Foreword

Phillip A. Sharp¹

The breadth of knowledge required for modern research in molecular biology is truly staggering. A single series of experiments can encompass genetic manipulation of specific bacterial strains and their phage, the appropriate use of several highly specific enzymes, and the culturing and genetic engineering of mammalian cells. For individuals who have followed the evolution of research in molecular biology, it was surprising to watch the mammalian λ immunoglobulin gene being cloned in the prokaryotic λ phage. Neither immunologists nor bacterial geneticists expected the ultimate union when the phage and gene were named. Now a single individual must master both fields to be successful. Research that depends upon such breadth of knowledge needs protocol books that explain why certain methods are used and provide references for further reading. This manual fulfills that need.

All scientists realize that they figuratively stand on the shoulders of their predecessors. Nothing more concretely reflects this dependence than a laboratory protocol book. It is a monument to the hours of labor that students, technicians and other professionals have expended in developing methods that work every time. Good methods have another characteristic: they have been honed to the minimum of time and effort required to achieve the desired results. Most investigators collect personal protocol books of “tried and true” recipes. This new manual with its continuously growing and evolving set of protocols is an excellent basis from which to begin such a collection.

There are two unique features of this manual that are in tune with the rapid advances in molecular biology. First, the manual evolves continuously with the addition of new protocols in emerging areas of research. These new protocols are added as quarterly supplements to the core manual. Second, the manual evolves through a “network” of the users. Readers are encouraged to contribute corrections and improvements on techniques in each supplement. Thus, the book is designed to grow and change as biology grows and changes.

Molecular biology has always been an intensely experimental science. Young people, more commonly, have the energy and intensity to push the field forward. The excellent group of young scientists who have contributed to this book are representatives of this tradition.

¹Cambridge, Massachusetts

Preface

Frederick M. Ausubel, Roger Brent, Robert E. Kingston, David D. Moore, J. G. Seidman, John A. Smith, and Kevin Struhl

Although mastery of the techniques in this manual will enable the reader to pursue research in molecular genetics, the manual is not intended to be a substitute for graduate-level courses in molecular biology or a comprehensive textbook in the field. Introductory texts that we recommend include: *Molecular Biology of the Gene* (4th ed.), by J.D. Watson, N.H. Hopkins, J.W. Roberts, J.A. Steitz, and A.M. Weiner; *Molecular Genetics: An Introductory Narrative*, by G.S. Stent and R. Calendar; *From Genes to Clones*, by E.-L. Winnacker; and *Genetics and Molecular Biology*, by R. Schleif. In addition, *An Introduction to Genetic Analysis*, by D.T. Suzuki, A.J.F. Griffiths, J.H. Miller, and R.C. Lewontin, is a good place to learn classical genetics, and *The Molecular Biology of the Cell*, by B. Alberts, D. Bray, J. Lewis, M. Raff, K. Roberts, and J.D. Watson is a compendium of useful information about many aspects of cellular and molecular biology. Finally, we strongly recommend that readers gain first-hand experience in basic techniques and safety procedures by working in a molecular biology laboratory.

An inevitable hazard of manual writing is that protocols become obsolete or that new techniques are developed—usually just as the pages are going to press. This problem is particularly severe in a fast-moving field such as molecular genetics. To safeguard our manual from inexorable obsolescence, and as a means of correcting errors in a timely manner, we provide a quarterly updating service. The looseleaf format facilitates the replacement of pages that contain errors or have become obsolete and will accommodate the addition of new protocols to the appropriate section of the manual. The publisher can provide further details about subscribing to the quarterly supplements.

How to Use This Manual

Format and Organization

This publication is available in looseleaf, CD-ROM and online formats. The material covered in each version is identical. For looseleaf purchasers, four binders are provided to accommodate the growth of the manual via the quarterly update service. The looseleaf format of the binders allows easy insertion of new pages, units, and chapters that are added. The index and table of contents are updated with each supplement.

CD-ROM purchasers receive a completely new disc containing the entire manual every quarter. The CD-ROM User's Guide describes in detail the many features designed for accessing information presented in the CD. Topics of interest can be located primarily by using either the search index (by typing in the desired word or string of words) or by scanning through the expandable table of contents and selecting the desired units. In addition, hyperlinks jump between related units when cross-references are selected and from solutions and reagents listed in the materials list to their corresponding recipes.

Subjects in this manual are organized by chapters and sections, and protocols are contained in units. Units generally describe a method and include one or more protocols with listings of materials, the protocol steps and annotations, recipes for unique reagents and solutions, and commentaries on the “hows” and “whys” of the method. Overview units contain theoretical discussions that lay the foundation for subsequent protocols. Page numbering in the looseleaf version reflects this modular arrangement; for example, page 15.1.3 refers to Chapter 15 (PCR), Unit 1 (standard procedures and optimization), page 3 of that particular unit.

Many reagents and procedures are employed repeatedly throughout the manual. Rather than duplicate this information, cross-references among units are used extensively. Early chapters (and appendices) describe these commonly used techniques (basic microbiology and basic manipulations of enzymes, DNA, and RNA), while later chapters describe their application (constructing libraries, DNA sequencing, mutagenesis, transfection, and protein analysis). Thus, whenever a particular enzyme is used in a protocol, the appropriate unit in Chapter 3—describing reaction conditions for that enzyme—is cross-referenced (e.g., unit 3.7 for reverse transcriptase). Similarly, throughout the book readers are referred to unit 1.3 for spreading or streaking a plate, to unit 2.1A for phenol extraction/alcohol precipitation, to unit 2.5A for agarose gel electrophoresis, and so on. By turning to these units, the reader will find instructions for the techniques, recipes for relevant reagents, and commentary. As a result, protocols in the later chapters of the book—which can be lengthy and complex—are not overburdened with steps describing auxiliary procedures required to prepare, purify, and analyze the sample or molecule of interest.

Introductory and Explanatory Information

Because this publication is first and foremost a compilation of molecular biology techniques we have not provided extensive instructive material. We have, however, included explanatory information where required to help readers gain an intuitive grasp of the procedures. First, the chapter, section, and unit introductions describe how the protocols that follow connect to each other. Second, annotations to the actual protocol steps describe what is happening. Third, the commentary sections that close each unit give background information and review the relevant literature so that readers are aware of the historical and theoretical development of a technique, as well as alternative approaches. Fourth, key references are sometimes included to inform users of particularly useful background reading or original descriptions or applications of the technique. Finally, in some cases special “overview” units have been included early in the chapter.

Protocols

Many units in the manual contain groups of protocols. The basic protocol is presented first in each unit and is generally the recommended approach. Alternate protocols are provided where different equipment or reagents can be employed to achieve similar ends, where the starting material requires a variation in approach, or where requirements for the end product differ from those in the basic protocol. Support protocols describe additional steps that are required to perform the basic or alternate protocols; these steps are separated from the core protocol because they might be applicable to other uses in the manual, or because they are performed in a time frame separately from the basic protocol steps.

Reagents and Solutions

Reagents required for a protocol are listed in the “materials” list before the procedure begins. Many are common stock solutions, others are commonly used buffers or media, while others are solutions unique to a particular protocol. Recipes for the latter solutions are provided in each unit, following the protocols (and before the commentary) under the heading Reagents and Solutions. It is important to note that the names of some of these special solutions might be similar from unit to unit (e.g., hybridization solution, high-salt solution, etc.) while the recipes differ; thus, make certain that reagents are prepared from the proper recipes. On the other hand, recipes for commonly used buffers and media are provided once in an appendix or in early units in the manual. These universal recipes are cross-referenced parenthetically in the materials lists rather than repeated with every usage.

NOTE: Deionized, distilled water should be used in all protocols in this manual, and in the preparation of all reagents and solutions.

Commercial Suppliers

In some instances throughout the manual, we have recommended commercial suppliers of chemicals, biological materials, kits, or equipment. This has been avoided wherever possible, because preference for a specific brand is subjective and is generally not based on extensive comparison testing. Our guidelines for recommending a supplier are that (1) the particular brand has actually been found to be of superior quality, or (2) the item is difficult to find in the marketplace. An appendix lists the full names and addresses of all recommended suppliers, but these are by no means the only vendors of biological supplies. Readers may experiment with substituting their own favorite brands.

Safety Considerations

Anyone carrying out these protocols will encounter the following hazardous or potentially hazardous materials: (1) radioactive substances, (2) toxic chemicals and carcinogenic or teratogenic reagents, (3) pathogenic and infectious biological agents, and (4) recombinant DNA. Most governments regulate the use of these materials; it is essential that they be used in strict accordance with local and national regulations. Cautionary notes are included in many instances throughout the manual, but we emphasize that users must proceed with the prudence and precaution associated with good laboratory practice, and that all materials be used in strict accordance with local and national regulations.

Reader Response

Most of the protocols included in this manual are used routinely in our own laboratories. These protocols work for us; to make them work for you we have annotated critical steps and included critical parameters and troubleshooting guides in the commentaries to most units. However, the successful evolution of this manual depends upon readers' observations and suggestions. Consequently, a self-mailing, reader-response survey is included at the back of the manual (and is included with each supplement); we encourage readers to send in their comments. Electronic contact information is available at <http://www.currentprotocols.com>.

Acknowledgments

Continuing to keep this manual up to date would be impossible without massive assistance from the Current Protocols staff at John Wiley & Sons. Among those who help us, we are extremely grateful to Joe Ingram, Virginia Chanda, Scott Holmes, Tom Cannon, Tom Downey, Susan Lieberman, Allen Ranz, and Joseph White. We are particularly indebted to Sarah Greene and her staff at Greene Publishing Associates who initially conceived of this project and helped to shape it with skill and unbounded patience.

We are especially grateful to our co-workers who have helped with the manual by contributing material to it, by commenting on the chapters, or by field-testing the procedures. To those people—in our own labs, and in academic and industrial labs all over the world—we offer our deepest thanks.

Contents

CHAPTER 1 ESCHERICHIA COLI, PLASMIDS, AND BACTERIOPHAGES

Introduction

Section I Escherichia coli

- Unit 1.1 Media Preparation and Bacteriological Tools
- Unit 1.2 Growth in Liquid Media
- Unit 1.3 Growth on Solid Media
- Unit 1.4 Selected Topics from Classical Bacterial Genetics

Section II Vectors Derived from Plasmids

- Unit 1.5 Introduction to Plasmid Biology
- Unit 1.6 Minipreps of Plasmid DNA
- Unit 1.7 Large-Scale Preparation of Plasmid DNA
- Unit 1.8 Introduction of Plasmid DNA into Cells

Section III Vectors Derived from Lambda and Related Bacteriophages

- Unit 1.9 Introduction to Lambda Phages
- Unit 1.10 Lambda as a Cloning Vector
- Unit 1.11 Plating Lambda Phage to Generate Plaques
- Unit 1.12 Growing Lambda-Derived Vectors
- Unit 1.13 Preparing Lambda DNA from Phage Lysates

Section IV Vectors Derived from Filamentous Phages

- Unit 1.14 Introduction to Vectors Derived from Filamentous Phages
- Unit 1.15 Preparing and Using M13-Derived Vectors

Section V Specialized Techniques

- Unit 1.16 Recombineering: Genetic Engineering in Bacteria Using Homologous Recombination

CHAPTER 2 PREPARATION AND ANALYSIS OF DNA

Introduction

Section I Manipulation of DNA

- Unit 2.1A Purification and Concentration of DNA from Aqueous Solutions
- Unit 2.1B Purification of DNA by Anion-Exchange Chromatography
- Unit 2.2 Preparation of Genomic DNA from Mammalian Tissue
- Unit 2.3 Preparation of Genomic DNA from Plant Tissue
- Unit 2.4 Preparation of Genomic DNA from Bacteria

Section II Resolution and Recovery of Large DNA Fragments

- Unit 2.5A Agarose Gel Electrophoresis
- Unit 2.5B Pulsed-Field Gel Electrophoresis
- Unit 2.6 Isolation and Purification of Large DNA Restriction Fragments from Agarose Gels

Section III Resolution and Recovery of Small DNA Fragments

Unit 2.7 Separation of Small DNA Fragments by Conventional Gel Electrophoresis

Unit 2.8 Capillary Electrophoresis of DNA

Section IV Analysis of DNA Sequences by Blotting and Hybridization

Unit 2.9A Southern Blotting

Unit 2.9B Dot and Slot Blotting of DNA

Unit 2.10 Hybridization Analysis of DNA Blots

Section V Synthesis and Purification of Oligonucleotides

Unit 2.11 Synthesis and Purification of Oligonucleotides

Unit 2.12 Purification of Oligonucleotides Using Denaturing Polyacrylamide Gel Electrophoresis

CHAPTER 3 ENZYMATIC MANIPULATION OF DNA AND RNA

Introduction

Section I Restriction Endonucleases

Unit 3.1 Digestion of DNA with Restriction Endonucleases

Section II Restriction Mapping

Unit 3.2 Mapping by Multiple Endonuclease Digestions

Unit 3.3 Mapping by Partial Endonuclease Digestions

Section III Enzymes for Modifying and Radioactively Labeling Nucleic Acids

Unit 3.4 Reagents and Radioisotopes Used to Manipulate Nucleic Acids

Unit 3.5 DNA-Dependent DNA Polymerases

Unit 3.6 Template-Independent DNA Polymerases

Unit 3.7 RNA-Dependent DNA Polymerases

Unit 3.8 DNA-Dependent RNA Polymerases

Unit 3.9 DNA-Independent RNA Polymerases

Unit 3.10 Phosphatases and Kinases

Unit 3.11 Exonucleases

Unit 3.12 Endonucleases

Unit 3.13 Ribonucleases

Unit 3.14 DNA Ligases

Unit 3.15 RNA Ligases

Section IV Construction of Hybrid DNA Molecules

Unit 3.16 Subcloning of DNA Fragments

Unit 3.17 Constructing Recombinant DNA Molecules by the Polymerase Chain Reaction

Section V Specialized Applications

Unit 3.18 Labeling and Colorimetric Detection of Nonisotopic Probes

Unit 3.19 Chemiluminescent Detection of Nonisotopic Probes

Unit 3.20 Recombinational Cloning

CHAPTER 4 PREPARATION AND ANALYSIS OF RNA

Introduction

Section I Preparation of RNA from Eukaryotic and Prokaryotic Cells

Unit 4.1 Preparation of Cytoplasmic RNA from Tissue Culture Cells

Unit 4.2 Guanidine Methods for Total RNA Preparation

Unit 4.3 Phenol/SDS Method for Plant RNA Preparation

Unit 4.4 Preparation of Bacterial RNA

Unit 4.5 Preparation of Poly(A)⁺ RNA

Section II Analysis of RNA Structure and Synthesis

Unit 4.6 S1 Analysis of Messenger RNA Using Single-Stranded DNA Probes

Unit 4.7 Ribonuclease Protection Assay

Unit 4.8 Primer Extension

Unit 4.9 Analysis of RNA by Northern and Slot Blot Hybridization

Unit 4.10 Identification of Newly Transcribed RNA

CHAPTER 5 CONSTRUCTION OF RECOMBINANT DNA LIBRARIES

Introduction

Section I Overview of Recombinant DNA Libraries

Unit 5.1 Genomic DNA Libraries

Unit 5.2 cDNA Libraries

Section II Preparation of Insert DNA from Genomic DNA

Unit 5.3 Size Fractionation Using Sucrose Gradients

Unit 5.4 Size Fractionation Using Agarose Gels

Section III Preparation of Insert DNA from Messenger RNA

Unit 5.5 Conversion of mRNA into Double-Stranded cDNA

Unit 5.6 Ligation of Linkers or Adapters to Double-Stranded cDNA

Section IV Production of Genomic DNA and cDNA Libraries

Unit 5.7 Production of a Genomic DNA Library

Unit 5.8A Production of a Complete cDNA Library

Unit 5.9 Construction of Bacterial Artificial Chromosome (BAC/PAC) Libraries

Section V Amplification of Transformed or Packaged Libraries

Unit 5.10 Amplification of a Bacteriophage Library

Unit 5.11 Amplification of Cosmid and Plasmid Libraries

CHAPTER 6 SCREENING OF RECOMBINANT DNA LIBRARIES

Introduction

Section I Plating Libraries and Transfer to Filter Membranes

Unit 6.1 Plating and Transferring Bacteriophage Libraries

Unit 6.2 Plating and Transferring Cosmid and Plasmid Libraries

Section II Hybridization with Radioactive Probes

Unit 6.3 Using DNA Fragments as Probes

Unit 6.4 Using Synthetic Oligonucleotides as Probes

Section III Purification of Bacteriophage, Cosmid, and Plasmid Clones

Unit 6.5 Purification of Bacteriophage Clones

Unit 6.6 Purification of Cosmid and Plasmid Clones

Section IV Screening with Antibodies

Unit 6.7 Immunoscreening of Fusion Proteins Produced in Lambda Plaques

Unit 6.8 Immunoscreening after Hybrid Selection and Translation

Section V Yeast Artificial Chromosome Libraries

Unit 6.9 Overview of Strategies for Screening YAC Libraries and Analyzing YAC Clones

Unit 6.10 Analysis of Isolated YAC Clones

Section VI Specialized Strategies for Screening Libraries

Unit 6.11 Use of Monoclonal Antibodies for Expression Cloning

Unit 6.12 Recombination-Based Assay (RBA) for Screening Bacteriophage Lambda Libraries

CHAPTER 7 DNA SEQUENCING

Introduction

Unit 7.1 DNA Sequencing Strategies

Unit 7.2 Constructing Nested Deletions for Use in DNA Sequencing

Unit 7.3 Preparation of Templates for DNA Sequencing

Unit 7.4A DNA Sequencing by the Dideoxy Method

Unit 7.4B Dideoxy DNA Sequencing with Chemiluminescent Detection

Unit 7.5 DNA Sequencing by the Chemical Method

Unit 7.6 Denaturing Gel Electrophoresis for Sequencing

Unit 7.7 Computer Manipulation of DNA and Protein Sequences

Unit 7.8 Polony DNA Sequencing

CHAPTER 8 MUTAGENESIS OF CLONED DNA

Introduction

Unit 8.1 Oligonucleotide-Directed Mutagenesis without Phenotypic Selection

Unit 8.2A Mutagenesis with Degenerate Oligonucleotides: Creating Numerous Mutations in a Small DNA Sequence

Unit 8.2B Gene Synthesis: Assembly of Target Sequences Using Mutually Priming Long Oligonucleotides

Unit 8.3 Random Mutagenesis by PCR

Unit 8.4 Linker-Scanning Mutagenesis of DNA

Unit 8.5 Directed Mutagenesis Using the Polymerase Chain Reaction

CHAPTER 9 INTRODUCTION OF DNA INTO MAMMALIAN CELLS

Introduction

Section I Transfection of DNA into Eukaryotic Cells

Unit 9.1 Calcium Phosphate Transfection

Unit 9.2 Transfection Using DEAE-Dextran

Unit 9.3 Transfection by Electroporation

Unit 9.4 Transfection of Cultured Eukaryotic Cells Using Cationic Lipid Reagents

Unit 9.5 Selection of Transfected Mammalian Cells

Section II Uses of Fusion Genes in Mammalian Transfection

Unit 9.6 Overview of Genetic Reporter Systems

Unit 9.7A Isotopic Assays for Reporter Gene Activity

Unit 9.7B Nonisotopic Assays for Reporter Gene Activity

Unit 9.7C Use of the *A. Victoria* Green Fluorescent Protein to Study Protein Dynamics in Vivo

Unit 9.8 Direct Analysis of RNA after Transfection

Section III Transduction of Genes Using Retrovirus Vectors

Unit 9.9 Overview of the Retrovirus Transduction System

Unit 9.10 Preparation of a Specific Retrovirus Producer Cell Line

Unit 9.11 Transient Transfection Methods for Preparation of High-Titer Retroviral Supernatants

Unit 9.12 Large-Scale Preparation and Concentration of Retrovirus Stocks

Unit 9.13 Detection of Helper Virus in Retrovirus Stocks

Unit 9.14 Retrovirus Infection of Cells In Vitro and In Vivo

Section IV Inactivation of Genes in Mammalian Cells

Unit 9.15 Human Somatic Cell Gene Targeting

CHAPTER 10 ANALYSIS OF PROTEINS

Introduction

Section I Quantitation of Proteins

Unit 10.1A Spectrophotometric and Colorimetric Determination of Protein Concentration

Unit 10.1B Quantitative Amino Acid Analysis

Section II Electrophoretic Separation of Proteins

Unit 10.2A One-Dimensional SDS Gel Electrophoresis of Proteins

Unit 10.2B One-Dimensional Electrophoresis Using Nondenaturing Conditions

Unit 10.3 Two-Dimensional Gel Electrophoresis Using the ISO-DALT System

Unit 10.4 Two-Dimensional Gel Electrophoresis

Unit 10.5 Overview of Digital Electrophoresis Analysis

Section III Detection of Proteins

- Unit 10.6 Staining Proteins in Gels
- Unit 10.7 Detection of Proteins on Blot Transfer Membranes
- Unit 10.8 Immunoblotting and Immunodetection

Section IV Purification of Proteins by Conventional Chromatography

- Unit 10.9 Gel-Filtration Chromatography
- Unit 10.10 Ion-Exchange Chromatography
- Unit 10.11A Immunoaffinity Chromatography
- Unit 10.11B Metal-Chelate Affinity Chromatography

Section V Purification of Proteins by High-Performance Liquid Chromatography

- Unit 10.12 HPLC of Peptides and Proteins: Preparation and System Set-Up
- Unit 10.13 HPLC of Peptides and Proteins: Standard Operating Conditions
- Unit 10.14 Reversed-Phase Isolation of Peptides

Section VI Specialized Applications

- Unit 10.15 Purification of Recombinant Proteins and Study of Protein Interaction by Epitope Tagging
- Unit 10.16 Immunoprecipitation
- Unit 10.17 Synthesizing Proteins In Vitro by Transcription and Translation of Cloned Genes
- Unit 10.18 Metabolic Labeling with Amino Acids
- Unit 10.19 Isolation of Proteins for Microsequence Analysis
- Unit 10.20 Capillary Electrophoresis of Proteins and Peptides
- Unit 10.21 Overview of Peptide and Protein Analysis by Mass Spectrometry
- Unit 10.22 Protein Identification and Characterization by Mass Spectrometry
- Unit 10.23 Difference Gel Electrophoresis (DIGE) Using CyDye DIGE Fluor Minimal Dyes
- Unit 10.24 Solution Radioimmunoassay of Proteins and Peptides

CHAPTER 11 IMMUNOLOGY

Introduction

Section I Immunoassays

- Unit 11.1 Conjugation of Enzymes to Antibodies
- Unit 11.2 Enzyme-Linked Immunosorbent Assays (ELISA)
- Unit 11.3 Isotype Determination of Antibodies

Section II Preparation of Monoclonal Antibodies

- Unit 11.4 Immunization of Mice
- Unit 11.5 Preparation of Myeloma Cells
- Unit 11.6 Preparation of Mouse Feeder Cells for Fusion and Cloning
- Unit 11.7 Fusion of Myeloma Cells with Immune Spleen Cells
- Unit 11.8 Cloning of Hybridoma Cell Lines by Limiting Dilution
- Unit 11.9 Freezing and Recovery of Hybridoma Cell Lines
- Unit 11.10 Production of Monoclonal Antibody Supernatant and Ascites Fluid
- Unit 11.11 Purification of Monoclonal Antibodies

Section III Preparation of Polyclonal Antisera

Unit 11.12 Production of Polyclonal Antisera

Unit 11.13 In Vitro Antibody Production

Unit 11.14 Purification of Immunoglobulin G Fraction from Antiserum, Ascites Fluid, or Hybridoma Supernatant

Section IV Preparation of Antipeptide Antibodies

Unit 11.15 Introduction to Peptide Synthesis

Unit 11.16 Synthetic Peptides for Production of Antibodies that Recognize Intact Proteins

Section V Determination of Specific Antibody Titer and Isotype

Unit 11.17 Determination of the Specific Antibody Titer

Section VI Preparation and Use of Specialized Antibodies

Unit 11.18 Identification of Polyol-Responsive Monoclonal Antibodies for Use in Immunoaffinity Chromatography

CHAPTER 12 DNA-PROTEIN INTERACTIONS

Introduction

Unit 12.1 Preparation of Nuclear and Cytoplasmic Extracts from Mammalian Cells

Unit 12.2 Mobility Shift DNA-Binding Assay Using Gel Electrophoresis

Unit 12.3 Methylation and Uracil Interference Assays for Analysis of Protein-DNA Interactions

Unit 12.4 DNase I Footprint Analysis of Protein-DNA Binding

Unit 12.5 UV Crosslinking of Proteins to Nucleic Acids

Unit 12.6 Purification of DNA-Binding Proteins Using Biotin/Streptavidin Affinity Systems

Unit 12.7 Detection, Purification, and Characterization of cDNA Clones Encoding DNA-Binding Proteins

Unit 12.8 Rapid Separation of Protein-Bound DNA from Free DNA Using Nitrocellulose Filters

Unit 12.9 Analysis of DNA-Protein Interactions Using Proteins Synthesized In Vitro from Cloned Genes

Unit 12.10 Purification of Sequence-Specific DNA-Binding Proteins by Affinity Chromatography

Unit 12.11 Determination of Protein-DNA Sequence Specificity by PCR-Assisted Binding-Site Selection

Unit 12.12 Yeast One-Hybrid Screening for DNA-Protein Interactions

CHAPTER 13 YEAST

Introduction

Section I Basic Techniques of Yeast Genetics

Unit 13.1 Preparation of Yeast Media

Unit 13.2 Growth and Manipulation of Yeast

Unit 13.3 Genome-Wide Transposon Mutagenesis in Yeast

Section II Yeast Vectors

Unit 13.4 Yeast Cloning Vectors and Genes

Unit 13.6 Yeast Vectors and Assays for Expression of Cloned Genes

Section III Manipulation of Yeast Genes

Unit 13.7 Introduction of DNA into Yeast Cells

- Unit 13.8 Cloning Yeast Genes by Complementation
- Unit 13.9 Manipulation of Plasmids from Yeast Cells
- Unit 13.10 Manipulation of Cloned Yeast DNA

Section IV Preparation of Yeast DNA, RNA, and Proteins

- Unit 13.11 Preparation of Yeast DNA
- Unit 13.12 Preparation of Yeast RNA
- Unit 13.13 Preparation of Protein Extracts from Yeast

Section V *Schizosaccharomyces pombe*

- Unit 13.14 Overview of *Schizosaccharomyces pombe*
- Unit 13.15 *S. pombe* Strain Maintenance and Media
- Unit 13.16 Growth and Manipulation of *S. pombe*
- Unit 13.17 Introduction of DNA into *S. pombe* Cells

CHAPTER 14 IN SITU HYBRIDIZATION AND IMMUNOHISTOCHEMISTRY

Introduction

- Unit 14.1 Fixation, Embedding, and Sectioning of Tissues, Embryos, and Single Cells
- Unit 14.2 Cryosectioning
- Unit 14.3 In Situ Hybridization to Cellular RNA
- Unit 14.4 Detection of Hybridized Probe
- Unit 14.5 Counterstaining and Mounting of Autoradiographed In Situ Hybridization Slides
- Unit 14.6 Immunohistochemistry
- Unit 14.7 In situ Hybridization and Detection Using Nonisotopic Probes
- Unit 14.8 In situ Polymerase Chain Reaction and Hybridization to Detect Low-Abundance Nucleic Acid Targets
- Unit 14.9 Whole-Mount In Situ Hybridization and Detection of RNAs in Vertebrate Embryos and Isolated Organs
- Unit 14.10 Principles and Application of Fluorescence Microscopy
- Unit 14.11 Basic Confocal Microscopy
- Unit 14.12 Measurement of In Situ Hybridization
- Unit 14.13 Morphological, Biochemical, and Flow Cytometric Assays of Apoptosis
- Unit 14.14 Whole-Mount Histochemical Detection of β -Galactosidase Activity
- Unit 14.15 Overview of Image Analysis, Image Importing, and Image Processing using Freeware
- Unit 14.16 Three-Dimensional Reconstruction of Tissues

CHAPTER 15 THE POLYMERASE CHAIN REACTION

Introduction

- Unit 15.1 Enzymatic Amplification of DNA by PCR: Standard Procedures and Optimization
- Unit 15.2 Direct DNA Sequencing of PCR Products
- Unit 15.3 Ligation-Mediated PCR for Genomic Sequencing and Footprinting
- Unit 15.4 Molecular Cloning of PCR Products
- Unit 15.5 Enzymatic Amplification of RNA by PCR (RT-PCR)
- Unit 15.6 cDNA Amplification Using One-Sided (Anchored) PCR
- Unit 15.7 Quantitation of Rare DNAs by PCR
- Unit 15.8 High-Throughput Real-Time Quantitative Reverse Transcription PCR

CHAPTER 16 PROTEIN EXPRESSION

Introduction

Section I Expression of Proteins in *Escherichia coli*

- Unit 16.1 Overview of Protein Expression in *E. coli*
- Unit 16.2 Expression Using the T7 RNA Polymerase/Promoter System
- Unit 16.3 Expression Using Vectors with Phage λ Regulatory Sequences
- Unit 16.4A Introduction to Expression by Fusion Protein Vectors
- Unit 16.4B Enzymatic and Chemical Cleavage of Fusion Proteins
- Unit 16.5 Expression and Purification of lacZ and trpE Fusion Proteins
- Unit 16.6 Expression and Purification of Maltose-Binding Protein Fusions
- Unit 16.7 Expression and Purification of Glutathione-S-Transferase Fusion Proteins
- Unit 16.8 Expression and Purification of Thioredoxin Fusion Proteins

Section II Expression of Proteins in Insect Cells Using Baculovirus Vectors

- Unit 16.9 Overview of the Baculovirus Expression System
- Unit 16.10 Maintenance of Insect Cell Cultures and Generation of Recombinant Baculoviruses
- Unit 16.11 Expression and Purification of Recombinant Proteins Using the Baculovirus System

Section III Expression of Proteins in Mammalian Cells

- Unit 16.12 Transient Expression of Proteins Using COS Cells
- Unit 16.13 Expression and Purification of Epitope-Tagged Multisubunit Protein Complexes from Mammalian Cells
- Unit 16.14 Inducible Gene Expression Using an Autoregulatory, Tetracycline-Controlled System
- Unit 16.15 Overview of the Vaccinia Virus Expression System
- Unit 16.16 Preparation of Cell Cultures and Vaccinia Virus Stocks
- Unit 16.17 Generation of Recombinant Vaccinia Viruses
- Unit 16.18 Characterization of Recombinant Vaccinia Viruses and Their Products
- Unit 16.19 Gene Expression Using the Vaccinia Virus/T7 RNA Polymerase Hybrid System
- Unit 16.20 Expression of Proteins Using Semliki Forest Virus Vectors
- Unit 16.21 Overview of the HIV-1 Lentiviral Vector System
- Unit 16.22 Generation of HIV-1-Based Lentiviral Vector Particles
- Unit 16.23 Amplification Using CHO Cell Expression Vectors
- Unit 16.24 Helper-Dependent Adenoviral Vectors

CHAPTER 17 PREPARATION AND ANALYSIS OF GLYCOCONJUGATES

Introduction

Section I Special Considerations for Glycoproteins and Their Purification

- Unit 17.1 Special Considerations for Glycoproteins and Their Purification
- Unit 17.2 Special Considerations for Proteoglycans and Glycosaminoglycans and Their Purification
- Unit 17.3 Special Considerations for Glycolipids and Their Purification

Section II Detection of Saccharides on Glycoconjugates

- Unit 17.4 Metabolic Radiolabeling of Animal Cell Glycoconjugates
- Unit 17.5 Chemical Labeling of Carbohydrates by Oxidation and Sodium Borohydride Reduction

CHAPTER 1

Escherichia coli, Plasmids, and Bacteriophages

INTRODUCTION

Mastery of current DNA technology requires familiarity with a small number of basic concepts and techniques. The goal of this chapter is to present this information concisely, yet in enough detail to be useful when a procedure goes wrong. Section I is devoted to *Escherichia coli*. Recipes are provided for media that support *E. coli* growth, as well as instructions for making the simple tools needed to work with bacterial cells. Growth of *E. coli* in liquid and solid media is then detailed. The final unit in Section I describes a few detailed aspects of *E. coli* biology learned from classical bacterial genetic studies, the understanding of which is especially relevant to the techniques used in modern DNA work.

The remainder of the chapter discusses vectors used to introduce foreign DNA into *E. coli*. For the purposes of this chapter, vectors are said to be derived from plasmids, from bacteriophage lambda and related phages, or from filamentous phages. (Many modern vectors incorporate elements from more than one of these classes, and it is likely that this classification scheme will be hopelessly outdated by the time this chapter is revised.) Section II is concerned with plasmid vectors. Following a brief introduction to plasmid biology, procedures are described for purifying small and large amounts of plasmid DNA (“minipreps” and large preps). Finally, procedures for reintroducing plasmid DNA into bacterial cells are described. Section III covers vectors derived from bacteriophages. The biology of bacteriophage lambda is first introduced, followed by detailed aspects of biology that are especially significant when lambda derivatives are used as cloning vectors. Protocols in this section describe techniques for manipulating lambda-derived vectors, making single plaques, making and titering phage stocks, and isolating phage DNA. Finally, Section IV covers the biology and manipulation of vectors derived from filamentous phages.

This chapter will be meaningful primarily to readers with some knowledge of the principles of molecular biology. Several books on molecular biology are recommended in the preface. For further advanced reading in the topics of this chapter, we recommend five books, all from Cold Spring Harbor Laboratory: *Methods in Molecular Genetics* (Miller, 1972), *Advanced Bacterial Genetics* (Davis et al., 1980), *The Bacteriophage Lambda* (Hershey, 1971), *Lambda II* (Hendrix et al., 1983), and *Experiments with Gene Fusions* (Silhavy et al., 1984).

Many terms and jargon used by molecular biologists are introduced in this chapter. These terms are italicized at their first mention, and are defined below.

alpha fragment peptide containing the amino terminus of β -galactosidase, the *lacZ* gene product. Alpha fragments lack enzymatic activity, but can associate with omega fragments (see below) to form proteins whose β -galactosidase activity has been restored.

alpha-complementation restoration of β -galactosidase activity to omega fragments by association with alpha fragments.

amplification increase in copy number of some plasmids that occurs when host protein synthesis is inhibited.

cloning site site on a vector into which foreign DNA is inserted.

competent state in which bacterial or yeast cells are able to take up foreign DNA (for example, as the result of calcium treatment).

cos site of action of phage lambda *ter* function. Cos site is cut by *ter* to yield two cohesive ends (cos ends).

dilution, 10^x-fold a solution or suspension that contains 1/10^x as much (10^{-x} as much) of the dissolved or suspended species as does the starting liquid. For example, to “do a 10²-fold dilution” is to dilute a solution 100×.

early-log phase period during the growth of a culture after the lag period. During early log phase growth, cells have begun exponential growth.

efficiency of plating (EOP) titer of bacterial colonies or phage plaques under some experimental conditions divided by the titer of bacteria or phage obtained by growth on some reference medium.

exponential growth period during which the number of cells in the culture increases as an exponential function of time, that is, during which cell number = ke^t .

F factor genetic element found in some strains of *E. coli* and related species. F encodes proteins used in formation of sex pili which allow its transfer from bacterium to bacterium.

female strain strain that does not contain the F factor and that receives genetic information when crossed with a strain containing F.

helper phages bacteriophages that encode essential proteins and that allow other phages which do not encode these essential proteins to grow.

incompatible phenomenon in which two plasmids cannot replicate in the same cell without continual selection for both of them.

incompatibility group consists of plasmids that cannot be maintained together in the same cell. Compatible plasmids belong to different incompatibility groups.

induction the onset of transcription of a new gene or operon, usually in response to some environmental stimulus. Phage induction or lysogenic induction describe the process in which prophage excise from the chromosome of bacteria that harbor them and begin to grow lytically.

inoculation introduction of cells into a container of sterile growth medium.

lag period period just after inoculation of a culture when cells have not yet begun to grow exponentially.

late-log phase last period of exponential growth of a culture, after which growth slows and then stops altogether due to nutrient exhaustion or accumulation of waste products.

lawn uniform layer of bacteria that covers the surface of a plate.

log phase period during growth of a culture in which cells are growing exponentially.

low-copy-number plasmids plasmids found in less than about 20 copies per cell when cells containing them are grown in rich medium.

lysogen *E. coli* cell or strain that harbors a dormant bacteriophage.

male strain strain of bacteria that contains the F factor.

male-specific phages bacteriophages that only grow on male strains because they adsorb to sex pili.

marker detectable genetic difference between one organism and another (usually wild-type) organism of the same species.

minimal medium growth medium for cells that contains only salts, vitamins, trace elements, and simple compounds which serve as carbon, nitrogen, and phosphorous sources.

miniprep small-scale preparation or purification of some desired species, usually of plasmid or phage DNA.

mobilization transfer of DNA from one cell to another caused by a mobile genetic element such as the F factor.

multiplicity of infection (MOI) ratio of infecting bacteriophage to host cells.

nonsense suppression the insertion of amino acids into proteins at positions where translation would normally not occur because the mRNA contains a UAG (amber), UAA (ochre) or UGA nonsense codon.

nonsense suppressor tRNA that inserts amino acids at nonsense codons. The term is sometimes used for the genes encoding these tRNAs.

omega fragment protein containing the carboxy-terminal fragment of β-galactosidase. This protein lacks enzymatic activity, but β-galactosidase activity can be restored when the peptide is complexed with an alpha fragment.

ori (origin) site on genome at which DNA replication begins.

outgrowth the growth of freshly transformed cells under nonselective conditions for enough time to allow proteins encoded by the foreign DNA to be expressed.

overnight a small, freshly saturated liquid culture of bacteria.

packaging extract extract from special strains of *E. coli* that contains bacteriophage lambda head proteins, tail proteins, and packaging proteins. Phage DNA added to such an extract is assembled into phage particles.

par site on some plasmids which ensures that each daughter cell receives a plasmid copy.

pilot protein protein in the coat of filamentous phages that helps phage DNA enter the cell.

plates petri dishes filled with solid medium, used to grow separated bacterial colonies or plaques. The term is sometimes used to refer to 96-well microtiter dishes.

plating out the placement of bacteria or phage on plates so that colonies or plaques are formed.

polylinker stretch of DNA that contains contiguous restriction sites.

prophage dormant bacteriophage, usually integrated into the host chromosome, that replicates with the host bacterium.

relaxed control applies to plasmids whose replication does not depend on the bacterial cell cycle.

replicative form double-stranded circular filamentous phage DNA found inside infected cells.

replicator stretch of DNA on a phage or plasmid that enables the phage or plasmid to replicate.

rich medium growth medium that contains complex organic molecules (peptides, nucleotides, etc.). Typical components of rich media include tryptone (made from beef) and yeast extract (made from yeast).

rolling-circle replication mechanism of replication sometimes used by circular molecules in which DNA polymerase continually circumnavigates the template, and thus synthesizes a long tail.

satellite colonies small colonies that grow around a large colony on a plate containing selective medium. These are usually composed of cells unable to grow on selective medium, but which are able to grow near the large colony because the cells in the large colony neutralize the selective agent.

saturated culture culture of cells in liquid medium that has stopped growing because nutri-

ents are exhausted or because waste products have accumulated.

SOS response response of *E. coli* to DNA damage or other treatments that inhibit DNA replication. Lambda-derived phages are induced during this response.

stringent control applies to plasmids whose replication is synchronized with the *E. coli* cell cycle.

temperate describes bacteriophages capable of lysogenic growth.

transfection introduction of bacteriophage DNA into competent *E. coli* cells. Also describes the introduction of any DNA (including plasmid DNA) into cells of higher eukaryotes.

transformation introduction of plasmid DNA into *E. coli* or yeast. Also used to denote any of a number of changes in cultured higher eukaryotic cells to characteristics more typical of cancer cells (immortal growth, loss of contact inhibition, etc.).

ESCHERICHIA COLI

SECTION I

Escherichia coli is a rod-shaped bacterium with a circular chromosome about 3 million base pairs (bp) long. It can grow rapidly on *minimal medium* that contains a carbon compound such as glucose (which serves both as a carbon source and an energy source) and salts which supply nitrogen, phosphorus, and trace metals. *E. coli* grows more rapidly, however, on a *rich medium* that provides the cells with amino acids, nucleotide precursors, vitamins, and other metabolites that the cell would otherwise have to synthesize. The purpose of this first section is to provide basic information necessary to grow *E. coli*. A more detailed introduction to certain aspects of *E. coli* biology may be found in UNIT 1.4.

When *E. coli* is grown in liquid culture, a small number of cells are first *inoculated* into a container of sterile medium. After a period of time, called the *lag period*, the bacteria begin to divide. In rich medium a culture of a typical strain will double in number every 20 or 30 min. This phase of *exponential growth* of the cells in the culture is called *log phase* (sometimes subdivided into *early-log*, *middle-log*, and *late-log phases*). Eventually the cell density increases to a point at which nutrients or oxygen become depleted from the medium, or at which waste products (such as acids) from the cells have built up to a concentration that inhibits rapid growth. At this point, which, under normal laboratory conditions, occurs when the culture reaches a density of $1-2 \times 10^9$ cells/ml, the cells stop dividing rapidly. This phase is called *saturation* and a culture that has just reached this density is said to be freshly saturated.

With very few exceptions, bacterial strains used in recombinant DNA work are derivatives of *E. coli* strain K-12. Most advances in molecular biology until the end of the 1960s came from studies of this organism and of bacteriophages and plasmids that use it as a host. Much of the cloning technology in current use exploits facts learned during this period.

Media Preparation and Bacteriological Tools

UNIT 1.1

Recipes are provided below for minimal liquid media, rich liquid media, solid media, top agar, and stab agar. Tryptone, yeast extract, agar (Bacto-agar), nutrient broth, and Casamino Acids are from Difco. NZ Amine A is from Hunko Sheffield (Kraft).

MINIMAL MEDIA

Ingredients for these media should be added to water in a 2-liter flask and heated with stirring until dissolved. The medium should then be poured into separate bottles with loosened caps and autoclaved at 15 lb/in² for 15 min. Do not add nutritional supplements or antibiotics to any medium until it has cooled to <50°C. After the bottles cool to below 40°C, the caps can be tightened and the concentrated medium stored indefinitely at room temperature. All recipes are on a per liter basis.

M9 medium, 5×

- 30 g Na₂HPO₄
- 15 g KH₂PO₄
- 5 g NH₄Cl
- 2.5 g NaCl
- 15 mg CaCl₂ (optional)

Escherichia coli, Plasmids, and Bacteriophages

1.1.1

M63 medium, 5×

10 g (NH₄)₂SO₄
68 g KH₂PO₄
2.5 mg FeSO₄·7H₂O
Adjust to pH 7 with KOH

A medium, 5×

5 g (NH₄)₂SO₄
22.5 g KH₂PO₄
52.5 g K₂HPO₄
2.5 g sodium citrate·2H₂O

Before they are used, concentrated media should be diluted to 1× with sterile water and the following sterile solutions, per liter:

1 ml 1 M MgSO₄·7H₂O
10 ml 20% carbon source (sugar or glycerol)
and, if required:
0.1 ml 0.5% vitamin B1 (thiamine)
5 ml 20% Casamino Acids *or*
L amino acids to 40 μg/ml *or*
DL amino acids to 80 μg/ml
Antibiotic (see Table 1.4.1)

RICH MEDIA

Unless otherwise specified, rich media should be autoclaved for 25 min. Antibiotics and nutritional supplements should be added only after the solution has cooled to 50°C or below. A flask containing liquid at 50°C feels hot but can be held continuously in one's bare hands. All recipes are on a per liter basis.

H medium

10 g tryptone
8 g NaCl

Lambda broth

10 g tryptone
2.5 g NaCl

LB medium

10 g tryptone
5 g yeast extract
5 g NaCl
1 ml 1 N NaOH

The original recipe for LB medium (sometimes referred to as Luria or Lenox broth), does not contain NaOH. There are many different recipes for LB that differ only in the amount of NaOH added. We use this formula in our own work. Even though the pH is adjusted to near 7 with NaOH, the medium is not very highly buffered, and the pH of a culture growing in it drops as it nears saturation.

NZC broth

10 g NZ Amine A
5 g NaCl
2 g MgCl₂·6H₂O
Autoclave 30 min
5 ml 20% Casamino Acids

Superbroth

32 g tryptone
20 g yeast extract
5 g NaCl
5 ml 1 N NaOH

TB (terrific broth)

12 g Bacto tryptone
24 g Bacto yeast extract
4 ml glycerol

Add H₂O to 900 ml and autoclave, then add to above sterile solution 100 ml of a sterile solution of 0.17 M KH₂PO₄ and 0.72 M K₂HPO₄.

