing.

Suggested markers are the 25-bp and 100-bp ladders from Invitrogen, and the Takara wide-range DNA ladder. The use of multiple DNA ladders facilitates accurate sizing.

35. Electrophorese \sim 1 hr at 200 V or until the bromphenol blue tracking dye is at the bottom of the gel. Stain for 15 to 30 min in SYBR Green I and visualize on a Dark Reader transilluminator for band excision.

36. Excise the concatenated DNA in three separate fractions by molecular weight: low (400 to 1000 bp), medium (1000 to 2000 bp), and high (>2000 bp).

It is important when excising the high-molecular-weight fraction to avoid collecting the DNA trapped in the wells. This debris appears to poison the subsequent ligation (or is itself favorably inserted) such that no high-molecular-weight concatemers are cloned.

37. Place the gel slice of each excised size fraction into a 0.6-ml microcentrifuge tube that has been pierced at the bottom with a 21-G needle and extract concatemers by the gel-crush method (step 26b).
38. Add 200 μ l of 167:33 (v/v) LoTE buffer/ammonium acetate to each tube and elute by heating 2 hr at 65°C.
39. Separate the supernatant (containing eluted concatenated PETs) from the gel pieces with the aid of microspin filter units (step 28b).
40. Perform phenol/chloroform extraction on each eluted size fraction and then ethanol precipitate as in step 9. Wash each pellet with 70% ethanol and resuspend each in 6 μ l LoTE or EB buffer.

If there is more than one pellet per size fraction, pool pellets from the same size fraction and resuspend in a total volume of 6 μ l LoTE or EB buffer.

The excised DNA can also be recovered by electroelution using ElutaTubes.

Ligate concatenated PETs to pZErO-1 vector

41. Prepare the cloning vector by digesting 2 μ g pZErO-1 plasmid DNA with 10 U *Bam*HI for 2 hr at 37°C. Perform phenol/chloroform extraction and ethanol precipitation as in step 9, wash the pellet with 75% ethanol, and resuspend in LoTE buffer at a concentration of 33 ng/ μ l. Validate preparation before use (see Support Protocol 1).

Agarose gel purification of the vector is not necessary.

42. Set up the ligation as follows (total 10 μ l):

6 μ l concatemer DNA fraction
1 μ l *Bam*HI-digested pZErO-1 DNA
2 μ l 5 \times ligase buffer with PEG
1 μ l 5 U/ μ l T4 DNA ligase.

Also set up a vector self-ligation in parallel as a control. Incubate overnight at 16°C. Do not heat inactivate.

43. Adjust volume to 200 μ l with deionized water, and perform phenol/chloroform extraction and ethanol precipitation as in step 9. Wash the pellet at least two times with 70% ethanol, and resuspend in 20 μ l EB buffer.

This removes salts prior to transformation.

Transform cells

44. Add 1 μ l purified ligation reaction to 25 μ l electrocompetent cells (e.g., OneShot electrocompetent TOP10 cells) in prechilled 1.7-ml microcentrifuge tubes. Gently stir with a pipet tip (do not pipet up and down). Let cells stand 5 min on ice.
45. Transfer to prechilled electroporation cuvettes (0.1-cm gap) and perform electroporation.
46. Add 1 ml room temperature LB medium (not SOC) within 10 sec of pulsing to maximize efficiency. Transfer cells to 15-ml conical tubes (or equivalent) and allow cells to recover 1 hr at 37°C, shaking at 200 rpm.

Surprisingly, improved results (i.e., higher titers) have been confirmed using LB medium instead of SOC medium.

47. Plate 20 to 50 μ l (out of 1 ml) on on a small LB agar plate plus Zeocin (25 μ g/ml final concentration). Incubate overnight at 37°C.

Perform QC on GIS-PET library

48. Count the number of colonies and determine library efficiency taking into consideration the self-ligation background. Pick colonies (24 to 48 is sufficient and convenient) for PCR screening (*UNIT 15.1*) using PMR011 and PMR012 primers. Include a control PCR on the pZerO-1 vector itself. Analyze PCR products by agarose gel electrophoresis.
49. If PCR shows a satisfactory range of insert sizes, pick one to four 96-well plates of colonies for overnight culture (in low-salt LB medium plus 25 $\mu\text{g}/\text{ml}$ Zeocin), purify plasmids (*UNIT 1.6*), and sequence to determine the average number of PETs per insert.
50. Store the library in the form of a purified ligation mix at -20°C until ready to perform large-scale transformations, plasmid extractions, and sequencing of GIS-PETs.

BASIC PROTOCOL 3

CONSTRUCTION OF A ChIP-DNA PLASMID LIBRARY

Chromatin immunoprecipitation (ChIP)-PET analysis (Fig. 21.12.3) is a minor modification of the GIS-PET analysis procedure. ChIP-enriched genomic DNA (gDNA) fragments are end-polished and inserted into another unique cloning vector (pGIS3) that has the requisite restriction enzyme recognition sites built into the vector arms flanking the inserted DNA. This results in the formation of a ChIP-DNA library (analogous to the fICDNA library in GIS-PET). The ChIP-DNA library is then ditagged exactly as described in Basic Protocol 2.

This procedure assumes that the reader is familiar with the construction of a GIS fICDNA library as described in Basic Protocol 1, especially with regard to basic molecular biology procedures. The method of ChIP is not covered in this protocol (see *UNIT 21.3*). For best results, the de-linked, fragmented ChIP-enriched gDNA should show a smear between 100 and 2000 bp, centering around 500 bp. These parameters can be met by adjusting

Figure 21.12.3 An overview of the ChIP-PET analysis method for mapping ChIP-enriched genomic DNA fragments.

sonication conditions. In addition, the minimum starting quantity of DNA should be 100 ng. Due to the interfering presence of glycogen in the ChIP-enriched gDNA fragments, quantitation must be done by PicoGreen fluorimetry (see Support Protocol 3).

Materials

End-It DNA end-repair kit (Epicentre) containing:

End-repair enzyme mix: T4 DNA polymerase and T4 polynucleotide kinase
End-repair 10× buffer
dNTP solution
ATP

Sample of interest: ChIP-enriched genomic DNA fragments (at least 100 ng)

25:24:1 (v/v/v) phenol/chloroform/IAA, pH 7.9 (Ambion)

3 M sodium acetate, pH 5.2 (*APPENDIX 2*)

70% and absolute ethanol

GlycoBlue (Ambion)

1× TEN buffer (see recipe)

pGIS3 cloning vector (obtain from authors; prepare as in Support Protocol 1)

5 U/μl T4 DNA ligase and 5× T4 DNA ligase buffer with PEG (Invitrogen)

EB buffer (10 mM Tris-Cl, pH 8.5; Qiagen)

20 μM PMR011 and 20 μM PMR012 PCR primers (Fig. 21.12.2)

Phase Lock Gel Light tubes (Eppendorf), optional

Heat/chill block or thermal cycler

Additional reagents and equipment for size-fractionation, transformation, and PCR screening (see Basic Protocol 1)

1. Set up an end-polishing reaction using the End-It kit (total 50 μl):

34 μl (100 to 200 ng) ChIP-enriched gDNA

5 μl end-repair 10× buffer

5 μl 2.5 mM dNTP mix

5 μl 10 mM ATP

1 μl end-repair enzyme mix.

Incubate 45 min at 25°C, then inactivate 10 min at 70°C.

The End-It kit is convenient as it simultaneously blunts and 5'-phosphorylates the DNA termini.

2. Adjust volume to 200 μl with deionized water, extract with 25:24:1 phenol/chloroform/IAA, pH 7.9, and ethanol precipitate as follows:

200 μl end-polished DNA

20 μl 3 M sodium acetate, pH 5.2

2 μl 15 mg/ml GlycoBlue

600 μl absolute ethanol.

Keep 30 min at –80°C, then microcentrifuge 30 min at maximum speed, 4°C.

Refer to UNIT 2.1A for phenol extraction and ethanol precipitation. As in Basic Protocol 1, the use of Phase Lock Gel Light tubes greatly facilitates the extraction procedure.

3. Wash with 70% ethanol. Resuspend the pellet of purified, blunted, and phosphorylated DNA in 100 μl of 1× TEN buffer for size fractionation. Size-fractionate the DNA on cDNA size fractionation columns (one per sample; see Basic Protocol 1, steps 36 to 43).

The objective of the optional electrophoresis step (see Basic Protocol 1, step 42) is to remove any DNA fragments that are too small (<100 bp), as these will be cloned preferentially, but are relatively uninformative relative to the bulk of the fragmented DNA (which should be centered between 200 and 500 bp). Fractions 7 to 12 are usually suitable.

4. To ligate DNA to the cloning vector, set up the following reactions on ice using 1.7-ml microcentrifuge tubes (total 10 μ l):

- 1 μ l 40 ng/ μ l prepared pGIS3
- 6 μ l selected ChIP DNA fractions
- 2 μ l 5 \times ligase buffer with PEG
- 1 μ l 5 U/ μ l T4 DNA ligase.

Also set up a vector self-ligation control. Incubate overnight (12 to 16 hr) at 16°C.

5. Adjust volume to 200 μ l with deionized water, and perform phenol/chloroform extraction and ethanol precipitation as in step 2.
6. Wash the pellet at least two times with 70% ethanol, and resuspend in 20 μ l EB buffer.

This removes salts prior to transformation.

7. Transform cells by electroporation and pick colonies for PCR screening using PMR011 and PMR012 primers (see Basic Protocol 1, steps 46 to 50).

A range of different-sized PCR products should be observed, corresponding in size to the inserted DNA fractions.

8. Store the library in the form of a purified ligation mix at -20°C .
9. Construct the ChiP-PET library (ditagging) as described for GIS-PET (see Basic Protocol 2).

SUPPORT PROTOCOL 1

PREPARATION AND VALIDATION OF pGIS4 AND pGIS3 CLONING VECTORS

The pGIS4 vector (Fig. 21.12.4) was created as an improvement to the published prototype pGIS1, and renders 3'-adapter ligation unnecessary. It contains an \sim 800-bp stuffer that must be excised before use by *NotI* and *BseRI* digestion, which simultaneously creates a *NotI* cohesive site to receive the 5'-adapter terminal region of the cDNA, and a TT overhang ready to receive the corresponding AA overhang at the 3' end of the prepared cDNA insert.

The pGIS3 vector (Fig. 21.12.5) was created to facilitate direct ditagging of inserted blunt-ended DNA fragments. The restriction sites important for ditagging were built into the vector backbone itself. There is no stuffer fragment in pGIS3.

Materials

- pGIS4 and pGIS3 plasmids (obtain from authors; ngwp@gis.a-star.edu.sg)
- HiSpeed plasmid maxi kit (Qiagen)
- Qiaquick gel extraction kit (Qiagen)
- 10 \times NEBuffer 2 and NEBuffer 3 (NEB)
- 10 U/ μ l *NotI* restriction enzyme (NEB)
- 4 U/ μ l *BseRI* restriction enzyme (NEB)
- 10 mg/ml BSA
- EB buffer (Qiagen)
- Compatible stuffers for validation

5 U/μl T4 DNA ligase and 5× T4 DNA ligase buffer with PEG (Invitrogen)
20 U/μl *Xho*I restriction enzyme (NEB)
70 U/μl mung bean nuclease and 10× reaction buffer (Promega)
10% SDS
Qiaquick PCR purification kit (Qiagen)
5 U/μl Antarctic phosphatase and 10× Antarctic phosphatase buffer (NEB)
TE buffer (APPENDIX 2; optional)
Nanodrop spectrometer (optional)
Additional reagents and equipment for agarose gel electrophoresis (UNIT 2.5A) and transformation (see Basic Protocol 1)

For pGIS4 plasmid DNA

- 1a. Purify pGIS4 plasmid using the HiSpeed plasmid maxi kit according to the manufacturer's instructions.
- 2a. To ensure that no contaminating bacterial genomic DNA is subsequently inserted into the prepared vector, perform an extra agarose gel purification (UNIT 2.5A) of the maxiprep to isolate supercoiled DNA.
- 3a. Recover DNA using the Qiaquick gel extraction kit according to the manufacturer's instructions (recovery is ~50%).

The maximum capacity of each Qiaquick spin tube is only 10 μg, so be sure to predetermine the number of tubes needed.

- 4a. Set up the digestion as follows:

5 μg purified supercoiled pGIS4
20 μl 10× NEBuffer 3
5 μl 10 U/μl *Not*I (five-fold excess)
12.5 μl 4 U/μl *Bse*RI (five-fold excess)
2 μl 10 mg/ml BSA
Water to 200 μl.

Incubate as two 100-μl aliquots no more than 3 hr at 37°C.

It is important to follow the conditions given here closely, as BseRI exhibits some nonspecific activity and is also only 75% active in NEBuffer 3.

- 5a. Purify by agarose gel electrophoresis. Quantitate using a Nanodrop (if available) and resuspend in EB buffer at 40 ng/μl.
- 6a. To validate, set up three test ligations as shown in Table 21.12.1. Incubate overnight at 16°C.

*This procedure is generally applicable to any cloning vector. The purpose of vector validation is to ensure that there is minimal contamination of the *Not*I/*Bse*RI-cut vector with either uncut or single-cut plasmid, which would otherwise contribute to unwanted background.*

*In this case, a compatible stuffer would be a dsDNA fragment with a cohesive 5'-*Not*I site, and a 3'-AA overhang. It is possible to simply gel extract the smaller digestion product (after the *Not*I/*Bse*RI vector digestion) and use this as an insert; however, any nonspecific cutting would be preserved in this product, giving rise to false positives in the positive control. It is far better to construct a predetermined dsDNA adapter and use this as a control insert. The authors use the adapter obtained by annealing the oligonucleotides pGIS7/4VERIF-TOP and pGIS7/4VERIF-BOT (see Fig. 21.12.2 and Support Protocol 2).*

Figure 21.12.4 (A) Schematic diagram of the pGIS4 cloning vector for GIS-PET analysis. (B) Sequence details of the cloning site in pGIS4.

Figure 21.12.5 (A) Schematic diagram of the pGIS3 cloning vector for ChIP-PET analysis. (B) Sequence details of the cloning site in pGIS3.

Table 21.12.1 Test Ligations for Validation of Cloning Vector^a

Reagent	No ligase (uncut plasmid test)	Self-ligation (single-cut plasmid test)	Plus insert (positive control)
40 ng (<i>NotI</i> + <i>BseRI</i>) pGIS4	1	1	1
80 ng compatible stuffer	—	—	4
5× ligation buffer with PEG	2	2	2
T4 DNA ligase (5 U/μl)	—	—	1
Deionized water	7	6	2

^aVolumes (in μl) are for illustrative purposes only.

7a. Transform into bacteria (see Basic Protocol 1, steps 46 to 49) and count colonies.

There should be no or very few colonies for the uncut and single-cut ligations, and many for the positive control.

For pGIS3 plasmid DNA

1b. Purify pGIS3 plasmid DNA as in steps 1a to 3a.

2b. Perform *Xho*I digestion as follows to linearize the vector (and expose the cloning arms):

5 µg purified supercoiled pGIS3
10 µl 10× NEBuffer 2
1 µl 10 mg/ml BSA
2 µl 20 U/µl *Xho*I
Water to 100 µl.

Incubate 2 hr at 37°C.

3b. Purify by agarose gel electrophoresis.

4b. Polish off the exposed 3' overhangs using mung bean nuclease as follows:

~ 2µg *Xho*I-digested pGIS3
3 µl 10× reaction buffer
5 U mung bean nuclease per µg DNA
Deionized water to 30 µl.

Incubate 30 min at 30°C, then stop the reaction by adding 3.3 µl of 10% SDS (final 0.01%).

T4 DNA polymerase or Klenow enzyme cannot be used for this end-polishing step, as they will not remove the 5' overhangs to leave the MmeI sites directly adjacent to the inserted DNA fragment.

Mung bean nuclease is supplied at high concentration (70 U/µl) and must be diluted before use. It is typically diluted to 5 U/µl using 1× reaction buffer. It is critical to do the dilution just prior to use, as the dilute enzyme is unstable.

The mung bean nuclease polishing step can be difficult, hence the importance of the vector validation step below.

5b. Remove buffer salts and enzymes using Qiaquick PCR purification columns. Quantitate using a Nanodrop or other spectrometer.

6b. Remove 5'-phosphate groups to prevent self-circularization:

5 µg *Xho*I-cut, end-polished pGIS3
5 µl 10× Antarctic phosphatase buffer
5 µl 5 U/µl Antarctic phosphatase (use 5 U/µg target)
Deionized water to 50 µl.

Incubate exactly 30 min at 37°C; then heat inactivate 20 min at 65°C.

Volumes are only indicative; adjust as needed.

There is no need for a phenol extraction, as Antarctic phosphatase is completely inactivated by heating.

7b. If necessary, dilute prepared plasmid DNA in EB buffer (or TE buffer) to a final concentration of ≤40 ng/µl.

8b. If desired, run 2 µl (estimated to be 80 ng) of the diluted DNA on an agarose gel against known standards to confirm the quantity of DNA.

- 9b. Validate vector as in steps 6a and 7a, using 40 ng *Xho*I-digested vector. For the stuffer, use at least 80 ng of a blunt, phosphorylated stuffer fragment.

The prepared pGIS3 vector MUST be validated and sequenced to ensure that the MmeI sites were not damaged during the end-polishing step, as this would render the vector (and the entire library) useless.

PREPARATION OF ADAPTERS

Oligonucleotides are ordered pre-adjusted to 100 μ M concentration (Proligo). Since they are supplied in water, they must be adjusted to the correct concentration of Tris/NaCl/EDTA (TNE) prior to annealing.

Materials

Oligonucleotides A and B to be tested
2 \times TNE buffer (see recipe)
PAGE minigel (either 20% or 4% to 20% gradient)
*Not*I enzyme (NEB)
0.2-ml PCR tubes
Thermal cycler

1. In a 0.2-ml PCR tube, mix together:

20 μ l oligonucleotide A
20 μ l oligonucleotide B
40 μ l 2 \times TNE buffer.

2. Run in a thermal cycler using the following parameters:

hold 2 min at 95°C	
ramp from 95°C to 75°C at 0.1°C/sec	hold 2 min at 75°C
ramp from 75°C to 65°C at 0.1°C/sec	hold 2 min at 65°C
ramp from 65°C to 50°C at 0.1°C/sec	hold 2 min at 50°C
ramp from 50°C to 37°C at 0.1°C/sec	hold 2 min at 37°C
ramp from 37°C to 20°C at 0.1°C/sec	hold 2 min at 20°C
ramp from 20°C to 4°C at 0.1°C/sec	hold indefinitely at 4°C (until ready to collect).

IMPORTANT: *Keep all annealed adapters cold.*

3. Run ssDNA oligos and annealed adapters on the same PAGE minigel (either 20% or 4% to 20% gradient).
4. For GIS-(N)5 and GIS-(N)6 adapters, perform a simple *Not*I digestion, which should fragment the adapter in two, showing that the *Not*I site is present and correct.

PICOGREEN ASSAY FOR QUANTITATION OF DNA

Adapted from <http://www.molecularprobes.com/media/pis/mp07581.pdf>.

Materials

PicoGreen reagent (Invitrogen)
TE buffer (APPENDIX 2)
Calf thymus DNA (Sigma-Aldrich)
DNA samples

SUPPORT PROTOCOL 2

SUPPORT PROTOCOL 3

Chromatin Assembly and Analysis

21.12.27

Table 21.12.2 Standard Curve Preparation for PicoGreen Assay

Concentration after 50 μ l of 1 \times PicoGreen added (ng/ μ l)	1 ng/ μ l calf thymus DNA (μ l)	TE buffer (μ l)
0.1	10	40
0.05	5	45
0.025	2.5	47.5
0.01	1	49
0.005	0.5	49.5
0.0025	0.25	49.75

96-well, clear flat-bottom plate (Greiner)
Genios (Tecan) or other suitable fluorometer
Fluorometer software (e.g., Magellan)

1. Dilute 200 \times concentrated PicoGreen reagent to 1 \times in TE buffer just before the experiment. Prepare 50 μ l of 1 \times PicoGreen for each sample to be analyzed.
2. Prepare a 100 ng/ μ l stock solution of calf thymus DNA to make the standard curve. Determine the standard curve range according to the estimated concentration of DNA in the sample (see Table 21.12.2).
3. Dilute the DNA samples so that the diluted DNA concentration falls in the range of the standard curve. Prepare 50 μ l diluted DNA sample for each assay.
4. Add 50 μ l of each DNA sample to a 96-well, clear flat-bottom plate. Add 50 μ l TE buffer to a separate well as blank control.
5. Add 50 μ l of 1 \times PicoGreen into blanks and samples, protected from light. Measure the fluorescence of samples using a Tecan Genios or other suitable fluorometer.
6. Subtract the fluorescence of the reagent blank from that of each sample and determine the DNA concentration of samples from the standard curve using the fluorometer software (e.g., Magellan).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Alkaline hydrolysis buffer

50 mM NaOH
5 mM EDTA, pH 8.0
Prepare fresh before use

Binding buffer, 1 \times

2 M NaCl
50 mM EDTA, pH 8.0
Stable for years at 4 $^{\circ}$ C

Blocking buffer, 1 \times

0.4% SDS
50 μ g/ml yeast tRNA
Stable for years at -20° C

Ligase buffer with spermidine, 10×

60 mM Tris·Cl, pH 7.5 (*APPENDIX 2*)
60 mM MgCl₂
50 mM NaCl
1 mg/ml BSA
70 mM 2-mercaptoethanol
1 mM ATP
20 mM DTT
10 mM spermidine (Sigma)
Stable for years at −20°C

LoTE buffer

3 mM Tris·Cl, pH 7.5 (*APPENDIX 2*)
0.2 mM EDTA (*APPENDIX 2*)
Stable for years at room temperature

Modified 10 mM dNTP with 5-Me-dCTP

100 μl 100 mM stock solution of dATP (final 10 mM)
100 μl 100 mM stock solution of dTTP (final 10 mM)
100 μl 100 mM stock solution of dGTP (final 10 mM)
50 μl 100 mM stock solution of 5-Me-dCTP (final 5 mM)
10 μl 1 M Tris·Cl, pH 8.0 (final 10 mM)
640 μl deionized water
Stable for years at −20°C

All dNTPs are available from Roche.

Saturated trehalose (RNase-free)

Place a magnetic stir bar into a small beaker and heat 10 ml water to 42°C. Slowly add 8 g D-(+)-trehalose dihydrate powder (Sigma) and allow it to dissolve by stirring. While carefully maintaining the temperature at 42°C, continue adding trehalose until saturation is reached. Cool solution to room temperature, allowing trehalose crystals to form. At this stage, add enough diethylpyrocarbonate (DEPC) to give a 0.1% final concentration. Shake vigorously for 5 to 10 min (or stir overnight), then autoclave the saturated trehalose solution to deactivate the DEPC. Store saturated trehalose in aliquots at −20°C (stable for years).

Because the solubility of trehalose increases with temperature, it is important to maintain the temperature at not more than 42°C when making this solution. This is the temperature at which the trehalose is used in the protocol.

SOC medium

0.5% yeast extract
2% tryptone
10 mM NaCl
2.5 mM KCl
10 mM MgCl₂
10 mM MgSO₄
20 mM glucose
Store at room temperature (stable for years)

TEN buffer, 1 ×

10 mM Tris·Cl, pH 8.0 (APPENDIX 2)
0.1 mM EDTA, pH 8.0 (APPENDIX 2)
25 mM NaCl
Stable for years at 4°C

TNE buffer, 2 ×

20 mM Tris·Cl, pH 8.0 (APPENDIX 2)
0.2 mM EDTA, pH 8.0 (APPENDIX 2)
100 mM NaCl
Stable for years at 4°C

Wash buffer, 1 ×

10 mM Tris·Cl, pH 7.5 (APPENDIX 2)
0.2 mM EDTA, pH 8.0 (APPENDIX 2)
10 mM NaCl
20% glycerol
40 µg/ml yeast tRNA

If buffer is made up with yeast tRNA, then store at −20°C (stable for years). Alternatively, it is convenient to store the buffer (minus yeast tRNA) for years at 4°C, remembering to add the yeast tRNA before use (to a final concentration of 40 µg/ml).

COMMENTARY

Background Information

GIS-PET analysis

Sequence-based methods of extracting information from completed genome sequences include full-length cDNA sequencing, DNA tagging methods such as serial analysis of gene expression (SAGE; UNIT 25B.6; Velculescu et al., 1995; Saha et al., 2002), massively parallel signature sequencing (MPSS; Brenner et al., 2000), expressed sequence tag (EST) analysis (Adams et al., 1991), and more recently, terminal tag isolation procedures such as cap analysis gene expression (CAGE; Shiraki et al., 2003), 5'/3' LongSAGE (Wei et al., 2004), 5-SAGE (Hashimoto et al., 2004), and the gene identification signature-paired end ditagging (GIS-PET) analysis method (Ng et al., 2005), which is described here. These methods require extensive sample preparation and can be technically challenging, but may be implemented in any standard molecular biology laboratory, and are advantageous because they are “open” systems querying entire genomes. They allow quantitative gene expression comparisons by simple tag-counting, and are “portable,” i.e., the results are not affected by different instruments or experimenters.

The original DNA tagging methods of SAGE and MPSS, while providing an accurate and highly-efficient means to analyze tran-

scripts, were hindered by the inherent positional ambiguity of a short single tag, and the possibility of incomplete enzymatic digestion during tagging. This was partially resolved by methods that separately extracted only either 5' or 3'-terminally located tags, culminating in this present strategy of linking both terminal tags from a contiguous DNA fragment (in this case, flcDNA) into paired-end ditags (PETs) that can be mapped back onto assembled genomes to precisely locate the original sequence. The PET-based transcriptome analysis procedure called gene identification signature (GIS) analysis is as accurate as flcDNA sequencing, but potentially 30-fold more efficient (estimation based on Sanger sequencing results) for genome annotation (Ng et al., 2005). GIS-PET can also be used to characterize splice variant expression in the transcriptome; however, it is only able to differentiate variants that differ in either the first or last exons. The high-quality flcDNA library that is constructed as an intrinsic part of the procedure is an added resource, facilitating the recovery of transcripts of interest by simple PCR for downstream functional studies.

In GIS-PET, the quality of the flcDNA library is of paramount importance. During development of the GIS-PET procedure, several different approaches were tested

for generating *flcDNA*, and the CapTrapper approach (Carninci and Hayashizaki, 1999), which utilizes chemical biotinylation, produced the highest percentage of full-length clones in the library (typically >92%). The drawbacks of the CapTrapper procedure are that it is tedious, requiring multiple hands-on steps, and that it requires a relatively large quantity of starting mRNA (~10 µg). This latter requirement currently precludes the use of GIS-PET with clinical samples, which are usually present in very small quantities, although strategies to overcome this problem are currently being developed.

ChIP-PET analysis

Chromatin immunoprecipitation (ChIP; UNIT 21.3) is a powerful technique for the global identification of transcription factor binding sites *in vivo*. To map the TFBS in a high-throughput manner, the technique of ChIP-on-chip is widely used: this involves the hybridization of ChIP-enriched genomic fragments onto a series of genomic microarrays. While this has succeeded in simpler organisms such as yeast (Ren et al., 2000), the greater size and complexity of mammalian genomes has rendered a complete global survey of TFBS by ChIP-on-chip unfeasible at present, although some important progress has been made on a limited scale, such as with specific chromosomal arrays, or promoter microarrays containing CpG islands or sequences flanking transcription start sites (Horak et al., 2002; Weinmann et al., 2002; Cawley et al., 2004; Boyer et al., 2005). In another recent report, high density tiling oligo arrays covering 25% of the sequenced human genome were used to map active promoters (Kim et al., 2005).

Alternatively, immunoprecipitated DNA fragments from ChIP experiments can be directly cloned and sequenced (Weinmann et al., 2001; Hug et al., 2004). The main drawback of this is that ChIP typically presents a high background of non-specific DNA, complicating the task of identifying authentic TFBS, especially if every cloned fragment has to be sequenced. The increase in sampling efficiency offered by DNA tagging methods such as SAGE presents a possible solution, and has been applied to genome scanning for TFBS and histone modification (Impey et al., 2004; Chen and Sadowski, 2005; Kim et al., 2005; Roh et al., 2005). However, the inherent ambiguity of mapping short single tags limits the ability of such ChIP-SAGE approaches to accurately pinpoint the boundaries of each frag-

ment, thereby making it difficult to distinguish true ChIP enrichment from amplified noise generated during molecular cloning.

ChIP-PET makes use of the increased accuracy offered by mapping dual-terminal tags to the genome, while at the same time maintaining the increased efficiency of DNA tagging methods. The approach has been successfully validated in studies that identified, on a global scale, p53 TFBS within human colorectal cancer cells (Wei et al., 2006), and Oct4/Nanog binding sites in mouse embryonic stem cells (Loh et al., 2006).

Critical Parameters and Troubleshooting

***flcDNA* library**

Cloning vector quality. For library construction purposes, the quality of the cloning vector is critical, in that it should produce only a low background of no-insert clones, and a library with a high titer. For this reason, always ensure that the vector preparation is prevalidated before use, following the procedure described in Support Protocol 1. It is very important to freeze the validated vector preparation in small aliquots, as repeated freezing and thawing of the vector DNA results in degradation and, consequently, undesirable results including decreased library titers and the prevalence of clones in which the polyA tails were not removed.

Generation of *flcDNA*. Do not use glycerol at any stage where it is not specifically mentioned, as this will interfere with the CapTrapper selection process. For all steps involving single-stranded DNA or RNA, it is preferable to use a siliconized or low-binding 1.5- or 1.7-ml microcentrifuge tube to avoid loss of nucleic acid. Phase Lock Gel tubes (Eppendorf) are very convenient for the numerous phenol/chloroform/IAA extraction steps, and help to reduce loss of aqueous samples. It is important that Phase Lock Gel *not* be used after reverse-transcription, as the presence of trehalose and sorbitol increases the solution density to the point that both phases form *below* the gel layer, making recovery difficult.

Vector-insert ligations. The quantity of size-fractionated cDNA used for ligation to the pGIS vector is important; at least 100 ng per 30 to 40 ng vector is best. Additionally, one should avoid the temptation of using the smallest fractions—these contain excess adapter DNA, which can block the vector cloning sites. Finally, ensure that separate ligations are set up for different size fractions of cDNA, and avoid

pooling all size fractions together for the ligation. This ensures a more complete collection of cDNA of different sizes.

Quality of flcDNA library. Before proceeding to the ditagging procedure, it is important to assay the quality of the flcDNA library. The quality of the library can be inferred from a combination of different quality control (QC) checks, including counting total titer, determining the range of insert sizes by colony PCR, and most importantly, by sequencing a selection of clones. Check the DNA sequences for the percentage of full-length transcripts, as well as for the presence of all expected flanking restriction enzyme recognition sites. To obtain an estimated ten-fold coverage of a human transcriptome, aim for a flcDNA library with a total titer of 1×10^6 cfu.

Large-scale library plating. For the use of Q-trays, it is important to dry the plates (containing LB agar) sufficiently before use, otherwise the condensate produced during subsequent incubation will result in smearing/merging of growing colonies. Leave the plates open in a sterile hood until a pattern of “waves” appear on the agar surface. During incubation, do not stack Q-trays more than three high, to avoid excessive condensation.

Plasmid DNA maxiprep from bacteria scraped from Q-trays. Extraction of plasmid DNA from these “bacterial scrapings” is less efficient than starting with the usual liquid cultures. Expect a yield of ~ 1 mg plasmid DNA starting from 1×10^6 scraped colonies (about ten Q-trays); if yields are < 600 μg of plasmid DNA, check that enough solution volume was used at each stage, e.g., if using the Qiagen maxiprep system, ensure that 20 to 50 ml of each buffer P1, P2, and P3 is used. There is a very large quantity of precipitated flocculant debris after the P3 neutralization step, which can lead to poor recovery of the supernatant if one uses Qiafilters directly, so it would be better to preclear the precipitate by centrifugation (in 50-ml tubes, e.g., Oak Ridge, Nalgene, 30 min at 12,000 rpm in an SS34 rotor), followed by the use of Qiafilters, if necessary for a final removal of particulates before introducing the supernatant into the maxiprep tips.

GIS-PET ditagging

PET concatenation. The duration of the ligation step may need to be optimized, depending on the quality of the purified PETs obtained. Aim for a majority of concatenated DNA ~ 1000 to 2000 bp. Ensure that spermidine is added to the ligase buffer, as this

greatly increases the efficiency of the desired linear concatenation.

Cloning of BamHI-derived PET concatemers. The partial redigestion of the concatenated DNA by *Bam*HI prior to gel fractionation appears to be critical to the success of the subsequent cloning step. Follow the recommended conditions carefully, to avoid either under- or over-digestion. The authors have successfully used *Bam*HI at a specific activity of 1 to 3 U/ μg substrate DNA.

Recovery of gel-purified DNA. There is not much difference in yields between the gel-crush method of recovering DNA or electroelution using ElutaTubes. Electroelution, however, can result in significant time savings.

ChIP-PET

The general precautions listed for the GIS-PET analysis method are also applicable to ChIP-PET. In addition, it is critical that the starting material, i.e., ChIP-enriched gDNA fragments, are of a sufficient quality to generate a high-quality ChIP-DNA library. Before starting, ensure that the fragments were completely de-crosslinked, are of sufficient quantity (≥ 100 ng), and are of an appropriate size-range (centered ~ 500 bp). Poor quality starting DNA manifests itself in a ChIP-DNA library with low titer and/or excessively short inserts.

Anticipated Results

GIS-PET

Starting with ~ 10 μg of high-quality polyA RNA, one should be able to obtain a flcDNA library with a total titer of 5×10^5 to $> 2 \times 10^6$ cfu. A pool of $\sim 1 \times 10^6$ colonies scraped from ten or more Q-trays should generate ~ 1 mg of plasmid DNA. When ditagging, 10 μg of plasmid DNA from the flcDNA library should produce ~ 1 μg of purified, linearized, single-PET plasmid DNA that will be self-circularized to generate the single-PET plasmid library. This single-PET plasmid library has a typical total titer of $> 5 \times 10^6$ cfu. The final GIS-PET library in pZErO-1, constructed by cloning various size fractions of ~ 1 μg of concatenated 50-bp PETs, should have a total titer of $\sim 1 \times 10^6$ cfu, with seven to twelve PETs present per clone.

ChIP-PET

Starting with 200 ng of ChIP-enriched DNA, one should be able to generate a ChIP-DNA library with a total titer of $\sim 4 \times 10^6$ to $> 1 \times 10^7$ cfu. The other downstream results

would be similar to what is expected for GIS-PET.

Time Considerations

For GIS-PET, it will take 6 days to construct the flcDNA library starting from purified polyA RNA, and an additional 9 days to prepare the GIS-PET library for sequencing. Factor in another 4 days for preparation and validation of cloning vectors. For ChIP-PET starting from ChIP-enriched DNA fragments, it should take 3 days to construct the ChIP-DNA library, and an additional 9 days to prepare the GIS-PET library for sequencing.

CHAPTER 22

Nucleic Acid Arrays

INTRODUCTION

Nucleic acid arrays present a near-textbook case of a technology in which an increase in throughput results in a qualitative change in the usefulness of the technique. Arrays of nucleic acids on nitrocellulose have been around for many years (consider dot blots and slot blots, used for gene-expression monitoring since the late 1970s). But in recent years, nucleic acid arrays have followed a now typical “genomic” pattern, in which, above some point where the representation of genes on the array begins to comprise a substantial fraction of the genes of a genome or of a set of important genes, the experimental value gained from the use of that array increases by more than the fractional increase in the number of genes on the array.

For insight into a variety of current and potential future applications of microarray technology in molecular biology, the reader is referred to *UNIT 22.1*. This unit also describes how and why methods that use these arrays have gone from costly—and requiring special technical sophistication—to mainstream. The Basic Protocol in the first procedural unit in this chapter details the preparation and biotin labeling of mRNA for expression-profiling analysis (*UNIT 22.2*). *UNIT 22.3* describes fluorescent cDNA microarray technology. This involves the production and spotting of cDNAs on glass slides, the extraction of mRNA, the synthesis of fluor-derivatized cDNAs by reverse transcription, to be hybridized to the microarray, the hybridization itself, and subsequent data extraction. *UNIT 22.4* provides a comparison of the various technologies that can be used for transcriptional profiling analysis including Affymetrix, NimbleGen, and spotted arrays, along with an introductory discussion about a variety of statistical considerations involved in analyzing microarray data. The discussion of the analysis of microarray data begins in *UNIT 22.4* and is continued in *UNIT 22.5*, which introduces the general concepts and mathematical procedures used to extract useful information from a comparison of multiple expression profiles, including a discussion of a variety of pattern discovery tools.

Both methods and ideology (i.e., “heuristics”) for use of DNA micorarrays are developing rapidly, and the editors will be particularly vigilant in adding new methods as those prove useful.

Roger Brent and Fred Ausubel

Nucleic acid array technology refers to the fabrication and use of arrays containing thousands of nucleic acid samples bound to solid substrates, such as glass microscope slides or silicon wafers. Because the physical area occupied by each sample is usually 50 to 200 μm in diameter, nucleic acid samples representing entire genomes, ranging in size from 3,000 to 32,000 genes, may be efficiently packaged onto a single regular microscope slide in an area easily covered by a coverslip (Fig. 22.1.1). Such “genomes on a chip” then serve as a target to which fluorescently labeled nucleic acid probes can be applied. Nucleic acid arrays, or microarrays, allow all genes of a given genome to be simultaneously monitored with respect to some experimental condition of interest. This fact has fundamentally changed the manner in which the study of genomics and gene expression can be pursued.

The majority of applications discussed in this overview relate to DNA microarrays fabricated by the mechanical deposition of nucleic acid samples onto glass. Typically, these samples are in the form of PCR products, ranging in size from 100 bps to 9 kb. However, the term “DNA microarray” may apply to several different forms of the technology, each differing in the type of nucleic acid applied and the method of application. For example, Affymetrix sells DNA arrays produced by photolithographic synthesis of individual short oligonucleotides directly on the substrate. (Fodor et al., 1991).

WHAT ARE MICROARRAYS GOOD FOR?

Gene Expression Analysis

Undoubtedly the most common use for DNA microarrays is for monitoring gene expression levels. The broad appeal of this approach stems from the fact that it can be applied to virtually any organism, tissue, or cell line from which RNA may be isolated. In a typical experiment, total RNA or mRNA is collected from two or more individuals, cultures, or conditions. The amount of RNA needed for a microarray experiment depends on many factors, such as genome complexity and message content. Most experiments use anywhere from 100 ng to as much as 20 μg of RNA. The next step is the separate conversion of the RNA samples into cDNA by reverse transcription. This is

usually accomplished by priming with randomized oligonucleotides or, in the case of organisms that produce polyadenylated messages, an oligo-dT primer. The basic principle behind these manipulations is to convert the RNA from each sample into a form that can be readily distinguished from another RNA sample. This is usually accomplished by labeling the cDNA samples with different fluorescent dyes, either during the reverse transcription process through direct incorporation by reverse transcriptase, or afterwards by chemical conjugation.

The resulting pools of cDNA are mixed together, and when the pool is hybridized to a microarray, the ratio between the intensities observed for two of the fluorophores at any given location in the array is a direct measure of the relative abundance of the corresponding cDNA transcript (see Fig. 22.1.2). By using a single reference sample as the control for a series of experimental samples collected over time, one can compare relative levels of transcript abundance among samples (see Fig. 22.1.3). This in turn allows one to identify gene expression trends. For those who wish to study global regulation of gene expression, the most significant data lies in these trends and patterns. Many instances where this methodology has been successfully put into practice can be found in the literature (DeRisi et al., 1997, Alizadeh et al., 1998, Cho et al., 1998; Chu et al., 1998, Eisen et al., 1998, Spellman et al., 1998; Amundson et al., 1999; Iyer et al., 1999; Perou et al., 1999).

It is certain that the use of microarrays to analyze gene expression will continue to increase. Aside from looking at developmental time courses, mutations, and other genetic modifications, many other novel expression experiments will undoubtedly be developed. One recent variation includes the use of expression analysis to reverse-engineer the changes that occurred during a 200-generation yeast evolution experiment (Ferea et al., 1999). In addition to well-established model systems, gene expression analysis involving microarrays may be used as a method to attack problems that were formerly too cumbersome to approach using standard molecular biology techniques. This is especially true for potentially dangerous and difficult-to-culture organisms such as *Mycobacterium tuberculosis* and

Nucleic Acid
Arrays

22.1.1

Supplement 49

Plasmodium falciparum (Hayward et al., 1999, Wilson et al., 1999). The primary reason for this is that only relatively small amounts of RNA are required to determine expression profiles for entire genomes. In other words, the data return on the up-front labor investment is much more substantial than with older techniques for studying gene expression, thus enlarging the potential scope and depth of experiments. For example, consider the case of *Plasmodium*: genetic crosses are extremely difficult and transformation efficiencies are abysmal. These facts make many of the tools researchers have relied upon for cloning new genes nearly useless. Therefore, determining which genes are induced by various drugs becomes a large un-

dertaking, especially considering that the *Plasmodium* genome has yet to be sequenced completely. However, it is a relatively simple matter to collect RNA samples, so DNA microarrays (utilizing known or random genomic fragments) provide an easy means to answer these questions.

WHAT ELSE ARE NUCLEIC ACID MICROARRAYS GOOD FOR?

Despite all the recent emphasis on gene expression analysis, the number of different uses for DNA microarrays is currently limited by our imagination. The most fundamental feature of microarray analysis is that meaningful data can be derived from any set of biological

Figure 22.1.1 Yeast “genome on a chip.”

experiments that result in a differential recovery of nucleic acid material. Aside from gene expression, these uses fall into several basic categories: genetic mapping and genotyping, assessment of genome structure and copy number, polysome analysis, and assays of DNA-protein interaction. Given that there are dozens of variations in experimental design and approach within each of these categories, the following is meant only to pique the imagination and alert readers to the diverse opportunities afforded by microarray technology.