Tryptone broth

10 g tryptone
5 g NaCl

2× TY medium

16 g tryptone
10 g yeast extract
5 g NaCl

TYGPN medium

20 g tryptone
10 g yeast extract
10 ml 80% glycerol
5 g Na₂HPO₄
10 g KNO₃

SOLID MEDIA

Liquid media can be solidified with agar. For minimal plates, dissolve the agar in water and autoclave separately from the minimal medium; autoclaving the two together will give rise to an insoluble precipitate. For rich plates, autoclave the agar together with the other ingredients of the medium. Cool the agar to about 50°C and add other ingredients if necessary. At this temperature, the medium will stay liquid indefinitely, but it will rapidly solidify if its temperature falls much below 45°C. Finally, pour the medium into sterile disposable petri dishes (*plates*) and allow to solidify.

Freshly poured plates are wet and unable to absorb liquid spread onto them. Moreover, plates that are even slightly wet tend to exude moisture underneath bacteria streaked on them, which can cause the freshly streaked bacteria to float away. So for most applications, dry the plates by leaving them out at room temperature for 2 or 3 days, or by leaving them with the lids off for 30 min in a 37°C incubator or in a laminar flow hood. Store dry plates at 4°C, wrapped in the original bags used to package the empty plates. Plates should be inverted when incubated or stored.

Minimal Plates

Autoclave 15 g agar in 800 ml water for 15 min. Add sterile concentrated minimal medium and carbon source. After medium has cooled to about 50°C, add supplements and antibiotics. Pouring 32 to 40 ml medium into each plate, expect about 25 to 30 plates per liter.

Rich Plates

To ingredients listed below, add water to 1 liter and autoclave 25 min. Pour LB and H plates with 32 to 40 ml medium, in order to get 25 to 30 plates per liter. Pour lambda plates with about 45 ml medium for about 20 plates per liter.

H plates

10 g tryptone
8 g NaCl
15 g agar

Lambda plates

10 g tryptone
2.5 g NaCl
10 g agar

LB plates

10 g tryptone
5 g yeast extract
5 g NaCl
1 ml 1 N NaOH
15 g agar or agarose

Additives

Antibiotics (if required):

Ampicillin to 50 µg/ml
Tetracycline to 12 µg/ml
Other antibiotics, see Table 1.4.1

Galactosides (if required):

Xgal to 20 µg/ml
IPTG to 0.1 mM
Other galactosides, see Table 1.4.2

TOP AGAR

Top agar is used to distribute phage or cells evenly in a thin layer over the surface of a plate. In a typical application, molten top agar is mixed with bacteria and the mixture poured onto a plate to make a thin layer that is allowed to solidify. This layer of cells then grows denser, forming the opaque *lawn* of cells. Top agar contains less agar than plates, and so stays molten for days when it is kept at 45° to 50°C. Top agarose is sometimes used when DNA is to be prepared directly from phage, and is also used when libraries are plated out to be screened by plaque lifting.

Prepare top agar in 1-liter batches, autoclave for 15 min to melt, cool to 50°C, swirl to mix, pour into separate 100-ml bottles, reautoclave, cool, and store at room temperature. Before use, melt the agar by heating in a water bath or microwave oven (see *UNIT 1.11*) then cool to and hold at 45° to 50°C.

H top agar

10 g tryptone
8 g NaCl
7 g agar

LB top agar

10 g tryptone
5 g yeast extract
5 g NaCl
7 g agar

Lambda top agar

10 g tryptone
2.5 g NaCl
7 g agar

Top agarose

10 g tryptone
8 g NaCl
6 g agarose

STAB AGAR

Stab agar is used for storing bacterial strains (see *UNIT 1.3*). The recipe below is for 1 liter.

Stab agar

10 g nutrient broth
5 g NaCl
6 g agar
10 mg cysteine·Cl
10 mg thymine

Thymine is included so that thy⁻ bacteria can grow. Cysteine is thought to increase the amount of time bacteria can survive in stabs.

TOOLS

Inoculating Loops

Inoculating loops are used to move small numbers of bacteria or phage to a plate or to a new container of liquid medium. Inoculating loops may be purchased from any general scientific supply company. However, most researchers prefer to use loops made in the laboratory. These are made by inserting both ends of a 10-in. piece of 28-G platinum wire into an inoculating loop holder (also widely available) and twirling the holder while tugging on the middle of the wire with the point of a pencil (see Fig. 1.1.1).

Sterilize the loop by holding it in a bunsen burner flame until it is red hot. Cool the loop by touching it to a sterile portion of the surface of an agar plate until it stops sizzling.

Sterile Toothpicks

The broad side of flat wooden toothpicks may also be used for streaking out bacteria. Round wooden toothpicks, or the pointed end of flat toothpicks, are sometimes used to pick individual colonies or phage plaques. To sterilize, place toothpicks in a small beaker, cover the beaker with foil, and autoclave. Alternatively, simply autoclave the whole box of toothpicks and hold them in the middle when picking them up out of the opened box. It is convenient to put used toothpicks into another smaller beaker which, when full, is covered with foil and autoclaved. Used toothpicks can be saved, reautoclaved, and used again (see Fig. 1.1.2).

Spreaders

Spreaders are used to distribute liquid containing bacterial cells evenly over a plate. They are made by heating and bending a piece of 4-mm glass tubing (see Fig. 1.1.3). Less durable spreaders can be made from a Pasteur pipet. Before each use, sterilize the spreader by dipping the triangular part into a container of ethanol, passing the spreader through a gas flame to ignite the ethanol, and letting the flame burn out. Be careful not to ignite the

Figure 1.1.1 Making a loop.

Figure 1.1.2 Preparing sterile toothpicks.

ethanol in the container. Cool the spreader by touching it to the surface of an agar plate that has not yet been spread with cells.

Glass Beads

Although spreaders are useful for many applications, when processing large numbers of plates it can become a time-consuming process. A popular practice is to use 4-mm glass beads that have been sterilized. A half dozen or more beads distribute the liquid culture on surface of the agar when the plate is shaken horizontally in all directions. The beads are then discarded and the plate inverted and placed in the incubator. Stacks of plates can be handled together when plating many culture samples.

Growth in Liquid Media

UNIT 1.2

GROWING AN OVERNIGHT CULTURE

BASIC
PROTOCOL 1

Small freshly saturated cultures of *E. coli* are called *overnights*. To make an overnight, remove the cap from a sterile 16- or 18-mm culture tube. Working quickly to minimize contact of the tube with the possibly contaminated air, use a sterile pipet to transfer 5 ml of liquid medium into the tube. Inoculate the liquid with a single bacterial colony by touching a sterile inoculating loop to the colony, making certain that some of the cells have been transferred to the loop, and then dipping the loop into the liquid and shaking it a bit. Replace the tube's cap, and place the tube on a roller drum at 60 rpm, 37°C. Grow until the culture is freshly saturated (at a density of $1\text{--}2 \times 10^9$ cells/ml, which typically takes at least 6 hr).

GROWING LARGER CULTURES

BASIC
PROTOCOL 2

Larger cultures are generally inoculated with overnight cultures diluted 1:100. Use an Erlenmeyer or baffle flask whose volume is at least 5 times the volume of the culture. Grow the culture at 37°C with vigorous agitation (~300 rpm) to ensure proper aeration. If it is necessary to grow a culture without shaking (for example, if the strain is temperature-sensitive for growth and no low-temperature shaker is available), then, to ensure that the cells get adequate aeration, grow the culture in an Erlenmeyer flask whose volume is at least 20 times that of the culture.

MONITORING GROWTH

BASIC
PROTOCOL 3

With a Count Slide

Take a clean count slide (or hemacytometer) and cover it with a clean cover slip. Dip a 0.1- or 1-ml pipet into the culture medium, allow a small drop of liquid to form on the end of the pipet, and touch it lightly to the surface of the slide at the periphery of the cover slip. The liquid will quickly spread under the cover slip. Put the slide on the stage of a phase-contrast microscope set to 400 \times , and focus on the cells. Each cell in a small square is equivalent to 2×10^7 cells/ml (see Fig. 1.2.1).

Figure 1.2.1 Monitoring growth via a hemacytometer or count slide.

Escherichia coli,
Plasmids, and
Bacteriophages

With a Spectrophotometer

The concentration of cells in a culture can also be determined with a spectrophotometer by measuring the amount of 600-nm light scattered by the culture. The level of absorbance (A) at 600 nm will depend on the distance between the cuvette and the detector and will vary among spectrophotometers, often by a factor of 2. It is thus wise to calibrate each instrument by recording the OD_{600} (sometimes expressed as A_{600}) of a culture that contains a known number of cells determined by some other method, such as observation on a count slide or titering for viable colonies (*UNIT 1.3*).

If the culture is visibly turbid, also measure a *10-fold dilution* of it. For a culture grown in rich medium, a good rule of thumb is that each 0.1 OD unit is roughly equivalent to 1×10^8 cells/ml.

Calculate the number of cells/ml from whichever suspension (the undiluted or the diluted) has an $OD_{600} < 1$.

Growth on Solid Media

UNIT 1.3

TITERING AND ISOLATING BACTERIAL COLONIES BY SERIAL DILUTIONS

BASIC
PROTOCOL 1

Bacteria are grown from single colonies to ensure that each cell in a population is descended from a single founder cell, and thus to help ensure that each cell in the culture has the same genetic makeup. One way to generate single colonies is to titer a culture with serial dilutions and to pick colonies from one of the dilution plates. In this procedure, a small, measured amount of a bacterial culture is diluted into fresh liquid in another tube. A small amount of liquid is taken from this tube and diluted into another fresh tube. This process is repeated several times. Equal volumes of liquid are then taken from each of the dilution tubes and plated on petri plates. The plates are incubated overnight at 37°C; well-separated single colonies will arise on some of the dilution plates. The number of living bacteria in the culture is calculated from the number of colonies formed on the dilution plates.

A typical saturated culture contains 1×10^9 cells/ml. Phage suspensions can also be titered; a concentrated phage stock might typically contain 1×10^{11} phage/ml.

Materials

LB medium (UNIT 1.1)

LB plates (UNIT 1.1)

Sterile 16- or 18-mm-diameter culture tubes

1. Use pipets to introduce 5 ml LB medium into three sterile culture tubes. Line the tubes up, or label them so that they can be distinguished.
2. Using a pipettor, transfer 5 μ l from the suspension of cells into the first tube of LB medium. Set the vortexer to a mild setting and agitate the tube 5 sec.
3. Put a new tip on the pipettor and transfer 5 μ l from the first tube of LB medium into the second tube, and vortex the second tube. Take 5 μ l from the second tube and repeat step 3 until you have serial dilutions in all three tubes.

The first dilution tube now contains a 1×10^3 -fold dilution, generated by diluting the culture by a factor of one thousand (i.e., it contains 1×10^{-3} as many cells/ml as were present in the original culture). The second tube contains a 1×10^6 -fold dilution, generated by diluting the original culture by a factor of one million (i.e., it contains 1×10^{-6} as many cells/ml as the original culture), etc.

Many investigators prefer to perform serial dilutions with different volumes and different factors of dilution. These parameters can be modified in steps 1 to 3.

4. Spread 100 μ l of liquid from the culture and from each dilution tube onto separate, labeled, dry LB plates (as described on p. 1.3.2). Incubate overnight at 37°C.

During this incubation, each living bacterial cell will grow into a separate colony on the plate.

5. Count the colonies from these plates. Since only 100 μ l was plated from the undiluted culture and from each dilution tube, each plate has $1/10$ as many colonies on it as were present in each milliliter of liquid in the corresponding tube. Therefore, one can determine the number of cells that were present per milliliter of the culture by counting the number of colonies on a plate, and then multiplying that number by 10 times the factor of dilution.

Escherichia coli,
Plasmids, and
Bacteriophages

1.3.1

For example, if 22 colonies were observed on the plate corresponding to the 1×10^6 -fold dilution, then the number of living cells in each milliliter of the original culture was $22 \times 10 \times 10^6$, or 2.2×10^8 cells/ml.

- Any of the single colonies may be saved for further use. Store plates at 4°C wrapped in parafilm or in the plastic sleeve in which the plates were supplied.

Commentary

Titering by serial dilutions is a good way to determine the number of any kind of living organism present in a suspension. The organisms do not even need to be able to grow into colonies—i.e., the concentration of living bacteriophage in a tube can be determined by titering with serial dilutions and counting the number of plaques made when an aliquot of each dilution is plated on a lawn of phage-sensitive bacteria (see *UNIT 1.11*).

It is sometimes useful to use smaller factors of dilution. Mixing $50 \mu\text{l}$ of the culture into 5 ml medium will give dilutions of $100\times$. Mixing $100 \mu\text{l}$ into $900 \mu\text{l}$ will give dilutions of $10\times$.

BASIC PROTOCOL 2

ISOLATING SINGLE COLONIES BY STREAKING A PLATE

Another way to isolate single colonies is called streaking or streaking for single colonies. This method is easier and faster than serial dilutions for isolating single colonies, but it cannot be used to count the number of cells in a culture. An inoculum of bacteria is streaked across one side of an agar plate with an inoculating loop or sterile toothpick. The resterilized loop or a fresh toothpick is then passed once through the first streak and streaked across a fresh part of the plate (see Fig. 1.3.1). This process is repeated at least once more, and the plate is incubated at 37°C until colonies become visible. If single colonies must be isolated from many bacteria, it is convenient to divide a plate into 4, 6, or 8 sectors and to streak for single colonies in each sector.

Figure 1.3.1 Streaking a plate.

ISOLATING SINGLE COLONIES BY SPREADING A PLATE

It is sometimes necessary to distribute a liquid culture of bacteria evenly over the surface of a plate (for example, when plasmid-containing colonies are to be isolated after treatment of cells with plasmid DNA and calcium chloride, *UNIT 1.8*). This is usually done with a glass spreader. From 0.05 to 1 ml of liquid is pipetted onto a dry plate (see *UNIT 1.1*) and spread using a circular motion as shown in Figure 1.3.2. Alternatively, the edge of the spreader can be used to make a raster pattern on the plate's surface. The plate can be turned at right angles and the process repeated. Evenly spread plates should be placed in the incubator with the lids ajar until they are completely dry.

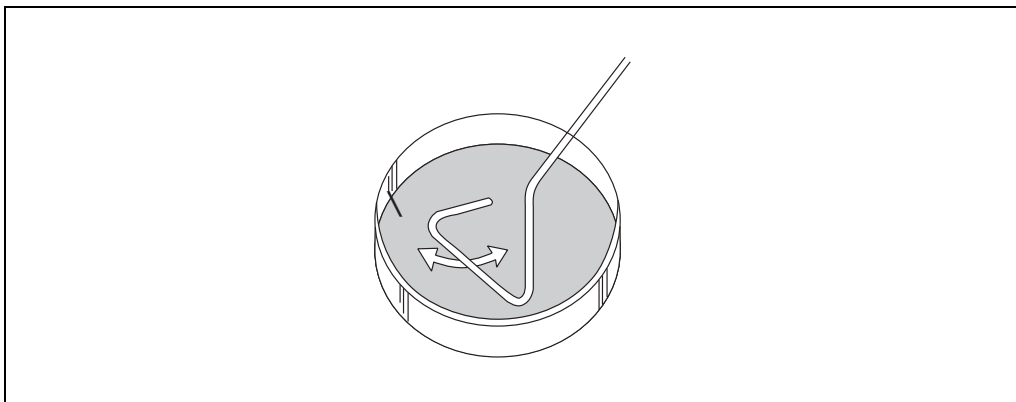

Figure 1.3.2 Spreading a plate.

REPLICA PLATING

Replica plating is a convenient way to test many colonies for their ability to grow under different conditions. In this technique, bacterial colonies are transferred from one plate to another in a way that maintains the original pattern of colonies. This technique has many applications to recombinant DNA work. As an example, consider the plasmid pBR322, which contains two antibiotic resistance genes, encoding resistance to ampicillin and tetracycline (see Fig. 1.5.9). A piece of foreign DNA cloned into the tetracycline resistance gene inactivates it; cells that carry such a plasmid are ampicillin resistant but tetracycline sensitive. These cells can be identified by replica plating colonies from ampicillin-containing master plates onto plates containing tetracycline. Tetracycline-sensitive colonies can be identified by their inability to grow on the tetracycline plates, rescued from the master plate, and analyzed further.

This procedure requires two specialty items: a replica block and sterile velvets. The replica block is a wooden or metal cylinder that fits snugly inside a petri plate (see Fig. 1.3.3). One method for constructing these has been described by Adams (1965). A metal ring is used to secure the velvets to the block. Squares of velvet should be cut so as to cover the base (a diameter of 14 cm is suggested). These velvets can be washed, autoclaved, and reused. If velvets are not available, pieces of sterile filter paper or disposable replica plates can be used ("Repli-Plate" Colony Transfer Pads, American Laboratories #59901). Replica plating also requires a master plate composed of well-separated colonies. The master plate can be a fresh plate onto which 50 to 100 colonies have been gridded (using toothpicks and the grid in Fig. 1.3.4), or it can be a plate on which bacteria were spread that have now grown up into well-separated colonies.

Figure 1.3.3 Replica block with velvet.

Figure 1.3.4 Grid for replica plating.

Mark the top of the master plate to enable alignment with the grid. Press the plate down *lightly* onto the velvet. Do not bear down hard on the plate; pressing too hard will cause the colonies to run together on the velvet or may even cause the plate to collapse. Press new plates, oriented like the master plate, *lightly* onto the imprinted velvet to transfer the colonies. As many as 10 plates per velvet can often be replica plated.

**SUPPORT
PROTOCOL 2**

STRAIN STORAGE AND REVIVAL

Most strains of *E. coli* can be stored for years in stab vials, or indefinitely if frozen at -70°C . It is prudent to check the genetic markers of a strain revived from storage. Ways to verify the presence of other selective markers are described in Table 1.4.4.

Figure 1.3.5 Inoculating a stab vial.

Stabs

Use airtight, autoclavable vials with rubber or Teflon caps (not cardboard). These are available from Wheaton Glassware and John's Scientific ($\frac{1}{4}$ -oz. Bijoux bottles, #15690-001). Fill the vials $\frac{2}{3}$ full with stab agar (*UNIT 1.1*). Inoculate them with a single colony (see Fig. 1.3.5) by collecting most of the cells in the colony with an inoculating loop, then repeatedly poking the loop deeply into the agar. Leave the cap of the stab vial slightly loose and incubate 8 to 12 hr at 37°C, or until cloudy tracks of bacterial growth are evident. Seal the vials tightly and store them in a cool (15° to 22°C), dark place. To revive a stored strain, flame sterilize an inoculating loop (*UNIT 1.1*), allow it to cool, insert it into the stab agar, and move the loop around until a gobbet of bacteria-laden agar is stuck onto the loop. Smear the gobbet onto one section of an LB plate and streak for single colonies (Fig. 1.3.1).

Frozen Stocks

Add 2 ml of a mid-log culture or 1 ml of a freshly saturated culture to a stab vial or a Nunc vial (Nunc #1087) containing 1 ml glycerol solution or DMSO solution (see recipes). Vials can be stored at -20° to -70°C , but most strains remain viable longer if stored at -70°C . Revive stored cells by scraping off splinters of solid ice with a toothpick or sterile pipet and streaking these splinters onto an LB plate (*UNIT 1.1*). Do not allow the contents of the vial to thaw.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see *APPENDIX 2*; for suppliers, see *APPENDIX 4*.

Glycerol solution

65% glycerol (vol/vol)
0.1 M MgSO_4
0.025 M Tris-Cl, pH 8

DMSO solution

7% dimethylsulfoxide (vol/vol)

The only advantage DMSO seems to have over glycerol for frozen stocks is that it is easier to pipet because it is less viscous. Use a bottle of reagent- or spectrophotometric-grade DMSO that has been kept tightly sealed.

Selected Topics from Classical Bacterial Genetics

Current cloning technology exploits many facts learned from classical bacterial genetics. This unit covers those that are critical to understanding the techniques described in this book.

ANTIBIOTICS

Antibiotics are chemicals that kill microorganisms but are relatively nontoxic to eukaryotic organisms. Antibiotics are very important for the techniques described in this book; genes encoding resistance to them are carried on plasmid and phage vectors and cells that contain the vector are identified by their ability to grow and form colonies in the presence of the antibiotic. Table 1.4.1 gives stock and working concentrations, and mechanisms of action of most of the antibiotics that are used in recombinant DNA work.

Antibiotics are usually added to freshly autoclaved solid medium after it has cooled to below 50°C. In an emergency, antibiotics can be added directly to existing plates using the same final concentration as above (assume that a plate 100 mm in diameter contains a total medium volume of 30 ml). Allow the antibiotic time to diffuse away from the very surface of the plate; an hour is usually sufficient. Since many antibiotics (especially ampicillin) lose potency at room temperature, plates are usually stored at 4°C. In addition, rifampicin and tetracycline should be stored in the dark (see Table 1.4.1).

THE LAC OPERON

Many of the techniques described in this book were made possible by early studies of the *E. coli* *lac* operon. The *lac* operon consists of three genes—*lacZ*, *lacY*, and *lacA* (see Fig. 1.4.1). When the cell grows on rich medium or glucose minimal medium, transcription is blocked by *lac* repressor (product of the neighboring *lacI* gene) which binds to a single site (operator) upstream of *lacZ* and prevents RNA polymerase from binding to the promoter. When the cell grows on medium that contains lactose or certain related compounds (see Table 1.4.2), *lac* repressor no longer binds the operator, and RNA polymerase synthesizes a single mRNA which encodes *lacZ*, *lacY*, and *lacA*. (In the wild-type *lac* operon, transcription initiation also requires the presence of a cAMP-CRP activator complex; all *lac* promoters used in

cloning experiments are independent of this control.) Two of these genes are necessary for growth on lactose. *lacY* encodes a permease which is necessary for the uptake of lactose and certain related sugars. *lacZ* encodes a β -galactosidase, which cleaves lactose into glucose and galactose, which the cell then utilizes. The third structural gene, *lacA*, encodes an enzyme called galactoside acetyltransferase (GAT). This enzyme is not required for lactose metabolism, but is thought to play a role in cellular detoxification of nonmetabolizable lactopyranosides (Lewendon et al., 1995; Wang et al. 2002).

Alpha-Complementation

Vectors such as the pUC series and the M13mp series (see UNITS 1.5, 1.14, & 1.15) contain a piece of DNA that encodes an alpha fragment of β -galactosidase. These vectors exploit a phenomenon called *alpha-complementation* (see Fig. 1.4.2), which was discovered by Ullman, Jacob, and Monod in 1967. They showed that a cell that bears any of a number of deletions of the 5' end of the *lacZ* gene synthesizes an inactive C-terminal fragment of β -galactosidase, called an *omega* (ω) fragment. Similarly, a cell that bears a deletion of the 3' end of *lacZ* encodes an inactive N-terminal fragment of β -galactosidase called an *alpha* (α) fragment. However, if a cell contains two genes, one directing the synthesis of an alpha fragment, the other directing synthesis of an omega fragment, the β -galactosidase activity is observed. Many vectors incorporate a *lac* α -fragment gene, which is small and easily manipulated. Exploitation of these vectors requires use of a strain carrying the complementing ω -fragment gene to allow assembly of an active complex. This gene is often carried on an F' plasmid (see below). When these vectors are used, cells containing them are grown on medium containing IPTG, which inactivates *lac* repressor and thus derepresses ω peptide synthesis, and Xgal, which is turned blue by the enzymatic activity of β -galactosidase (see Table 1.4.2). On this medium, these vector-containing cells possess β -galactosidase activity and turn blue.

Lactose Analogs

There are many compounds related to lactose that were first used for the biochemical and genetic analysis of *lac* operon activity and are

Escherichia coli,
Plasmids, and
Bacteriophages

1.4.1

Table 1.4.1 Antibiotics, Their Modes of Action, and Modes of Bacterial Resistance^a

Antibiotic ^b	Stock conc. (mg/ml)	Final conc. (μg/ml)	Mode of action	Mode of resistance
Ampicillin ^c	4	50	Bacteriocidal; only kills growing <i>E. coli</i> ; inhibits cell wall synthesis by inhibiting formation of the peptidoglycan cross-link	β-lactamase hydrolyzes ampicillin before it enters the cell
Chloramphenicol, in methanol	10	20	Bacteriostatic; inhibits protein synthesis by interacting with the 50S ribosomal subunit and inhibiting the peptidyltransferase reaction	Chloramphenicol acetyltransferase inactivates chloramphenicol
D-Cycloserine, ^d in 0.1 M sodium phosphate buffer, pH 8	10	200	Bacteriocidal; only kills growing <i>E. coli</i> ; inhibits cell wall synthesis by preventing formation of D-alanine from L-alanine and formation of peptide bonds involving D-alanine	Mutations destroy the D-alanine transport system
Gentamycin	10	15	Bacteriocidal; inhibits protein synthesis by binding to the L6 protein of the 50S ribosomal subunit	Aminoglycoside acetyltransferase and aminoglycosidenucleotidyltransferase inactivate gentamycin; mutations in <i>rplF</i> (encodes the L6 protein) prevent the gentamycin from binding
Kanamycin	10	30	Bacteriocidal; inhibits protein synthesis; inhibits translocation and elicits miscoding	Aminoglycoside phosphotransferase, also known as neomycin phosphotransferase, aminoglycoside acetyltransferase, and aminoglycoside nucleotidyltransferase; inactivates kanamycin
Kasugamycin	10	1000	Bacteriocidal; inhibits protein synthesis by altering the methylation of the 16S RNA and thus an altered 30S ribosomal subunit	Mutations prevent kasugamycin from binding to the ribosome; mutations decrease uptake of kasugamycin
Nalidixic acid, pH to 11 with NaOH	5	15	Bacteriostatic; inhibits DNA synthesis by inhibiting DNA gyrase	Mutations in the host DNA gyrase prevent nalidixic acid from binding
Rifampicin, ^e in methanol	34	150	Bacteriostatic; inhibits RNA synthesis by binding to and inhibiting the β subunit of RNA polymerase; rifampicin sensitivity is dominant.	Mutation in the β subunit of RNA polymerase prevents rifampicin from complexing; rifampicin resistance is recessive
Spectinomycin	10	100	Bacteriostatic; inhibits translocation of peptidyl tRNA from the A site to the P site	Mutations in <i>rpsE</i> (encodes the S5 protein) prevent spectinomycin from binding; spectinomycin sensitivity is dominant and resistance is recessive
Streptomycin	50	30	Bacteriocidal; inhibits protein synthesis by binding to the S12 protein of the 30S ribosomal subunit and inhibiting proper translation; streptomycin sensitivity is dominant	Aminoglycoside phosphotransferase inactivates streptomycin; mutations in <i>rpsL</i> (encodes the S12 protein) prevent streptomycin from binding; streptomycin resistance is recessive
Tetracycline, ^e in 70% ethanol	12	12	Bacteriostatic; inhibits protein synthesis by preventing binding of aminoacyl tRNA to the ribosome A site	Active efflux of drug from cell

^aData assembled from Foster (1983), Gottlieb and Shaw (1967), and Moazed and Noller (1987).

^bAll antibiotics should be stored at 4°C, except tetracycline, which should be stored at -20°C. All antibiotics should be dissolved in sterile distilled H₂O unless otherwise indicated. Antibiotics dissolved in methanol often can be dissolved in the less hazardous ethanol.

^cCarbenicillin, at the same concentration, can be used in place of ampicillin. Carbenicillin can be stored in 50% ethanol/50% water at -20°C.

^dD-cycloserine solutions are unstable. They should be made immediately before use.

^eLight-sensitive; store stock solutions and plates in the dark.

1.4.2

Figure 1.4.1 The first line shows the genes of the *lac* operon. *lacZ*, *lacY*, and *lacA* transcription is repressed by *lac* repressor. In the next line, inactive repressor is no longer bound to the operator, and the genes are being transcribed by RNA polymerase. In the third line, RNA polymerase transcribes the operon. Finally, RNA polymerase encounters a transcription terminator and, in a reaction requiring rho protein, RNA polymerase is detached from the DNA and the nascent transcript.

used in the cloning technology described in this book. These are described in Table 1.4.2.

THE F FACTOR

The F (fertility) factor is a genetic unit found in some strains of *E. coli*. Bacteria that contain the F factor are used in many techniques described in this book, mainly for two reasons. First (as described later in this chapter), possession of F allows a cell to be infected by vectors based on filamentous phages, which bind to cell surface structures called pili elaborated by F-containing cells. Second, defective *lacZ* genes that encode the ω fragment of β -galactosidase (described above) are commonly carried on F' factors.

The F factor is found in three alternative forms: as double-stranded, single-copy, circular extrachromosomal plasmid DNA (F⁺); as plasmid DNA like F⁺ but also including other bacterial genes (F'); and as a stretch of linear

DNA integrated into various sites on the bacterial chromosome (Hfr). Possession of the F factor confers on *E. coli* the ability to donate DNA in bacterial crosses (or matings). For this reason cells that carry F are sometimes called *male*. F or F' plasmids can transfer themselves to other cells, and may occasionally cause transfer of other plasmids. This latter process is called *mobilization*. Mutations called *tra* prevent F from transferring itself or mobilizing other plasmids. Integrated Tra⁺ F factors (Hfr) can cause transfer of chromosomal DNA to other cells, but the recipient usually does not receive the F sequence.

NONSENSE SUPPRESSORS

Some vectors used in recombinant DNA research (e.g., plasmid π VX and phage Charon 4a) contain nonsense mutations in essential genes. These vectors must be propagated in special strains of *E. coli*. In these strains, trans-

Table 1.4.2 Lactose Analogs Used in DNA Cloning Technology

Galactoside	Stock concentration ^a	Use	Characteristics	Reference
Isopropyl-1-thio- β -D-galactoside (IPTG)	100 mM	Very effective inducer	Nonmetabolizable inducer	Barkley and Bourgeois, 1978 (pp. 177-220)
5-Bromo-4-chloro-3-indolyl- β -D-galactoside (Xgal)	20 mg/ml (dissolved in <i>N,N</i> dimethyl formamide)	Identification of <i>lacZ</i> ⁺ bacteria, especially useful for detecting β -galactosidase made by recombinant vectors	Noninducing chromogenic substrate of β -galactosidase (cleavage of Xgal results in blue color); production of blue color independent of <i>lacY</i> gene product	Miller, 1972
Orthonitrophenyl- β -D-galactoside (ONPG)	10 mM	β -galactosidase assays	Chromogenic substrate of β -galactosidase (cleavage of ONPG results in yellow color)	Miller, 1972 (pp. 352-355)
6-O- β -D-Galactopyranosyl D-glucose (allolactose)			Inducer of the lactose operon in vivo; lactose is converted into allolactose by β -galactosidase	Zabin and Fowler, 1978 (pp. 89-121)
Phenyl- β -D-galactoside (Pgal)	2 mg/ml	Selection for <i>lac</i> constitutive mutants	Noninducing substrate of β -galactosidase; uptake partly dependent on <i>lacY</i> gene product	Miller, 1978 (pp. 31-88)
Orthonitrophenyl- β -D-thiogalactoside (TONPG)	10 mM	Selection for <i>lac</i> ⁻ mutants	Transported into cells by <i>lac</i> permease (the <i>lacY</i> gene product); inhibits cell growth at high concentration	Miller, 1978 (pp. 31-88)

^aStock solutions should be dissolved in sterile water unless otherwise noted.

lation of messages does not always stop when the ribosome encounters a chain termination codon (amber or ochre), but sometimes continues, with a new amino acid installed at the end of the growing polypeptide. This process is called *nonsense suppression* and strains of *E. coli* in which it occurs are said to contain *nonsense suppressors*. In a strain that contains an efficient or a “strong” suppressor, suppression might occur 50% of the time an amber codon is encountered.

The mechanism of nonsense suppression is a simple one: the cell contains a mutant species of tRNA in which the anticodon loop has mutated so that it base pairs with the UAG amber codon or the UAA ochre codon. Nonsense suppressors commonly used in cloning technology are given in Table 1.4.3. UGA (opal) suppressors also exist but are rarely used.

GENETIC MARKERS

Genetic markers in *E. coli* are named according to the convention proposed by Demerec et al. (1966). All genes of a given strain are presumed to be in the wild-type state unless otherwise noted in the genotype (see Table 1.4.4). Gene names have three italicized lowercase letters, sometimes followed by an italic uppercase letter, and sometimes also followed by an italic arabic number that specifies the precise mutation (allele) in question (e.g., *lacY1*, *trp-31*). The three-letter combination is usually a mnemonic intended to suggest the function of the gene. Proper notation omits superscript + and – in a genotype, but these are sometimes used redundantly for clarity. Deletion mutations are described by Δ , followed by the names of deleted genes in parentheses, followed by the allele number [e.g., $\Delta(lac-pro)X111$]. The delta may be replaced by “del” or “d.” Sometimes a

Table 1.4.4 Examples of Genotype and Phenotype Nomenclature

Genotype	Phenotype	Description of phenotype
<i>Some straightforward examples</i>		
<i>trp-31</i>	Trp ⁻	Requires tryptophan for growth on minimal media
<i>uvrA</i>	UV ^s	Sensitive to UV light
<i>recA</i>	Rec ⁻	Recombination defective
<i>Some common examples that are not so straightforward</i>		
<i>supE44</i>	Sup ⁺	Carries a tRNA suppressor gene. The <i>mutant</i> gene product, not the wild type, suppresses nonsense mutations; wild type is indicated as <i>sup⁰</i> , Sup ⁻ , and does not suppress
<i>rpsL104</i>	Str ^r	Resistant to streptomycin (this makes a mutant ribosomal protein, small subunit, the target of the drug)
<i>rpsE</i>	Spc ^r	Resistant to spectinomycin (also codes for a ribosomal protein, a different one)
<i>gyrA</i>	Nal ^r	Resistant to nalidixic acid (the mutation affects DNA gyrase)
<i>One mutation may create several phenotypes</i>		
<i>dam-3</i>	Dam ⁻ , 2-AP ^s UV ^s	DNA not methylated at adenines in GATC Sensitive to 2-aminopurine Sensitive to UV light
<i>hsdS</i>	<i>EcoK</i> R ⁻ , <i>EcoK</i> M ⁻	Neither restricts nor modifies DNA that enters the cell
<i>Some mutations lead to counterintuitive phenotypes</i>		
<i>recD</i>	ExoV ⁻ but Rec ⁺	Exonucleolytic activity of the RecBCD protein is defective, but the recombinational activity is intact

phenotype designation (see box) in parentheses follows the genotype designation, if the former is not obvious from the latter [e.g., *rpsL104* (Str^r)]. However, this usage is by no means universal.

Table 1.4.5 lists commonly used genetic markers, with methods for verifying their presence or absence in bacterial cells. Genotypes of several strains used for different applications are listed in Table 1.4.6.

GENOTYPE AND PHENOTYPE

Genotype indicates what genes are mutated in a strain. A genotype is a theoretical construct describing a genetic constitution that would explain the phenotype of the strain. It is derived from considerations of the strain's behavior and ancestry.

Phenotype describes the observable behavior of the strain—e.g., Lac⁻ fails to grow on lactose as a sole carbon source. Phenotypes are in Roman type, the first letter is capitalized, and the letters are always followed by superscript + or - (sometimes r, resistant, or s, sensitive). A phenotype is a datum to be explained.

Genotype and phenotype names are usually related, but the relationship is not always obvious. Examples are provided in Table 1.4.4.

DNA RESTRICTION, MODIFICATION, AND METHYLATION

This section and the next two describe *E. coli* functions that can prevent cloning the sequence of interest. *E. coli* has at least four restriction systems that identify foreign DNA and destroy it. These systems, encoded by *hsdRMS*, *mcrA*, *mcrB*, and *mrr*, can be avoided by using host strains in which they are disabled by mutation. Restriction of DNA and the content of methylated bases in the DNA are interrelated as described below. To select the appropriate strain, it is necessary to know the content of methylated bases in the DNA to be cloned.

The *EcoK* restriction system, encoded by the *hsdRMS* genes, is the best understood of the *E. coli* restriction mechanisms (Bickle, 1982). It attacks DNA that carries the site:

Table 1.4.5 Commonly Used Genetic Markers and How to Test Them^a

Nutritional markers	Streak or replica plate colonies of the strain onto plates with and without the nutrient to be tested, but which contain all other necessary nutrients.
Antibiotic resistance markers	Streak or replica plate colonies of the strain onto plates with and without the antibiotic.
<i>Other markers</i>	
<i>lacZ</i> ⁺	Streak strain on an LB plate with Xgal and IPTG (UNIT 1.4). Colonies should turn blue. Colonies of control <i>lacZ</i> ⁻ strain should not turn blue.
<i>lacZΔM15</i> ^b	Transform strain with pUC plasmid and with control plasmid such as pBR322. Streak transformants onto LB/ampicillin plate with Xgal and IPTG. Colonies bearing pUC plasmid should turn blue, while colonies bearing pBR322 should not.
F ⁺ or F'	Spot M13 phage onto a lawn of the cells. Small plaques should appear (see UNIT 1.15).
<i>recA</i>	Using a toothpick, make a horizontal stripe of cells across an LB plate. Also make a stripe of <i>recA</i> ⁺ control cells. Cover half of the plate with a piece of cardboard, and irradiate the plate with 300 ergs/cm ² of 254 nm UV light from a hand-held UV source (typically 20 sec exposure from a lamp held 50 cm over the plate). <i>recA</i> ⁻ cells are very sensitive to killing by UV light, and <i>recA</i> ⁻ cells in the unshielded part of the plate should be killed by this level of irradiation.
<i>recBCD</i>	Spot dilutions of λ <i>gam</i> ⁻ (UNIT 1.9) on a lawn of cells side by side with dilutions of λ <i>gam</i> ⁺ . The <i>gam</i> ⁻ plaques should be almost as big as the <i>gam</i> ⁺ plaques.
<i>hsdS</i> ⁻	(1) Use the strain and a wild-type strain to plate out serial dilutions of a λ-like phage stock grown on an <i>hsdS</i> ⁻ or <i>hsdR</i> ⁻ host. If the phage stock came from an <i>hsdS</i> ⁻ host, then it should make plaques with 1 × 10 ⁴ to 1 × 10 ⁶ higher efficiency on the putative <i>hsdS</i> ⁻ host than on a wild-type host. If the phage stock came from an <i>hsdR</i> ⁻ (<i>hsdS</i> ⁺ <i>hsdM</i> ⁺) host, it should make plaques with the same efficiency on both strains. (2) Suspend one of the fresh plaques from the putative <i>hsdS</i> ⁻ host in 1 ml lambda dilution buffer. Titer this suspension on the putative <i>hsdS</i> ⁻ strain and on a wild-type strain. The suspension should make plaques at 1 × 10 ⁴ to 1 × 10 ⁶ higher efficiency on the <i>hsdS</i> ⁻ strain than on the wild-type strain. One plaque contains ~1 × 10 ⁷ phage.
<i>hsdR</i> ⁻	(1) Perform step 1 described above, using a plate stock made from an <i>hsdS</i> ⁻ host.
(<i>hsdS</i> ⁺ <i>hsdM</i> ⁺)	(2) Suspend one of the fresh plaques in 1 ml lambda dilution buffer. Titer this suspension on the putative <i>hsdR</i> ⁻ strain and on a wild-type strain. This suspension should make plaques with the same efficiency on the <i>hsdR</i> ⁻ as on a wild-type strain.
<i>dam</i>	Transform the strain and a wild-type strain with a plasmid that contains recognition sites for the enzymes <i>Mbo</i> I or <i>Bcl</i> I. Prepare plasmid DNA from both strains and verify that plasmid DNA isolated from the <i>dam</i> ⁻ strain is sensitive to digestion by the enzyme.
<i>dcm</i>	Transform the strain and a wild-type strain with a plasmid that contains recognition sites for <i>Scr</i> FI. Prepare plasmid DNA from both strains to verify that only plasmid DNA from the <i>dcm</i> strain is fully sensitive to digestion by the enzyme. Half of the <i>Scr</i> FI sites will be cut even when the DNA is <i>dcm</i> -methylated.
<i>lon</i>	Streak LB plate for single colonies. Also streak a control plate of a wild-type strain. Incubate at 37°C. Colonies of the <i>lon</i> ⁻ strain should be larger, glistening, and mucoidal.

^aCommonly used protocols in this table are media preparation (UNIT 1.1), streaking and replicating a plate (UNIT 1.3), and growing lambda-derived vectors (UNIT 1.12).

^bEncodes omega fragment of β-galactosidase.

continued

and results in double-strand cleavage at a variable distance from the site, leading eventually to degradation of the resulting fragments. DNA is not attacked if it lacks the site, or if the site is present but methylated at the adenines shown (^mA).

The *EcoK* enzyme is both genetically and enzymatically complex. The HsdR, HsdM, and HsdS subunits are required for restriction of an unmethylated substrate. The same complex will methylate the same substrate, but at a very slow rate, so that an unmethylated target rarely

survives. A substrate methylated on only one strand (hemimethylated) will be methylated on the other strand by the three-protein complex, but will not be cut. HsdM and HsdS together can methylate either an unmethylated or a hemimethylated substrate. The three-protein complex is inactive for restriction if any of the three subunits is defective, but can still methylate if HsdR is defective.

In summary, a strain defective in the *hsdR* gene is described as having the phenotype HsdR⁻M⁺ (or, equivalently, *EcoK* R⁻M⁺ or

^aThe original *E. coli* K-12 strain was an F⁺ λ lysogen, but most K-12 derivatives in common use have been cured of the F factor and prophage and these are indicated only when present. All other genes in these strains are presumed to be wild-type except for the genotype markers noted in the second column.

^bReference for all *mcr* and *mrr* genotypes is Raleigh et al., 1988.

^cReference for genotype of strain.

^dSource of additional genotype information.

^eThought to be responsible for original strain construction.

^fAS1 is also known as MM294c1⁺. BNN102 is also known as C600 *hflA*.

^gBoth CJ236 and BW313 are commonly used in oligonucleotide-directed mutagenesis. pCJ105, the plasmid CJ236 carries, is not relevant for this application.

^hThree strains are in circulation. DH5 is a derivative of DH1 that transforms at slightly higher efficiency. DH5 α and DH5 α F' are derivatives that carry a deletion of the *lac* operon and a Φ 80 prophage that directs synthesis of the omega fragment of β -galactosidase. DH5 α F' carries an F' factor as well. DH5 α and DH5 α F' are proprietary strains and the cells are prepared in some way that allows them to be transformed with slightly higher efficiency than DH5.

ⁱIn this strain, the area of the chromosome that contains the *hsd* genes was derived from the related B strain of *E. coli*.

^jThe continued presence of the F' factor in JM strains can be insured by starting cultures only from single colonies grown on minimal plates that do not contain proline. These strains encode the omega fragment of *lacZ* and are frequently used with vectors that direct the synthesis of the *lacZ* alpha fragment. These strains are frequently used with M13 vectors for DNA sequencing (*UNITS 1.14, 1.15, & 7.4*).

^kIt is not known whether this strain has markers other than those listed.

^lpMC9, the plasmid in the Y strains listed here, directs the synthesis of large amounts of *lac* repressor. It also confers resistance to tetracycline and ampicillin (Lebrowski et al., 1984, *EMBO. J.* 3:3117-3121).

R_K⁻M_K⁺; see box): it will methylate newly introduced DNA but will not restrict it. However, a strain defective in either *hsdM* or *hsdS* will neither restrict nor methylate, and has the phenotype HsdR⁻M⁻ (or *EcoK* R⁻M⁻ or R_K⁻M_K⁻).

In contrast with *EcoK*, the other three restriction systems of *E. coli* K-12—*mcrA*, *mcrB*, and *mrr*—specifically attack DNA that is methylated at particular sequences, rather than DNA that is not. Either methylated cytosine residues or methylated adenine residues can create problems (see below).

The action of either *mcrA* or *mcrB* reduces the number of clones recovered from libraries made with genomic DNA from other organ-

isms, and leads to bias against recovery of specific fragments from those libraries (Raleigh et al., 1988; Whittaker et al., 1988; Woodcock et al., 1988, 1989; *mrr* has not been tested). For *McrB* there is evidence that a nuclease is responsible for these effects (E. Sutherland and E.A. Raleigh, unpub. observ.), but no such evidence is available for the other two systems.

Even without biochemical characterization, something can be said of the recognition sites for these systems. *McrA* restricts DNA modified by the *HpaII* (5' C^mCGG) methylase and possibly other methylases. *McrB* restricts DNA modified by any one of 14 other modification

methylases, which led to the suggestion that the McrB recognition site is 5' G^mC (Raleigh and Wilson, 1986). Mrr restricts DNA modified by the *Hha*II (5' G^mANTC) or *Pst*I (5' CTGC^mAG) methylases, but *not* that modified by the *Eco*RI methylase, among others (Heitman and Model, 1987).

Many commonly used *E. coli* strains are McrA⁻; including (from Table 1.4.5) BNN102 (also known as C600*hflA*), C600, JM107, JM109, LE392, Y1088, and Y1090. Of the strains listed in Table 1.4.5, only BNN102, HB101, and MC1061 are McrB⁻; and only HB101 is Mrr⁻ (see also Raleigh et al., 1988).