Genotyping and Genetic Mapping

Efficient genotyping of hundreds or thousands of markers for the purpose of mapping multigenic traits may be carried out using DNA microarrays. In one approach, genotyping by array analysis is accomplished by directly detecting hybridization differences caused by single-nucleotide polymorphisms (SNPs). Arrays utilizing short oligo features are well suited for the former method due to their low annealing

temperatures (Hacia et al., 1996). Another approach, genomic mismatch scanning (GMS), uses mismatch repair enzymes to recognize and selectively degrade hybrid DNA fragments between two individuals that possess SNPs (Nelson et al., 1993). The hybrid DNA is created by denaturing and reannealing fragments from two related individuals. The resulting perfectly matched DNA fragments can then be fluorescently labeled and applied to a microarray, revealing which segments are identical by descent (Cheung et al., 1998; McAllister et al., 1998). Regardless of the method used, genotyping by array analysis has the potential to increase the throughput by several orders of magnitude when compared to traditional gel electrophoresis-based methods.

Comparative Genomic Hybridization

Differences in gene copy number have been associated with various tumorigenic phenotypes. These polymorphisms, which consist of deletions and/or amplifications, can easily be

Figure 22.1.2 Scheme for a typical gene expression experiment.

assayed using DNA microarrays, which provide a viable alternative to traditional comparative genomic hybridization (CGH) techniques. The primary limitation of traditional cytogenetic CGH techniques lies in the fact that the resolution to which an amplification or deletion may be mapped is ~20 Mb (Kallioniemi et al., 1992). With array-based CGH methods, the resolution depends only on how many DNA elements are present on the microarray. Therefore, it is entirely feasible that all human genes may be represented as discrete elements on future microarrays, taking the resolution of the map to its logical limit. Indeed, with the conclusion of the human genome sequencing project, it should be feasible to detect the deletion or amplification of virtually any and all genes simultaneously for a given human cell population. Several examples already exist in the literature, and advances in the use of the technology are sure to follow (Solinas-Toldo et al., 1997; Trent et al., 1997; Pinkel et al., 1998; Behr et al., 1999; Pollack et al., 1999).

Polysome Analysis

Although transcriptional regulation is the primary focus of most microarray experiments, changes in translation can also be readily assayed. This may be accomplished by fluorescently labeling the nucleic acid portion of polysomes, which are typically isolated as low-velocity nucleoprotein fractions separated on sucrose gradients. Higher-molecular-weight material, representing messages bound by several ribosomes, may be differentially labeled

with respect to lower-molecular-weight material, representing those messages with few or no bound ribosomes. The resulting hybridization can then be used to assay simultaneously the degree to which each individual mRNA is associated with translation machinery. Tracking these associations provides a means to measure the degree to which the expression of any particular message is likely to be controlled at this level (K. Kuhn and P. Sarnow, pers. comm.). In one interesting variation on this approach, membrane-bound polysomes may also be collected and analyzed. Because membrane-bound polysomes contain messages undergoing cotranslational secretion, it is then possible to quickly identify these gene products with respect to any given experimental condition, whether it be time, cell type, or environment (Diehn et al., 1999).

DNA-Protein Interaction

The separation of nucleoprotein components for array analysis is not limited to mRNA bound to polysomes. Indeed, any method that creates a stable or covalent cross-link between the nucleic acid and the protein component may be used. Subsequent separation by immunoprecipitation (*UNIT 20.5*), filter binding, or other chromatographic procedures may then produce a nucleic acid fraction that can be directly labeled and applied to a microarray representation of the genome. Such genome-wide studies are underway for epitope-tagged DNA binding proteins and for proteins that cross-link enzymatically to DNA as part of their normal

Figure 22.1.3 Monitoring levels of transcript abundance. Time zero is the reference probe for each comparison.

function. Obvious applications of this approach include the study of DNA binding proteins (Chapter 12), endonucleases, and chromatin-associated proteins (*UNIT 21.3*). These methods often produce vanishingly small amounts of nucleic acid source material, often in the sub-nanogram range. For this reason, there is likely to be much development in the area of linear DNA and RNA amplification. Indeed, amplification technology coupled to microarray analysis will allow the study of single-cell expression patterns (Eberwine, 1996).

WHAT ABOUT DATA ANALYSIS?

In addition to the many ways microarray experiments may be carried out, there are equally many ways to analyze the resulting data. Especially for gene expression, it is likely that genome-wide expression analysis will become a field of its own and that an ever-increasing number of innovative approaches will be developed to address the problem of reverse engineering the mechanisms guiding the observed expression patterns. Several methods for visualization and analysis already exist, and many of the necessary tools are readily available to be downloaded from the Internet. The method known as clustering, whereby similar expression patterns are grouped together, has been particularly successful. (Eisen et al., 1998; Bassett et al., 1999; Brown and Botstein., 1999; Iyer et al., 1999). Its success relies upon the fact that genes which participate in a common process, pathway, or function often share common regulatory mechanisms and this, in turn, results in similar expression profiles. Therefore, the functions of previously uncharacterized genes may be revealed by what other genes cluster with it over a broad range of experiments.

WHERE CAN I GET MORE INFORMATION?

The field of microarray technology is evolving rapidly, and therefore the uses and methods of this field will be continuing to change as researchers innovate and disseminate new techniques and ideas. One way to stay connected to this rapid progression is to frequent the various noncommercial web sites listed below. The sites listed contain directions for the fabrication of microarray robots, up-to-date protocol revisions, public access to genome wide expression data, free microarray software tools, forums, and database information.

www-genome.stanford.edu

Stanford Genomic Resources. One-stop shopping for genome-wide expression analysis. This site contains links to several yeast expression databases and research article companions in areas including cell-cycle analysis, sporulation, the diauxic shift, yeast evolution, and yeast clustering. Links to several human expression databases are also available here, including databases relevant to serum starvation, breast cancer expression patterns, and microarray-based CGH.

rana.stanford.edu/software

Stanford Genome Analysis Group software download area. This site provides access to several free microarray-analysis tools that run on your PC, written by Mike Eisen. They include ScanAlyze, an advanced image-analysis package, and clustering/data-visualization applications.

cmgm.stanford.edu/pbrown/mguide

The MGuide. Home of a do-it-yourself guide to building your own microarraying robot, maintained by Patrick Brown's lab at Stanford University. A step-by-step guide, technical drawings, and parts lists, as well as free software, are available for downloading here.

www.nhgri.nih.gov/DIR/LCG/15K/HTML

National Human Genome Research Institutes (NHGRI) Microarray Project. This site features database and data handling information, as well as protocols and research projects.

web.wi.mit.edu/young/expression

Genome-Wide Expression Homepage maintained by Rick Young of the Whitehead Institute. Access to various yeast transcription experiments, protocols, and experiment designs are available.

industry.ebi.ac.uk/~alan/MicroArray

Large-Scale Gene Expression and Microarray Links and Resources. A "personal not-for-profit web site" containing literally hundreds of links to microarray articles, databases, and companies, maintained by Alan Robinson, a researcher at the EMBL-European Bioinformatics Institute (EBI).

Preparation of mRNA for Expression Monitoring

The ability to construct comprehensive gene expression profiles comprising hundreds to thousands of genes whose RNA levels are monitored simultaneously represents an exciting new capability in molecular biology. This is accomplished by hybridizing mRNA, which has been quantitatively amplified and labeled with biotin, to DNA chips that display thousands of oligonucleotides complementary to the mRNAs of interest. An overview of the entire process is shown schematically in Figure 22.2.1. The Strategic Planning section outlines considerations in starting with poly(A)⁺ versus total RNA, and also discusses oligonucleotide selection for chip design. The Basic Protocol outlines RNA amplification and labeling, which entails cDNA synthesis followed by *in vitro* transcription (IVT), and hybridization of the resulting biotinylated antisense RNA to the chip. An Alternate Protocol is included for purification of cDNA and *in vitro* transcription products on carboxy-coated magnetic beads, making the amplification reaction amenable to automation. Support Protocols 1 and 2 provide methods for quantifying the cDNA product and for producing *in vitro* transcripts of control genes.

CAUTION: Diethylpyrocarbonate (DEPC) is a suspected carcinogen and should be handled with care.

STRATEGIC PLANNING

As this is an RNA-based procedure, care should be taken at every step to avoid contamination of reagents and materials with RNases (*UNIT 4.1*). New plasticware can be used without decontamination processes if kept free of dust and handled exclusively with gloved hands. Filtered pipet tips should be used routinely to avoid contamination with the micropipettor. Any reagent that needs to be made in the laboratory, or that is not supplied RNase-free by the manufacturer, should be treated with DEPC (*UNIT 4.1*).

The amplification procedure is absolutely dependent on clean, intact starting RNA. For cultured cells, the authors use a protocol of lysis in guanidine followed by resin-based purification (such as the Qiagen RNeasy kit). The authors' results using one-step protocols (in which guanidine and phenol are combined) have been variable, presumably because inhibitors of the amplification reaction enzymes can be carried along. Tissues are immediately snap-frozen in liquid nitrogen, then ground to a powder in a dry ice-embedded mortar and pestle. RNA is then extracted in guanidine reagent in a Polytron mixer, followed by extraction with phenol (e.g., Promega RNAgents kit, Ambion Totally RNA kit).

The mRNA amplification can be performed starting with either poly(A)⁺ or total RNA. Although poly(A)⁺ RNA gives higher sensitivity because it largely eliminates mispriming on rRNA during the cDNA reaction, the ability to use total RNA makes it possible to analyze biological systems in which cells or tissues are limited. A key modification in using total RNA is elevation of the first-strand cDNA reaction temperature from 37° to 50°C. Although this will decrease cDNA yield somewhat, it dramatically decreases mispriming on rRNA. The protocol outlined here will preferentially amplify the 3' end of long mRNAs, owing to its dependence on priming with oligo(dT). It is therefore best to use either custom or commercially available chips that display probes toward the 3' end of the mRNA. In general, the authors restrict probe selection to the last 600 bases of coding sequence unless the 3'-untranslated region (3'-UT) is >800 bases, in which case some untranslated sequence is also included.

Figure 22.2.1 Chip analysis overview. Abbreviations: GIT, guanidine isothiocyanate, PE, phycoerythrin; SPRI, solid-phase reversible immobilization.

**BASIC
PROTOCOL**

**AMPLIFICATION OF mRNA FOR EXPRESSION MONITORING AND
HYBRIDIZATION TO OLIGONUCLEOTIDE ARRAY CHIPS**

The Basic Protocol details the quantitative amplification and biotin labeling of mRNA to produce antisense RNA for the purpose of gene expression monitoring. Starting RNA is first converted to double-stranded cDNA using a primer containing a T7 RNA polymerase site, so that amplified and labeled RNA can be produced directly in an *in vitro* transcription reaction. The resulting RNA is hybridized to a DNA chip.

Materials

SuperScript cDNA kit (Life Technologies), including:

- 5× First Strand Buffer
- 200 U/μl SuperScript II reverse transcriptase
- 5× Second Strand Buffer
- 10 mM dNTPs
- 10 U/μl *E. coli* ligase
- 2 U/μl *E. coli* RNase H
- 10 U/μl *E. coli* DNA polymerase
- 5 U/μl T4 DNA polymerase

T7T24 primer: 5'-GGCCAGTGAATTGTAATACGACTCACTATAGGGAGGCCGG
TTTTTTTTTTTTTTTTTTTTTTTTTTTTTT-3' (HPLC purification is recommended)

RNase inhibitor (Life Technologies or Ambion)

RNase-free H₂O (see UNIT 4.1 for DEPC treatment of solutions; prepare from glass-distilled H₂O)

Sample RNA: poly(A)⁺ or total RNA

Sense control transcript pool (see Support Protocol 1)

**Preparation of
mRNA for
Expression
Monitoring**

22.2.2

25:24:1 (v/v/v) phenol/chloroform/isoamyl alcohol (molecular biology grade; *UNIT 2.1A*)

7.5 M ammonium acetate (*APPENDIX 2*)

Absolute ethanol

70% (v/v) ethanol in RNase-free H₂O, prechilled to -20°C

10× transcription buffer (Ambion)

10× rNTP mix (see recipe)

100 mM dithiothreitol (DTT)

10 mM Bio-11-CTP and Bio-11-UTP (Enzo Diagnostics)

2500 U/μl T7 RNA polymerase (Epicentre)

RNeasy mini columns with RLT and RPE buffers and collection tubes (Qiagen)

5× fragmentation buffer (see recipe)

20× SSPE (Bio-Whittaker)

0.5% (v/v) Triton X-100 (molecular biology grade; Sigma) in RNase-free H₂O

10 mg/ml herring sperm DNA (Promega)

500 pM Bio948 (see recipe)

20× antisense control transcript pool (see Support Protocol 1)

6× SSPET: 6× SSPE containing 0.005% (v/v) Triton X-100

Thermocycler (e.g., Perkin-Elmer 9600 PCR machine with heated lid)

0.1- to 10-μl filtered micropipet tips (Continental)

Lyophilizer

Small, thin-walled PCR tubes

GeneChip (Affymetrix)

1- to 200-μl filtered gel-loading micropipet tips (Fisher)

Rotisserie-type rotator (Appropriate Technical Resources)

50°C oven

Additional reagents and equipment for quantitation of cDNA (see Support Protocol 2), for quantitation of DNA by spectrophotometry (*APPENDIX 3D*), and for washing, staining, and scanning the GeneChip (see manufacturer's instructions)

NOTE: Many buffers and enzymes are supplied with the SuperScript II cDNA kit. Kit enzymes that are limiting may be ordered separately from Life Technologies.

NOTE: All temperature-controlled reactions are performed in an appropriate thermocycler.

Perform first-strand synthesis

1. Set up a linked program on a thermocycler as follows:

10 min	70°C
65 min	37°C (or 50°C for total RNA)
150 min	15.8°C
indefinitely	4°C (hold).

2. Prepare 10 μl first-strand reagent cocktail for each sample RNA by combining the following reagents, using filtered pipet tips:

- 4 μl 5× First Strand Buffer
- 200 pmol T7T24 primer
- 1 μl RNase inhibitor
- 1 μl 200 U/μl SuperScript II reverse transcriptase
- RNase-free H₂O to 10 μl.

3. Combine each sample RNA with sense control transcript pool. Use 5 μl sense control transcript pool per 1 μg sample poly(A)⁺ RNA or 1 μl control pool per 10 to 20 μg total RNA. Lyophilize to reduce the volume per tube to $<10 \mu\text{l}$. Adjust volume to 10 μl with RNase-free H₂O. Prewarm first-strand reagent cocktail in hand during this time.

Do not dry completely, as this will make it very difficult to resuspend the RNA.

4. Transfer each RNA to a small, thin-walled PCR tube and place in the thermocycler. Begin linked program (step 1).
5. After the 70°C step has completed, allow 2 min for solution temperature to reach 37°C (or 50°C), and add the prewarmed (in hand) first-strand reagent cocktail (10 μl per tube).
6. Hold at the appropriate reaction temperature for the remaining 60 min.

Perform second-strand synthesis

7. Prepare 130 μl second-strand reagent cocktail per tube:

91 μl RNase-free H₂O
30 μl 5 \times Second Strand Buffer
3 μl 10 mM dNTPs
1 μl 10 U/ μl *E. coli* ligase
1 μl 2 U/ μl *E. coli* RNase H
4 μl 10 U/ μl *E. coli* DNA polymerase.

This cocktail can be prepared in advance and kept on ice for up to 90 min.

8. Add 130 μl second-strand reagent cocktail to the tube (total 150 μl) once the thermocycler has shifted to 15.8°C. Mix by pipetting up and down after addition of cocktail.
9. Incubate at 15.8°C for ≥ 2 hr.
10. Add 2 μl of 5 U/ μl T4 DNA polymerase and incubate an additional 5 min.
11. Remove samples and place on ice.

Purify cDNA

12. Add 150 μl of 25:24:1 phenol/chloroform/isoamyl alcohol, vortex, and centrifuge 5 min at 13,000 $\times g$, room temperature.

Many methods are appropriate for removing enzymes and unincorporated nucleotides. Phenol/chloroform extraction followed by ethanol precipitation works well and is outlined here. See Alternate Protocol for a second method for purifying cDNA and IVT products.

13. Carefully remove aqueous top phase to new tube, avoiding contamination with interface.
14. Add 70 μl of 7.5 M ammonium acetate and 0.5 ml absolute ethanol and mix. Centrifuge 20 min at 13,000 $\times g$, room temperature.
15. Remove supernatant. Wash pellet with 0.5 ml of cold (-20°C) 70% ethanol. Vortex well.

The pellet should be vortexed well with the 70% ethanol to prevent inhibition of the in vitro transcription reaction by organic contamination.

16. Centrifuge 10 min at 13,000 $\times g$, room temperature, remove supernatant, and allow pellet to air dry for several minutes.

17. Resuspend the cDNA pellet in 25 μ l RNase-free H₂O and quantitate cDNA (see Support Protocol 2).

Perform in vitro transcription (IVT)

18. For each cDNA, set up one reaction as follows:

100 ng cDNA
6 μ l 10 \times transcription buffer
6 μ l 10 \times rNTP mix
3 μ l 100 mM DTT
2.4 μ l 10 mM Bio-11-UTP
2.4 μ l 10 mM Bio-11-CTP
2 μ l RNase inhibitor
2 μ l 2500 U/ μ l T7 RNA polymerase
RNase-free H₂O to 60 μ l.

The cocktail can be prepared in advance and kept on ice for up to 3 hr. It should be prewarmed to room temperature before adding to cDNA to avoid precipitates.

19. Incubate at 37°C for 8 hr to overnight.

If desired, the IVT reaction can be stored up to 48 hr at -80°C before purification.

Purify IVT RNA

20. Bring volume of IVT reaction to 100 μ l with RNase-free H₂O, add 350 μ l RLT buffer, and mix.
21. Add 250 μ l absolute ethanol and mix.
22. Apply each sample to an RNeasy mini column placed in a collection tube. Microcentrifuge 15 sec at >8000 \times g, room temperature.

Qiagen RNeasy columns work well for removal of unincorporated nucleotides. It is very important to remove the nucleotides in order to accurately quantitate the IVT RNA. This protocol follows the manufacturer's protocol with the following changes: no 2-mercaptoethanol is used in the RLT buffer, and final elution is done twice using 50 μ l RNase-free H₂O each time.

23. Transfer column to a new collection tube. Add 500 μ l RPE buffer.

The RPE working solution is prepared as described in the kit directions; the supplied stock is diluted with 4 vol absolute ethanol.

24. Centrifuge 15 sec at >8000 \times g, room temperature.
25. Discard flowthrough and replace column on the same collection tube. Add 500 μ l RPE buffer and microcentrifuge 2 min at maximum speed.
26. Transfer column to a new collection tube. Add 50 μ l RNase-free H₂O and centrifuge 1 min at >8000 \times g. Repeat elution step, pooling the second eluate with the first.
27. Quantitate RNA yield spectrophotometrically at 260 nm (APPENDIX 3D).

Fragment RNA

28. Bring volume of 10 μ g IVT RNA to 24 μ l with RNase-free H₂O.
29. Add 6 μ l of 5 \times fragmentation buffer. Mix carefully and incubate 35 min at 95°C in the thermocycler. Allow to cool to room temperature.

Fragmented RNA can be stored up to 1 year at -80°C. Thaw at 37°C for 5 min before preparing hybridization solution.

Hybridize RNA to chip

30. For each reaction, prepare 170 μ l hybridization master mix as follows:

- 51 μ l 20 \times SSPE
- 1.7 μ l 0.5% Triton X-100
- 1.7 μ l 10 mg/ml herring sperm DNA
- 20 μ l 500 pM Bio948
- 10 μ l 20 \times antisense control transcript pool
- 85.6 μ l RNase-free H₂O.

31. Add 170 μ l hybridization master mix to 30 μ l of each fragmented IVT RNA.
32. Heat to 99°C for 10 min in the thermocycler, then move to 37°C for \geq 5 min.
33. Microcentrifuge 5 min at maximum speed.
34. Insert a filtered micropipet tip into the upper septum of a GeneChip to provide a vent. Fill the chip from the bottom septum with the 200 μ l hybridization solution using a filtered gel-loading micropipet tip. Remove the vent and cover both septa with transparent tape.
Use one GeneChip for each IVT RNA.
35. Incubate in a 40°C oven overnight (16 to 18 hr) on a rotisserie-type rotator running at \sim 60 rpm.
36. Transfer the chip to a 50°C oven and continue rotating the chip for exactly one hour.
37. Remove chip from the oven and insert a filtered micropipet tip into the upper septum to vent the chip.
38. Using a micropipettor with plunger fully depressed, insert a 200- μ l gel-loading pipet tip into the lower septum. Holding the chip vertically, slowly draw out all of the hybridization solution and store it in a microcentrifuge tube at -20° C.
39. Fill the chip with 6 \times SSPET.
40. Wash and stain the chip with phycoerythrin according to the manufacturer's protocols. Scan the chip as soon as possible.

If the chip cannot be washed right away, seal the two septa with transparent tape and store at 4°C for up to a few hours.

Once the chips have been stained with phycoerythrin they should be kept wrapped in foil to avoid photobleaching. Although it is recommended that they be scanned as soon as possible, if necessary, they can be stored at 4°C, wrapped in foil, for several hours before scanning.

SUPPORT PROTOCOL 1

IN VITRO TRANSCRIPTION OF CONTROL GENES AND PREPARATION OF TRANSCRIPT POOLS

It is essential to include labeled antisense control RNAs of known concentration in each hybridization reaction to normalize chip-to-chip variation and to allow construction of a standard curve for converting hybridization intensity to mRNA frequency. It is also very helpful to add unlabeled sense transcripts to monitor performance of the amplification protocol. This protocol describes the preparation of these two control pools.

Preparation of mRNA for Expression Monitoring

22.2.6

Additional Materials (also see Basic Protocol)

Plasmids (Table 22.2.1; ATCC #87482 to 87490)
2500 U/μl T3 RNA polymerase (Enzo Diagnostics)
25 mM 4rNTP mix: 25 mM each rGTP, rCTP, rATP, and UTP (Ultrapure; Pharmacia Biotech) in RNase-free H₂O

Additional reagents and equipment for purifying IVT products (see Alternate Protocol)

Prepare sense and antisense transcripts

1. Prepare linearized plasmid templates according to Table 22.2.1.

See UNIT 3.1 and manufacturer's instructions for additional information on reaction conditions.

2. Purify plasmid DNA by phenol/chloroform extraction and ethanol precipitation (see Basic Protocol, steps 12 to 16). Resuspend at ~0.1 mg/ml in RNase-free H₂O and quantitate DNA (see Support Protocol 2).
3. For labeled antisense transcripts, prepare four tubes containing a master mix that includes all components except plasmid DNA:

6 μl 10× transcription buffer
6 μl 10× rNTP mix
3 μl 100 mM DTT
2.4 μl 10 mM Bio-11-UTP
2.4 μl 10 mM Bio-11-CTP
2 μl RNase inhibitor
2 μl 2500 U/μl T7 RNA polymerase
RNase-free H₂O to 60 μl.

The 60-μl volume must include the 100 ng DNA that will be added in step 5.

The master mix can be prepared in advance and held on ice for up to 3 hr, but should be warmed to room temperature before adding to plasmid DNA to avoid precipitates.

Table 22.2.1 Preparation of Plasmid Template Controls

Name ^a	ATCC #	Transcript size (kb)	Sense RNA		Antisense RNA	
			Linearize with	Polymerize with	Linearize with	Polymerize with
pGIBS-LYS ^b	87482	1.0	<i>NotI</i>	T3		
pGIBS-PHE ^b	87483	1.3	<i>NotI</i>	T3		
pGIBS-THR ^b	87484	2.0	<i>NotI</i>	T3		
pGIBS-TRP ^b	87485	2.5	<i>NotI</i>	T3		
pGIKS-BioB	87487	1.1			<i>XhoI</i>	T7
pGIKS-BioC	87488	0.8			<i>XhoI</i>	T7
pGIKS-BioD	87489	0.7			<i>XhoI</i>	T7
pGIKS-CRE	87490	1.0			<i>XhoI</i>	T7

^aAbbreviations: BioB, BioC, and BioD are cloned fragments from the *E. coli bioB*, *bioC*, and *BioD* genes, respectively. LYS, PHE, THR, and TRP are fragments from the *Bacillus subtilis lysA*, *pheA*, *thrBC*, and *trpEDCF* genes, respectively. CRE is a fragment from the Cre recombinase derived from *E. coli* bacteriophage P1. pGIBS and pGIKS are derived from the Bluescript KS II vector (Stratagene).

^bpGIBS-LYS, -PHE, -THR, -TRP, and DAP contain a 40-nucleotide synthetic poly(A) tract at the 3' end of the respective genomic fragments derived from *B. subtilis*. Sense IVT transcripts derived from *NotI*-linearized plasmid templates will contain the artificial poly(A) tail. Plasmids linearized with *Bam*HI prior to T3 IVT will generate sense transcripts without the synthetic poly(A) tract.

4. For unlabeled sense transcripts, prepare four tubes of master mix as in step 3, but substitute 25 mM 4rNTP mix for the 10× rNTP mix, eliminate the biotinylated nucleotides, and substitute T3 for T7 RNA polymerase.
5. Add 100 ng of each linearized plasmid DNA to a separate tube and incubate at 37°C for 8 hr to overnight.

The transcripts can be stored for up to 48 hr at –80°C, if desired, before purification.

6. Purify IVT products as described (see Alternate Protocol).
7. Quantitate carefully by absorbance at 260 nm (*APPENDIX 3D*).
8. Dilute unlabeled sense transcripts to 200 nM stock solutions in RNase-free H₂O for long-term storage (up to 1 year) at –80°C.
9. Fragment biotin-labeled antisense transcripts for standard chip controls (BioB, BioC, BioD, CRE) as described (see Basic Protocol, steps 18 and 19).
10. Dilute fragmented antisense transcripts to 20 nM stock solutions in 6× SSPET with 0.1 mg/ml herring sperm DNA for long-term storage (up to 1 year) at –80°C.

Prepare control transcript pools

11. Prepare 20× antisense control transcript pool by combining the following transcripts in 6× SSPET with 0.1 mg/ml herring sperm DNA. Store up to 6 months at –80°C.

30 pM fragmented BioB transcript
100 pM fragmented BioC transcript
500 pM fragmented BioD transcript
2 nM fragmented CRE transcript.

12. Prepare sense control transcript pool by combining the following transcripts in RNase-free H₂O. Store up to 6 months at –80°C in aliquots of 50 to 100 µl.

10 pM LYS transcript
30 pM PHE transcript
90 pM THR transcript
180 pM TRP transcript.

ALTERNATE PROTOCOL

SOLID-PHASE REVERSIBLE IMMOBILIZATION (SPRI) PURIFICATION OF cDNA AND IVT PRODUCTS

Because of the labor-intensive nature of the mRNA amplification protocol, the procedure has been adapted for automation. Although the assembly of the reactions is easily converted to liquid handling robotics, purification of final products should be free of organic solvents and the requirement for centrifuges. A magnetic bead-based purification protocol of cDNA and IVT products has been developed to meet this requirement. This protocol was adapted from a protocol for the automated preparation of DNA sequencing templates (DeAngelis et al., 1995). It is equivalent to the purification methods described in the Basic Protocol (steps 12 to 17 or steps 20 to 27).

Materials

Carboxy-coated magnetic beads (PerSeptive BioSystems for cDNA purification;
Bangs Laboratories for IVT purification)

0.5 M EDTA (*APPENDIX 2*)

Sample to be purified: cDNA (see Basic Protocol, step 11) or IVT RNA (see Basic Protocol, step 19, or see Support Protocol 1, step 6)

2.5 M NaCl/20% (w/v) PEG 8000 (molecular biology grade; RNase free)

70% (v/v) ethanol in RNase-free H₂O
10 mM Tris acetate, pH 7.8 (RNase free)
Magnetic stand (CPG)

Additional reagents and equipment for determining concentration of cDNA (see Support Protocol 2) or RNA (*APPENDIX 3D*)

Purification of cDNA

- 1a. Aliquot 10 μ l PerSeptive carboxy-coated magnetic beads per 150- μ l cDNA reaction, dispensing the total volume of beads into a single microcentrifuge tube.
- 2a. Place the tube on a magnetic stand and allow the beads to separate to the side of the tube. Carefully remove supernatant with a micropipet.
- 3a. Add 0.5 M EDTA equal to the starting volume and resuspend the beads by gentle vortexing or agitation. Replace tube on magnetic stand, wait for beads to separate, and remove supernatant. Repeat this washing procedure two more times.
- 4a. Resuspend beads in 0.5 M EDTA equal to the starting volume.
- 5a. To each tube of cDNA, add 150 μ l of 2.5 M NaCl/20% PEG 8000 and 10 μ l beads and mix by gentle vortexing or agitation. Incubate 10 min at room temperature.
- 6a. Place tubes on magnetic stand and allow beads to separate to the side of the tube (~2 min for the original separation, faster for the washes).
- 7a. Draw off the supernatant, then wash the beads twice with 150 μ l of 70% ethanol. Remove as much of the final ethanol wash as possible and allow to air dry for 2 min.
- 8a. Elute RNA by adding 25 μ l of 10 mM Tris acetate, pH 7.8, and incubating 5 min at room temperature.
- 9a. Place tube on magnetic stand and save supernatant.
- 10a. Determine cDNA concentration by PicoGreen fluorescence (see Support Protocol 2).

Purification of IVT RNA

- 1b. Aliquot 20 μ l Bangs Laboratories carboxy-coated magnetic beads per 60- μ l IVT reaction, dispensing the total volume of beads into a single microcentrifuge tube.
- 2b. Place the tube on a magnetic stand and allow the beads to separate to the side of the tube. Carefully remove supernatant with a micropipet.
- 3b. Add 0.5 M EDTA equal to the starting volume and resuspend the beads by gentle vortexing or agitation. Replace tube on magnetic stand, wait for beads to separate, and remove supernatant. Repeat this washing procedure two more times.
- 4b. Resuspend beads in 1.25 M NaCl/10% PEG equal to the starting volume.
- 5b. To each tube of IVT RNA, add 60 μ l of 2.5 M NaCl/20% PEG 8000 and 20 μ l beads and mix by gentle vortexing or agitation. Incubate 10 min at room temperature.
- 6b. Place tubes on magnetic stand and allow beads to separate to the side of the tube (~2 min for the original separation, faster for the washes).
- 7b. Draw off the supernatant, then wash the beads twice with 150 μ l of 70% ethanol. Remove as much of the final ethanol wash as possible and allow to air dry for 3 min.

- 8b. Elute RNA by adding 25 μ l of 10 mM Tris acetate, pH 7.8, and incubating 5 min at room temperature.
- 9b. Place tube on magnetic stand and save supernatant.
- 10b. Determine RNA concentration by absorbance at 260 nm (*APPENDIX 3D*).

**SUPPORT
PROTOCOL 2**

QUANTITATION OF cDNA

If IVT yield is low, it can be helpful to determine the amount of cDNA that is being produced. For optimal IVT yield, do not exceed 100 ng cDNA in the standard reaction. Quantitation of cDNA can be performed with Molecular Probes PicoGreen reagent.

Materials

PicoGreen dsDNA Quantitation Kit (Molecular Probes), including
100 ng/ μ l standard DNA stock solution
20 \times TE buffer
PicoGreen reagent
cDNA to be quantitated (see Basic Protocol and Alternate Protocol)
Black-walled 96-well plate (Corning)
Fluorimager (Molecular Dynamics, model FSI)

1. Prepare 1 ml of 2 μ g/ml diluted standard DNA by diluting 20 μ l of 100 ng/ μ l standard DNA stock solution in 980 μ l of 1 \times TE buffer.
2. Dilute PicoGreen reagent 1:200 (v/v) with 1 \times TE buffer. Prepare enough diluted reagent so that 100 μ l can be placed in each well.
3. Pipet 100, 50, 20, 10, 5, 2, and 0 μ l dilute standard DNA into seven wells in a black-walled 96-well plate. Bring each to a total of 100 μ l with 1 \times TE buffer.
The amounts of DNA in the standard wells are 200, 100, 40, 20, 10, 4, and 0 ng, respectively.
4. Pipet 2 μ l cDNA to be quantitated into additional wells, as needed.
5. Add 100 μ l diluted PicoGreen reagent to each well.
6. Read fluorescence of each well using a fluorimager.
7. Generate a volume report on each well according to manufacturer's instructions. Use volume number versus ng per well to generate a standard curve.
8. Calculate the concentration of cDNA in test wells.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Bio948, 500 pM

500 pM biotinylated control oligonucleotide Bio948 (5'-GTCAA-GATGCTACCGTTCAG-3')
6 \times SSPE (Bio-Whittaker)
0.1 mg/ml herring sperm DNA (Promega)
0.005% (v/v) Triton X-100 (molecular biology grade; Sigma)
Prepare in RNase-free H₂O
Store up to 1 year at -20°C

Fragmentation buffer, 5×

Dissolve 6.06 g Tris base (Sigma; molecular biology grade) in 175 ml RNase-free H₂O. Adjust pH to 8.1 with glacial acetic acid. Add 12.3 g potassium acetate (from an unopened or dedicated bottle) and 8.04 g magnesium acetate (Sigma; molecular biology grade) and adjust volume to 250 ml (final pH ~8.4). Filter sterilize with a 0.2- μ m filter. Store up to 6 months at -20°C.

rNTP mix, 10×

30 mM rGTP
15 mM rATP
12 mM rCTP
12 mM UTP

Prepare using RNase-free H₂O and Ultrapure reagents from Pharmacia Biotech. Store up to 3 months at -20°C in small aliquots (e.g., 50 to 100 μ l) to prevent multiple freeze/thaw cycles.

COMMENTARY

Background Information

The availability of thousands of gene sequences through high-throughput sequencing efforts, including the Human Genome Project, created an immediate need for highly parallel methods for assessing RNA levels of many genes simultaneously. One approach that is being practiced by an ever-expanding number of laboratories is the hybridization of labeled cellular RNA or cDNA to microarrays displaying DNA probes complementary to the genes of interest. Both cDNA (Schena et al., 1995) and oligonucleotide (Lockhart et al., 1996) probe arrays are used, and each type has its relative merits and shortcomings. The strength of cDNA arrays lies in the ability to display probes on the array prior to obtaining any sequence information, allowing the possibility of novel gene discovery. The disadvantages are that (1) quantitation is possible in a relative sense (i.e., fold-induction) but not an absolute sense (i.e., number of mRNA molecules per million), and (2) it is difficult to discern expression of different members of multigene families due to cross-hybridization. Construction of oligonucleotide arrays, on the other hand, requires that DNA sequence information be available for every gene to be monitored, precluding use of the arrays for novel gene discovery. This limitation is partially mitigated, however, by the recent availability of chips monitoring tens of thousands of expressed sequence tags (ESTs) with no known function. Advantages of oligonucleotide arrays include (1) the possibility of absolute quantitation, by virtue of averaging across multiple probes for every gene being monitored, and (2) the ability to inde-

pendently follow the expression of closely related gene family members through judicious probe selection.

Critical Parameters

The most critical parameter affecting the success of the protocol is the quality of the starting RNA. It is absolutely essential to start with RNA that is intact and free from inhibitors of the enzymes in the amplification procedure. For sample comparisons, e.g., control versus treated sample, it is necessary that the RNA samples be of similar quality and, preferably, that samples are hybridized to arrays within the same lot to minimize chip-to-chip variation.

Troubleshooting

The problems that can arise during expression monitoring procedures are detailed in Table 22.2.2.

Anticipated Results

The yield of amplified *in vitro* transcription (IVT) product reflects the quality and quantity of the starting RNA and, in general, is an indicator of the success of the subsequent chip hybridization. A good amplification reaction from 1 μ g poly(A)⁺ or 10 μ g total RNA can yield 50 to 60 μ g IVT product. Successful hybridizations can be obtained with lesser yields, but yields of \leq 10 μ g, when the quantity of starting RNA was not limiting, are generally predictive of nonoptimal IVT product.

Time Considerations

The entire protocol is generally carried out over a three-day period, starting with purified

Table 22.2.2 Troubleshooting Guide for Expression Monitoring

Problem	Possible cause	Action
Little or no cDNA yield	Beginning RNA quality was poor	Visualize size range of starting RNA on a gel. There should be a smear extending well above 5 kb, and not much <500 bases.
	RNA or reactants were RNase contaminated	Check RNA by incubating an aliquot at room temperature several hours and running on gel as above. Reactants can be incubated with test RNA and run on gel for visualization of degradation. Include RNase inhibitor in cDNA reaction.
	Enzyme inhibitors present in RNA preparation	Check signals for members of the sense control transcript pool. If 5' end signals are poor and there is no evidence for RNase contamination, reisolate sample RNA using a protocol with a more stringent purification method.
Little or no IVT yield	Too little cDNA template	Quantitate cDNA, use ≥ 50 ng in IVT reaction. If cDNA yield is low, refer to above section (little or no cDNA yield).
	Inhibitor of polymerase present	Residual phenol/chloroform or dNTPs can inhibit polymerase reaction. Reprecipitate cDNA, being careful to wash pellet with 70% ethanol.
	Wrong polymerase used	Be sure polymerase matches the incorporated promoter
	DTT inactive	Make fresh DTT stock
	Limiting nucleotide concentration	If making unlabeled RNA, be sure to substitute 25 mM 4rNTP solution for the $10 \times$ rNTP mix used with biotin nucleotides.
Blank or low signal on GeneChip	Poor RNA quality	Even when cDNA and IVT yields seem adequate, poor RNA quality can be a cause of poor chip data. Look at housekeeping gene data for ratio of 5' and 3' signal. With oligo(dT)-primed cDNA, expect 5' signal of β -actin and GAPDH ^a to be at least half of the 3' signal.
	Stringency too high	Check incubator temperature and buffer solutions
	Poor staining of biotin with streptavidin conjugate, or bleaching of phycoerythrin	SA-PE ^a reagents can be variable. Try a different lot, or increase the amount of SA-PE used in the staining solution. Store SA-PE in the dark. Wrap chips in aluminum foil after staining to prevent bleaching before scanning.
	Scanning at wrong wavelength (even edge controls will be very light or absent)	Ensure that scanner is set at 560 nm and rescan
	Hybridization inhibitor in solution	Try using the same hybridization solution on a second chip of the same lot. If signal improves, it may be necessary to incorporate a prehybridization step.
	Scanner needs adjustment	Call for service; try another scanner if available
	Defective lot of GeneChips	Rehybridize saved hybridization solution to a lot of chips that has previously given strong signals. If signal improves, and hybridization inhibitor is not indicated, contact manufacturer.

continued

Table 22.2.2 Troubleshooting Guide for Expression Monitoring, continued

Problem	Possible cause	Action
A few very bright features per gene, the rest very quiet	Failure of fragmentation reaction	Check 5× fragmentation buffer and 94°C temperature control unit. If additional IVT RNA is available, try repeating the fragmentation reaction and check on a gel. Size should be ~20 to 50 bases.
High background values	Stringency too low	Try rewashing the chips at increased temperature and rescanning
	Contaminant	Recommend hybridization solutions be made with glass-distilled water. Some deionization systems can be problematic. If this is suspected, glass-distilled water is commercially available.
Sporadic pattern of round dots all over chip	SA-PE ^a aggregates	Manufacturer recommends the solution be vortexed and then microcentrifuged 2 min prior to taking aliquot
Round area in middle of chip has very low signal compared to rest of chip	Volume of hybridization solution is too low	Need a minimum of 180 µl. If hybridization solution cannot be remade, add 6× SSPET, 0.1 mg/ml herring sperm DNA to the saved hybridization solution to bring the volume to 200 µl and rehybridize to new chip.
	Rotator stopped during hybridization	Rehybridize saved solution to new chip, checking that rotator is functioning properly.

^aGAPDH, glyceraldehyde 3-phosphate dehydrogenase; SA-PE, streptavidin-phycoerythrin.

poly(A)⁺ or total RNA, and the time estimates are for six samples or less being processed simultaneously. On the first day, first- and second-strand cDNA synthesis reactions are carried out (3.5 hr), followed by cDNA purification (1 hr). IVT reactions are then set up and incubated overnight. On the second day, the IVT product is purified (1.5 hr) and quantitated. The RNA is fragmented (40 min), then added to hybridization reagents and loaded on the chip for overnight hybridization. On the third day, the hybridization is continued at elevated temperature (1 hr), then the chips are washed and stained on a fluidics station (40 min/4 chips). Scanning each chip takes ~25 min.

Profiling Human Gene Expression with cDNA Microarrays

The study of the timing and extent of expression of mRNAs coding for particular genes is one of the central research areas of molecular biology. The literature is full of compelling examples of the utility of knowing that a particular message appears, disappears, or is highly modulated at the time a particular natural or pathological process is affecting a cell. The tools available for making such determinations have steadily advanced. Early efforts utilized kinetic studies (Bishop et al., 1974) of how rapidly the various component populations of mRNA from different cells hybridized to each other to obtain an overview of the likely number and abundance of messages. Such studies were augmented by a variety of techniques that immobilized size-fractionated message populations on substrates and determined the abundance of individual species of mRNA within the pools (Alwine et al., 1977). Current methods for large surveys of gene expression patterns immobilize single cDNA representatives of many independent genes in regular arrays on substrates and quantify the relative abundance of many specific mRNAs present in the message pool of a sample simultaneously (Schena et al., 1995; Lockhart et al., 1996). The data from such surveys can be used to compare patterns of gene expression to delineate sets of genes regulated in a particular process (Spellman et al., 1998; Iyer et al., 1999) or coregulated by specific transcriptional regulators (DeRisi et al., 1997). Overall patterns of expression can be used to evaluate similarities in cell types (Khan et al., 1998).

Fluorescent cDNA microarray technology is a particularly potent variation of the latter technique. This method is especially useful for making estimates of the abundance of particular messages relative to a designated source of mRNA that serves as a reference point. Commercial support of this technology has recently reached a level where it is reasonable for departments or large laboratories to consider setting up their own cDNA array facility. This set of protocols is intended to serve as a basic introduction to making and using cDNA microarrays for those embarking on this path.