A strain should be used which lacks the appropriate methyl-specific restriction system(s) when cloning genomic DNA from an organism containing methylated bases. All mammals and higher plants, and many prokaryotes, contain methylcytosine (Ehrlich and Wang, 1981), so McrA⁻B⁻ strains should be used for libraries of DNA from these organisms. Bacteria and lower eukaryotes may contain methyladenine, so Mrr sensitivity should be considered. However, the important experimental organisms *Drosophila melanogaster* and *Saccharomyces cerevisiae* contain no detectable methylated bases.

In addition, any time DNA is methylated in vitro during a manipulation, an appropriate restriction-deficient host should be used as DNA recipient. Methylases are used to generate novel restriction enzyme specificities or to protect cDNA from subsequent digestion (see *UNITS 3.1 & 5.6*). For example, the *Alu*I methylase (*M.Alu*I) is sometimes used to protect *Hind*III sites. McrB will restrict DNA modified by *M.Alu*I.

Once the DNA introduced into *E. coli* has been replicated, the foreign methylation pattern will be lost (and the *E. coli* methylation pattern will be acquired) unless the clone carries a methylase activity. Once successfully introduced, clones can be freely transferred among Mcr⁺ Mrr⁺ *E. coli* strains, since the methylation pattern will no longer be foreign. It is important that the clone be passed through an HsdM⁺ strain before trying to introduce it into an HsdR⁺ strain.

The normal methylation pattern of *E. coli* DNA is the product of three methylases. The *Eco*K methylase modifies the sequences indicated above. The *dam* and *dcm* gene products are also methylases (Marinus, 1987). The recognition sites for these are:

These modifications will render DNA resistant or partially resistant to some restriction endonucleases used for in vitro work (see Table 3.1.1), such as *Mbo*I and *Bcl*II (for Dam-modified DNA) or *Eco*RII (for Dcm-modified DNA). The Dam and Dcm methylases are *not* associated with any *E. coli* restriction function. Loss of Dam and/or Dcm methylation will not make the DNA sensitive to *Eco*K restriction, although loss of K modification will. However, Dam and Dcm modification confer sensitivity to Mrr and Mcr analogues in *Streptomyces* species (MacNeil, 1988).

RECOMBINATION AND ITS EFFECTS ON CLONED DNA INSERTS

During propagation in *E. coli*, DNA inserted into vectors is sometimes rearranged by the proteins involved in DNA recombination. Fortunately, although the genetics and enzymology of recombination in *E. coli* are still not well understood, there are mutant strains available that can provide solutions to two common cloning problems.

Problem 1. The DNA contains dispersed repeated sequences. Recombination occurs between these repeated sequences, causing loss of pieces of the DNA (see Fig. 1.4.3).

For plasmid libraries, this problem can be solved by propagating the DNA in a *recA*⁻ host, where homologous recombination does not occur. For libraries made using λ-derived vectors, the vector must also be recombination-defective (*red*). However, only about 30% to 50% of the cells are viable in such a strain, and libraries, particularly phage libraries, may be hard to propagate. Phage λ vectors that are *red* will not make high-titer lysates in *recA* strains, and *red gam* phage will not grow at all, unless the *recBCD* enzyme is also inactivated (see below). Many λ vectors are *red gam* to make use of the Spi⁻ selection or to make room for larger insert pieces (see *UNIT 1.10*).

Problem 2. The inserted DNA contains closely spaced inverted repeat sequences (palindromes or interrupted palindromes). Such stretches of DNA are not stably propagated in either phage or plasmid vectors. Available

Figure 1.4.3 Recombination between homologous direct repeats.

knowledge is consistent with the idea that large (>300-bp) palindromes can sometimes form an alternative, hairpin structure that resembles an intermediate found in normal recombination called a Holliday junction, and are then acted upon by the host recombination system in such a way that the hairpin is eliminated or made smaller.

There are strains of bacteria from which phage and plasmid clones containing palindromes are recovered at higher frequency. These bacteria have inactivated exonuclease V (ExoV; encoded by the *recB*, *recC*, and *recD* genes) or the SbcC product (encoded by the *sbcC* gene). Many strains permissive for palindromes have defects in *recB recC* combined with a defect in *sbcA* (which probably encodes the RecE protein) or *sbcB* (which encodes exonuclease I).

Involvement of ExoV (RecBCD enzyme) in palindrome stabilization was first noticed by Leach and Stahl (1983) using artificially constructed palindromes in λ phages, and hosts

mutant in *recB*, *recC*, and *sbcB*. Because *recB recC* strains are sick, they tend to accumulate two additional mutations, one in *sbcB* (the gene for exonuclease I; suppressor of *recBC*), and one in *sbcC*, the biochemical nature of which is unknown (Lloyd and Buckman, 1985). Together these mutations restore recombination and increase cell viability. Wertman et al. (1986) and Wyman et al. (1986) found that both the *recB recC* defect and the *sbcB* defect independently contributed to stabilization of cloned palindromes in λ libraries.

Involvement of *recD* was first investigated by Wertman et al. (1986) and Wyman et al. (1986). *recD* codes for the nuclease activity of ExoV, as distinct from the recombination activity of that enzyme. Strains mutant in *recD* alone are Rec⁺ and healthy, and are not known to accumulate secondary mutations. Such strains were the best hosts for palindrome stabilization using λ -derived phages in the studies cited above.

The effect of *sbcC* was examined by Chalker et al. (1988), who found that *sbcC* alone was better at maintaining palindromes in λ than *recD* alone and better than *recB recC sbcB*, but that *recD sbcC* strains attained the highest palindrome stability (*recA recD sbcC* strains also maintained the palindrome). A further advantage of *sbcC* mutant strains is that palindromes were maintained in plasmids as well as phage (Chalker et al., 1988), whereas ExoV⁻ deficient mutants are poor hosts for plasmids regardless of palindrome content (see below).

EFFECTS OF RECOMBINATION-DEFECTIVE STRAINS ON VECTORS

Lambda-derived vectors or clones that are *red gam* (see *UNIT 1.10*, especially the *spi*⁻ selection) must be propagated on ExoV⁻ hosts, because the long linear multimers that are the normal substrate for lambda packaging are exonucleolytically degraded by ExoV in the absence of the Gam protein (Stahl, 1986). These phage will grow well on ExoV⁻ RecA⁺ hosts, reasonably well on ExoV⁻ RecA⁻ hosts, very poorly on ExoV⁺ RecA⁺ (the phage are packaged by an alternative packaging mechanism using circular dimers produced by recombination that depends on *E. coli* proteins), and not at all on ExoV⁺ RecA⁻. With ExoV⁻ RecA⁺ hosts, clones carrying a recombination hot spot called a Chi site (5' GCTGGTGG 3') will outgrow those that don't, resulting in a biased library. The ExoV⁻ RecA⁺ host can be *recBC sbcB* or *recD*, and the ExoV⁻ RecA⁻ host can be *recB recC sbcB recA* or *recD recA*.

Most cloning plasmids, including ColE1 derivatives like pBR322, and p15A derivatives like the pACYC vectors, are very unstable in ExoV⁻ deficient strains unless selection is maintained. Moreover, they are often unstable or difficult to maintain even with selection. Both *recB recC sbcA* strains (Basset and Kushner, 1984) and *recD* strains (Biek and Cohen, 1986, and references therein) behave this way. However, RecA⁻ suppresses this effect. Instability is probably due to recombination-initiated rolling-circle replication of the plasmids that leads to synthesis of long linear multimers, which fail to segregate properly at cell division (Silberstein and Cohen, 1987). The problem is particularly severe with very high-copy-number ColE1 derivatives such as pUC vectors, which may be impossible to establish at all in *recD* strains (E.A. Raleigh, unpublished observation).

From the above considerations, a universal host strain for phage and plasmid cloning vec-

tors would have the markers *recA recD sbcC hsdR mcrA mcrB mrr*. Although no such strain has been made, a *recD sbcC hsdR mcrA mcrB* strain, DL491, has been reported recently (Whittaker et al., 1988).

Introduction to Plasmid Biology

UNIT 1.5

Plasmids are self-replicating, extrachromosomal DNA molecules found in virtually all bacterial species. In nature, plasmids occur in exuberant profusion, varying in structure, size, mode of replication, number of copies per bacterial cell, ability to propagate in different bacteria, transferability between bacterial species, and perhaps most important, in the traits they carry. Most prokaryotic plasmids are double-stranded circular DNA molecules; however, linear plasmids have been identified in both gram-positive and gram-negative bacteria. The size of plasmids varies widely, from several kilobases to hundreds of kilobases. Replication of plasmids depends on host-cell proteins but also may require plasmid-encoded functions. Plasmid replication may be synchronized with the bacterial cell cycle, resulting in a low number of plasmid molecules per bacterial cell, or independent of the host cell cycle, allowing for the proliferation of hundreds of plasmid copies per cell. Some plasmids freely transfer their DNA across bacterial species, some only transfer their DNA into bacteria of the same species, and some do not transfer their DNA at all. Plasmids carry genes that specify a wide variety of functions including: resistance to antibiotics, resistance to heavy metals, sensitivity to mutagens, sensitivity or resistance to bacteriophages, production of restriction enzymes, production of rare amino acids, production of toxins, determination of virulence, catabolism of complicated organic molecules, ability to form symbiotic relationships, and ability to transfer DNA across kingdoms.

Starting in the 1970s, vectors for propagation, manipulation, and delivery of specific DNA sequences were constructed with fragments from naturally occurring plasmids, primarily *Escherichia coli* plasmids. All plasmid vectors contain three common features: a **replicator**, a **selectable marker**, and a **cloning site**. The replicator is a stretch of DNA that contains the site at which DNA replication begins (the origin of replication or *ori*), and that also includes genes encoding whatever plasmid-encoded RNAs and proteins are necessary for replication. The selectable marker, necessary for following and maintaining the presence of the plasmid in cells, is usually dominant and is usually a gene encoding resistance to some

antibiotic. The cloning site is a restriction endonuclease cleavage site into which foreign DNA can be inserted without interfering with the plasmid's ability to replicate or to confer the selectable phenotype on its host. Over the years, plasmid vectors have increased in sophistication; in addition to these three basic elements many vectors now include features that make them particularly suitable for specific types of experiments.

UNITS 1.6 & 1.7 describe procedures for making plasmid DNA. The process by which plasmids are introduced into *E. coli* is called **transformation**. Transformation protocols are given in UNIT 1.8. For a list of vectors and their salient features see APPENDIX 5.

REPLICATORS

One of the ways that replicators are classified is based on the number of plasmid molecules maintained per bacterial cell under some set of standard growth conditions, the so-called **copy number** of the plasmid. This book defines **high-copy-number plasmids** as those which exist in ≥ 20 copies per bacterial cell grown in liquid LB medium, and **low-copy-number plasmids** as those which exist in < 20 copies per cell. High-copy-number-plasmids tend to be smaller than low-copy-number plasmids. They are more commonly used in molecular biological techniques since it is easier to prepare large quantities of pure plasmid DNA from cells that bear them. Low-copy-number plasmids are utilized when it is important to control the gene dosage of a cloned sequence, for example when the DNA sequence or the protein it encodes makes the host organism sick (see Table 1.5.1).

High-copy-number plasmids tend to be under **relaxed control** of replication. These relaxed plasmids initiate DNA replication in a process controlled by plasmid-encoded functions (see Mechanism of Replication and Copy-Number Control), and replication does not depend on the unstable host replication initiation proteins synthesized at the start of the bacterial cell cycle. Because their replication depends only on the stable host enzymatic replication machinery, the copy number of these plasmids can be greatly increased, or amplified, by treatment of the plasmid-containing cells with protein synthesis inhibitors such as chlorampheni-

^aCopy numbers are for the prototype plasmid. Plasmid vectors that contain replicators derived from these plasmids may have different copy numbers due to introduction of mutations into the replicator. For example, pUC series (pMB1-derived) has copy numbers of 1000-3000.

^bTemperature sensitive.

^cNot known.

col or spectinomycin. These protein synthesis inhibitors prevent synthesis of the replication-initiation proteins required for chromosomal replication, allowing the replication enzymes to be commandeered for plasmid replication. High-copy-number plasmids usually do not have any mechanism to ensure correct segregation of the plasmids to the daughter cells; they rely on random assortment to partition at least one copy of the plasmid to each daughter.

Low-copy-number plasmids are usually under *stringent control*. Initiation of replication of these plasmids depends on unstable proteins synthesized at the start of the bacterial cell cycle and thus is synchronized with the replication of the bacterial chromosome. As copy number decreases, random segregation of plasmid copies is not sufficient to ensure that each daughter cell acquires a copy of the plasmid. However, most low-copy-number plasmids carry genes that guarantee their maintenance in the bacterial population. Stabilizing loci that encode a mechanism for postsegregational killing of plasmid-free daughter cells and a system for efficiently resolving plasmid multimers so that they can be appropriately partitioned have been identified. In addition, *cis*- and *trans*-acting partitioning loci (*par*) that are thought to constitute an active mechanism for distribution of plasmid copies to daughter cells have also been identified.

MECHANISM OF REPLICATION AND COPY-NUMBER CONTROL

While there are many different replicators, the majority of plasmid vectors used in routine recombinant DNA work contain one of the functionally similar replicators derived from plasmids ColE1 or pMB1 (for example, the popular pBluescript series contain a ColE1 origin, and the pUC plasmids are derived from pMB1). The ColE1 replicator is a 600-nucleotide DNA fragment that contains the origin of replication (*ori*), encodes an RNA primer, and encodes two negative regulators of replication initiation. All enzymatic functions for replication of the plasmid are provided by the bacterial host.

Plasmid replication begins with transcription of an RNA primer upstream of the *ori* (RNAII; see Fig. 1.5.1) by the host RNA polymerase. RNAII is elongated through and terminated downstream of the *ori*. Interaction of a specific secondary structure in the nascent RNAII transcript with the DNA template results in formation of a persistent hybrid between RNAII and the DNA template such that RNAII remains paired with the DNA template at the *ori*. The RNAII transcript is cleaved by RNaseH at the *ori* sequence. This processed RNAII primer is extended by DNA polymerase I to initiate plasmid replication. Regulation of the proper RNAII secondary structure controls initiation of DNA replication and is responsible

for determining the number of plasmid molecules per cell.

Both ColE1 and pMB1 plasmids are high-copy-number plasmids, maintained at between 15 and 25 copies per bacterial cell, respectively. The copy number of these plasmids is regulated by an antisense RNA transcript, RNAI, and the protein ROP, the product of the *rop* gene. RNAI and the ROP protein act in concert to intercept formation of the proper RNAII secondary

structure. RNAI is exactly complementary to the 5' end of the RNAII transcript. RNAI base pairs with the 5' end of RNAII, preventing the formation of the specific secondary structure necessary for establishment of a persistent hybrid between RNAII and the DNA template that is a prerequisite for maturation of the RNAII primer. ROP protein stabilizes the interaction between the antisense RNAI and the primer RNAII. Mutations that disrupt or destabilize

Figure 1.5.1 ColE1 replication initiation and copy number control. ColE1 replication requires the formation of a RNA primer to initiate DNA synthesis. The RNA primer is derived from processing of a transcript, RNAII (bold), that starts upstream of the *ori*. Appropriate processing of the RNAII transcript is dependent on formation of a persistent hybrid between RNAII and the *ori*/DNA template. If the proper RNAII secondary structure forms, then the RNA/DNA duplex is maintained at the *ori* and RNase H can cleave the RNAII transcript to generate the primer for DNA synthesis. Processing of RNAII to form the primer is regulated by a second transcript, RNAI. RNAI is complementary to the 5' end of RNAII. If the RNAI transcript forms a duplex with RNAII, RNAII cannot take on the secondary structure necessary to create the persistent hybrid at the *ori* and maturation of the RNAII primer is inhibited. The copy number of ColE1 plasmids is determined by the balance between successful RNAII processing events and those inhibited by RNAI. Adapted from Gerhart et al. (1994) with permission from the *Annual Review of Microbiology*.

the RNAI/RNAII interaction result in a higher plasmid copy number. For example, the pUC plasmid series have pMB1 replicators that do not contain an intact *rop* gene, which accounts for a 2-fold increase in copy number over plasmids with intact pMB1 replicons. Interestingly, additional mutation(s) in the origin are the main factor in the ultra-high-copy number (1000 to 3000) of this plasmid series (K. Struhl, unpub. observ.).

PLASMID INCOMPATIBILITY

For experiments that require that more than one plasmid vector be maintained in a bacterial cell at the same time, another critical feature of plasmid replicators is whether or not two plasmid replicators are *compatible*. Two plasmids are said to be *incompatible* with one another, and hence belong to the same *incompatibility group*, if they cannot stably co-exist. Plasmids are generally incompatible if they share any function required for the regulation of plasmid replication. For example, ColE1- and pMB1-derived plasmids are incompatible with one another but are compatible with p15A plasmids. The incompatibility of ColE1 and pMB1 plasmids is a consequence of two facts: first, that plasmid DNA replication of these plasmids is negatively controlled by RNAI which acts in *trans* on other plasmids with the same primer RNA, and second, that these plasmids lack a mechanism to ensure that each plasmid in a cell replicates once per cell cycle. Therefore, if a cell that contains a pMBI-derived plasmid is subsequently transformed with a ColE1-derived plasmid, cells selected to contain the ColE1 plasmid will usually have lost the pMBI plasmid.

SELECTABLE MARKERS

In order to guarantee that a plasmid vector is taken up by and maintained in bacterial cells, there must be a way to select for plasmid-containing cells. Genes encoding resistance to antibiotics such as ampicillin, tetracycline, kanamycin and chloramphenicol are the most common bacterial selectable markers for plasmid vectors. Typically, cells are transformed with plasmid DNA using the technique described in *UNIT 1.8* and then plated out on LB plates that contain the proper antibiotic (see recipes in *UNIT 1.1*). Only the bacterial cells containing the plasmid will grow on the selective medium; the antibiotic-resistance phenotype conferred is dominant to the antibiotic-sensitive phenotype of cells that do not possess the plasmid vector. Another dominant select-

able marker that is occasionally used is the immunity to infection by phage lambda (lambda repressor). In addition, recessive markers are sometimes used in plasmid selections; for example, *leuB⁻ E. coli* cannot grow in the absence of leucine, and selection for growth of these strains in the absence of leucine allows isolation of colonies transformed with a plasmid that contains a gene that complements *leuB*.

For experiments that involve introduction of plasmid vectors into systems other than bacteria, such as yeast or mammalian cells, it is usually necessary to select for the presence of plasmid DNA in these hosts. Selectable markers for yeast and mammalian systems are generally distinct from those used in *E. coli* (see Plasmid Vectors for Yeast and Plasmid Vectors for Expression in Cultured Mammalian Cells). In cases where a vector is needed that will be used in both *E. coli* and another host, it is necessary for the plasmid vector to carry selectable markers for both hosts.

CLONING SITE

Today's plasmid vectors contain a multiple cloning site (MCS) or *polylinker* cloning region that can include >20 tandemly arranged restriction endonuclease sites. The sites in the polylinker are almost always designed to be unique within the vector sequence so that cutting the vector with a restriction endonuclease in the polylinker and cloning foreign DNA into this site does not disrupt other critical features of the vector. The plethora of sites in the polylinker ensures that the appropriate enzyme sites will be available for cloning most DNA fragments, provides unique reference restriction sites for rapid restriction mapping of the insert, and generally allows for a great deal of flexibility when manipulating the cloned DNA.

The sequences that directly flank the polylinker site are often useful for manipulation or analysis of insert DNA. Many polylinker sites are flanked by sequences for which there are commercially available complementary oligonucleotides, for example the M13 reverse, -20, and -40 primers, that can be used for priming polymerase chain reactions (PCR) or DNA sequencing reactions. Such primers are useful tools for amplification or sequencing of any DNA fragment inserted into the polylinker. Some polylinkers are bordered by 8-bp-cutter restriction sites, like *Not1*. These sites occur infrequently in DNA and thus allow for the easy excision of an intact insert fragment from the plasmid vector.

Many plasmid vectors have been developed with bacteriophage—SP6, T7, or T3—promoters flanking the polylinker cloning sites. These promoters can be used *in vitro* or *in vivo*, if the bacteriophage RNA polymerase is also present, to produce large quantities of RNA transcripts from DNA inserted into the polylinker.

In order to make it easier to identify plasmids that contain insert DNA, the polylinkers of some vectors have been engineered so that introduction of DNA into the polylinker results in a scorable phenotype. The most common example of this is insertion of the polylinker of many basic cloning vectors, the pUC series for example, into the *lacZ* gene α fragment. In the appropriate genetic background, production of the *lacZ* α fragment allows for formation of an active β -galactosidase enzyme which results in the formation of blue colonies on Xgal/IPTG indicator plates. Cloning into these polylinkers prevents production of a functional *lacZ* α fragment, allowing for rapid identification of plasmids containing inserts as white colonies on Xgal/IPTG indicator plates. Vectors have also been developed that allow for direct selection of plasmids containing inserts by location of the polylinker in the *ccdB* (control of cell death) gene which causes cell death in *E. coli*. Disruption of the *ccdB* gene by introduction of an insert into the polylinker allows the cells to survive, and thus only recombinants will grow under conditions where the *ccdB* gene is expressed.

CHOOSING A PLASMID VECTOR

Some of the basic features to consider when selecting a plasmid vector include the size of the vector, its copy number, the polylinker, and the ability to select and/or screen for inserts. Large plasmids, >15 kb, do not transform well and frequently give lower DNA yields. Consider the final size of the vector plus insert when planning an experiment and wherever possible use smaller vectors. The higher the copy number the more vector DNA is produced, but high-copy-number vectors may not be applicable to all situations (see Mechanism of Replication and Copy-Number Control). When choosing a plasmid vector, consider both what sites are present in the polylinker and the order of the sites. If it will be necessary to manipulate the cloned sequence subsequent to insertion into the polylinker, plan ahead to ensure that the necessary sites will remain available in the polylinker. Selections or screens for identification of recombinant clones are useful for experiments where cloning efficiency is expected

to be low or when generation of a large number of clones is necessary. However, for routine subcloning experiments the advent of PCR (UNIT 15.1) has made it possible to rapidly screen through a large number of transformants to identify potential recombinant molecules, obviating the need for histochemical and genetic screening methods.

The primary factor in choosing a plasmid vector is to understand and anticipate the experiments for which the recombinant clone will be used. The specialized functions of plasmid vectors are generally the key to selecting the correct vector for an experiment. For example, completely different types of vectors would be used for generating large quantities of DNA, expressing a fusion protein in bacteria, or for undertaking a two-hybrid screen in yeast. Once the type of vector required is determined then deciding upon a particular vector is dependent on both the details of the ancillary vector features, for example the type of promoter used to express a recombinant protein, and the properties of the replicator, polylinker, and selectable marker.

PLASMID VECTORS FOR PRODUCTION OF SINGLE-STRANDED DNA

Plasmids have been developed that contain a filamentous phage origin of replication in addition to a plasmid *ori*. These “phagemid” vectors (UNIT 1.14) can be grown and propagated as plasmids. However, upon super-infection of a plasmid-containing cell with a wild-type helper phage, the phage *ori* becomes active, and single-stranded DNA (ssDNA) is produced and secreted. There are usually (+) and (–) versions of these vectors where the phage *ori* is in opposite orientation so that it is possible to produce ssDNA from either DNA strand. For many years, ssDNA was the substrate of choice for DNA sequencing (UNIT 7.4) and oligonucleotide-directed mutagenesis (UNIT 8.1). Development of sequencing and mutagenic protocols that use double-stranded templates has made the production of ssDNA a less frequently utilized feature of plasmid vectors. The pBluescriptI, pBluescriptII, and pBS phagemid vectors derived from the general cloning vector pUC19 (Fig. 1.5.2) are examples of phagemids that incorporate the f1 filamentous phage *ori*.

PLASMID VECTORS FOR CLONING LARGE INSERTS

Cosmid vectors, plasmids carrying a lambda phage *cos* site (e.g., pWE15, Fig. 1.5.3), were

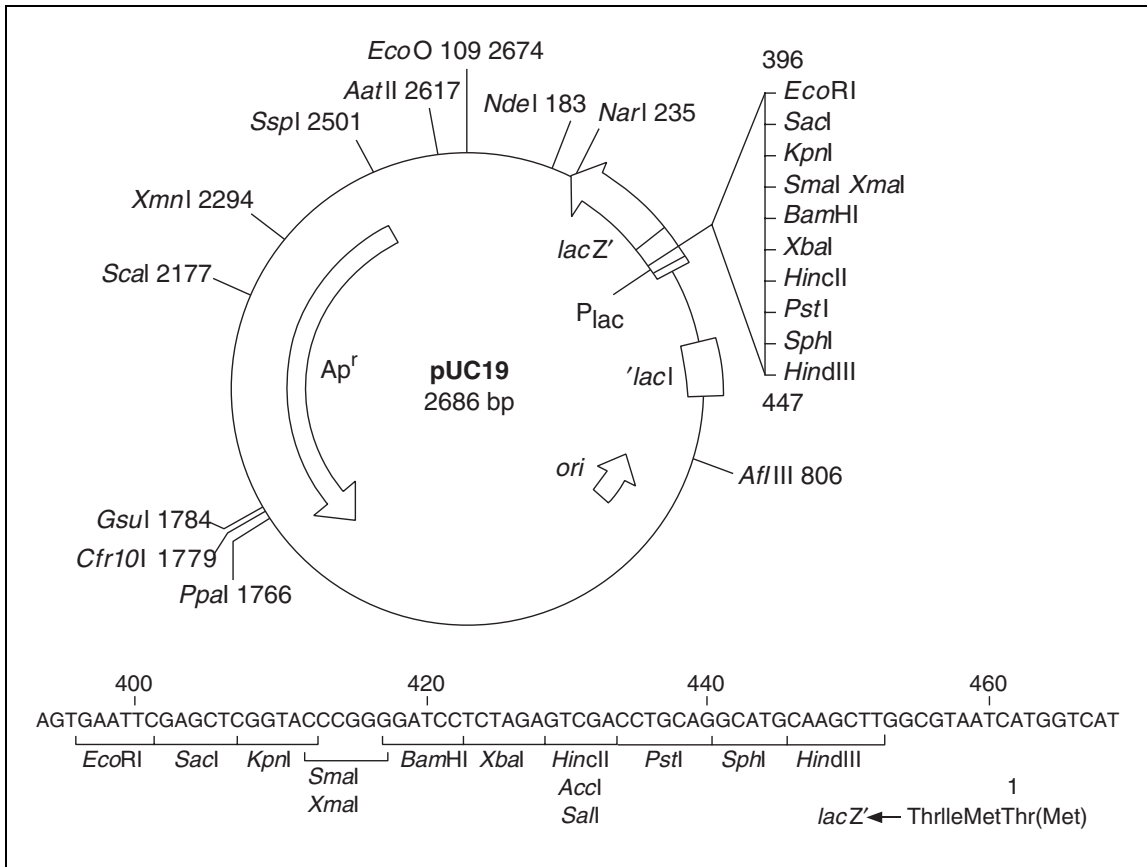

Figure 1.5.2 Map of pUC19.

Figure 1.5.3 Map of pWE15 (adapted from Wahl et al., 1987, with permission).

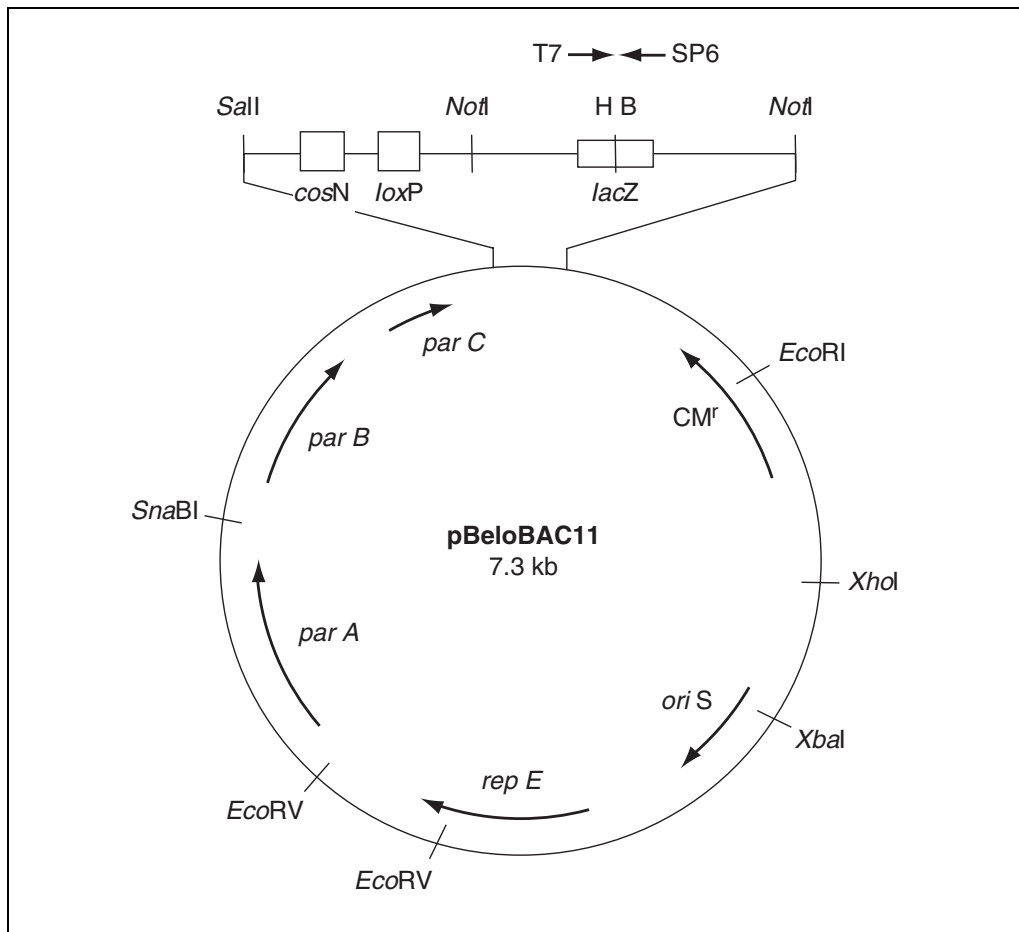

Figure 1.5.4 Map of pBeloBAC11 (adapted from Shizuya et al., 1992, with permission). Abbreviation: CM, chloramphenicol.

developed to facilitate cloning of large DNA fragments (UNIT 1.10). Cosmids can be transformed into cells like plasmids and once in the cells, replicate using their plasmid *ori*. The ColE1 type replicators are the most commonly used in these vectors, and cosmids can generally be maintained at high-copy-number in *E. coli*. Cosmids can also be packaged into lambda phage heads. In order for packaging to occur the *cos* sites must be separated by 40 to 50 kb, the approximate length of the wild-type lambda genome. Many cosmid vectors are between 5 to 10 kb in size and therefore can accept inserts of 30 to 45 kb. Because of the size of inserts they can accept, the high efficiency of packaging recombinant molecules into phage, and the efficiency of infection of cosmid-containing phage heads, cosmid vectors are frequently used for making genomic libraries. Unfortunately, propagation of insert-containing cosmid vectors in *E. coli* sometimes results in the deletion of all or a portion of the insert. To address this problem, a new set of cosmid vectors have been developed that replace the ColE1 replica-

tor with the F factor replicator. These “fosmid” vectors are maintained at low-copy-number, 1 to 2 copies per cell, and are more stable than higher-copy-number cosmid vectors when grown in *E. coli* (Kim et al., 1992).

Another type of plasmid cloning vector, called bacterial artificial chromosome (BAC; Fig. 1.5.4), has been developed using the F factor replicator for propagation of very large pieces of DNA (100 to 500 kb). The vectors are used in a similar manner to yeast artificial chromosome (YAC) vectors but have the advantage of being manipulated solely in *E. coli*.

PLASMID VECTORS FOR EXPRESSION OF LARGE QUANTITIES OF RECOMBINANT PROTEINS

There are a wide variety of vectors for expressing high levels of recombinant proteins in *E. coli*, insect, and mammalian cells (Chapter 16). The general goal of expressing proteins in any of these systems is to produce large quantities of a particular protein upon demand.

While the features of the protein expression systems vary considerably, the basic properties outlined for expressing proteins in *E. coli* are common to all of them. Expression vectors are usually designed such that production of the foreign protein is tightly regulated. This is necessary because the host cellular machinery is co-opted to produce large quantities of the foreign protein, the sheer amount of which may be toxic to the cell, and/or the foreign protein may encode a function that will inhibit cell growth or kill the host cell. Generally, expression vectors are configured so the polylinker cloning site is downstream of an inducible promoter. One of the promoters commonly used in *E. coli* expression vectors is the hybrid *trp/lac* promoter (*trc*) which contains the *lacO* operator site. This promoter is turned off in the presence of the *lacI^q* repressor; the repressor gene is either carried by the bacterial host or is encoded on the expression vector itself. Expression of the foreign protein from the *trc* promoter is induced by the addition of IPTG.

The quantity of foreign protein produced will be determined by both the rate of transcription of the gene and the efficiency of translation of the mRNA. Therefore, in addition to regulated highly inducible promoters, many *E. coli* protein expression vectors are designed to optimize translation of the foreign protein in bacterial cells. These expression vectors include an efficient ribosome binding site and an ATG start codon upstream of the polylinker cloning site. Usually the cloning sites in the polylinker are designed so that it is possible to make an in-frame fusion to the protein of interest in all three reading frames.

For many experiments, high levels of pure recombinant protein are required, and some expression vectors are designed to create tagged or fusion proteins that facilitate purification of the recombinant protein. Tag sequences may be located 5' or 3' to the polylinker, creating either amino- or carboxy-terminal-tagged fusion proteins. Six polyhistidine residues (*UNIT 10.11B*), the FLAG epitope, and glutathione-S-transferase protein (*UNIT 16.7*) are some of the sequences that are appended to proteins to assist in purification. Tagged or fusion proteins can be rapidly and efficiently purified using an appropriate affinity column designed to tightly bind the tag or fusion region. Many protein expression vectors are created with specific protein cleavage sites adjacent to the tag or fusion sequences to allow for removal of these sequences from the purified protein. This feature may prove to be essential if the tag

or fusion sequence impairs the function of the protein in the relevant assays.

PLASMID VECTORS FOR REPORTER GENE FUSIONS

Plasmid vectors have been designed to simplify the construction and manipulation of reporter gene fusions, where a promoter of interest is used to drive an easily scored marker gene (*UNIT 9.6*). Gene fusions provide a rapid and simple method for following the expression pattern conferred by a particular promoter. There are generally two types of reporter fusions, transcriptional and translational fusions. For transcriptional fusions, the ATG start codon is provided by the marker gene. In translational fusions, the 5' untranslated region and ATG are provided by the gene of interest; in fact these constructs may fuse a large portion, or even entire coding region, to the amino terminus of a marker. In the reporter vector, the polylinker cloning site is located directly upstream of the reporter gene for insertion of the promoter fragment. In vectors that are designed for expression in eukaryotic cells, a polyadenylation signal is located downstream of the reporter gene. There are a variety of reporter genes used including chloramphenicol acetyltransferase, luciferase, β -galactosidase, secreted alkaline phosphatase, human growth hormone, β -glucuronidase, and green fluorescent protein (also see *UNITS 9.6-9.7C*). An example of a reporter vector pEGFP, is shown in Figure 1.5.5. The choice of reporter gene will depend on the cell type or organism, whether the assay will be done in vivo or in vitro, and whether quantitative or qualitative data is desired. The replicator, selectable marker, and other elements of the reporter vector will also have to be compatible with the system.

PLASMID VECTORS FOR YEAST

Yeast plasmid vectors contain the same basic features as *E. coli* vectors—replicator, selectable marker, and cloning site (*UNIT 13.4*). There are two primary types of replicators used in yeast plasmid vectors, autonomously replicating sequences (ARS) derived from the yeast chromosomes and the natural yeast 2 μ m plasmid replicator. ARS-containing plasmids frequently contain yeast centromeric sequences to ensure their stable maintenance in the population of cells. Both ARS and 2 μ m vectors average 10 to 30 copies per cell. Many yeast vectors are “shuttle” vectors that can be maintained in both *S. cerevisiae* and *E. coli* (e.g., pRS303; see Fig. 1.5.6). These vectors have an *E. coli* plas-

mid replicator, frequently pMB1 derived, and a yeast replicator. Conversely, the yeast integrating plasmid vectors, used for introduction of genes into the yeast chromosome, have a bacterial replicator but no yeast replicator.

The selectable markers in yeast are for the most part recessive markers, usually cloned yeast genes that are used to complement muta-

tions in a biosynthetic pathway. For example, the *URA3* marker carried on a plasmid is used to restore the ability to grow in the absence of uracil to a *ura3⁻* yeast. Therefore, yeast selectable markers, unlike most bacterial selectable markers, are strain dependent.

There are a wide variety of yeast vectors available that have a range of specialized func-

Figure 1.5.5 Map of pEGFP-1.

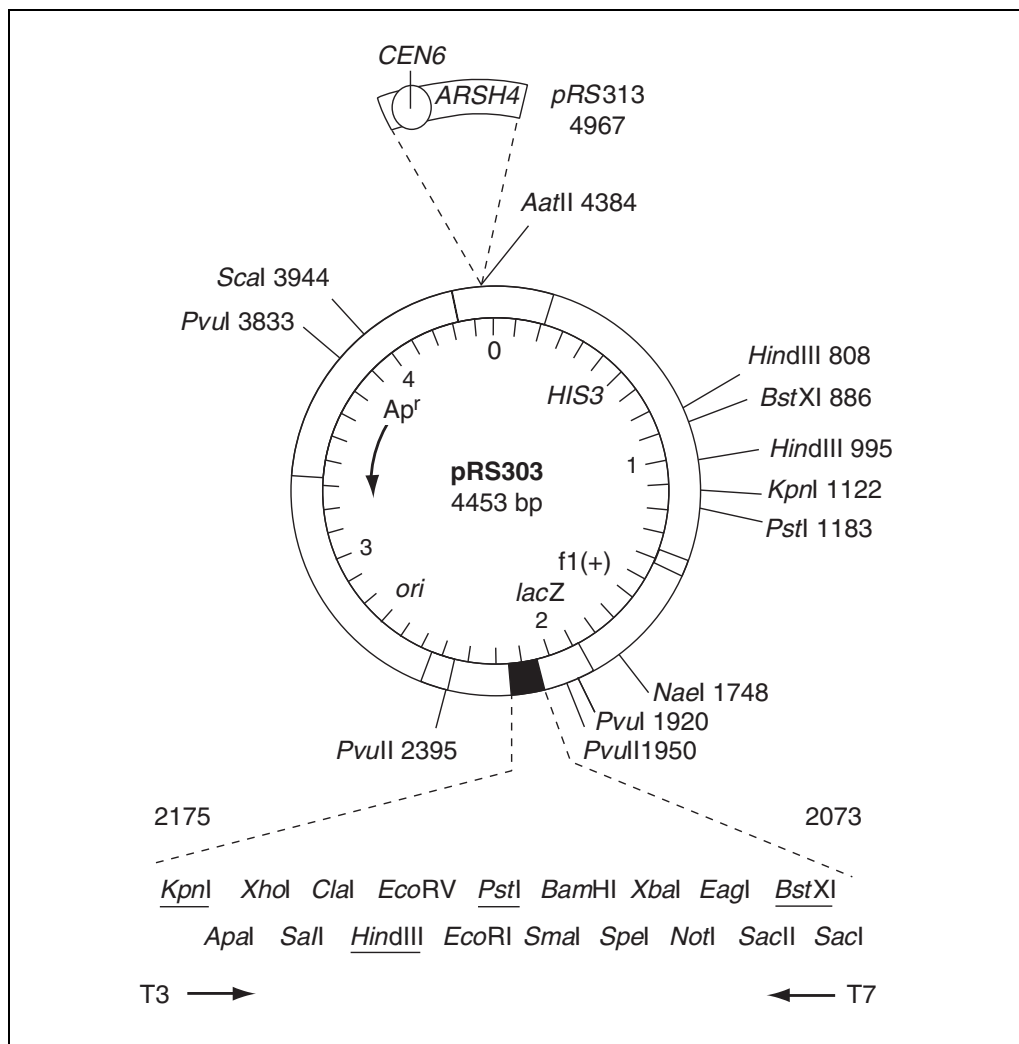

Figure 1.5.6 Map of pRS303 (adapted from Sikorski and Heiter, 1989, with permission).

tions—e.g., expression of recombinant proteins in yeast, integration of sequences into the yeast genome, and cloning of very large fragments (hundreds of kilobases) of genomic DNA.

PLASMID VECTORS FOR EXPRESSION IN CULTURED MAMMALIAN CELLS

The type of vector that is used in mammalian cells depends on whether the experiment involves transient transfection into mammalian cells or the generation of stable mammalian cell lines carrying the construct of interest (UNITS 9.1-9.5). Virtually any plasmid vector that contains an appropriate construct for expression in mammalian cells can be used in transient assays. In transient assays, the plasmid vector carrying the DNA of interest is transfected into mammalian cells, the cells are harvested some time later (24 to 96 hr), and the pertinent assay

is performed. It is not necessary for plasmid vectors used in these assays to carry a mammalian selectable marker or to replicate in mammalian cells; therefore easily manipulatable bacterial plasmids, like pUC, are usually the vectors of choice.

Plasmid vectors carrying a selectable marker that functions in mammalian cells are necessary for the generation of stable transgenic lines (UNITS 9.5; e.g., pcDNA3.1, Fig. 1.5.7). In order to generate a stable mammalian cell line, the plasmid DNA is transfected into the mammalian cells, and over a period of several weeks the DNA of interest is selected for based on expression of the vector-borne marker. Many mammalian vectors cannot replicate in mammalian cells, and the only way to maintain the DNA of interest and the selectable marker is for the vector to randomly integrate into the mammalian genome. However, there are some plasmid vectors that carry the simian

Figure 1.5.7 Map of pcDNA3.1.

virus (SV40) or bovine papilloma virus (BPV) *ori* that can replicate in mammalian cells if the necessary viral replication proteins are provided; in most cases the viral replication proteins must be provided by the host cell line, limiting the range of cell types in which these vectors are useful.

The most critical general feature of plasmid vectors (and also viral vectors) for creation of stable mammalian cell lines is the selectable marker (see *UNIT 9.5*). Unlike transient assays, formation and maintenance of stable cell lines requires selection. The number of selectable markers available for mammalian cells is limited; resistance to hygromycin, puromycin, G418, and neomycin are the predominant markers used. Since expression of foreign proteins or assaying the expression of a mammalian gene may require multiple plasmids and/or integration of constructs into the mammalian chromosome, careful planning must take place to ensure that all constructs can be selected for with the limited number markers. Further, since selection may be necessary over a long period

of time—weeks for generation of the lines and years for their maintenance—it is important to recognize that some of the antibiotics used in selection are very expensive and thus cost may be a factor in experimental design.

Specialized plasmid vectors are also used for production of viruses that can infect mammalian cells. Plasmid vectors have been designed to produce infectious retroviral particles when transfected into the appropriate packaging cell line (*UNIT 9.9*). These retroviral vectors are then used to create stable transgenic lines in mammalian cell types not amenable to transfection. In addition, plasmid vectors have been designed to allow easy insertion of DNA sequences into vaccinia virus for the purpose of creating recombinant viruses that overexpress recombinant proteins (*UNIT 16.15*).

PLASMID VECTORS FOR NON-*E. COLI* BACTERIA

Three features required of all bacterial plasmid vectors are that they replicate (unless they are suicide vectors), carry a selectable marker,

Escherichia coli,
Plasmids, and
Bacteriophages

1.5.11

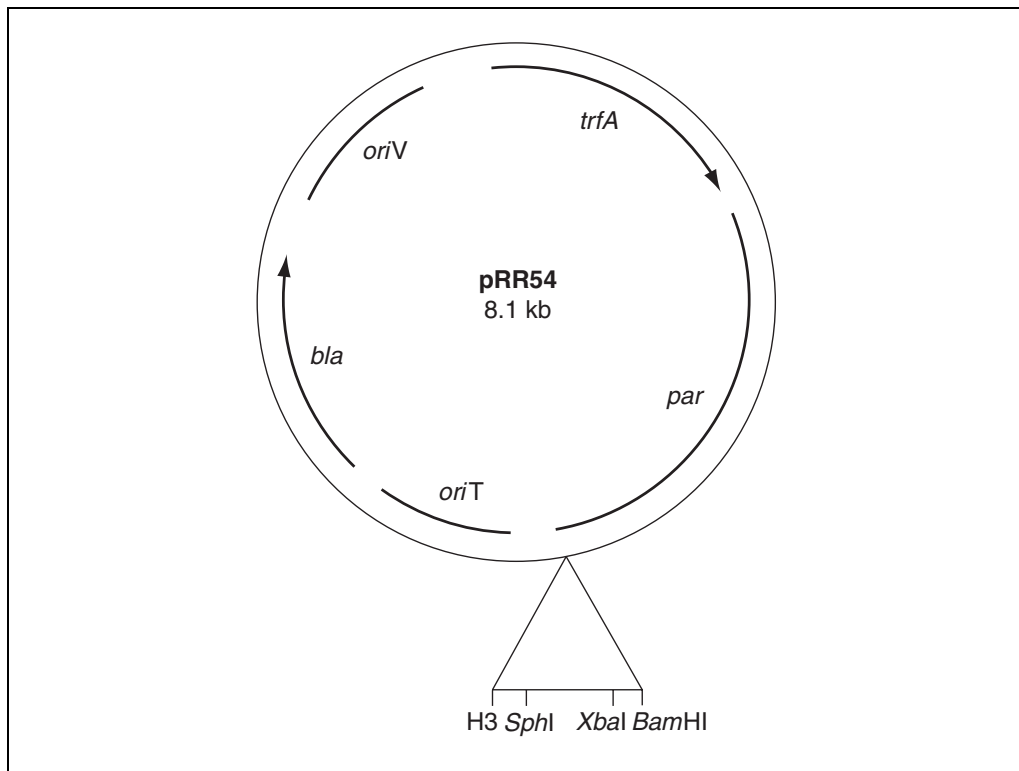

Figure 1.5.8 Map of pRR54 (adapted from Roberts et al., 1990, with permission).

and can be easily introduced into host cells. The first thing to consider when selecting a plasmid vector for use in a non-*E. coli* host is whether or not it can replicate and be stably maintained in the particular strain. Different plasmid replicators have different host ranges, some have a narrow host range and can only replicate in a specific strain while others are promiscuous and can replicate in a wide variety of host (e.g., pRR54, Fig. 1.5.8). Unfortunately, the ColE1-type replicators have a narrow host range, thus many standard *E. coli* vectors cannot be maintained in other bacteria. However, a number of broad-host-range replicators, such as RK2 and RSF1010, have been well characterized and used to construct vectors that can replicate in many gram-negative bacterial species (and in the case of RSF1010, some gram-positive species as well).

Antibiotic resistance genes are used as selectable markers in non-*E. coli* bacterial hosts; however, the quantity of an antibiotic used to select against non-plasmid-containing cells is usually higher than the quantity used for *E. coli* selection. Furthermore, some bacterial strains are inherently resistant to particular antibiotics, thus it is important to determine whether the selectable marker carried on a plasmid vector is functional in a particular strain.

The favored method for introduction of plasmid DNA into bacterial host cells varies widely with the bacterial strain. Unlike *E. coli*, many bacteria cannot be efficiently transformed by chemical procedures or electroporation. In these cases bacterial mating is used to introduce plasmid DNA into the desired bacterial host. Mating to transfer a plasmid vector from an *E. coli* host where the vector is maintained and manipulated to a recipient bacterium requires both *cis*- and *trans*-acting functions. The *tra* (or *mob*) genes encode the *trans*-acting proteins necessary to transfer the plasmid DNA from one bacterium to another, and they are usually located on a helper plasmid that is distinct from the plasmid vector. Any plasmid vector that is to be mobilized must contain the *cis*-acting site called *oriT* where the DNA is cleaved and transfer is initiated.

MAPS OF PLASMIDS

Figures 1.5.2-1.5.11 present maps of plasmids that are in widespread use or are examples of plasmids whose special functions make them useful for particular techniques described in this manual. Note that the trend in development of vectors is to include multiple features on a single vector, and many of these examples span the vector categories described.

Figure 1.5.9 Map of pBR322 (Bolivar et al. 1977; sequence in Sutcliffe, 1978).

pBR322 is one of the classic cloning vectors from which many other vectors are derived. It contains an amplifiable pMB1 replicator and genes encoding resistance to ampicillin and tetracycline. Insertion of DNA into a restriction site in either drug-resistance gene usually inactivates it and allows colonies bearing plasmids with such insertions to be identified by their inability to grow on medium with that antibiotic (see Fig. 1.5.9; Bolivar et al., 1977; sequence in Sutcliffe, 1978).

pUC19 belongs to a family of plasmid vectors that contains a polylinker inserted within the alpha region of the *lacZ* gene. The polylinkers are the same as those used in the m13mp series (Fig. 1.14.2). pUC19 and pUC18 have the same polylinker but in opposite orientations. Under appropriate conditions (see UNIT 1.4 for a description), colonies that bear plasmids containing a fragment inserted into the polylinker form white colonies instead of blue ones. These pMB1-derived plasmids (see Fig. 1.5.2) maintain a very high-copy-number (1000 to 3000 per genome). Wild-type and recombinant plasmids confer ampicillin resistance and can be amplified with chloramphenicol (Norrandar et al., 1983). In addition wild-type plasmids confer a LacZ⁺ phenotype to appropriate cells (e.g., JM101 cells, UNIT 1.4).

pBluescript is a commonly used phagemid cloning vector that contains a polylinker in-

serted into the alpha region of the *lacZ* gene and T3 and T7 promoter sequences flanking the cloning sites. The f1 (+) filamentous phage origin of replication in pBluescript SK⁺ allows for the recovery of the sense strand of the *lacZ* gene as ssDNA; the pBluescript SK(-) vector (Fig. 1.5.10) with the f1 origin in the opposite orientation, f1(-), facilitates recovery of the other strand. The position of the polylinker in the alpha region of the *lacZ* gene allows for identification of inserts based on a blue/white color screen under the appropriate conditions. The T3 and T7 promoters are recognized by bacteriophage RNA polymerases. Transcription from these promoters reads into the polylinker from either side. RNA transcripts of any DNA cloned into the polylinker can thus be produced by run-off transcription in vitro.

pWE15 is an example of a cosmid vector used for cloning DNA fragments ~35 to 45 kb (see Fig. 1.5.3; Wahl et al., 1987). The *cos* sites allow the DNA to be cut and packaged into phage heads by the appropriate lambda proteins. There is a single unique *Bam*HI cloning site flanked by T3 and T7 promoter sequences. These promoters are particularly useful for production of labeled RNA probes corresponding to the ends of the insert DNA, and these can be used to identify overlapping cosmids for chromosome walking and construction of cosmid contigs. *Not*I sites flanking the cloning site can

Figure 1.5.10 Map of pBluescript SK (+/-).

Figure 1.5.11 Map of pTrc99A,B,C.

potentially be used to excise an intact insert fragment from the vector. The ColE1-derived *ori* and ampicillin resistance gene allow for replication and selection in bacteria. The SV40 promoter (included in SV40 *ori*) which drives the neomycin phosphotransferase gene enables selection in eukaryotic cells.

pBeloBAC11 is an example of the family of bacterial-artificial-chromosome vectors based on the low-copy-number F factor replicator (see Fig. 1.5.4; Shizuya et al., 1992). BAC vectors are used for cloning large DNA fragments (100 to 500 kb) in *E. coli* and are used commonly in genome-mapping strategies. *oriS*, *repE*, *parA*, *parB*, and *parC* genes are the

essential genes that compose the F factor replicator. *oriS* and *repE* genes are required for unidirectional replication of the plasmid, and *parABC* loci stably maintain the copy number at one to two per *E. coli* genome. There are two unique cloning sites (*HindIII* and *BamHI*) inserted into the *lacZ* alpha region. Other useful features of the cloning region are (1) T7 and SP6 promoter sequences flanking the cloning sites, (2) *NotI* restriction sites flanking the cloning sites for potential excision of the insert, and (3) presence of the *loxP* and *cosN* sites that can be cleaved by specific enzymes. The ends generated by cleavage at *loxP* or *cosN* can be used as fixed reference points in building an

ordered restriction map by end labeling and partial restriction digestion.

pEGFP-1 is a selectable vector for monitoring promoter activity in mammalian cells via fluorescence of a green fluorescent protein (GFP) derivative (Clontech; see Fig. 1.5.5; Yang et al., 1996). The vector contains a neomycin resistance gene downstream of the SV40 early promoter for selection of stably transformed mammalian cells. It has a polylinker located upstream of the EGFP gene, so that the function of promoter sequences introduced into the polylinker can be assessed based on EGFP activity. The EGFP gene is modified from wild-type GFP to ensure expression in mammalian cells, it has silent base mutations that correspond to human codon-usage preferences, and sequences flanking the coding region have been converted to a Kozak consensus translation initiation signal. The vector backbone contains an *f1 ori* for production of ssDNA, a pUC-derived *ori* for propagation in *E. coli* and a kanamycin resistance gene for selection in bacteria.

A series of yeast shuttle vectors (pRS304, 305, and 306) has been created to facilitate manipulation of DNA in *Saccharomyces cerevisiae* (see Fig. 1.5.6; Sikorski and Hieter, 1989). These vectors have a backbone derived from pBLUESCRIPT into which the features necessary for replication and maintenance in yeast have been introduced. The members of this series of plasmids differ only in the yeast selectable marker incorporated; pRS303 carries the *HIS3* marker that complements a non-reverting *his3* chromosomal mutation in specific yeast strains. These plasmids contain an autonomously replicating sequence as well as a centromere sequence, *CEN6*, that ensures stable maintenance in yeast cells.

pCDNA3.1 is a selectable cloning and expression vector for use in mammalian cells. The features of this vector include a neomycin resistance gene driven by the SV40 early promoter (contained within the SV40 *ori*) and terminated by an SV40 polyadenylation signal for selection in mammalian cells (see Fig. 1.5.7). In addition, due to the inclusion of the SV40 *ori*, the vector can replicate as an episome in cells expressing the SV40 large T antigen. The polylinker cloning site is located downstream of strong cytomegalovirus enhancer-promoter sequences and upstream of the bovine growth hormone gene termination signals for high-level expression of protein-coding sequences cloned into this vector. This vector also contains some of the more standard features of

other plasmid vectors, including a ColE1 replicator for propagation in *E. coli*, the ampicillin resistance gene for selection in *E. coli*, the *f1 ori* for production of ssDNA, and the T7 promoter sequence for in vitro transcription of DNA inserted into the polylinker.

pRR54 is an example of a broad-host-range mobilizable plasmid vector. This vector contains replicator and stabilization sequences derived from the natural RK2 broad-host-range plasmid (see Fig. 1.5.8; Roberts et al., 1990). *oriV* is the vegetative origin of replication, *trfA* encodes *trans*-acting functions necessary for replication, and *par* encodes a locus that enhances stability of the plasmid. This plasmid can be mated into diverse gram-negative species as long as the appropriate mobilization machinery is provided in *trans* because it contains the origin of conjugal transfer, *oriT*. The plasmid carries the β -lactamase gene, allowing for ampicillin/carbenecillin selection of plasmid containing bacteria.

The pTrc series of plasmid expression vectors facilitates regulated expression of genes in *E. coli*. These vectors carry the strong hybrid *trp/lac* promoter, the *lacZ* ribosome-binding site (RBS), the MCS of pUC18 that allows insertion in three reading frames, and the *rrnB* transcription terminators (see polylinker sequences given below the vector diagram in Fig. 1.5.11). These vectors are equally useful for expression of unfused proteins (resulting from insertion in the *NcoI* site) or for expression of fusion proteins (using one of the cloning sites in the correct translational frame). The presence of the *lacI^q* allele on the plasmid ensures complete repression of the hybrid *trp/lac* promoter during cloning and growth in any host strain (see Amann et al., 1988, for further details).

Minipreps of Plasmid DNA

Although there are a large number of protocols for the isolation of small quantities of plasmid DNA from bacterial cells (minipreps), this unit presents four procedures based on their speed and success: the alkaline lysis prep, a modification of the alkaline lysis prep that is performed in 1.5-ml tubes or 96-well microtiter dishes, the boiling method, and a lithium-based procedure. A support protocol provides information on storing plasmid DNA.

ALKALINE LYSIS MINIPREP

The alkaline lysis procedure (Birnboim and Doly, 1979, and Birnboim, 1983) is the most commonly used miniprep. Plasmid DNA is prepared from small amounts of many different cultures (1 to 24) of plasmid-containing bacteria. Bacteria are lysed by treatment with a solution containing sodium dodecyl sulfate (SDS) and NaOH (SDS denatures bacterial proteins, and NaOH denatures chromosomal and plasmid DNA). The mixture is neutralized with potassium acetate, causing the covalently closed plasmid DNA to reanneal rapidly. Most of the chromosomal DNA and bacterial proteins precipitate—as does the SDS, which forms a complex with potassium—and are removed by centrifugation. The reannealed plasmid DNA from the supernatant is then concentrated by ethanol precipitation.

Materials

LB medium (UNIT 1.1) containing appropriate antibiotic (Table 1.4.1)

Glucose/Tris/EDTA (GTE) solution

TE buffer (APPENDIX 2)

NaOH/SDS solution

Potassium acetate solution

95% and 70% ethanol

10 mg/ml DNase-free RNase (optional; UNIT 3.13)

1.5-ml disposable microcentrifuge tubes

1. Inoculate 5 ml sterile LB medium with a single bacterial colony. Grow to saturation (overnight).
2. Spin 1.5 ml of cells 20 sec in a microcentrifuge at maximum speed to pellet. Remove the supernatant with a Pasteur pipet.

The spins in steps 2 and 6 can be performed at 4°C or at room temperature. Longer spins make it difficult to resuspend cells.

3. Resuspend pellet in 100 µl GTE solution and let sit 5 min at room temperature.

Be sure cells are completely resuspended.

4. Add 200 µl NaOH/SDS solution, mix by tapping tube with finger, and place on ice for 5 min.

5. Add 150 µl potassium acetate solution and vortex at maximum speed for 2 sec to mix. Place on ice for 5 min.

Be sure mixing is complete.

6. Spin 3 min as in step 2 to pellet cell debris and chromosomal DNA.

7. Transfer supernatant to a fresh tube, mix it with 0.8 ml of 95% ethanol, and let sit 2 min at room temperature to precipitate nucleic acids.

BASIC PROTOCOL

**Escherichia coli,
Plasmids, and
Bacteriophages**

1.6.1

Contributed by JoAnne Engebrecht, Roger Brent, and Mustak A. Kaderbhai

Current Protocols in Molecular Biology (1991) 1.6.1-1.6.10

Copyright © 2000 by John Wiley & Sons, Inc.

8. Spin 1 min at room temperature to pellet plasmid DNA and RNA.
9. Remove supernatant, wash the pellet with 1 ml of 70% ethanol, and dry pellet under vacuum.
10. Resuspend the pellet in 30 μ l TE buffer and store as in support protocol. Use 2.5 to 5 μ l of the resuspended DNA for a restriction digest.

Contaminating RNA may interfere with detection of DNA fragments on the agarose gel; it can be destroyed by adding 1 μ l of a 10 mg/ml RNase solution (DNase-free) to the digestion mixture.

ALTERNATE PROTOCOL

ALKALINE LYSIS IN 96-WELL MICROTITER DISHES

Escherichia coli cells that contain plasmids are grown and lysed, and the plasmid DNA is precipitated—all in the wells of 96-well microtiter dishes. This procedure makes it possible to perform hundreds of rapid plasmid preps in a day. It is based on an unpublished procedure by Brian Seed of Massachusetts General Hospital.

Additional Materials

TYGPN medium (UNIT 1.1)

70% ethanol, ice-cold

Isopropanol

96-well microtiter plates (Dynatech PS plates or equivalent)

Multichannel pipetting device (8-prong Costar; 12-prong Titer Tek)

Multitube vortexer

Sorvall RT-6000 low-speed centrifuge, or equivalent, with microplate carrier in H-1000B rotor

1. Add 0.3 ml sterile TYGPN medium to each well of a 96-well microtiter plate (see sketch 1.6A). Inoculate each well with a single plasmid-containing colony.

The 96-well microtiter plates used must have U-shaped bottoms. To take full advantage of this protocol, one should perform all pipetting steps with a multichannel pipetting device.

Sketch 1.6A

2. Grow bacteria to saturation at 37°C (~48 hr).

All subsequent steps are performed at room temperature unless otherwise noted.

Potassium nitrate in the TYGPN medium presumably acts as a terminal electron acceptor when the bacteria in the wells are growing anaerobically, resulting in high cell densities.

3. Spin saturated cultures in H-1000B rotor with microplate carrier for 10 min at 2000 rpm (600 × g), 4°C. Decant supernatant with brief flick.

A microplate carrier is available for the Beckman JS-4.2 rotor. The same rpm values can be used for the JS-4.2 as those given here for the Sorvall H-1000B (see APPENDIX 1 for rotor conversion values).

4. Resuspend cells in the well bottoms by clamping the plate in a multitube vortexer and running it 20 sec at setting 4.
5. Add 50 µl GTE solution to each well.
6. Add 100 µl NaOH/SDS solution to each well. Wait 2 min.
7. Add 50 µl potassium acetate solution to each well.
8. Cover with plate tape or parafilm. Agitate vigorously in vortexer 20 sec at setting 4. Spin 5 min at 2000 rpm (600 × g), 4°C.
9. Insert a pipet tip just at the edge of the U in the bottom of the well. Remove 200 µl from each well and transfer to a new plate.

Do not try to recover all the fluid in each well.

10. Add 150 µl isopropanol to each well of the new plate. Cover with plate tape, agitate, and chill 30 min at -20°C.
11. Spin 25 min at 2000 rpm, 4°C, and decant supernatant. Wash pellets with cold 70% ethanol, gently decant supernatant, wash with 95% ethanol, and again gently decant supernatant.

Pellets often shrink visibly during the 70% ethanol wash, as impurities in them are dissolved.

Restriction enzymes will not cut well if the DNA is contaminated with even very small amounts of NaOH/SDS or potassium acetate solutions. It is therefore very important to decant the supernatants from the isopropanol precipitation and ethanol washes thoroughly, but not so vigorously that the pellets are flung out of the well bottoms.

If pellets become detached during either washing step, the plate should be respun at 2500 rpm for 5 min to bring the pellets to the bottom of the wells again.

12. Air dry pellets for 30 min, then resuspend in 50 µl TE buffer. Store as in support protocol and use 10-µl aliquots for digestion.

BOILING MINIPREP

Bacteria that contain plasmid DNA are broken open by treatment with lysozyme, Triton (a nonionic detergent), and heat. The chromosomal DNA remains attached to the bacterial membrane and is pelleted to the bottom of a centrifuge tube during a brief spin. Plasmid DNA is precipitated from the supernatant with isopropanol (Holmes and Quigley, 1981). This procedure is recommended for preparing small amounts of plasmid DNA from 1 to 24 cultures. It is extremely quick, but the quality of DNA produced is lower than that from the alkaline lysis miniprep.

Materials

LB medium (*UNIT 1.1*) containing appropriate antibiotic (Table 1.4.1)

STET solution

Hen egg white lysozyme

Isopropanol, ice-cold

TE buffer (*APPENDIX 2*)

10 mg/ml DNase-free RNase (optional; *UNIT 3.13*)

1.5-ml disposable microcentrifuge tubes

Boiling water bath (100°C)

1. Inoculate 5 ml sterile LB medium with a single bacterial colony. Grow at 37°C at least until mid-log phase ~6 hr, (a freshly saturated overnight culture works even better; see *UNIT 1.2*).
2. Transfer 1.5 ml of the saturated culture to a 1.5-ml microcentrifuge tube and pellet the cells by spinning 20 sec in microcentrifuge at maximum speed. Discard supernatant with a Pasteur pipet.

The spins in steps 2, 6, and 7 can be performed at 4°C or room temperature. Longer spins make it difficult to resuspend cells.

3. Resuspend the bacteria in 300 µl of STET solution containing 200 µg lysozyme. Vortex to achieve complete suspension.

Be sure cells are completely resuspended in order to maximize the number of cells exposed to the lysozyme and consequently the yield of plasmid DNA.

4. Place tube on ice for 30 sec to 10 min.

The time required for this step can vary between the limits indicated without affecting the yield or quality of the plasmid DNA.

5. Place tube in a boiling water bath (100°C) 1 to 2 min.

Heat and detergents cause the weakened cell walls to break, releasing plasmid DNA and RNA, but not the larger bacterial chromosome which remains attached to or trapped inside the lysed cells.

6. Spin in microcentrifuge 15 to 30 min at maximum speed.

The pellet, which should be fairly gummy, contains bacterial debris as well as chromosomal DNA. The supernatant contains plasmid DNA and RNA.

7. Pipet off supernatant into a new tube, carefully, without dislodging pellet. Mix with 200 µl (an equal volume) of cold isopropanol. Place at -20°C for 15 to 30 min. Spin 5 min in microcentrifuge at maximum speed.

The cold isopropanol precipitates the plasmid DNA and cellular RNA. Considerably shorter incubation periods (e.g., 2 to 5 min) may be sufficient for precipitation.

8. Remove the supernatant by inverting the tube and flicking it several times. Dry the

pellet by placing under a vacuum until it looks flaky.

If a vacuum source is unavailable, the pellet can be air dried.

9. Resuspend the pellet in 50 μ l TE buffer and store as in the support protocol. Use 5 μ l of the resuspended DNA for a restriction digest.

Contaminating RNA may interfere with detection of DNA fragments on the agarose gel; it can be destroyed by adding 1 μ l of a 10 mg/ml RNase solution (DNase-free) to the digestion mixture.

LITHIUM MINIPREP

Plasmid DNA is obtained from *E. coli* grown on plates as colonies or in liquid cultures. Bacterial cells harboring plasmid DNA are sequentially treated with Triton X-100/LiCl and phenol/chloroform. These steps solubilize plasmid DNA while precipitating chromosomal DNA with cellular debris. The debris is removed by centrifugation. This isolation procedure yields preparations of plasmid DNA that are virtually devoid of chromosomal DNA.

The procedure described here (originally presented by He et al., 1990) for small-scale isolation of plasmid DNA can also be readily extended for large-scale preparations as described in the annotation to the final step. The merit of the approach is that it is extremely reliable and rapid—requiring no more than 20 min of simple and economical operations for a preparation. The final plasmid DNA preparations are of a purity and quality usable for most biological applications.

Materials

TELT solution

LB medium (*UNIT 1.1*) containing appropriate antibiotic (Table 1.4.1)

1:1 (w/v) phenol/chloroform (*UNIT 2.1*)

100% ethanol, prechilled to -20°C

TE buffer (*APPENDIX 2*)

10 mg/ml DNase-free RNase A (optional; *UNIT 3.13*)

1.5-ml disposable microcentrifuge tubes

NOTE: All steps are performed at room temperature.

1. To isolate plasmid DNA from transformant colonies grown on agar plates, prepare the cells as follows:
 - a. Using a microspatula, scoop out an entire bacterial colony grown to 2- to 5-mm diameter on an LB agar plate. Transfer the colony to a 1.5-ml microcentrifuge tube containing 100 μ l TELT solution.
 - b. Vortex thoroughly to suspend the cells. Proceed to step 3.
2. To isolate plasmid DNA from liquid cultures, prepare the cells as follows:
 - a. Inoculate a colony of bacteria into 1.8 ml of sterile LB medium supplemented with appropriate antibiotic. Grow to saturation with shaking for 18 to 24 hr at 30°C (see *UNIT 1.2*).

Glass test tubes with plastic caps are suitable. Place the tubes at a suitably inclined angle to achieve good agitation.

- b. Carefully transfer the entire culture volume into a 1.5-ml microcentrifuge tube.

At this stage the volume of the liquid culture will have been reduced to ~ 1.5 ml.

BASIC PROTOCOL

**Escherichia coli,
Plasmids, and
Bacteriophages**

1.6.5

- c. Pellet the cells by spinning in a microcentrifuge ($10,000 \times g$) for 20 sec.
The spins in steps 2, 4, 7, and 9 can be performed at 4°C or room temperature. Centrifugation for longer periods or at higher speeds makes it difficult to resuspend the cells in the following step.
- d. With the tube held in a vertical position, aspirate the supernatant using a long-tipped Pasteur pipet connected to a vacuum line.
- e. Add 100 μl of TELT solution to the pellet and resuspend by vortexing.
Ensure that the cells are thoroughly suspended. See annotation to step 11 for scaled-up DNA preparations.
3. Add 100 μl of 1:1 phenol/chloroform and thoroughly vortex for 5 sec.
This mixture may be left at room temperature for ≤ 15 min. Plasmid yield will elevate with increasing duration of incubation; however, incubation periods > 15 min may result in phenol-mediated modification of DNA.
4. Microcentrifuge 1 min at $15,000 \times g$ (maximum speed).
5. Using a pipettor or similar device, carefully withdraw 75 μl of the upper aqueous phase and transfer the contents into a clean microcentrifuge tube.
Do not agitate the resolved phases. If mixing occurs, recentrifuge. When collecting the top layer avoid picking the debris at the interface.
6. To the supernatant, add 150 μl of chilled 100% ethanol. Mix the contents well to precipitate the plasmid DNA.
7. Pellet the nucleic acids by microcentrifuging 5 min at maximum speed.
8. Discard the supernatant by inverting the tube. When all the supernatant has drained, hold the tube in the same position for a few seconds and wipe off the last droplet from the rim of the tube by touching the edge of a Kleenex paper tissue.
9. Wash the pellet with 1 ml of cold 100% ethanol and harvest the nucleic acid pellet as in steps 6 and 7.
After centrifugation, decant the supernatant carefully as the pellet may be loose.
10. Cap the tube. Stab a small hole in the cap with a thumbtack or a syringe needle. Place the tube in a vacuum desiccator (without desiccant). Apply vacuum until the nucleic acid pellet appears completely dry.
A water-pumped vacuum line suffices for the purpose and usually takes ≤ 15 min.
11. Dissolve the pellet in 30 μl TE buffer. Vortex the contents well, capturing most of the DNA around the inner surface of the microcentrifuge tube. Store as in the support protocol and use 2 to 5 μl of DNA solution in a final 20- μl reaction volume for restriction digestion.

Contaminating RNA may interfere with detection of DNA fragments on the agarose gel; it can be destroyed by adding 1 μl of a 10 mg/ml RNase solution (DNase-free) to the digestion mixture.

For scaled-up plasmid DNA preparations (He et al., 1991), increase the amounts of TELT solution and 1:1 phenol/chloroform in direct proportion to the culture volume used. For cultures ≤ 5 ml, transfer the cells after suspension in TELT buffer into a microcentrifuge tube. Wash the final nucleic acids pellet twice with 1 ml of 100% ethanol. For cultures between 5 and 100 ml, use Corex glass tubes for treatment with TELT and phenol/chloroform and for centrifugations (Sorvall RC-5C centrifuge at $6000 \times g$).

STORAGE OF PLASMID DNA

Plasmids can be maintained for a short period (up to 1 month) in bacterial strains simply by growing on selective plates and storing at 4°C. For permanent storage, bacteria harboring the plasmid should be grown to saturation in the presence of the appropriate selective agent. An equal volume (~1 to 2 ml) of bacteria should be added to sterile 100% glycerol or a DMSO-based solution (recipe in *UNIT 1.3*) and frozen at -70°C in sterile vials. Cells taken from storage should again be grown on a selective plate (*UNIT 1.1*), and the plasmid DNA should be checked by restriction analysis (*UNIT 3.1*).

Plasmid DNA can be stored in TE buffer at 4°C for several weeks or preserved for several years by storing at -20° or -70°C. Most investigators prefer to store plasmids as frozen DNA, due to the widely held belief that plasmids stored in bacteria are sometimes lost, are rearranged, or accumulate insertion sequences and transposons during storage or on revival. Although such rearrangements certainly occur during storage of plasmids in bacteria in stab vials, we are unaware of any report of rearrangements affecting plasmids stored in frozen cells.

REAGENTS AND SOLUTIONS***Glucose/Tris/EDTA (GTE) solution***

50 mM glucose
25 mM Tris·Cl, pH 8.0
10 mM EDTA
Autoclave and store at 4°C

NaOH/SDS solution

0.2 N NaOH
1% (wt/vol) sodium dodecyl sulfate (SDS)
Prepare immediately before use

5 M potassium acetate solution, pH 4.8

29.5 ml glacial acetic acid
KOH pellets to pH 4.8 (several)
H₂O to 100 ml
Store at room temperature (do not autoclave)

STET solution

8% (wt/vol) sucrose
5% (wt/vol) Triton X-100
50 mM EDTA
50 mM Tris·Cl, pH 8.0
Filter sterilize and store at 4°C

TELT solution

2.5 M LiCl
50 mM Tris·Cl, pH 8.0
62.5 mM Na₂ EDTA
4% (wt/vol) Triton X-100
Store as 1- to 5-ml aliquots frozen at -20°C (do not filter sterilize or autoclave)

COMMENTARY

Background Information

Isolation of small quantities of plasmid DNA from bacterial cells is essential for the analysis of recombinant clones (UNITS 3.2 & 6.3). A myriad of plasmid DNA miniprep methods now exist and investigators are generally remarkably loyal to his or her own particular protocol. This unit presents three of the most widely used and reliable methods—alkaline lysis, the boiling method, and a lithium-based miniprep. The success of any of these procedures is largely a function of the expertise of the investigator; choice of method is therefore determined by personal preference as well as the size and type of the plasmid and the host strain of *E. coli*. With practice, all three protocols yield plasmid DNA of sufficient quantity and quality for use in most enzymatic manipulations (Chapters 3 & 7), and in most bacterial (UNIT 1.8) and yeast (UNIT 13.7) transformation procedures.

The procedures presented in this unit allow for the preferential recovery of circular plasmid DNA over linear chromosomal DNA. Treatments with either base or detergent (used in all three procedures) disrupt base pairing and cause the linear chromosomal DNA to denature and separate. In contrast, because of its supercoiled configuration, covalently closed circular plasmid DNA is unable to separate and readily reforms a correctly paired superhelical structure under renaturing conditions.

In the alkaline lysis miniprep, treatment with SDS and NaOH breaks open bacterial cells. Subsequent addition of potassium acetate preferentially reanneals covalently closed plasmid DNA, while chromosomal DNA and proteins are trapped in a complex formed between the potassium and SDS. The lysis treatment in the boiling miniprep causes chromosomal DNA to remain attached to the bacterial membrane, while plasmid DNA remains in the supernatant. In the lithium method, treatment of bacterial cells with Triton X-100/LiCl results in dissolution of the inner bacterial plasma membrane. However, this treatment has no effect on the overall morphology of the cells as observed microscopically, nor does it lead to release of plasmid DNA from the cells. Subsequent addition of phenol/chloroform leads to denaturation and precipitation of intracellular proteins. The concomitant rapid shrinkage of the cells preferentially expels soluble, super-

coiled plasmid DNA into the medium while retaining chromosomal DNA and denatured cellular protein with the bulk of the cell mass. Bacterial morphology, particularly of the cell wall envelope, is preserved under these conditions for at least 30 min, at which point cell lysis ensues. In all preparations, chromosomal DNA is removed with cellular debris by centrifugation, and soluble, supercoiled plasmid DNA is concentrated by ethanol precipitation.

In general, all three methods provide plasmid DNA of comparable yield and quality suitable for most biological applications. Yield of DNA is determined more by the type of plasmid than by method of isolation. Plasmids derived from pBR322 generally give lower (but, for most applications, sufficient) yields compared with the more recently derived pUC-like vectors, which contain a lesion in the plasmid-encoded *rop* gene, causing the plasmid to be maintained in high copy number in the cell (see UNIT 1.5).

All three methods are successful for the isolation of small (<10-kb) plasmids. Larger plasmids are generally poorly isolated using the lithium method, with yields <10% of those in the pUC-size range. These larger-sized plasmids may be retained along with chromosomal DNA in the mesh-like structure of the cell wall. In rare instances this problem may extend to plasmids that exist in low copy number and to those contained in strains with unusual cell wall compositions (see discussion of strain considerations below). The alkaline prep is better suited for efficient isolation of large-sized or low-copy-number plasmids (see critical parameters).

Strain background is also a consideration when selecting a miniprep procedure. When lysed with detergent or heat (as in the boiling or lithium procedures), strains such as HB101 and its derivatives may release a large amount of carbohydrate that contaminates plasmid DNA and inhibits many restriction endonucleases. In addition, HB101-related strains express endonuclease A which, if not inactivated, may degrade plasmid DNA in the presence of magnesium (during restriction enzyme digestion). Plasmids harbored in these strains may be better isolated using the alkaline lysis method.

In general, the alkaline lysis miniprep can be used for a variety of plasmid types and

sizes carried in most host strains. The boiling method is perhaps the most forgiving of the three, and the lithium miniprep, although restricted for use with small plasmids in certain hosts, is the most rapid method.

Critical Parameters and Troubleshooting

The successful isolation of small quantities of DNA from bacterial cells, regardless of the protocol, is largely dependent on the strain of *E. coli* used. For example, DNA isolated from strains C600, DH1 and LE392 is of good quality, while DNA isolated from strains HB101 and the JM100 series is of lesser quality (see Table 1.4.5). The latter strains have high nuclease activity (endonuclease A, which is not completely inactivated by boiling), necessitating further purification with a phenol extraction (UNIT 2.1) or an additional precipitation with ammonium acetate (UNIT 2.1). If one protocol fails to yield DNA with a particular strain of *E. coli*, it would be best to try an alternative method. The alkaline lysis miniprep seems to be the most consistent regardless of strain used, while the lithium method incorporates a phenol extraction and may be well suited for isolation of plasmid from strains with high nuclease activity.

Failure to isolate DNA using any of the protocols could be due to DNase contamination of the RNase. This problem can be circumvented by leaving out or using considerably less RNase. Other procedure-specific guidelines are described below.

Alkaline lysis miniprep. The DNA yield can generally be increased by adding 500 mg/ml of lysozyme to the 100- μ l suspension of cells in the glucose/Tris/EDTA (GTE) solution (step 3).

With a few variations, this protocol can also be used to isolate low-copy-number plasmids (UNIT 1.5), as follows: Increase the number of starting cells to 3 ml and include lysozyme in the GTE solution as described above. Because yields are lower with strains harboring low-copy-number plasmids, it will be necessary to use at least 5 μ l of DNA for a restriction digest.

If the isolated DNA fails to cut with restriction endonucleases, the most common cause is inadequate washing of the pellets after the ethanol precipitation step. Precipitating the DNA a second time with ethanol, or washing the pellets from the first precipitation with 70% ethanol, will usually clean up the DNA enough for restriction enzyme cutting.

Boiling miniprep. Failure to isolate DNA is

sometimes caused by incomplete cell lysis. If this appears to be the case, try using a new bottle of lysozyme powder. Apparent failure to recover DNA is also sometimes caused by DNase contamination of the freshly prepared plasmid DNA, or of the RNase. If miniprep DNA is contaminated with DNase, it can usually be cleaned up by an additional precipitation with ammonium acetate (UNIT 2.1) or by phenol extraction (UNIT 2.1). This method should not be used with endonuclease A-containing strains (such as HB101).

Lithium miniprep. This procedure eliminates many of the lengthy fractionation steps commonly employed in other minipreps of plasmid DNA and is quite effective for isolating plasmids ≤ 10 kbp. The high quality of the plasmid DNA obtained by this method has been verified by the fact that no problems are encountered with regard to inhibition of some sensitive restriction enzyme activities—for instance *NdeI*, which is sensitive to trace quantities of impurities (see Fig. 1.6.1). Any DNA cleavage inhibition is likely to be due to contamination of the DNA with cellular debris from the phenol/chloroform interface. However, this can be readily overcome by reducing the volume of DNA in the reaction mixture. The plasmid DNA is suitable for direct transformation of bacteria. If speed is required, DNA recovered from the aqueous phase following phenol/chloroform extraction (after step 4) can be used for transformation. However, such DNA should be used immediately to minimize the likelihood of phenol-mediated modification of DNA.

This technique has been used to purify shuttle vectors from yeast for high-frequency back-transformation in *E. coli* (Ward, 1990).

Anticipated Results

Two to five micrograms of DNA are obtained from 1.5 ml of a culture of cells containing a pBR322-derived plasmid by using either the alkaline lysis miniprep, the boiling protocol, or the lithium method. Three- to five-fold higher yields can be expected from pUC-derived plasmids. DNA yield from alkaline lysis in 96-well microtiter dishes (0.3 ml of culture/well) is ~ 2 μ g for high-copy-number plasmids (e.g., pUC plasmids). All three methods provide plasmid DNA of comparable quality, suitable for use in many applications.

Time Considerations

Using the alkaline lysis procedure, it is possible, with practice, to produce twelve samples

Figure 1.6.1 Restriction mapping of three preparations of plasmid DNA (pVS-WH) from transformant of *E. coli* TB strain. The three clones are numbered 1, 2, and 3 and were treated as follows: **U**, uncleaved DNA; **H-N**, plasmid DNA doubly cut with *Hind*III and *Nde*I; **H-S**, plasmid DNA doubly cut with *Hind*III and *Sph*I; λ , *Hind*III-digested λ DNA. A volume of 2.5 μ l of plasmid DNA (about 1 μ g) was used for digestion. The samples were separated on a 0.7% agarose gel containing 80 mM Tris-phosphate (pH 8.0) and 1 mM EDTA using Pharmacia Submarine electrophoresis tank with a current of 70 mA for 1 hr. All of the three clones are positive.

of DNA from saturated bacterial cultures in <1 hr. Although it is possible to do a large number of samples in a single day, we recommend using the alkaline lysis in 96-well microtiter dishes for such mass screenings. With the latter protocol, it is easy to process two plates in 4 hr. However, an incubation period of 48 hr is often required for cells to grow to saturation in the wells of the dish.

Starting with saturated cultures, the boiling method allows for the isolation of twelve DNA samples in 1 hr.

The lithium method is extremely quick—DNA samples can be processed in 20 min. With proper organization and availability of the materials, twelve plasmid preparations can be accomplished in substantially less than 1 hr. The entire operation involving plasmid preparation, restriction digestion, and agarose gel electrophoresis can be easily completed within half a day.

Large-Scale Preparation of Plasmid DNA

UNIT 1.7

Although the need for large quantities of plasmid DNA has diminished as techniques for manipulating small quantities of DNA have improved, occasionally large amounts of high-quality plasmid DNA are desired. This unit describes the preparation of milligram quantities of highly purified plasmid DNA. The first part of the unit describes three methods for preparing crude lysates enriched in plasmid DNA from bacterial cells grown in liquid culture. The second part describes three methods for purifying plasmid DNA in such lysates away from contaminating RNA and protein.

Methods for crude lysate preparation—alkaline lysis (see Basic Protocol 1), boiling (see Alternate Protocol 1), and Triton lysis (see Alternate Protocol 2)—separate chromosomal and plasmid DNA by exploiting the structural differences between these molecules. Plasmids are covalently closed and smaller than chromosomal DNA. When the cell lysate is centrifuged to pellet chromosomal DNA and cellular debris, these differences permit plasmid DNA to remain in the supernatant (see Key References for the theory behind each protocol). All three protocols yield a solution greatly enriched for plasmid DNA but that still contains significant amounts of RNA and protein. These contaminants must be removed if certain procedures, including 5' end labeling with T4 polynucleotide kinase and transfection of higher eukaryotic cells, are to be performed with the DNA. Accordingly, three procedures are described for purifying plasmid DNA from crude lysates. CsCl/ethidium bromide density gradient centrifugation (see Basic Protocol 2) permits separation by the different capacities of covalently closed plasmid DNA and chromosomal DNA to bind the intercalating agent ethidium bromide. Because binding of ethidium bromide lowers the density of DNA and plasmid DNA can bind less ethidium bromide than chromosomal DNA, plasmid DNA forms bands in a region of greater density (lower in the tube) than chromosomal DNA (see Fig. 1.7.1). Polyethylene glycol (PEG) precipitation (see Alternate Protocol 3) takes advantage of the inverse relationship between macromolecular size and concentration of PEG required for precipitation. There are two chromatographic methods for purifying plasmid DNA (see Alternate Protocol 4): anion-exchange chromatography, which exploits the strong negative charge of nucleic acids, and size-exclusion chromatography, which takes advantage of the large size of plasmid DNA molecules relative to other molecules present in the crude lysate.

PREPARATION OF CRUDE LYSATE BY ALKALINE LYSIS

Alkaline lysis is probably the most generally useful plasmid preparation procedure. It is fairly rapid, very reliable, and yields reasonably clean crude DNA that can be further purified by any of the purification methods described in this unit. Plasmid-bearing *E. coli* cells are lysed with lysozyme. The lysate is treated with NaOH/SDS solution and potassium acetate and centrifuged to separate plasmid DNA from proteins and chromosomal DNA. The supernatant is treated with isopropanol to precipitate plasmid DNA.

Materials

- LB medium or enriched medium (e.g., superbroth or terrific broth; UNIT 1.1)
containing ampicillin or other appropriate selective agent (Table 1.4.1)
- Plasmid-bearing *E. coli* strain
- Glucose/Tris/EDTA solution (UNIT 1.6)
- 25 mg/ml hen egg white lysozyme in glucose/Tris/EDTA solution (prepare fresh)
- 0.2 M NaOH/1% (w/v) SDS [prepare fresh from 10 M NaOH and 10% (w/v)
SDS stocks]
- 3 M potassium acetate solution, pH ~5.5 (see recipe)

**BASIC
PROTOCOL 1**

***Escherichia coli*,
Plasmids, and
Bacteriophages**

Isopropanol
70% ethanol

Sorvall GSA, GS-3, or Beckman JA-10 rotor (or equivalent)
High-speed centrifuge tubes with ≥ 20 -ml capacity (e.g., Oak Ridge centrifuge tubes)
Sorvall SS-34 or Beckman JA-17 rotor (or equivalent)

Grow and concentrate cells

1. Inoculate 5 ml LB medium or enriched medium containing selective agent (most commonly ampicillin) with a single colony of *E. coli* containing the desired plasmid. Grow at 37°C with vigorous shaking overnight.
2. Inoculate 500 ml LB medium or enriched medium containing selective agent in a 2-liter flask with ~1 ml of overnight culture. Grow at 37°C until culture is saturated ($OD_{600} \cong 4$).

To increase yields, maximize aeration using a flask with high surface area (whose volume exceeds the culture volume—i.e., is >2 liters), add baffles, and shake at >400 rpm. Alternatively, treat cultures of cells growing logarithmically with chloramphenicol to amplify the plasmids (see UNIT 1.5). Growing the bacteria in medium that supports higher cell densities also increases the yield. These media include M9, terrific broth, and LB medium containing 0.1% (w/v) glucose (UNIT 1.1). These media can increase plasmid yields 2- to 10-fold; different plasmids respond to the media differently. Most plasmids commonly used today, particularly derivatives of the pUC series (Fig. 1.5.2), grow at a copy number high enough to routinely yield 1 to 5 mg plasmid DNA from a 500-ml culture grown in LB medium.

An important consideration when using enriched medium is the method to be used for final purification of plasmid DNA. Increased yield poses no problems when using CsCl/ethidium bromide or PEG purification. In addition, commercially available chromatography columns have been designed for large-scale plasmid purification. For example, the larger Qiagen-tip columns can purify 500 μ g to 10 mg of plasmid DNA.

3. Collect cells by centrifuging 10 min at $6000 \times g$ (~6000 rpm in Sorvall GSA/GS-3 or Beckman JA-10 rotors), 4°C.

If necessary the pellets can be stored frozen indefinitely at -20° or -70° C.

4. Resuspend pellet from 500-ml culture in 4 ml glucose/Tris/EDTA solution and transfer to high-speed centrifuge tube with ≥ 20 -ml capacity.

Lyse the cells

5. Add 1 ml of 25 mg/ml hen egg white lysozyme in glucose/Tris/EDTA solution. Resuspend the pellet completely in this solution and allow it to stand 10 min at room temperature.

Neither glucose nor lysozyme is absolutely necessary for the success of the procedure. Glucose serves as a buffer in step 6 when the pH of the solution is greatly increased by addition of NaOH. Glucose provides buffering in the range of pH 12 and, by preventing the pH from rising too drastically in step 6, increases the efficiency of precipitation in step 7 (when the pH is lowered by addition of potassium acetate).

Lysozyme assists in the destruction of bacterial cell walls and subsequent release of plasmid DNA. Bacterial debris and soluble proteins are precipitated in step 7. One problem that can reduce recovery of plasmid DNA is inefficient separation of plasmid DNA from cellular debris. Lysozyme helps increase yield by reducing the amount of plasmid DNA trapped in partially degraded cell material and subsequently lost by precipitation at step 7. Omitting lysozyme reduces plasmid recovery by 5% to 10%.

The effort and expense required to include glucose and lysozyme in step 5 is negligible. The efficiency gained in streamlining the procedure by omitting them is also negligible. However, the potential for loss of plasmid DNA when these components are not included is measurable and worth avoiding. It should be noted that some commercially available chromatographic systems (e.g., Qiagen) do not use lysozyme for lysate preparation. The Qiagen modified alkaline lysis procedure relies on inefficient bacterial lysis (facilitated by sodium hydroxide lysis and acidic potassium acetate neutralization) to reduce contamination of plasmid DNA with chromosomal DNA. Although omitting lysozyme reduces the recovery of plasmid DNA, the Qiagen protocol yields high-quality DNA. When using Qiagen-tips for large-scale plasmid preparation, the manufacturer's recommendations should be followed.