There are three fundamental types of operations required in a cDNA microarray experiment. The first (see Basic Protocol 1), cDNA amplification and printing, deals with making the cDNA microarray itself. It is necessary to collect an inventory of cDNA bacterial clones that represent the genes whose message abundance one wishes to survey. Plasmid templates are made from these clones and used as PCR substrates to produce DNA representations of the expressed-sequence tag (EST) inserts. The PCR products are characterized by agarose gel electrophoresis (see Support Protocol 1) and quantitated by fluorometry as described in Support Protocol 2. The PCR products are then purified and spotted onto poly-L-lysine-coated microscope slides. Preparation of poly-L-lysine-coated slides is described in Support Protocol 3. In the second operation (see Basic Protocol 2), RNA extraction and labeling, RNA is extracted from the cell samples to be examined, purified, and used as the substrate for reverse transcription in the presence of fluor-derivatized nucleotides. This procedure provides the tagged representations of the mRNA pools of the samples that will be hybridized to the gene-specific cDNA detectors immobilized on the microarray. The third fundamental operation (see Basic Protocol 3), hybridization and data extraction, covers the steps in which fluor-labeled cDNAs hybridize to their complements on the microarray, and the resulting localized concentrations of fluorescent molecules are detected and quantitated.

cDNA AMPLIFICATION AND PRINTING

This protocol describes the steps required to produce a cDNA microarray. Gene-specific DNA is produced by PCR amplification of purified template plasmid DNAs from cloned ESTs. The PCR product is purified by ethanol precipitation, thoroughly resuspended in 3× SSC, and printed onto a poly-L-lysine-coated slide (see Support Protocol 3).

Materials

Master set of clone-purified, sequence verified human ESTs (e.g., gf211 release, Research Genetics) in bacterial cells
LB medium (Biofluids, or see *UNIT 1.1*) containing 100 µg/ml carbenicillin (added from 100 mg/ml stock; see recipe)
70% ethanol
100% denatured ethanol
Super Broth (Biofluids) containing 100 µg/ml carbenicillin (add from 100 mg/ml carbenicillin stock; see recipe)
45% (w/v) glycerol (enzyme grade, sterilize by autoclaving and store at room temperature)
96-well alkaline lysis miniprep kit (Edge BioSystems)
Lysis buffer
RNase solution
Resuspension buffer
96-well receiving plates and filter plates
Precipitation buffer
Neutralization buffer
Wide-bore pipet tips
Deep-well plates
T low E buffer (see recipe)
10× PCR buffer
100 mM dATP
100 mM dGTP
100 mM dCTP
100 mM dTTP
1 mM PCR primer AEK M13F (5'-GTTGTAAAACGACGGCCAGTG-3')
1 mM PCR primer AEK M13R (5'-CACACAGGAAACAGCTATG-3')
Taq DNA polymerase (AmpliTaq, PE Biosystems), store at -20°C
Ethanol/acetate solution (see recipe)
20× SSC (*APPENDIX 2*)
Succinic anhydride (Sigma-Aldrich)
1-methyl-2-pyrrolidinone (Sigma-Aldrich)
1 M sodium borate, pH 8.0 (see recipe)
96-well round-bottom and V-bottom plastic cell culture plates (Corning)
Centrifuge with a horizontal microplate carrier with a depth capacity of 6.2 cm for spinning microtiter plates and filtration plates (e.g., Sorvall Super T 21, Sorvall with ST-H750 microplate carrier rotor)
96-pin multi-blot replicator (V&P Scientific)
Household 1-gallon sealable storage bags (e.g., Glad Lock)
Deep-well plates
Microporous tape sheets (e.g., AirPore Tape Sheets, Qiagen)
Platform shaker with holders for deep-well plates at 37°C
Sterile 96-well plate seals (e.g., Elkay Products)
Thin-wall 96-well PCR plates and PCR plate sealer (e.g., CycleSeal plate sealer, Robbins Scientific)

96-well thermal cycler (MJ Research)
Microtiter plate washer (e.g., Immunowash Microplate washer, Bio-Rad)
Heat sealable storage bags and heat sealer
65°C incubator
Robotic slide printer (e.g., GeneMachines, Genetic Microsystems, Genetix, Cartesian Technologies) and pens (e.g., Majer Precision Engineering, TeleChem International)
Diamond scribe for writing on slides
Slide box, plastic with no paper or cork liners (e.g., PGC Scientifics)
~24 × 34 × 5-cm Pyrex baking dish
Poly-L-lysine-coated glass slides (see Support Protocol 3)
30-slide stainless steel rack and 30-slide glass tank (Shandon/Lipshaw)
1-liter glass tank
Additional reagents and equipment for fluorometric DNA determination (see Support Protocol 2) and agarose gel electrophoresis (see Support Protocol 1)

Grow EST clones

1. Incubate sealed master plates of clone-purified, sequence verified human ESTs overnight at 37°C.

Most suppliers provide low-density bacterial cultures. Replicating directly from these dilute stocks frequently results in non-growth in the secondary culture. If making template from a plate that has previously been cultured to high density before freezing, this initial growth step should not be used, as it will reduce the viability of the cultures.

2. Prepare replicate sets of standard 96-well round-bottom plates by labeling all plates and placing 100 µl LB medium containing 100 µg/ml carbenicillin in each well.

These plates will be used as working copies.

To preserve the master set of plates, it is useful to make replicate copies of the master plate to serve as working copies when the master plate is first replicated. Check to insure that the EST clones are in a vector conferring ampicillin resistance, as is common with human IMAGE clones.

3. Centrifuge the master plates briefly for 2 min at $167 \times g$ (1000 rpm in a horizontal microplate carrier), 20° to 25°C, to remove condensation and droplets from the seals before opening.

Bacterial culture fluid on the sealers can easily be transferred from one well of the plate to others, cross-contaminating the stocks.

4. Partially fill a container with 100% ethanol, dip the 96-pin multi-blot replicator, remove from the ethanol bath, and then flame the pins.
5. Allow the 96-pin multi-blot replicator to cool briefly, then dip the replicating tool in the master plate, and then into the corresponding LB daughter plate. Repeat as necessary for each plate to be inoculated.

It is useful to color the plate corner near the A-1 well of all master and daughter plates with a marker pen before beginning the replication process, to reduce mistakes in relative orientation of the plates. The suggested plates have a notch at this corner as well.

6. Place the inoculated LB daughter plates with lids on into a 1-gallon sealable storage bag containing a moistened paper towel and grow overnight at 37°C.

Many 37°C incubators tend to dry out microtiter plate cultures. Placing the plates in a highly humidified bag avoids this problem.

7. Fill 96-well deep-well plates with 1 ml Super Broth containing 100 µg/ml carbenicillin per well.

These plates will serve as the source of culture for template preparation.

8. Using the 96-pin replicating tool, inoculate the deep-well plates directly from the freshly grown LB plates.
9. Cover the openings of the deep-well plates with microporous tape sheets and place the plastic lid over the sheet. Place the plates on a platform shaker for 24 hr at 200 rpm, 37°C.
10. Add 50 µl of 45% sterile glycerol to each well of any working plates that are to be frozen (−80°C) and subsequently used as culture sources.

Isolate plasmid templates

11. Warm the lysis buffer (from lysis miniprep kit) to 37°C until the SDS dissolves.

This buffer can be stored at room temperature.

12. Add 1 ml RNase solution to 100 ml resuspension buffer (from lysis miniprep kit) and store at 4°C.

The remaining reagents from the kit, neutralization buffer and precipitation buffers, are ready to use and should be stored at 4°C.

13. Prepare the 96-well receiving plates (from lysis miniprep kit) by adding 350 µl of 100% denatured ethanol to each well of the receiving plates. Place the filter plate on top and secure in place with tape.

Handle with care as the wells will be very full.

14. Centrifuge the bacterial cultures in the deep-well plates for 7 min at 1500 × g, 20° to 25°C, in a centrifuge equipped with a horizontal rotor for 96-well plates.
15. Invert briefly to remove the supernatant and tap out excess medium on a clean paper towel.

Do not delay or the pellets will loosen and may be lost when pouring off excess media.

16. Resuspend the pellet in 100 µl resuspension buffer. Vortex until entire pellet is re-suspended.

This step is critical.

Poor resuspension of the cells results in clumps of cells that do not lyse in subsequent steps. This reduces the yield and decreases the purity of the product.

17. Add 100 µl lysis buffer. Mix gently by rocking the plates from side; avoid shearing the bacterial chromosomal DNA.
18. Add 100 µl precipitation buffer to each well. Mix briefly.
19. Add 100 µl neutralization buffer to each well. Vortex.
20. Transfer the contents of the deep wells to the prepared filter plates/receiving plate stacks using the wide-bore pipet tips provided in the kits.
21. Centrifuge the stacked plates for 12 min at 1500 × g, 20° to 25°C.
22. Remove the stacked plates from the centrifuge and discard the filter plates. Decant the ethanol and filtrate from the receiver plate. Touch plate on clean paper towels to remove excess ethanol.

23. Add 500 μ l of 70% ethanol to each well. Decant immediately. Touch on clean paper towels to remove excess ethanol.
24. Place plates without lids in a clean drawer, cover with a clean paper towel, and allow to dry overnight.
25. Resuspend DNA pellet in 200 μ l of T low E buffer. Seal top with sterile 96-well plate seals. Rehydrate for at least 2 days at 4°C before using. Store at -20°C.

Amplify EST inserts

26. For each 96-well plate to be amplified, prepare a PCR reaction master mix containing the following ingredients:

1000 μ l 10 \times PCR buffer
 20 μ l 100 mM dATP
 20 μ l 100 mM dGTP
 20 μ l 100 mM dCTP
 20 μ l 100 mM dTTP
 5 μ l 1 mM AEK M13F primer
 5 μ l 1 mM AEK M13R primer
 100 μ l 5 U/ μ l *Taq* DNA polymerase
 8800 μ l H₂O.

27. Label 96-well PCR plates and pipet 100 μ l of PCR reaction master mix into each well. Gently tap plates to ensure that no air bubbles are trapped at the bottom of the wells.
28. Add 1 μ l of purified EST plasmid template to each well.

Mark the donor and recipient plates at the corner near the A1 well to facilitate correct orientation during transfer of the template. It is important to watch that the pipet tips are all submerged in the PCR reaction mix when delivering the template. Missing the liquid is easier when multichannel pipets are used.

29. Perform the following thermal cycling series:

1 cycle:	30 sec	96°C (initial denaturation)
25 cycles:	30 sec	94°C (denaturation)
	30 sec	55°C (annealing)
	150 sec	72°C (extension)
1 cycle:	5 min	72°C (final extension).

After PCR, plates may be stored at 4°C while quality controls are performed.

Check PCR products for purity and yield

30. If this is the first time the template for these ESTs is being amplified, analyze 2 μ l of each PCR product on a 2% agarose gel (see Support Protocol 1) with appropriate molecular-weight markers. If amplified products from this template have been previously tested, then analyze one row of wells from each plate amplified.
31. Analyze 1 μ l of amplified products from one row of wells from each amplified plate by fluorometry (see Support Protocol 2).

Purify PCR products

32. Fill 96-well V-bottom cell culture plates with 200 μ l per well of ethanol/acetate solution.

The ethanol/acetate solution used for precipitation is less acidic (i.e., pH 6) than is typically used. In this instance, more acidic solutions produce precipitates that are harder to resuspend, without improving yield.

33. Transfer 100 μ l per well of PCR product (from step 29) into corresponding 96-well V-bottom plates and mix by pipetting a volume of 75 μ l per well four times.
34. Place the plates for 1 hr at -80°C or store overnight at -20°C .
Place plates at -20°C if they are to be left for more than 1 hr; aggressive chilling produces precipitates that are hard to resuspend.
35. Thaw the plates to reduce brittleness and melt any ice that may have formed in the wells.
36. Centrifuge for 40 min at $2600 \times g$, 4°C .
37. Aspirate the supernatant from each well using a microtiter plate washer.
Settings for the depth of aspiration by the plate washer will need to be adjusted to suit the microtiter plates used. It is advisable to leave ~ 10 to 20μ l in the bottom of the well to avoid disturbing the pellet.
38. Wash pellets with 200 μ l of 70% ethanol per well using the microtiter plate washer.
39. Centrifuge plates for 40 min at $2600 \times g$, 4°C .
40. Aspirate the supernatant from each well using the microtiter plate washer.
41. Allow the plates to dry overnight in a closed drawer.
Do not dry in a Speedvac evaporator. Desiccated PCR products are hard to resuspend.

Resuspend the PCR products

42. Add 40 μ l of $3\times$ SSC per well. Seal plates with a foil sealer, taking care to achieve a tight seal over each well.
43. Place the plates in heat-sealable bags with paper towels moistened with $3\times$ SSC and seal the bag with a heat sealer.
The high external humidity within the sealed bag helps keep the volumes in the individual wells from varying.
44. Place the bags in a 65°C incubator for 2 hr, then turn off the heat in the incubator.
Allowing the plates to cool down gradually in the incubator avoids condensation on the sealers.

Check PCR products for yield and resuspension

45. Analyze 1 μ l of resuspended PCR product from one row of wells from each plate on a 2% agarose gel (see Support Protocol 1).
Adequate precipitation and resuspension will produce very intense bands, with no material failing to leave the loading well and no smear of material from the band towards the loading well.
46. Store the plates at -20°C after resuspension.

Print PCR products

The variety of printers and pens for transferring PCR products from titer plates to slides preclude highly detailed descriptions of the process. The following steps provide a general description of the processing.

47. Preclean the print pens according to the manufacturer's specification.
48. Load the printer slide deck with poly-L-lysine-coated slides (see Support Protocol 3).

49. Thaw the plates containing the purified EST PCR products and centrifuge briefly for 2 min, at $167 \times g$ (1000 rpm in a horizontal microtiter plate rotor), 20° to 25°C, to remove condensation and droplets from the seals before opening.

50. Transfer 5 to 10 μl of the purified EST PCR products to a plate that will serve as the source of solution for the printer.

Printing with quill-type pens usually requires that the volume of fluid in the print source be sufficiently low that when the pen is lowered to the bottom of the well, it is submerged in the solution to a depth of <1 mm. This keeps the pen from carrying a large amount of fluid on the outside of the pen shaft and producing variable, large spots on the first few slides printed.

51. Run a repetitive test print on the first slide.

In this operation, the pens are loaded with the DNA solution, and then the pens serially deposit this solution on the first slide in the spotting pattern specified for the print. This test is run to check the size and shape of the specified spotting pattern and its placement on the slide. It also serves to verify that the pens are loading and spotting, and that a single loading will produce as many spots as are required to deliver material to every slide in the printer.

52. If one or more of the pens is not performing at the desired level, reclean or substitute another pen and test again. If all pens are performing, carry out the full print.

53. At the end of the print, remove slides from the printer, label with the print identifier and the slide number by writing on the edge of the slide with a diamond scribe, place in a dust-free slide box, and age for 1 week.

It is useful to etch a line that outlines the printed area of the slide onto the first slide. This serves as a guide to locate the area after the slides have been processed and the salt spots washed off.

54. Place slides, printed side face up, in a Pyrex baking dish and cover with plastic wrap. Expose slides to a 450 mJ of UV irradiation in a cross-linker.

Slides should have been aged at ambient temperature in a closed slide box for one week prior to blocking.

55. Transfer slides to a 30-slide stainless steel rack and place rack into a small glass tank.

56. Dissolve 6.0 g succinic anhydride in 325 ml of 1-methyl-2-pyrrolidinone in a glass beaker by stirring with a stir bar.

This reaction adds succinate to the lysine primary amines, removing the positive charge from the surface of the slides.

CAUTION: Nitrile gloves should be worn and work carried out in a chemical fume hood while handling 1-methyl-2-pyrrolidinone (a teratogen).

57. Add 25 ml of 1 M sodium borate buffer, pH 8.0, to the beaker. Allow the solution to mix for a few seconds, then pour rapidly into glass tank with slides.

Succinic anhydride hydrolyzes quite rapidly once the aqueous buffer solution is added. To obtain quantitative passivation of the poly-L-lysine coating, it is critical that the reactive solution be brought in contact with the slides as quickly as possible.

58. Place the glass tank on a platform shaker in a fume hood for 20 min, shaking at 70 to 90 cycles/min.

Small particulates resulting from precipitation of reaction products will be visible in the fluid.

59. While the slides are incubating on the shaker, prepare a boiling water bath to denature the DNA on the slides.
60. After the slides have incubated for 20 min, transfer into the boiling water bath. Immediately turn off the heating element after submerging the slides in the bath. Allow slides to stand in the water bath for 2 min.
61. Transfer slides into a glass tank filled with 100% ethanol and incubate for 4 min.
62. Remove the slides and centrifuge for 3 min at $167 \times g$ (1000 rpm in a horizontal microtiter plate rotor) 20° to 25°C, to dry the slides.
63. Transfer slides to a clean, dust free slide box and let stand overnight before hybridizing.

**BASIC
PROTOCOL 2**

RNA EXTRACTION AND LABELING

This protocol details the methods used to extract RNA from cells and purify the RNA by a combination of phase extraction and chromatography. The protocol also describes the process of making fluorescent cDNA representations of the message pools within the isolated total RNA pools. This is accomplished by using the pure total RNA as a substrate for reverse transcription in the presence of nucleotides derivatized with either a Cy3 or a Cy5 fluorescent tag.

Materials

- Cells harvested from tissue culture, in tissue culture, or whole frozen tissue
- Phosphate-buffered saline (PBS; see recipe)
- TRIzol reagent (Life Technologies)
- Chloroform
- 100%, 75%, 70% ethanol
- RNeasy Maxi Kit (Qiagen)
 - 50-ml Maxi spin columns with collection tubes
 - RW1 buffer
 - RPE buffer
 - DEPC-treated water (provided with kit or see *UNIT 4.1*)
- 3 M sodium acetate, pH 5.2 (*APPENDIX 2*)
- 2 mg/ml anchored oligo-dT primer (anchored; 5'-TTT TTT TTT TTT TTT TTT TTT N-3'; e.g., Genosys)
- 1 mg/ml pd(T)12-18 (Amersham Pharmacia Biotech)
- 10× low-T dNTP mix (see recipe)
- 1 mM Cy 3-dUTP or Cy 5-dUTP, store -20°C, light sensitive
- RNasin RNase inhibitor (Promega)
- Superscript II RNase H⁻ Reverse Transcriptase Kit with 5× first strand buffer and 1 M DTT (Life Technologies)
- 0.5 M EDTA, pH 8.0 (*APPENDIX 2*)
- 1 N NaOH
- 1 M Tris·Cl, pH 7.5 (*APPENDIX 2*)
- TE buffer, pH 7.5 (*APPENDIX 2*)
- 1 mg/ml C₀t-1 DNA (Life Technologies)
- 2% (w/v) agarose gel (6-cm wide × 8.5-cm long, 2-mm wide wells) in TAE buffer
- 50× TAE buffer (*APPENDIX 2*)
- Tissue homogenizer (e.g., Polytron PT1200, Brinkmann Instruments)
- 15-ml round-bottom polypropylene centrifuge tubes
- 50-ml conical polypropylene centrifuge tubes

Clinical centrifuge with horizontal rotor for 50-ml conical tubes
1.5-ml microcentrifuge tubes
Centrifugal filter units (e.g., Microcon YM-100, Amicon)
0.2-ml thin-wall PCR tube with cap
Thermal cycler
Fluorescence scanner (e.g., Storm system for gel analysis, Molecular Dynamics)
Additional reagents and equipment for agarose gel electrophoresis (UNIT 2.5A)

NOTE: Use RNase-free water (e.g., DEPC-treated water, UNIT 4.1) to make up all solutions, unless indicated otherwise.

Extract and purify RNA

- 1a. *If starting with cells harvested from tissue culture:* Wash the cell pellet twice in PBS.
- 1b. *If starting with cells from tissue culture:* Add 1 ml TRIzol per 2×10^7 cells and mix by shaking.
- 1c. *If starting with tissue:* Add 100 mg of frozen tissue directly to 4 ml TRIzol, and dissociate by homogenization with a rotating blade tissue homogenizer.
2. Add 1/5 vol of chloroform, shake for 15 sec, and let stand for 3 min. Centrifuge for 15 min at $12,000 \times g$, 4°C .
3. Decant the supernatant, place in a 15-ml polypropylene tube, and record the volume.
4. Add 1 vol of 70% ethanol to the supernatant dropwise while vortexing.

This will produce a final ethanol concentration of 35%. The ethanol should be added drop by drop and allowed to mix completely with the supernatant before more ethanol is added. If a high local concentration of ethanol is produced, the RNA in that vicinity will precipitate.
5. Add the supernatant from an extraction of 2×10^7 to 1×10^8 cells to an RNeasy Maxi column that has been placed in a 50-ml conical tube.
6. Centrifuge for 5 min at $2880 \times g$, room temperature, in a clinical centrifuge with a horizontal rotor.
7. Collect the eluate and pour back onto the top of the column and centrifuge again as in step 6.

A significant amount of RNA is not captured by the column matrix in the first pass of the RNA-containing solution through the column.
8. Discard the eluate and add 15 ml RW1 buffer to the column. Centrifuge for 5 min at $2880 \times g$, 20° to 25°C .
9. Discard eluate and add 10 ml RPE buffer to the column. Centrifuge for 5 min at $2880 \times g$, 20° to 25°C .
10. Discard eluate and add another 10 ml RPE buffer to the column. Centrifuge for 10 min at $2880 \times g$, 20° to 25°C , and discard eluate.
11. Put the column in a fresh 50-ml conical polypropylene centrifuge tube and add 1 ml DEPC-treated water from the kit to the column. Let stand for 1 min and centrifuge for 5 min at $2880 \times g$, 20° to 25°C ; do not discard the eluate.
12. Add another 1 ml DEPC-treated water to the column, let stand for 1 min, and centrifuge for 10 min at $2880 \times g$, 20° to 25°C , into the same collection tube.
13. Dispense 400- μl aliquots of the column eluate into 1.5-ml microcentrifuge tubes.

14. Add 1/10 vol of 3 M sodium acetate, pH 5.2. Then add 1 ml of 100% ethanol to each tube, vortex, and let stand for 15 min at room temperature.
15. Microcentrifuge for 15 min at $12,000 \times g$, 4°C . Wash pellet two times in 75% ethanol and store in 75% ethanol at -80°C , indefinitely.

Clean up RNA

16. Microcentrifuge for 15 min at $12,000 \times g$, 4°C . Remove supernatant, air dry, and then resuspend RNA at ~ 1 mg/ml in DEPC-treated water. Determine concentration by reading A_{260} of 1 μl of this solution in 100 μl of 50 mM NaOH.
17. Concentrate to >7 mg/ml by centrifuging at $500 \times g$ on a Microcon YM-100 filter unit, checking as necessary to determine the rate of concentration.

This step removes many residual small- to medium-sized molecules that inhibit the reverse transcription reaction in the presence of fluorescently derivatized nucleotides.

18. Determine the concentration of RNA in the concentrated sample by spectrophotometry (APPENDIX 3D). Store at -80°C .

Reverse transcribe RNA

Typically, the same results are produced with either pdT or anchored pdT. Some cell types may give more signal with anchored pdT.

- 19a. *If using an anchored oligo-dT primer:* Anneal the primer to the RNA in the following 17- μl reaction (use a 0.2-ml thin-wall PCR tube so that incubations can be carried out on a thermal cycler):

<i>Component</i>	<i>For Cy5 labeling</i>	<i>For Cy3 labeling</i>
total RNA (>7 mg/ml)	150 to 200 μg	50 to 80 μg
anchored primer (2 $\mu\text{g}/\mu\text{l}$)	1 μl	1 μl
DEPC-treated H_2O	up to 17 μl	up to 17 μl .

- 19b. *If using an oligo d(T)12-18 primer:* Anneal the primer to the RNA in the following 17- μl reaction (use a 0.2-ml thin-wall PCR tube so that incubations can be carried out on a thermal cycler):

<i>Component</i>	<i>For Cy5 labeling</i>	<i>For Cy3 labeling</i>
total RNA (>7 mg/ml)	150 to 200 μg	50 to 80 μg
dT(12-18) primer (1 $\mu\text{g}/\mu\text{l}$)	1 μl	1 μl
DEPC-treated H_2O	up to 17 μl	up to 17 μl .

The incorporation rate for Cy5-dUTP is less than that of Cy3-dUTP, so more RNA is labeled to achieve a more equivalent signal from each species.

20. Heat to 65°C for 10 min and cool on ice for 2 min.
21. Prepare a master mix with the following components (total volume, 23 μl).

8 μl 5 \times first strand buffer
 4 μl 10 \times low-T dNTP mix
 4 μl 1 mM Cy5 or Cy3 dUTP
 4 μl 0.1 M DTT
 1 μl 30 U/ μl RNasin
 2 μl 200 U/ μl Superscript II.

Superscript polymerase is very sensitive to denaturation at air/liquid interfaces, so be very careful to suppress foaming in all handling of this reaction.

22. Add 23 μl of reaction mixture containing either Cy5-dUTP or Cy3-dUTP nucleotides to each sample, mix well by pipetting, and centrifuge briefly to concentrate in the bottom of the tube.
23. Incubate 30 min at 42°C, then add 2 μl more Superscript II. Make sure the enzyme is well mixed in the reaction volume and incubate for 30 to 60 min at 42°C.
24. Add 5 μl of 0.5 M EDTA, pH 8.0, to stop the reaction.

Be sure to stop the reaction with EDTA before adding NaOH, since nucleic acids precipitate in alkaline magnesium solutions.

25. Add 10 μl of 1 N NaOH, then incubate for 60 min at 65°C to hydrolyze residual RNA. Cool to room temperature.

The purity of the sodium hydroxide solution used in this step is crucial. Slight contamination or long storage in a glass vessel can produce a solution that will degrade the Cy5 dye molecule, turning the solution yellow. Some researchers achieve better results by reducing the time of hydrolysis to 30 min.

26. Neutralize by adding 25 μl of 1 M Tris-Cl, pH 7.5.
27. Desalt the labeled cDNA by adding 400 μl of TE buffer, pH 7.5, and 20 μg of human C₀t-1 DNA in a Microcon YM-100 cartridge. Pipet to mix, spin for 10 min at 500 \times g, room temperature.
28. Wash again by adding 200 μl TE buffer, pH 7.5, and concentrating in a Microcon YM-100 cartridge to about 20 to 30 μl (~8 to 10 min at 500 \times g).

Alternatively, a smaller-pore Microcon YM-30 can be used to speed the concentration step. In this case, centrifuge the first wash for ~4.5 min at 16,000 \times g and the second (200- μl wash) for ~2.5 min at 16,000 \times g.

Figure 22.3.1 Fluorescence scan of a 2 Cy5 labeled cDNAs electrophoresed on a 2% agarose gel.

29. Recover by inverting the concentrator over a clean collection tube and spinning for 3 min at $500 \times g$, room temperature.

In some cases, the Cy5-labeled cDNA will form a gelatinous blue precipitate that is recovered in the concentrated volume. The presence of this material signals the presence of contaminants. The more extreme the contamination, the greater the fraction of cDNA that will be captured in this gel. Even if heat solubilized, this material tends to produce uniform nonspecific binding to the DNA targets.

When concentrating by centrifugal filtration, the time required to achieve the desired final volume is variable. Overly long spins can remove nearly all the water from the solution being filtered. When fluor-tagged nucleic acids are concentrated onto the filter in this fashion, they are very hard to remove, so it is necessary to approach the desired volume by conservative approximations of the required spin times. If control of volumes proves difficult, the final concentration can be achieved by evaporating liquid in the Speedvac evaporator. Vacuum evaporation, if not carried to dryness, does not degrade the performance of the labeled cDNA.

30. Take a 2- to 3- μ l aliquot of the Cy5-labeled cDNA for analysis, leaving 18 to 28 μ l for hybridization.

31. Run this probe on a 2% agarose gel (e.g. UNIT 2.5A) in TAE buffer.

For maximal sensitivity when running samples on a gel for fluor analysis, use loading buffer with minimal dye and do not add ethidium bromide to the gel or running buffer.

32. Scan the gel on a Molecular Dynamics Storm fluorescence scanner (setting: red fluorescence, 200- μ m resolution, 1000 V on PMT).

Successful labeling produces a dense smear of probe from 400 bp to >1000 bp, with little pile-up of low-molecular-weight transcripts (as in Fig. 22.3.1, Lane A). Weak labeling and significant levels of low-molecular-weight material indicates a poor labeling (as in Fig. 22.3.1, Lane B). A fraction of the observed low-molecular-weight material is unincorporated fluor nucleotide.

BASIC PROTOCOL 3

HYBRIDIZATION AND DATA EXTRACTION

This protocol describes the conditions for hybridizing the fluor-tagged cDNA representations of the mRNA pools of samples (see Basic Protocol 2) to the EST PCR products immobilized on the glass microarrays (see Basic Protocol 1). The format for these hybridizations is simultaneous hybridization of both labeled species to a single microarray. The amount of immobilized cDNA on the slide is in excess of the amount of labeled sample that can hybridize to it, so that the amounts of labeled cDNA that do hybridize to any given immobilized cDNA are proportional to their original relative abundance in the cellular message pool. By measuring the ratio of fluorescent intensities at each immobilized cDNA spot, one obtains a measure of relative levels of messages in one sample pool versus the other. If a number of samples are measured against a common reference, the relative amounts of the messages across all of the samples can be compared for similarities and differences.

Materials

- Glass microarrays (see Basic Protocol 1)
- Cy3- and Cy5-labeled cDNAs (see Basic Protocol 2)
- DEPC-treated water (UNIT 4.1)
- 8 mg/ml poly(dA)₄₀₋₆₀ (Amersham Pharmacia Biotech)
- 4 mg/ml yeast tRNA (see recipe)
- 10 mg/ml human C₀t-1 DNA (see recipe)
- 20 \times SSC (APPENDIX 2)

50× Denhardt's solution (APPENDIX 2)
 10% SDS
 0.5× SSC/0.01% SDS wash buffer (see recipe)
 0.06× SSC wash buffer (see recipe)
 0.2-ml thin-wall PCR tubes
 Thermal cycler
 24-mm × 50-mm glass cover slips
 Microarray hybridization chamber
 65°C water bath
 Microarray scanner
 Image analysis software

NOTE: Use RNase-free water (e.g., DEPC-treated water, UNIT 4.1) to make up all solutions, unless indicated otherwise.

Hybridize fluorescent cDNA to slide

1. Determine the volume of hybridization solution required.

The rule of thumb is to use 0.033 μl for each mm^2 of slide surface area covered by the coverslip used to cover the array. An array covered by a 24-mm by 50-mm coverslip will require 40 μl of hybridization solution.

The volume of the hybridization solution is critical. When too little solution is used, it is difficult to seat the coverslip without introducing air bubbles over some portion of the arrayed ESTs, and the coverslip will not sit at a uniform distance from the slide. If the coverslip is bowed toward the slide in the center, there will be less labeled cDNA in that area and hybridization will be nonuniform. When too much volume is applied, the coverslip will move easily during handling, leading to misplacement relative to the arrayed ESTs, and nonhybridization in some areas of the array.

2. For a 40- μl hybridization, pool the Cy3- and Cy5-labeled cDNAs into a single 0.2-ml thin-wall PCR tube and adjust the volume to 30 μl by either adding DEPC-treated water or removing water in a Speedvac evaporator.

If using a vacuum device to remove water, do not use high heat or heat lamps to accelerate evaporation because this could degrade the fluorescent dyes.

3. For a 40- μl hybridization combine the following components:

	high sample blocking	high array blocking
Cy5 + Cy3 probe	30 μl	28 μl
8 mg/ml poly(dA)	1 μl	2 μl
4 mg/ml yeast tRNA	1 μl	2 μl
10 mg/ml C_0t-1 DNA	1 μl	0 μl
20× SSC	6 μl	6 μl
50× Denhardt's solution	1 μl (optional)	2 μl
Total volume	40 μl	40 μl

Arrays and samples can vary somewhat, making it necessary to vary the composition of the hybridization cocktail. In cases where there is residual hybridization to control repeat DNA samples on the array, more C_0t-1 DNA can be used, as in the high sample blocking formulation. When there is diffuse background or a general haze on all of the array elements, more of the nonspecific blocker components can be used, as in the high array blocking formulation. The authors generally try the high sample blocking formulation first.

4. Mix the components well by pipetting, heat at 98°C for 2 min in a thermal cycler, cool quickly to 25°C, and add 0.6 μl of 10% SDS.

5. Centrifuge for 5 min at $16,000 \times g$, 20° to 25°C .

The fluor-labeled cDNAs have a tendency to form small, very fluorescent, aggregates that result in bright, punctate background on the array slide. Hard centrifugation will pellet these aggregates, allowing one to avoid introducing them to the array.

6. Apply the labeled cDNA to a 24-mm \times 50-mm glass coverslip and then touch with the inverted microarray.

Applying the hybridization mix to the array and coverslipping it is an operation that requires some dexterity to get the positioning of the coverslip and the exclusion of air bubbles just right. It is helpful to practice this operation with buffer and plain slides before attempting actual samples. The hybridization solution is added to the coverslip first, since some aggregates of fluor remain in the solution and will bind to the first surface they touch.

7. Place the slide in a microarray hybridization chamber, add 5 μl of $3\times$ SSC in the reservoir, if the chamber provides one, or else at the scribed end of the slide, and seal the chamber. Submerge the chamber in a 65°C water bath and allow the slide to hybridize for 16 to 20 hr.

There are a wide variety of commercial hybridization chambers. It is worthwhile to prepare a mock hybridization with a blank slide, load it in the chamber, and incubate it to test for leaks or drying of the hybridization fluid, either of which will cause severe fluorescent noise on the array.

Wash off unbound fluorescent cDNA

8. Remove the hybridization chamber from the water bath, cool, and carefully dry off. Unseal the chamber and remove the slide.

As there may be negative pressure in the chamber after cooling, it is necessary to remove water from around the seals so that it is not pulled into the chamber and onto the slide when the seals are loosened.

9. Place the slide, with the coverslip still affixed, into a Coplin jar filled with $0.5\times$ SSC/ 0.01% SDS wash buffer. Allow the coverslip to fall from the slide and then remove the coverslip from the jar with forceps. Allow the slide to wash for 2 to 5 min.
10. Transfer the slide to a fresh Coplin jar filled with $0.06\times$ SSC. Allow the slide to wash for 2 to 5 min.

The sequence of washes may need to be adjusted to allow for more aggressive noise removal, depending on the source of the sample RNA. Useful variations are to add a first wash that is $0.5\times$ SSC/ 0.1% SDS or to repeat the normal first wash twice.

11. Transfer the slide to a slide rack and centrifuge 3 min at low speed— $167 \times g$ (700 to 1000 rpm) in a clinical centrifuge equipped with a horizontal rotor for microtiter plates.

If the slide is simply air dried, it frequently acquires a fluorescent haze. Centrifuging off the liquids results in a lower fluorescent background. As the rate of drying can be quite rapid, it is suggested that the slide be placed in the centrifuge immediately upon removal from the Coplin jar.

Acquire a fluorescent image of the slide and extract the signal data

The particulars of adjusting a microarray imaging device will vary considerably depending upon the type used and the manufacturer. Similarly, a number of methods for identifying the signal in the image, adjusting for the level of background, and normalizing the values between the two channels can be used. This section is intended only to provide some guidelines to the general considerations of imaging.

- Adjust the photomultiplier voltage and laser power so that the brightest signals produce slightly less than the maximum possible reading (i.e., 65,535, if a 16-bit scale), and the background values (between the arrayed spots) are consistently somewhat above zero, and then collect the data for the entire image.

The aim in imaging the fluorescent signals is to use as much of the linear range of detection of the instrument as possible, and to scale both signals so that they occupy roughly the same range. Setting the device so that the assay background level is at the base of the range of values insures that the minimal detectable signal can be evaluated, and helps in the determination of whether one of the two signals is considerably stronger than the other.

- Load the captured image into the data extraction software and examine images for overall quality of hybridization, noting the uniformity and level of backgrounds, the level and distribution of signals, the relative strengths of the signals in each channel, and the comparability of signals for most of the genes.

A very good characterization of the performance of the system can be carried out with a series of four hybridizations. These basically ask whether the system accurately judges two identical samples to be identical, and checks the reproducibility of the detected differences when two samples are different. For a sample of this type of data, see Troubleshooting.

AGAROSE GEL ELECTROPHORESIS OF ESTs

Gel imaging allows a rough quantitation of product while giving an excellent characterization of the product. Band size, as well as the number of bands observed in the PCR products, contribute to understanding the final results of the hybridization. The use of gel-well formats suitable for loading from 96-well plates, as well as programmable pipettors, make this form of analysis feasible on a large scale.

Materials

2% (w/v) agarose gel in 1× TAE buffer (see *UNIT 2.5A*)

50× TAE buffer (*APPENDIX 2*)

Loading buffer (see recipe)

100-bp size standards (see recipe)

Electrophoresis apparatus with capacity for four 50-well combs, (e.g., Owl Scientific)

Disposable microtiter mixing trays (e.g., Becton Dickinson)

Programmable, 12-channel pipettor with disposable tips (e.g., Matrix Technologies)

Electrophoresis power supply

Additional reagents and equipment for agarose gel electrophoresis (*UNIT 2.5A*)

Perform gel electrophoresis

- Cast a 2% agarose gel in 1× TAE buffer with 4 combs (i.e., 50-tooth) and submerge in an electrophoresis apparatus with sufficient 1× TAE buffer to just cover the surface of the gel (see *UNIT 2.5A*).
- Prepare a reservoir of loading buffer, using 12 wells of a microtiter plate.
- Program 12-channel pipettor to sequentially carry out the following steps:
 - fill with 2 μ l
 - fill with 1 μ l
 - fill with 2 μ l
 - mix a volume of 5 μ l five times
 - expel 5 μ l.

SUPPORT PROTOCOL 1

Figure 22.3.2 Ethidium bromide staining pattern of EST PCR products electrophoresed on a 2% agarose gel.

4. Place 12 disposable tips on the pipettor.
5. Load 2 μ l of PCR product from wells A1 to A12 of the PCR plate.
6. Load 1 μ l of air.
7. Load 2 μ l loading buffer from the reservoir.
8. Place tips in clean wells of disposable microtiter mixing tray and allow pipettor to mix the sample and loading dye.
9. Place the pipettor in a 50-well row so that the tip containing the PCR product from well A1 is in the second well of the row, and the other tips are in every other succeeding well.
10. Repeat the process (changing tips each time), loading PCR plate row B starting in the third well, interleaved with the A row, the C row starting at well 26, and the D row at well 27, interleaved with the C row.
11. Place 5 μ l of 100-bp size standard in wells 1 and 50.
12. Repeat this process, loading samples from rows E, F, G, and H in the second, 50-well row of gel wells, loading samples from two 96-well PCR plates per gel, or single-row samples from 16 PCR plates.

To reduce diffusion and mixing, apply voltage to the gel for a minute between loading each well strip. This will cause the DNA to enter the gel, and reduce band spreading and sample loss.

13. Apply voltage to the gel and run until the bromphenol blue (faster band) has nearly migrated to the next set of wells.

For a gel that is 14 cm in the running dimension, and 3 cm between each row of wells, apply 200 V for 15 min.

14. Take a digital photo of gel and store image for future reference.

The gels should show bands of fairly uniform brightness distributed in size between 600 to 2000 bp as in Figure 22.3.2. Further computer analysis of such images can be carried out with image-analysis packages to provide a list of the number and size of bands. Ideally this information can be made available during analysis of the data from hybridizations involving these PCR products.

FLUOROMETRIC DETERMINATION OF DNA CONCENTRATION

While it would be ideal to be able to quantify exactly each EST PCR product and spot all DNA species at equivalent concentrations, it is impractical for most laboratories to do so when thousands of ESTs must be prepared. Fortunately, it is possible to use a strategy where excess DNA is spotted, so that the exact quantities used do not produce much variation in the observed results. When using this strategy, it is necessary to track the average productivity of the PCR reactions. Fluorometry provides a simple way to obtain an approximate concentration of the double-stranded PCR product in the PCR reaction mix.

Materials

FluoReporter Blue dsDNA Quantitation Kit (Molecular Probes)
Fluor buffer (see recipe)
PCR product (see Basic Protocol 3)
TE buffer, pH 8 (APPENDIX 2)
50, 100, 250, and 500 µg/ml dsDNA reference standards (e.g., see recipe)
96-well plates for fluorescent detection (e.g., Dynex)
12-channel multipipettor
Fluorometer (e.g., PE Biosystems)
Computer equipped with Microsoft Excel software

Quantitate dsDNA

1. Label 96-well plates for fluorescence assay. With a 12-channel multipipettor, add 200 µl of fluor buffer to each well.
2. Add 1 µl PCR product from each well in a row of a PCR plate to a row of the fluorometry plate.

Samples can be added to rows A through G of the fluorometry plate.

3. In the final row of the fluorometry plate, add 1 µl TE buffer to first well and add 1 µl of each of the series of dsDNA standards—50, 100, 250, and 500 µg/ml—dsDNA to the subsequent wells. Repeat this series twice in the final row.
4. Set the fluorometer for excitation at 346 nm and emission at 460 nm. Adjust as necessary to read the plate.

If the fluorometer does not support automated analysis, export the data table to Excel.

5. Test to see that the response for the standards is linear and reproducible from the range of 0 to 500 µg/ml of dsDNA.

6. Calculate the concentration of dsDNA in the PCR reactions using the following equation after subtracting the average 0 µg/ml value from all other sample and control values:

$$[\text{dsDNA } (\mu\text{g/ml})] = [(\text{PCR sample value})/(\text{average } 100 \mu\text{g/ml value})] \times 100$$

Constantly tracking the yields of the PCRs makes it possible to rapidly detect many ways in which PCR can fail or perform poorly. This assay can also be applied after precipitation and resuspension of the PCR products to monitor overall recovery of product.

COATING SLIDES WITH POLY-L-LYSINE

Slides coated with poly-L-lysine have a surface that is both hydrophobic and positively charged. The hydrophobic character of the surface minimizes spreading of the printed spots, and the charge appears to help position the DNA on the surface in a way that makes cross-linking more efficient.

Materials

Cleaning solution (see recipe)

Poly-L-lysine solution (see recipe)

Gold Seal microscope slides (Becton Dickinson)

50-slide stainless steel rack and 50-slide glass tank (Wheaton)

25-slide plastic rack and 25-slide plastic box (Shandon Lipshaw)

Plastic slide box with no paper or cork liners (e.g., PGC Scientific)

Coat slides

1. Place slides into 50-slide racks and place racks in glass tanks with 500 ml of cleaning solution.

Gold Seal slides are highly recommended, as they have been found to have consistently low levels of autofluorescence.

It is important to wear powder-free gloves when handling the slides. Change gloves frequently, as random contact with skin and surfaces transfers grease to the gloves.