When chromatographic methods are used for final purification of plasmid DNA, it is essential to degrade RNA that contaminates the lysate and will copurify with plasmid DNA. Treating the lysate with RNase A is the most efficient and economical method for degrading RNA. This can be accomplished at any step in the preparation of crude lysate, but it is most convenient to do it at step 5, by adding RNase A to the glucose/Tris/EDTA solution to a final concentration of 50 µg/ml.

6. Add 10 ml freshly prepared 0.2 M NaOH/1% SDS and mix by stirring gently with a pipet until solution becomes homogeneous and clears. Let stand 10 min on ice.

The solution should become very viscous.

7. Add 7.5 ml of 3 M potassium acetate solution and again stir gently with a pipet until viscosity is reduced and a large precipitate forms. Let stand 10 min on ice.
8. Centrifuge 10 min at $20,000 \times g$ (13,000 rpm in Sorvall SS-34; 12,500 rpm in Beckman JA-17), 4°C.

A large, fairly compact pellet will form; this contains most of the chromosomal DNA, SDS-protein complexes, and other cellular debris. Plasmid DNA remains in the translucent supernatant.

Addition of ~0.5 ml chloroform before the centrifugation can help reduce floating material.

Precipitate plasmid DNA

9. Decant the supernatant into a clean centrifuge tube. Pour it through several layers of cheesecloth if any floating material is visible. Add 0.6 vol isopropanol, mix by inversion, and let stand 5 to 10 min at room temperature.

If the supernatant is cloudy or contains floating material, repeat centrifugation (step 8) before adding isopropanol.

10. Recover nucleic acids by centrifuging 10 min at $15,000 \times g$ (11,500 rpm in SS-34 rotor; 10,500 rpm in JA-17 rotor), room temperature.
11. Wash the pellet with 2 ml of 70% ethanol; centrifuge briefly at $15,000 \times g$, room temperature, to collect pellet. Aspirate ethanol and dry pellet under vacuum.

The pellet can be stored indefinitely at 4°C.

PREPARATION OF CRUDE LYSATE BY THE BOILING METHOD

The boiling method is extremely simple and fast but typically yields crude DNA containing more contaminating bacterial DNA and proteins than other methods. In this protocol a bacterial cell lysate is boiled to denature chromosomal DNA and protein. These denatured macromolecules are precipitated by centrifugation, whereas plasmid DNA remains in the supernatant. The plasmid DNA is then precipitated with isopropanol.

Additional Materials (also see *Basic Protocol 1*)

STET solution (*UNIT 1.6*)

10 mg/ml hen egg white lysozyme in 25 mM Tris·Cl, pH 8.0 (prepare fresh)

Boiling and ice-water baths

Sorvall HB-4 rotor (or equivalent) and appropriate centrifuge tube

1. Grow and concentrate cells (see *Basic Protocol 1*, steps 1 to 3).
2. Resuspend pellet from a 500-ml culture in 20 ml STET solution and transfer to a glass tube or flask.
3. Add 2 ml hen egg white lysozyme and mix solution by inverting several times. Heat to near boiling over an open flame, then incubate 1 min in a boiling water bath.

Be certain that enough room remains between the top of the solution and the top of the tube to permit safe handling and to prevent boiling over. Submerge the tube deep enough into the boiling water to allow the entire solution to heat rapidly.

4. Place tube into an ice-water bath to cool.
5. Pour solution into centrifuge tube and centrifuge 20 min at $\geq 25,000 \times g$, preferably in a swinging-bucket rotor (e.g., 12,000 rpm in HB-4), room temperature.

After boiling, the solution will be extremely viscous due to denatured chromosomal DNA. It will tend to behave as a goeey, semisolid mass. Therefore, be careful not to allow the solution to overflow when pouring it into centrifuge tubes.

Centrifugation in a swinging-bucket rotor permits concentration of chromosomal DNA and denatured proteins at the bottom of the tube in a more compact pellet than is possible in a fixed-angle rotor. However, fixed-angle rotors can be used—e.g., Sorvall SS-34 at $47,000 \times g$ (20,000 rpm), Beckman JA-17 at $40,000 \times g$ (17,000 rpm), Beckman 70Ti at $200,000 \times g$ (44,000 rpm), or SW-41 at $100,000 \times g$ (25,000 rpm).

6. Decant supernatant to a clean centrifuge tube.

*The supernatant can be used without further treatment for purifying plasmid DNA by CsCl/ethidium bromide equilibrium gradient centrifugation (see *Basic Protocol 2*). If the volume is greater than necessary and inconvenient to handle, plasmid DNA can be precipitated with isopropanol. Precipitation is required for purification by PEG precipitation (see *Alternate Protocol 3*) or column chromatography (see *Alternate Protocol 4*).*

7. Add 0.6 vol isopropanol, mix by inversion, and let stand 5 to 10 min at room temperature.
8. Pellet nucleic acids by centrifuging 10 min at $15,000 \times g$ (11,500 rpm in SS-34 rotor; 10,500 rpm in JA-17 rotor), room temperature.
9. Wash the pellet with 2 ml of 70% ethanol. Centrifuge briefly to collect pellet. Aspirate ethanol and dry pellet under vacuum.

The pellet can be stored indefinitely at 4°C.

PREPARATION OF CRUDE LYSATE BY TRITON LYSIS

ALTERNATE PROTOCOL 2

The method described below is a modification of that described by Clewell and Helinski (1970, 1972) in which Brij-58 and sodium deoxycholate were used. In this protocol plasmid DNA is extracted from a bacterial cell lysate that has been treated with Triton X-100 (TX-100). This is a very gentle procedure and is therefore useful for isolating very large plasmids such as cosmids. Plasmid DNA can be further purified by any of the methods described in the second part of this unit.

Additional Materials (also see Basic Protocol 1)

Sucrose/Tris/EDTA solution (see recipe)

10 mg/ml hen egg white lysozyme in 25 mM Tris·Cl, pH 8.0 (prepare fresh)

0.5 M EDTA (APPENDIX 2)

10 mg/ml DNase-free RNase (UNIT 3.13)

Triton lysis solution (see recipe)

1:1 (v/v) buffered phenol/chloroform (UNIT 2.1)

24:1 (v/v) chloroform/isoamyl alcohol (UNIT 2.1)

Additional reagents and equipment for phenol/chloroform extraction (UNIT 2.1)

1. Grow and concentrate cells (see Basic Protocol 1, steps 1 to 3).
2. Resuspend pellet from a 500-ml culture in 5 ml sucrose/Tris/EDTA solution. Transfer to appropriate centrifuge tube (tube should be less than $\sim\frac{1}{3}$ full).
3. Add to tube:
 - 1.5 ml 10 mg/ml hen egg white lysozyme in 25 mM Tris·Cl
 - 2 ml 0.5 M EDTA
 - 25 μ l 10 mg/ml DNase-free RNase.

Let stand 15 min on ice.

4. Overlay with 2.5 ml Triton lysis solution. Mix gently but thoroughly by inversion and let stand 20 min at 4°C.

This solution should not be vortexed or shaken hard because that will shear chromosomal DNA and prevent it from precipitating in the next step. The solution will become extremely viscous as the cells lyse. Streaks of opaque material will be visible and may remain throughout the incubation.

5. Centrifuge 70 min at 40,000 \times g (18,000 rpm in Sorvall SS-34; 17,000 rpm in Beckman JA-17), 4°C.
6. Decant supernatant carefully to a clean centrifuge tube.

Avoid contaminating plasmid DNA with the gelatinous pellet. The pellet contains chromosomal DNA and cellular debris. The pellet may detach from the bottom of the tube, so it is helpful to hold a Pasteur pipet against the mouth of the tube while pouring to prevent the pellet from sliding into the clean tube. The integrity of the pellet varies greatly between preparations; occasionally it is necessary to leave behind some of the viscous supernatant to avoid contaminating it with pellet material.

This supernatant can be used without further treatment for purifying plasmid DNA by CsCl/ethidium bromide equilibrium gradient centrifugation (see Basic Protocol 2). If the volume is greater than necessary and inconvenient to handle, plasmid DNA can be extracted and precipitated with isopropanol. Extraction and precipitation are required for purification by PEG precipitation (see Alternate Protocol 3) or column chromatography (see Alternate Protocol 4).

***Escherichia coli,
Plasmids, and
Bacteriophages***

1.7.5

7. Extract the supernatant with 1:1 buffered phenol/chloroform, then with 24:1 chloroform/isoamyl alcohol. Add 0.6 vol isopropanol to the final aqueous phase and let stand 5 to 10 min at room temperature.

Phenol extraction and isopropanol precipitation are done as described in UNIT 2.1.

8. Pellet nucleic acids by centrifuging 10 min at $15,000 \times g$ (11,500 rpm in SS-34 rotor; 10,500 rpm in JA-17 rotor), room temperature.
9. Wash the pellet with 2 ml of 70% ethanol and centrifuge briefly to collect pellet. Aspirate ethanol and dry pellet under vacuum.

The pellet can be stored indefinitely at 4°C.

BASIC PROTOCOL 2

PURIFICATION OF PLASMID DNA BY CsCl/ETHIDIUM BROMIDE EQUILIBRIUM CENTRIFUGATION

This purification procedure yields high-quality plasmid DNA free of most contaminants, but it requires the use of ethidium bromide (a mutagen) and often requires long ultracentrifuge runs to establish the density gradient. A crude bacterial cell lysate is mixed with cesium chloride (CsCl) and ethidium bromide and centrifuged to equilibrium. Ethidium bromide is removed by passing plasmid DNA over a cation exchange column, and CsCl is removed by ethanol precipitation.

Materials

Pellet from crude lysate of plasmid-bearing bacterial cell culture (see Basic Protocol 1 or Alternate Protocol 1 or 2)

TE buffer, pH 7.5 (APPENDIX 2)

Cesium chloride

10 mg/ml ethidium bromide (APPENDIX 2)

CsCl/TE solution (see recipe)

Dowex AG50W-X8 cation-exchange resin (see recipe)

TE buffer (pH 7.5)/0.2 M NaCl

100% and 70% ethanol

Beckman VTi65 or VTi80 rotor (or equivalent)

5-ml quick-seal ultracentrifuge tubes

3-ml syringes with 20-G needles

Additional reagents and equipment for ethanol precipitation (UNIT 2.1)

CAUTION: Ethidium bromide is a mutagen and environmental hazard. It should be handled carefully with gloves and disposed of properly. Methods for disposal vary between different institutions. Consult the institution's environmental safety office for the preferred means of storage and disposal of ethidium bromide-containing waste.

1. Resuspend pellet from a crude lysate preparation in 4 ml TE buffer. Add 4.4 g CsCl, dissolve, and add 0.4 ml of 10 mg/ml ethidium bromide. If using supernatants resulting from boiling or Triton lysis preparations, add 1.1 g CsCl/ml supernatant and 0.1 ml of 10 mg/ml ethidium bromide/ml supernatant.

Ethidium bromide will form a complex with protein remaining in the solution to form a deep red flocculent precipitate. This can be removed by centrifuging the lysate-CsCl/ethidium bromide solution 5 min at $\sim 2000 \times g$, room temperature. After this procedure, the protein-ethidium bromide complex will form a disc at the top of the solution. The solution can be pipetted out from beneath the disc or poured carefully, allowing the floating disc to adhere to the side of the tube.

2. Transfer the solution to a 5-ml ultracentrifuge tube. Top up the tube, if necessary, with CsCl/TE solution and seal tube. Band plasmid by centrifuging 3.5 hr at $500,000 \times g$ (77,000 rpm in VTi80 rotor) or ≥ 14 hr at $350,000 \times g$ (65,000 rpm in VTi80 rotor; 58,000 rpm in VTi65 rotor), 20°C .

This centrifugation must be done at a temperature no lower than 15°C . Because of the high concentration of CsCl and the high centrifugal force necessary to establish the gradient, lower temperatures will cause the CsCl at the bottom of the tube (where the density is highest) to precipitate during the run. CsCl precipitate moves the center of mass towards the bottom of the tube. This can unbalance the rotor and cause breakage of the rotor and destruction of the centrifuge at least, and serious personal injury at worst. Also, equilibrium is achieved more quickly by warmer gradients.

Other rotors can be used, including fixed-angle and swinging-bucket rotors (e.g., centrifuge ≥ 24 hr at 56,000 rpm in Ti70 rotor). These rotors require longer centrifugation times than vertical rotors, but allow larger volumes or more samples to be included in the run.

3. Carefully remove the tube from the centrifuge. Insert a 20-G needle gently into the top of the tube. Recover the plasmid band (the lower of the two bands) by inserting a 3-ml syringe with a 20-G needle attached into the side of the tube ~ 1 cm below the plasmid band as shown in Figure 1.7.1. Insert the needle with the beveled side up.

Do not allow the gradient to be mixed by rough handling or turbulence. Be certain not to cover the top of the first needle with gloved finger. The needle serves to provide an inlet for air to displace the volume of solution being withdrawn.

If chromosomal DNA has been thoroughly removed in previous steps, only the plasmid band may be visible. Large amounts of plasmid DNA will be visible in the gradient in ordinary light. Smaller amounts can be visualized more easily by side illumination with low-intensity shortwave UV light. Prolonged exposure of the DNA–ethidium bromide complex to UV light will cause damage to the DNA and should be avoided. RNA may be detected as a diffuse region of fluorescence at the bottom of the tube.

CAUTION: *To avoid potentially serious eye injury by UV light, wear UV-blocking glasses or face shield. Wear gloves when handling ethidium bromide.*

Figure 1.7.1 Collecting plasmid DNA from a CsCl gradient.

Protein–ethidium bromide complexes will pellet on the outside edge of the tube if not removed earlier. To prevent contamination of plasmid DNA, avoid this area when inserting the collection needle.

There should be no resistance in the syringe when drawing off the plasmid DNA. If there is resistance, check that needles are clear. Occasionally the needle will become clogged if a piece of tube enters it. Do not try to draw harder on the syringe, as this may create turbulence in the tube when the obstruction is sucked in and cause mixing of the gradient. Instead, insert another needle and use it to draw off the band. Leave the clogged needle in place in the tube. (If the clogged needle is removed, the tube will empty through the hole that remains.) The air inlet needle can also become clogged; if it does, remove it and allow air to enter through the remaining hole. If plasmid DNA is drawn through a very small opening in a clogged needle, it may be sheared.

4. If higher-purity plasmid DNA is required, perform a second ultracentrifugation to eliminate any contaminating RNA or chromosomal DNA. Add plasmid DNA band to another ultracentrifuge tube, top up with CsCl/TE solution containing 1.0 mg/ml ethidium bromide, and repeat steps 2 and 3.
5. Pour a Dowex AG50W-X8 column, 1.5 to 2 times the volume of the plasmid DNA/ethidium bromide solution, in a glass or plastic column. Pass several volumes of TE buffer/0.2 M NaCl through the column to wash and equilibrate it.

The column can be set up in a Pasteur pipet plugged with a little glass wool or in a commercially purchased plastic column.

6. Load the plasmid DNA/ethidium bromide solution directly from syringe to top of resin bed without disturbing the resin.
7. Begin collecting the solution flowing through the column immediately after loading the plasmid solution. Wash the column with a volume of TE buffer/0.2 M NaCl equal to twice that of the volume of plasmid solution loaded.

The final volume collected from the column should be three times the volume of plasmid DNA solution removed from the gradient.

As the plasmid DNA flows through the column the ethidium bromide will be retained in the resin and form a red band at the top. All of the DNA will flow through in the volume recommended. This procedure will dilute the CsCl sufficiently to allow the DNA to be precipitated.

Ethidium bromide can also be removed by extracting the plasmid DNA–ethidium bromide solution with an equal volume of TE-saturated n-butanol (UNIT 2.1). Shake the tube or vortex it vigorously to maximize the efficiency of extraction. Remove the organic upper phase and extract the aqueous phase repeatedly until no red color remains. Dilute the solution 3-fold with TE buffer to dilute the CsCl. This procedure generates contaminated organic solvent waste. Follow correct procedure for its disposal.

8. Ethanol precipitate plasmid DNA, using 2 vol of 100% ethanol at room temperature or -20°C , and centrifuge 10 min at $10,000 \times g$, 4°C .

Do not cool this solution below -20°C , as this may cause the CsCl to precipitate.

An alternative to ethanol precipitation at this step is to dialyze the plasmid DNA, from which the ethidium bromide has been removed, against 500 to 1000 vol TE buffer. Dialysis buffer should be changed at least twice with ≥ 2 hr between changes at room temperature, or 4 hr at 4°C (see APPENDIX 3C).

9. Wash pellet with 70% ethanol and dry under vacuum. Resuspend pellet in TE buffer and store at 4°C .

PLASMID DNA PURIFICATION BY PEG PRECIPITATION

ALTERNATE
PROTOCOL 3

Polyethylene glycol (PEG) precipitation is a rapid, reliable, and convenient method for plasmid DNA purification. It can be stopped at any step without affecting the ultimate recovery of plasmid DNA. No ultracentrifugation is required and the use of ethidium bromide (a mutagen) is avoided. RNA and chromosomal DNA contaminants are removed from a crude lysate pellet by treating it with RNase, NaOH/SDS, and potassium acetate. Plasmid DNA is extracted from the supernatant and precipitated with PEG. This method is suitable for preparing plasmid DNA for procedures that require plasmid DNA free of any contaminants.

Additional Materials (also see Basic Protocol 2)

- Glucose/Tris/EDTA solution (UNIT 1.6)
- 0.2 M NaOH/1% (w/v) SDS [prepare fresh from 10 M NaOH and 10% (w/v) SDS stocks]
- 10 mg/ml DNase-free RNase (UNIT 3.13)
- 3 M potassium acetate solution, pH ~5.5 (see recipe)
- Buffered phenol (UNIT 2.1)
- 24:1 (v/v) chloroform/isoamyl alcohol (UNIT 2.1)
- 10 M ammonium acetate (APPENDIX 2)
- PEG solution (see recipe)
- 3 M sodium acetate, pH 5.5 (APPENDIX 2)
- Sorvall SS-34 or Beckman JA-17 rotor (or equivalent)
- Sorvall HB-4 rotor

Remove contaminants from crude lysate pellet

1. Resuspend the pellet obtained in the final step of crude lysate preparation in 1 ml glucose/Tris/EDTA solution.
2. Add RNase to a final concentration of 20 µg/ml and incubate 20 min at 37°C.
3. Add 2 ml freshly prepared 0.2 M NaOH/1% SDS, mix by inverting the tube, and let stand 5 to 10 min at room temperature.
4. Add 1.5 ml of 3 M potassium acetate solution, mix by inverting the tube, and let stand 5 to 10 min at room temperature.
5. Centrifuge 10 min at 20,000 × g (11,000 rpm in SS-34 rotor; 12,500 rpm in HB-4 or JA-17 rotor), room temperature.

If restriction fragments of the plasmid are to be prepared for use as probes in filter hybridizations, gel purification will rid the desired fragments of any contaminating traces of chromosomal DNA. In that case steps 1 to 5 can be omitted. Resuspend the pellet from the crude lysate in 4 ml TE buffer and add RNase to 20 µg/ml final. Incubate 20 min at 37°C and treat as described in steps 7 to 12 of this protocol.

6. Transfer the supernatant to a clean tube.

The white precipitate is primarily SDS-potassium complex. It includes any chromosomal DNA that remained in the crude lysate. The amount remaining after crude lysate preparation varies. It may not be necessary to remove the chromosomal DNA completely, depending on the procedures to which the plasmid DNA is to be subjected. However, some procedures, such as hybrid selection (UNIT 6.8), require that plasmid DNA be free of any contaminants.

7. Extract plasmid DNA with buffered phenol, then with 24:1 chloroform/isoamyl alcohol.

***Escherichia coli,
Plasmids, and
Bacteriophages***

1.7.9

8. Add $\frac{1}{4}$ vol of 10 M ammonium acetate (2 M final concentration) to the aqueous phase and mix. Add 2 vol of 100% ethanol and place tube in dry ice for 10 min.
9. Recover plasmid DNA by centrifuging 10 min at $10,000 \times g$ (8000 rpm in HB-4 or SS-34 rotor; 8500 rpm in JA-17 rotor), 4°C.
10. Wash the pellet with 70% ethanol and dry briefly under vacuum.

PEG precipitate plasmid DNA

11. Resuspend the pellet in 2 ml TE buffer and add 0.8 ml PEG solution. Incubate 1 to 15 hr at 0°C.

The percentage of plasmid DNA recovered with PEG precipitation increases with time of incubation at 0° to 4°C. Usually $\geq 50\%$ (~0.5 to 3 mg) can be recovered by centrifuging the PEG-precipitated DNA solution after 1 hr at 0°C. Incubating the supernatant ≥ 12 hr at 4°C will permit complete recovery of remaining plasmid DNA while plasmid DNA collected after the first centrifugation can be used for other procedures.

12. Recover plasmid DNA by centrifuging 20 min at $10,000 \times g$ (8000 rpm in HB-4 or SS-34 rotor; 8500 rpm in JA-17 rotor; 10,000 rpm in most microcentrifuges), 4°C.
13. Resuspend pelleted plasmid DNA in 1 ml TE buffer. Ethanol precipitate plasmid DNA using 3 M sodium acetate, pH 5.5.

ALTERNATE PROTOCOL 4

PLASMID DNA PURIFICATION BY ANION-EXCHANGE OR SIZE-EXCLUSION CHROMATOGRAPHY

Chromatographic methods for purifying plasmid DNA take advantage of distinctions between the physical properties of plasmid DNA and those of molecules that copurify with it in the crude lysate. Nucleic acids are negatively charged and can therefore be purified away from contaminants using anion-exchange chromatography (see *UNIT 2.1B* for a protocol and discussion of one anion-exchange method). Similarly, the large size of plasmid DNA allows it to be purified away from smaller contaminants by gel-filtration chromatography. The specific properties of most matrices provided by commercial suppliers are unknown, due to the reluctance of the suppliers to divulge proprietary information, but they typically exploit one or both of these methods.

This protocol describes modifications for preparing a crude lysate for chromatographic purification of plasmid DNA and discusses features of three commercially available columns. Because no single protocol is appropriate for all of the chromatography methods, it is important to adhere to the manufacturer's suggested methodology. Most columns are supplied as kits that include reagents for preparing crude lysate using alkaline lysis (see Basic Protocol 1; e.g., Qiagen Plasmid Kits). Most manufacturers will also provide the columns separately.

Preparation of Crude Lysate

It is important to match the bacterial culture volume and cell density to the quantity of DNA expected and the plasmid DNA binding capacity of the column to be used. For large-scale plasmid preparation, most commercial suppliers provide a range of column sizes, with plasmid DNA yields of up to 10 mg. If too much culture volume is used, alkaline lysis will be inefficient, the column will be overloaded, and the performance of the system reduced. Furthermore, the excessive viscosity of the lysate will require vigorous mixing, resulting in shearing of bacterial genomic DNA and subsequent contamination of the plasmid DNA.

Successful chromatographic purification of DNA using the Qiagen-tips requires that the bacterial cells be incompletely lysed, so lysozyme should be omitted from the preparation of crude lysate.

The most frequent contaminant of plasmid DNA prepared by chromatographic methods is high-molecular-weight RNA. This contamination is reduced by adding 50 µg/ml RNase A (from frozen 1 mg/ml stock, *UNIT 3.13*) to the resuspended cell pellet. The reagents provided with Qiagen-tips contain RNase A. However, RNase A is stable for no more than several months at 4°C, the storage temperature of the working solutions. The Qiagen protocol uses RNase at 100 µg/ml; following addition of the RNase to the bacterial pellet resuspension buffer (P1), it is stable for 6 months at 4°C. The reagents provided by 5 Prime→3 Prime include a mixture of RNase A and RNase T1. The manufacturer suggests adding the RNases to a resuspended crude lysate pellet (see Basic Protocol 1, step 11) because the pellet is resuspended in a smaller volume at this step and less RNase is required.

Column flow is greatly impeded or completely prevented by the presence of solid material in the lysate when it is loaded onto the column. The most common source of solids is floating material from the precipitation (see Basic Protocol 1, step 7). To be certain that no floating material is loaded onto the column, decant the supernatant through cheesecloth, add chloroform before centrifugation, or recentrifuge the supernatant. The Qiagen protocol allows the lysate to be loaded on the Qiagen-tip column directly following removal of the protein and cellular debris by precipitation and centrifugation (see Basic Protocol 1, steps 7 to 9). Alternatively, Qiagen supplies a Qiafilter which rapidly filters bacterial lysates without centrifugation. The Qiafilter is available in syringe form for filtration of lysates from ≤250 ml of culture, or in cartridge format for filtering lysates from ≤2.5 liters of culture. These filtration units efficiently remove protein, cell debris, and even small SDS precipitates. Following lysate clearing using either centrifugation or filtration through a Qiafilter, the plasmid DNA can be purified directly on a Qiagen-tip column. The pZ523 protocol requires the crude lysate plasmid DNA to be precipitated with isopropanol. This reduces the volume of material to be loaded on the column and allows the buffer in which plasmid DNA is loaded to be optimized for the column. Isopropanol precipitation can be used with either of the alternate protocols for preparation of crude lysate, and the final pellet can be resuspended in the buffer appropriate for the chromatographic matrix to be used.

Column Capacity

Overloading columns with large lysate volumes can affect separation characteristics, leading to reduced yield and purity. Suppliers offer a range of column sizes to allow maximum plasmid DNA binding and recovery from large bacterial lysate volumes. The maximum plasmid-binding capacities of Qiagen tips 2500 and 10000 are 2.5 mg and 10 mg, respectively. The pZ523 column has a capacity of 4 to 5 mg and does not require that DNA bind to the column, so overloading is less likely to be a problem. The standard protocols for most other commercial columns are adjusted to provide a “good” yield for a plasmid that is maintained at a moderate copy number when cells that bear it are grown in ~500 ml LB medium.

To optimize plasmid DNA recovery, culture volume, culture medium, plasmid copy number, size of the insert, and the host strain should be considered. Very-low-copy-number plasmids and cosmids often require large culture volumes to yield significant amounts of DNA. When preparing DNA from high-copy-number plasmids such as pUC and its derivatives, culture volumes one-fourth to one-half the standard volume may be appropriate. When using media that support growth to high cell density such as terrific broth (*UNIT 1.1*; Tartoff and Hobbs, 1987), culture volumes one-fourth to one-tenth the standard

may be appropriate. The protocol provided by Qiagen includes a table of recommended culture volumes for plasmid isolation from a variety of sources, including high- to very-low-copy-number plasmids.

Plasmid DNA exceeding the capacity of the column will in no way prevent recovery of DNA. The excess DNA will simply run through the column and be discarded. One way to increase the yield is to recover and save the material that flows through the column when it is initially loaded. Some columns can be regenerated following elution of the plasmid DNA and the initial flowthrough reloaded. Qiagen resin is stable for up to 6 hr after equilibration and Qiagen-tips may be reused within 6 hr for the same sample. Beyond this time the separation characteristics of the resin will begin to change. The manufacturer's recommendations should be followed. Columns such as pZ523, which require vacuum and centrifugation respectively, collapse during use and cannot be reused. In this case, excess DNA in the flowthrough can be purified on a second column of the same type.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

CsCl/TE solution

100 ml TE buffer, pH 7.5 (APPENDIX 2)

100 g CsCl

Store indefinitely at room temperature

Dowex AG50W-X8 cation exchange resin

Prepare large batches (200 to 400 ml packed resin) of Dowex AG50W-X8 resin (100- to 200-mesh; Bio-Rad) by performing the following series of washing steps. Use a large Buchner funnel and filter paper to collect the resin between changes of wash solution.

1. Wash resin in ≥ 10 vol of 0.5 N NaOH until no color is observed in wash solution (resin will retain its buff color).
2. Wash with 5 to 10 vol of 0.5 N HCl.
3. Wash with 5 to 10 vol of 0.5 M NaCl.
4. Wash with 5 to 10 vol of distilled H₂O.
5. Wash with 5 to 10 vol of 0.5 N NaOH.
6. Wash with distilled H₂O until pH = 9.
7. Store prepared resin indefinitely in 0.5 M NaCl/0.1 M Tris (pH 7.5) at 4°C.

Polyethylene glycol (PEG) solution

30% (w/v) PEG 8000

1.6 M NaCl

Store indefinitely at 4°C

Potassium acetate solution (3 M), pH ~5.5

294 g potassium acetate (3 M final)

50 ml 90% formic acid (1.18 M final)

H₂O to 1 liter

Store indefinitely at room temperature

Sucrose/Tris/EDTA solution

25% (w/v) sucrose

50 mM Tris-Cl, pH 8.0 (APPENDIX 2)

100 mM EDTA, pH 8.0 (APPENDIX 2)

Store indefinitely at 4°C

Triton lysis solution

3% (v/v) Triton X-100
200 mM EDTA, pH 8.0 (APPENDIX 2)
150 mM Tris·Cl, pH 8.0 (APPENDIX 2)
Store indefinitely at 4°C

COMMENTARY

Critical Parameters and Troubleshooting

Preparation of crude lysate by alkaline lysis. This is a reliable procedure and one in which few irretrievable disasters can occur. One potential problem is failure of chromosomal DNA and proteins to precipitate after addition of potassium acetate solution. The cause of this is probably improper pH of the potassium acetate solution. The NaOH/SDS solution denatures linear (chromosomal) DNA. When the solution is neutralized in the presence of a high salt concentration (as when potassium acetate solution is added), the linear DNA precipitates. This precipitation presumably is due to inter-strand reassociation of denatured, linear DNA molecules at multiple sites. It results in the formation of a large, insoluble DNA network. Protein–SDS complexes also precipitate under these conditions. If the pH of the potassium acetate solution is not ~5.5, these precipitates will not form. If precipitation fails to occur because the pH is incorrect, the preparation can be saved by adding concentrated formic or acetic acid dropwise to the solution. Mix after each addition until the viscosity decreases, which will happen suddenly. A precipitate will then appear.

Preparation of crude lysate by the boiling method. The drawback to this procedure is that if it fails there are few chances for recovery. The only easily assayed step is the final recovery of plasmid DNA. Failure is often caused by inactive lysozyme or incorrect boiling time. An indication of failure will be that the solution is not extremely viscous following step 4. The remedy for inactive lysozyme is to try a new preparation of lysozyme. The optimal boiling time may vary slightly between bacterial strains. Using a strain for which the correct time is already known is the simplest remedy to this problem. Alternatively, the correct time may be determined empirically by performing the boiling miniprep procedure in UNIT 1.6.

Preparation of crude lysate by Triton lysis. This method is much gentler than the others described in this unit because of the relatively mild conditions used to disrupt the cells (i.e.,

use of Triton X-100 and lysozyme rather than boiling or severe changes in ionic strength and pH). Because the conditions used are near the lower limits of their effectiveness, solutions must be prepared correctly and the lysozyme must be active. Although powdered lysozyme is stable for long periods when stored properly, it is occasionally necessary to purchase and use a new bottle. The solution should become extremely viscous when Triton lysis solution is added, indicating that lysis has occurred. Centrifugation is also critical for separating plasmid DNA from the bulk of contaminants. If the pellet is not reasonably firm at this stage it will pour out of the tube when the plasmid DNA-containing supernatant is decanted. If this happens, repeat the centrifugation. If it happens routinely, increase the reagent volumes proportionately throughout the procedure or centrifuge for longer times or at higher *g* forces, if necessary using an ultracentrifuge.

Plasmid DNA purification by CsCl/ethidium bromide centrifugation. It is important that the density of the DNA–CsCl/ethidium bromide solution be correct for this procedure to work. Therefore, be precise (using graduated plastic tubes) when measuring the solution volume as this determines the amount of CsCl to be added. If the amount of added CsCl is incorrect, the position of the bands will be high (if too much was added) or low (if too little was added). Ideally the bands should appear slightly above the center of the tube. It is also important to allow sufficient time for the establishment of the gradient during centrifugation. If the bands appear diffuse at the end of the run, resolution is not adequate and centrifugation should be continued. In a gradient that has achieved equilibrium, bands are well defined.

Occasionally an ultracentrifuge tube breaks and its contents leak into the rotor compartment. This can occur if the tube is defective or if it is not filled or sealed properly. If most of the solution remains in the rotor compartment it can be pipetted into a clean tube, topped up with CsCl/TE solution, and centrifuged again. The quality of the DNA should not be affected,

***Escherichia coli,
Plasmids, and
Bacteriophages***

1.7.13

although the yield will be lower due to loss of material. The rotor should be rinsed with warm water if it comes in contact with CsCl solution. Cesium chloride is very corrosive and can cause pitting and weakening of the rotor. The centrifuge chamber should be inspected after every run, and cleaned with warm water and dried thoroughly if red stains are evident.

If the CsCl precipitates, as evidenced by a large, white, crystalline pellet observed when precipitating plasmid DNA in the final steps, warm the solution to room temperature and centrifuge it at room temperature. If this problem persists, be certain the solution is diluted 3-fold with TE buffer before adding ethanol.

Plasmid DNA purification by PEG precipitation. The purity of plasmid DNA obtained by polyethylene glycol (PEG) precipitation of crude bacterial lysate depends on the amount of chromosomal DNA remaining in the solution when the PEG solution is added. Steps 1 to 5 of Alternate Protocol 3 remove any remaining traces of chromosomal DNA. These steps are not necessary for PEG precipitation to succeed. For size fractionation by PEG to be effective, the concentration of DNA in the crude lysate must be $>10 \mu\text{g/ml}$. This is not a concern when applied to plasmid DNA purification, where the concentrations should be orders of magnitude greater than that figure.

Plasmid DNA purification by anion-exchange or size-exclusion chromatography. The columns available in kit form from a number of manufacturers are quite reliable. Almost all necessary reagents are provided, including common buffers such as TE buffer. Because the composition of the matrix is undisclosed, it is impossible to evaluate the procedure carefully and attempt to optimize it. Therefore, users of kits are strongly encouraged to follow the manufacturer's recommended procedures. Additional discussion of one type of anion-exchange procedure (Qiagen) can be found in the Commentary of *UNIT 2.1B*.

A major drawback to some prepared columns is the limited capacity of the matrix. A 500-ml culture of plasmid-containing bacteria can often yield 2 to 8 mg of plasmid DNA in the crude lysate. Some columns routinely yield only 500 to 1000 μg purified plasmid DNA, which is adequate for most purposes. Recovering the column flowthrough and rechromatographing it is the most practical method of increasing recovery of plasmid DNA. Not all columns can be reused, however, and recovery may require use of additional columns. Alter-

natively, smaller culture volumes can be used as suggested. If optimal recovery of DNA is desired, CsCl/ethidium bromide centrifugation or PEG precipitation should be used.

DNA obtained from chromatographic purification of plasmid DNA is comparable in quality to that prepared by the other methods. It is of sufficient purity for virtually any procedure for which it can be used. For example, plasmid DNA prepared using Qiagen-tips is at least equivalent in purity to that obtained following two rounds of CsCl-gradient centrifugation. It is suitable for all applications from cloning to transfection, radioactive and fluorescent sequencing, and gene therapy research. Qiagen also offers an endotoxin-free plasmid DNA kit which yields plasmid DNA containing lower levels of endotoxins than DNA purified by two rounds of CsCl centrifugation, which is essential in gene therapy studies.

The two most frequent contaminants are chromosomal DNA and high-molecular-weight RNA. These contaminants may be detected by the presence of large, diffuse ethidium bromide-binding material in agarose gel electrophoresis of purified plasmid DNA. To prevent such contamination, follow the manufacturer's suggestions for the use of RNase.

Only common laboratory equipment is required for chromatographic purification of plasmid DNA. Another consideration with commercial kits is the large amount of packaging material and waste. In addition to the plastic columns and excess packaging, kits contain standard reagents supplied in plastic bottles. These reagents are solutions of buffers, salts, ethanol, and detergent—all of which can be, and usually are, prepared in the lab. Most suppliers will provide the column without the reagents. However, the major advantage of using prepared anion-exchange column kits includes the absence of organic extractions and exposure to toxic chemicals such as phenol, chloroform, ethidium bromide, and CsCl.

The toxicity of DNA prepared by several methods has been assessed by performing a biological assay. Crude lysate from a 1-liter culture of plasmid-containing bacteria was prepared by the alkaline lysis procedure and divided into four equal aliquots. The aliquots were then subjected to purification by CsCl/ethidium bromide centrifugation, PEG precipitation, or chromatography on Qiagen and pZ523 columns. Purified plasmid DNA was injected into *Drosophila* embryos, and the frequency of germline transformation and killing

of injected embryos was determined. No significant differences attributable to the method of purification were observed.

Anticipated Results

Most plasmids currently used are derivatives of the pUC series (Fig. 1.5.2). These plasmids contain an origin of replication significantly more efficient than that of the previous generation of pBR322-derived plasmids. This allows recovery of 1 to 5 mg of plasmid DNA (free of contaminating bacterial products) from a 500-ml culture following any of the crude lysate preparation methods or PEG precipitation. Purification by CsCl/ethidium bromide density gradient centrifugation yields 75% to 90% of the amount of plasmid DNA obtained using PEG precipitation. Yields obtained from column chromatography are limited by the capacity of the column and are generally <1 mg.

Time Considerations

Cell growth and concentration require one overnight growth period to collect the starting 5-ml culture and most of the next day for its outgrowth and concentration. Crude lysate preparation can be completed in 90 min using alkaline lysis, ~35 min using the boiling method, and 2.5 to 3 hr using Triton lysis. Plasmid DNA purification by CsCl/ethidium bromide density gradient centrifugation takes 4 hr to 3 days depending upon the quality of plasmid DNA desired and the type of centrifuge and rotor used. PEG precipitation of the crude lysate can yield pure plasmid DNA in as little as 2 hr; however, complete recovery may require 13 to 16 hr. Column chromatography takes 30 to 90 minutes. High-quality plasmid DNA recovery from an *E. coli* strain containing the desired plasmid using any combination of these procedures takes 1 day to 1 week.

In addition to the total time necessary to obtain pure plasmid DNA, it is important to consider the hands-on time required for individual steps of the different procedures. PEG precipitation can yield pure plasmid DNA 4 or 5 hr after harvesting cells but requires direct attention and manipulations every 10 to 30 min. Purification using CsCl/ethidium bromide centrifugation takes 6 to 18 hr after harvesting cells, but the final 4-5 hr are taken up by a centrifugation step that requires no direct attention. Column chromatography can yield purified DNA within 3 hr of harvesting cells. With Qiagen protocols, plasmid purification times can also be reduced by using a Qiafilter to clear the bacterial lysate. In addition, most of these

columns operate by gravity flow for maximum handling convenience; the columns never run dry. Therefore, if pure plasmid DNA is needed the same day the large culture is harvested, it is perhaps best to prepare crude lysates by alkaline lysis and purify plasmid DNA by PEG precipitation, collecting the PEG precipitate after ~1 hr at 0°C, or by chromatography. If it has been a long day and the priority is to go home, crude lysate can be prepared by the boiling method and plasmid DNA purified by the CsCl/ethidium bromide centrifugation. The variety of methods and the opportunity to interrupt them at different steps (such as at the precipitation steps) facilitate selection of methods most convenient for specific work situations.

Introduction of Plasmid DNA into Cells

UNIT 1.8

Transformation of *E. coli* can be achieved using any of the four protocols in this unit. The first method (see Basic Protocol 1) using calcium chloride gives good transformation efficiencies, is simple to complete, requires no special equipment, and allows storage of competent cells. The one-step method (see Alternate Protocol 1) is considerably faster and also gives good transformation efficiencies (although they are somewhat lower). However, because it was developed relatively recently, its reproducibility and reliability are not as well established.

If considerably higher transformation efficiencies are needed, the third method (see Basic Protocol 2) using electroporation should be followed. Although this procedure is simple, fast, and reliable, it requires an electroporation apparatus. As in the calcium chloride protocol, prepared cells can be stored. The final method described (see Alternate Protocol 2) describes an adaptation based on electroporation that allows direct transfer of vector DNA from yeast into *E. coli*.

TRANSFORMATION USING CALCIUM CHLORIDE

**BASIC
PROTOCOL 1**

Escherichia coli cells are grown to log phase. Cells are concentrated by centrifugation and resuspended in a solution containing calcium chloride. Exposure to calcium ions renders the cells able to take up DNA, or *competent*. Plasmid DNA is mixed with the cells and presumably adheres to them. The mixture of DNA and cells is then heat shocked, which allows the DNA to efficiently enter the cells. The cells are grown in nonselective medium to allow synthesis of plasmid-encoded antibiotic resistance proteins, then plated on antibiotic-containing medium to allow identification of plasmid-containing colonies.

Materials

Single colony of *E. coli* cells
LB medium (UNIT 1.1)
CaCl₂ solution (see recipe), ice cold
LB plates (UNIT 1.1) containing ampicillin (Table 1.4.1)
Plasmid DNA (UNITS 1.6 & 1.7)

Chilled 50-ml polypropylene tubes
Beckman JS-5.2 rotor or equivalent
42°C water bath

Additional reagents and equipment for growth of bacteria in liquid media (UNIT 1.2)

NOTE: All materials and reagents coming into contact with bacteria must be sterile.

Prepare competent cells

1. Inoculate a single colony of *E. coli* cells into 50 ml LB medium. Grow overnight at 37°C with moderate shaking (250 rpm; see UNIT 1.2).

Alternatively, grow a 5-ml culture overnight in a test tube on a roller drum.

2. Inoculate 4 ml of the culture into 400 ml LB medium in a sterile 2-liter flask. Grow at 37°C, shaking at 250 rpm, to an OD₅₉₀ of 0.375.

This procedure requires that cells be growing rapidly (early- or mid-log phase). Accordingly, it is very important that the growing cells have sufficient air. A 1-liter baffled flask can be used instead of the 2-liter flask. Overgrowth of culture (beyond OD₅₉₀ of 0.4) decreases the efficiency of transformation.

***Escherichia coli*,
Plasmids, and
Bacteriophages**

3. Aliquot culture into eight 50-ml prechilled, sterile polypropylene tubes and leave the tubes on ice 5 to 10 min.

Cells should be kept cold for all subsequent steps.

Larger tubes or bottles can be used to centrifuge cells if volumes of all subsequent solutions are increased in direct proportion.

4. Centrifuge cells 7 min at $1600 \times g$ (3000 rpm in JS-5.2), 4°C. Allow centrifuge to decelerate without brake.

We have not attempted to determine whether deceleration without braking is critical to this procedure. However, we do not use the brake for this step or for the subsequent centrifugation steps.

5. Pour off supernatant and resuspend each pellet in 10 ml ice-cold CaCl_2 solution.

Resuspension should be performed very gently and all cells kept on ice.

6. Centrifuge cells 5 min at $1100 \times g$ (2500 rpm), 4°C. Discard supernatant and resuspend each pellet in 10 ml ice-cold CaCl_2 solution. Keep resuspended cells on ice for 30 min.

7. Centrifuge cells 5 min at $1100 \times g$, 4°C. Discard supernatant and resuspend each pellet in 2 ml ice-cold CaCl_2 solution.

It is important to resuspend this final pellet well. The suspension may be left on ice for several days. For many strains (e.g., DH1) competency increases with increasing time on ice, and reaches a maximum at 12 to 24 hr. This is not true for MC1061 cells, which should be frozen immediately.

8. Dispense cells into prechilled, sterile polypropylene tubes (250- μl aliquots are convenient). Freeze immediately at -70°C .

Assess competency of cells

9. Use 10 ng of pBR322 to transform 100 μl of competent cells according to the steps provided below. Plate appropriate aliquots (1, 10, and 25 μl) of the transformation culture on LB/ampicillin plates and incubate at 37°C overnight.
10. Calculate the number of transformant colonies per aliquot volume (μl) $\times 10^5$: this is equal to the number of transformants per microgram of DNA.

*Transformation efficiencies of 10^7 to 10^8 and 10^6 to 10^7 are obtained for *E. coli* MC1061 and DH1, respectively. Competency of strains decreases very slowly over months of storage time.*

Transform competent cells

11. Aliquot 10 ng of DNA in a volume of 10 to 25 μl into a sterile 15-ml round-bottom test tube and place on ice.

Plasmid DNA can be used directly from ligation reactions. When this is done, more DNA is usually used. However, if there is $>1 \mu\text{g}$ of DNA in the ligation reaction, or if the ligation reaction is from low gelling/melting temperature agarose, it is wise to dilute the ligation mix (see UNIT 3.16).

12. Rapidly thaw competent cells by warming between hands and dispense 100 μl immediately into test tubes containing DNA. Gently swirl tubes to mix, then place on ice for 10 min.

Competent cells should be used immediately after thawing. Remaining cells should be discarded rather than refrozen.

- Heat shock cells by placing tubes into a 42°C water bath for 2 min.

Alternatively, incubate at 37°C for 5 min.

- Add 1 ml LB medium to each tube. Place each tube on a roller drum at 250 rpm for 1 hr at 37°C.

- Plate aliquots of transformation culture on LB/ampicillin or other appropriate antibiotic-containing plates.

It is convenient to plate several different dilutions of each transformation culture. The remainder of the mixture can be stored at 4°C for subsequent platings.

- When plates are dry, incubate 12 to 16 hr at 37°C.