2. Place tanks on platform shaker for 2 hr at 60 rpm.
3. Pour out cleaning solution and wash in water for 3 min. Repeat wash four times.
4. Transfer slides to 25-slide plastic racks and place into small plastic boxes for coating.
5. Submerge slides in 200 ml poly-L-lysine solution per box and shake for 1 hr at 60 rpm.
6. Rinse slides three times with water and submerge slides in water for 1 min.
7. Centrifuge for 2 min at 400 × g and dry slide boxes used for coating.
8. Place slides back into slide box used for coating and let stand overnight before transferring to new slide box for storage.

This allows the coating to dry before handling.

9. Allow slides to age for two weeks on the bench, in a new slide box, before printing on them.

The coating dries slowly, becoming more hydrophobic with time.

Slide boxes used for long-term storage should be plastic and free of cork lining. The glue used to affix the cork will leach out over time and give slides stored in these types of boxes a greasy film that has a high degree of autofluorescence. Clean all glassware and racks used for slide cleaning and coating with highly purified water only. Do not use detergent.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps, unless otherwise noted. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Carbenicillin stock solution, 100 mg/ml

1 g carbenicillin (Life Technologies)
10 ml sterile water
Sterile filter with a 0.2- μ m filter
Store frozen at -20°C up to 2 months

Cleaning solution

400 ml H_2O
600 ml 100% ethanol
100 g NaOH
Dissolve NaOH in water. Add ethanol and stir until the solution clears. If the solution does not clear, add water until it does. Store up to 24 hr at room temperature.

dsDNA reference standards

50 $\mu\text{g/ml}$:
90 μl TE buffer (APPENDIX 2)
10 μl 0.5 mg/ml dsDNA (Life Technologies)

100 $\mu\text{g/ml}$:
80 μl TE buffer (APPENDIX 2)
10 μl 0.5 mg/ml dsDNA (Life Technologies)

250 $\mu\text{g/ml}$:
50 μl TE buffer (APPENDIX 2)
50 μl 0.5 mg/ml dsDNA (Life Technologies)

500 $\mu\text{g/ml}$:
0 μl TE buffer (APPENDIX 2)
100 μl 0.5 mg/ml dsDNA (Life Technologies)

It is good practice to check both the integrity (i.e., on a agarose gel) and the concentration (i.e., absorbance) of the standard before use. The reference lambda dsDNA is available from Life Technologies.

Ethanol/acetate solution

950 ml 100% ethanol
50 ml 3 M sodium acetate, pH 6.0 (see recipe)
 H_2O to 1000 ml
Store up to 2 weeks at room temperature

Fluor buffer

25 μl Hoechst 33258 solution (from FluoReporter Blue kit; Molecular Probes)
10 ml TNE buffer (from FluoReporter Blue kit; Molecular Probes)
10 ml water

Hoechst 33258 solution contains the dye at an unspecified concentration in a 1:4 mixture of DMSO: H_2O .

TNE Buffer is 10 mM Tris·Cl (pH 7.4), 2 M NaCl, 1 mM EDTA.

Human $\text{C}_0\text{t-1}$ DNA, 10 mg/ml

Add 925 μl of 100% ethanol and 75 μl of 3 M sodium acetate (pH 5.2) to 500 μl of 1 $\mu\text{g}/\mu\text{l}$ human $\text{C}_0\text{t-1}$ DNA. Centrifuge at $14,000 \times g$. Aspirate supernatant and allow pellet to air dry for 5 min. Resuspend the pellet in 50 μl DEPC-treated water (UNIT 4.1). Store up to 6 months at -20°C .

Low-T dNTP mix, 10×

25 μ l 100 mM dGTP (0.5 mM in 1 \times)
25 μ l 100 mM dATP (0.5 mM in 1 \times)
25 μ l 100 mM dCTP (0.5 mM in 1 \times)
10 μ l 100 mM dTTP (0.2 mM in 1 \times)
415 μ l DEPC-treated H₂O (*UNIT 4.1*)
Total volume, 500 μ l
Store up to 2 months at -20°C

Loading buffer

4.0 ml glycerol (enzyme grade)
0.9 ml DEPC-treated H₂O (*UNIT 4.1*)
0.1 ml 0.25% (w/v) xylene cyanol FF/0.25% (w/v) bromphenol blue
Store up to 1 month at room temperature

Phosphate-buffered saline (PBS)

8.00 g/liter NaCl
0.20 g/liter KCl
1.44 g/liter Na₂HPO₄ (anhydrous)
0.24 g/liter KH₂PO₄ (anhydrous)
Bring components to 1 liter volume with H₂O
Autoclave 20 min
Cool to room temperature
Pass through a 0.2- μ m filter
Store up to 6 months at room temperature

Poly-L-lysine solution

35 ml poly-L-lysine (0.1% w/v; Sigma)
35 ml PBS (see recipe)
280 ml H₂O
Store up to 24 hr at room temperature

Size standards, 100-bp

50 μ l 1 mg/ml DNA ladder (Life Technologies)
5 μ l 1 M Tris·Cl, pH 8.0 (*APPENDIX 2*)
5 μ l 0.5 M EDTA, pH 8.0 (*APPENDIX 2*)
440 μ l loading buffer (see recipe)
Store up to 1 month at 4°C

Sodium acetate, 3 M (pH 6.0)

Dissolve 408.24 g/liter sodium acetate trihydrate to prepare 3 M sodium acetate. Prepare 3 M acetic acid by diluting 172.4 ml glacial acetic acid to 1 liter with water. Titrate the pH of 3 M sodium acetate solution to pH 6.0 with the 3 M acetic acid solution. Filter sterilize using a 0.2- μ m filter. Store up to 6 months at room temperature.

Sodium borate, 1 M (pH 8.0)

Dissolve 61.83 g boric acid in 900 ml DEPC-treated water (*UNIT 4.1*). Adjust the pH to 8.0 with 1 N NaOH. Bring volume up to 1 liter. Sterilize with a 0.2- μ m filter and store up to 6 months at room temperature.

T low E buffer

10 ml 1 M Tris·Cl, pH 8.0 (*APPENDIX 2*)
0.2 ml 0.5 M EDTA, pH 8.0 (*APPENDIX 2*)
900 ml DEPC-treated H₂O (*UNIT 4.1*)
Autoclave and store up to 6 months at room temperature.

Wash buffer, 0.5× SSC/0.01% (v/v) SDS

Add 25 ml of 20× SSC to 974 ml DEPC water. Filter sterilize on a 0.5- μ m filter device. Add 1 ml of 10% SDS, and mix well. Store up to 2 months at room temperature.

Wash buffer (0.06× SSC)

Add 3 ml of 20× SSC (*APPENDIX 2*) to 997 ml DEPC-treated water (*UNIT 4.1*). Filter sterilize on a 0.5- μ m filter device. Store up to 2 months at room temperature.

Yeast tRNA, 4 μ g/ml

1. Resuspend yeast tRNA at 10 mg/ml (based on the supplier's quantitation of the RNA) in DEPC-treated water (*UNIT 4.1*) in a 1.5-ml polypropylene conical centrifuge tube.
2. Add 0.5 vol of buffered phenol (*UNIT 2.1A*), then vortex.
3. Add 0.5 vol chloroform, then vortex again.
4. Centrifuge 5 min at 10,000 \times g. Transfer aqueous layer to a new 1.5-ml polypropylene conical centrifuge tube.
5. Add 1 vol chloroform, and vortex. Centrifuge 5 min at 10,000 \times g.
6. Repeat chloroform extraction.
7. Transfer aqueous layer to a new 1.5-ml polypropylene conical centrifuge tube. Add 0.1 vol of 3 M sodium acetate, pH 5.2 (*APPENDIX 2*). Add 2 vol 100% ethanol.
8. Centrifuge 5 min at 10,000 \times g. Aspirate supernatant, then add 1 vol of 70% ethanol.
9. Centrifuge 5 min at 10,000 \times g. Aspirate supernatant again and allow pellet to dry.
10. Resuspend in DEPC-treated water (*UNIT 4.1*) at the original volume.
11. Determine the RNA concentration by spectrometry (*APPENDIX 3D*).
12. Dilute to 4 mg/ml and store frozen at -20°C .

COMMENTARY

Background Information

The possibility of examining the expression patterns of many genes simultaneously has been more and more enthusiastically pursued as the sequences and clones of a greater fraction of genes from model organisms have become available. A large part of the enthusiasm derives from the growing recognition of the extraordinary levels of integration and interaction between genes in all cell systems. It is clear that the same cues can provoke a wide variety of cellular responses, dependent in large part upon the proteins currently expressed in the cell being examined. By observing changes in a particular gene's expression against the backdrop of the patterns of change of other genes, it is possible to ask contextual questions about cellular function. Some of the simple but intriguing questions of this class that can be asked revolve around longstanding, basic issues. These would include questions about what activities are jointly regulated, what chains of events are involved in normal processes such

as cell division, and what expression patterns are correlated with particular processes or pathologies.

Most of the large-scale expression profiling done today is carried out either on arrays of short oligonucleotides or on arrays of ESTs. A good single-source comparative review of the strengths and weakness of the techniques, as well as example applications of both can be found in a 1999 supplement of *Nature Genetics* (Phimister, 1999; also see overview in *UNIT 22.1*). Both of these technologies are still in their early phases, and it is reasonable to expect that the methodologies for obtaining and analyzing gene expression profiles will change at a very rapid pace.

Critical Parameters

Fluorescent noise

Assays based on fluorescent staining are vulnerable to many environmental sources of noise. Nearly all dust derived from paper or

cloth fibers is intensely fluorescent across the visible spectrum. Many organic molecules are fluorescent in the spectral regions used for this type of study. It is necessary to keep exposure to dust to a minimum and to carefully monitor the purity of the reagents used to fabricate microarrays. All sources of grease in the preparation of slides must be carefully avoided, since greasy films will bind fluorescent molecules nonspecifically. For those steps where the array slides are handled, all glassware should be carefully cleaned and soaked in 1 N nitric acid before initial use, and then separately shelved and used only for arrays. Water should minimally be from either a glass still or prepared by reverse osmosis and then run through deionizing tanks and charcoal filtration tanks.

RNA handling

The routine precautions required for successful lab handling of RNA should be observed (see Chapter 4 introduction). For all DNA and RNA manipulations in these protocols use DEPC-treated water unless otherwise specified.

RNA purity

The quality of the RNA coming into the labeling will have a marked effect on the quality of the labeling and hybridization. RNA preparations judged good by standard molecular biology criteria often produce poor results. Typical problems include disperse, fine-grain noise over the entire hybridized surface and nonspecific binding of fluorescent molecules to the zones of DNA immobilization on the slide. These problems seem likely to have some roots in contaminating carbohydrate, and, as would be expected with carbohydrate, the problems are exacerbated by ethanol precipitation before and after labeling. Very impure preparations will frequently produce visible aggregates if precipitated after labeling, which are essentially resistant to solubilization. It is well known that nucleic acids form strong aggregates with carbohydrate when either dried together or when coprecipitated. This interaction is the basis for nucleic acid immobilization onto chromatography supports such as cellulose. To minimize this sort of problem, the authors recommend preparative procedures that use few or preferably no ethanol precipitations during RNA preparation and labeling.

Purity also exerts strong effects on the efficiency of labeling. Reverse transcription of RNA in the presence of nucleotides derivatized with fluorescent molecules is not an efficient

process at best, and is further impaired by impurities in the incoming template. The typical problems observed are total failure of the labeling or production of many very short reverse transcripts. The purification scheme described in this Basic Protocol 2 is designed to minimize carbohydrate and lipid carryover. It is a modification of the authors' previous method combining chromatography and phase extraction, kindly suggested by Dr. Alvydas Mikulskis of New England Nuclear.

Validation and verification

A very important step in qualifying the reliability of an array assay system is to validate experimental results. An early experiment with two samples where there is an expectation that some of the genes on the array will be differentially expressed is strongly recommended. The expected differences should be observed, and verified by northern analysis with probes made from the EST segments immobilized as reporters. Additional observed differences beyond the initial expectations should also be observed. Testing should be carried out over a range of signal strengths and a range of differential expression.

Clones and informatics

The ability to collect and manage numerous human EST clones inevitably adds clone verification and database requirements that are not easily met by public databases and repositories. It is important that the complications associated with ESTs be understood before array experiments are designed. The major obstacles in human EST usage arise from three sources. The first problem is that the categorization of the structures of human genes is not complete. Human EST sequences and the clones from which these sequences are derived are continually being deposited in publicly available repositories. The deposited sequences are then examined for similarity to each other and to known genes, and are clustered into groups of sequences thought to represent multiple examples of a single type of transcript. Organizations such as NCBI carry out this operation on a periodic basis, reforming the clusters to account for new EST sequences and name assignments and make the results publicly available (<http://www.ncbi.nlm.nih.gov/UniGene/Hs.Home.html>) as part of their UniGene project. The rate of change in assignment of an EST to a cluster remains fairly high, so that the assigned identities of many ESTs fluctuate. It is thus necessary to be able to update identity

Figure 22.3.3 Scatter plots of Cy3 (green) and Cy5 (red) mean intensities observed in three hybridizations. The labeled cDNAs in the hybridizations were made from: (A) cell line ML1, Cy3 and Cy5, (B) cell line UACC903, Cy3 and Cy5, and (C) cell line UACC903, Cy5, and cell line ML1, Cy3.

and cross-referenced data, which depends on that identity, for any EST inventory.

The second obstacle derives from the fact that it is not currently possible to obtain such data for lists of ESTs from the public databases. The databases are set up to provide answers to queries on a gene by gene or EST by EST basis. Efficiently answering questions such as “What are the current chromosomal position assignments of the ESTs in a particular set?” or “Do any of the ESTs in my inventory correspond to a particular UniGene cluster?” requires a local relational database. A frequently updated minimal relational database for human ESTs based on UniGene, that can be set up and run on an

ordinary desktop computer, can be obtained to serve this purpose (<http://www.nhgri.nih.gov/DIR/LCG/15K/DATA/>).

The final serious difficulty is that many public and private EST inventories have a relatively high rate of inaccuracy. For instance, IMAGE clones available from public distributors have an ~20% chance of either not having the 3' sequence ascribed to them in the public databases or having multiple EST clones in a single well. For this reason, a number of EST suppliers are now supplying clone sets that have been clone purified and sequence verified.

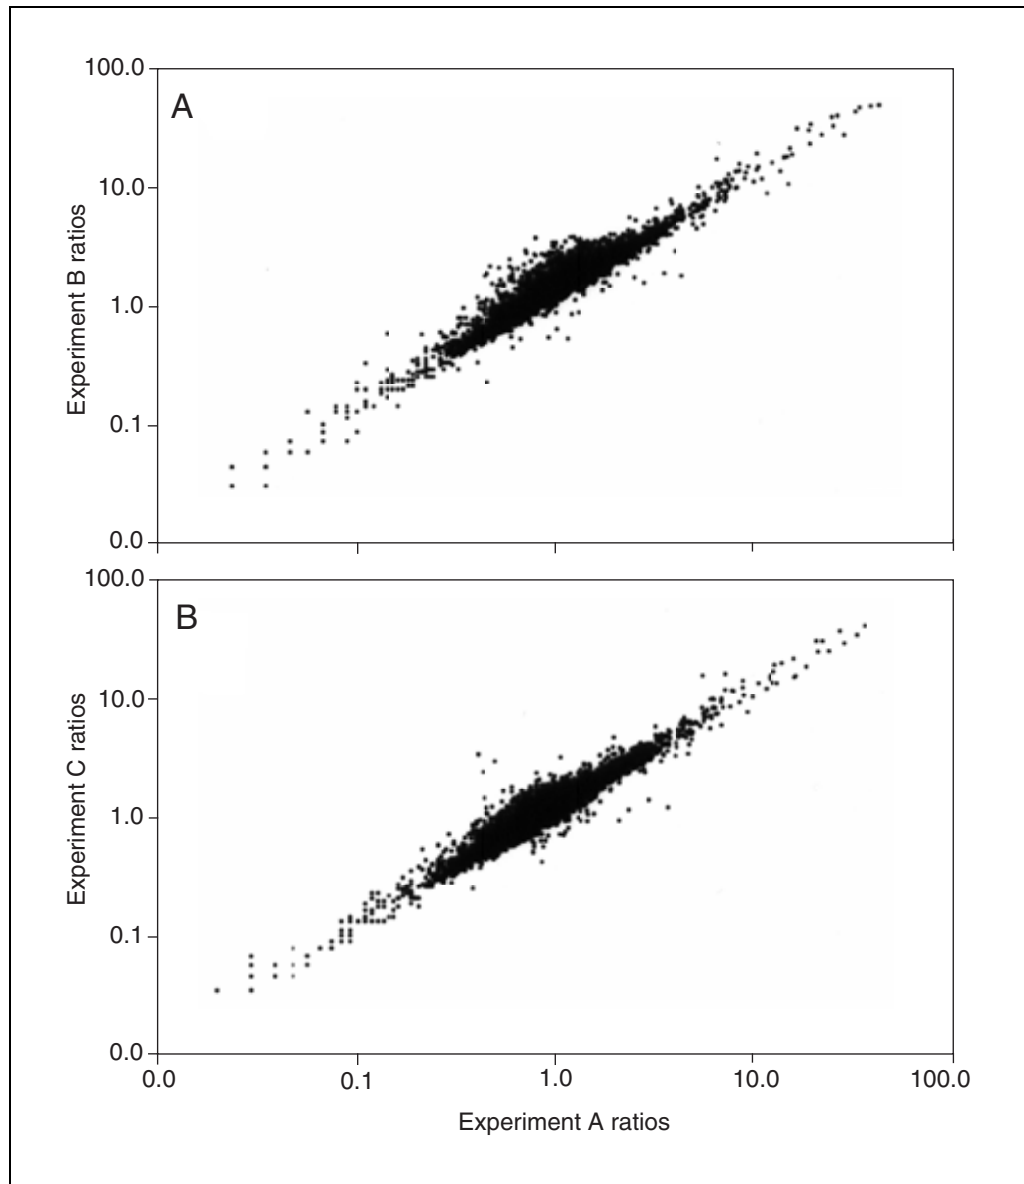

Figure 22.3.4 Scatter plots comparing the expression ratios of genes in cell line UACC903 and ML1 in three separate experiments. In panel **A**, the ratios in experiment **A** are compared to the ratios in experiment **B**. In panel **B**, the ratios in experiment **A** are compared to the ratios in experiment **C**.

Troubleshooting

One of the most illuminating diagnostics for array performance is a hybridization that reveals how tightly an array estimates that two samples from the same source produce equivalent signals. An example of a panel of three experiments that can rigorously test this capability is shown in Figure 22.3.3. Panels A and B of Figure 22.3.3 are scatter plots of the normalized mean intensities of readings from 6782 array detectors, when a single sample source is used to generate both the Cy3 and Cy5 labeled cDNA hybridized to the array. Panel C is a scatter plot of the normalized mean intensities when the two very different sample types, a melanoma cell line and a myeloid cell line used in A and B, respectively, are the sources for the labeled cDNAs in the hybridization. From such plots, one can obtain an immediate qualitative sense of the level of error in judging identity and the extent of difference in excess of error that nonidentical samples display. These parameters may obviously be more rigorously defined by statistical analysis.

After achieving satisfactory performance at the level of finding identity, it is worthwhile to examine the reproducibility with which differences are determined in multiple assays. In large measure, this is a test of the reproducibility of the printing process. A sample of this kind of testing is shown in Figure 22.3.4. Three repetitions of the experiment seen in Panel C of Figure 22.3.3 were carried out. Filtering for genes that had a minimum mean intensity of 50 in both channels developed a subset 3861 of well-detected genes. Scatter-plot comparisons of the ratios of the UACC903 (Cy5) to ML1 (Cy3) signal for genes that were well detected in all the experiments were then carried out. Panels A and B of Figure 22.3.4 show plots comparing the ratios observed in the first hybridization, experiment A, with the ratios observed in experiments B and C, respectively. Analysis at this level can easily show whether the assay is essentially working, failing in some areas of the array, or failing generally. Faults will show up as significant deviations from the diagonal. If only some portion of the genes are far from the diagonal, then their position on the array can be determined and the properties of local background and signal can be checked to see why the assay failed in those instances.

Anticipated Results

Microarray experimentation should provide a means for determining whether there is a difference in the expression level between those

genes that are present at sufficient levels in the sample to be detected by hybridization to the EST PCR products represented on the array.

Time Considerations

Time considerations for various operations described in this unit are as follows.

- Prepare replicates and cultures for template: 8 plates–5 hr.
- Prepare plasmid template from cultures: 4 plates–2.5 hr.
- Set up PCR using templates from cultures: 12 plates–2 hr.
- Prepare 200-well agarose gel: 2 gels–45 min.
- Load 2 plates of PCR samples: 1 gel–30 min.
- Ethanol precipitate and resuspend PCR products: 12 plates–5.5 hr. (with overnight incubation)
- Extract RNA: 4 samples–4 hr.
- Label RNA: 4 samples–4 hr.
- Set up hybridization: 2 slides–0.5 hr.

Acknowledgements

The authors would like to acknowledge the many excellent suggestions and kind support of our colleagues at NHGRI, Jeffrey Trent, Paul Meltzer, Yidong Chen, Javed Khan, Abdel El-kahloun, and Anthony Masiello. We would also like to thank the members of the Brown lab, especially Joe DeRisi for sharing the details of the printing methods that they developed, and the many members of the array research community who have generously shared their observations and insights with us.

Overview of mRNA Expression Profiling Using Microarrays

mRNA expression profiling using microarrays is a technology that allows simultaneous determination of the mRNA levels of many genes. Microarrays range from small custom arrays designed to monitor expression of a few hundred genes to very large arrays that represent tens of thousands of genes or entire genomes. Presently, there are three major applications for microarray data. One application treats microarray data as massively parallel expression assays. Typically, this data is used for identification of particular genes that undergo expression changes in response to particular treatments, in particular cell types, or in particular mutants. Such genes are often considered candidates for players in a biological process, such as response to a treatment. A second application involves treating expression profiles as descriptions of collective behaviors. The state of the cell from which the sample was prepared is collectively characterized by determining the expression levels of tens of thousands of genes. For example, an expression profile of a drug-treated cell describes the effect of the drug, and drugs with similar modes of action can be identified by comparing expression profiles of drug-treated cells. A third application which is becoming feasible is the mining of large expression profiling databases to characterize expression patterns of genes of interest over a wide range of tissue types, after various treatments, or in different mutants.

Due to the complexity of microarray data, computational tools are required for analysis. These tools must be tailored according to the type of analysis being carried out. If the goal is to identify genes that show expression-level changes between different samples, statistical tools are needed to sort genes based on the degree of confidence that they are actually differentially expressed. If the goal is to identify patterns in expression profiles that are diagnostic of particular cell states, pattern-recognition tools are needed. Another aspect of handling complex data is that in many cases subjective decisions are applied. For example, subjective criteria are used to decide how two different types of data, such as microarray data analysis results and gene annotation, should be combined for selection of candidate genes for further study. In the following discussion, an

overview of issues to consider when designing microarray experiments and analyzing the data is presented.

STRENGTHS AND WEAKNESSES OF EXPRESSION PROFILING

RNA and corresponding cDNA species have relatively homogenous chemical characteristics, and can be specifically detected based on hybridization of complementary strands. These advantages enable simultaneous monitoring of tens of thousands of genes with very good sensitivity and accuracy at reasonable cost. Another advantage of using cDNA species is that they can be amplified by PCR and/or in vitro transcription. Consequently, the amount of RNA required for expression profiling has been decreasing as methods for quantitative amplification of cDNA have improved (Wang et al., 2000; Baugh et al., 2001; Iscove et al., 2002). This feature allows expression profiling of very small amounts of tissue. Thus, microarray analysis could potentially have a very high spatial resolution (Ohshima et al., 2000). In terms of obtaining global quantitative information about a particular class of molecules, large-scale profiling technologies for other classes of molecules, such as proteins and metabolites, cannot match the performance of expression profiling.

On the other hand, the information obtained by expression profiling is simply the amount of each mRNA species present. mRNA levels do not necessarily correlate with levels of active, properly localized proteins or the amounts of metabolites that they produce. Consequently, the biological significance of observed changes in mRNA levels is open to question. This limitation must be kept in mind when interpreting the results of expression profiling experiments.

MICROARRAY TECHNOLOGIES

In its first incarnation, microarray technology involved spotting random cDNA clones for the purpose of detecting genes with differential expression levels in different samples in organisms with very limited DNA sequence information. The cDNA clones corresponding to genes that were found to be differentially expressed were then sequenced. Such an approach is quite inefficient, and other methods are now available to identify differentially-expressed genes

in organisms lacking extensive sequence information. An early example is differential display of mRNA (Liang and Pardee, 1992; UNIT 25B.3), followed more recently by methods including serial analysis of gene expression (SAGE; <http://www.sagenet.org>; UNIT 25B.6; Velculescu et al., 1995) and massively parallel signature sequencing (MPSS; http://www.lynxgen.com/wt/tert.php3?page_name=mpss; Brenner et al., 2000). Due to their capacities for covering large numbers of genes and rapid short sequence tag determination, SAGE and MPSS are also used for discovery of new mRNA species in organisms where genome information is available. Generally, the cost per sample of these methods is fairly high.

Affymetrix Arrays

These days the more common use of microarray technology is in monitoring expression of genes with known sequences. There are several different microarray technology platforms in use. Some platforms use arrays that must be purchased from commercial entities, while other types can be produced using widely available equipment. GeneChip arrays from Affymetrix (<http://www.affymetrix.com>) consist of a collection of short (typically 25-mer) oligonucleotides that are synthesized directly on the array (Lockhart et al., 1996). The oligonucleotides can be arrayed at extremely high density, so these arrays are usually used to represent entire genomes, or tens of thousands of different genes. Each gene is represented by eleven to sixteen pairs of exactly hybridizing oligonucleotides and oligonucleotides containing single-base mismatches. The signal from the mismatch oligos can be used for estimation of noise resulting from nonspecific hybridization. A single sample is hybridized to each array and the expression level for each gene is obtained by combining the signals from the multiple oligonucleotide probes. To compare data from different samples, the signals from each gene are normalized to the average signal for all the genes on the array, based on the assumption that most of the genes in the genome are not changing expression levels between any two experimental conditions. The main advantage of Affymetrix arrays is their excellent technical reproducibility due to the physical uniformity of the arrays themselves and the statistical power resulting from having multiple measurements for each gene. The disadvantages are that the design of the arrays cannot be altered to suit individual experiments, and the arrays are relatively expensive.

NimbleGen Arrays

NimbleGen arrays (<http://www.nimblegen.com>) are also high density arrays of oligonucleotides synthesized directly on a substrate (Nuwaysir et al., 2002). In contrast to Affymetrix arrays, the composition of the arrays can be changed very easily, so arrays can be tailored to particular experiments. In addition, longer oligonucleotides can be used for NimbleGen arrays. NimbleGen arrays are not available for purchase; rather, RNA samples must be sent to the company, which carries out the experiments and returns the data. NimbleGen arrays have not yet been widely used so it is difficult to evaluate the quality of the data; however, the similarity to the Affymetrix technology and published validation experiments (Nuwaysir et al., 2002) suggest high accuracy. The main advantage is the flexibility of the system—the design of individual arrays can be customized using a simple computer interface. The disadvantage is that the total cost of obtaining expression data from an RNA sample, including array production, hybridization, and scanning, is, at the time of this writing, even more expensive for a NimbleGen array than it is for a standard Affymetrix array.

Spotted Arrays

Rather than synthesizing oligonucleotides directly on a substrate, they can be spotted onto a glass slide. The required spotting robots are widely available, so this technology is suitable for production of custom arrays in academic laboratories. However, oligonucleotides cannot presently be spotted at the density required for representing tens of thousands of genes with multiple oligonucleotides per gene. Therefore, each gene is usually represented by one or two spots of an oligonucleotide of 60 to 70 bp, which can be purchased commercially or synthesized in-house by automated oligonucleotide synthesizers. The advantages of this technology are its flexibility and relatively low cost. However, there are technical challenges associated with production of high-quality data. Spotted arrays are less uniform than Affymetrix or NimbleGen arrays, making it difficult to compare data obtained from different arrays. Consequently, two-color methods are often used. In these experiments, two samples are labeled with different fluorescent dyes, and hybridized to the same array. The ratio of the two samples is used for further analysis. This method compensates for variation in the amount of oligonucleotide present in each spot although it can also result in a high level of error

(see below). Arrays on which each oligonucleotide is spotted only once or twice have inherently less statistical power than those on which each gene is represented by multiple oligonucleotides. For specialized arrays representing only a few hundred genes, the entire array can be spotted multiple times. Multiple measurements for each gene increase statistical power and result in reduced technical error.

Spotted arrays can also be produced using cDNA clones or PCR products rather than oligonucleotides. Such arrays can have high sensitivity due to the long lengths of the probes, but suffer from cross-hybridization of related genes. In addition, there is much more labor involved in the production, quality control, and tracking of the necessary PCR products or clones than in acquisition of a set of oligonucleotides. These arrays are also usually used with two-color methods.

Choosing an Array or an Alternative Technology

Choosing an appropriate microarray technology platform requires consideration of a number of questions, including: Is a satisfactory commercial array available? Is a satisfactory array available from an academic cooperative? How many genes must be monitored? What is the budget for the project? If the number of genes to be monitored is low and the number of samples is large, it might be wise to consider alternatives to microarrays. One is high-throughput quantitative RT-PCR, which offers much better sensitivity than microarrays. There are also bead-based technologies in which gene-specific probes are attached to fluorescently-labeled beads that are then counted using an instrument similar to a flow cytometer (Yang et al., 2001).

COMMON APPLICATIONS OF EXPRESSION PROFILING BY MICROARRAYS

Applications of microarray analysis fall into three major classes. One application is discovery of genes with different expression levels in particular samples. These might be genes induced in response to pathogen attack, genes expressed specifically in certain cell types, genes with altered expression after drug treatment, and so forth. Such genes might then be used as molecular markers for certain biological states, or investigated further to determine if they are causally associated with the biological process of interest. For example, one might test pathogen-induced genes for contributions

to disease resistance. To create accurate lists of differentially-expressed genes, experimental design and statistical analysis of the data are crucial. Generally, greater numbers of biological and technical replicates allow greater confidence in the accuracy of the lists of differentially-regulated genes.

Another application is the use of expression profiles as descriptions of the collective behavior of many genes for each sample (i.e., description of the cell state) or of many samples for each gene (i.e., description of the expression behavior of each gene). By comparing expression profiles of various mutants, it is possible to recognize mutants with defects similar to those of known mutants. For example, Hughes et al. (2000) discovered a yeast gene involved in sterol metabolism based on the observation that a mutation in it resulted in an expression profile similar to those of other mutants with defects in sterol metabolism. For this sort of analysis, it is critical to have powerful methods for pattern recognition to allow the investigator to recognize similarities among profiles. In contrast to conclusions about differential expression of individual genes, patterns composed of the expression values of many genes are statistically robust. Indeed, Hughes et al. (2000) showed that even when genes with high-magnitude changes are excluded from an analysis, similarity relationships among expression profiles are still quite stable. By comparing expression levels of genes in many different samples, genes that are regulated very similarly in many different situations can be identified. These genes may be involved in a common biological process (e.g., Kim et al., 2001).

Lastly, databases consisting of large amounts of expression profiling data can be used to rapidly obtain information about a gene of interest. For example, a database consisting of expression profiles from different tissues, mutants, and variously-treated samples can be mined to determine in what tissues a gene of interest is expressed, what signaling pathways control its expression, and what treatments alter its expression. The content of various microarray databases is rapidly increasing, so this sort of study will soon be possible for a variety of well-studied organisms. For this application, standardization of microarray data formats, data size and data quality are all important.

VARIATION IN MICROARRAY DATA

Two kinds of variation affect microarray data: biological and technical variation. Bio-

logical variation refers to real differences in the level of mRNA species between two samples that the investigator considers to be experimental replicates. They are caused by uncontrolled variables in experimental conditions as well as by stochastic biological events. For some samples, such as budding yeast growing in liquid culture, experimental conditions can be very tightly controlled. However, samples from two different mice, or worse yet, two different humans, are subject to many variations in experimental conditions that are beyond the investigator's control. Biological variation is also dependent on the stability of the biological process of interest in the presence of small perturbations (Tao et al., 2003). Irrespective of the source of biological variation, greater variation results in lower statistical power. The adverse effects of relatively high system variation may be overcome by increasing the number of replicates.

Technical variation results from variations in the mechanics of the microarray experiment itself (e.g., fabrication of the array, preparation of RNA from the sample, labeling, hybridization, washing, scanning). A simple way to assess the level of technical variation is to hybridize RNA from the same sample to two or more different arrays. Improvements in array technology and statistical procedures for dealing with background signal and normalization can reduce technical variation. In two-color methods, dye-swap technical replicates are highly desirable because the relative efficiencies of labeling with different dyes vary for different mRNA/cDNA species. While it is a good idea to assess technical variation for each sample in a microarray experiment, in the interests of economy, so-called "technical replicates" for experimental samples can be reduced (Churchill, 2002) or even omitted in favor of biological replicates, which include both the technical and biological variation in the system.

STATISTICS AND PRACTICAL DECISIONS

Statistics are important for many aspects of microarray data analysis. To begin with, microarray experiments should be designed based on statistical considerations, such as randomization (Churchill, 2002). For example, if mice cages for corresponding samples in biological replicates are kept in the same places, the correlation observed in gene expression might be due to the cage location rather than the intended experimental conditions. Data from a carefully designed experiment are particularly useful

when the data are shared for general use. However, for focused research, an experimental design that is not as rigorous may be used, dependent on the goals, bottlenecks, and budget of the research. For example, if the research goal is to identify a few good expression marker genes, running a microarray experiment with a small number of replicates, choosing a small number of candidate genes, and running a rigorous test for the candidate genes using quantitative RT-PCR could be more time- and cost-effective than running a microarray experiment with a large number of replicates.

Calculating Expression Values

For data analysis, there is the question of how to calculate a signal value for a probe spot based on the fluorescence intensity of a group of pixels in the scanned array image. Statistical principles are used to determine a small number of values (for example, the mean and standard deviation) that represent a larger group of values (such as the fluorescence intensity for a group of pixels). Microarray data must also be adjusted to compensate for nonspecific background signal. These calculations are usually performed using specialized software packages and require relatively little thought on the part of the typical user. For arrays on which each gene is represented by more than one probe spot, the values from each spot must be combined to yield a value for each gene. Normalization is required to allow comparisons between independent arrays with different overall signal intensities. There are multiple ways of doing this, which are often specific to particular microarray technology platforms. Comparison of different normalization methods is outside the scope of this overview. Interested readers may refer to other literature (e.g., Quackenbush, 2002; Bolstad et al., 2003).

Statistical Challenges in Comparing Expression Profiles

Once data has been obtained in the form of normalized expression values, the next common issue is determination of which genes have different expression levels in one sample relative to another. This requires calculation of the probability that the observed differences in expression values merely represent random samples taken from an underlying single population of possible values. If this probability is small, it is likely that the expression level of the gene really is different between the two samples (the underlying populations are separate), while if it is large, the gene likely does not have a different expression level in the two samples.

Significance of gene expression level differences

Determination of genes that are expressed at different levels in different samples from microarray data presents statistical challenges. Due to the high cost of carrying out the experiments, it is usually not practical to produce many independent replicates. If one assumes that the percent error (or coefficient of variation) of each gene is completely independent, analyses using small numbers of replicates have little statistical power, so only large expression differences are called statistically significant. One way to reduce the impact of this problem might be to assume the same percent errors for all genes. However, this is not a good assumption because weak signals (genes with low expression levels) typically have larger percent errors than strong signals (Jain et al., 2003). Commonly used tests for the significance of gene expression level differences, such as *t*-tests, assume that the underlying population of expression values is normally distributed; however, this assumption may not be valid, and its validity cannot be tested when the number of experimental replicates is small. It is possible to use nonparametric methods, in which no particular distribution is assumed, but these methods have less statistical power than parametric methods.

Another problem arises from the fact that microarray experiments are massively parallel assays. If 1000 genes are monitored and a 5% rejection rate (i.e., cutoff at $P = 0.05$) for each gene is applied to detect genes that are differentially expressed between two samples, on average 50 genes are falsely called differentially expressed. Multiple-testing corrections are statistical methods that increase the stringency of *P*-value cutoffs according to the number of genes monitored to reduce the frequency of such false-positives. They also increase the number of false negatives, thereby excluding genes that really are differentially expressed.

Permutation methods (SAM)

Permutation methods have been developed to respond to the statistical challenges presented by microarray data. One such method that is often used is significance analysis of microarrays (SAM; Tusher et al., 2001). In an example of SAM, an experiment with four replicate control samples and four replicate experimental samples was performed (Tusher et al., 2001). The relative difference value was calculated for each gene. The relative difference value was the difference between the mean

expression level of each gene in the experimental versus control samples, divided by the gene-specific scatter, defined as the standard deviation of repeated expression measurements. To assess the significance of this relative difference, the eight data sets were then randomly assigned to two groups of four data sets each (this is permutation), and the relative difference value for each gene was similarly calculated for the permuted groups. The expected relative difference for each gene was calculated by averaging the relative difference values of the gene from all the appropriate permuted group comparisons. The difference between the relative difference value of each gene determined in the control versus experiment comparison and the expected relative difference value of the gene was used as a measure of the likelihood that apparent expression differences were real.

Examples of Common Situations

Since there are practical limitations on the level of confidence that can be obtained from microarray data, it is important to have a clear idea of the purpose of the experiment and the effects of statistical limitations, and to apply statistical methods that are appropriate to the data set under study. The following examples illustrate some common situations.

Example 1: Identifying genes that may be important in a biological process

If genes are selected using stringent criteria to reduce false positives, very few candidate genes are obtained. If the criteria are relaxed, more genes are obtained, but these certainly include false positives. The key question is capacity for testing candidate genes. If many candidates can be tested, then it is better to use less stringent criteria and rely on downstream testing to eliminate false positives. If downstream testing is onerous, it is better to use more stringent selection criteria.

Example 2: Replicate data generated by two different individuals

The variance among replicate samples generated by different individuals is large relative to the variance among replicates generated by the same individual. Data generated by the two individuals should not be simply combined in an analysis.

Example 3: Non-normal distributions

If the distributions of values among replicate samples clearly deviate substantially from the bell shape of a normal distribution, statistical

tests that assume an underlying normal distribution should not be used. Either the values should be transformed first so that their distribution approximates a normal distribution, or a nonparametric test should be employed.

CHOICE OF STATISTICS FOR COMPARISON

When using array platforms with single-color detection methods (e.g., see Affymetrix Arrays), it is possible to compare expression values directly. This is convenient when many different combinations of data sets are used for comparison. When needed, by combining expression values from two appropriate experiments, expression ratio values can be calculated. With two-color methods commonly used with spotted arrays, only ratio values can be used. There is an advantage to using expression ratio values for comparisons. Unlike expression values, ratio values are independent of technology platform, so ratios obtained from one platform can be used for comparisons with ratios obtained from a different platform; however, when using ratio values, it is very important to consider the effect on error levels. The ratios are obtained from two measurements, each with an associated error, so the percent error in the ratio is larger than the percent error in either measurement. Ratios in which the expression level in one sample is very low will generally have large errors, since weak signals tend to have large percent errors. Deriving ratios from two different arrays rather than from a direct comparison on a single array, such as deriving the ratio of C/A from the ratios B/A obtained from one array and B/C obtained from another array, further increases errors. Therefore, it is ideal to have a direct comparison of each interesting pair of samples when using a two-color method. On the other hand, if many pair-wise comparisons are needed, using a common reference sample may be more practical despite the error problem discussed above. Factors affecting the choice of suitable reference samples have been discussed elsewhere (e.g., Churchill, 2002). For compiling standardized databases for general use, data from a single color method or data from a two-color method using the same reference sample for all the arrays is more valuable than other types of ratio data due to ease of comparison among various data sets.

Expression values and ratio values are often log-transformed before comparison. This is appropriate if log-transformation brings the dataset closer to a normal distribution, improv-

ing the accuracy of statistical tests based on the assumption of a normal distribution. In addition, when expression ratios are log-transformed, the characteristics of the transformed values are more intuitive. X-fold induction and repression have the same absolute value with opposite signs. Also, the scale is compressed for larger numbers. On a \log_2 scale, the difference between a fold change of 2 ($\log = 1$) and a fold change of 8 ($\log = 3$) is 2, rather than 6 on a linear scale, while the difference between a fold change of 10 ($\log = 3.32$) and a fold change of 16 ($\log = 4$) is 0.68, rather than 6 on a linear scale.

THE PROBLEM OF CLASSIFYING GENES INTO A SMALL NUMBER OF GROUPS

Genes are often classified into two groups such as those that are induced and those that are not. Such groups of genes are sometimes used to make arguments about how many genes are common to two groups that are induced under different conditions. Imagine that genes are divided into induced and uninduced genes using either a two-fold cutoff or a probability cutoff. Typically the cutoff values lie in the tail of the distribution of the values for all the genes. Consequently, many genes have values close to the cutoff value. For example, if the cutoff value is a two-fold change, there will be many genes with values of 1.9 or 2.1. Genes with a value of 1.9 will be judged as uninduced while those with a value of 2.1 will be judged as induced. Is there really a major difference between a 1.9-fold change and a 2.1-fold change? Among the genes that pass the cutoff, there will be large variations in the extent to which they pass, yet they are all classified in the same group. For example, a gene that shows a 2.1-fold change is grouped together with a gene that shows a 200-fold change. Are these fold-changes really similar? These problems become greater when two sets of induced genes are compared to determine the set of genes induced in common by two different treatments. The impact of these limitations on conclusions drawn from microarray data should be kept in mind.

ADVANTAGES OF COMMERCIAL SOFTWARE

Several expensive software packages for microarray analysis are commercially available. Programs that will perform most of the analytical methods implemented in these packages are freely available somewhere on the web, so why should anyone spend a lot of money on the

commercial products? First, such products have the various methods put together nicely. It is quick and easy to apply different analytical methods and combine or compare the results. Second, they have integrated database management mechanisms, which can also take care of database security and sharing issues. Third, they are designed to be highly interactive. Well-organized, highly interactive databases provide access to information that helps the investigator make subjective decisions about how to integrate different types of information. Fourth, they offer many ways to visualize the data and the results of analyses. People have excellent visual pattern recognition abilities, so visualization of data is a powerful tool aiding comprehension of large data sets. Fifth, they often offer ways to record a series of analyses applied to the data. Such a record is very important because various criteria used in analyses could be subjectively decided. In addition, such a recorded series of analyses can be used as a macro, so the same series of analyses are easily applied to different data sets.