ONE-STEP PREPARATION AND TRANSFORMATION OF COMPETENT CELLS

ALTERNATE PROTOCOL 1

This procedure is considerably easier than Basic Protocol 1 because it eliminates the need for centrifugation, washing, heat shock, and long incubation periods (Chung et al., 1989). Moreover, competent cells made by this simple procedure can be directly frozen at -70°C for long-term storage. A variety of strains can be made competent by this procedure, and the transformation frequency can be as high as that achieved by Basic Protocol 1. However, frequency is considerably lower than can be obtained by electroporation.

Additional Materials (also see *Basic Protocol 1*)

2× transformation and storage solution (TSS; see recipe), ice cold
LB medium (UNIT 1.1) containing 20 mM glucose

- Dilute a fresh overnight culture of bacteria 1:100 into LB medium and incubate at 37°C until the cells reach an OD₆₀₀ of 0.3 to 0.4.

The procedure will work if cells are harvested at other stages of the growth cycle (including stationary phase), but with reduced efficiency.

- Add a volume of ice-cold 2× TSS equal to that of the cell suspension, and gently mix on ice.

For long-term storage, freeze small aliquots of the suspension in a dry ice/ethanol bath and store at -70°C. To use frozen cells for transformation, thaw slowly and then use immediately.

Cells can also be used if pelleted by centrifugation 10 min at 1000 × g, 4°C, and this may increase the frequency of transformation (according to Chung et al., 1989). Discard supernatant and resuspend cell pellet at one-tenth of original volume in 1× TSS (prepared by diluting 2× TSS). Proceed with transformation as in step 3.

- Add 100 μl competent cells and 1 to 5 μl DNA (0.1 to 100 ng) to an ice-cold polypropylene or glass tube. Incubate 5 to 60 min at 4°C.

As is the case for related procedures, the transformation frequency as measured by transformants/μg DNA is relatively constant at amounts of DNA <10 ng. However, the frequency decreases at higher concentrations. The time of incubation at 4°C is relatively unimportant.

- Add 0.9 ml LB medium containing 20 mM glucose and incubate 30 to 60 min at 37°C with mild shaking to allow expression of the antibiotic resistance gene. Select transformants on appropriate plates.

It is unnecessary to heat shock the transformation mixture. The expected transformation frequency should range between 10⁶ and 10⁷ colonies/μg DNA.

Escherichia coli,
Plasmids, and
Bacteriophages

1.8.3

HIGH-EFFICIENCY TRANSFORMATION BY ELECTROPORATION

Electroporation with high voltage is currently the most efficient method for transforming *E. coli* with plasmid DNA. The procedure described may be used to transform freshly prepared cells or to transform cells that have been previously grown and frozen. With freshly grown cells, it routinely gives more than 10^9 bacterial transformants per microgram of input plasmid DNA.

Materials

- Single colony of *E. coli* cells
- LB medium (UNIT 1.1)
- H₂O, ice cold
- 10% glycerol, ice cold
- SOC medium (see recipe)
- LB plates (UNIT 1.1) containing antibiotics (Table 1.4.1)
- 1-liter centrifuge bottle, 50-ml narrow-bottom polypropylene tube, and microcentrifuge tubes, chilled ice cold
- Beckman J-6M centrifuge (or equivalent)
- Beckman JS-4.2 rotor (or equivalent) and adaptors for 50-ml narrow-bottom tubes
- Electroporation apparatus with a pulse controller or 200- or 400-ohm resistor
- Chilled electroporation cuvettes, 0.2-cm electrode gap
- Additional reagents and equipment for growth of bacteria in liquid media (UNIT 1.2)

NOTE: All materials and reagents coming into contact with bacteria must be sterile.

Prepare the cells

1. Inoculate a single colony of *E. coli* cells into 5 ml LB medium. Grow 5 hr to overnight at 37°C with moderate shaking (see UNIT 1.2).
2. Inoculate 2.5 ml of the culture into 500 ml LB medium in a sterile 2-liter flask. Grow at 37°C, shaking at 300 rpm, to an OD₆₀₀ of ~0.5 to 0.7.

Best results are obtained by harvesting cells at an OD₆₀₀ of ~0.5 to 0.6.

3. Chill cells in an ice-water bath 10 to 15 min and transfer to a prechilled 1-liter centrifuge bottle.

Cells should be kept at 2°C for all subsequent steps.

4. Centrifuge cells 20 min at 4200 rpm in Beckman J-6M, 2°C.
5. Pour off supernatant and resuspend the pellet in 5 ml ice-cold water. Add 500 ml ice-cold water and mix well. Centrifuge cells as in step 4.
6. Pour off supernatant immediately and resuspend the pellet by swirling in remaining liquid.

Because the pellet is very loose, the supernatant must be poured off immediately. The pellet can be made tighter by substituting ice-cold sterile HEPES (1 mM, pH 7.0) for the ice-cold water in step 5.

7. Add another 500 ml ice-cold water, mix well, and centrifuge again as in step 4.
8. Pour off supernatant immediately and resuspend the pellet by swirling in remaining liquid.

- 9a. If fresh cells are to be used for electroporation, place suspension in a prechilled, narrow-bottom, 50-ml polypropylene tube, and centrifuge 10 min at 4200 rpm in Beckman J-6M centrifuge with JS-4.2 rotor and adaptors, 2°C.

Fresh cells work better than frozen cells.

Estimate the pellet volume (usually ~500 μ l from a 500-ml culture) and add an equal volume of ice-cold water to resuspend cells (on ice). Aliquot 50- to 300- μ l cells into prechilled microcentrifuge tubes. The cell density is $\sim 2 \times 10^{11}$ /ml.

- 9b. If frozen cells are to be used for electroporation, add 40 ml ice-cold 10% glycerol to the cells and mix well. Centrifuge cells as described in step 9a.

Estimate the pellet volume and add an equal volume of ice-cold 10% glycerol to resuspend cells (on ice). Place 50- to 300- μ l aliquots of cells into prechilled microcentrifuge tubes and freeze on dry ice (not in liquid nitrogen). Store at -80°C .

Prolonged incubation of cells in ice-water at all stages can increase transformation efficiency of some strains, such as BW313/P3 and MC1061/P3, >3-fold.

Transform the cells

10. Set the electroporation apparatus to 2.5 kV, 25 μ F. Set the pulse controller to 200 or 400 ohms.

The pulse controller is necessary when high-voltage pulses are applied over short gaps in high-resistance samples (see Background Information).

11. Add 5 pg to 0.5 μ g plasmid DNA in 1 μ l to tubes containing fresh or thawed cells (on ice). Mix by tapping the tube or by swirling the cells with the pipettor.

12. Transfer the DNA and cells into a cuvette that has been chilled 5 min on ice, shake slightly to settle the cells to the bottom, and wipe the ice and water from the cuvette with a Kimwipe.

The volume of DNA added to the cells should be kept small. Adding DNA up to one-tenth of the cell volume will decrease the transformation efficiency 2- to 3-fold. Also, since the resistance of the sample should be high, make sure that addition of the DNA to the cells does not increase the total salt concentration in the cuvette by >1 mM.

13. Place the cuvette into the sample chamber.

If using a homemade apparatus, connect the electrodes to the cuvette.

14. Apply the pulse by pushing the button or flipping the switch.

15. Remove the cuvette. Immediately add 1 ml SOC medium and transfer to a sterile culture tube with a Pasteur pipet. Incubate 30 to 60 min with moderate shaking at 37°C.

If the actual voltage and time constant of the pulse are displayed on the electroporation apparatus, check this information. Verify that the set voltage was actually delivered, and record the time constant of the pulse so that you may vary it later if necessary (see Critical Parameters).

16. Plate aliquots of the transformation culture on LB plates containing antibiotics.

DIRECT ELECTROPORETIC TRANSFER OF PLASMID DNA FROM YEAST INTO *E. COLI*

The use of “shuttle vectors”—plasmids that can be grown successfully in at least two different organisms—facilitates the transfer of DNA between, for example, yeast and *E. coli*. In this adaptation of the electroporation protocol, plasmid DNA from a shuttle vector is transformed directly from yeast into *E. coli*. Components of the interaction trap/two-hybrid system (UNIT 20.1) are used as an example in this protocol. The transfer and selection of a “prey” plasmid from the yeast strain EGY48 into the *E. coli* strain KC8 is described here, but the approach can be adapted for use with other yeast and *E. coli* strains.

Additional Materials (also see Basic Protocol 2)

Single colony of *E. coli* KC8 cells (UNIT 20.1)

Streak colony of Trp⁻ plasmid-harboring EGY48 yeast cells on Gal/Raff/Xgal/CM plates (UNIT 20.1), no older than 2 weeks

M9 minimal medium and plates (UNIT 1.1) containing 100 µg/ml ampicillin (Table 1.4.1) and standard concentrations of leucine, histidine, and uracil

Additional reagents and equipment for growth and manipulation of yeast (UNIT 13.2) and for plasmid DNA miniprep (UNIT 1.6) or PCR (UNIT 15.1)

1. Prepare electrocompetent KC8 cells (see Basic Protocol 2, steps 1 to 9a), resuspending the final cell pellet in ice-cold water to obtain an OD₆₀₀ of 100.

Fresh KC8 cells work better in this electroporation method than frozen ones.

To measure OD, dilute 5 µl of the cell suspension with water to 1 ml and measure the OD₆₀₀. If necessary add more water to the suspension to get an OD₆₀₀ of 100.

2. Distribute 65-µl aliquots of the electrocompetent *E. coli* KC8 cells into ice-cold microcentrifuge tubes.
3. With a sterile wooden or plastic stick, scrape off ~10 µl of yeast from a streak colony of EGY48 harboring the respective “prey” plasmid derivative of pJG4-5 and grown on Gal/Raff/Xgal/CM plates. Resuspend the yeast cells in the KC8 suspension by swirling the stick used for scraping off the cells.

Avoid scraping off plate medium when collecting the yeast streak cells.

Keep the microcentrifuge tube on ice as much as possible. Try to get an even distribution of the two cell types but do not vortex. Yeast grown on plates other than Gal/Raff/Xgal/CM will probably work as well; do not worry if the yeast colony used is blue.

4. Set the electroporation apparatus to 1.5 kV, 25 µF, and the pulse controller to 100 ohms. Transfer the cell suspension into a 0.2-cm cuvette that has been chilled 5 min on ice, shake slightly to settle the cells to the bottom, and wipe the ice and water from the cuvette with a Kimwipe.

The use of Pasteur pipettes will facilitate placing the cell suspension at the bottom of the cuvette. Avoid any air bubbles.

5. Place the cuvette in the sample chamber of the apparatus and pulse. Take the cuvette out and place it on ice for ≥45 sec. Meanwhile, change the settings in preparation for the second pulse.

The expected time constant for the first pulse is 2.2 to 2.4 msec.

6. Set the electroporation apparatus to 2.5 kV, 25 µF, and the pulse controller to 200 ohms. Wipe the cuvette again, place it in the sample chamber, and pulse.

The expected time constant for the second pulse is 4.2 to 4.8 msec.

7. Remove the cuvette, immediately add 1 ml LB medium, and transfer the suspension into a microcentrifuge tube. Incubate 45 min at room temperature.

Incubation of the suspension after electroporation for 1 hr at 37°C decreases the yield of transformants, probably due to prolonged adhesion of the E. coli cells to the yeast cell debris.

8. Spread 150 μ l of the suspension evenly onto M9 minimal medium plates containing 100 μ g/ml ampicillin and leucine, histidine, and uracil. Incubate \geq 24 hr at 37°C.

A slight yeast background might appear on the plates but single E. coli colonies are easy to pick. Between 50 and 200 KC8 colonies have been obtained per plate employing 150 μ l out of the 1 ml LB suspension.

9. Pick a single KC8 colony, inoculate it into 1.5 to 5 ml M9 minimal medium (Leu⁺, His⁺, Ura⁺, 100 μ g/ml Amp) or LB (100 μ g/ml Amp) and grow at 37°C. Harvest at an appropriate OD to prepare miniprep DNA (UNIT 1.6) or perform PCR analysis (UNIT 15.1).

Using M9 minimal medium to grow KC8 in liquid culture is an additional safety measure but not absolutely necessary. It ensures isolation of the plasmid whose marker complements the auxotrophic defect in KC8; in addition, slightly increased plasmid copy number and improved DNA quality have been reported.

REAGENTS AND SOLUTIONS

CaCl₂ solution

60 mM CaCl₂

15% glycerol

10 mM PIPES [piperazine-*N,N'*-bis(2-hydroxypropanesulfonic acid)], pH 7

Filter sterilize using a disposable filter unit, or autoclave

Store at room temperature (stable for years)

SOC medium

0.5% yeast extract

2% tryptone

10 mM NaCl

2.5 mM KCl

10 mM MgCl₂

10 mM MgSO₄

20 mM glucose

Store at room temperature (stable for years)

Transformation and storage solution (TSS), 2×

Dilute sterile (autoclaved) 40% (w/v) polyethylene glycol (PEG) 3350 to 20% PEG in sterile LB medium containing 100 mM MgCl₂. Add dimethyl sulfoxide (DMSO) to 10% (v/v) and adjust to pH 6.5.

COMMENTARY

Background Information

Calcium and one-step transformation

Transformation of *E. coli* was first described by Mandel and Higa (1970). Subsequent modifications to improve transformation efficiencies have included prolonged exposure of cells to CaCl₂ (Dagert and Ehrlich, 1974), substitution of calcium with other cations such as Rb⁺

(Kushner, 1978), Mn²⁺, and K⁺, and addition of other compounds such as dimethyl sulfoxide, dithiothreitol, and cobalt hexamine chloride (Hanahan, 1983). Basic Protocol 1 given here provides good transformation efficiencies, permits long-term storage of competent cells, and is relatively uncomplicated to perform. Variations on this protocol can be obtained from the references provided. Alternate Proto-

***Escherichia coli,*
Plasmids, and
Bacteriophages**

1.8.7

col 1, a one-step preparation and transformation procedure, is considerably faster.

Transformation by electroporation

Electroporation has become a valuable technique for transfer of nucleic acids into eukaryotic and prokaryotic cells. The method can be applied to many different *E. coli* strains and to other gram-negative and gram-positive bacteria.

In this technique, a high-voltage electric field is applied briefly to cells, apparently producing transient holes in the cell membrane through which plasmid DNA enters (Shigekawa and Dower, 1988). The field strength used for mammalian cell and plant protoplast electroporation is usually 0.5 to 1 kV/cm. The field strength needed for high-efficiency transformation of *E. coli* is much greater, usually ~12.5 kV/cm. Under these conditions up to 10^{10} transformants/ μg plasmid DNA have been reported (Calvin and Hanawalt, 1988; Miller et al., 1988; Dower et al., 1988). Recently, field strength up to 8 kV/cm was also used successfully to electroporate both mammalian cells and plant protoplasts.

The capacitor discharge circuit of the electroporation apparatus typically generates an electrical pulse with an exponential decay waveform. The voltage across the electrodes rises rapidly to a peak voltage, which then declines over time as follows:

$$V_t = V_0 [e^{-t/T}]$$

where V_t = voltage at a given time t after the time of V_0 , V_0 = initial voltage, t = time (sec), T = pulse time constant = RC , R = resistance of circuit (ohms); and C = capacitance of circuit (Farads).

The pulse time constant is ~5 to 10 msec for electroporating *E. coli* cells and ranges from 5 μsec to 50 msec for higher eukaryotic cells.

The pulse controller contains a number of different-sized resistors, any one of which is placed in parallel with the sample, and one resistor of fixed (20-ohm) resistance, which is placed in series with the sample. The resistor placed in parallel with the sample (usually 200 or 400 ohms) swamps out the effect of changes in the resistance of the sample on the total resistance of the circuit, thus determining the total resistance across the capacitor, and controlling the time constant (T) of the capacitor discharge. The 20-ohm resistor in series with the sample protects the circuitry by limiting the current should a short circuit (arc) occur and the capacitor discharge instantly.

The pulse controller is required when high-voltage electroporation pulses are delivered to high-resistance samples across narrow electrode gaps. In this procedure, the resistance of washed *E. coli* in the 0.2-cm cuvette is ~5000 ohms. A pulse controller is not necessary when samples of low (<1000-ohm) resistance are used, for example for electroporation of mammalian cells suspended in PBS.

Direct transfer of plasmid DNA from yeast into *E. coli*

Alternate Protocol 2 presents an application of electrophoretic transformation whereby a "shuttle vector" (a vector designed to be used in at least two different organisms to facilitate interspecies transfer of DNA) can be directly transferred between two species. Shuttle vectors have become increasingly popular in recent years, with those designed to facilitate the transfer of plasmid DNA between yeast and *E. coli* proving to be particularly useful. With the widespread use of the two-hybrid system (or interaction trap; see UNIT 20.1), transfer of plasmid DNA from yeast into *E. coli* using shuttle vectors has become a common task. As an alternative to rescuing a shuttle plasmid from a yeast clone and subsequently transforming an appropriate *E. coli* strain, the procedure described in Alternate Protocol 2 bypasses the need for plasmid isolation and offers a one-step method to obtain the same result. The direct transfer method was first mentioned by Marcil and Higgins (1992) and further modified by Karen Clemens (NIH, Bethesda, Md., pers. comm.). Alternate Protocol 2 comprises an optimization of the procedure and an adaptation to the interaction trap; however, although outlined for that specific case, the procedure is generally applicable to other yeast and *E. coli* strains. As presented, this protocol accomplishes the transfer of a "prey" plasmid from the yeast strain EGY48, designed to be used in interactor hunts, into the *E. coli* strain KC8. EGY48 contains three different plasmids (bait, prey, and lacZ reporter), all of which confer ampicillin resistance if transferred into *E. coli*. Therefore, the TRP1 selectable marker of the new interactor (prey plasmid), which complements the Trp^- phenotype of EGY48 as well as KC8, is used to rescue the plasmid. During the electroporation procedure the yeast cells are destroyed in the first pulse and the liberated plasmids transformed into *E. coli* KC8 cells in the second pulse. Selection of the prey plasmid is achieved by choosing the correct medium on which to plate the transformed KC8.

Critical Parameters

Calcium transformation

In Basic Protocol 1, preparation of competent cells with a high transformation efficiency is thought to depend on (1) harvesting bacterial cultures in logarithmic phase of growth, (2) keeping cells on ice throughout the procedure, and (3) prolonged CaCl_2 exposure.

At least 30 min of growth in nonselective medium (*outgrowth*) after heat shock is necessary for plasmids containing the pBR322 tetracycline resistance promoter and gene to express enough of the protein to allow the cells to form colonies with an efficiency of 1 on tetracycline plates. Cells expressing the common plasmid-encoded ampicillin resistance (β -lactamase) gene may not require such prolonged outgrowth to form colonies on ampicillin plates. When an ampicillin-resistant plasmid is used, transformation mixtures should be diluted so that transformed colonies arise at a relatively low density (≤ 500 cells/plate). Otherwise, the β -lactamases present in the colonies may lower the ampicillin level in the plate near them, and permit growth of weakly ampicillin-resistant *satellite colonies*. This problem can be ameliorated if carbenicillin (a related antibiotic slightly less sensitive to destruction by the pBR322 β -lactamase) is substituted for ampicillin in the medium. Carbenicillin should be used at a concentration of 50 to 100 $\mu\text{g}/\text{ml}$.

Usually only 3% to 10% of cells are competent to incorporate plasmid DNA. Transformation frequencies decrease with increasing plasmid size (Hanahan, 1983). The number of transformants obtained usually increases linearly with increasing numbers of plasmid molecules up to a point, reached at ~ 10 ng DNA/100 μl competent cells in the procedure given here. After this point the number of transformants does not increase linearly with increasing numbers of plasmid DNA molecules.

Transformation by electroporation

Although the procedure works with cells grown to many different densities, best results are obtained when cells are harvested at an OD_{600} of 0.5 to 0.6. After the cells are centrifuged in water, the cell pellet is very loose and the supernatant should be poured off as quickly as possible to prevent a big loss in yield; to achieve this, it is best to handle no more than two centrifuge bottles simultaneously. Fresh

cells in either water or 10% to 20% glycerol usually work better than frozen cells.

As described above, the relevant parameters for exponential electroporation pulses are the time constant of the exponential curve (how long the pulse lasts) and the initial voltage or field strength (how strong the pulse is). Generally speaking, successful electroporation of *E. coli* requires long, strong pulses. In this procedure the capacitance of the circuit is relatively large (25 μF), ensuring a relatively long pulse; fine tuning of the pulse time constant is achieved by varying the size of the resistor placed in parallel with the sample.

The SOC medium must be added immediately after electroporation. Do not let the electroporated cells sit in the cuvette.

In the procedure given here, the number of transformants increases linearly with input DNA over a very wide range (from 5 pg to 500 ng). The amount of plasmid DNA added can be as little as 4 to 5 pg in 50 μl of cells, and as much as 0.5 μg in 300 μl of cells, without affecting the transformation efficiency significantly. However, transformation efficiency falls off with < 5 pg of DNA; in one experiment, the number of transformants obtained with 1 pg of plasmid DNA was 30 times lower than with 5 pg.

The size of the DNA does not seem to be important for this procedure; plasmid DNA can be as large as 14 kb without significant effects on transformation efficiency. Religated DNA (still in the ligation mix) can be transformed almost as efficiently as intact supercoiled DNA.

The general recommendations given for electroporation apply to the direct transfer method as well. Although outlined for a specific case, the procedure described in Alternate Protocol 2 should be generally applicable to other yeast and *E. coli* strains. The yeast streak colony should not be older than 2 weeks. Scraping medium off the plate when collecting the yeast cells should be avoided. Fresh KC8 cells work better than frozen ones. Incubation of the 1 ml LB suspension after electroporation at 37°C for 1 hr decreases the yield of transformants, probably due to prolonged adhesion of the *E. coli* cells to the yeast cell debris. Using M9 minimal medium to grow KC8 in liquid culture is an additional safety measure, but is not absolutely necessary. It ensures isolation of the plasmid whose marker complements the auxotrophic defect in KC8; in addition slightly increased plasmid copy number and improved DNA quality have been reported.

Anticipated Results

Calcium and one-step transformation. In Basic Protocol 1, transformation efficiencies of 10^7 to 10^8 and 10^6 to $10^7/\mu\text{g}$ plasmid DNA should be obtained for *E. coli* MC1061 and DH1, respectively. In Alternate Protocol 1, transformation frequencies should range from 10^6 to 10^7 colonies/ μg DNA.

Transformation by electroporation. Using Basic Protocol 2, efficiencies of $2.5\text{--}14 \times 10^{10}$ transformants/ μg have been obtained with superpure pUC19 DNA (from BRL) and $6.2\text{--}12 \times 10^9$ transformants/ μg with home-made pUC18 DNA and cDNA libraries in MC1061/P3. In addition, 5×10^9 transformants/ μg have been obtained with the expression plasmid CDM8 in MC1061/P3. Similar results may be anticipated with MC1061 (see Table 1.4.5) and with many other commonly used lab strains. Using direct plasmid transfer from yeast to *E. coli* (Alternate Protocol 2), between 50 and 200 KC8 colonies have been obtained per plate when 150 μl out of the 1 ml LB suspension was employed.

Time Considerations

Calcium and one-step transformation. Growth of competent cells from an aliquot of an overnight culture to logarithmic phase requires ~3 hr. In Basic Protocol 1, cells are then exposed to calcium as long as overnight. Once competent cells are available, transformation requires ~90 min for either strain. In Alternate Protocol 1, preparation and transformation of competent cells requires 1 to 2 hr.

Transformation by electroporation. In Basic Protocol 2, once the culture of bacterial cells is ready to be harvested, the cells can be washed and concentrated within an hour. Electroporation takes only a few minutes, and growth and plating of the transformed cells should not take more than 90 min. The time frame for direct plasmid transfer (Alternate Protocol 2) is essentially the same as for the electroporation basic protocol. It should be noted that using M9 minimal medium slows down the growth of *E. coli*.

VECTORS DERIVED FROM LAMBDA AND RELATED BACTERIOPHAGES

Introduction to Lambda Phages

The biology of lambda-derived vectors is extremely well understood. This introduction to the biology of λ and related phages is included to help readers use the λ vectors that are employed in the manual (e.g., UNIT 1.11 and Chapters 5 and 6), and to help readers understand new λ vectors that are being developed.

Lambda is a *temperate* phage, which means

Sketch 1.9A

that it can grow lytically or lysogenically. When λ infects a cell, it injects its DNA into the host bacterium. When it grows lytically, it makes many copies of its genome, packages them into new phage particles, and lyses the host cell to release the progeny phage. When λ grows lysogenically, it inserts its DNA into the chromosome of the host cell. The integrated phage DNA is replicated along with the host chromosome (but sometimes, e.g., when the cell's DNA is damaged, phage DNA is excised from the chromosome and the phage begins to grow

lytically). Lysogens are immune to superinfection by additional λ phages carrying a homologous immunity region. Plaques of temperate phages are turbid because they contain both cells lysed by phage that have grown lytically and cells spared from further phage infection because they have become lysogens (see sketch 1.9A).

The λ genome is grouped into discrete blocks of related genes. This fact is quite convenient to the molecular biologist, as it has allowed construction of many phage-based cloning vectors which have deletions in large stretches of DNA nonessential to lytic growth (see gray areas in sketch 1.9B). In addition to these large areas, much of the immunity region, including the *cII*, *cro*, *cI* and *rex* genes, is inessential for lytic growth of otherwise wild-type phage; even the *N* gene is not essential if *t_{R2}* is deleted.

LYTIC GROWTH

Early Gene Expression

Lytic growth results in the production of progeny phage and the eventual lysis of the host cell. Lytic growth begins either on infection, if a phage does not grow lysogenically, or after the inactivation of existing *cI* repressor in a lysogen (see box E).

Transcription initiates from the early promoters, *P_R* and *P_L*. The *P_R* transcript terminates at *t_{R1}* and encodes the *cro* gene. The *P_L* tran-

Sketch 1.9B

 Copyright © 2000 by John Wiley & Sons, Inc.

script continues to t_{L1} and encodes the N gene. The product of the N gene is an antitermination factor; that is, it allows the transcripts which initiate at P_L or P_R to proceed through t_{L1} and t_{R1} respectively. The N -antiterminated P_R transcript, which terminates at t_{R2} , encodes the O , P , and Q genes. The O and P proteins are required for phage DNA replication; Q protein is another antitermination protein, in this case, specific for transcripts initiating at a promoter located to the right of Q called P_R' . Q -antiterminated transcription from P_R' proceeds through another terminator called t_{R65} and the late region, then through the head and tail genes which have been joined to the same transcription unit when the incoming phage DNA circularized, and finally terminates in b . The P_R' transcript encodes proteins necessary for head and tail assembly, DNA packaging, and host cell lysis.

This sequential expression of phage functions allows for the replication of the λ genome, its subsequent packaging into phage heads, and lysis of the host in the correct temporal order.

A. REQUIREMENTS FOR LYTIC GROWTH

N antitermination factor. Causes RNA polymerase to read through early terminators and expresses Q protein as well as the replication proteins.

Q antitermination factor. Causes RNA polymerase to read through t_{R65} and expresses the proteins required for head and tail assembly and host cell lysis.

Replication proteins. Phage O and P proteins work together with host proteins to replicate DNA.

Packaging and lysis proteins. Other proteins essential for phage growth.

DNA Replication

Replication during lytic growth requires both host proteins and phage-encoded proteins. Lytic DNA replication can be divided into an early and late phase. The early phase begins with the injection of linear phage DNA into the bacterial cell. This DNA has, at either end, complementary, single-stranded cohesive ends generated by cleavage of the cos site. These sticky ends base pair, and are ligated by host enzymes to yield a covalently closed circular molecule. After supercoiling by host topoisom-

erases, this molecule is able to initiate DNA replication. Replication begins at a unique site (called ori), and proceeds bidirectionally. This type of replication results first in the formation of a theta-shaped replication intermediate and later in the production of two daughter circles.

Approximately 15 min after phage infection, replication switches to the late phase. This is characterized by *rolling-circle replication*, which produces long polymers (called *concatemers*) of repeated, full-length phage genomes. The gam gene product protects the concatemers from degradation by an exonuclease encoded by the host $recB$ and $recC$ genes. Concatemers are substrates for packaging (see below and UNITS 5.8 & 5.9).

B. REQUIREMENTS FOR DNA REPLICATION

cos ends. 12-bp cohesive overhangs that pair and cause circularization in vivo. These are generated by cutting at cos sites, which occurs during packaging.

ori . Site at which DNA replication starts.

O and P proteins. O protein binds DNA; P protein interacts with host-encoded $dnaB$ protein.

gam protein. Inhibits *E. coli* exonuclease V ($recBC$ nuclease) and thus protects the end of the rolling circle concatemer from degradation by this enzyme.

Packaging and Lysis

Late in infection, DNA replication and packaging of λ occur concurrently. Once concatemeric DNA structures are formed, they are condensed into λ proheads (incomplete head particles). Cos sites are recognized by λ proteins, and the DNA between two cos sites is cleaved from the concatemer coincident with its packaging into a single prohead (linearizing the DNA and regenerating the cohesive ends). The remaining head proteins then assemble, and the tail, which has assembled independently, attaches to the head to form the intact phage. DNA located between two cos sites will only be packaged in a form that can be injected if it is between 38 and 53 kb long (a fact important in choosing the proper vector to construct a library; see UNITS 5.1 and 5.2). The last event during lytic growth is the lysis of the host. Phage-encoded proteins disrupt the bacterial inner membrane and degrade the cell wall.

C. REQUIREMENTS FOR PACKAGING AND LYSIS

cos sites. DNA is cleaved here, and DNA between the sites is packaged into phage heads.

NuI and A proteins. Components of the “terminase” that cleaves at *cos* sites.

B, C, D, E, and Nu3 proteins. Involved in the structure or assembly of the phage head.

G, H, I, J, K, L, M, T, U, V, and Z proteins. Involved in the structure or assembly of the tail and tail fibers.

R, S, and Rz proteins. *S* disrupts the inner membrane and the *R* and *Rz* proteins conspire to degrade the cell wall to achieve cellular lysis.

growth) with the joining of the cohesive ends and circularization of the genome. *cII* protein then binds to the P_{int} promoter and activates its transcription. *Int* protein is made from this transcript. *Int* protein catalyses a recombination event between the phage sequence, *attP*, and a site on the bacterial chromosome, *attB*, resulting in integration of the phage.

Immunity Regions

D. REQUIREMENTS FOR LYSOGENIZATION

imm region. Contains the promoters and genes (such as *cI*) that are essential for establishment and maintenance of lysogeny (see also section on immunity region).

cII and cIII proteins. *cII* is required for *int* synthesis; *cIII* protects *cII* from degradation by host proteases.

int protein. Along with host proteins, catalyzes the integration of the phage into the chromosome.

attP site. Required for integration of the phage into the host chromosome.

cos ends. Necessary for circularization of the molecule upon infection.

LYSOGENIC GROWTH

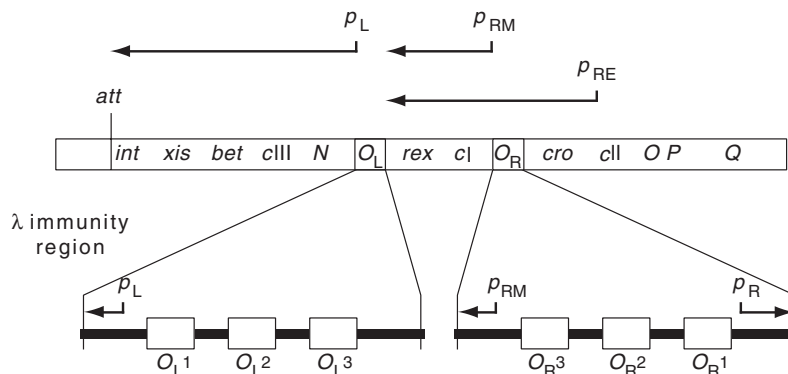

Gene Expression

Following infection, wild-type λ phage sometimes shuts down the majority of its genome and integrates into the bacterial chromosome; such a phage is called a *prophage* and the cell that contains it is called a *lysogen*. The product of the *cI* gene, λ repressor, is essential for lysogenic growth. This protein binds to the operators, O_L and O_R , blocking transcription of the early genes (from P_L and P_R) and preventing lytic growth. Binding to O_R also stimulates transcription from P_{RM} , a promoter that transcribes the *cI* gene. Lambda repressor thus maintains the lysogenic state by repressing the transcription of genes necessary for lytic growth as well as stimulating transcription of itself. There are mutant strains of *E. coli* called *hfl⁻*, used for the construction of λ gt10 libraries (UNIT 1.11 and Chapter 5), in which a wild-type phage almost always becomes a lysogen.

The actual sequence of events leading to integration begins (as it does during lytic

A number of bacteriophages—including 434, 21, 82, and 80—are related to phage λ , as evidenced by significant stretches of DNA homology. Unique to each phage, however, is its immunity (*imm*) region (see sketch 1.9C). This region includes a number of important regulatory sites and genes such as P_L and P_R , *cI* and *cro*, as well as O_R and O_L , and P_{RM} . A host cell stably lysogenized with a particular lambdoid phage is immune to infection by a second phage carrying the same *imm* region as the lysogen, because transcription from P_L and P_R of the incoming phage is repressed. A lyso-

Sketch 1.9C

gen can, however, be infected by a phage carrying a different *imm* region. This phenomenon occurs because the repressor encoded by a particular immunity region specifically recognizes and represses only its own promoters.

Induction

Lambda lysogens are *induced* when they excise from the host chromosome and undergo lytic growth. Excision requires the phage *int* and *xis* (excise) gene products. These are synthesized from the *N*-antiterminated P_L transcript. Initiation of P_L transcription occurs when the *cI* product (λ repressor) is inactivated. Induction occurs spontaneously at a low frequency in λ lysogens. However, it is more often due to (1) cleavage of λ repressor during the SOS response (see below), or (2) destabilization of a thermosensitive mutant repressor at nonpermissive temperatures.

In the laboratory, the bacterial *SOS response* is often induced by DNA damage caused by exposure of the cells to agents such as UV light or mitomycin C. During this response, LexA, a bacterial repressor protein, is inactivated and various bacterial genes are induced. Repressor proteins of λ and related bacteriophages resemble LexA and are also inactivated. Some clon-

ing vectors contain a temperature-sensitive mutation in the *cI* gene (*cI^{ts}*). As a result, the repressor is stable and behaves like the wild-type repressor at 30°C, but is unstable at 42°C. *cI^{ts}* mutations allow lytic growth to be induced simply by increasing the temperature at which the lysogen is grown.

E. REQUIREMENTS FOR INDUCTION OF A LYSOGEN

***int* and *xis* proteins.** Necessary for the excision of the phage DNA from the host chromosome.

Lytic growth requirements. Necessary for a productive burst of phage (see box A).

Lambda as a Cloning Vector

ADVANTAGES OF USING LAMBDA

About the middle third of the λ genome is dispensable for lytic growth. Derivatives of phage λ that are used as cloning vectors typically contain restriction sites that flank some or all of these dispensable genes. The major advantage to using lambda-derived cloning vectors is that DNA can be inserted and packaged into phages in vitro. Although the efficiency of packaging only approaches 10%, phages, once packaged, form plaques on *E. coli* with an efficiency of 1. While techniques for transformation of bacterial plasmids have improved greatly in recent years (see UNIT 1.8), the best routinely attainable frequencies are about 10^8 transformants/ μg pBR322, which means that less than 1 in 1000 plasmids become transformed into cells.

SELECTIONS FOR INSERTED DNA

Some phage vectors exploit the fact that λ has a minimum genome size requirement for packaging, so that vector phages that do not contain inserts above a minimum size are never detected. Other phage vectors utilize some genetic means to distinguish between phages that still retain the block of nonessential genes and recombinant phages in which the block of genes has been replaced with foreign DNA. Since the selection for the insert does not depend on the size of the inserted fragment, many of these vectors allow small fragments to be cloned.

Size selection. Lambda cannot be packaged into phage heads if its genome is less than 78% or more than 105% of the length of wild-type λ DNA. When a vector is chosen on the basis of size selection, the region dispensable for growth is cut out; the left and right arms of the phage are then purified and ligated to cut foreign DNA under conditions that favor concatemer formation. Those phages whose left and right arms have not been joined to an insert will have *cos* sites too close together to be packaged into viable phage. The existence of the size requirement for efficient phage packaging makes it impossible to use a single phage vector to clone fragments of all sizes: phages that can accommodate large inserts cannot be packaged if they contain small inserts, and vice versa. There are two special size selection tricks that have sometimes found use in phage cloning. In the first, packaged phage are treated with EDTA or other chelating agents. The population of surviving phage is enriched for phages with shorter than wild-type genomes. In the second, phage are plated on a mutant strain of *E. coli* called *pel⁻* which allows plaque formation by phages of

up to 110% of wild-type length and which severely inhibits plaque formation by phages of less than wild-type length.

***spi⁻* selection.** *red⁺ gam⁺* phages do not form plaques on a host lysogenic for the unrelated bacteriophage P2. These phages are said to be *spi⁺* (sensitive to P2 interference). *red⁻ gam⁻* phages do form plaques on P2 lysogens, and so are said to be *spi⁻* (Zissler et al., 1971). P2 inhibition of *red⁺ gam⁺* phage growth only occurs if the P2 is wild-type for a gene called *old*. Commonly used vectors like λ 2001 (Karn et al., 1984) and λ EMBL3 (Frischauf et al., 1983) contain a fragment with the *red⁺* and *gam⁺* genes. These vectors will not form plaques on a P2 lysogen unless the *red⁺ gam⁺* fragment is deleted and replaced with a piece of foreign DNA.

***hfl⁻* selection.** The product of the λ *cII* gene is necessary for infecting phages to synthesize repressor efficiently. The *E. coli hflA* and *hflB* genes encode products whose effect is to decrease the stability of the *cII* gene product (Banuett et al., 1986; Hoyt et al., 1982). When wild-type λ infects an *hfl⁻* strain, so much repressor is made that the phage almost always lysogenizes the infected cell, causing it to form either no plaque or an extremely turbid plaque. Vectors like λ gt10 contain a restriction site in the *cI* gene. Insertion of foreign DNA into this site inactivates the *cI* gene. The vector phage does not form plaques on the *hfl⁻* strain, but phages containing inserts instead of the *cI* gene form clear, normal-sized plaques.

MAPS OF LAMBDA-DERIVED CLONING VECTORS

Maps are presented for phage cloning vectors that are currently used to construct libraries, as well as maps for not-so-modern vectors which were employed to construct libraries that are still important.

The top of each page shows a simplified version of the map of wild-type lambda. The next lines show the changes that were made in the wild-type λ genome to generate that derivative. Deletions of lambda DNA are indicated by parentheses, and insertions of new DNA are indicated by bars. The bottom lines show transcripts, a genetic map, and a physical map of the resulting λ derivatives. The genetic nomenclature used, especially for deletions and changes in restriction sites, is extremely complicated. More explanation can be found in UNIT 1.9, in Lambda II by Hendrix et al. (1983), and in the articles cited in the figure legends.

1.10.1

Figure 1.10.1 Wild-type lambda. Role of the major phage transcripts (arrows) and phage genes (boxes) in the lifecycle of bacteriophage λ is described in *UVITS 1.9 & 1.10*.

Figure 1.10.2 λ EMBL3. This phage vector is used for cloning large (10.4 to 20 kb) fragments. It contains a polylinker with cloning sites for *Bam*HI, *Sal*I, and *Eco*RI; in EMBL4, the polylinker is reversed. Recombinant phages containing DNA inserted into these sites become *cl'*, *gam'*, *red'*, and *int'*, and thus have the *Spi* phenotype. Although the phage is said to carry *cl857*, we believe that it does not carry a *cl* gene, and it has been drawn accordingly. The polylinker sequence is GGATCTGGTCCGACGGATCCGGGAATCCAGATCC. EMBL4's full genotype is λ sbh1 λ 1° b189 < polylinker (SalI-EcoRI) *int*29 *nin*L44 *cl857* *trpE* polylinker (EcoRI-SalI) > KH54 *chiC* srl λ 4° *nin*5 srl λ 5° (Frischauff et al., 1983).

Figure 1.10.3 $\lambda 2001$. This phage is used for cloning large (10.4 to 20 kb) DNA fragments. Phages containing foreign DNA become cl^- , gam^- , int^- , and red^- . Since recombinants are red^- and gam^- , they have the Spi^- phenotype, and form plaques on a strain lysogenic for bacteriophage P2 (see *UNITS 1.9* and *1.10*). The vector contains cloning sites for *Bam*HI, *Eco*RI, *Hind*III, *Sac*I, *Xba*I, and *Xho*I. The polylinker sequence is **TCTAGAGCTCGAGGATCCCAAGCTTCAATTC**TAGA. $\lambda 2001$'s full genotype is λ sbhl $\lambda 1^\circ$ b189 Eint(linker) srl $\lambda 3^\circ$ ninL44 EshndIII $\lambda 4$ (bio) (linker) δ (sbhl) $\lambda 3$ -sbhl $\lambda 4$ KH54 srl $\lambda 4^\circ$ chiC nin5 srl $\lambda 5^\circ$ shndIII $\lambda 6^\circ$ (Kam et al., 1984).

Figure 1.10.4 λ_{gt10} . This phage vector accepts small (0 to 5 kb) DNA fragments which are inserted into an RI site in its *ci* gene. Insertion of DNA into this site inactivates the *ci* gene and enables insert-containing phages to form plaques on a *hrfI* host. Since insert-containing phage form plaques very efficiently on this host, and since the plaques formed by insert-containing phage are usually very healthy, λ_{gt10} is very frequently used to construct libraries for which only very small amounts of DNA are available, for example in the construction of cDNA libraries. Insert-containing λ_{gt10} phage are *ci⁻* and *int⁺* but *red⁺*. Its full genotype is λ_{b527} *srI* λ_3^+ *imm⁺* *srI* λ_4^+ *srI* λ_5^+ (Huynh et al., 1984).

Figure 1.10.8 λ ZAP. λ ZAP carries pBluescript SK (-), which is excised in vivo upon infection with f1 or M13 helper phages. Inserts are cloned into λ ZAP within Bluescript sequences. Specifically, inserts are cloned within a polylinker located within *lacZ*. As with λ gt11, a fusion protein may be expressed if the insert DNA is in frame with the *lacZ* sequence; thus, libraries made in this vector can be screened with antibodies. In λ ZAP, T7 and T3 promoters flank the inserts, which allows RNA probes to be easily obtained. pBluescript M13 (-), the excised plasmid (shown on the right), is normally propagated as a double-stranded circular DNA, but infection with a helper phage enables the plasmid to be propagated as single-stranded DNA. These properties facilitate sequencing of the insert, site-directed mutagenesis, and the construction of unidirectional cloning sites are available. λ ZAP/R is shown in the figure. Within the polylinker, unique *XhoI*, *EcoRI*, *SpeI*, *XbaI*, *NofI*, and *SacI* λ ZAP vectors are available from Stratagene.

THE COSMID, A USEFUL LAMBDA-DERIVED PLASMID VECTOR

Cosmids were developed to allow cloning of large pieces of DNA. How they work is diagrammed in Figure 1.10.9. Cosmids contain a selectable marker, a plasmid origin of replication, a site into which DNA can be inserted, and a *cos* site from phage λ . The vector is cut with a restriction enzyme and mixed with pieces of DNA to be cloned. DNA ligase joins cut vector and insert fragments into concatemeric molecules. The ligation mixture is then mixed with a *packaging extract* (see UNIT 1.11) containing the proteins necessary to package

naked phage DNA into phage heads. Whenever two *cos* sites are present on a concatemer and separated by 40,000 to 50,000 nucleotides, they will be cut and packaged into phage heads. The cosmid-containing phages are infectious, they inject DNA into cells, but the DNA is plasmid DNA: the phage adsorbs to the host and the cosmid DNA is injected into the cell, which circularizes due to its sticky ends. The annealed ends are then covalently joined by the host's ligase, and the resulting large circular molecule replicates as a plasmid (see map, Fig. 1.10.10).

Cosmid vectors within cells replicate using

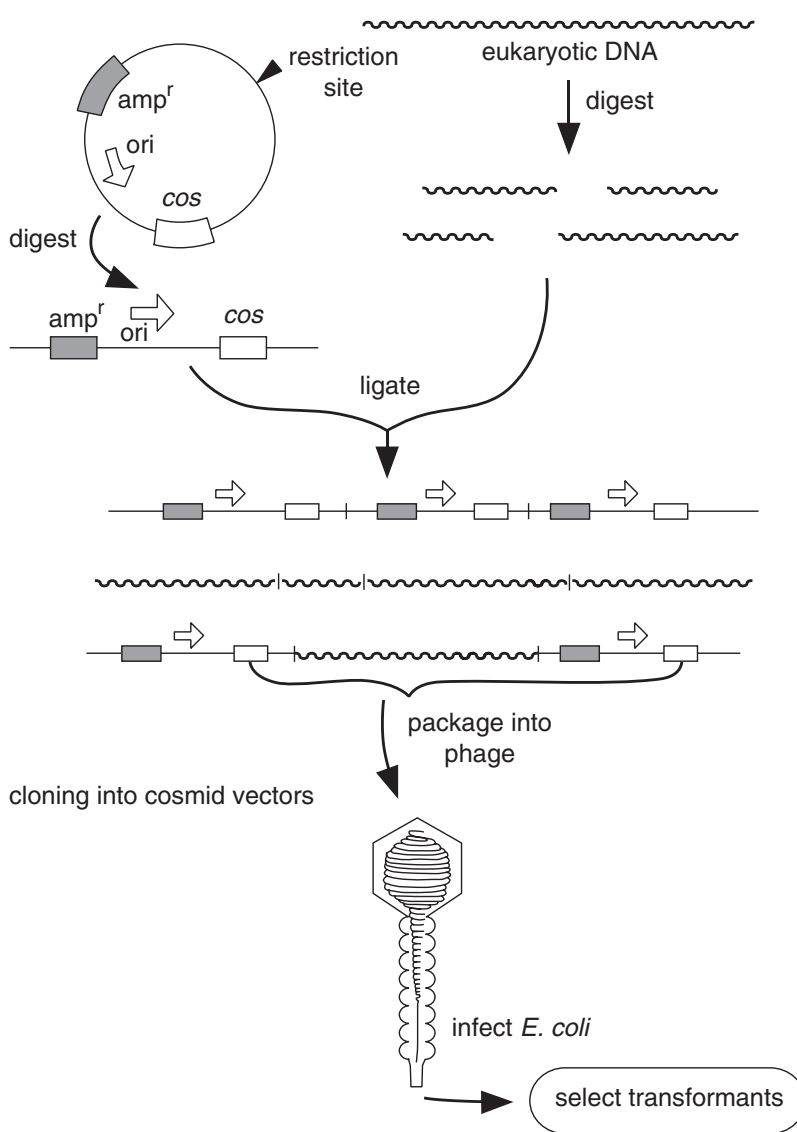

Figure 1.10.9 Cloning into cosmids.

Figure 1.10.10 pJB8 is a commonly used cosmid vector. It contains a *cos* site, an ampicillin resistance gene, and a pMB1 replicator, so it can be amplified with chloramphenicol. In a typical application, libraries are constructed by insertion of random *Sau3a* partial-digestion fragments of DNA into its *Bam*HI site. The inserts can be excised by cleaving the plasmid at its flanking *Eco*RI sites (Ish-Horowitz and Burke, 1981).

their pBR322 origins. Intracellular cosmids sometimes rearrange DNA inserted into them, perhaps because the time it takes pBR322-dependent replication to replicate the 50,000-bp cosmid is almost as long as the generation time of *E. coli*, so that cosmids which have deleted sections of DNA have a growth advantage on antibiotic-containing medium. Although this problem can be ameliorated by propagating the cosmids in cells that are less prone to rearrange vector DNA (UNIT 1.4), another approach may well become more popular. Cosmid vectors (called *lorist vectors*) have recently been developed that are said to circumvent this problem by using the λ *ori* and *O* and *P* proteins to replicate (see, for example, Gibson et al., 1987). It takes only a few minutes for these vectors to replicate inside cells, and insertions in them are said to be more stable.

Plating Lambda Phage to Generate Plaques

ISOLATING A SINGLE PLAQUE BY TITERING SERIAL DILUTIONS

This procedure is used to isolate pure populations of phage from a single plaque and provide the titer of the phage stock. Serial dilutions are made of a phage lysate. In separate tubes, aliquots of each dilution are mixed with *E. coli*. Phage are allowed to adsorb to the cells and the cell/phage mixture is then heated to 37°C, causing the phage to inject their DNA into the cells. Top agar is added to each tube, and the mixture is poured onto rich plates, which are incubated at 37°C until plaques appear. Each plaque contains phages derived from a single infecting phage.

Materials

Lambda broth (UNIT 1.1)
 0.2% maltose
 10 mM MgSO₄
 Lambda top agar (UNIT 1.1)
 Suspension medium (SM)
 Fresh lambda plates (UNIT 1.1), prewarmed to 37°C

Microwave oven or boiling water bath
 45° to 50°C water bath
 8 × 80–mm tubes
 37°C water bath or heat block
 Capillary tubes or toothpicks

NOTE: All materials coming into contact with *E. coli* must be sterile.

1. Grow a culture of *E. coli* to saturation in lambda broth + 0.2% maltose + 10 mM MgSO₄.

Growth in maltose induces production in E. coli of the λ receptor (lamB protein), which is necessary for maltose transport. Mg⁺⁺ ions also aid phage adsorption.

2. Melt top agar in microwave oven set to defrost setting, or in boiling water bath for 15 min. After agar is melted, let bottle cool at room temperature for 5 min, then place bottle of melted agar in 45° to 50°C water bath.

The cap to the bottle of top agar must be loose before putting it in microwave! Watch the microwave oven to make sure that the contents of the bottle of top agar do not boil over. If agar boils over, carefully take the bottle out and swirl it around to see if there are any unmelted flecks of agar. If there are, reinsert into oven and microwave longer, inspecting occasionally, until the agar is completely melted.

Be sure top agar is left in the water bath enough time to cool to 45° to 50°C. Cells will be killed by even brief exposure to agar that is hotter than 65°C.

3. Add 0.3 ml of the *E. coli* culture to five 8 × 80–mm tubes.
4. Make serial dilutions of the phage lysate in SM (see UNIT 1.3 for serial dilutions).

Dilution factors of 100-fold are usually used. Label the dilution tubes so that they do not get mixed up.

5. Add 0.1 ml of the first dilution to one tube of *E. coli*, 0.1 ml of the next dilution to the next tube, etc. Label the tubes of *E. coli*/phage mixture, so that they do not get mixed up. Incubate tubes at room temperature for 20 min.

The phage adsorb to the E. coli during this step.

6. Move tubes to a 37°C water bath or heat block for 10 min. While tubes are in

water bath, label 5 fresh, prewarmed lambda plates to correspond with the labels on the dilution tubes.

During this step, the phage inject their DNA into the cells.

Plates should be fresh, but not so fresh that they are wet on their surfaces, nor so wet that they will exude moisture and cause the lawn of cells in top agar to slide away.

7. Remove tubes from the water bath. Add 2.5 ml top agar to one tube, vortex lightly to mix, and pour the contents of tube onto a plate. Spread agar over the entire surface of the plate by tilting it gently.
8. Place the plates in a 37°C incubator. Plaques of lambda-derived phages will appear after 6 to 8 hr, but will be easier to score, count, and pick if left for 12 hr.
9. From one of the dilution plates that is not too crowded with plaques, pick a single plaque with a sterile capillary tube or toothpick. To save the plaque for future use (for example, to make a plate stock), cut out a plug of agar containing the plaque with a capillary tube, and blow the plug into a tube containing 1 ml of SM (or place the tip of the toothpick in the liquid and agitate gently). If desired, count the number of plaques on one of the dilution plates and use this number to compute the number of viable phage in the starting stock.

Background Information

Titration of bacteriophage, and isolation of phage from single plaques, was first described by d'Herelle in 1920. The best general background to bacteriophage growth protocols is probably found in Stent (1971).

Genes encoding the tail proteins of most lambda-derived cloning vectors come from phage λ . Vectors with these tail proteins, said to be “h λ ” (for host range of λ), adsorb to the cell *lamB* protein, which is involved in maltose uptake. These vectors make plaques with sharp boundaries. Some vectors have tail proteins derived from phage 80 and are said to be “h80.” These vectors adsorb to the host *tonA* protein, which is involved in ion transport. They make slightly larger plaques with fuzzier borders than those made by h λ phages. Stocks of h80 phages usually have a higher titer than stocks of corresponding h λ phages.

Troubleshooting

It is sometimes helpful to include two other control plates in the procedure. One is a plate that contains a lawn made from a separate tube of the *E. coli* culture that has not been infected with phage. The other is a plate that contains top agar that did not contain any cells. These two controls provide benchmarks for growth of the lawn, as it becomes denser during the time in the incubator. If the lawn appears crinkled, then the top agar/*E. coli*/phage mixture was probably too cold by the time it was poured onto the plate. If this occurs, try warming the plates up to 37°C before pouring the lawn onto them, or pouring the lawns more quickly after the top agar is added to the *E. coli*/phage mixture. If the top agar layer floats off the plate, then the plates were too wet. If this occurs, use dryer plates.

Time Considerations

It takes from 6 to 8 hr of incubation at 37°C before plaques appear, and is often 12 to 14 hr before differences in morphology can be reliably distinguished.

ISOLATING SINGLE PLAQUES BY STREAKING ON A LAWN OF CELLS

Phages are streaked for single plaques on a plate containing a pre-poured lawn of *E. coli*. This procedure is easier than titering by serial dilutions, and is recommended if only a few isolated plaques are needed.

Materials

- LB medium (UNIT 1.1)
- Lambda top agar (UNIT 1.1)
- Rich plate (UNIT 1.1), prewarmed to 37°C
- 32-G platinum wire loop or sterile 1½ × ⅛ in. strips of paper

1. Grow a lambda-sensitive strain of *E. coli* to saturation in 5 ml LB medium.
2. Add 0.2 ml of the saturated culture to 2 ml of melted top agar (cooled to about 45°C; see step 2, p. 1.11.1), and pour evenly over the top of a prewarmed, rich plate.

In the recipe for top agar (UNIT 1.1), agar can be replaced with 6 g agarose.

3. After top agar has hardened, cool plates by placing in refrigerator ≥15 min.
4. Spot 100 µl of λ stock culture (usually around 10⁸ phage/ml) on the corner of the plate.
5. Using the techniques described in UNIT 1.3 to streak out single bacterial colonies, *lightly* streak out the phage using a thin wire loop or the edge of a sterile 1½ × ⅛ in. piece of paper.

Paper should be cut into strips and sterilized by autoclaving (dry) in screw-cap vials.

PHAGE TRANSFECTION AND IN VITRO PACKAGING

Construction of a library with lambda-derived cloning vectors results in a population of phage DNA molecules. In order for these molecules to be replicated, they must be introduced into cells so that they can grow as phage. Phage DNA is typically introduced into cells either by infection after packaging into phage particles *in vitro* or, much less frequently, by *transfection*, that is, transformation of phage DNA that has been circularized by treatment with DNA ligase into competent cells.

In vitro packaging uses lysates of phage-infected *E. coli* called *packaging extracts*. These lysates contain empty phage heads, unattached phage tails, and the phage-encoded proteins required for DNA packaging (see UNIT 1.9). If ATP is present, then concatemeric phage DNA mixed with the extract is cut at one *cos* site by the terminase (probably a complex of the *A* and *Nul* proteins) and loaded into the phage head by an unknown mechanism. DNA continues to be loaded into the phage head until the terminase encounters and cuts the next *cos* site on the molecule. The phage tails then attach themselves to the filled heads.

In the early 1980s, production of high-efficiency packaging extracts was considered one of the biggest inconveniences in library construction. To avoid the work involved, most researchers now use frozen packaging extracts purchased from commercial suppliers (see Enquist and Sternberg, 1979). Commercial extracts typically yield 2 × 10⁸ to 2 × 10⁹ plaque-forming particles per µg of concatemeric phage DNA. Phage DNA can also be introduced into *E. coli* by transformation of competent cells. In this procedure, linear or circular phage DNA is mixed with competent *E. coli*, and the mixture of cells and DNA is treated as in UNIT 1.8. After the heat shock step, the calcium-treated cells are mixed with *E. coli* that have been grown in lambda broth and maltose as described in first basic protocol. Molten top agar is then added, the mixture is poured

onto a lambda plate, allowed to solidify, and incubated at 37°C until plaques appear. This procedure typically yields 10⁴ plaques/μg of phage DNA.

REAGENTS AND SOLUTIONS

Suspension medium (SM), per liter

5.8 g NaCl

2 g MgSO₄·7H₂O

50 ml 1 M Tris·Cl, pH 7.5

0.01% gelatin (Difco)

Growing Lambda-Derived Vectors

It is often necessary to grow large quantities of lambda-derived vectors, so that DNA can be made from them (see UNIT 1.14). The following basic protocol tells how to make a phage stock by plate lysis, while the alternate protocol tells how to make a liquid lysate. Storage of phage lysates is described in the support protocol.

BASIC PROTOCOL

MAKING A STOCK OF PHAGE BY PLATE LYSIS

Phage from a single plaque are mixed with cells and top agar and poured onto a plate. Although there are initially more cells than phage in the lawn, the phage increase their number more rapidly than the cells, and eventually lyse most cells on the plate. The top agar is then scraped off the plate and the phage in it are extracted and saved.

Materials

Fresh lambda top agar (UNIT 1.1)
 Fresh lambda plates (UNIT 1.1), prewarmed to 37°C
 Suspension medium (SM; UNIT 1.11)
 Chloroform
 45° to 50°C water bath
 Capillary tube or toothpick
 Beckman JA-21 rotor or equivalent

NOTE: All materials coming into contact with *E. coli* must be sterile.

1. Dilute a fresh overnight culture of a lambda-sensitive strain of *E. coli* 50-fold and grow in culture tube on a roller drum at 37°C.
2. Melt 100-ml bottle of fresh lambda top agar by heating in microwave oven set to defrost. Place in 45° to 50°C water bath.
3. When cell density reaches 2 to 3 × 10⁸/ml (OD₆₀₀ = 0.4), place 0.75 to 1 ml of cells into a test tube. Pick a single fresh plaque with capillary tube or toothpick, blow the plug into cells, and vortex lightly for 10 sec.
4. Add 7.5 ml top agar, vortex gently, and pour equal amounts of the mixture onto three prewarmed fresh lambda plates.

If agar in the top agar and plate recipes is replaced by agarose, the extractable DNA will be an acceptable substrate for restriction enzymes and ligases.

5. Incubate plates at 37°C, typically for 4 to 6 hr, until plaques are clearly visible and when 90% to 100% of the lawn is lysed.
6. Pipet 3 ml SM onto plate. Using clean microscope slide, scrape top agar from all 3 plates into a small centrifuge tube (e.g., a 15-ml screw-top tube for the Beckman JA-21 rotor).
7. Add 3 drops chloroform. Vortex vigorously for 10 sec.
8. Leave at room temperature 10 min.

As an alternative to steps 6 through 8, 3 ml SM and 3 drops chloroform can be dribbled onto the plate, the plate left overnight at 4°C, and the liquid decanted and centrifuged as below.

9. Centrifuge 10 min at 10,000 rpm in JA-21 rotor (11,400 × g), 4°C.
10. Gently decant and save supernatant.

MAKING A LIQUID LYSATE

Host bacteria grown to saturation are infected with 10^5 to 10^8 phage/ml. Following phage adsorption, the infection mixture is diluted into a rich medium and shaken vigorously until cell lysis. Any remaining viable cells are lysed with chloroform, and cell debris is removed with a low-speed spin.

Additional Materials

LB medium (UNIT 1.1)
Lambda dilution buffer
10 mM $MgCl_2$ /10 mM $CaCl_2$
NZC medium (UNIT 1.1)
Beckman JA-20 rotor or equivalent

1. Grow an overnight culture of a lambda-sensitive strain of *E. coli* in LB medium at 37°C.

Lambda-sensitive strains will support lytic growth. This can be tested by spotting 10 μ l of a lambda lysate onto a lawn of bacteria. If the strain is lambda-sensitive, a plaque will form where the phage were spotted.

2. Using a sterile toothpick or capillary tube, pick a single plaque (see step 3 of basic protocol), blow it into a tube that contains 0.4 ml lambda dilution buffer, and place tube at 4°C for 2 hr to allow phage to elute.

Alternatively, 10^5 to 10^8 phage from a liquid lysate or plate stock can be used.

3. Combine 0.1 ml eluted phage with 0.1 ml of saturated culture and 0.1 ml of 10 mM $MgCl_2$ /10 mM $CaCl_2$ solution and incubate 15 min in a 37°C water bath.

Incubating with Mg^{++} and Ca^{++} allows the phage to adsorb to the bacteria.

4. Transfer this solution to 50 ml of NZC medium and shake *vigorously* at 37°C until lysis occurs (usually between 6 and 8 hr).

Good aeration is important for high yields.

5. The culture should be checked frequently after 6 hr, and harvested immediately upon clearing.

6. Add a few drops of chloroform to lyse any remaining cells, transfer the solution to Co-rex or Nalgene tubes (being careful to leave the chloroform behind), and spin 10 min at 10,000 rpm ($12,100 \times g$), 4°C, to pellet the cell debris.

7. Save as much of the lysate as desired. Transfer to a screw-cap tube, add a few drops of chloroform, vortex briefly, and store at 4°C.

The titer of the phage should be determined as described in UNIT 1.11.

STORING PHAGE LYSATES

Phage stocks should be stored in SM (UNIT 1.11) plus a few drops of chloroform at 4°C. Screw-cap glass tubes with rubber-lined or teflon caps, capable of holding at least 1 ml, are generally used, although disposable plastic tubes work well. Lambda titers drop over a period of several years. Stocks should be dated and checked occasionally to determine phage titer. Addition of 0.1% gelatin to the SM slows down the rate at which phage titers drop when stored under these conditions. Lysates can also be stored frozen in 15% glycerol.

REAGENTS AND SOLUTIONS

Lambda dilution buffer

20 mM Tris·Cl, pH 8
20 mM $MgCl_2$

SUPPORT PROTOCOL

*Escherichia coli,
Plasmids, and
Bacteriophages*

1.12.2

COMMENTARY

Background Information

Plate lysis is typically used to make small phage stocks, which are then used as intermediates for making larger stocks for preparation of phage DNA. However, if agar is replaced by agarose in the plate recipe and in the top agar (see *UNIT 1.1*), then DNA extracted from phage in the lysate is an acceptable substrate for restriction enzymes and ligases.

Liquid lysates generally give slightly lower yields than plate lysates. Less work is required, however, especially when large quantities of phage are needed. This fact, taken together with the fact that there is no contaminating agar in the lysate, makes this method preferable for isolating phage for DNA preps. In the liquid lysis procedure, cells are diluted into NZC medium after phage adsorption. This is a rich medium that contains amino acids but no glucose or other sugars. In cells grown in this medium, sugar receptors like LamB protein are fractionally induced (so phage can adsorb to the cell), but cells are not covered with so many receptors that adsorption to their debris depletes the yield of phage from the lysate. In addition, cells grown on this medium seem to cause infecting phage to grow lytically, which helps to obtain high titers of turbid phages.

Critical Parameters

LB medium and top agar can replace lambda plates and top agar for the plate lysis method, but the phage yield is usually lower. It is important that the plates be freshly poured, and that the top agar be freshly melted. The plates do not even have to be dry; a loose lawn is no problem as long as the plates are not tilted. If the yield is less than expected, it may be because the plates were not fresh, or because the particular phage used does not give a burst as large as that given by wild-type lambda. The size of single plaques made by the phage sometimes gives a clue that the second problem obtains. If plaques made by the phage in question are smaller than those made by closely related phages, it is often worthwhile to reduce the number of starting cells, or to increase the starting number of phage by combining several plaques, and to incubate the plates longer until

the lawn is completely lysed.

In the liquid lysis method, good aeration is essential for high yields. Flasks should be no more than $\frac{1}{5}$ full. Cultures should be watched carefully as they approach lysis and harvested soon after lysis is complete to prevent released phage from reinfecting cell debris. Lysis usually takes between 6 and 8 hr. If there is no sign of lysis after 8 hr, there probably will not be any, and one can either go on to add the chloroform and complete the procedure, or abandon hope and start over.

Anticipated Results

The plate lysis procedure yields ~10 ml of a phage stock containing 10^{10} to 10^{11} phage/ml. The liquid lysis procedure usually yields a stock with 5×10^9 to 3×10^{10} phage/ml.

Time Considerations

The plate lysate procedure usually takes about 8 hr. The liquid lysate procedure takes 2 hr to elute the phage from the plaque, and 6 to 9 hr between the time the cells are infected and the time the lysate is harvested. The time required to elute the phage is very flexible. Two hours will ensure that more than 90% of the phages are eluted from the plaque; shorter elution times allow less phage to be eluted. Elution times as short as 30 min generally work but do not always give good lysis. Phage may be eluted for longer periods of time; overnight is often convenient. Once the host cells are infected, it takes ~6 to 9 hr for lysis and preparation of the lysate.

Preparing Lambda DNA from Phage Lysates

UNIT 1.13

DNA extracted from lambda-derived vectors is typically subcloned into plasmid or filamentous phage vectors. The first two protocols describe methods for isolating phage DNA from large- and medium-scale liquid lysates. These two methods use either density-gradient centrifugation or ion-exchange chromatography to purify the phage particles. The third protocol describes a rapid procedure for isolating phage DNA, suitable for small-scale liquid lysates.

PREPARING DNA BY STEP- AND EQUILIBRIUM-GRADIENT CENTRIFUGATION

BASIC
PROTOCOL

A scaled-up liquid lysate is used to prepare a large quantity of highly purified phage DNA. Phage is separated from cellular debris by a CsCl step gradient followed by equilibrium-gradient centrifugation. Two alternate sets of steps are provided for extracting λ DNA from CsCl-purified phage particles. In the first method, CsCl is removed by dialysis and the DNA is extracted by phenol and chloroform. In the second approach, phage DNA is extracted directly from CsCl-purified phage particles with high-grade formamide.

Materials

- 5 \times polyethylene glycol (PEG) solution
- Suspension medium (SM; UNIT 1.11)
- Potassium chloride
- CsCl solutions
- Low-salt buffer
- Buffered phenol (UNIT 2.1)
- Chloroform
- 2 M Tris·Cl (pH 8.5)/0.2 M EDTA (optional, for formamide extraction)
- Formamide (*very* high grade, preferably recrystallized; optional)
- TE buffer, pH 8.0 (APPENDIX 2)
- Beckman JA-10, JA-20, SW-28, and VTi50 rotors and bottles/tubes (or equivalents)
- 3-ml syringe with 25-G needle
- Beckman VTi50 quick-seal tubes
- Additional materials for preparing liquid phage lysate (UNIT 1.12), titering lambda phage (UNIT 1.11), and quantitation of DNA (APPENDIX 3)

Prepare and concentrate the phage

1. Use 25 ml liquid lysate to make a 1000-ml lysate (see UNIT 1.12).
2. Split the lysate into two JA-10 centrifuge bottles and spin 10 min at 10,000 rpm (17,700 \times g), 4°C, to remove cell debris.
3. Transfer supernatant to a 1000-ml graduated cylinder and add 5 \times PEG solution to a final concentration of 1 \times . Invert gently to mix. Let sit overnight at 4°C.

The PEG solution causes the phage to precipitate.

4. Remove ~50 ml of supernatant and save for step 5. Pour off remaining supernatant, being careful not to lose any of the white precipitate.
5. Transfer precipitate to Nalgene centrifuge tube. Rinse cylinder with saved supernatant and transfer to centrifuge tube. Spin 10 min in JA-20 rotor at 5000 rpm (3000 \times g), 4°C.

1.13.1

Supplement 10

- Place centrifuge tubes on ice. Remove the top layer, being careful not to remove any of the thick white phase, which contains the PEG solution and the phage.
- Resuspend the white phase in a minimum volume of SM. Transfer to a 125-ml flask.
The volume of the suspension medium added should not be more than three times the volume of the white phase.

- Determine the amount of solid KCl needed to make a 1 M solution. Add this amount of KCl in four aliquots of approximately equal size, mixing well after each addition. Let sit on ice for 15 to 30 min.
Adding KCl precipitates the PEG solution slowly while leaving the phage behind.

- Transfer to Nalgene centrifuge tube and spin 10 min in a JA-20 rotor at 10,000 rpm ($12,100 \times g$), 4°C .
The PEG solution will be pelleted and the phage will remain in the supernatant.

- Measure the phage titer and keep the supernatant in a 16- or 18-mm glass test tube.
The phage titer should be $\sim 1 \times 10^{12}$ to 5×10^{13} pfu/ml.

Isolate the phage particles

- Pour a CsCl step gradient in an SW-28 centrifuge tube as follows:

First layer: 3.5 ml CsCl solution, $d = 1.7 \text{ g/ml}$
 Second layer: 2.5 ml CsCl solution, $d = 1.5 \text{ g/ml}$
 Third layer: 2.5 ml CsCl solution, $d = 1.3 \text{ g/ml}$

The layers must be added very slowly to avoid mixing.

- Carefully layer the lambda lysate (supernatant from step 10) on top of this gradient (see sketch 1.13A).
- Fill tube to just below the top with SM. Spin 2 hr in an SW-28 rotor at 24,000 rpm ($104,000 \times g$), 4°C .
- Recover the phage band by inserting a 3-ml syringe with a 25-G needle into the side of the tube just below the band and drawing it into the syringe (see Fig. 1.7.1 in CsCl/EtBr plasmid prep, UNIT 1.7).

Usually, three bands are visible: one blue phage band at the lowest gradient, one blue

Sketch 1.13A

band containing empty phage heads, and one white cell debris band. Occasionally one or two of these bands are missing. This is not a problem as long as the band that is visible is in the $d = 1.5$ g/ml layer. If no band is visible, there are probably not enough phage to make it worthwhile continuing the procedure. If the layers are not clearly defined, but a bluish band appears at about the right place, recover the band and determine its density by weighing 100 μ l of the lysate. If its density is ~ 1.5 , it probably is phage.

15. Transfer the phage to Beckman VTi50 quick-seal tubes. Fill tubes with CsCl solution ($d = 1.5$ g/ml).

About half the weight of the phage particle is protein; the other half is DNA. Phage DNA is denser than phage proteins. Thus, phages with genomes larger than wild-type are denser than phages with wild-type-length genomes, and phages with smaller genomes are less dense.

16. Spin 24 hr in VTi50 rotor at 30,000 rpm ($81,500 \times g$), 4°C.
17. Remove the band as shown in Figure 1.7.1 of CsCl/EtBr plasmid prep (UNIT 1.7), using a 3-ml syringe and a 25-G needle. Only one band should be visible.

Extract the phage DNA

Two methods are presented below for extracting DNA from purified phage. In steps 18a to 21a, cesium chloride is removed by dialysis prior to extraction of DNA with phenol and chloroform. In steps 18b to 21b, DNA is extracted directly from the isolated phage with high-grade formamide. The latter approach is quicker and possibly gentler.

Dialysis and phenol/chloroform extraction:

- 18a. Dialyze, with stirring, in 500 ml low-salt buffer for ≥ 4 hr at 4°C. Repeat twice.
- 19a. Extract three times by agitating gently for 20 min with an equal volume of buffered phenol.
- 20a. Extract twice using an equal volume of chloroform.
- 21a. Dialyze, with stirring, in 500 ml TE buffer, pH 8.0, for 8 hr at 4°C. Change buffer once. Proceed to step 22.

Residual phenol and chloroform are removed by dialysis rather than ethanol precipitation because purified phage DNA is very difficult to resuspend.

Formamide extraction:

- 18b. Measure the volume of phage band from step 17. Add 0.1 vol of 2 M Tris-Cl (pH 8.5)/0.2 M EDTA and invert to mix.
- 19b. Add 1 vol formamide, mix, and let stand 30 min at room temperature.
- 20b. Add 2 vol (each equal to the original volume of phage band in step 18b) of 100% ethanol at room temperature. Mix gently and microcentrifuge 1 to 2 min.
- 21b. Discard supernatant and rinse pellet with 70% ethanol. Remove all droplets of ethanol with a drawn-out pipet and dissolve the moist pellet in TE buffer, pH 8.0.
22. Measure DNA concentration as described in APPENDIX 3.

PREPARING DNA USING DEAE-CELLULOSE COLUMN CHROMATOGRAPHY

This protocol employs an ion-exchange resin to preferentially bind contaminants in crude phage lysate (*E. coli* DNA, RNA, and protein) while phage particles pass through the column. The result is a highly purified phage preparation. The DNA is then extracted from the purified phage with organic solvents and precipitated with ethanol. The method is simple, rapid, and does not require DNase, RNase, or CsCl density gradient centrifugation of either phage particles or DNA. The high-quality λ DNA obtained is suitable for cloning, sequencing, restriction enzyme digestion, ligation, and in vitro packaging.

Materials

TM buffer
2% sodium dodecyl sulfate (SDS; optional)
0.1 M EDTA (optional)
Sodium chloride
Polyethylene glycol (PEG) 8000
DEAE-cellulose (microgranular anion exchanger; Whatman DE52 #4057-050)
0.05 N HCl
10 M NaOH
Sodium azide
5 M NaCl
Ice-cold 100% isopropanol
TE buffer, pH 8.0 (APPENDIX 2)
25:24:1 phenol/chloroform/isoamyl alcohol (UNIT 2.1)
3 M sodium acetate, pH 6.0
70% ethanol and ice-cold 100% ethanol

Beckman JA-14 and JA-20 rotors (or equivalents)
15- and 30-ml Corex centrifuge tubes
10-ml disposable syringe (1.4 cm-i.d., optional; Becton Dickinson) *or*
1.5 \times 10-cm standard glass or disposable column (Bio-Rad)
Glass-fiber filter or glass wool (optional)

Additional reagents and equipment for preparing liquid or plate lysate (UNIT 1.12),
titering lambda phage (UNIT 1.11), agarose gel electrophoresis (UNIT 2.5), and
phenol extraction/ethanol precipitation (UNIT 2.1)

Prepare concentrated crude phage lysate

1. Prepare liquid or plate lysate and determine the phage titer. The lysate should contain $1\text{--}2 \times 10^{10}$ pfu/ml in a volume of 200 ml.

When using plate lysates, collect phage in TM buffer (instead of SM) from six big (150 mm) or fifteen small (90 mm) petri dishes and adjust volume to 200 ml.

Alternatively, a 0.7% agarose minigel can be used to detect λ DNA in phage lysates. Treat 20 μ l lysate with 2 μ l of 2% SDS and 2 μ l of 0.1 M EDTA for 5 min at room temperature. Load onto gel. Include size standard and control (nontreated) lanes. In this gel, the SDS/EDTA-treated lysate sample should show a distinct λ DNA band compared to the nontreated sample (Fig. 1.13.1).

2. Add 5.8 g NaCl (0.5 M final) and 20 g PEG 8000 (10% wt/vol final) to 200 ml phage lysate.

If the phage titer is low, it may be necessary to add NaCl first to release phage adhering to the debris. Remove debris by centrifuging 10 min in JA-14 at 6000 rpm (5500 \times g), 4°C, and then add PEG. Dissolve the PEG flakes by gentle stirring and place on wet ice 1 hr. This is enough time to precipitate most of the phage.

3. Separate precipitated phage by centrifuging 10 min in a JA-14 rotor at 6000 rpm, 4°C.

Drain liquid from the bottles by placing in an inverted position; and shake by hand to remove any remaining liquid.

4. Resuspend phage pellet in 3 ml TM buffer and transfer to a 15-ml Corex centrifuge tube. Add 3 ml chloroform, mix gently, and centrifuge 10 min in a JA-20 rotor at 5000 rpm ($3000 \times g$), 4°C. Collect the phage-containing upper aqueous phase without disturbing the PEG interface.

Corex tubes make it easy to see the PEG interface and the well-separated supernatant.

5. Add 3 ml TM buffer to the tube, mix, and centrifuge as in step 4. Save the aqueous fraction and combine with aqueous fraction from step 4. Adjust the volume to 6 ml with TM buffer.

This step removes phage particles trapped at the PEG interface.

Prepare the DEAE-cellulose column

6. Prepare a slurry of DEAE-cellulose by adding several volumes of 0.05 N HCl. Make sure the pH of the solution is below 4.5.

It is convenient to prepare enough DEAE-cellulose for 30 to 40 columns. Each column requires ~9 ml resin (for 200 ml phage lysate).

7. While stirring, add 10 M NaOH until the pH approaches 7.5.
8. Let the resin settle, decant or aspirate, and equilibrate the resin with TM buffer (see manufacturer's instructions).

Make sure the DEAE-cellulose is completely equilibrated with TM buffer. This may require repeating step 8 four or five times. This process also removes fine particles from the resin.

9. Adjust the slurry to 75% resin and 25% TM buffer.

For long-term storage (several months), add NaN_3 to a final concentration of 0.02% and place at 4°C.

10. Pour 9 ml resin in a 10-ml disposable syringe (1.4-cm i.d.) or a 1.5×10 -cm column. This will result in a bed height of 5 to 6 cm, appropriate for 200 ml of phage lysate.

Figure 1.13.1 Agarose minigel of bacteriophage lambda lysates. Lane 1: λ DNA digested with *Hind*III. Lane 2: 20 μ l of lysate without SDS and EDTA. Lane 3: 20 μ l of lysate treated with 2% SDS and 0.1 M EDTA.

When using a disposable syringe, place a glass-fiber filter or glass wool at the bottom of the syringe to support the resin. Attach a small piece of tubing with a stopcock to the syringe tip to control the flow. Column preparation is easier with a standard glass or disposable column. See UNIT 10.10 for complete discussion of ion-exchange chromatography and Figure 3.4.1 for a sketch of homemade column setup.

Isolate the DNA

11. Load 6 ml crude phage solution from step 5 onto DEAE-cellulose column and elute with 10 ml TM buffer. Discard the first 3 ml of the eluate (void volume); collect the next 13 ml in a 30-ml Corex tube.

The 13-ml eluate may be collected in 1-ml fractions, if desired. Generally, phage elute immediately after the void volume. Fractions containing high-titer phage appear bluish due to light scattering. This indicates that the column is working well. Phage purification can also be confirmed by analyzing 5 μ l of each fraction on an agarose minigel (Fig. 1.13.1).

12. Add 2 ml of 5 M NaCl (400 mM final) and 10 ml of ice-cold 100% isopropanol (40% final) to the 13-ml eluate. Place at -20°C for 15 min.
13. Centrifuge 10 min in JA-14 rotor at 5000 rpm ($3800 \times g$), 4°C , and discard supernatant.

Invert centrifuge tubes until liquid is completely drained. Using tissue paper, wipe the walls of the centrifuge tube without touching the phage pellet. The pellet will appear as a feathery design adhering to wall of the tube. If there is not a sufficient pellet, abandon the experiment and start again from new lysate.

14. Resuspend the phage pellet in 0.8 ml TE buffer, pH 8.0, and divide equally into two 1.5-ml microcentrifuge tubes.
15. Extract once with phenol, twice with phenol/chloroform/isoamylalcohol, and finally with chloroform. Repeat extractions until no visible protein precipitate is seen at the interface.
16. Precipitate λ DNA by adding $\frac{1}{10}$ vol of 3 M sodium acetate, pH 6.0, and 2 vol ice-cold 100% ethanol.

In general, λ DNA forms a fibrous precipitate immediately after the addition of ice-cold ethanol at room temperature. A white cloudy precipitate indicates leftover protein. The λ DNA may be spooled out with a glass rod or condensed into a globule by gentle mixing.

17. Rinse the DNA pellet with 70% ethanol, air dry, and resuspend in TE buffer, pH 8.0. After dissolving completely, measure DNA concentration (UNIT 1.7) and adjust to 200 $\mu\text{g}/\text{ml}$ in TE buffer. Store at 4°C .

It may take several hours for the λ DNA to go into solution.

PREPARING DNA FROM SMALL-SCALE LIQUID LYSATES

ALTERNATE PROTOCOL

This protocol is useful for making small quantities of DNA to be used for restriction analysis. Phage are concentrated by centrifugation and their capsids are destroyed with phenol. The DNA is then ethanol precipitated.

Additional Materials

- 5 mg/ml DNase (*UNIT 3.12*)
- 10 mg/ml DNase-free RNase (*UNIT 3.13*)
- 0.05 M Tris·Cl, pH 8.0
- 3 M sodium acetate, to pH 4.8 with acetic acid

1. To approximately 50 ml liquid phage lysate (*UNIT 1.12*), add 10 μ l of 5 mg/ml DNase and 25 μ l of 10 mg/ml DNase-free RNase. Incubate 1 hr at 37°C.

This treatment will degrade the bacterial DNA and RNA released during lysis. The viscosity of the mixture should decrease.

2. Centrifuge 1½ hr at 27,000 rpm in an SW-28 rotor (132,000 \times g), 4°C.

Alternatively, pellet the phage by spinning 2¼ hr in JA-20 rotor at 20,000 rpm (48,000 \times g), 4°C. The pellet obtained in this manner will resuspend somewhat more easily.

3. Discard supernatant. Invert the tubes on an absorbent surface, e.g., paper towels, to remove any remaining liquid. Resuspend the phage pellet in 200 μ l of 0.05 M Tris·Cl, pH 8.0.

A small translucent pellet should be visible after the tubes are inverted.

4. Transfer the solution to a microcentrifuge tube and add 200 μ l buffered phenol. Vortex 20 min or shake 20 min in microcentrifuge tube shaker. Spin 2 min in microcentrifuge and save the aqueous (top) layer. Repeat phenol extraction.

Phenol denatures the phage capsids and releases the DNA. This denatured capsid protein appears as a thick white precipitate at the phenol/water interface. Vigorous agitation is necessary because the pellet is difficult to resuspend.

There should be less white precipitate after the second phenol extraction. If there is still a large amount at the interface, do a third extraction.

5. Add 200 μ l chloroform, shake well, and spin in microcentrifuge briefly. Save the aqueous (top) layer. Repeat.
6. Add 20 μ l of 3 M sodium acetate, pH 4.8, and precipitate DNA with 2 vol of 100% ethanol at room temperature. Spin in microcentrifuge for 10 min.
7. Remove supernatant. Wash pellet by adding 1 ml of 70% ethanol and spinning 5 min.
8. Remove supernatant. Dry pellet under a vacuum and resuspend the DNA in 100 μ l TE buffer, pH 8.0.

The DNA will resuspend more quickly if the pellet is still slightly wet.

3 μ l of the DNA suspension should be used for a restriction digest.

REAGENTS AND SOLUTIONS

CsCl solutions

$d = 1.3$ g/ml: 31.24 g CsCl + 68.76 ml H₂O

$d = 1.5$ g/ml: 45.41 g CsCl + 54.59 ml H₂O

$d = 1.7$ g/ml: 56.24 g CsCl + 43.76 ml H₂O

The equation for preparing the CsCl solutions is: % w/w = 137.48 - 138.11/d. This calculation assumes the CsCl has no water in it. Typically, CsCl from the shelf will have adsorbed water from the air; and the densities of these stock solutions will be lower than claimed. However, in our experience, the phage band is always found in the middle layer of the step gradient.

Low-salt buffer

0.05 M NaCl

0.05 M Tris·Cl, pH 7.5

0.01 M MgSO₄

5× polyethylene glycol (PEG) solution, 600 ml

207 g Carbowax (PEG 6000)

6 g dextran sulfate

49.5 g NaCl

350 ml H₂O

TM buffer

50 mM Tris·Cl, pH 7.5

10 mM MgSO₄

COMMENTARY

Background Information

This unit provides three methods for extracting and purifying DNA from intact phage particles. The three methods differ in the amount of starting material or phage lysate, and in the manner in which phage are concentrated and purified before lysing and DNA release.

The large-scale preparation (basic protocol) is useful when large quantities of highly purified DNA (over 200 μg) are required—for example, in the construction of libraries. It is based on traditional methods of bacteriophage lambda isolation, involving precipitation of phage from the lysate by polyethylene glycol (PEG) and subsequent purification by CsCl step and equilibrium density-gradient centrifugation (Yamamoto et al., 1970; Davis et al., 1980; Maniatis et al., 1982). It is necessary to use two different gradients to purify phage away from the considerable amount of cellular debris present in a large lysate. Following phage purification, DNA is extracted from capsids by one of two approaches. In one method, phage proteins are removed by a series of phenol extractions and resulting phage DNA is dialyzed in TE buffer to remove any remaining phenol or chloroform. In the other method, DNA is extracted directly from the capsids with high-grade formamide.

The first alternate protocol describes a moderate-scale procedure, capable of yielding enough pure lambda DNA (about 200 μg) for most standard DNA manipulations, such as cloning, sequencing, in vitro packaging, and Southern blotting. Phage particles are separated from cellular components in the lysate by ion-exchange chromatography, resulting in a high degree of purification in a single step. The chromatographic purification works as follows. DEAE (diethyl aminoethyl)-cellulose is an anion-exchange resin—i.e., it has positively charged groups that adsorb negatively charged molecules in buffer of near neutral pH and medium ionic strength. The major cellular contaminants in bacteriophage lysates are negatively charged (polyanionic) molecules (DNA, RNA, and proteins) which are preferentially adsorbed onto the positively charged groups of DEAE-cellulose (Creaser and Taussig, 1957; Benson and Taylor, 1984; Shuang-Young, 1986).

Two different ways to use column chromatography with Whatman DE52 anion exchange resin for phage purification have been reported. In the procedure described here, cellular contaminants are bound to the column, leaving phage particles free (Reddy et al., 1988;

White and Rosenzweig, 1989). Because SDS and proteinase K are not used in the nucleic acid extraction, the resulting DNA can be used with restriction endonucleases and DNA-modifying enzymes without further purification, and has been used successfully to make genomic expression libraries (Webb et al., 1989). Alternatively, binding phage particles to the resin with subsequent elution using a high-salt buffer (Helms et al., 1985) is used for processing several clones simultaneously to obtain a few micrograms of DNA for subcloning.

The second alternate protocol describes a rapid, small-scale method for phage purification which yields small amounts of moderately pure DNA, suitable for restriction analysis. In this procedure, phage are pelleted out of solution with a high-speed spin, and host nucleic acids are destroyed using RNase and DNase. (These enzymes have no effect on phage DNA as it is still packaged in phage heads.) Phage DNA is subsequently extracted from the capsids with phenol and is concentrated with ethanol precipitation.

Critical Parameters

Regardless of procedure, most failures to isolate lambda DNA are due to low phage titer in the initial lysate. Thus, hours of wasted time can be spared by first titrating the phage lysate. Phage can be titered by dilution plating (UNIT 1.11); if the titer is less than 10^9 pfu/ml, a new lysate should be made. An alternative and usually superior method to determine the amount of DNA is to treat 20 μ l of lysate with SDS/EDTA followed by electrophoresis on an agarose minigel (UNIT 2.5). The gel assay takes less time and provides a more accurate estimation of DNA present in both viable and nonviable phage particles. Figure 1.13.1 (lane 3) shows a typical gel resolving relative amounts of cellular nucleic acids and λ DNA (~50 ng) present in a lysate. One should be able to visualize ≥ 10 ng of λ DNA in the band. If there is no visible band, it is advisable to start from fresh lysate.

In chromatographic purification, the ratio of lysate to column size is an important variable. A 9-ml bed volume is sufficient for 200 ml of liquid lysate (at 10^{10} pfu/ml); if more lysate is used (or, if lysate has more highly concentrated cellular debris), the bed volume should be increased proportionately. If the column is overloaded, cellular DNA and RNA may coelute with the phage (to assess this, monitor column fractions with sample of crude lysate by running on an agarose gel). If DNA is contami-

nated, column fractions can be pooled and treated with DNase and RNase (UNITS 3.12 & 3.13) before organic solvent extraction of phage DNA. One should carefully prepare, equilibrate, and pack DEAE-cellulose according to instructions in the Whatman information leaflet (see also UNIT 10.10). Note that the type of DEAE-cellulose (Whatman DE52), as well as the pH and ionic strength of the buffer (use TM buffer recipe provided), are important. Chloroform-lysed cultures often contain very viscous, high-molecular-weight chromosomal DNA which can block the DEAE column. Such a lysate can be treated with DNase before loading onto the column.

After organic extraction, it may be preferable to dialyze rather than precipitate phage DNA, because large DNA can be difficult to resuspend. Lambda DNA is large and easily sheared after it is isolated. When intact DNA is desired (e.g., when phage arms are to be prepared for making a library), the DNA should be treated with special care: shaken, swirled, or vortexed very gently to mix.

Anticipated Results

Yield of λ DNA from each of these procedures depends upon the phage titer and the original lysate volume. If the initial lysate titer is around $1-2 \times 10^{10}$ pfu/ml, then 1 ml of phage lysate ought to yield ~1 μ g of DNA; that is, 2×10^{10} phage particles gives ~1 μ g purified phage DNA. Thus, the large-scale procedure, starting with 1000 ml of lysate, gives ~1 mg of phage DNA; the DEAE-column procedure (200 ml lysate) results in ~200 μ g DNA; and the small-scale procedure (50 ml lysate), provides ~50 μ g DNA.

Time Considerations

The large-scale prep employing gradient purification typically takes at least 3 days: ~30 min the first day to set up the PEG precipitation; ~5 hr the next day to spin down and collect the precipitate, run the step gradient, and load the equilibrium gradient; and ~30 min the third day to collect and phenol extract the phage band, followed by two dialysis steps lasting 8 hr. The phage lysates made as intermediates can be stored for months at 4°C without decreasing in titer. The small-scale prep takes ~4 to 6 hr and it is fairly easy to process a number of samples at once.