In using sophisticated software tools, it is necessary to understand the analytical tools being applied to avoid drawing faulty conclusions. For example, when using false color to display differences in gene expression levels, the eye is drawn to the boundaries between different colors, and one tends to conclude that genes in different color groups have very different expression levels, when they may actually be quite similar.

SUMMARY

Expression profile data obtained from microarrays can be enormously useful in addressing a variety of biological questions, including genome-scale questions that were previously unapproachable. Maximizing the potential of microarray experiments requires attention to aspects of experimental design and data analysis. Experiments should be designed so as to minimize systematic errors and errors arising in the process of data analysis. Good design can also make it possible to determine how much of the variation among replicates arises from various sources, such as technical variation or biological variation. When analyzing data, it is important to understand the limitations of the analytical methods used to avoid drawing erroneous conclusions. Public databases consisting of microarray data will be very useful for a variety of large-scale analyses, provided that the data sets are of high quality. Investigators

who produce data through carefully-designed and executed experiments thus have the opportunity to benefit the larger scientific community as well as to further their own research goals.

COMPARISON OF MULTIPLE PROFILES

In an upcoming supplement, another aspect of expression profile data analysis will be considered: comparison of multiple profiles. Similarities among profiles can be used in a number of ways. For example, tumors that respond similarly to treatments can have similar expression profiles, and this can be used to determine which treatment may be most effective (Lapointe et al., 2004). Also, expression profiles of mutants can be used to predict the nature of the defects in the mutants (e.g., Hughes et al., 2000; Glazebrook et al., 2003). Detection of similarities among expression profiles is a problem of pattern-recognition among distributions of points in n -dimensional space, where each point represents an expression profile and n is the number of genes represented in each profile. While people have difficulty recognizing patterns in spaces of more than three dimensions, computer algorithms can handle as many dimensions as needed. Many computational methods for pattern recognition have developed, and several are routinely used for analysis of expression profiling data. These methods, together with methods under development, may prove to be even more useful in the future.

Pattern Discovery in Expression Profiling Data

Expression profile data typically consists of many profiles, each of which has many parameters. Such data are typically represented by a table with many columns and rows. This makes it extremely difficult to recognize trends in the data without the assistance of analytical tools. Recognition of major trends in the data enables the investigator to formulate new hypotheses. In this unit, some analytical tools for recognition of trends in large data collections, known as pattern discovery tools, are discussed. Pattern discovery tools are also known as multivariate analysis methods in which factors that are responsible for trends are assumed to be unknown. This unit is intended to explain pattern discovery tools to biologists, who do not necessarily have extensive mathematical knowledge. As a consequence, explanations are not mathematically rigorous. They are based mainly on viewpoints from geometry rather than viewpoints from statistics or linear algebra in hopes that many readers will find this more intuitive.

GENERAL CONCEPTS

The Same Mathematical Procedures Can Be Used to Compare Genes or Samples

There are two ways in which expression profiles can be considered. One way is to compare individual genes to each other based on their expression values in various samples. The expression values of each gene in different experimental samples are considered as parameter values comprising one profile. Another way is to compare individual samples to each other based on the expression levels of various genes. Expression values for different genes in each experimental sample are considered as parameter values comprising one profile. Once genes and samples have been assigned as profiles or parameters, the mathematical procedures used by a pattern discovery tool are the same for either comparison.

Data points in a high-dimensional Euclidian space

The principles used by computer algorithms to find genes that are similarly regulated or experimental samples with similar expression

profiles are generally based on distributions of data points in a high-dimensional Euclidian space, in which all the dimensions are perpendicular to one another. For example, when expression profiles of many genes in three different experimental samples (parameters) are compared, the profile for each gene is represented by a single data point in a 3-D linear space, in which each dimension corresponds to one experimental sample (parameter). If expression values of gene A in experimental samples x_1 , x_2 , and x_3 are 300, 500, and 220, respectively, the data point for gene A is expressed as the coordinates of $(x_1, x_2, x_3) = (300, 500, 220)$ (Fig. 22.5.1A). Thus, an expression profile of any gene in the three samples can be expressed as a single data point in this space. According to how the distance between two data points is defined (see below), the similarity between the expression profiles of the two corresponding genes can be calculated—the closer the points are, the more similar their expression profiles. If many data points form a relatively dense group, such a group can be considered as a cluster of similarly regulated genes (Fig. 22.5.1B). Thus, finding a cluster of similarly regulated genes is equivalent to recognizing closely distributed data points. Different computer algorithms use different principles to discover patterns in the distribution of data points.

For comparison of expression profiles of many genes through 100 different experimental samples, a 100-dimensional Euclidian space $(x_1, x_2, \dots, x_{100})$ is used. Again, an expression profile of a single gene can be described as one data point in the 100-D space. In other words, a profile with n parameters can be expressed as a single data point in an n -dimensional space. In the following discussion, “profile” and “data point” are used interchangeably, as are “parameter” and “dimension.” The mathematical definition of distance between two data points can be easily expanded to a high dimensional space. While a space with >3 dimensions is difficult to visualize, a computer can easily apply the same principle regardless of the number of dimensions in the space. This is why computers are valuable for analysis of data with high dimensionality (i.e., with many parameters).

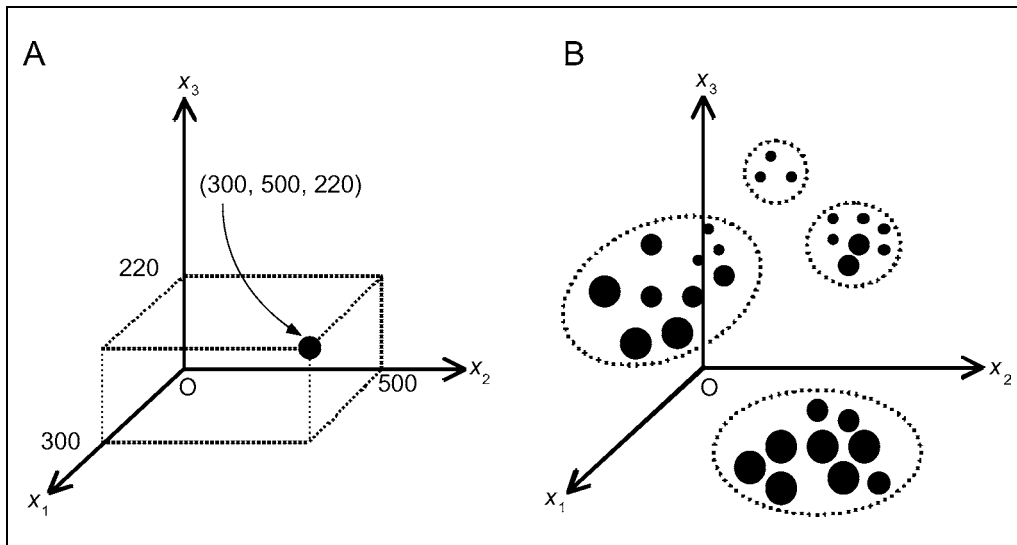

Figure 22.5.1 Representation of expression profiles in a Euclidian space. **(A)** A single point can be specified for a profile in a Euclidian space with a number of dimensions equal to the number of parameters. **(B)** Pattern discovery among expression profiles is equivalent to pattern discovery in the distribution of data points.

Figure 22.5.2 Distance metrics. **(A)** Euclidian distance. Euclidian distance is the length of the straight line between two points in a Euclidian space. **(B)** Uncentered Pearson correlation coefficient (R). R is the cosine of the angle made at the origin between A and B .

Distance Metrics

There are multiple ways to define the distance between two data points. Only two commonly used distance metrics are described here. One is the Euclidian distance. In a 3-D space, this is seen as the length of the straight line connecting two data points (Fig. 22.5.2B). In this figure, the Euclidian distance D between data points A and B is defined as

$$D = \sqrt{(a_1 - b_1)^2 + (a_2 - b_2)^2 + (a_3 - b_3)^2}.$$

It is easy to expand this distance metric to an n -dimensional space, where it is defined as

$$D = \sqrt{\sum_{k=1}^n (a_k - b_k)^2}.$$

The other is the uncentered Pearson correlation coefficient. This is the equivalent of the cosine of angle θ that is made between two data points at the origin (Fig. 22.5.2B). The smaller the angle is, the closer the data points

are. Since it is the cosine value, its range is from 1 (perfect correlation when $\theta = 0^\circ$) to -1 (perfect negative correlation when $\theta = 180^\circ$). When the uncentered Pearson correlation coefficient is 0, there is no correlation between two profiles and $\theta = 90^\circ$. Note that the uncentered Pearson correlation coefficient ignores the distance of a data point from the origin; it is based only on the angle between two data points. In Figure 22.5.2B, the uncentered Pearson correlation coefficient R between data points A and B is defined as

$$R = \frac{a_1b_1 + a_2b_2 + a_3b_3}{\sqrt{a_1^2 + a_2^2 + a_3^2} \sqrt{b_1^2 + b_2^2 + b_3^2}}$$

This distance metric can be expanded to an n -dimensional space as

$$R = \frac{\sum_{k=1}^n a_k b_k}{\sqrt{\sum_{k=1}^n a_k^2} \sqrt{\sum_{k=1}^n b_k^2}}$$

If the vector expression is used,

$$R = \frac{\overline{OA} \cdot \overline{OB}}{|\overline{OA}| |\overline{OB}|},$$

which the reader may recognize as the cosine function.

The distance metric is the metric that describes to what extent two profiles are similar.

In Figure 22.5.2A, the distance between data points A and B is the same as that between data points B and C. However, from data point B, the directions to data points A and C are different. The direction represents the way in which profiles are similar. For example, the difference between data points A and B could be explained by the expression difference in sample x_1 , while the difference between data points B and C could be explained by the expression differences in samples x_2 and x_3 . Some of the pattern discovery tools described below do not consider the ways in which data points are similar, while others do.

Shapes and Amplitudes of Expression Profiles

When the number of parameters and the number of profiles are limited, one good way to visualize expression profiles is to use line graphs as shown in Figure 22.5.3A. Although line graphs are generally not recommended in ordinary biology unless the parameters represent consecutive points in a single metric, such as consecutive time points, the line graph representation strongly enhances the ability to visually compare patterns. The expression values of gene A, (300, 500, 220) are exactly four times as high as those of gene D (75, 125, 55). That is, the amplitude of the gene A profile is four times larger than the amplitude of the gene D profile. Compare two representations of these two profiles in Figures 22.5.3A and 22.5.3B. In Figure 22.5.3B, the amplitude difference is seen as the difference in the

Figure 22.5.3 Shapes and amplitudes of expression profiles are represented (A) by line graphs and (B) in a Euclidian space.

distance from the origin: data point A is four times further away from the origin than data point D. The shape of the profile defined by the relative ratio of expression values is the same for genes A and D as seen in Figure 22.5.3A. The fact that the shapes of the profiles are the same is represented in Figure 22.5.3B as the same direction of data points A and D from the origin O. In other words, the vectors \vec{OA} and \vec{OD} point in the same direction. The profile of gene E (220, 300, 500) has the same amplitude as gene A, as their distances from the origin are the same. However, the shapes of their profiles are different as seen in Figure 22.5.3A. The profile shape difference is represented in Figure 22.5.3B as different directions of \vec{OA} and \vec{OE} .

The shapes and amplitudes of profiles are distinct characteristics. Generally, they should be considered separately. The reader should be aware that methods of combining these two characteristics into one metric, such as using the Euclidian distance, are subjective. For example, imagine that profile B and profile A have the same shape, but profile B is three times larger than profile A and that profile C and profile A have the same amplitude but their shapes are totally unrelated (i.e., the uncentered Pearson correlation coefficient between them is zero). Using the Euclidian distance, the distance between profiles A and B is larger than that between profiles A and C. Whether this is appropriate or not depends on subjective decisions.

What Profiles Should Be Considered the Same?

Centering and normalization

Before applying pattern discovery analysis, expression values or ratio values can be transformed. They can be log-transformed as described in the previous unit. Two other transformations are often applied—typically called “centering” and “normalization.” Centering is adjusting the mean or median of the values to 0. When an expression profile with the expression values (300, 500, 220) is centered using the mean value, it results in a profile with (−40, 160, −120). Note that centering could change both the shape and amplitude of the profile. Normalization means adjusting the Euclidian distance of each data point from the origin to 1. For example, when a profile with the expression values (300, 500, 220) is normalized, it results in a profile with (0.481, 0.802, 0.353). Note that normalization does not alter the shapes of the profiles, but could

change the amplitude of the profile. Normalization is an integral part of the uncentered Pearson correlation coefficient, and therefore, the distance of each data point from the origin, i.e., the amplitudes of profiles, is ignored in the uncentered Pearson correlation coefficient. Calculating the centered Pearson correlation coefficient is the same as applying the uncentered Pearson correlation coefficient after centering the profiles.

These transformations are applied to each profile. When the profiles for genes are being compared (samples as parameters), if any of these transformations are used, they should be applied to the set of values for each gene, not the set of values for each sample. In contrast, when the profiles for samples are being compared (genes as parameters), if any of these transformations are used, they should be applied to the set of values for each sample, not the set of values for each gene.

Statistically speaking, centering and normalization of each profile are recommended as they allow more robust statistical comparisons. However, these transformations can change the biological meaning of the profiles. Figure 22.5.4A shows profiles that become the same after centering. Figure 22.5.4B shows profiles that become the same after normalization. Figure 22.5.4C shows profiles that become the same after both centering and normalization. If both transformations are applied, centering should be performed first. The choice of transformations should be made on a case-by-case basis, depending on what profiles should be considered the same. For example, if the values are log-transformed ratio values (positive values for induced and negative values for repressed), it is not a good idea to center the values because centering could change the signs of the values. In another example, if Euclidian distance is used as the distance metric and if the amplitude of the profile is intended to be factored into the distance, normalization is not appropriate.

PATTERN DISCOVERY TOOLS

Various pattern discovery tools have been used to help find major trends in expression profile data. The principles, advantages, and disadvantages of several methods are discussed below. These analyses are generally processes of information reduction that reveal major trends in the data. For example, two drug candidates might be found to have very similar effects on expression profiles, suggesting that they have similar modes of action. However, in the course of identifying major

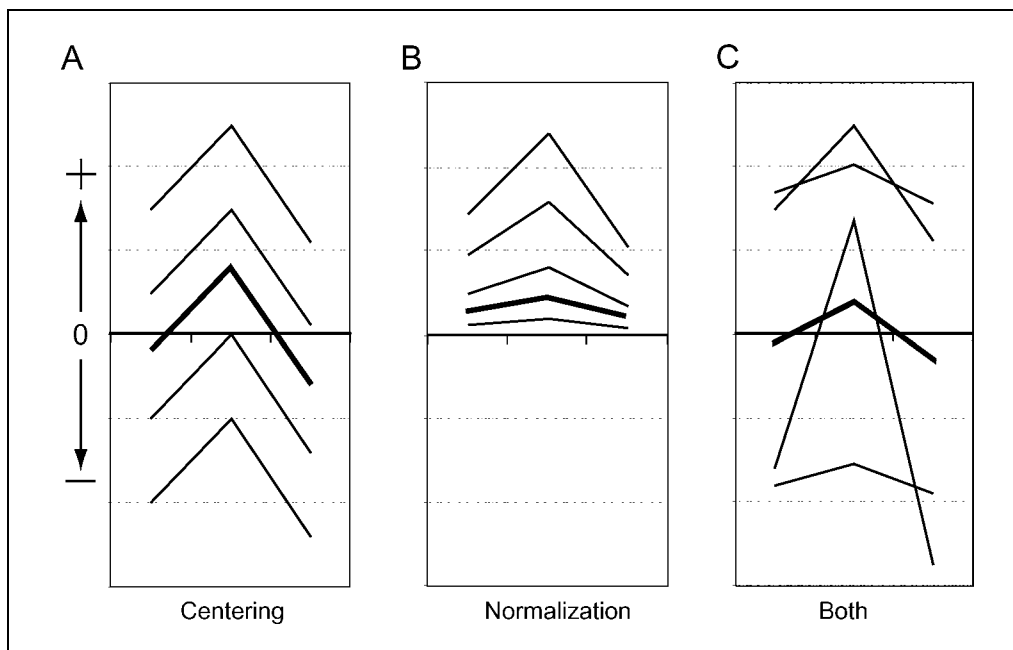

Figure 22.5.4 Effects of (A) centering, (B) normalization, and (C) both on expression profiles. In each panel, the transformation results in all the profiles being converted to the profile indicated by the thick line.

trends in the data, minor patterns are discarded, resulting in loss of some information that may actually be important. Different methods define major trends in different ways, and discard different types of minor patterns. These differences should be kept in mind when applying a pattern discovery tool to biological data.

As discussed in the beginning of the unit, large numbers of profiles and parameters create challenges for pattern discovery. Generally, the strategies used by pattern discovery tools are reducing the number of profiles by clustering similar profiles together, or reducing the number of parameters by mathematical combination. By clustering similar profiles, the number of profiles that need to be handled at once can be reduced; the profiles within a cluster can be compared or profiles representing the clusters can be compared. The number of parameters can be reduced by dimensionality reduction methods. A space with a small number of dimensions that still holds most of the information in the data can be derived by combining initial parameters appropriately. If the resulting space has three or fewer dimensions, the overall relationship among the profiles is easily visualized.

Clustering Methods

Hierarchical clustering

The version of hierarchical clustering commonly used for expression profile analysis is

agglomerative hierarchical clustering, which is a bottom-up method for generating a hierarchical tree (Eisen et al., 1998). Like a phylogenetic tree, the idea is to place similar profiles in the same branch of the tree. Among all the possible pair-wise combinations of data points, the one with the shortest distance gets connected first. The connected data points are replaced by a node, which is treated as a new data point. This process of connecting the data points is repeated until all the data points are connected. In this way, the tree (dendrogram) is built from peripheral branches towards the root (Fig. 22.5.5). There are three common ways to define nodes: (1) in average linkage, the node is the average point of all the data points represented by the node; (2) in complete linkage, the point among a set of connected data points that is furthest away from another point being considered for linkage is used as the node; and (3) in single linkage, the point among a set of connected data points that is closest to another point being considered for linkage is used as the node.

Hierarchical clustering performs well in detecting similar data points at local levels. This is very useful for detecting highly similarly regulated genes or very similar samples. However, as branches become bigger, multiple groups of data points that are fairly similar are often placed on relatively distant branches. Two factors contribute to this. First, hierarchical clustering forms a single connection at a

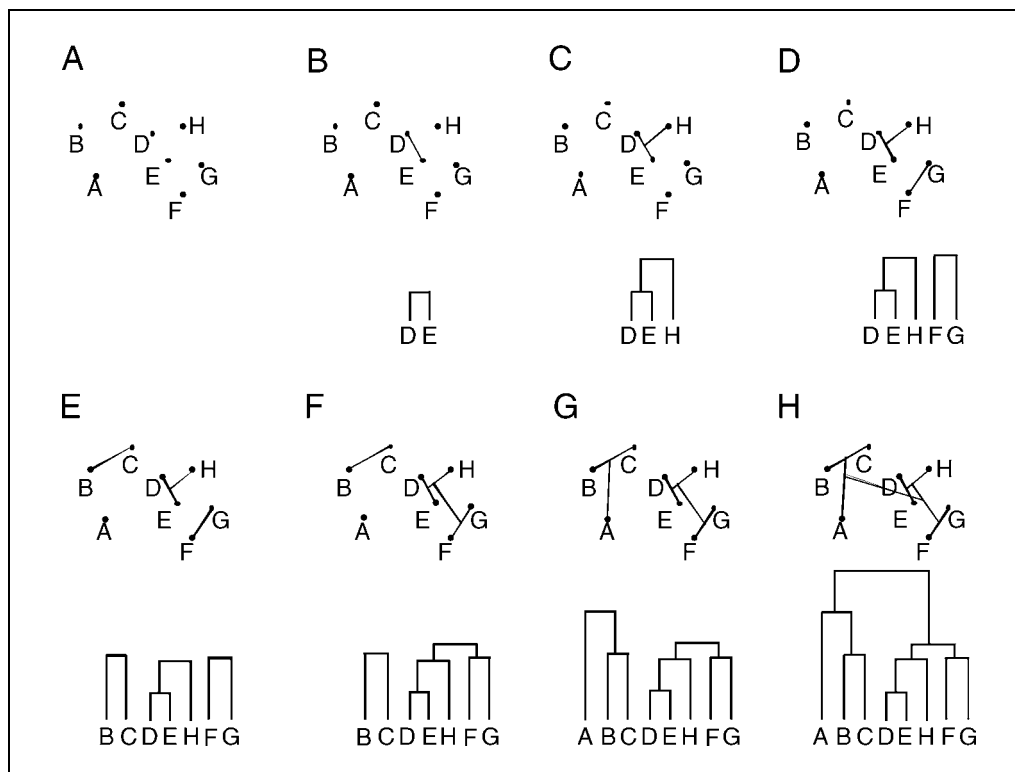

Figure 22.5.5 Agglomerative hierarchical clustering. (A through H) schematically depict sequential steps in building a hierarchical tree based on the 2-D positions of the data points shown in A. Average linkage was used to determine nodes.

time by considering only the degree of similarity and not the nature of the similarity. Second, each new connection affects the position of the node (i.e., process dependency). For example, in Figure 22.5.5, data points C and D are relatively close, but due to the effects of other data points during the clustering process, data points C and D appear to be distantly located from each other in the final dendrogram (Fig. 22.5.5H). Thus, a data point that is somewhat similar to other data points in a cluster may not be incorporated into the growing cluster until a relatively late cycle of connection forming, when the node has moved away from it.

An important advantage of hierarchical clustering is that by putting similarly behaving parameters together, it can generate a color-coded 1-D pattern for each profile with thousands of parameters, e.g., a profile with the values for thousands of genes in a sample (Eisen et al., 1998). This allows researchers to visually inspect such color-coded patterns for different samples to identify which samples are similar and which parts of the pattern (i.e., expression of which genes) are different between samples. Hierarchical clustering is a simple, powerful visualization method.

K-means clustering

This is a method that divides data points into K clusters (Herwig et al., 1999). The number of clusters, K , is given by the user. Each cluster of data points is represented by a centroid. First, K centroids are placed in the data space, and then the assignments of each data point to a particular centroid and the positions of the centroids are iteratively optimized (Fig. 22.5.6). There are several variants of K -means clustering that vary according to what metric is used for optimization of the positions of the centroids. Such a metric could be the sum of the average distance to the centroids, the total distances of all data points from their centroids, the sum of the variance over all clusters, and so on.

The results of K -means methods are highly dependent on the number and the initial positions of the centroids. Such clusters are well-separated, round-shaped (i.e., convex-shaped) clusters. K -means clustering is useful for discovery of such well-defined clusters (Xu et al., 2002).

Network-building methods

Converting similarities among data points into a network structure could help to

Figure 22.5.6 *K*-means clustering. **A** through **C** schematically illustrate sequential steps in the process of optimization in a 2-D space when $K = 2$. **(A)** shows the initial positions of the centroids and data point assignments to the centroids. Small circles represent data points and large circles with an "X" represent centroids. The color of each data point indicates which centroid it is assigned to. Note that during the optimization, not only the positions of the centroids but also the assignments of some data points changes.

Figure 22.5.7 Network building. Among the data points in **(A)**, pairs of data points are linked when their distances are shorter than a predetermined distance **(B)**. It is clear that data points in the upper left region are highly connected to one another. For example, in the sub-network featured in **C**, each data point within the sub-network is connected to the other data points in the group.

visualize the data point distribution. For example, links can be made between all the data point pairs that have distances shorter than a certain value. When many data points are located within a small part of the space, they are highly linked to one another, and such a group can be recognized as a cluster (Fig. 22.5.7). In practice, the rule for making links between data points could be more sophisticated, such as using a cutoff for the probability value determined by a certain statistical analysis, but the basic idea is the same. Such network structures can be visualized using network visualization tools, such as Pajek (<http://vlado.fmf.uni-lj.si/pub/networks/pajek/>); Batagelj and Mrvar, 1998) and VxInsight (<http://www.cs.sandia.gov/projects/VxInsight.html>); Davidson et al., 1998). Kim et al. (2001) provide a good example of visualization of a network built on

analysis of expression profile data. Pajek is also a network analysis tool, and can be used to define clusters according to mathematically defined network characteristics.

Dimensionality Reduction Methods

Principal component analysis (PCA), a linear dimensionality reduction method

In a linear space, when the number of data points is smaller than the number of dimensions, the number of dimensions can be reduced to the number of data points by linear transformations without any loss of information. This situation is illustrated in Figure 22.5.8. However, this number is still likely to be too large to allow the investigator to grasp the relationships among the data points. Linear dimensionality reduction methods, such as

Figure 22.5.8 The number of necessary dimensions is at most the number of data points. When three data points A, B, and C are in a high-dimensional space with origin O (**A**), the first dimension \vec{x}_1 can be chosen along the line \overline{OA} (**B**). The second dimension \vec{x}_2 can be chosen parallel to $\overline{B'B}$, where B' is on \overline{OA} or its extension, and $\overline{B'B}$ is perpendicular to \overline{OA} or its extension (**C**). The third dimension \vec{x}_3 can be chosen parallel to $\overline{C'C}$, where C' is on the plane defined by \vec{x}_1 and \vec{x}_2 and $\overline{C'C}$ is perpendicular to the plane (**D**). Although it is difficult to visualize a space with a dimension higher than three, by repeating this procedure, it can be shown that the number of necessary dimensions is at most the number of data points.

PCA (Alter et al., 2000; Holter et al., 2000), are used to further reduce the number of dimensions while minimizing loss of information. Linear dimensionality reduction in data analysis is based on the belief that apparently complex data can be closely approximated by linear combinations of a relatively small number of independent parameters. Linear dimensionality reduction is equivalent to factor analysis in statistical terms, in which independent parameters are the equivalents of unknown independent factors.

Figure 22.5.9 illustrates a very simple case using a 2-D space to explain the principle of PCA. If all the data points are perfectly aligned in a straight line, one dimension along the straight line, instead of two dimensions, is sufficient to describe all the differences among all the data points (Fig. 22.5.9A). If all the data points are almost aligned in a straight line, loss of information by using only one dimension along the straight line is limited to

very small deviations of the data points from the straight line (Fig. 22.5.9B). Just using one dimension, the relationships among the data points are easily visualized. The dimension that explains the largest difference, defined as the variance along the dimension, among the data points is called the first principal component (PC) of the data. The dimension along the straight line in the Figure 22.5.9B example is the first PC of the data. The dimension that explains the largest remaining differences among the data points is called the second PC. In Figure 22.5.9B, the dimension perpendicular to the first PC is the second PC. When the initial parameter number is higher, the third and subsequent PCs can be defined similarly. Note that all the PCs are perpendicular to one another, and a Euclidian space can be defined using PCs, i.e., the data points can be expressed using PCs as the parameters. The number of PCs that should be considered can be assessed by the residual variance, i.e., how much of the

Figure 22.5.9 The idea of PCA. (A) If all the data points are aligned along a line, one dimension along the line is sufficient to describe the relationships among the data points. (B) If the data points are almost aligned along a line, the dimension along the line can describe most of the relationship information among the data points. This dimension is the one defined by the first PC. The remaining differences can be explained by adding another dimension, which is seen as the second PC. Filled circles represent data points.

difference among the data points is still not accounted for by the first x PCs. If increasing the number of PCs beyond a certain number does not reduce the residual variance much, the remaining variance may be caused by random noise. If the first two PCs are sufficient to describe most differences, all the data points can be well approximated in the 2-D space defined by the first two PCs. In this way, all the data points are plotted in the 2-D space, and the relationships among the data points can be easily visualized.

PCA and singular value decomposition (SVD) used in expression profile analysis are essentially the same. SVD is the name of a method that can be used to determine PCs.

Self-organizing maps (SOM) as a nonlinear dimensionality reduction method

Biological processes are typically nonlinear and, therefore, it is reasonable to expect that simple rules to explain major trends in expression profiles are better described in a nonlinear space. For example, imagine a group of genes that are induced by a particular chemical. When using a different concentration of the chemical, expression of different genes may hit a plateau at different concentrations. Using a linear dimensionality reduction, a description of the profiles for samples with different concentrations of the chemical using these genes as parameters could require several dimensions. However, a nonlinear method may

find that just one nonlinear dimension would be sufficient.

In PCA, a linear space with a small number of dimensions is assumed to be sufficient to describe most differences among the data points. What if the data points lie mostly on a 1-D space but it is nonlinear (Fig. 22.5.10A)? Two dimensions would be needed according to PCA. For this case, SOM (Tamayo et al., 1999) works well. Initially, nodes are placed in a straight line (1-D linear space), which is typically defined by the first PC (Fig. 22.5.10B). Then, the node positions and the assignments of data points to each node are iteratively optimized. This iterative optimization process is conceptually similar to the process used in K -means clustering. When the node positions and the data point assignments are optimized, nodes are placed in the curve, and each data point is assigned to the closest node (Fig. 22.5.10C). So, groups of data points can be mapped back to the initial positions of the nodes on the line (Fig. 22.5.10D). In other words, the curve defined by the data points can be approximately converted into a straight line by the SOM procedure.

Typically, the initial nodes in SOM are placed in a 2-D linear space (plane) defined by the first two PCs, instead of a 1-D linear space. If the data points define a 2-D nonlinear space in a high-dimensional space, SOM could closely approximate the data points in a plane. Essentially, SOM performs nonlinear dimensionality reduction.

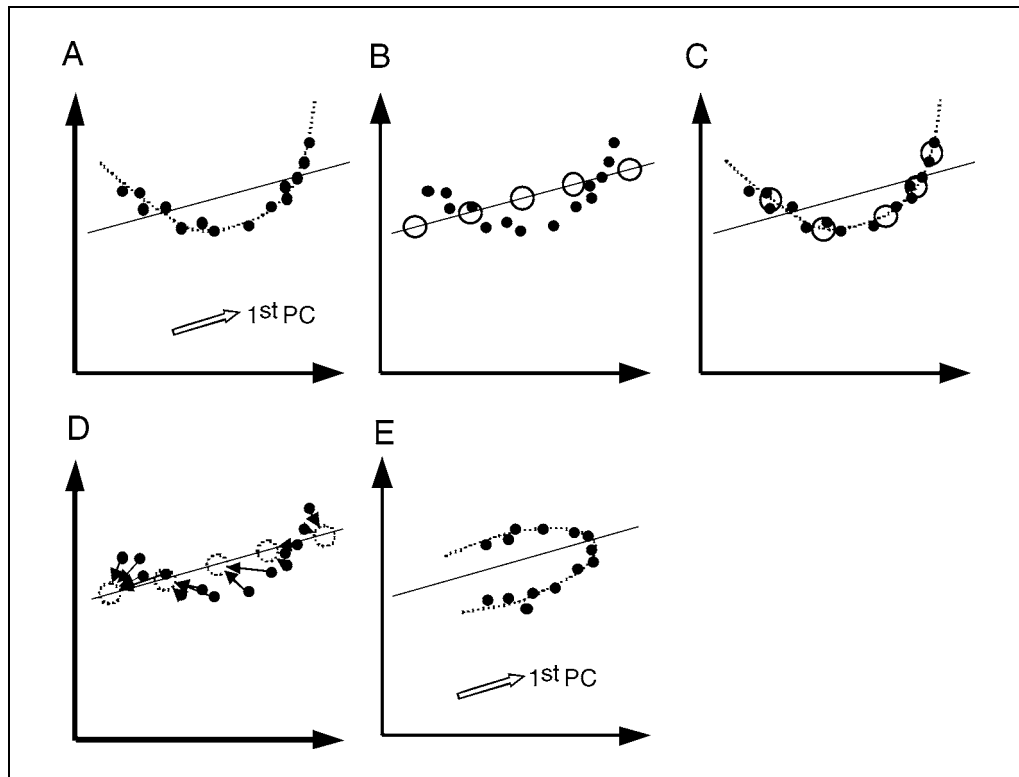

Figure 22.5.10 SOM works as a nonlinear dimensionality reduction method. (A) The data points are aligned along a curve instead of a straight line. (B) The nodes can be placed initially along the first PC. (C) The nodes are aligned along the curve after optimization. (D) Using the initial position of the nodes, each data point can be mapped onto the straight line defined by the first PC. (E) If the 1-D space defined by the data points has a high level of nonlinearity, such as in this case, SOM does not perform well as a nonlinear dimensionality reduction method. Small filled circles represent data points and large open circles represent nodes.

In principle, nodes can be initially placed in a space with three dimensions or more. However, this makes the visualization of relationships among nodes and the profiles assigned to them more difficult, especially when there are more than three dimensions. In addition, if the nonlinearity of the space defined by the data points is too high, SOM's principle of approximation starting with a linear space would not work well (Fig. 22.5.10E).

SOM is also known as a clustering method. When it is used as a clustering method, it is useful for the discovery of well-separated, round-shaped clusters (Xu et al., 2002).

When a large number of nodes are used for SOM, the data points can be finely mapped on the initial linear 2-D space. Such a fine map generated by having genes as profiles can be used as a visualization matrix for the entire profile of an experimental sample by color-coding expression values for a representative of each node (i.e., genes are assigned to nodes; Eichler et al., 2003). This SOM-based visualization method can be considered as a 2-D version of the 1-D profile visualization method

using hierarchical clustering described in the section above. The SOM-based method could work better for visualization of more information in the profile than is possible using a method based on hierarchical clustering. Note that the numbers of genes assigned to different nodes (i.e., the density of genes) in the SOM-based visualization method are not homogenous, whereas the density of genes along the axis in the hierarchical clustering-based method is homogenous. It is possible that a change that affects a large area in the SOM-based visualization matrix could be caused by a relatively small number of genes.

Nonlinear dimensionality reduction

To select important information, PCA linearly reduces dimensionality, and SOM can be interpreted as a modestly nonlinear approximation of PCA with a fixed number of reduced dimensions. What if the space defined by the data points is highly nonlinear (e.g., Fig. 22.5.10E)? In such a case, nonlinear dimensionality reduction could be used (Roweis and Saul, 2000; Tenenbaum et al., 2000). The

authors have been developing a method for microarray data analysis using nonlinear dimensionality reduction (Katagiri and Glazebrook, 2003). They have also proposed to translate the result of nonlinear dimensionality reduction into a network structure, so that network analysis methods can be used when more than three dimensions are required to explain particular data. This type of approach may prove useful.

CHAPTER 23

Manipulating the Mouse Genome

INTRODUCTION

Defining the role of a mammalian nucleic acid segment can be a difficult process. The first steps involve mRNA identification, gene cloning, and nucleic acid sequence determination. A variety of cell-free and cultured cell systems have been developed (see Chapters 8 to 22, 24) that can provide important clues to the function of a particular DNA sequence in regulating gene transcription or RNA translation. Many segments of DNA appear inert or function inappropriately in these model systems; thus, an important test of any functional model of a DNA segment is to characterize the phenotype of a viable organism carrying the sequence in its genome. Today the tools exist for manipulating DNA segments in a variety of mammals, from mice and rats to sheep and cows. However, the mouse, because of its small size (30 g) and short life cycle (about 8 weeks) from birth to the production of progeny, has been selected for the vast majority of laboratory experiments. Thus, this chapter focuses on the manipulation of the mouse genome.

Two general methods are available for the introduction and modification of mouse genomic DNA sequence. Embryonic stem cell–derived mice are produced by the introduction of embryonic stem cells into the blastocyst, which is reimplanted in a foster mother, where it goes through normal mouse development, producing a mouse pup (*UNITS 23.1–23.8*). Transgenic mice are produced by the injection of one or more transgenes (usually a DNA segment bearing its own promoter) into the pronucleus of a fertilized mouse oocyte, which, after reimplantation in a foster mother, gives birth to a transgenic mouse bearing one to several hundred copies of the transgene (*UNIT 23.9*). Transgenic mice are useful for testing the overexpression of a gene segment while embryonic stem–cell derived mice are generally useful for defining the phenotype of mice lacking a gene segment. Both types of mice can be used to express altered protein sequences; transgenic mice will usually overproduce the altered protein, while embryonic stem cell–derived mice will usually express normal levels of protein. In this chapter we describe the production of embryonic stem cell derived–mice and transgenic mice.

The production of transgenic mice involves two steps: (1) production of DNA suitable for injection and (2) injection of the DNA into a fertilized mouse oocytes and re-implantation of the injected oocyte into a foster mother. A variety of approaches are used to produce injected DNA. Perhaps the most common DNA constructs contain a eukaryotic promoter, cDNA sequence, introns and 3' untranslated region. The production of these DNA segments involves the tools that of molecular cloning (Chapters 4 and 5). Producing transgenic mice is faster than producing mice by homologous recombination because DNA is injected directly into oocytes rather than first being introduced into embryonic stem cells. However, the injection of DNA into fertilized mouse oocytes and re-implantation is technically more demanding than electroporation of DNA into cells. Nanoliter volumes containing transgene DNA are injected with a micropipette into a pro-nucleus (*UNIT 23.9*). After injection the oocyte is re-implanted into the foster mother. Despite the technical difficulties of producing transgenic mice this technology allows for rapid evaluation of the effects of over-expression of a mutationally altered or wildtype protein.

Manipulating
the Mouse
Genome

23.0.1

Supplement 68

The production of embryonic stem cell–derived mice can be thought of as a three-stage process that normally takes about 6 months. These steps involve the production of a targeting vector (*UNIT 23.1*), the introduction of DNA sequences into the embryonic stem cell genome by homologous recombination (*UNIT 23.5*) and eventually to the production of genetically altered mice derived from embryonic stem cells. A critical part of this procedure is the maintenance of the cells. Embryonic stem cells are cultured on feeder cells and require constant attention; these procedures are described in *UNITS 23.2 & 23.3*. A procedure describing the derivation of embryonic stem cells is described in *UNIT 23.4*. After the genetically engineered embryonic stem cells are obtained they are injected into mouse blastocysts, which are then re-implanted into a foster mother that eventually gives birth to chimeric mice composed of wild-type cells and ES-derived cells (*UNIT 23.7*). Chimeric mice are then mated to wild-type mice and eventually mice derived from the ES cell genome are obtained. The genetically engineered mice are now available for physiologic and biochemical evaluation. The production and management of a colony of genetically engineered mice requires careful planning (*UNIT 23.8*) in order to have adequate numbers of mice of appropriate ages for study.

The function of genes expressed in embryonic stem cells can be assessed directly in these cells. In *UNIT 23.5*, procedures for producing a single knockout or heterozygous cell line by homologous recombination are described. Homozygous (double-knockout) cells can be produced in tissue culture and these cells can be a useful tool for analyzing gene function in embryonic stem cells (*UNIT 23.6*). Taken together, these steps provide a powerful method for introducing a wide variety of specific changes into murine embryonic stem cells and eventually into the genome of a mouse.

J.G. Seidman

Overview of Gene Targeting by Homologous Recombination

The analysis of mutant organisms and cell lines has been important in determining the function of specific proteins. Gene targeting by homologous recombination in mammalian systems enables the production of mutants in any desired gene (Mansour, 1990; Robertson, 1991; Zimmer, 1992). Over the past two decades, gene targeting by homologous recombination has become a mainstay in gene-function investigation. This technology can be used to produce mutant mouse strains and mutant cell lines. Because most mammalian cells are diploid, they contain two copies, or alleles, of each gene encoded on a pair of autosomal (nonsex) chromosomes. In most cases, both alleles must be inactivated to produce a discernible phenotypic change in a mutant. The conversion from heterozygosity to homozygosity is accomplished by breeding in the case of mouse strains and by direct selection in cell lines.

More recent technological advances that have greatly increased the power to investigate gene function include spatial and temporal control of knockouts, mutation analysis, heterologous expression of proteins by “knock in” of coding regions into another gene, and recombineering for targeting construct production. Bacteriophage recombinase systems such as Cre with its recognition sequence, *loxP*, have played key roles in these technologies. Another recombinase system, the FLP/FRT system, can also be used (Fiering et al., 1993, 1999; Branda and Dymecki, 2004). The control can function along actual spatial coordinates when a viral gene transfer system is used, or in a cell- or tissue-specific fashion when restricted promoters are employed. Adding temporal regulation of Cre, as with the tetracycline-regulatable system (UNIT 16.14) or the modified Cre-ER fusion, allows temporal control as well.

To produce a mutant mouse strain by homologous recombination, two major elements are needed. An embryonic stem (ES) cell line capable of contributing to the germ line, and a targeting construct containing target-gene sequences with the desired mutation. ES cell lines are derived from the inner cell mass of a blastocyst-stage embryo. Maintaining ES cells in their undifferentiated state is a major task

during gene targeting (UNIT 23.3). This usually is accomplished by growing cells on a layer of feeder cells (UNIT 23.2), which supply factors, most notably leukemia inhibitory factor (LIF), to keep cells undifferentiated. The targeting construct is then transfected into cultured ES cells (see UNIT 23.5). Homologous recombination occurs in a small number of the transfected cells, resulting in introduction of the mutation in the targeting construct into the target gene. Once identified, mutant ES cell clones can be microinjected into a normal blastocyst in order to produce a chimeric mouse. Because many ES cell lines retain the ability to differentiate into every cell type present in the mouse, the chimera can have tissues, including the germ line, with contribution from both the normal blastocyst and the mutant ES cells. Breeding germ-line chimeras yields animals that are heterozygous for the mutation introduced into the ES cell, and these offspring can be interbred to produce homozygous mutant mice.

Homologous recombination can also be used to produce homozygous mutant cell lines (see UNIT 23.6). Previously, inactivation of both alleles of a gene required two rounds of homologous recombination and selection (te Riele et al., 1990; Cruz et al., 1991; Mortensen et al., 1991). Now, however, inactivation of both alleles of many genes requires only a single round of homologous recombination using a single targeting construct (Mortensen et al., 1992). The homozygous mutant cells can then be analyzed for phenotypic changes to determine the function of the gene.

SOURCE OF DNA

Although nonisogenic DNA was used for constructs early in the history of homologous recombination, isogenic DNA (from the same mouse strain) gives higher recombination rates because homologous recombination requires stretches of exact base pair matches. Bacterial artificial chromosomes (BACs) from C57BL/6 and 129 strains are now available from genome repositories, making it more convenient to obtain DNA for constructs. Manipulations of large constructs is also possible using Red/ET recombineering methodology (Copeland et al., 2001).

ANATOMY OF TARGETING CONSTRUCTS

Two basic configurations of constructs are used for homologous recombination—insertion constructs and replacement constructs (Fig. 23.1.1). Each can be used for different purposes in specific situations, as discussed below. The insertion construct is rarely used. It contains a region of homology to the target gene cloned as a single continuous sequence, and is linearized by cleavage of a unique restriction site within the region of homology. Homologous recombination introduces the insertion construct sequences into the homologous site of the target gene, interrupting normal target-gene structure by adding sequences. As a result, the normal gene can be regenerated from the mutated target gene by an intrachromosomal recombination event.

The replacement construct is the more commonly used construct. It contains two regions of homology to the target gene located on either side of a mutation (usually a positive selectable marker; see below). Homologous recombination proceeds by a double cross-over event that replaces the target-gene sequences with the replacement-construct sequences. Because no duplication of se-

quences occurs, the normal gene cannot be regenerated.

METHODS OF ENRICHMENT FOR HOMOLOGOUS RECOMBINANTS

Positive Selection by Drug-Resistance Gene

Nearly all constructs used for homologous recombination rely on the positive selection of a drug-resistance gene (e.g., neomycin or *neo*) that is also used to interrupt and mutate the target gene. When either insertion or replacement constructs are linearized, the drug-resistance gene is flanked by two regions of homology to the target gene. Selection of the cells using drugs (e.g., G418) eliminates the great majority of cells that have not stably incorporated the construct (see UNIT 9.5). However, in many of the surviving clones the construct has incorporated into the genome not by homologous recombination but rather through random integration. Therefore, methods to enrich for homologous recombinant clones have been developed.

Positive-Negative Selection

The most commonly used method for eliminating cells in which the construct integrated into the genome randomly, thus further

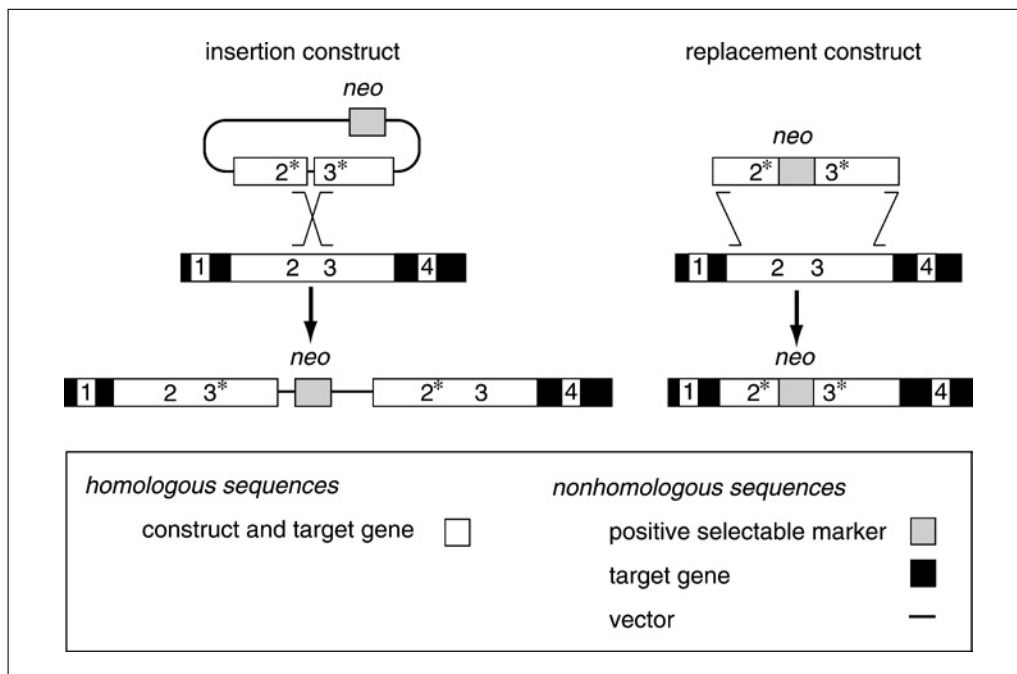

Figure 23.1.1 Two configurations of constructs used for homologous recombination. Numbers indicate target-gene sequences in the genome. An asterisk indicates homologous target-gene sequences in the construct. Replacement constructs substitute their sequences (2*, *neo*, and 3*) for the endogenous target-gene sequences (2 and 3). Insertion constructs add their sequences (2*, *neo*, and 3*) to the endogenous target gene, resulting in tandem duplication and disruption of the normal gene structure.

Figure 23.1.2 Enrichment for homologous recombinants by positive-negative selection using the TK gene. Homologous recombination involving cross-overs on either side of the *neo* gene results in loss of the TK gene. Random integration tends to preserve the TK gene. The presence of TK can be selected against because any cell expressing the gene will be killed by gancyclovir (GANC). Although both homologous recombinants and clones in which the construct integrated randomly are G418-resistant, only homologous recombinants are gancyclovir-resistant. The construct is shown linearized so that the plasmid vector sequences remain attached to the TK gene. This configuration helps preserve the integrity of the TK gene.

enriching for homologous recombinants, is known as positive-negative selection. It is only applicable to replacement constructs (Fig. 23.1.2; Mansour et al., 1988). In these constructs, a negative selectable marker (e.g., herpes simplex virus thymidine kinase, HSV-TK) is included outside the region of homology to the target gene. In the presence of the TK gene, the cells are sensitive to acyclovir and its analogs (e.g., gancyclovir, GANC). The HSV-TK enzyme activates these drugs, resulting in their incorporation into growing DNA, causing chain termination and cell death. During homologous recombination, sequences outside the regions of homology to the target gene are lost due to crossing over. In contrast, during random integration all sequences in the construct tend to be retained because recombination usually occurs at the ends of the construct. The presence of the TK gene can be selected against by growing the cells in gancyclovir; the homologous recombinants will be G418-resistant and gancyclovir-resistant,

whereas clones in which the construct integrated randomly will be G418-resistant and gancyclovir-sensitive. In some cases, TK is inactivated without homologous recombination; thus, the gancyclovir-resistant clones must be screened to identify the true homologous recombinants. Other markers that are lethal to cells have also been used (e.g., diphtheria toxin; Yagi et al., 1990).

Endogenous Promoters

Constructs that rely on an endogenous promoter to express the positive selectable marker can also give enrichment of homologous recombinants (Fig. 23.1.3), but can only be used if the gene of interest is expressed in the cell line. They contain the coding region of a selectable marker (e.g., *neo*) but lack a promoter for the marker. The coding sequence for the marker usually interrupts, and is in frame with, an exon of the target gene. Thus, when homologous recombination occurs, a fusion protein is produced driven by the endogenous

Figure 23.1.3 Enrichment for homologous recombinants using a positive selectable marker (*neo*) lacking a promoter. Clones in which integration of the construct provides an endogenous promoter to drive *neo* expression will be G418-resistant. The construct is designed so that homologous recombination will provide a promoter leading to *neo* expression, whereas random integration will most likely not provide a promoter, thus precluding *neo* expression.

target-gene promoter. In contrast, when random integration occurs, the selectable-marker protein is not usually produced. Therefore, homologous recombinants are G418-resistant, whereas cells in which the construct integrated randomly are G418-sensitive. Constructs containing a promoterless selectable marker can be generated in either replacement or insertion structure and can result in dramatic enrichment for homologous recombinants.

TYPES OF MUTATIONS

Gene Inactivation

Homologous recombination has most often been used to completely inactivate a gene (commonly termed “knockout”). Usually, an exon encoding an important region of the protein (or an exon 5' to that region) is interrupted by a positive selectable marker (e.g., *neo*), preventing the production of normal mRNA from the target gene and resulting in inactivation of the gene.

A gene may also be inactivated by creating a deletion in part of a gene, or by deleting the entire gene. By using a construct with two regions of homology to the target gene that are far apart in the genome, the sequences intervening the two regions can be deleted. Up to 15 kb have been deleted in this way; thus, many genes could be completely eliminated (Mombaerts et al., 1991). Gene inactivations may also be controlled using the *Cre/loxP* recombinase system either spatially, through cell- or tissue-specific knockout, or temporally, through control of the activity or expression of the recombinase (see *Cre/loxP* System, below).

Mutations can be introduced that have multiple purposes. Homologous recombination has been used to introduce a replacement construct containing the coding sequence of β -galactosidase in frame with the 5' end of the target gene. Downstream of the *lacZ* gene is a positive selectable marker driven by a

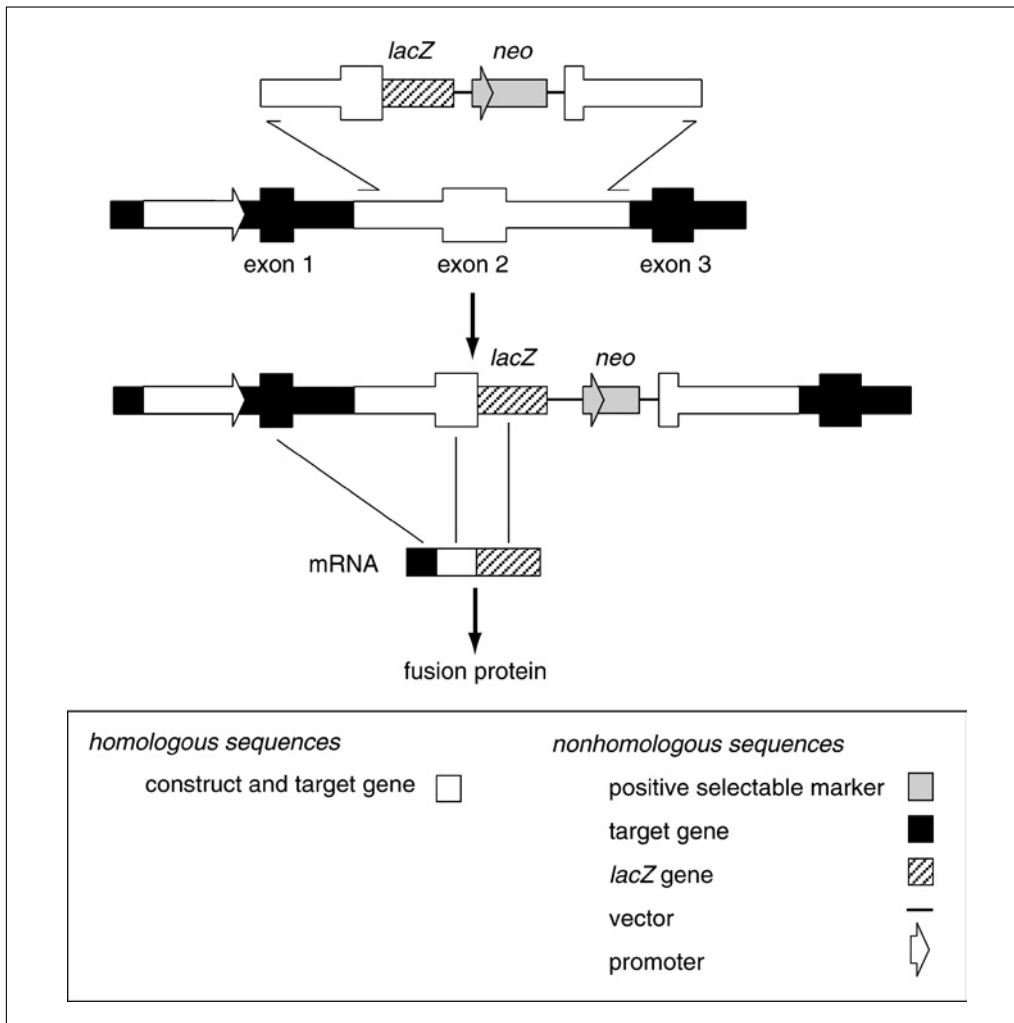

Figure 23.1.4 *LacZ* reporter construct for gene targeting. This construct has two purposes: to disrupt the target gene and to express the *lacZ* gene as a marker to monitor activity of the endogenous target gene's promoter.

heterologous promoter (Fig. 23.1.4). This construct not only disrupts target-gene function but also expresses a fusion protein with β -galactosidase activity, and thus can be used to monitor the activity of the endogenous gene's promoter in various tissues during development (Mansour et al., 1990). Targeting vectors can also be made that express β -gal without the fusion protein. Similarly, other coding sequences can be expressed from the endogenous promoter to achieve selective heterologous expression. Since this results in disruption of the gene, this approach is typically used only if the heterozygous knockout does not have a phenotype.

Subtle Gene Mutations

Homologous recombination can also be used to introduce subtle mutations in a gene. One method is analogous to a method in yeast called transplacement or allele replacement (UNIT 13.10). It is called "hit and run" (Hasty

et al., 1991) because duplications are introduced into the target gene and then removed. An insertion construct containing both positive and negative selectable markers (e.g., *neo* and TK) is used to introduce a duplication that contains a subtle mutation, such as a point mutation, into the target gene sequence (Fig. 23.1.5). After selection for integration of the construct using the positive selectable marker (e.g., G418), homologous recombinants are identified by screening. A homologous recombinant clone is cultured and then the presence of the negative selectable marker is selected against (e.g., selection against TK using gancyclovir). This selects for an intrachromosomal recombination that eliminates the target-gene duplications and the selectable markers but leaves the mutant target-gene sequences substituting for the normal target-gene sequences. Surviving clones are screened for the correct intrachromosomal rearrangements, leaving the desired mutation. A second

Figure 23.1.5 Allele replacement “hit and run.” Cells are cultured in G418 to select for the integration of *neo*, then homologous recombinants are identified by screening and are cultured in gancyclovir (GANC) to select against the presence of the TK gene. This strategy may yield a reconstituted gene containing the subtle mutation present in the construct (indicated by the dark bar and †). Because intrachromosomal recombination may result in the loss of the subtle mutation, its presence must be verified (e.g., by a change in restriction site).

method of introducing subtle mutations into a gene is to insert the mutation by homologous recombination and then use the *Cre/loxP* system to remove the selectable marker.

Cre/loxP SYSTEM

The *Cre/loxP* system is derived from the bacteriophage P1. The recombinase Cre acts on the DNA site *loxP*. If there are two *loxP* sites in the same orientation near each other, Cre can act to loop out the sequence between the two sites, leaving a single *loxP* site in the original DNA and a second *loxP* in a circular piece of DNA containing the intervening sequence. Therefore, a properly designed targeting construct containing *loxP* sites can be used for introducing subtle mutations or for a tem-

porally or spatially controlled knockout (for a review of the control of transgenes, see Sauer, 1993). Other recombinase systems, such as the *Flp/FRT* system, can be similarly useful (Fiering et al., 1995; Vooijs et al., 1998).

Removing the Positive Selectable Marker

Although many gene-inactivation approaches involving homologous recombination still use constructs that leave the positive selectable marker in the genomic DNA, it has become increasingly clear that this can cause a number of unanticipated effects. For example, the presence of the *neo* gene, often with its own promoter, can alter the expression of neighboring loci (Olson et al., 1996; Pham

et al., 1996). This can be a particular problem in gene clusters where neighboring genes are in the same family, since the genes affected may have similar or identical functions. As a result, slight differences in targeting constructs have led to marked differences in phenotype.

If the targeting construct includes *loxP* sites flanking the *neo* gene, then *neo* can be removed after targeting by transient expression of the Cre recombinase (as discussed in UNIT 9.5 and Fig. 23.1.3). This will leave the small *loxP* site in the genomic DNA, but the construct can be engineered so that this is in an innocuous location, such as an intron. Although theoretically even a *loxP* site could cause alterations in the expression of neighboring genes, no such cases have yet been reported. The efficiency of Cre recombination from transient expression reported in the literature varies widely, from ~2% to ~15% (Sauer and Henderson, 1989; Abuin and Bradley, 1996). This rate should be

distinguished from the efficiency of Cre recombination *in vivo*, where the expression of Cre is derived from sequences integrated into the genome and therefore will show longer-lasting expression in nearly all cases.

Introduction of Subtle Mutations Using Cre/*loxP*

The strategy described in the previous section involves introducing subtle mutations by first duplicating sequences and then screening for intrachromosomal recombination that removes the redundant sequences and leaves the mutation. A limitation to this approach is that the second homologous recombination event occurs only infrequently. A more efficient method is to use a replacement construct containing the subtle mutation and then remove the positive selectable marker, which is flanked by *loxP* sites, using the Cre recombinase system (Fig. 23.1.6). This is

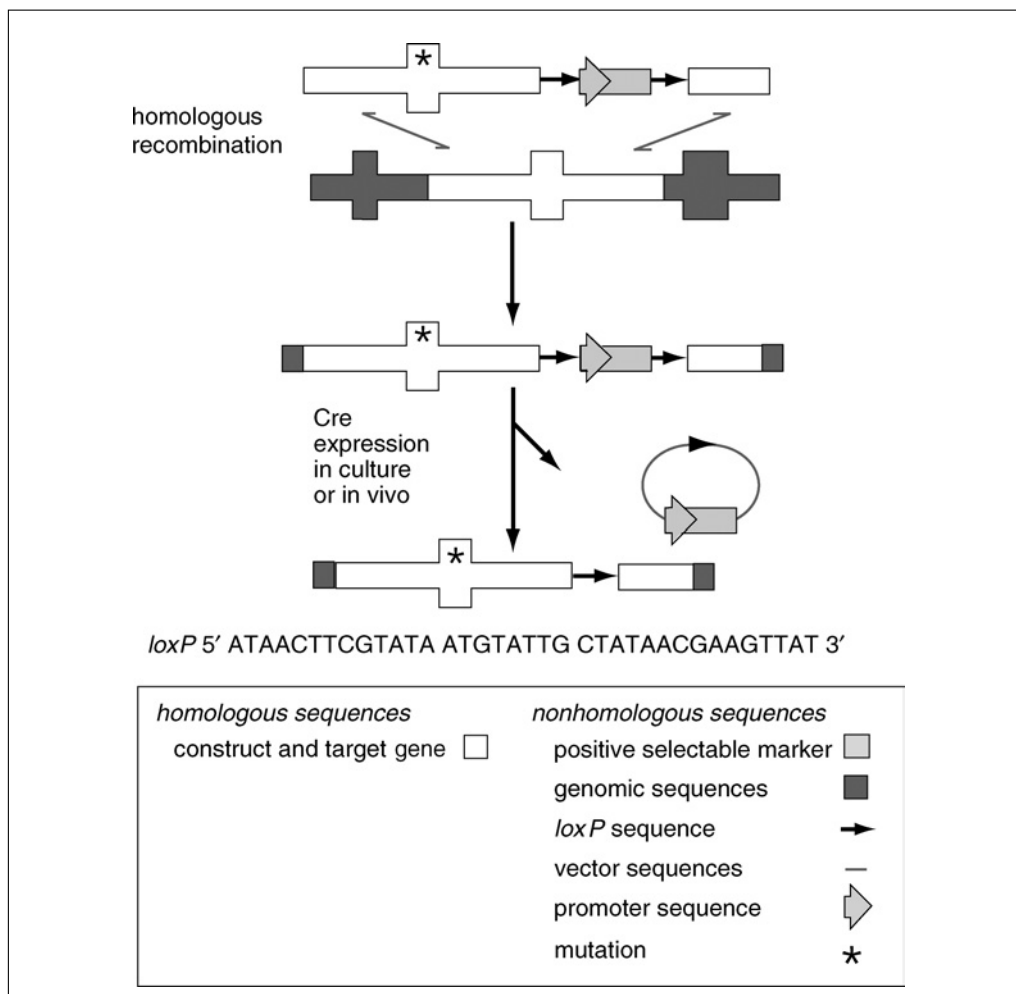

Figure 23.1.6 Using the Cre/*loxP* system to introduce subtle mutations. The subtle mutation is introduced along with the selectable marker in the targeting vector. The selectable marker is then removed by transient expression of Cre, which leaves only the subtle mutation and the small *loxP* site in a silent location.

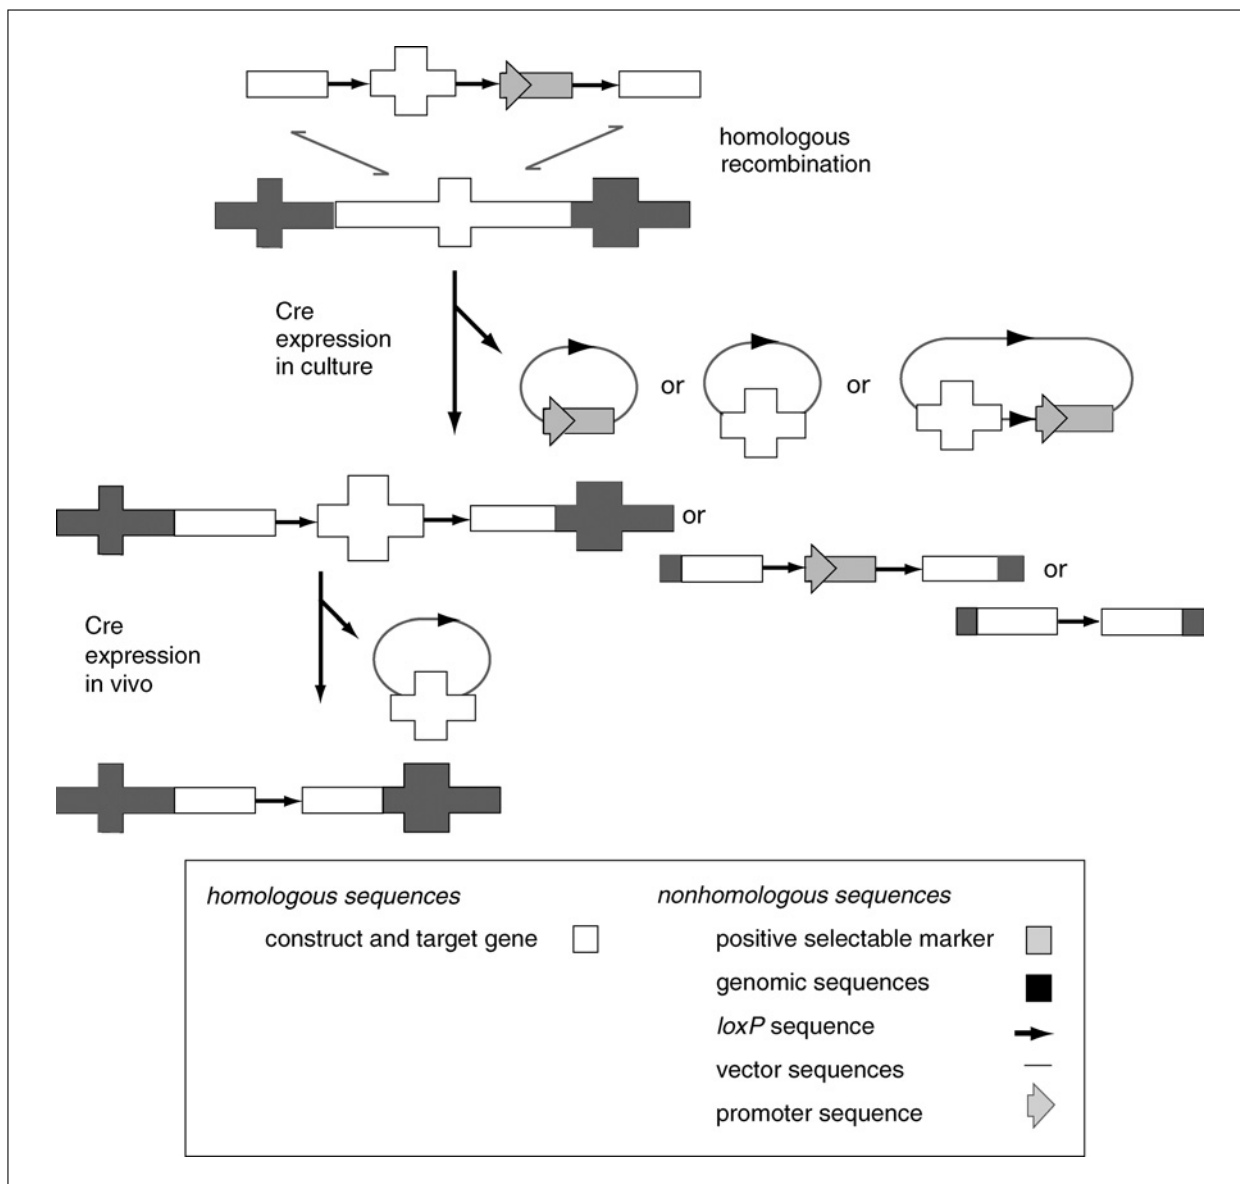

Figure 23.1.7 Conditional gene targeting using the *Cre/loxP* system. The targeting vector contains three *loxP* sites that flank the regions of the gene to be removed and the positive selectable marker *neo*. After homologous recombination is obtained, the selectable marker is excised from the gene by transient expression of Cre. The correct recombination is identified by screening by Southern analysis or PCR. The mutant ES cells are then used to produce a transgenic animal, which is finally bred to an animal line expressing Cre under either temporal or spatial control. Cre can also be ubiquitously expressed to obtain a knockout in all tissues, including the germ line.

identical in effect to removing the *neo* locus after gene inactivation, except that instead of an inactive gene, the replaced sequences contain a subtly mutated version. The selectable marker sequences can be removed by transient Cre expression in culture or by breeding animals to a Cre-deleter line (Williams-Simons and Westphal, 1999), provided that the marker does not cause lethality.

Spatial Control of Knockout

Spatially controlled targeted gene inactivations can be performed in two ways. The most

common makes use of cell-specific promoters (sometimes called tissue-specific promoters, even though tissues are actually made of a number of different cell types). This approach begins with the creation of a transgenic animal that expresses Cre in only some cells using a cell-restricted promoter. A second transgenic animal line is then created by homologous recombination that contains *loxP* sites flanking a portion of the gene that is critical for activity, typically important exons (Fig. 23.1.7). Initially there are three *loxP* sites flanking this important gene region and the selectable

marker. After homologous recombination has been verified, Cre is transiently expressed and loops out regions of DNA between pairs of *loxP* sites. The resultant colonies are screened for the desired recombination (loss of the selectable marker but retention of all regions of the gene). Depending on the frequency of recombination at the site, it may be useful to use a construct that contains a negative selectable marker (such as cytosine deaminase in the example shown in Fig. 23.5.2) between the *loxP* sites along with the positive selectable marker (also see UNIT 9.5). In this way cells that have lost the markers can be selected.

While this approach was successful for many genes, the requirement for correct partial Cre recombination led to difficulties with other genes. Although recombination in vitro could go to completion, in other instances, and for unknown reasons, the desired recombination would not take place. Fortunately, use of another recombinase with its own sequence recognition sequences has simplified this technology (Fig. 23.1.8). A construct is created that uses Cre for the conditional mutation and Flp to remove the selectable marker. The removal of the selectable marker can be accomplished by Flp expression in vitro, but also by using a

Figure 23.1.8 Alternative strategy for removal of selectable marker using Flp recombinase. The selectable marker is flanked by FRT sites for recognition and removal by the Flp recombinase allowing generation of a gene with only the *loxP* sites remaining. Otherwise the strategy is similar to that in Figure 23.1.7.

Figure 23.1.9 (A) Spatial control of Cre activity. Cre-mediated cell type–specific knockout relies on the production of a transgenic mouse expressing Cre only in the cell type of interest. By breeding these animals to an animal containing the construct with *loxP* sites flanking a critical region of the gene (called a “floxed” gene, for “flanking *lox*”), recombination occurs only in the cell types expressing Cre. The remainder of cells continue to express the target gene since the *loxP* sites typically do not alter expression. (B) Temporal control of Cre activity. In the absence of tamoxifen, the fusion protein is sequestered in the cytoplasm bound to heat-shock proteins (HSP). When tamoxifen is added, the fusion protein is released and translocates to the nucleus, where it is active for recombination. Abbreviations: ER, estrogen receptor; TM, tamoxifen.

Flp-deleter line (Rodriguez et al., 2000) after germline transmission. In vivo deletion has the advantage of minimizing the manipulation of the ES cell line, which can decrease germline transmission.

The targeted line will have normal expression of the targeted gene, since its only modification is the presence of *loxP* sites in innocuous sites (e.g., introns). When the two lines are bred together, the Cre recombinase will loop out the DNA—inactivating the gene—only in those cells where it is expressed (Fig. 23.1.9A). In this way, tissue-specific knockouts of a number of genes have been generated (Gu et al., 1994; Agah et al., 1997). The method also has the advantage that, once a transgenic line is generated with the desired restricted expression of Cre, the approach can be applied to a number of targeted lines. In addition, it is not necessary to make separate constructs for a restricted and a complete knockout, since Cre-expressing lines (called deleter lines) have been made that will produce re-arrangement in all tissues when bred to the targeted line (Schwenk et al., 1995).

Another way of spatially controlling knock-out is to use an expression system for Cre that can be applied to absolute location. In some cases, no restricted expression pattern is known for a gene that matches the desired spatial alteration; in others, the site may be particularly amenable to viral manipulation (as with an epithelial or endothelial surface) or accessible by direct injection (such as stereotactic injection of the central nervous system). By using a viral vector to express the Cre protein, it is possible to obtain knockouts that are spatially limited by the viral infection. This strategy has been applied to a number of tissues including the brain, liver, colon, and heart (Rohlmann et al., 1996; Wang et al., 1996; Agah et al., 1997; Shibata et al., 1997; van der Neut, 1997).

More refined spatial control has been achieved by using a combination of Cre and Flp in overlapping expression patterns. Effective recombination is achieved only where both recombinases are expressed (Awatramani et al., 2003).

Temporal Control of Knockout

In many cases, the phenotype of interest is in the adult animal but, because the gene is necessary for development, no adult animals are obtained. Delaying the expression of Cre activity until the animal is an adult would allow normal development, and then the knockout could be created in the adult (Rajewsky et al., 1996). This can be accomplished by using a conditional expression system (e.g., the tet-on, tet-off, or ecdysone systems; see *UNIT 16.14* and St-Onge et al., 1996) or other inducible system (such as an interferon-inducible promoter; Kuhn et al., 1995) to express Cre at the proper time. This would, however, require the construction of animals containing three transgenes. Another approach that has been used is the creation of a fusion protein with either a modified estrogen receptor (Feil et al., 1996, 1997; Zhang et al., 1996; Brocard et al., 1997) or a modified glucocorticoid receptor (Brocard et al., 1998). The estrogen receptor (ER) has been mutated so that it no longer responds to endogenous estrogens, but is activated by the administration of the partial estrogen agonist tamoxifen (Fig. 23.1.9B). Temporal control using Flp/FRT has also been achieved using a fusion of Flp with a modified estrogen receptor (Hunter et al., 2005).

Mouse Embryo Fibroblast (MEF) Feeder Cell Preparation

UNIT 23.2

The production of mouse mutants using homologous recombination and blastocyst-mediated transgenesis requires the maintenance of mouse embryonic stem (ES) cells in an undifferentiated state. Many investigators rely on feeder layers to prevent ES cell differentiation; feeder layers prepared from mitotically inactivated primary mouse embryo fibroblasts (MEFs) are used most commonly. This unit describes a simple method to isolate and store MEFs (Basic Protocol 1 and Support Protocol) and two common techniques for mitotic inactivation: γ -irradiation (Basic Protocol 2) and mitomycin C treatment (Alternate Protocol).

NOTE: All cell culture incubations are performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

ISOLATION OF PRIMARY MOUSE EMBRYO FIBROBLASTS

**BASIC
PROTOCOL 1**

MEFs are isolated from 12.5 to 13.5 postcoitum (p.c.) mouse embryos. The embryos are dissociated and then trypsinized to produce single-cell suspensions. After expansion, aliquots can be frozen and stored in liquid nitrogen indefinitely. Alternatively, MEFs suitable for ES cell culture may be obtained from commercial sources (see <http://www.biosupplynet.com> for a current list of suppliers). Commercial MEFs may be useful to researchers new to ES cell culture or to those who will grow ES cells on a limited scale.

Materials

Mouse embryos, 12.5 to 13.5 days postcoitum (Hogan et al., 1994)

DPBS (see recipe), sterile

Trypsin/EDTA solution (see recipe)

MEF medium (see recipe) with penicillin/streptomycin

Laminar flow hood

Inverted microscope

100-mm tissue culture dish

Dissecting forceps and fine scissors, sterilized by autoclaving or ethanol flaming

10-ml syringe and 16-G needle

100-mm tissue culture plates or 75-cm² flasks

Additional reagents and equipment for passaging and freezing MEFs (see Support Protocol)

1. Dissect mouse embryos (12.5 to 13.5 days postcoitum) into 10 to 20 ml sterile DPBS in a 100-mm tissue culture dish. Process embryos from one mouse together. Remove embryonic internal organs from the abdominal cavity using dissecting forceps. Transfer the carcass to a clean dish with fresh DPBS.

Organ removal can be done crudely. Initial dissection can be performed at the bench. Subsequent procedures should be performed in a laminar flow hood.

Any mouse strain can be used as an embryo source. However, outbred mice or F1 hybrids will usually produce more embryos per mating than inbred mice. If possible, use mice maintained in a viral-antibody-free (VAF) facility to reduce the chance of contamination. If the feeder cells will be used during the selection of antibiotic-resistant ES cells, use embryos from a transgenic mouse expressing the appropriate selectable marker. Appropriate transgenic mice may be obtained from the ES cell community or from standard mouse vendors such as The Jackson Laboratory and Taconic.

Supplement 51

2. Rinse embryos again in 10 to 20 ml DPBS. Transfer the embryos to a clean 100-mm tissue culture dish containing 3 to 5 ml trypsin/EDTA solution.
3. Dissociate embryos by aspirating into a 10-ml syringe through a 16-G needle and expelling the contents. Repeat two to four times.

Too many repetitions will reduce the cell yield. The embryos should be dissociated to the extent that they can be easily aspirated into a 5- or 10-ml pipette.

4. Add trypsin/EDTA solution to 10 ml. Mix contents by trituration, return to dish, and incubate 5 to 10 min in a 37°C incubator.
5. Mix again by trituration and incubate for an additional 5 to 10 min at 37°C.
6. Transfer contents to a 50-ml conical tube and add an equal volume of MEF medium with penicillin/streptomycin. Let stand 3 to 5 min at room temperature to allow large tissue pieces to settle to the bottom.
7. Remove solution, avoiding large tissue pieces, and place in a fresh 50-ml tube. Centrifuge 5 min at 1000 × g, room temperature.
8. Remove supernatant and resuspend pellet in 10 to 50 ml fresh MEF medium with penicillin/streptomycin. Plate cells on 100-mm tissue culture plates or 75-cm² flasks, using approximately one embryo per plate or flask. Add medium to a final volume of 10 to 15 ml/plate.
9. Grow cells until confluent (2 to 5 days). Monitor cell density using an inverted microscope. Change medium after the first day and every other day thereafter.
10. Passage cells by trypsinizing (see Support Protocol, steps 1 to 4), resuspending the cell pellet in 10 to 50 ml MEF medium with penicillin/streptomycin, and plating at a dilution of 1:5 to 1:10. Add medium to a final volume of 10 to 15 ml per 75-cm² flask or 10-mm plate.

Using this dilution, fibroblasts from each original embryo are now plated on five to ten 75-cm² flasks or 100-mm plates.

11. Grow again until confluent (3 to 5 days) and freeze (see Support Protocol, steps 1 to 7) at $\sim 5 \times 10^6$ cells/ml.

A representative vial should be thawed to check for viability. It is also a good habit to check each new batch for mycoplasma contamination using a commercial service or a PCR-based screening kit (e.g., Pan Vera, Stratagene; also see Coté, 2000). In addition, MEFs made from previously untested transgenic mice should be grown in the appropriate antibiotic to ensure that they are resistant to the concentration of antibiotic used for selection.

BASIC PROTOCOL 2

MITOTIC INACTIVATION OF MEFS WITH γ -IRRADIATION

MEFs must be inactivated prior to use as a feeder layer for mouse ES cells. Mitotic inactivation prevents the dilution of ES cell lines with dividing fibroblasts. MEFs can be inactivated using γ -irradiation, as described here, or mitomycin C treatment (see Alternate Protocol). This procedure is faster and less labor intensive, but requires a convenient radiation source. Both methods produce feeder layers suitable for the maintenance of undifferentiated ES cells.

Materials

- Frozen MEF culture (see Basic Protocol 1)
- MEF medium (see recipe) without penicillin/streptomycin
- Ca²⁺- and Mg²⁺-free HBSS (see recipe)

100-mm tissue culture plates or 75-cm² flasks

150-cm² tissue culture flasks

100-mm Petri dishes

γ-Radiation source

Additional reagents and equipment for passaging, freezing, and thawing MEFs
(see Support Protocol)

1. Thaw a vial of frozen MEFs as described below (see Support Protocol, steps 8 to 10) and plate in a 75-cm² tissue culture flask or 100-mm plate. Grow until confluent (3 to 5 days). Change medium after the first day and every other day thereafter.
2. Passage cells by trypsinizing (see Support Protocol, steps 1 to 4), resuspending the cell pellet in 10 to 50 ml MEF medium without penicillin/streptomycin, and plating at a 1:10 dilution. Add medium to a final volume of 10 to 15 ml per 75-cm² flask or 100-mm plate.
3. Grow until confluent (3 to 5 days), and passage at a 1:5 to 1:10 dilution, using twenty-five to fifty 150-cm² flasks.

Primary fibroblasts undergo a limited and variable number of cell divisions. Further passaging may be possible, but the rate of cell division slows quickly. Thawing a fresh vial is usually the fastest way to generate more feeders.

4. Remove medium from confluent flasks, rinse with 15 ml Ca²⁺- and Mg²⁺-free HBSS, and trypsinize again (see Support Protocol, steps 1 to 4).

MEFs from ten to fifteen 150-cm² flasks can be processed together.

5. Resuspend pellet in 10 ml MEF medium without penicillin/streptomycin and transfer suspension in a 100-mm Petri dish.

Use a constant volume of medium regardless of the number of cells to ensure consistent results. Use a Petri dish rather than a cell culture plate to prevent adherence of the MEFs to the surface during irradiation.

6. Expose cells to 4000 rads from a γ-radiation source.
7. Dilute suspension to 50 ml with MEF medium without penicillin/streptomycin. Count the number of cells and freeze as described below (see Support Protocol, steps 4 to 7).

MITOTIC INACTIVATION OF MEFS WITH MITOMYCIN C

MEFs may be inactivated by mitomycin C treatment if a γ-radiation source is not available. Although this method is more time and labor intensive, the inactivated feeders are equally suitable for ES cell culture.

Additional Materials (also see Basic Protocol 2)

1 mg/ml mitomycin C (Sigma) stock solution, filter sterilized (store at 4°C protected from light)

1. Expand a vial of MEFs as described above (see Basic Protocol 2, steps 1 to 3).
2. Add 1 mg/ml mitomycin C stock solution to the medium to a final concentration of 10 μg/ml. Return plates to the incubator for 2 to 3 hr.
3. Rinse plates twice with 10 to 15 ml Ca²⁺- and Mg²⁺-free HBSS.
4. Trypsinize as if passaging (see Support Protocol, steps 1 to 4).

**ALTERNATE
PROTOCOL**

**Manipulating the
Mouse Genome**

23.2.3

5. Add an equal volume of MEF medium without penicillin/streptomycin.
6. Count and freeze cells (see Support Protocol, steps 4 to 7).

FREEZING AND THAWING MEFs

Freezing MEFs, particularly inactivated fibroblasts, is a great convenience. Large stocks of active or inactivated fibroblasts can be prepared at any time, obviating the need to coordinate MEF preparations with ES cell manipulations. Cells are frozen slowly in medium containing 10% (v/v) dimethyl sulfoxide and thawed rapidly.

Materials

Plates containing MEFs (see Basic Protocols 1 and 2; see Alternate Protocol)
Ca²⁺- and Mg²⁺-free HBSS (see recipe)
Trypsin/EDTA solution (see recipe)
Freezing medium (see recipe)
MEF medium (see recipe) with or without penicillin/streptomycin
Cryovials
Additional reagents and equipment for counting cells with a hemacytometer
(APPENDIX 3F)

Freeze cells

1. Remove MEF medium and rinse plates with 10 to 15 ml Ca²⁺- and Mg²⁺-free HBSS.

Washing the plates removes residual serum that will inhibit trypsin.

2. Remove HBSS and add trypsin/EDTA solution to cover the surface of the cells (e.g., 3 to 5 ml in a 75-cm² flask). Incubate 3 to 5 min at 37°C and tap the flask to release the cells.

When trypsinization is complete, tapping and rocking the plate should release the cells. Loose sheets of cells are visible to the naked eye. Incubate at 37°C for an additional 1 to 2 min if the cells do not slough off.

3. When the cell layer has loosened, add an equal volume of MEF medium and mix by trituration to produce a single-cell suspension.

MEF medium should contain penicillin/streptomycin when preparing initial MEFs (i.e., Basic Protocol 1, step 10), but not for other protocols. Addition of medium containing serum will inhibit further trypsinization.

4. Count cells using a hemacytometer (APPENDIX 3F) and then pellet by centrifuging 3 to 5 min at 1000 × g, room temperature.
5. Resuspend pellet at 3 × 10⁶ cells/ml in freezing medium and mix by trituration.
6. Dispense into cryovials in 1-ml aliquots, place cryovials in an insulated container at -80°C, and leave overnight.

Under these conditions, the cells will freeze slowly enough to maintain viability.

7. Transfer cryovials to liquid nitrogen.

Cells should not be quick-frozen in liquid nitrogen. Vials can be stored at -80°C for several months and in liquid nitrogen for years.

Thaw cells

8. Thaw cells rapidly by placing vials in a 37°C water bath.

9. Add cells to a tube with 10 ml MEF medium without penicillin/streptomycin. To remove DMSO, pellet by centrifuging 3 to 5 min at $1000 \times g$, room temperature.
10. Resuspend in a volume appropriate for the surface area of the plate (e.g., 10 to 15 ml for a 75-cm^2 flask or 100-mm plate).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

NOTE: Prepare all cell culture solutions from tissue culture–grade reagents. Use tissue culture–grade water (high resistance and endotoxin free). Sterilize all final solutions by filtration or prepare from sterile stocks. Use disposable sterile plasticware to prevent microbial and detergent contamination.

Dulbecco's phosphate-buffered saline (DPBS)

0.1 g/liter anhydrous CaCl_2
0.1 g/liter $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$
0.2 g/liter KCl
0.2 g/liter KH_2PO_4
8.0 g/liter NaCl
2.16 g/liter $\text{Na}_2\text{HPO}_4 \cdot 7\text{H}_2\text{O}$
Adjust pH, if necessary, to 7.0 to 7.2 with 1 N HCl or 1 N NaOH
Sterilize by filtration or by autoclaving
Store at 4°C (stable indefinitely)

Freezing medium

Dulbecco's modified Eagle medium (DMEM) with high glucose (4500 mg/liter), L-glutamine, sodium pyruvate, and pyridoxine hydrochloride or pyridoxal hydrochloride (e.g., Life Technologies, JRH Biosciences, or Sigma) containing:
20 mM HEPES, pH 7.3
20% (v/v) FBS, heat inactivated for 30 min at 56°C
10% (v/v) dimethyl sulfoxide (DMSO)
Store up to 1 year at -20°C

Freezing and thawing should be avoided. Commercial freezing media based on 10% DMSO can be used. Consult UNIT 23.3 regarding the selection of FBS.

Hank's balanced salt solution (HBSS), Ca^{2+} and Mg^{2+} free

0.4 g/liter KCl
0.06 g/liter KH_2PO_4
8.0 g/liter NaCl
0.35 g/liter NaHCO_3
0.048 g/liter Na_2HPO_4
1 g/liter D-glucose
0.01 g/liter phenol red
Adjust pH, if necessary, to 7.0 to 7.4 with 1 N HCl or 1 N NaOH
Store up to 6 months at 4°C

Mouse embryo fibroblast (MEF) medium

Dulbecco's modified Eagle medium (DMEM) with high glucose (4500 mg/liter), L-glutamine, sodium pyruvate, and pyridoxine hydrochloride or pyridoxal hydrochloride (e.g., Life Technologies, JRH Biosciences, or Sigma) containing:
10% (v/v) FBS, heat inactivated for 30 min at 56°C
1× MEM nonessential amino acids (from 100× stock; Life Technologies)
2 mM L-glutamine (from 100× stock; Life Technologies)
0.1 mM 2-mercaptoethanol
20 mM HEPES, pH 7.3
1× penicillin/streptomycin when indicated (from 100× stock; Life Technologies)
Store up to 2 weeks at 4°C

Consult UNIT 23.3 regarding the selection of FBS. Penicillin/streptomycin should be included during the initial isolation of MEFs. It is not needed after Basic Protocol 1.

Trypsin/EDTA solution

Ca²⁺- and Mg²⁺-free HBSS (see recipe) containing:
2.5 g/liter porcine trypsin (0.25%)
0.38 g/liter EDTA·4H₂O
Store aliquots up to 1 year at -20°C

Aliquots can be thawed and stored at 4°C for up to 1 week. Repeated freezing and thawing should be avoided.

COMMENTARY

Background Information

Historically, ES cells have been cultured under a variety of conditions to prevent differentiation (Wurst and Joyner, 1993; *UNIT 23.3*). The most common method utilizes feeder layers prepared from mouse embryo fibroblasts or from SIM mouse embryo fibroblasts resistant to thioguanine and ouabain (STO cells; Hogan et al., 1994; Martin and Evans, 1975). Whereas MEFs are primary cultures with a limited mitotic potential, STO fibroblasts will divide indefinitely. STO cells resistant to G418 are readily available from the ES cell community. STO cells can be grown and inactivated using the protocols for MEFs. For more details see Robertson (1987), Wurst and Joyner (1993), or Hogan et al. (1994).

The advantage of MEFs is that they provide a more consistent source of feeder cells. Early passage cells with reproducible characteristics must be used because they rapidly lose their ability to divide. Long-term propagation of STO cells can lead to changes that result in characteristics that are less favorable for ES cell growth. Because of these potential problems, researchers who are new to ES cell culture and who wish to generate ES cell clones capable of germ-line transmission will probably have more success with primary MEFs.

Critical Parameters and Troubleshooting

The major problems encountered during the isolation and inactivation of MEFs are typically a result of poor aseptic technique, low cell yields during isolation, or inefficient mitotic inactivation. Special attention should be paid to the use of aseptic technique. After the initial primary cultures have been frozen, antibiotics should not be used; antibiotics can mask bad aseptic technique. Each new batch of MEFs should be checked for mycoplasma after growth without antibiotics (Coté, 2000). Inadvertent contamination will spread to ES cells and reduce their germ-line potential. Contaminated batches should be disposed of; it is best not to try to treat them. Contamination should be a rare occurrence.

Aseptic technique is also important in the preparation of media and solutions. All solutions should be prepared using tissue culture-grade reagents and water (high resistance and endotoxin free). Although they are more expensive, solutions that have been screened for toxicity and mycoplasma are available from many companies. Laboratories with little cell culture experience will probably have the greatest success with commercial, prescreened solutions.

Occasionally low cell yields are observed after the initial embryo dissociation. Plates from the initial dissociation should reach con-

fluence in 2 to 5 days. If this does not occur, it is likely due to low trypsin activity or cell lysis during dissociation with the needle and syringe. Some cells may be recovered by passaging without dilution or by concentrating the cells from several plates onto a single plate. Under these circumstances, the cells may still be used as long as they resume dividing and reach confluence. During future preparations, fresh trypsin solutions should be used and the number of times each embryo is passed through the needle should be reduced.

Occasionally evidence of cell division is observed in cultures of mitotically inactivated MEFs. When preparing inactivated feeders for the first time, check to make sure that the treatment was effective. This can be accomplished by plating out an aliquot of the inactivated feeders at a density of $\sim 6 \times 10^4$ cells/cm². The cells are then cultured for 10 to 14 days, with periodic changes of medium, and cultures are assessed for increases in cell density and foci of mitotic activity. Foci can be observed by eye as opaque splotches on the plate, but should be confirmed with a microscope. No growth should be seen on a 100-mm plate; however, feeders may still be used if there are only a few foci. If there is a dramatic change in cell density or there are many colonies of dividing cells, the preparation should be discarded and the procedure repeated with newly expanded cells. If mitomycin C was used, a fresh solution should be prepared. If γ -irradiation was used, the radiation source should be properly calibrated. Distance and shielding can affect the dose dramatically.

In addition to these concerns, it is important to remember that MEFs are primary cells with limited mitotic potential. Expanding the cells more than suggested may work, but the rate of growth will decrease. Plates can still become confluent because the cell size will increase; however, the number of cells per plate will decrease and the time to reach confluence will increase. Feeder layers made under these conditions may not be ideal for ES cell culture.

Anticipated Results

Expect 10 to 30 vials of frozen cells from each embryo. Each vial can be expanded to produce 50 to 100 vials containing 1 ml of mitotically inactive feeders. Each vial should be sufficient for one targeting experiment.

Time Considerations

Processing a single litter of embryos (six to ten) should take 1 to 2 hr. After plating the dissociated embryos, cultures should reach confluence within 2 to 5 days. Cells can be frozen at this point, but the total yield will be dramatically reduced. After passaging, the cells should be ready to freeze in 3 to 5 days. Thawed vials should reach confluence in 3 to 5 days. After each passage the cells should take 3 to 5 days to reach confluence. The cells can be inactivated at any stage, but the yield will be lower with less expansion.

Mouse Embryonic Stem (ES) Cell Culture

UNIT 23.3

**BASIC
PROTOCOL**

Culturing mouse embryonic stem (ES) cells has many similarities to the culture of any adherent cell line. However, there are some special concerns that warrant elaboration because ES cells must not be allowed to differentiate if they are to be used to generate germ-line chimeras. This unit describes a common method for ES cell culture utilizing gelatinized plates, feeder layers of mitotically inactive mouse embryo fibroblasts (MEFs; UNIT 23.2), and recombinant leukemia inhibitory factor (LIF). Special attention is paid to the timing of passaging to prevent differentiation during routine culture.

NOTE: All cell culture incubations are performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

Materials

- 0.1% (w/v) gelatin solution (see recipe)
- Mitotically inactive mouse embryo fibroblasts (MEFs; UNIT 23.2)
- ES cell medium (see recipe)
- Embryonic stem (ES) cells (<http://www.biosupplynet.com>)
- Ca²⁺- and Mg²⁺-free HBSS (UNIT 23.2)
- DPBS/EDTA solution (see recipe)
- Trypsin/EDTA solution (see recipe)
- Freezing medium (UNIT 23.2)
- Cryovials

- Additional reagents and equipment for counting cells with a hemacytometer (APPENDIX 3F)

Prepare gelatin-coated plates

1. Pipet a sufficient volume of 0.1% gelatin solution onto plates to cover the bottom of the plate.
2. Leave the solution on the plate for ≥1 hr at room temperature or in a 37°C incubator.
The temperature is not critical. Plates can be prepared in advance by adding the gelatin solution and storing the plate in the incubator (to prevent drying) for up to a week.

Prepare feeder plates

3. Aspirate gelatin solution just before adding feeder cells.
4. Plate mitotically inactive MEFs (feeders) in ES cell medium on gelatinized plates at ~6 × 10⁴ viable cells/cm². Place cells in the incubator.

Either freshly inactivated MEFs or frozen inactivated MEFs can be used. Frozen cells should be thawed rapidly at 37°C and DMSO should be removed (see UNIT 23.2). Note that some cell death occurs during the freezing and thawing procedure. Frozen MEFs should thus be plated at approximately twice the density (1.2 × 10⁵ cells/cm²) of fresh MEFs (6 × 10⁴ cells/cm²) to achieve a similar density of viable feeders. If the density is too high, the cells may lift off the plate.

Feeders can be plated in either ES medium or MEF medium (see UNIT 23.2). Both have similar components, and it is often more convenient to prepare only one. The feeders attach to the plate within 30 min and begin to spread out over the next few hours.

5. Change medium to remove dead feeders the next day.

The fibroblasts should spread to cover the entire surface of the plate by the day after plating.

Feeder plates can be prepared in advance and used for routine ES cell culture within 7 to 10 days after plating. The medium should be changed every other day if they are not used immediately.

Supplement 51

Culture ES cells

6. Thaw a vial of ES cells rapidly at 37°C. Remove DMSO by diluting in 10 ml ES cell medium and centrifuging 3 to 5 min at 1000 × g, room temperature.
7. Resuspend pellet in ES cell medium and plate on feeder layers prepared at least one day earlier.

The number of ES cells depends on the surface area of the feeder plate. Plate 1–3 × 10⁶ cells on a 25-cm² flask or a 60-mm plate. Plate cells frozen at a higher density on 75-cm² flasks or 100-mm plates, and fewer cells in 6- or 24-well feeder plates.

8. Change medium daily and passage cells every 2 to 3 days depending on total cell density and colony size (see Critical Parameters and Troubleshooting for more details).

Cells may require passaging the day after plating if the cell density is very high.

Passage ES cells

9. Change medium several hours before passaging to maximize plating efficiency.
10. Rinse plates with Ca²⁺- and Mg²⁺-free HBSS (e.g., 10 ml per 100-mm plate).

Washing the plates removes residual serum that will inhibit trypsin.

11. Add sufficient DPBS/EDTA solution to cover the cells and incubate 3 min at 37°C.
12. Add an equal volume of Trypsin/EDTA solution. Rock the plate to mix and return to the incubator for 1 to 2 min.
13. Tap the plate to release the cells. If the cells do not slough off, return the plate to the incubator for another minute and tap again.

Alternatively, the DPBS/EDTA step can be skipped, and the plate can be incubated for 3 to 7 min after addition of trypsin/EDTA, with periodic tapping to see if the cell layer has loosened. With either approach, the goal is to achieve a single-cell suspension with minimal trypsinization. Preincubation with DPBS/EDTA reduces the time necessary for trypsin treatment and yields the same degree of dispersion.

14. When the cell layer has loosened, add 2 to 3 vol ES cell medium and disperse the cells thoroughly by trituration.
15. Centrifuge 3 to 5 min at 1000 × g, room temperature. Resuspend the pellet in ES cell medium and plate on feeders at a 1:10 dilution.

Freeze cells

16. Trypsinize cells (steps 9 to 13).
17. Add an equal volume of ES cell medium and mix by trituration to produce a single-cell suspension.

Addition of medium containing serum will inhibit further trypsinization.

18. Count cells using a hemacytometer (*APPENDIX 3F*) and then pellet by centrifuging 3 to 5 min at 1000 × g, room temperature.
19. Resuspend pellet at 3 × 10⁶ cells/ml in freezing medium and mix by trituration.
20. Dispense into cryovials in 1-ml aliquots, place the cryovials in an insulated container at –80°C, and leave overnight.

Under these conditions, the cells will freeze slowly enough to maintain viability.

21. Transfer cryovials to liquid nitrogen.

Cells should not be quick-frozen in liquid nitrogen. Vials can be stored at –80°C for several months and in liquid nitrogen for years.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see *APPENDIX 2*; for suppliers, see *APPENDIX 4*.

NOTE: Prepare all cell culture solutions from tissue culture–grade reagents. Use tissue culture–grade water (high resistance and endotoxin free). Sterilize all final solutions by filtration or prepare from sterile stocks. Use disposable sterile plasticware to prevent microbial and detergent contamination.

DPBS/EDTA solution

Prepare DPBS (*UNIT 23.2*) but without calcium and magnesium
Add 0.2 g/liter EDTA·4H₂O
Sterilize by filtration or autoclaving
Store at 4°C (stable indefinitely)

ES cell medium

Dulbecco's modified Eagle medium (DMEM) with high glucose (4500 mg/liter), L-glutamine, sodium pyruvate, and pyridoxine hydrochloride or pyridoxal hydrochloride (e.g., Life Technologies, JRH Biosciences, or Sigma) containing:
15% (v/v) FBS, heat inactivated for 30 min at 56°C
1× MEM nonessential amino acids (from 100× stock; Life Technologies)
2 mM L-glutamine (from 100× stock; Life Technologies)
0.1 mM 2-mercaptoethanol
20 mM HEPES, pH 7.3
500 to 1000 U/ml murine leukemia inhibitory factor (LIF; e.g., ESGRO, Life Technologies; Chemicon)
Store up to 1 week at 4°C

The quality of FBS should be screened by assessing plating efficiency, morphology, and toxicity on ES cells plated at low density in 10%, 15%, and 30% heat-inactivated FBS. Plating efficiency should be ~10% and should be similar for all FBS concentrations. The author has had good success with FBS from Hyclone. Several companies sell FBS that has been screened for ES cell growth using the same techniques. Although it is expensive, laboratories that are new to ES cell culture may benefit from prescreened FBS. In addition, prescreened FBS provides a standard of comparison for other FBS lots.

Gelatin solution, 0.1% (w/v)

Prepare 0.1% (w/v) porcine skin gelatin (Sigma) in water and sterilize by autoclaving. Filter after cooling. Store up to 1 year at 4°C.

Trypsin/EDTA solution

Ca²⁺- and Mg²⁺-free HBSS (*UNIT 23.2*) containing:
0.5 g/liter porcine trypsin (0.05%)
0.2 g/liter EDTA·4H₂O
Store aliquots up to 1 year at –20°C

*Note that this recipe contains one-fifth the trypsin that is used for preparing MEFs (*UNIT 23.2*).*

Aliquots can be thawed and stored at 4°C for up to 1 week. Repeated freezing and thawing should be avoided.

COMMENTARY

Background Information

ES cells can be obtained from a number of investigators, from commercial sources, or by establishing new lines directly from mouse embryos (see <http://www.biosupplynet.com> for a current list of commercial suppliers). Historically, ES cells have been cultured under a variety of conditions to prevent differentiation. Lines have been successfully maintained in Buffalo rat liver (BRL) cell-conditioned medium (Smith and Hooper, 1987), in LIF-containing medium (Smith et al., 1988), and on STO or MEF feeder layers with or without LIF (Evans and Kaufman, 1981; Martin, 1981; Wurst and Joyner, 1993). ES cells may become accommodated to the culture conditions in which they were isolated; therefore, it may be advisable to modify the protocol outlined in this unit to match the growth conditions recommended for specific ES cell lines. However, most ES cell lines should do well on MEF feeder layers supplemented with LIF.

Critical Parameters and Troubleshooting

The major problems encountered during ES cell culture are contamination and differentiation. Special attention should be paid to aseptic technique. ES cells should not be cultured routinely in antibiotics. Although penicillin and streptomycin do not reduce the germ-line potential of ES cells, the antibiotics can mask bad aseptic technique. Mycoplasma contamination can reduce germ-line potential and is not eliminated by penicillin and streptomycin. Cultures should be checked periodically for mycoplasma (Coté, 2000), and contaminated cultures should be discarded. It is best not to try to treat them. Contamination should be a rare occurrence.

Aseptic technique is also important in the preparation of media and solutions. All solutions should be prepared using tissue culture-grade reagents and water (high resistance and endotoxin free). Although they are more expensive, solutions that have been screened for toxicity and mycoplasma are available from many companies. Laboratories with little cell culture experience will probably have the greatest success with commercial, prescreened solutions (<http://www.biosupplynet.com>).

ES cells grow as three-dimensional colonies, not monolayers. Undifferentiated colonies have a rounded appearance with sharp refractal edges; individual cell borders within

a colony are difficult to discern (Fig. 23.3.1A). All cultures will contain some differentiated colonies (Fig. 23.3.1B). Typically these colonies grow as monolayers with ragged edges and easily distinguishable cell borders. The appearance of ES cell colonies can change depending on total cell density and the time since passaging. To assess the quality of the culture, the cells should be observed over several days. During this period most of the colonies should be undifferentiated.

Assuming that quality reagents are used, differentiation of ES cells can be minimized by limiting the number of cell divisions and by passaging cultures at the appropriate density. It is advisable to keep track of the number of passages. New ES cell lines should be expanded with a minimum number of passages and frozen in many aliquots. A new low-passage vial should be thawed for each experiment. The passage number is relevant only because it is a rough estimate of the number of cell divisions the culture has undergone. Thus, one should not skip passaging at the appropriate density to avoid increasing the passage number. Cells should be viewed every day until their growth patterns become familiar. One day after passaging, ES cell colonies can be difficult to distinguish from cell debris on the surface of the feeder layer. By the second day, distinct colonies are apparent (Fig. 23.3.1C).

Determining the appropriate density for passaging is the most difficult aspect of ES cell culture. Both the total plate density and the individual colony size should be considered. Cells will tend to differentiate within large colonies or at very high total plate densities. For example, the cells in Figure 23.3.1C can be cultured for another day; the plate density is low and the colonies are small. The cells in Figure 23.3.1D are ready to passage; the plate density is moderate but the individual colonies are large. Although the cells seem to grow best at relatively high densities, the cells should not be allowed to become confluent; colonies should remain separated. Passaging every 2 days at a dilution of 1:8 or 1:10, when the cells are growing well, will maintain an ideal plate density and colony size. Passaging at a lower frequency is necessary when the cells are seeded at a low density. Under these conditions, it is best to pay attention to individual colony size and to passage with little dilution to disperse colonies and increase plate density.

Figure 23.3.1 Morphology of ES cell colonies. Phase-contrast images of ES cell colonies on MEF feeders. **(A)** Appearance of an ideal ES cell colony that is ready to passage. **(B)** Appearance of a differentiating ES cell colony. Note that the colony has grown as a monolayer with distinct borders between cells. The edge of the colony is not yet ragged. **(C)** Appearance of ES cell colonies, at lower magnification, 2 days after plating at low density. Colonies can be distinguished from the feeder layer by their sharp refractal borders and their three-dimensional appearance. **(D)** Appearance of ES cell colonies 3 days after plating at an intermediate density. These cells are ready to passage.

Anticipated Results

When plates are grown at maximum density, there should be $2.5\text{--}4.0 \times 10^5$ cells/cm². For routine growth, the total density should be somewhat lower (e.g., $1.5\text{--}2 \times 10^5$ cells/cm²) and the cells should be passaged every 2 days.

Time Considerations

A single vial (frozen at 3.0×10^6 cells/ml) can be expanded in ~5 days to produce enough cells for a standard electroporation ($2\text{--}4 \times 10^7$ cells). A single vial can be expanded to produce 50 to 100 vials of a low-passage stock in 7 to 8 days.

Mouse Embryonic Stem (ES) Cell Isolation

UNIT 23.4

Undifferentiated mouse embryonic stem (ES) cells are necessary for the production of mouse mutants using homologous recombination and blastocyst-mediated transgenesis. Suitable ES cell lines are available from commercial sources (UNIT 23.3) and from many investigators. However, investigators planning to use ES cells extensively may find that the isolation of new lines provides a simple and economical method for maintaining stocks of early passage ES cells. In addition, ES cells obtained from mutant mouse lines may facilitate the analysis of mutant phenotypes, particularly when the mutation causes early embryonic lethality.

ISOLATION OF MOUSE ES CELLS

ES cell isolation is straightforward, although success rates can be quite variable. ES cells are derived from the inner cell mass of blastocysts (i.e., 3.5-day-old embryos). Blastocysts are simply cultured for several days, during which time they attach to the surface of the tissue culture plate. Both trophoblast and inner cell mass cells divide after attachment. Inner cell mass outgrowths are picked, dispersed by trypsinization, and replated. Under appropriate conditions a percentage of the isolated outgrowths will continue to divide and maintain an undifferentiated ES cell morphology.

**BASIC
PROTOCOL**

Materials

- Modified ES medium (see recipe)
- Blastocysts, 3.5-day-old post-coitum embryos (Hogan et al., 1994)
- Hanks' balanced salt solution (HBSS), calcium- and magnesium-free (UNIT 23.2)
- DPBS-EDTA (UNIT 23.3)
- 0.25% (w/v) trypsin-EDTA (UNIT 23.2)
- Inverted microscope
- Gilson-style automatic pipettor with 20- μ l pipet tips
- 96-well U-bottom plate
- Additional reagents and equipment for preparing gelatin-coated plates with MEF feeder layers for embryonic stem cell culture (UNIT 23.3) and for passaging and freezing embryonic stem cells (UNIT 23.3)

NOTE: All cell culture incubations are performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

Plate out embryos

1. Prepare gelatinized 24-well tissue culture plates with mitotically inactivated MEF (mouse embryo fibroblast) feeder layers as described in UNIT 23.3.

Plates can be prepared a few hours in advance or the day before.

2. Replace medium in each well with modified ES medium prior to use. Drop individual blastocysts into separate wells and return plates to incubator.

Aim for the center of the well, otherwise the blastocysts will be difficult to observe with the microscope because of distortion near the edge of wells.

3. Observe embryos daily with an inverted microscope.

The majority of blastocysts will hatch from the zona pellucida and attach to the plate by the second or third day. Figure 23.4.1A shows an attached blastocyst approximately 48 hr after plating. The zona pellucida is not present. In this early stage, the embryo still retains its original shape.

**Manipulating the
Mouse Genome**

23.4.1

Supplement 52

Figure 23.4.1 Morphology of plated blastocysts as shown in phase-contrast images of blastocysts at various time points after plating on MEF feeder cells. **(A)** Appearance of a blastocyst shortly after attachment to the plate ~48 hr after plating. **(B)** Typical appearance of a blastocyst 3 to 4 days after plating. Note the expansion of inner cell mass and trophoblast cells spreading out beneath. **(C)** Typical appearance of blastocyst ready to pick. **(D)** Appearance of a blastocyst that has been left on the plate 1 day too long. Note the pigmentation on the top surface indicating substantial differentiation.

4. Change medium after embryos have attached to the plate.

The trophoblast cells will spread out quickly under the embryo. Over the next several days the inner cell mass will begin to expand. Figure 23.4.1B shows the inner cell mass at an early stage of expansion. Note the large flattened trophoblast cells under the inner cell mass. The inner cell mass is expanding as a multilayered colony.

Pick inner cell mass outgrowths

Approximately 5 or 6 days after plating, the inner cell mass outgrowths will be ready to disperse. Figure 23.4.1C shows an outgrowth ready to pick. Figure 23.4.1D shows an outgrowth that has been left too long. If the outgrowth is left on the plate for too long, the cells begin to differentiate. This is typically observed as an accumulation of pigmented cells on the top of the colony. Round, loosely attached cells may also appear on the top of the outgrowth as differentiation occurs. Outgrowths should be picked before significant pigment accumulates. Outgrowths with a small amount of differentiation should still be dispersed, because they can yield decent lines.

5. Prepare gelatinized 24-well plates with feeder cells in advance with enough wells for each of embryo (UNIT 23.3).

6. Replace medium in embryo cultures 2 to 4 hr prior to picking.

This is thought to maximize plating efficiency.

7. Rinse wells with Hanks' balanced salt solution (HBSS, calcium- and magnesium-free). After aspirating, add a small volume of HBSS to wells to keep the cell layer from drying out.

Process only a few wells at a time.

8. Pick up inner cell mass outgrowth using an automatic pipettor with a 20- μ l tip and place the cell clump in a well of a 96-well U-bottom plate containing 25 μ l DPBS-EDTA in each well.

Try to transfer the cell mass in a minimal volume (i.e., $\leq 5 \mu$ l). Some investigators find that picking is more easily performed using an inverted microscope with a low-power objective or a dissecting microscope. However, the cell mass can be seen by eye at this stage. With some practice, picking by eye is less tedious than picking with a microscope. In either case, the outgrowth can be dislodged by scraping the tip of the pipet around the cell mass to tear the trophoblast and MEF layer. Then, the inner cell mass can be picked up by simultaneously nudging the clump with the pipet tip and releasing the pipet plunger to aspirate the cells. It does not matter if some fibroblasts and trophoblasts are transferred with the inner cell mass. After placing the cells in the 96-well plate, check under the microscope to verify that the picking procedure was successful.

9. Add 50 μ l of 0.25% trypsin-EDTA to each cell containing well of the 96-well plate and place in incubator for 5 to 10 min.

Do not pick too many at one time. The first outgrowth picked should not sit in PBS-EDTA for longer than 10 min prior to addition of trypsin.

10. Add 100 μ l modified ES medium to each well to inhibit trypsin. Triturate 3 to 10 times using a Gilson-style pipettor with 200- μ l tips. Transfer cells to a new 24-well feeder plate.

Try to disperse the outgrowth into several small clumps. Check with microscope to determine the degree of dispersal. Differentiation will occur if cells are not dispersed. However, do not try to achieve a single-cell suspension; trypsinization and trituration sufficient to achieve single-cell suspension usually kills cells at this stage.

Screen and expand putative ES cell lines

11. Monitor plates daily (within 2 days after plating, colonies should be visible). Mark the wells with ES cell-like colonies and observe their morphology on successive days.

Look for ES cell colonies like those depicted in Figure 23.4.2A and B. These will appear as small rounded clumps of cells with sharp refractal edges; nuclei are usually distinct, but cell borders are not (see UNIT 23.3 for more detail and pictures). Most wells will contain some embryo-derived cells. Figure 23.4.2, panels C through E, shows common morphologies of non-ES cell colonies. 5% to 15% of the wells may contain ES cell-like colonies when using embryos from the 129 mouse strain (see Background Information and see Troubleshooting regarding the effects of mouse strain on ES cell yields).

12. After 3 to 6 days, passage ES cell colonies as follows:

- a. In wells with only a few ES cell colonies, pick cells by pipet as described for the initial inner cell mass outgrowths (steps 5 to 10) and replate on gelatinized 24-well feeder plates.

A**B****C****D****E**

Figure 23.4.2 Cell types observed after inner cell mass disaggregation. Phase-contrast images of some of the different cell morphologies seen 2 to 3 days after disaggregation. **(A, B)** Appearance of putative ES cells. **(C,D,E)** Appearance of common non-ES cell-like colonies. The cells in panel C resemble ES cells to some degree because of the distinct edge. However, unlike ES cells they are growing as a monolayer and the individual cells have distinct borders. Colonies of this type with more tightly packed cells look exactly like ES cells. After passage these misleading colonies will spread out and become easy to distinguish from true ES cells. The round, highly refractile cells in panel D look like the cells that often accumulate on the top of differentiating ES cell colonies. Note that the colony does not have a sharp, refractile edge. The colony in panel E has a diffuse border with giant trophoblast cells visible in the center.

Embryonic Stem
(ES) Cell Isolation**

23.4.4

- b. In wells with many ES cell colonies, trypsinize the entire well and replate on gelatinized feeder plates with a larger surface area (e.g., 6-well or 25-cm² plates) using the protocol described for passaging established ES cell lines (UNIT 23.3).

When picking individual colonies, all colonies from a single well can be combined. Deciding when to disperse the colonies depends on colony size and total plate density as described in UNIT 23.3. Passage all wells that have colonies that look remotely like ES cells and observe them daily afterwards; non-ES cells will become apparent after passage. In addition, colonies from wells with mixed morphologies should be split. ES cells will usually outgrow other cell types after several passages.

13. Expand each line that maintains an ES cell morphology until there are enough cells to freeze down 3 or more vials at a cell density per vial of 1–3 × 10⁶ cells/ml (see UNIT 23.3).

Typically, enough cells should be present on a 25-cm² flask at medium density. The protocols for expansion and freezing are described in UNITS 23.2 & 23.3. Samples of new cell lines should be analyzed for mycoplasma contamination. Investigators may want to karyotype new lines; however, most early-passage lines will have a normal complement of 40 chromosomes.

ES CELL SEX DETERMINATION

Male ES lines are used most commonly, primarily because of concerns of X chromosome instability in female ES lines (Robertson et al., 1983). This protocol describes a simple polymerase chain reaction (PCR) screen to determine the sex of an ES cell line.

Additional Materials (also see Basic Protocol)

Digestion buffer (UNIT 23.5)

Saturated NaCl

95% ethanol

10× amplification buffer (UNIT 15.1)

25 mM 4dNTP mix (UNIT 15.1)

Primers (Kunieda et al., 1992):

Set 1: SRY2: TCTTAAACTCTGAAGAAGAGAC

SRY4: GTCTTGCCTGTATGTGATGG

Set 2: NDS3: GAGTGCCTCATCTATACTTACAG

NDS4: TCTAGTTCATTGTTGAGTTGC

5 U/μl *Taq* DNA polymerase

3% (w/v) agarose gel

Molecular weight markers

1.5-ml microcentrifuge tubes

55°C incubator

Additional reagents and equipment for PCR amplification (UNIT 15.1), culture of ES cells (UNITS 23.2 and 23.3), and agarose gel electrophoresis (UNIT 2.5)

Prepare DNA

1. Plate ES cells onto gelatinized 24-well plates without feeder cells. Grow these cells for 3 to 5 passages without feeder cells. Dilute cells at least 1:10 at each split.

The cells must be diluted out to prevent contamination of the PCR reactions from any residual feeder cells. ES cells can be grown in standard ES cell medium (UNIT 23.3) without antibiotics at this stage. Some differentiation will occur in the absence of the feeder layer.

2. Remove medium. Rinse well with HBSS.

SUPPORT PROTOCOL

3. Add 300 μ l digestion buffer, transfer to a 1.5-ml microcentrifuge tube, and incubate overnight at 55°C.

Plenty of DNA can be obtained from a single well of a 24-well plate, but it is often more convenient to use a larger surface area, such as that of a 25-cm² flask.

Use 1.5 ml of digestion buffer for a 25-cm² flask and adjust the volume of subsequent solutions proportionally.

4. Add 150 μ l saturated NaCl and vortex vigorously (the solution will turn milky white). Add 2 vol of 95% ethanol (the solution will turn clear except for precipitated DNA).

Some investigators precipitate the DNA using 2 vol ethanol (or 1 vol isopropanol) without adding salt. However, the DNA pellet resuspends more easily if salt is added.

5. Resuspend DNA pellet in 50 μ l water. Determine DNA concentration by measuring the absorbance at 260 nm (APPENDIX 3D).

Perform PCR

6. Perform 2 PCR reactions with each sample: one with the SRY primers and the other with the NDS primers. Mix the following in a 0.5-ml thin-walled PCR tube for each primer set.

2.5 μ l 10 \times PCR buffer (final MgCl₂ concentration 1.5 mM)
0.2 μ l 25 mM 4dNTP mix
0.5 μ M primer 1
0.5 μ M primer 2
0.2 to 1.0 μ g DNA template
0.5 U *Taq* DNA polymerase
up to 25 μ l H₂O

7. Using the following parameters, run the PCR.

35 cycles	30 sec	94°C	(denaturation)
	30 sec	50°C	(annealing)
	60 sec	72°C	(extension)

Analyze the product

8. Run 10 μ l of the products on a 3% agarose gel with the appropriate molecular weight markers.

The SRY primers are derived from the sex-determining region of the Y chromosome. Male cells will show the 404-bp product; female cells will have no product. The NDS primers span a microsatellite dinucleotide repeat on the X chromosome and serve as a positive control; both male and female cells should show the 244-bp product.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

NOTE: Prepare all cell culture solutions from tissue culture-grade reagents. Use tissue culture-grade water (high resistance and endotoxin free). Sterilize all final solutions by filtration or prepare from sterile stocks. Use disposable sterile plasticware to prevent microbial and detergent contamination.

Modified ES medium

Dulbecco's modified Eagle medium (DMEM), with high glucose (4500 mg/liter), L-glutamine, sodium pyruvate, and pyridoxine (or pyridoxal) hydrochloride (e.g., Life Technologies, JRH Biosciences, or Sigma) containing:
20% (v/v) FBS, heat inactivated for 30 min at 56°C
1× MEM nonessential amino acids (Life Technologies)
2 mM glutamine (from 100× stock; Life Technologies)
0.1 mM 2-mercaptoethanol
20 mM HEPES, pH 7.3
500 to 1000 U/ml murine leukemia inhibitory factor (LIF; Life Technologies, Chemicon)
1× penicillin/streptomycin (from 100× stock; Life Technologies)
1× nucleoside stock (see recipe; optional)
Store at 4°C for up to 1 week

The quality of FBS should be screened by assessing plating efficiency, morphology, and toxicity on ES cells plated at low density in 10%, 15%, and 30% heat-inactivated FBS. Plating efficiency should be ~10% and should be similar for all FBS concentrations. The author has had good success with FBS from Hyclone. Several companies sell FBS that has been screened for ES cell growth using the same techniques. Although it is expensive, laboratories that are new to ES cell culture may benefit from prescreened FBS. In addition, prescreened FBS provides a standard of comparison for other FBS lots.

100× nucleoside stock

In 100 ml of tissue culture grade water dissolve:

80 mg adenine
73 mg cytidine
85 mg guanosine
24 mg thymidine
73 mg uridine

Dissolve by warming at 37°C and filter sterilize. Aliquot and freeze at –20°C. Thaw at 37°C and mix vigorously to redissolve nucleosides prior to use.

The addition of a nucleoside stock to the modified ES medium is recommended by Robertson (1987).

COMMENTARY

Background Information

Pluripotent mouse embryonic stem cells were first isolated by Evans and Kaufman (1981) and Martin (1981). The protocol outlined in this unit is essentially that of Axelrod (1984) and Robertson (1987) with some modifications. The primary differences are related to the culturing conditions including the use of MEFs as feeder layers instead of STO (SIM mouse embryo fibroblasts resistant to thioguanine and ouabain) cells and the addition of recombinant leukemia inhibitory factor (LIF) to inhibit differentiation. Evans and Kaufman (1981) used delayed blastocysts, reasoning that the increase in the number of cells in these embryos would increase the likelihood of successful stem cell isolation. Martin (1981) used immunosurgery to isolate the inner cell mass and cultured on STO feeder cell layers

with conditioned medium from embryonal carcinoma cells. Many of these ingenious tricks are no longer necessary because of a more refined understanding of the cell culture conditions required to maintain undifferentiated ES cells. Indeed, ES cell lines capable of contributing to the germ line have been isolated in media supplemented with LIF in the absence of feeder cell layers (Pease et al., 1990).

In addition to methodology, genetic background can affect the efficiency of ES cell isolation. The majority of ES cells used for gene targeting are derived from 129 substrains, in part because of the ease with which ES cells can be established from this strain. The nomenclature of the 129 strain has been revised recently; refer to Festing et al. (1999) to clarify strain names. Lines have been isolated with more difficulty from some other common

strains such as C57BL/6 (Ledermann and Burki, 1991), Balb/cJ (Noben-Trauth et al., 1996), and C3H/He (Kitani et al., 1996). The factors that influence strain permissiveness are not known.

Critical Parameters and Troubleshooting

The isolation of ES cell lines is not a complicated procedure; however, this does not mean that the procedure is always successful. Several factors are important to consider. High-quality cell culture reagents and proper aseptic technique are necessary for success. Consult *UNITS 23.2 & 23.3* for more detail on these issues. As indicated above, the strain of mouse from which the embryos are derived can have a dramatic effect on success. If a strain other than a standard 129 substrain must be used, first consult the literature for reports of successful ES cell derivation and for any strain-specific approaches. Second, increase the number of starting embryos, because the yield will probably be lower. Third, verify the technique and reagents used by isolating lines from a permissive strain. The procedure may not be successful even with these modifications. Consider more elaborate approaches such as that reported by McWhir et al. (1996).

The most common problems during isolation of ES cell lines are encountered during the initial dispersion of the inner cell mass outgrowth. Under-trypsinization or very limited trituration will result in transfer of the whole cell clump without dispersion. The large colony will differentiate rapidly. At this stage, the well can sometimes be saved by immediately picking the outgrowth a second time, trypsinizing, and replating. Over-trypsinization or extensive trituration also creates a problem. Single cells do not clone well at this stage. Dispersing the outgrowth into a single-cell suspension will usually result in cell death or differentiation. Both of these problems can be avoided by working with only a few outgrowths at one time and by monitoring the procedure with a microscope. In addition, after dispersal, the wells should be scanned carefully for several days. Single ES cell-like colonies are easy to miss, especially if they sit near the edge of the well, where the image is distorted.

Anticipated Results

With embryos derived from 129 strains (e.g., 129X1/SvJ or 129S6/SvEvTac), 5% to 15% of the inner cell mass outgrowths should give rise

to ES cell lines. Half of the resultant lines should be male.

Time Considerations

Initial inner cell mass outgrowths can be picked 5 to 6 days after plating the embryos. Within 3 to 5 days, ES cell-like clumps can be picked and dispersed; 3 to 5 days later wells containing ES cells can be expanded, and subsequently frozen 2 to 4 days later. For sex determination, aliquots of the cell lines should be expanded without feeder cells for 1 to 2 weeks (i.e., 3 to 5 passages).

Production of a Heterozygous Mutant Cell Line by Homologous Recombination (Single Knockout)

Gene targeting by homologous recombination allows the introduction of specific mutations into any cloned gene. In the method described here, the gene of interest is inactivated by interrupting its coding sequence with a positive selectable marker (e.g., *neo*). Expression of *neo* is obtained by including the phosphoglycerate kinase (PGK) promoter in the construct. To enrich for clones in which the target gene has undergone homologous recombination over those in which random integration of the construct has occurred, a negative selectable marker, herpes simplex virus thymidine kinase (HSV-TK), is included in the construct outside the region of homology to the target gene. Depending upon the target gene, it may be easier to assemble the construct by adding the *neo* and *TK* genes to the cloned target gene or by adding two fragments of the target gene to a plasmid containing the *neo* and *TK* genes (e.g., pNTK, Fig. 23.5.1).

If the Cre-*loxP* system (UNIT 23.1) is to be used for removing the selectable marker, or for tissue-specific or temporally controlled knockout, then a construct already containing *loxP* sites flanking the marker is more convenient (e.g., pTKLNL, Fig. 23.5.2A). If selection for loss of selectable marker is desired, a construct that also contains a negative selectable marker can be used (e.g., pTKLNCL, Fig. 23.5.2, panel B).

Figure 23.5.1 pNTK vector. Both the *neo* and *TK* genes are driven by a PGK promoter (p_{PGK}) that is expressed in ES cells. Unique restriction enzyme sites that are useful are indicated in bold. One genomic fragment can be cloned into the *Bam*HI site. A second genomic fragment can be cloned into the *Hind*III, *Cl*aI, *Sal*I, *Xho*I sites. A site should be preserved that will linearize the construct, leaving the majority of plasmid vector sequences attached to the *TK* gene (e.g., *Xho*I).

Figure 23.5.2 Constructs containing *loxP* sites surrounding a positive selectable marker, *neo* (**A**), or both a positive and a negative selectable marker, *neo* and cytosine deaminase (*CD*; **B**). Constructs can be made by insertion of homologous sequences in unique restriction sites outside the *loxP* sites. If conditional targeting constructs are desired (as in Fig. 23.1.7), a third *loxP* site can be inserted into the region of homology and then the two regions of homology inserted into the vectors. Another version of these plasmids is also available with the *TK* and *CD* reversed (Milstone et al., 1999).

STRATEGIC PLANNING

Figure 23.5.3 illustrates the production, selection, and identification of targeted gene disruption by homologous recombination. A replacement targeting construct requires the assembly of several different DNA sequences:

1. A genomic clone (preferably >10 kb) of the gene of interest, generally encoded on a bacteriophage or cosmid clone containing homologous sequences to be included in the construct. DNA isogenic to the ES cells (i.e., derived from the same animal strain) is preferred but not essential. An alternative for genes of sufficient size, and regions

Figure 23.5.3 Production, selection, and identification of targeted gene disruption by homologous recombination. An example of a restriction enzyme site (RE) and hybridization probe that can be used to identify cells in which homologous recombination has occurred (shaded colony) is shown. The predicted size of the restriction fragment generated from an unaltered target gene (E) and a target gene that has undergone homologous recombination (HR) is shown. If equal amounts of DNA are present in the lanes of the Southern blot, the intensity of each of the two hybridizing fragments from the DNA of a homologous recombinant clone will be half of the intensity of the hybridizing fragment from unaltered clones.

for which mouse sequences are known, is long PCR (Cheng et al., 1994). This approach works for many genes as long as they have large enough introns, and is particularly convenient when the intron-exon structure of the gene is known. Long PCR may introduce mutations, which may decrease homologous recombination rates just as nonisogenic DNA can. In addition, the mutations may occur in important parts of the gene; this risk makes the approach less suitable for conditional knockouts or subtle mutations.

2. Additional cloned target-gene DNA sequences not included in the construct, to be used as a hybridization probe to identify homologous recombinants. This probe can often be isolated from the same bacteriophage or cosmid clone that provided the homologous sequences included in the construct. The hybridization probe will hybridize with either an unaltered target gene or a target gene that has undergone homologous recombination, but will not hybridize with a construct that entered the genome by random integration.
3. A positive selectable marker, such as the gene encoding neomycin phosphotransferase (*neo*) or hygromycin-B-phosphotransferase (*hyg*), which is used to disrupt the target gene. If a homozygous mutant cell line is an ultimate goal, it is recommended that the *neo* coding sequence contain the point mutation that decreases the phosphotransferase activity (Yenofsky et al., 1990). Using the PGK promoter and the wild-type *neo* gene may result in cells containing a single *neo* gene that are resistant to >10 mg/ml G418, thus precluding the use of higher G418 concentration to isolate clones containing two *neo* genes (see UNIT 23.6).
4. A negative selectable marker such as HSV-TK, which is used to enrich for ES cell clones in which homologous recombination has occurred in the target gene over clones in which random integration of the construct has occurred.

BASIC PROTOCOL

GENE TARGETING IN EMBRYONIC STEM CELLS

The basic protocol is divided into three parts. First, it outlines the assembly of a replacement targeting construct and considerations in choosing its exact structure. Second, it briefly describes the culture of embryonic stem (ES) cells and the method for introducing the construct DNA into ES cells. A more detailed description of culturing ES cells and maintaining their undifferentiated state is found in UNITS 23.2 & 23.3. Third, it outlines the method for identifying clones in which the target gene has been altered by homologous recombination. The resulting homologous recombinants are heterozygous (one allele of the target gene is altered by homologous recombination and one allele is normal) and can be used to produce transgenic murine lines or to produce homozygous mutant cell lines (in which both alleles of the target gene are altered; UNIT 23.6).

Materials

Target gene from genomic library isogenic with ES cell line (e.g., 129 SV library; Stratagene)
Plasmid vector (e.g., pNTK, available from R. Mortensen; see Fig. 23.5.1)
95% ethanol
Sterile H₂O
Embryonic stem (ES) cells (UNITS 23.2 & 23.3; ATCC)
ES/LIF medium (see recipe)
Trypsin/EDTA: 0.25% (w/v) trypsin/1 mM EDTA (20 mM HEPES, pH 7.3, optional)
ES medium (see recipe)
Electroporation buffer (see recipe)

Production of a Heterozygous Mutant Cell Line

23.5.4

G418 (UNIT 9.5)

Gancyclovir (GANC)

Freezing medium (see recipe)

Digestion buffer (see recipe)

Saturated NaCl (see recipe)

1% agarose gel (UNIT 2.5A)

Tissue culture hood

Gelatin-coated tissue culture plates (UNIT 23.3): 100-mm plates and 24-well microtiter plates

4-mm electroporation cuvettes

Pipet tips, sterilized by autoclaving

Nylon membrane

Additional reagents and equipment for subcloning DNA (UNIT 3.16), restriction enzyme digestion (UNIT 3.1), phenol/chloroform extraction of DNA (UNIT 2.1A), agarose gel electrophoresis (UNIT 2.5A), electroporation (UNIT 9.3), ES cell culture (UNITS 23.2 & 23.3 and APPENDIX 3F), stable transformation using selective medium (UNIT 9.5), and Southern blotting and hybridization (UNITS 2.9 & 2.10)

NOTE: All tissue culture incubations should be performed in a humidified 37°C, 5% CO₂ incubator unless otherwise noted.

Create a replacement construct

1. Select a portion of the target gene to include in the construct and a separate portion of the target gene to use as a probe for hybridization of Southern blots to identify cells in which homologous recombination has occurred (see step 19).

It should contain a rare restriction site within an exon encoding an important region of the protein (or an exon upstream of such a region) that is ideally flanked by >1 kb of target gene DNA on each side (most constructs are made with 2 kb). The rate of homologous recombination may increase with increasing lengths of homologous DNA up to 15 kb.

2. Construct a clone in a plasmid vector (UNIT 3.16) such that the *neo* gene interrupts the gene of interest, leaving regions of homology on either side of the *neo* gene. Include a thymidine kinase (*TK*) gene in the replacement construct outside the regions of homology (Fig. 23.5.4).

*This construction can be accomplished by either adding the *neo* and *TK* sequences to the subcloned homologous sequences or by adding regions of homologous sequences to a plasmid already containing the *neo* and *TK* genes (e.g., *pNTK*, see Fig. 23.5.1).*

3. Digest the construct DNA with a restriction enzyme to linearize (UNIT 3.1).

*Linearize the construct DNA so that the plasmid vector sequences remain attached to the *TK* gene. This will help preserve the activity of *TK* gene if any loss of DNA sequence occurs during random insertion of the construct into the genome.*

4. Purify and sterilize the digested construct DNA by phenol/chloroform extraction (UNIT 2.1A).
5. Precipitate the DNA by adding 2 vol of 95% ethanol and microcentrifuging 30 sec. Using sterile technique in a tissue culture hood, remove the supernatant and allow the pellet to air dry until only slightly moist.
6. Dissolve the pellet in 100 µl sterile water. Check for complete digestion and estimate DNA concentration by electrophoresis on an agarose gel (UNIT 2.5A).

Figure 23.5.4 Two strategies to create a replacement construct. In method **A** the target gene fragment is subcloned into a plasmid vector, then $p_{PGK-neo}$ is inserted into a rare restriction enzyme site in the target-gene fragment and p_{PGK-TK} is inserted into the plasmid vector near the target gene. In method **B** the target-gene fragment is cleaved into two pieces that are subcloned into the polylinker sites of pNTK (see Fig. 23.5.1). Note that the relative orientation of homologous fragments in the construct must retain that found in the target gene.

Transfect construct and select ES cells

- Culture ES cells in ES/LIF medium (UNITS 23.2 & 23.3). Passage cells every 2 to 3 days by seeding a 100-mm gelatin-coated tissue culture plate with $1-2 \times 10^6$ cells/plate.

Leukemia inhibitory factor (LIF) prevents ES cells from differentiating.

Some investigators suggest passaging cells at a higher density if blastocyst injection of the cells (UNIT 23.4) is planned (e.g., 1.5×10^6 cells per 25-cm² flask). A detailed description of culture techniques for ES cells is found in UNITS 23.2 & 23.3.

- Harvest $\sim 5 \times 10^6$ to 1×10^7 cells by adding trypsin/EDTA and incubating for ~ 5 min until cells are freed from the plate surface. Dissociate to single cells by pipetting up and down five to ten times. Add 5 ml ES medium. Pellet cells and resuspend the cell pellet in 1 ml electroporation buffer in the same tube.

Typically, 10^7 cells can be obtained from a near-confluent 100-mm tissue culture plate.

- Add 1 pmol linearized, sterile construct DNA from step 6.
- Electroporate the mixture at 450 V and 250 μ F in a 4-mm electroporation cuvette (UNIT 9.3). Incubate 10 min at room temperature.

Many electroporation conditions can be used with ES cells.

- Plate cells in ES medium at $\sim 2 \times 10^6$ cells per 100-mm gelatin-coated tissue culture plate. Incubate 24 hr.
- Begin selection (UNIT 9.5) by changing ES medium to ES/LIF medium and adding G418 to 0.2 mg/ml and GANC to 2 μ M (final).

13. Continue incubation, changing medium daily using ES/LIF medium and adding G418 (0.2 mg/ml final) and GANC (2 μ m final), until single, isolated colonies are visible (typically 1 week after electroporation). Remove an individual colony from the plate using an autoclaved pipet tip, and place in a 35- μ l drop of trypsin/EDTA for 5 min. Pipet up and down about five times to dissociate cells. Transfer cells to a well of a gelatin-coated 24-well microtiter plate containing 1 ml ES/LIF medium.
14. Incubate until colonies are visible, but the cells are not differentiating (typically 3 to 4 days). Passage half of the cells to a well of a clean gelatin-coated 24-well microtiter plate. Add the remaining cells to 0.5 ml freezing medium and place at -70°C . Freeze overnight, then transfer to liquid nitrogen.

Undifferentiated cells grow in smooth, round colonies. Differentiated cells are flatter with distinct intercellular boundaries.

Proceed immediately to step 15 after placing half the cells in the freezer.

Screen for homologous recombinants

15. Incubate ES cells in 24-well microtiter plate (step 14) to near confluence (usually 2 to 3 days).

Because it is not critical to prevent differentiation of the ES cells at this stage, LIF can be omitted from the culture medium; however, the presence of LIF may help to maintain cell growth.

16. Add 300 μ l digestion buffer to each well. Transfer well contents to a 1.5-ml microcentrifuge tube, and incubate overnight at 55°C .

17. Add 150 μ l saturated NaCl and vortex vigorously (the solution will turn milky white). Add 2 vol of 95% ethanol (the solution will turn clear except for precipitated DNA).

Some investigators precipitate the DNA using 2 vol ethanol (or 1 vol isopropanol) without adding salt. However, the DNA pellet resuspends more easily if salt is added.

18. Resuspend DNA pellet in 50 μ l water. Determine DNA concentration by measuring the absorbance at 260 nm (*APPENDIX 3D*).
19. Digest 10 μ g DNA (or 10 μ l if DNA concentration was not determined) with the appropriate restriction enzyme (*UNIT 3.16*).
20. Fractionate the digested DNA on a 1% agarose gel (*UNIT 2.5A*). Transfer to a nylon membrane, and hybridize by Southern blotting (*UNITS 2.9 & 2.10*) to the target-gene hybridization probe chosen in step 1 to distinguish the unaltered target gene from a target gene that has undergone homologous recombination.
21. Select ES cell colonies that show two hybridizing fragments of approximately equal intensity—one fragment of the predicted size for the unaltered target gene and one fragment of the predicted size for a target gene that has undergone homologous recombination. If the two fragments are of unequal hybridization intensity, the cell population may not be clonal. Freeze cells and store in liquid nitrogen.
22. If desired remove selectable markers that are flanked by *loxP* sites by transient expression of Cre (see Support Protocol).

TRANSIENT EXPRESSION OF CRE FOR RECOMBINATION

Removal of sequences between the *lox* sites is accomplished by transient expression of Cre recombinase. If flanking *lox* sites are present in both alleles, Cre will recombine both alleles as efficiently as one. If selectable markers are between *lox* sites (as in Fig. 23.1.6), then sensitivity to selection media (e.g., containing G418) will be restored.

Additional Materials (also see *Basic Protocol*)

Cre expression plasmid using a promoter giving high expression levels in ES cells (e.g., pMC1 or pPGK)

12.5 mg/ml 5-fluorocytosine in PBS (if selecting against CD), sterile

1. Expand the homologously recombined clones obtained using the Basic Protocol by culturing and harvesting ES cells (see Basic Protocol, steps 7 and 8).
2. Prepare Cre expression plasmid DNA using the same procedure as for the original targeting vector (see Basic Protocol, steps 4 to 6).

Do not linearize the DNA, as this will increase the probability of genomic integration.

3. Use 1 to 2 pmol of this DNA to transfect the expanded ES cell clones (see Basic Protocol, step 10).

Transfecting more DNA will most likely increase expression; however, it also increases the probability of integration.

4. Plate cells at a lower density than for the original targeting (since survival is expected to be higher).

The target is a number of clones per plate that will allow convenient colony picking. If no selection is to be performed, plating at a few hundred electroporated cells per 100-mm plate is a reasonable starting point. A range of dilutions should be plated (at least to a few thousand per plate), since the exact survival is not accurately predictable and plating at low density will decrease survival. If the negative selectable marker cytosine deaminase (CD) is used, then plate at 1,000 to 10,000 cells per 100-mm plate, since higher densities will give complete killing due to a neighbor selection effect. The number of surviving colonies will depend on the frequency of recombination.

5. Continue to culture cells, replacing medium daily with fresh ES/LIF medium. If selecting against CD, include 250 µg/ml 5-fluorocytosine (from 12.5 mg/ml stock) in the medium.
6. Screen colonies loss of the selectable marker (Cre-induced recombination) by Southern analysis (see Basic Protocol, steps 14 to 21).

Although Cre-construct integration is an unlikely event, the clones for injection can also be screened for presence of Cre by reprobng the Southern blots or by PCR.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Digestion buffer

20 mM Tris·Cl, pH 8.0

10 mM NaCl

10 mM EDTA

0.5% (w/v) sodium dodecyl sulfate (SDS)

Store indefinitely at room temperature

Add 1 mg/ml proteinase K just before use

Electroporation buffer

20 mM HEPES, pH 7.3
137 mM NaCl
5 mM KCl
0.7 mM Na₂HPO₄
6 mM glucose
0.1 mM 2-mercaptoethanol (2-ME)
Store indefinitely at 4°C

ES medium

Dulbecco's minimum essential medium (DMEM), high-glucose + pyruvate formulation, containing:

15% FBS, heat-inactivated 1 hr at 56°C
0.1 mM 2-mercaptoethanol (2-ME)
20 mM HEPES, pH 7.3 (optional)

DMEM containing 4500 mg/liter D-glucose and pyruvate can be obtained from GIBCO/BRL.

A detailed description of culture conditions for embryo stem cells has been presented by Robertson (1987).

ES/LIF medium

ES medium (see recipe) containing 1000 U/ml leukemia inhibitory factor (LIF; GIBCO/BRL). Store ≤1 week at 4°C.

Conditioned medium from a CHO cell line overproducing LIF (Genetics Institute) can also be used at a dilution of 1:1000. An alternative to LIF for preventing differentiation of ES cells is to grow them on feeder layers of irradiated mouse embryo fibroblasts (MEF) in ES medium. Some investigators add 20 mM HEPES (pH 7.3) to culture medium.

Freezing medium

DMEM, high-glucose + pyruvate formulation, containing:

10% FBS (Hyclone), heat-inactivated 1 hr at 56°C
10% (v/v) dimethylsulfoxide (DMSO)
20 mM HEPES, pH 7.3 (optional)
Store at -20°C

Saturated NaCl

Add NaCl to distilled H₂O until no more dissolves (~6 M). Some solid NaCl should remain; decant solution for use. Store indefinitely at room temperature.

COMMENTARY

Background Information

See *UNIT 23.1* for an overview of gene targeting by homologous recombination.

Although homologous recombination has been used by yeast geneticists for some time, it has only recently been shown to occur in somatic mammalian cells. It was first demonstrated between exogenously introduced DNA sequences (Folger et al., 1982) and later between an exogenously introduced DNA construct and an endogenous gene (Smithies et al., 1985).

The mechanism of homologous recombination is not well understood but a number of characteristics are known. Homologous recom-

bination occurs more readily if the construct has free ends, rather than being circular (Wong and Capecchi, 1987). The rate of homologous recombination does not depend on the number of targets in the genome—at least when the target is present as tandem repeats of a dihydrofolate reductase (*DHFR*) amplified gene (Zheng and Wilson, 1990).

Initially homologous recombination in mammalian cells was studied by introducing a mutated *neo* or *TK* gene, then restoring *neo* or *TK* activity by correcting the mutation through homologous recombination (reviewed by Capecchi, 1989). This approach provided an

easy method to detect homologous recombination.

Embryonic stem (ES) cells and the related embryonic carcinoma (EC or EK) cells were first isolated and cultured in 1981 (Evans and Kaufman, 1981; Martin, 1981). They can give rise to a chimeric mouse when introduced into a normal blastocyst, which is then transferred into the uterus of a pseudopregnant foster mother. The ES cells contribute to all tissues of the chimeric mouse including the germ line (Bradley et al., 1984). Currently, ES cells, rather than EC cells, are used to produce chimeric mice, because the extent of chimerism and efficiency of germ line transmission is much higher with normal cells. Most ES cell lines used are derived from males because the karyotype of XY cells is more stable than that of XX cells and resulting chimeric male mice are easier to breed. Typically, the extent of the contribution of the ES cells to somatic tissues of the chimeric mouse is easily determined visually by choosing strains of mice for the sources of ES cells and blastocysts that have different coat colors.

Critical Parameters

The degree of homology between the construct and the target genome can have a dramatic effect on the rate of homologous recombination in two ways. First, homologous recombination requires stretches of exact DNA homology. The DNA used to construct the targeting vector must be from the same species as the cell in which the mutation is to be introduced. It should also be isogenic with the target cell (this is not absolutely required, but increases the probability of success). Because animal strains may differ just as individual outbred animals differ, there may be a mismatch of DNA on average every 500 bp. A single DNA mismatch is sufficient to dramatically decrease the rate of homologous recombination (Deng and Capecchi, 1992; teRiele et al., 1992). Mutations induced by making constructs using long PCR may similarly decrease homologous recombination rates.

Second, the rate of homologous recombination increases with increasing length of the homologous DNA sequence (within limits). The exact length of homologous DNA that gives the maximum recombination rate is controversial but may be as high as 15 kb (Deng and Capecchi, 1992; Hasty et al., 1991). Homology should also be >1 kb for the shorter arm (most constructs have used >2 kb). Further, fidelity of recombination can be lower if the

length of homology is <1 kb (Thomas et al., 1992).

The parameters outlined here are meant to be guidelines for the design of constructs. For some target genes and constructs, more or less homology may be required. Nonisogenic DNA recombines easily for some genes. If homologous recombination is not obtained initially, the same construct should be retransfected into the ES cells, as rate of homologous recombination can vary for unclear reasons. A second construct using a different region of the gene can also be used because different constructs of the same gene may recombine at different rates. If homologous recombination is occurring, but only at a low rate, screening pools of clones by the polymerase chain reaction (PCR; *UNIT 15.1*) may enable one to identify homologous recombinants (Koller et al., 1991).

Anticipated Results

In most cases, constructs prepared following the above guidelines should give rise to a number of homologous recombinant clones in a single transfection. Typically the frequency of homologous recombinant clones to surviving clones is 1:30 to 1:5; however, the range of reported results is large: the ratio may be $\geq 1:1000$, or homologous recombinants may even be in the majority.

The frequency of recombination reported in the literature varies from 1% to 16%; in the authors' hands, it has sometimes been as high as 30%.

Time Considerations

The entire procedure, from cloning to obtaining homologous clones, can take several months, depending on the difficulty in obtaining the construct. Once a construct is obtained however, transfection and selection of clones takes ~2 weeks. Screening clones takes 2 to 3 days. Addition of a *neo* removal step will add ~4 weeks for expansion of clones, transfection, and rescreeing.

Production of a Homozygous Mutant Embryonic Stem Cell Line (Double Knockout)

Homozygous mutant embryonic stem (ES) cell lines have proven very useful in studying gene and protein function, and there are several reasons why this system might be preferred. Because many genes express their phenotype at the level of individual cells, using these cell lines eliminates the time and expense of producing a mutant animal. They can be isolated directly from a heterozygous mutant cell line (UNIT 23.5) without rederiving a cell line or using primary tissues from a mutant animal. In some cases, analysis of the phenotype of homozygous mutant cells can be performed more easily in culture. In addition, homozygous mutant ES cell lines may be produced even when a homozygous mutation is lethal to the animal. Finally, microinjection of homozygous mutant ES cells into blastocysts may allow investigation of the developmental potential of cells with such lethal mutations.

Selection of a homozygous cell line depends on being able to increase antibiotic concentrations such that nearly all of the cells containing a single copy of the selectable marker gene will be killed. If the wild-type *neo* gene is used in combination with a strong promoter (e.g., phosphoglycerate kinase; PGK), cells containing one *neo* gene may not be killed by the highest G418 concentrations that can be obtained. For this technique to be effective, therefore, it is recommended that a mutant *neo* gene containing a point mutation that decreases phosphotransferase activity be used in place of wild-type *neo* (Yenofsky et al., 1990). This mutant *neo* gene is readily available because it is contained in some versions of both pMC1-*neo* and p_{PGK} -*neo* (see Fig. 23.5.1). The wild-type hygromycin-B-phosphotransferase (*hyg*) gene used in combination with the PGK promoter, p_{PGK} -*hyg*, has also worked well in the method described in the basic protocol.

Alternatively, using a construct with *loxP* sites flanking the *neo* marker, such as those derived from pTKLNL or pTKLNCL, allows the *neo* to be removed from both alleles simultaneously after homozygous cells are obtained. Using this strategy, one can insert a wild-type *neo* to inactivate a gene of interest and still use high-G418 selection to isolate homozygous cells.

SELECTION FOR HOMOZYGOUS CLONES

In this protocol, a homozygous mutant ES cell line is isolated from heterozygous mutant ES cells (UNIT 23.5) by culturing the cells in increasing concentrations of G418. The more stringent selection conditions favor cells that contain, as a result of the loss of heterozygosity, two selectable marker genes (e.g., for *neo*), and therefore two mutant alleles of the target gene. Resulting colonies are harvested and screened by northern hybridization or immunoblotting to confirm that the target gene is inactive.

Materials

- Heterozygous mutant ES cell line, frozen in liquid nitrogen (UNIT 23.5)
- ES/LIF medium (UNIT 23.5)
- G418 (UNIT 9.5)
- 100-mm tissue culture plates, gelatin coated (UNIT 23.5)

Additional reagents and equipment for recovery of frozen cell lines (UNIT 11.9), ES cell culture (UNIT 23.5), northern analysis (UNIT 4.9), and immunoblotting (UNIT 10.8)

NOTE: All tissue culture incubations should be performed in a humidified 37°C, 5% CO₂ incubator unless otherwise noted.

BASIC PROTOCOL

Manipulating the Mouse Genome

23.6.1

Contributed by Richard Mortensen

Current Protocols in Molecular Biology (2000) 23.6.1-23.6.3

Copyright © 2000 by John Wiley & Sons, Inc.

Supplement 52

1. Thaw heterozygous mutant ES cells. Culture in ES/LIF medium (UNIT 23.5), passaging cells every 2 to 3 days by seeding a 100-mm gelatin-coated tissue culture plate with $1-2 \times 10^6$ cells/plate.

Selection should be performed with more than one heterozygous mutant ES cell line clone because the efficiency of conversion to homozygosity varies among cell lines. In addition, more than one clone should be analyzed for the phenotype.

2. Begin the selection by plating three 100-mm gelatin-coated tissue culture plates at 10^5 cells/plate using ES/LIF medium and adding 1.0, 1.5, or 2.0 mg/ml G418 (final), respectively.

It is important to neutralize the G418 to ~pH 7.4.

Both the neo and hyg genes have been used successfully as selectable markers in mutant ES cells (R.M., unpub. observ.). To select for hyg, use ES/LIF medium containing 1.0, 1.5, or 2.0 mg/ml hygromycin-B (HPH; UNIT 9.5).

3. Incubate cells 7 to 10 days. Change the medium each day, using ES/LIF medium with the appropriate concentration of G418 added, until single colonies are detected.

If cells overgrow plates and no single colonies are obtained, repeat steps 2 and 3 using a higher G418 concentration (e.g., 2, 4, or 6 mg/ml final).

4. Screen colonies for homologous recombinants as described in UNIT 23.5 (Basic Protocol, steps 15 to 21).

The hybridizing fragment indicative of the unaltered target gene will be completely absent in homozygous mutant cells. Typically, 50% of the clones are homozygous but because the process is random, individual heterozygous clones may yield homozygous clones at a frequency of 4% to 100%.

5. Perform a northern hybridization analysis (UNIT 4.9) of mRNA or an immunoblot analysis of protein (UNIT 10.8) to confirm that the target gene is inactive. No normal mRNA or protein should be found.

6. If the constructs contain loxP sites flanking the neo gene, remove the neo by transient expression of Cre (see UNIT 23.5, Support Protocol).

Both copies of neo are removed with same efficiency as one copy.

COMMENTARY

Background Information

Comparison of the phenotype of wild-type and homozygous mutant cells should provide information concerning the function of the targeted gene, provided that the gene functions in the cell assayed. ES cells offer a unique opportunity because they are capable of differentiating into any cell type. Many cell types can be produced through manipulation of in vitro cultures, including beating cardiocytes, skeletal muscle cells, neurons, glial cells, and vascular endothelial cells. Provided that the phenotype can be analyzed with a single cell or with a few cells, these differentiated cells can then be used to analyze the phenotype of the disrupted gene.

Because the normal number of chromosomes is maintained in ES cells (Mortensen et al., 1992), this method should be applicable to the study of gene function in development. ES

cells can also differentiate within the entire organism when injected into normal blastocysts. Homozygous mutant cells offer no technical advantage over heterozygous cells if the goal is to obtain a mutant mouse line through germline transmission; however, if homozygous mutant cells are tagged by introducing a gene that has a histochemically detectable product (e.g., β -galactosidase), then the fate of the homozygous mutant cells in the animal can be determined easily. Studies of embryos derived from blastocysts injected with tagged mutant ES cells may reveal the role of the target gene during development even if the mutant gene is lethal for the animal when homozygous.

In some cases, the phenotype of the disrupted gene may be tested by introducing heterologous proteins into the cultured cells. For example, an intracellular signaling pathway

may be investigated by expression of the particular receptor that creates an intracellular response to an applied agonist.

Cells produced using this protocol are only resistant to *neo* and its analogs. Thus, further genetic manipulations of the cells, such as the targeting of other genes using homologous recombination, can be performed using other drug selections (e.g., HPH; *UNIT 9.5*).

The suitability of this technique for the production of homozygous mutant cell lines other than ES cells is less certain. Homologous recombination and spontaneous loss of heterozygosity occur in some other cell lines and these same methods have been used to produce homozygous mutant cell lines; however, the methods may not be widely applicable, as other types of immortalized cells (e.g., lymphocytes or fibroblasts) may not undergo homologous recombination of a targeting construct at the same frequency as ES cells. Furthermore, many immortalized cells are markedly polyploid or aneuploid. If more than two copies of the target gene are present, this method for producing homozygous mutant cells may not be suitable; however, because these cells often lose or gain chromosomes, some clones might be isolated with no endogenous gene remaining.

The loss of heterozygosity seems to occur by several different mechanisms that vary with cell type. The mechanism by which this conversion occurs is unknown. Some possibilities include nondisjunction, chromosomal loss and duplication, or gene conversion.

Critical Parameters and Troubleshooting

Homozygous mutant ES cells will not be obtained if the mutation is lethal for the ES cell. The critical technical factor in this method is determining the amount of G418 needed to select homozygous over heterozygous cells. Differences in G418 levels required for different constructs can arise from two sources: the strength of the promoter and the influence of the genomic site on *neo* expression. In addition, the resistance to G418 may vary, depending on the enzymatic activity of a wild-type or mutant *neo* gene (Yenofsky et al., 1990). If the heterozygous mutant ES cells are resistant to the highest concentration of antibiotic (i.e., 2 mg/ml G418), the G418 concentration should be increased (e.g., up to 6 mg/ml). The endpoint should be survival of individual colonies with death of nearly all cells.

It should be noted that this selection method allows only a minority of the homozygous

clones to survive. In one case, homozygous mutant cells constituted 25% of the cells (presumably due to the chance conversion of a heterozygous to homozygous cell early in the life of the clone). Nevertheless, <1% of the cells survived 1 mg/ml G418 (R.M., unpub. observ.).

It is also possible that loss of heterozygosity may not occur for all genomic sites, although no such genomic sites have yet been identified. Because the inability to isolate homozygous cells may lead to the erroneous conclusion that a homozygous mutation in a gene is lethal, the lethality of the mutation should be verified. A rescue experiment in which a third copy of the gene (or expressed cDNA) is introduced into the heterozygous mutant cells, followed by selection of the homozygous mutant, would distinguish between lethality and no loss of heterozygosity.

An alternative method for producing homozygous mutant cells is to disrupt the second allele of the target gene using a second targeting construct that uses a different positive selectable marker. For example, if *neo* was used in the first-round construct, the *hyg* gene can be used and cells selected in HPH as described in *UNIT 23.5*.

Anticipated Results

The hybridizing fragment indicative of the altered gene will be absent in homozygous mutant cells. Typically, 50% of the clones are homozygous, but because the process is random, individual heterozygous clones may yield homozygous clones at a frequency of 4% to 100%.

Time Considerations

Expanding and selecting clones requires ~2 to 3 weeks. Screening clones takes several days.

Chimeric Mouse Production by Microinjection

UNIT 23.7

The culmination of the creation of a mutation in mouse embryonic stem (ES) cells is, commonly, the generation of a mouse line that can propagate the mutation. The ability to combine methods of homologous recombination in ES cells with blastocyst-mediated transgenesis has resulted in an explosion of tailored mutant mouse strains. These animals provide research tools that are virtually impossible to create using other methodologies.

The most common method used to generate chimeras involves the injection of ES cells into the blastocoel cavity of 3.5-day-old embryos. The injected embryos are surgically implanted into the uterus of a foster mother. The resultant pups are true chimeras: their tissues are derived from both the host embryo and from the ES cells. If the ES cells are able to populate the germ line, the chimera can pass an altered gene to offspring, resulting in a new mouse strain in which all cells contain an altered gene.

The procedure is technically difficult, requiring proficiency with three methods: blastocyst isolation, blastocyst injection, and embryo reimplantation. Each of these techniques requires practice in addition to knowledge of the method; unlike many protocols, simply following the methodology is not sufficient. Because of the steep learning curve and the expense of the equipment, the procedure should not be undertaken without a serious commitment.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

NOTE: All mice used should be housed in a specific pathogen free (SPF) or virus antibody free (VAF) facility.

BLASTOCYST ISOLATION

The standard method for generating chimeras with ES cells uses 3.5-day-old mouse embryos (blastocysts). Embryos at this stage have a large fluid-filled cavity into which ES cells can be placed by injection. Blastocysts have already moved out of the oviducts and are found in the uterine horns. For injections, they must be harvested prior to hatching (loss of zona pellucida) and attachment to the uterine wall. C57BL/6 mice are used most commonly to generate blastocysts for ES cell injections. This strain yields reasonable numbers of embryos. It tends to produce high-grade chimeras that can be easily distinguished by coat color when used with ES cells derived from a variety of 129 sub-strains.

Materials

- C57BL/6 female mice (3 to 4 weeks old; e.g., Taconic)
- 50 U/ml pregnant mare's serum (PMS; see recipe)
- 50 U/ml human chorionic gonadotropin (HCG; see recipe)
- C57BL/6 stud males (8 weeks to 6 months old; e.g., Taconic)
- 95% ethanol
- Injection medium (see recipe)

Tuberculin syringe (1 ml, 26-G, $\frac{3}{8}$ in.)

Surgical equipment (thoroughly washed and sterilized by autoclaving or with ethanol; individual investigators may prefer slightly different instruments):

The following are available from Biomedical Research Instruments (similar instruments are available from several suppliers):

 cultures) in 35 × 10–mm petri dishes (Falcon)
 Light white mineral oil (Sigma)

Initiate superovulation

1. One week prior to the day of ES cell injection (see the time line, Fig. 23.7.1), inject 3 to 4 week old female C57BL/6 mice intraperitoneally (using a 1-ml tuberculin syringe with a $\frac{3}{8}$ -in., 26-G needle) with 0.1 ml of 50 U/ml PMS (5 U) between 11 a.m. and 2 p.m. to induce superovulation.

Blastocyst donors are superovulated to synchronize estrus and produce the greatest embryo yields. Mice can be mated naturally or after checking for estrus, but this requires housing

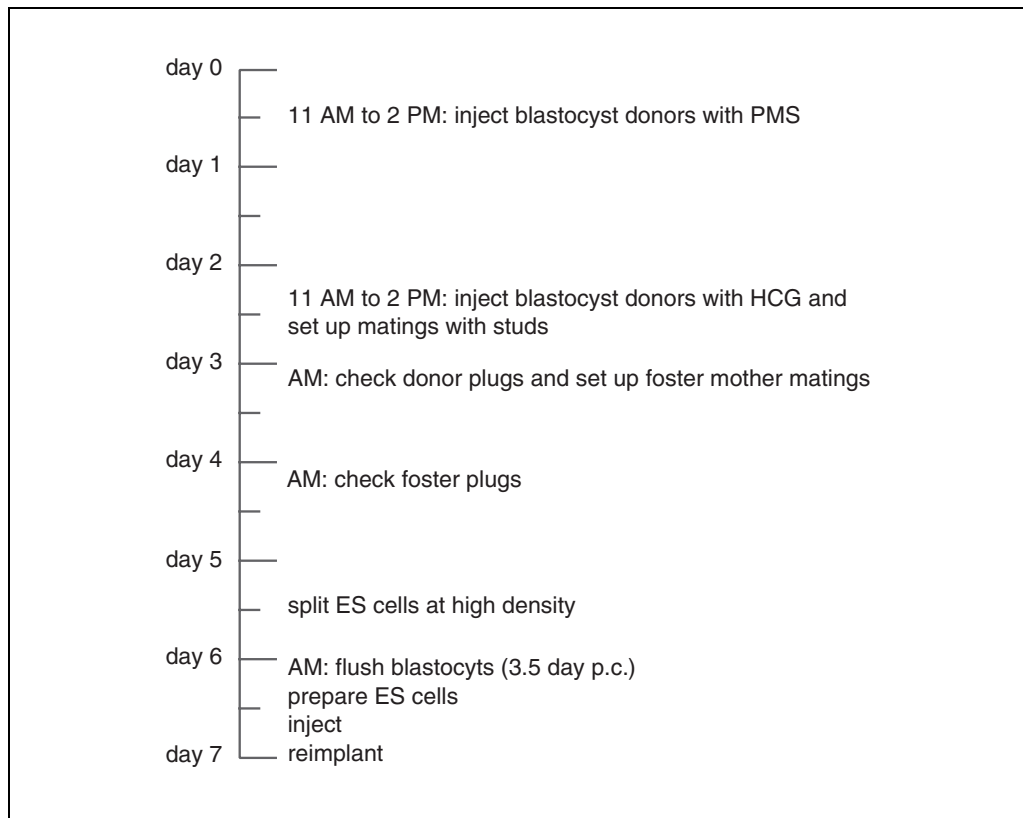

Figure 23.7.1 Time line of blastocyst injections. The major steps for a single day of injection are shown in the time line. The procedure begins 6 days before the actual day of injection with the initiation of superovulation of the donor mice. Mating is considered to occur in the middle of the dark cycle. Donors mate at the transition of the third and fourth 24-hr period. By the middle of the injection day, they are post-coital day 3.5. Fosters mate 24 hr later and are therefore post-coital day 2.5 at noon on the day of injection. ES cells should be thawed early enough in the procedure to produce high-density cultures for the day of injection—between day 0 and day 5, depending on cell density. The exact day of thawing will depend on the density at which the cells were frozen.

many more mice and will not produce more embryos. Young female mice that have not yet cycled will give the greatest embryo yields, whereas adult female C57BL/6 and even 5- to 6-week old females have more variable embryo yields. The timing of injection is important; it must be coordinated with the light/dark cycle to ensure that the females ovulate in response to the exogenous hormones prior to mating. A typical lighting cycle consists of 10 to 12 dark hours beginning at 6 to 7 p.m. and extending to 5 to 6 a.m. This represents the range of values that works well with a standard workday. For a specific animal room the timing and duration of the cycle should be held constant.

10 to 12 matings should generate enough blastocysts for 1 day of injection.

2. At 46 to 48 hr (again between 11 AM and 2 PM) after the PMS injection, inject each female intraperitoneally with 5 U of 0.1 ml of 50 U/ml HCG (5 U).

HCG replaces endogenous LH. HCG must be administered prior to the release of the endogenous hormone, which is controlled both by the timing of PMS injection and the light/dark cycle.

3. Place single superovulated females with individually caged C57BL/6 stud males.

Mice should mate in the middle of the next dark cycle. If injections are planned on consecutive days, it is a good idea to maintain a large enough colony of stud males so that no male is mated on consecutive days, otherwise embryo yields will usually drop on the second day.

4. The next morning, separate females and check for plugs.

Females plugged the next morning are considered to be 0.5-day post-coitum. Blastocysts are 3.5 days old. Most, but not all of the superovulated females should plug. Blastocyst yields drop with studs older than ~8 months. In the author's laboratory, the males are typically replaced when they are between 6 and 8 months old.

Mice typically mate in the middle of the dark cycle. A hard white or yellow mucous plug forms in the vagina after mating. The plug usually remains for 12 hr or longer. Females should be checked in the morning to avoid missing plugs. Check for plugs by picking up each female by the tail. Place her on a wire cage top and allow her to grasp the wires with her front paws. The vaginal opening can be observed by raising the hind legs off the cage top while lifting the tail. Plugs are often immediately visible. To ensure that a plug is not missed, the vagina can be probed gently with a disposable pipet tip (Gilson-style P-200). These tips are cheap, clean, and relatively blunt.

Isolate the blastocysts

5. On post-coital day 3.5 (see time line, Fig. 23.7.1), sacrifice females by cervical dislocation. Place the mouse on its back and wet the abdomen with 95% ethanol.

Work through the protocol with one mouse at a time until comfortable with the procedure. Blastocysts should be harvested before noon, when the mice are housed with a standard light/dark cycle. Later in the day, a higher percentage of the blastocysts will have hatched (lost the zona pellucida). Blastocysts without a zona cannot be used for injections.

6. Tear the skin away from the abdomen and cut through the peritoneal wall with scissors.

The skin can be cut, but with some practice the skin can be torn away quickly.

7. Remove the ovaries and uterine horns. Place them on a clean dry paper towel (see Fig. 23.7.2A for a diagram of the isolated tissues).

The ovaries and both uterine horns can be removed as a single piece. First, grasp an ovary and its associated fat pad with forceps. The ovary is easily found at the base of the kidney. Gently lift the ovary and uterine horn. As the uterine horn is lifted, cut away associated tissue and fat. Cut the cervix and continue to free the second uterine horn and ovary. The tissue will stick to the paper towel, making it less difficult to work with.

Figure 23.7.2 Blastocyst isolation. Diagram of the uterine horns during different stages of blastocyst isolation. **(A)** Appearance of the attached uterine horns immediately after removal from the mouse. At this stage fat and associated tissues can be removed easily if the uterus is placed on a clean paper towel. Note the indicated cut sites. Both horns should be cut in same locations. **(B)** Illustration of the flushing procedure. Insert the blunted 25-G needle into the opening while the uterus is still on the paper towel. Clamp down on the needle with forceps to pinch the tissue on the needle and move the assembly over a watch glass to begin flushing.

8. Trim fat and blood vessels from the uterine horns with fine scissors and forceps.

This step is not critical, but it is particularly helpful to remove debris from around the junction between the uterus and the oviduct and the uterine/cervical junction.

9. Cut the uterine horn at the cervical junction and then at the junction of the uterus and oviduct (Fig. 23.7.2A). Insert a blunted 25-G needle attached to a syringe filled with injection medium into the uterine horn (Fig. 23.7.2B). Grasp the tip of the needle and tissue with forceps. Lift the assembly over a watch glass and flush the blastocysts out of the uterine horn with 200 to 300 μ l of injection medium. Repeat for the remaining uterine horn.

The oviduct end should be cut at a point where it is wide enough to accept the needle. Blastocysts can be flushed into a tissue culture dish instead of a watch glass. The watchglass is convenient because the embryos tend to concentrate in the center due to the curvature. The volume of fluid is not critical. Observe the procedure closely to make sure the fluid is flushing the uterus; the uterine horn should expand slightly as the syringe is pushed and the fluid should come out of the other end, not dribble down the side. Blastocysts from many uterine horns can be collected in a single watch glass. The embryos can be left at room temperature during the procedure.

10. Collect blastocysts with an intact zona pellucida (Fig. 23.7.4B and Fig. 23.7.5) under a dissecting microscope using an embryo transfer pipet. Use illumination from both above and below for best visibility. Transfer the embryos to a microdrop of injection medium under oil in a petri dish and place the dish on a slide warmer set at 37°C (see Reagents and Solutions for description of microdrop cultures).

The blastocysts will remain healthy for the entire day under these conditions.

Invariably, the watchglass contains debris—air bubbles and embryos that have not developed properly. Embryos will settle to the bottom of the watch glass. Gently swirling the glass will help to concentrate the embryos in the center. Often, rocking the watch glass while focusing on the lower most layer of debris will help to distinguish embryos from debris and bubbles; embryos roll in a distinctive manner when the glass is rocked. Blastocysts are fairly easy to recognize because of the large cavity. At times it is difficult to determine if the blastocysts have a zona pellucida when viewed with a dissecting microscope. If there is any question, save the embryo; the zona pellucida is easily observed with the injection microscope. Blastocysts without zonae cannot be injected. Many poorly developed embryos are usually present. These appear as single large cells or clumps of cells enclosed in a zona pellucida and represent unfertilized embryos or embryos that were slow to develop. These cannot be injected and should be discarded. The final decision on any close calls can be made under the injection scope.

BLASTOCYST INJECTION

Conceptually, blastocyst injection is simple—blastocysts and single-cell suspensions of ES cells are placed in a microdrop under a microscope. Individual ES cells are collected by aspiration into capillary pipet. A single blastocyst is grasped by aspiration with a second pipet. The injection pipet is inserted into the blastocoel cavity and the cells are ejected into the cavity.

Materials

- Injection medium (see recipe)
- ES cell suspension (see Support Protocol 2)
- Blastocysts (see Basic Protocol 1)
- Injection chamber (Fig. 23.7.3)
- Injection apparatus (see recipe)
- Holding pipet (VacuTips, Eppendorf)
- Injection pipet (Transfer Tips, Eppendorf)

Prepare the blastocysts and injection chamber

1. Prepare an injection chamber, consisting of two 50- μ l microdrops of injection medium separated by a few millimeters and covered with mineral oil (Fig. 23.7.3A and B) in the inverted top of a Falcon 35 \times 10-mm petri dish.

The inverted top of a petri dish is used because the lip is shorter than the lip of the dish. It is less difficult to align the injection and holding pipets with the shorter lip. Not all 35-mm dishes have the short lip found on the top of the Falcon plate. Alternatively, a larger dish can be used, but this requires the addition of much more mineral oil. Use petri dishes rather than tissue culture plates to reduce cell sticking.

2. Place ES cells in the upper drop (Fig. 23.7.3A) by adding 5 or 10 μ l of the ES cell suspension to the drop.

The exact number of cells in the drop is not critical. However, too many cells will often lead to clumping and accumulation of debris on the tip of the injection pipet while too few cells will require too much searching. 5 μ l of a 1-5 \times 10⁶ cells/ml suspension is usually sufficient. With some practice there is no need to count cells. The number of cells on the plate can be adjusted by changing the volume added to the microdrop.

3. Place 10 to 15 blastocysts in the 12 o'clock position in the lower drop (Fig. 23.7.3A).