Column-purified phage and DNA isolation can be completed in 4 hr, starting from liquid or plate lysate. Preparation of the crude phage solution for the column takes ~2 hr. Another 2

hr are needed for column setup, column loading, elution, and DNA extraction. It is usually most convenient to process four to five different columns simultaneously. The DEAE-cellulose slurry can be prepared in advance and stored at 4°C for several months.

VECTORS DERIVED FROM FILAMENTOUS PHAGES

Introduction to Vectors Derived from Filamentous Phages

Many vectors in current use are derived from filamentous phages. These vectors are used because DNA inserted into them can be recovered in two forms—double-stranded circles and single-stranded circles. Foreign DNA is inserted into double-stranded vector DNA and, then, reintroduced into cells by transformation. Once inside the cells, double-stranded DNA replicates, giving rise both to new double-stranded circles and to single-stranded circles derived from one of the two strands of the vector. Single-stranded circles are packaged into phage particles and secreted from cells (which do not lyse). Centrifugation of a culture of infected cells yields a supernatant that is full of particles containing only a single strand of the phage DNA. This ready availability of single-stranded DNA has made possible new pro-

cedures for sequencing DNA (Chapter 7), mutagenesis (Chapter 8), and other techniques described in this book.

Techniques to isolate double-stranded DNA using these vectors are described in *UNIT 1.15*.

DEVELOPMENT AND USE OF FILAMENTOUS PHAGE VECTORS

Prototypes of the filamentous phage vectors are the M13mp derivatives (see Figs. 1.14.1 and 1.14.2). These vectors were developed by Joachim Messing and his co-workers, who also developed and disseminated simple and powerful techniques for working with them. The M13mp vectors are viable phages. Foreign DNA is inserted into a polylinker (a stretch of DNA that contains contiguous restriction sites) located in an inessential region

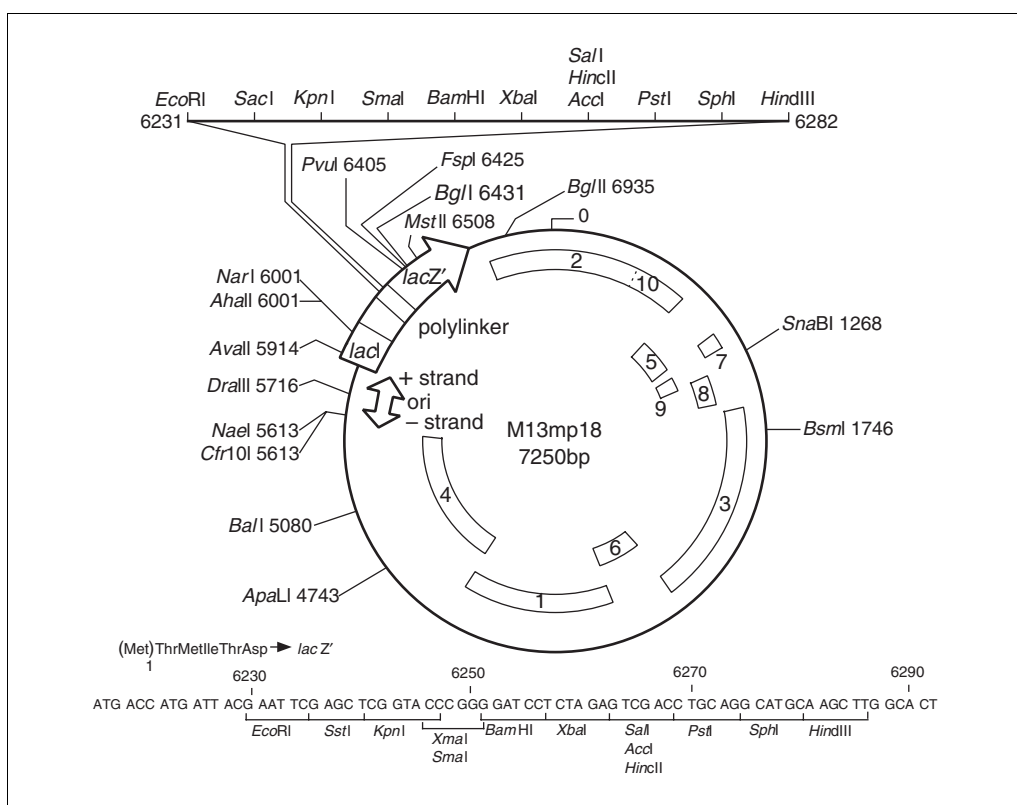

Figure 1.14.1 M13mp18. M13mp18 is one of the M13mp vectors made by Messing and colleagues. Insertion of DNA into the polylinker inactivates the *lacZ* alpha fragment. When insert-containing phages are plated under appropriate conditions (*UNIT 1.15*), they form colorless plaques; vectors that do not contain inserts form blue plaques (Yanisch-Perron et al., 1985, and references therein).

Supplement 13

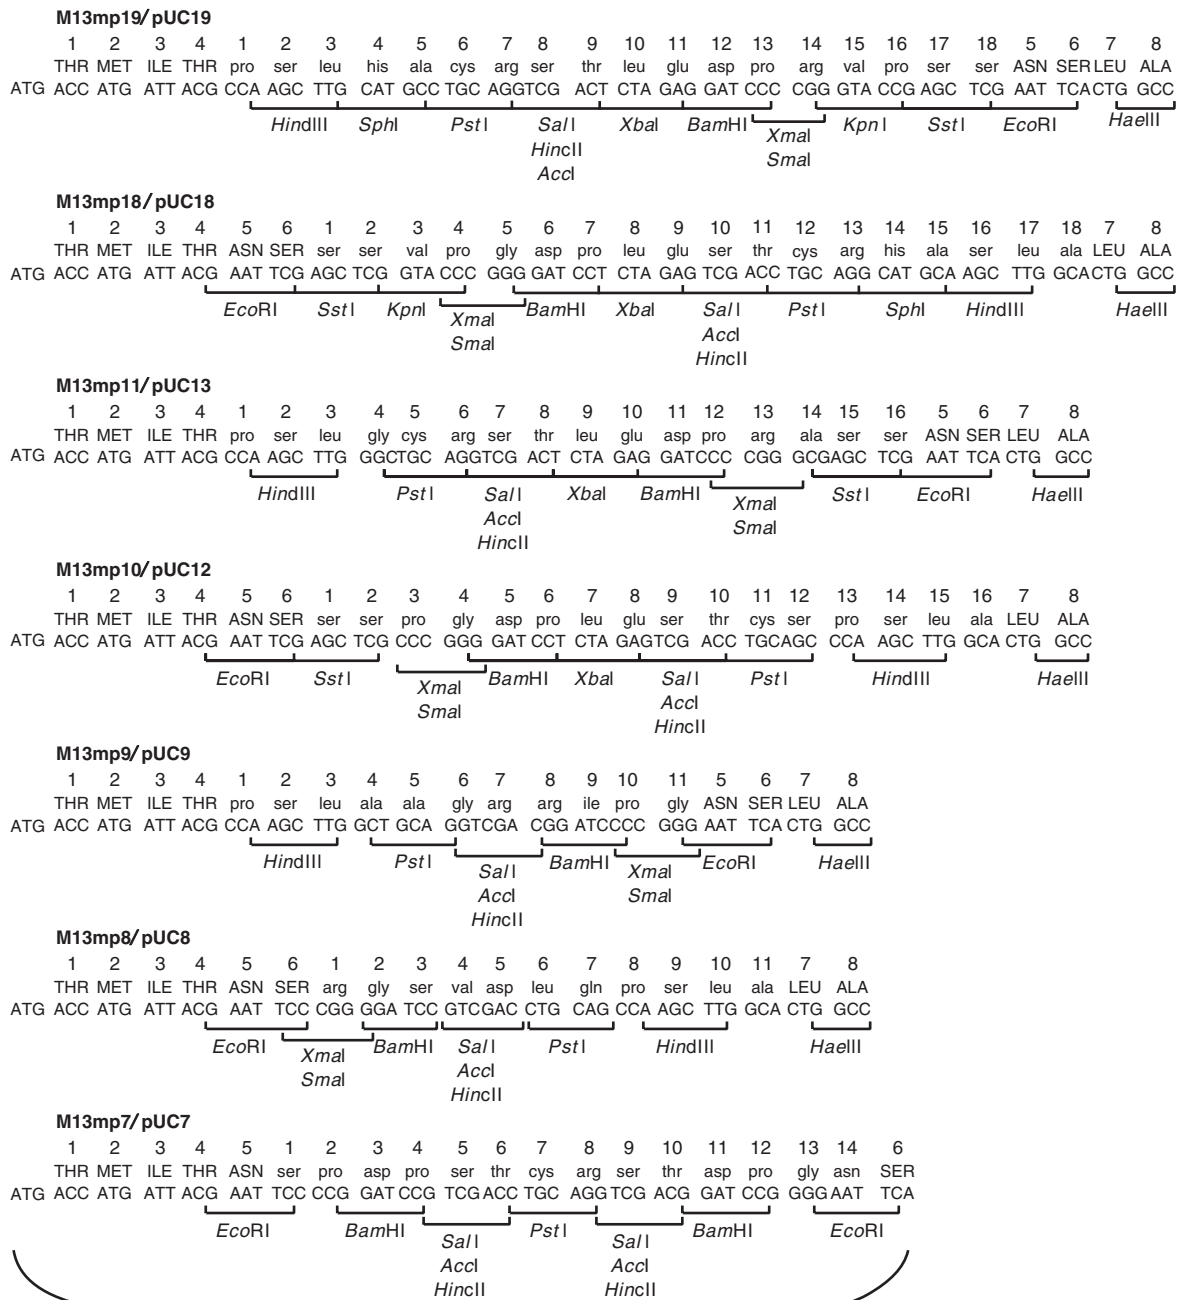

Figure 1.14.2 M13mp/pUC polylinkers. Sequence of polylinkers in the commonly used members of these two series of vectors (Yanisch-Perron et al., 1985, and references therein). Amino acids that have been added to the *lacZ* gene product by insertion of the polylinker are shown in lower case letters. The bracket shows location of polylinkers on vector.

1.14.2

of the phage genome. The polylinker is embedded in-frame within an alpha fragment of the *lacZ* gene. M13mp derivatives form blue plaques on lawns of cells that contain the *lacZ* omega fragment on plates with Xgal and IPTG. Double-stranded DNA is purified from phage-infected cells, cut within the polylinker with restriction enzymes, and foreign DNA is ligated to the cut vector. Insert-bearing phages form white plaques. Infected cells from the center of white plaques are grown in liquid culture then centrifuged to yield supernatants full of phage particles containing a single strand of DNA. Phage particles are concentrated and pure single-stranded DNA is extracted from them and used in other procedures.

Two inadequacies of the M13mp phages sparked development of subsequent generations of vectors. First, it is not always easy to obtain large amounts of double-stranded DNA. This is because DNA is obtained by lysing infected cells, but infected cells grow more slowly than uninfected cells, and there is no easy selection for cells that retain the phage. Second, phages that contain insertions of more than a few hundred nucleotides sometimes give rise to progeny phage in which some of the inserted DNA was deleted. This may be due to the fact that cells infected with large phages grow even more slowly than cells infected with small phages, so that cells containing deletion derivatives of phages with large inserts have a growth advantage.

In order to overcome these disadvantages, many vectors were developed (e.g., pEMBL) that contain a short stretch of DNA that includes the phage origin of replication. These vectors also contain a pMB1-derived origin of replication, a β -lactamase (ampicillin-resistance) gene, and a polylinker embedded within an alpha-complementing fragment of *lacZ*. The vectors, which are much smaller than the M13mp phages, are introduced into the cell by transformation; their continued presence can be ensured by growth of the cells in ampicillin-containing medium. Since these vectors do not encode phage proteins required for DNA replication, vector DNA replicates inside the cells using the pMB1 origin of replication. However, when cells containing these vectors are superinfected with wild-type *helper phage*, the phage origin of replication becomes active and single-stranded progeny phages are secreted into the medium together with progeny helper phage. Contamination with helper phage usually does not interfere with most applications because the helper does not contain genes en-

coding *lacZ* or ampicillin resistance, nor is it likely to contain any piece of nucleic acid used as a hybridization probe. Vectors developed even more recently (e.g., pUC118, pBluescribe) are designed to be used with a slightly improved helper phage and also often include SP6 or T7 phage polymerase promoters reading into the polylinker (see Fig. 1.5.3 and *UNIT 1.15* for details).

LIFECYCLE OF FILAMENTOUS PHAGES

The filamentous phages (f1, M13, and fd) are single-stranded DNA phages that are male-specific—that is, they infect male *E. coli* strains that contain an F factor (F⁺, F', or Hfr; see *UNIT 1.4*). These three phages are essentially independent isolates of the same phage, and differ only by a few nucleotide substitutions. The phage particle is shaped like a long thin tube. Its coat is composed primarily of thousands of monomers of the gene 8 product. The genome consists of a single-stranded, circular DNA molecule, 6407 nucleotides long, which runs down the length of the tube. In addition to coding for ten proteins, the genome contains an intergenic space (IG) between gene 4 and gene 2. The IG contains origins for (+)- and (–)-strand DNA synthesis, a signal for packaging the (+) strands into phage particles, and a transcription terminator. (A genetic map of the phage is shown in Figure 1.14.3.) Filamentous phages are useful cloning vectors because there appears to be no size limit for packaging; if longer genomes are generated, they are packaged into longer phage particles. The phage particle contains ~2700 monomers of the major coat protein, the product of gene 8, and several minor coat proteins at the ends. One of the minor coat proteins, the product of gene 3, attaches to the receptor at the tip of the F pilus of the host *E. coli*. Upon binding, the pilus is thought to retract, bringing the phage in contact with the bacterial cell surface. The coat proteins are removed from the phage particle and inserted into the bacterial cell membrane. After uncoating, the infecting circular single-stranded DNA is brought into the cytoplasm in a process that remains unclear.

Phage DNA replication takes place in three stages within the infected cell. In stage one (complementary strand synthesis), a complementary (–) strand of phage DNA is synthesized. This synthesis converts the infecting single-stranded circular DNA, the (+) strand, into double-stranded replicative-form (RF) DNA. Synthesis of the (–) strand begins at the (–)

strand origin (within the IG), and is carried out by the host *E. coli* replicative enzymes.

In the second stage of replication, the intracellular pool of RF DNA is increased by the sequential action of both replication origins. Rolling-circle type replication from the (+)-strand origin is followed by conversion of the progeny single-stranded circles to double strands by replication starting at the (–)-strand origin. The resulting RF DNA molecules are intermediates in DNA synthesis and transcription templates for the synthesis of the phage-encoded proteins. Transcription proceeds in the same direction as (+)-strand rolling-circle replication. It is suspected that transcription into the replication fork, in the direction of the (–) strand, would inhibit replication, as proposed for the replication of the *E. coli* chromosome (Brewer, 1988). Although this idea has not been rigorously tested, it is attractive because it provides an explanation for two common cloning problems: why certain pieces of DNA are not clonable, and why, occasionally, only one of two possible orientations of an insert are sometimes recovered in a subcloning experiment.

The (+)-strand replication origin that directs rolling-circle replication has a bipartite structure. It consists of an essential core origin region (~50 bp) and an adjacent A+T-rich “enhancer” sequence (~100 bp) which increases replication ~100-fold. The core origin binds the

initiator protein (gene 2 protein) and the enhancer binds the *E. coli* integration host factor (IHF). The polylinker cloning site in cloning vectors of the M13mp series disrupts the replication enhancer sequence, but these vectors have acquired compensatory mutations in gene 2 that restore efficient replication. Consequently, virtually any sequence can be introduced into the polylinker without disrupting DNA replication.

The gene 2 protein is a multifunctional protein that plays several roles in phage DNA replication. It binds cooperatively to the (+)-strand origin in two steps, bends the origin DNA, and introduces a specific nick in the (+) strand of RF DNA. The 3'-hydroxyl end of the nick serves as the primer for (+)-strand rolling-circle replication. (This activity makes the gene 2 protein a useful enzyme for producing uniquely nicked DNA molecules in vitro.) After nicking, the DNA molecules still need the gene 2 protein for unwinding and replication. Finally, upon completion of a round of synthesis, gene 2 protein cleaves and circularizes the displaced single strand (see UNIT 1.15).

The third stage of replication (single-strand production) occurs late in infection. This stage of DNA replication is asymmetric because the (–)-strand origin functions at a reduced level late in the infection and therefore mainly (+) strands are produced. These single-stranded circles, (+) strands, are packaged into phage

Figure 1.14.3 Lifecycle of wild-type M13, described in this unit and in Rasched and Oberer (1986).

particles for export instead of being converted into RF DNA.

Ordinarily, infection with filamentous phages is not lethal and the host cells do not lyse, although their growth rate slows ~2-fold. The reduced growth rate of the host cells accounts for the turbid plaques that the filamentous phage form on a lawn of sensitive cells. Surprisingly, several of the phage proteins have been found to be lethal to *E. coli* when expressed from a plasmid with enhanced replication (high copy number). Evidently, DNA replication in the infected cell is tightly regulated to prevent this lethality. The mechanism whereby this regulation is achieved is not completely understood, but the phage-encoded single-stranded DNA binding protein (gene 5 protein) appears to be required for it. In the steady state of infection, the RF DNA is maintained as a plasmid with a copy number of ~20 to 40, and phage are continuously exported at a rate of 100 to 200/hr. The infected state is quite stable with ~1 cell in every 1000 cells becoming uninfected each generation.

Preparing and Using M13-Derived Vectors

Cloning vectors derived from filamentous phage are extremely useful because they allow cloned DNA to be isolated as either single- or double-stranded DNA. This unit contains protocols for preparing both forms of DNA and for characterizing inserts in M13-derived vectors. A protocol is also presented for preparing single-stranded DNA from plasmids using superinfection with helper phage. This method is advantageous because it allows cloned DNA to be maintained in the form of a plasmid while permitting single-stranded DNA to be isolated for DNA sequencing.

BASIC PROTOCOL

ISOLATING SINGLE M13-DERIVED VECTORS

To ensure homogeneity of stocks of native or insert-containing vectors, it is necessary to start from a single infected cell, or from a single plaque. This is achieved by plating out serial dilutions of an original culture stock.

Materials

- E. coli* strain infected with M13-derived vector (e.g., JM101 infected with M13mp18)
- 2× TY medium (UNIT 1.1)
- 20 mg/ml IPTG in H₂O (stored in aliquots at −20°C)
- 20 mg/ml Xgal in dimethylformamide (stored in aliquots at −20°C)
- 45°C top agarose (UNIT 1.1)
- H plates, prewarmed to 37°C (UNIT 1.1)
- 5-ml Falcon tubes with caps or equivalent plastic tubes
- 37°C incubator

NOTE: All materials coming into contact with *E. coli* must be sterile.

1. Make a series of 1:10 dilutions of the infected strain or a phage stock in 2× TY medium. Place 100 μl of each dilution into separate 5-ml Falcon tubes with caps. Label the tubes in order to keep better track of them.

The vector is usually stored in an infected host at −80°C in 20% glycerol.

The vector can also be stored as isolated DNA or as phage. DNA is introduced into cells by transfection (UNIT 1.11); phage, by infection (described in steps 2 to 5 below). If the vector contains a plasmid origin and a drug-resistance marker, vector-containing cells can be isolated as single colonies on antibiotic-containing medium. If the vector forms viable plaques, vector-containing cells can be isolated by streaking single colonies from the tiny patch of cells in the center of the plaques.

The following steps assume the vector is an M13mp vector, which contains a stretch of DNA that encodes the alpha fragment of β-galactosidase. These vectors make blue plaques on cells containing the β-galactosidase omega fragment (UNIT 1.4). Insertion of DNA into the polylinker inactivates the gene encoding the alpha fragment and gives rise to vectors that have colorless plaques.

2. To each tube add the following:

- 200 μl noninfected bacteria grown to saturation
- 10 μl IPTG
- 40 μl Xgal
- 3 ml 45°C top agarose

It is convenient to prepare a larger batch of the first three ingredients beforehand.

3. Mix by rapidly inverting the tubes twice and pour on individual H plates prewarmed to 37°C.

4. Let the top agarose harden 10 min at room temperature and transfer the plates to a 37°C incubator.
5. After overnight growth, save only the plates that contain less than ~100 plaques.

PREPARING SINGLE-STRANDED PHAGE DNA FROM M13-DERIVED VECTORS

BASIC PROTOCOL

Cells containing the vector and the insert are grown up in liquid medium. The cells are collected by centrifugation, and single-stranded DNA is prepared from the phage particles in the supernatant.

Materials

E. coli strain (male-type, e.g., JM105)

M13-derived vector

2× TY medium (UNIT 1.1)

PEG solution (UNIT 1.7)

TE buffer (APPENDIX 2)

Buffered phenol (UNIT 2.1)

3 M sodium acetate

100% ethanol and cold 70% ethanol

Sterile toothpicks

37°C shaking water bath

Additional reagents and equipment for agarose gel electrophoresis (UNIT 2.5)

1. Inoculate 50 ml of 2× TY medium with 0.5 ml of an overnight culture of *E. coli*. The overnight should be grown from a single colony on a minimal plate that does not contain proline. Dispense 2-ml aliquots in 10-ml culture tubes. Inoculate each tube with a colorless phage plaque picked with a sterile toothpick.

Many male strains of E. coli used for propagation of single-stranded phage (e.g., JM101 or JM105; Table 1.4.5) carry a deletion that removes the proA and proB genes, but also contain an F' plasmid that contains the proA⁺ and proB⁺ genes. Picking a colony from a plate that lacks proline thus ensures that the cells contain the F' plasmid, and that the phage will be able to infect them.

2. Shake at 37°C for 5 to 8 hr.
3. Transfer 1.5 ml of the culture to a microcentrifuge tube. Centrifuge 5 min at room temperature.
4. Pour 1.25 ml of the supernatant into a fresh microcentrifuge tube.

To store the strain, resuspend the bacterial pellet by vortexing, adjust to 30% glycerol, and freeze at -80°C.

5. Add 250 µl PEG solution. Mix and leave for 15 min at room temperature.
6. Centrifuge 5 min and discard the supernatant.

The phage pellet should be visible at this stage.

7. Centrifuge again for 5 min. Carefully remove all remaining traces of PEG using a drawn-out Pasteur pipet.
8. Add to the viral pellet 200 µl TE buffer. Resuspend the pellet completely, then add 100 µl buffered phenol.

Escherichia coli,
Plasmids, and
Bacteriophages

1.15.2

9. Vortex 1 min, let stand for 5 min, vortex again, and centrifuge 5 min.
10. Remove 175 μ l from the upper aqueous phase; transfer to a new microcentrifuge tube.
11. Add 20 μ l of 3 M sodium acetate and 400 μ l of 100% ethanol.
12. Leave \geq 1 hr at -20°C to precipitate the DNA, or 15 min in a dry ice/ethanol bath.
13. Centrifuge 5 min, pour off the supernatant, add 1 ml cold 70% ethanol, centrifuge again, discard the supernatant, and dry briefly in a vacuum desiccator.

For some applications of the single-stranded DNA, such as oligonucleotide-directed mutagenesis (UNIT 8.1), it is advisable to use very clean DNA. For these applications, aspirate off the supernatants from this step using a drawn-out Pasteur pipet.

14. Dissolve the pellet in 25 μ l TE buffer.

Yield can be as high as 10 μ g DNA/ml culture.

15. Analyze 1 to 2 μ l of the DNA solution by electrophoresis on a 1% agarose gel and store the remainder at -20°C .

BASIC PROTOCOL

PREPARING DOUBLE-STRANDED REPLICATIVE-FORM DNA

The disadvantage of many protocols for isolating double-stranded replicative-form (RF) DNA is that the DNA is isolated late in the infectious cycle, at a time when it is least abundant. The following protocol involves isolation of double-stranded DNA from chloramphenicol-treated cells. Addition of chloramphenicol at a low concentration (15 μ g/ml) soon after infection prevents the accumulation of the phage gene 5 protein, which inhibits (–)-strand DNA synthesis. Enough gene 2 protein is synthesized in the first 15 min to allow accumulation of RF DNA.

Materials

F⁺ or Hfr *E. coli* strain
 2 \times TY medium (UNIT 1.1)
 Recombinant phage
 20% glucose
 1 mg/ml chloramphenicol in ethanol, freshly prepared
 Sorvall SS-34 rotor or equivalent

1. Inoculate 20 ml of 2 \times TY medium plus 0.1 ml of 20% glucose with uninfected bacteria. Incubate in a 37 $^{\circ}\text{C}$ shaking water bath until OD₆₀₀ = 0.8 to 1.0.
2. Infect the cells with the recombinant phage at an MOI (see glossary in chapter introduction) of 20 to 50. Incubate 15 min at 37 $^{\circ}\text{C}$.
3. Add 0.3 ml of 1 mg/ml chloramphenicol in ethanol (final concentration, 15 μ g/ml) to the culture. Incubate the culture an additional 2 hr.
4. Centrifuge 10 min at 4000 \times g (6000 rpm) to harvest the cells. Prepare double-stranded DNA using the usual procedures for isolation of plasmid DNA (see UNITS 1.6 & 1.7).

PREPARING SINGLE-STRANDED DNA FROM PLASMIDS USING HELPER PHAGE

BASIC PROTOCOL

Cells containing plasmids with filamentous phage origins (usually the f1 origin) are infected with helper phage. The helper phage provides the gene 2 protein that drives the plasmid into the f1 mode of replication. The gene 2 protein nicks the (+)-strand origin of the plasmid and initiates rolling-circle replication, resulting in the production of single-stranded circles of the plasmid DNA. The helper phage also provides the DNA packaging and export functions. Single strands of the plasmid are packaged into phage coats and secreted into the supernatant. It is important to remember that only the (+) strand is packaged efficiently. Therefore, only the DNA strand of the insert that is in the same 5'→3' orientation as the phage (+)-strand origin will be packaged.

Materials

F⁺ or Hfr *E. coli* strain (Table 1.4.5) containing a plasmid (pUC118, pBS, or equivalent; see commentary)

2× TY medium (UNIT 1.1)

37°C shaking water bath and 65°C water bath

Sorvall SS-34 rotor or equivalent

1. Grow cells in 2× TY (containing an appropriate antibiotic) at 37°C to an OD₆₀₀ of 0.1.

A fresh overnight culture started from a single colony can be diluted 1:50 and grown to an OD₆₀₀ of 0.1. Generally, 1- to 5-ml cultures will yield enough DNA for sequencing (typical yields are 0.2 to 1 μg plasmid single strands/ml culture).

2. Infect the cells at an MOI of 20. Some plasmids and bacterial strains seem to require addition of more phage (MOI of 50), while some give good yields with addition of less phage (MOI 5 to 10).

When performing this protocol for the first time, it is helpful to try several different MOIs (1, 10, 20, and 50). Use the least amount of phage necessary to give a good yield of plasmid single strands because a portion of the input phage will always be recovered.

3. Grow the cells 4.5 hr at 37°C with vigorous shaking.

For convenience, the infected cells can be grown overnight and the supernatant collected the following day. In many cases, this longer growth period will result in contamination of the supernatant with chromosomal DNA from lysed bacteria.

4. Centrifuge 10 min at 4000 × g (6000 rpm). Collect the supernatant and heat at 65°C for 15 min to kill any residual bacteria. Prepare single-stranded DNA from the supernatant (steps 4 to 13 of the second basic protocol, preparing single-stranded phage DNA from M13-derived vectors). Analyze the single-stranded DNA on an agarose gel (UNIT 2.5) with the helper phage serving as a control.

INTRODUCTION OF PHAGE DNA INTO CELLS

Both double-stranded and single-stranded vector DNA can be introduced into CaCl₂-treated competent bacteria by transfection, just as if the vector DNA molecules were plasmids. Single-stranded DNA usually yields about ten times fewer transformants than the same amount of double-stranded molecules.

Special applications may require vector DNA grown on an F- strain. The fact that phage DNA can be introduced into cells by transformation also makes it possible to produce phages from F-hosts. However, since phages produced by infection of these cells cannot infect neighboring cells, phages introduced into F- cells should always contain a drug-resistance marker so that transformed cells can be selected on antibiotic-containing plates.

Methods of transformation described in *UNIT 1.8* are used to introduce vector DNA into cells, with the following adaptations where appropriate.

1. If the vector contains a plasmid replicator and a drug-resistance gene, then simply select transformed cells on antibiotic-containing plates.
2. If the vector is able to form plaques, add 200 μ l of noninfected cells at late log phase ($OD_{600} = 0.6$ to 0.8)—grown as in *UNIT 1.2*—to the plating-out mixture. Add 2.5 ml H top agar (*UNIT 1.1*), plate the mixture as a lawn on an H plate (*UNIT 1.1*), and incubate at 37°C until plaques appear (as in first basic protocol).

DETERMINING SIZE OF INSERTS IN SINGLE-STRANDED VECTORS

This method allows a quick comparison of a large number of viral DNAs without purification of the single-stranded DNA (Messing, 1983).

The size of inserts is estimated by comparing the mobility of DNA purified from insert-containing phage to the mobility of DNA from phages lacking inserts or containing inserts of known size. This procedure allows one to compare the sizes of single-stranded circular molecules that are several kilobases long; however, the resolution on agarose gels usually does not allow detection of inserts that are <300 bp long.

Materials

2% sodium dodecyl sulfate (SDS)
Loading buffer

1. Pipet 1.5 ml of an infected culture into a microcentrifuge tube.
2. Spin for 1 min. Remove 20 μ l of the supernatant and mix with 1 μ l of 2% SDS and 3 μ l loading buffer. Repeat this process with supernatants of cultures of vector phage without inserts, and of other phage which contain inserts of known size.
3. Run these samples on a 0.7% agarose gel and analyze as described in *UNIT 2.5*. If desired, DNA can be transferred from gel to membrane and assayed with a radioactive probe, for example, to determine that the fragment has the right sequence as well as the right size.

DETERMINING INSERT ORIENTATION

Only one strand of the inserted DNA is contained in the phage's (+) strand and made into phage particles. This means that phage DNAs containing identical inserts in opposite orientations will hybridize with each other along the stretch of inserted DNA (see sketch 1.15A). The structures thus formed have different electrophoretic mobility than two unassociated single-stranded viral DNAs. This property of single-stranded phage vectors can be used to determine if two phages have an insert in opposite orientations (Howarth et al., 1981), which can be useful for sequencing both ends of a fragment of DNA.

Additional Materials

5 M NaCl

1. Mix 20 μ l of two supernatants with 1 μ l of 2% SDS in a microcentrifuge tube. In separate tubes mix 40 μ l of each individual supernatant with 2 μ l of 2% SDS.
2. Add 2 μ l of 5 M NaCl to each of the three tubes and incubate 30 min at 60°C.
3. Run all three samples on a 0.7% agarose gel and visualize bands by staining with ethidium bromide as described in *UNIT 2.5*.

If many samples must be screened, it is possible to grow, lyse, and process recombinant infected cells in wells of microtiter plates.

It is also possible to determine the relative orientation of inserts in purified preparations of single-stranded DNA. To do this, mix 5 μ l DNA from each of two independent plaques with 0.5 μ l of 5 M NaCl. Incubate 30 min at 60°C, then analyze on an agarose gel as described above.

REAGENTS AND SOLUTIONS**Loading buffer**

50% glycerol
0.2 M EDTA, pH 8.3
0.05% bromphenol blue

Sketch 1.15A

COMMENTARY

Background Information

In M13 cloning vectors (Messing, 1983), a portion of the *E. coli lac* operon which bears a polylinker (a stretch of DNA which contains contiguous recognition sites for many different restriction enzymes) is inserted in the intergenic region (Messing et al., 1977). On an omega-fragment producing host, these vectors form blue plaques, and vectors with inserts form white plaques.

A plaque formed by M13 vectors is a zone of infected cells within a lawn of noninfected cells. Infected cells grow more slowly than uninfected cells. Plaques made by phage that contain inserts are usually smaller than those made by wild-type phage. This is because phage DNA which contains inserts is replicated more slowly, and it takes longer for cells infected with those phages to produce progeny plaques. Many people prefer to store the recombinant phages not as plaques but as purified single-stranded DNA.

Other single-stranded cloning vectors contain the origins of replication of phages like ϕ 1. These vectors usually also contain the pBR322 plasmid origin of replication, a drug resistance coding gene, and a polylinker inserted in frame into the portion of the *lacZ* gene coding for the alpha peptide. Most of these vectors lack gene 2, or the other phage genes necessary to form single-strand phage particles.

In cells these vectors are double-stranded and replicate using the pBR322 origin of replication. However, when cells are infected with wild-type helper phages, the plasmids replicate using the phage origin of replication, and single-stranded copies of the plasmid are encapsidated into phage filaments, which are then secreted into the culture medium along with copies of the helper. Contamination with helper phage does not interfere with most applications because the helper does not contain genes encoding *lacZ* or ampicillin resistance, nor is it likely to contain any piece of nucleic acid used as a hybridization probe.

Perhaps the most common application of these vectors is in sequencing using the dideoxy method (UNIT 7.4). In this procedure, small fragments of DNA from a plasmid or lambda-derived vector are subcloned into M13mp vectors. Vectors containing the inserts are identified by the fact that they form colorless plaques on a lawn of omega-fragment producing cells growing on Xgal + IPTG plates (see UNIT 1.4).

For further background information see

lifecycle of filamentous phages, UNIT 1.14, and key references listed there.

Critical Parameters

Isolating single M13-derived vectors. Plates should be used immediately after plaques have appeared. Phages should be freshly plated every time a single plaque is to be picked for DNA amplification. Phages diffuse, and use of an old plate can result in cross contamination. Cells to be infected and lawns of infected cells must be grown at 37°C. If cells are grown at temperatures below 34°C, sex pili do not form and phages cannot infect.

Preparing single-stranded phage DNA from M13-derived vectors. It is critical to remove PEG from the preparations, since traces of PEG inhibit the activity of many DNA polymerases. Contaminated templates can be extracted with chloroform prior to ethanol precipitation. However if step 7 (of the first basic protocol) has been followed carefully, chloroform extraction is not necessary.

Preparing replicative-form (RF) DNA. Typical yields of double-stranded DNA from chloramphenicol-treated cells are 50 to 200 μ g per 20-ml culture depending on how well the particular recombinant phage grows. Too much chloramphenicol will result in reduced yields, while too little will result in contamination with single-stranded DNA.

Sometimes after the cesium chloride gradient is equilibrated, a third band appears between the plasmid DNA band (lowest) and the genomic DNA band (highest). This is made of single-stranded DNA and should be left behind.

Preparing single-stranded DNA from plasmids using helper phage. Start with a single colony of male *E. coli* strain that is harboring a recombinant plasmid containing a filamentous phage replication origin such as pUC118 (Viera and Messing, 1987) or pBS (Stratagene).

The strain of helper phage used must be appropriate for the experiment. Several helper phages such as IR-1 (Enea and Zinder, 1982), R408 (Russell et al., 1986), M13K07 (Viera and Messing, 1987), and VCSM13 (derived from M13K07; Stratagene) are available. The phages IR-1 and R408 are more stable than VCSM13 and M13K07, but the latter phages contain a kanamycin-resistance gene that aids in selection. The helper phages VCSM13 and R408 were designed to favor the production of plasmid single strands. VCSM13 has a phage (+)-strand replication origin with

a defective replication “enhancer” sequence. Therefore, it doesn’t compete as well for the gene 2 protein and hence favors the production of plasmid single strands. In contrast, the helper phage R408 has a defective packaging signal (see *UNIT 1.14*) causing the plasmid single strands to be preferentially packaged into phage particles. Regardless of the helper phage used, the single-stranded DNA prepared from the supernatant will contain some DNA from the helper phage. This is usually not a problem for DNA sequencing because a primer can be chosen that is specific for the plasmid single strands.

Introduction of phage DNA into cells.

Transformation of CaCl₂-treated competent bacteria is carried out as described in *UNIT 1.8*. If the vector forms plaques, it is not necessary to phenotypically express, and the cells can be plated out immediately following the heat shock step. Using F⁻ competent cells is a common mistake, since the recombinant phage will not form plaques on a lawn of F⁻ cells. However, F⁻ competent cells can be used if they are diluted with uninfected F⁺ cells following transformation and plated together. In this case, the F⁻ cells will produce phage that will make plaques on the mixed lawn. As long as the F⁺ cells are in abundance, plaques will be seen.

Determining size of inserts in single-stranded vectors. Single-stranded DNA is analyzed from a phage supernatant after extraction from the phage particle. It is important to vortex the phage with the SDS to remove the coat proteins from the phage DNA. Failure to do so will result in incomplete extraction and smearing of the DNA bands. If the culture supernatant contains bacteria or chromosomal DNA from lysed bacteria, the phage DNA will be contaminated and other DNA bands will be visible. If this is a recurrent problem, the position of these extra bands can be determined by running an uninfected culture supernatant as a control.

Time Considerations

Plaques can be seen after ~4 hr. The color of plaques can be determined after a few more hours of incubation.

When preparing single-stranded phage DNA, incubation and processing samples are performed the same day. The only limiting factor is the number of samples to process at the same time. If there are too many, it is possible to store the supernatants (step 5, first basic protocol) at 4°C for 24 hr and then recentrifuge before proceeding to the next step.

Preparing single-stranded DNA with helper

phage requires a shorter incubation period (4.5 hr) after inoculation with the phage. Preparing RF DNA from chloramphenicol-treated cells can be accomplished within one day after the incubation. An additional day may be required if the sample is to be purified on a CsCl gradient.

Introducing phage DNA into cells, determining insert size, and determining insert orientation each takes ~2 hr.

Recombineering: Genetic Engineering in Bacteria Using Homologous Recombination

UNIT 1.16

Over the past few years, *in vivo* technologies have emerged which, due to their efficiency and simplicity, already complement and may one day replace standard genetic engineering techniques. The bacterial chromosome and episomes can be engineered *in vivo* by homologous recombination using PCR products and synthetic oligonucleotides (oligos) as substrates. This is possible because bacteriophage-encoded recombination functions efficiently recombine sequences with homologies as short as 35 to 40 bases. This technology, termed recombineering, allows DNA sequences to be inserted or deleted without regard to presence or location of restriction sites.

To perform recombineering, a bacterial strain expressing a bacteriophage recombination system is required. The phage enzymes can be expressed from either their own promoter or from a heterologous regulated promoter. Expressing the genes from their endogenous phage promoter confers the advantage of tight regulation and coordinate expression, which results in higher recombination frequencies. This is an important advantage, since in many cases high recombination frequencies will be essential to obtaining a desired recombinant. The authors of this unit routinely use a defective λ prophage located on the *E. coli* chromosome, and have recently transferred the critical elements of this prophage to a number of different plasmids (Thomason et al., 2005; also see Commentary). In this prophage system, the phage recombination functions are under control of the bacteriophage λ temperature-sensitive *ci857* repressor. At low temperatures (30° to 34°C), the recombination genes are tightly repressed, but when the temperature of the bacterial culture is shifted to 42°C, they are expressed at high levels from the λ *p_L* promoter. In the plasmid construct of Datsenko and Wanner (2000), the recombination genes are located on a plasmid and expressed from the arabinose promoter. The Datsenko and Wanner plasmid and some of the authors' plasmid constructs have temperature-sensitive origins of DNA replication. The plasmid-based systems have the advantage of mobility—they can be transferred among different *E. coli* strains or to *Salmonella typhimurium* and possibly other gram-negative bacteria. Using the prophage system located on the bacterial chromosome is more facile if the recombineering is targeted to a plasmid. After induction of the recombination functions, the modifying DNA, either a double-stranded (ds) PCR product or a synthetic single-stranded (ss) oligonucleotide (oligo), is introduced into the prophage-containing strain by electroporation. Recombinants are obtained either by selection or screening of the population of cells surviving electroporation. Once the desired construct is obtained, the prophage can be removed by another recombination. Alternatively, engineered alleles on the chromosome can be moved into a different host by P1 transduction. Plasmids with temperature-sensitive replication origins can be lost from the recombinant strain by growth at the appropriate temperature.

Preparation of electrocompetent cells that have expressed the recombineering functions from the λ promoter and their transformation with double-stranded DNA (dsDNA) or single-stranded DNA (ssDNA) is the first procedure described in this unit (see Basic Protocol 1). Support Protocol 1 describes a two-step method of making genetic

Supplement 70

alterations without leaving any unwanted changes. In the latter protocol, the first of the two series of steps is a recombineering reaction that replaces the sequence to be modified with an antibiotic-resistance cassette and a counter-selectable marker (e.g., *sacB*, which is toxic when cells are grown on medium containing sucrose; Gay et al., 1985). The second series of steps is a subsequent recombination that replaces the antibiotic cassette and the counter-selectable marker with the desired genetic alteration. Moreover, the same selection and counter-selection can be reused to make further modifications. Support Protocol 2 describes retrieving a genetic marker (cloning) from the *E. coli* chromosome or a coelectroporated DNA fragment and moving it onto a plasmid. Whereas the above protocols generally use a selection to find the recombinants, Support Protocols 3 and 4 describe methods to screen for unselected mutations. A protocol is also included describing removal of the defective prophage (see Basic Protocol 2). Alternate Protocols 1 and 2 are methods for recombineering with an intact prophage and introducing mutations onto bacteriophage λ , respectively.

STRATEGIC PLANNING

Before attempting to modify the *E. coli* chromosome or a plasmid, the DNA sequence of the desired final construct should be determined. A DNA-analysis computer program such as Gene Construction Kit (GCK; Textco Software; <http://www.textco.com/>) or Vector NTI (Invitrogen) is invaluable for this task. Having the sequence of both the original genome arrangement and the designed final construct as electronic files facilitates the design of oligonucleotides to be used as primers for PCR or as ssDNA recombination substrates themselves. The computer-determined sequences also allow rapid design of primers to analyze and verify the potential recombinants. One must be aware of gene-regulation issues when designing the constructs. Bringing in a promoter with an antibiotic cassette can help in establishing drug resistance; however, transcription from this promoter can extend beyond the drug marker and affect distal genes. The authors of this unit have designed several drug cassettes with their promoter, open reading frame, and transcription terminator region, as described in Yu et al. (2000); primers for amplification are listed in Table 1.16.2. One must also be careful of possible polarity effects and avoid creating unwanted fusion proteins when generating recombinants.

The DNA substrate used for recombineering depends on the desired change. For a sizeable insertion, such as a drug cassette, a PCR product is generated that contains 40 to 50 base pairs of flanking homology to the chromosomal or plasmid target at each end. This homology is provided at the 5' end of each synthetic primer. Following this region of chromosomal homology, ~20 bases of homology to the drug cassette provides the primers to amplify the cassette sequence. Thus, two primers are designed that will each be 60 to 70 nucleotides (nt) long: the 5' ends provide homology to the targeted region and the 3' ends provide homology to the cassette (see Fig. 1.16.1). Careful primer design is crucial (see above). The efficiency of recombineering with dsDNA can approach 0.1% (Yu et al., 2000). If deletions, small substitutions, or base changes are desired, a synthetic single-stranded oligo of ~70 to 100 nt can be used. The oligo should have 35 to 40 nt of complete homology flanking the alteration. Recombineering with ssDNA in wild-type *E. coli* containing the defective λ prophage gives efficiencies approaching 1% (Ellis et al., 2001), and if host mismatch repair is inactivated, either by mutation or by using an oligo that creates a C-C mismatch, a 20% to 25% recombination frequency is achievable (Costantino and Court, 2003). This extremely high frequency means that, for oligo recombination, it is possible to create recombinants without a selection and find them by screening. Since an oligonucleotide corresponding to the lagging strand of DNA replication is some 20-fold more efficient than its complement, it is worthwhile to determine the direction of replication through one's region of interest and use the oligo

Figure 1.16.1 Targeting of an antibiotic cassette. Two primers with 5' homology to the target are used to PCR amplify the antibiotic cassette. The PCR product is introduced by electroporation into cells induced for the Red recombineering functions. The Red functions catalyze the insertion of the cassette at the target site, which may be on the bacterial chromosome or on a plasmid.

that corresponds to the lagging strand (Costantino and Court, 2003). It is also possible to rescue or clone gene(s) from the bacterial chromosome onto a plasmid. To do this, create a linear PCR product of the plasmid using primers with homology flanking the target sequence, designed so that the sequence will be incorporated onto the circular plasmid in the appropriate orientation. The PCR-amplified linear plasmid will require an origin of DNA replication and a selective marker.

MAKING ELECTROCOMPETENT CELLS AND TRANSFORMING WITH LINEAR DNA

This basic protocol describes making electrocompetent cells that are preinduced for the recombination functions and transforming them with the appropriate DNA to create the desired genetic change. As noted in Strategic Planning, the phage recombination functions are repressed by the phage λ temperature-sensitive cI857 repressor, so that they are not expressed when the cells are grown at low temperature (30°C to 34°C) but are highly expressed when the culture is shifted to 42°C. See Commentary for additional considerations before executing the procedure.

Materials

- Purified PCR product or oligonucleotide primers with ~40 to 50 bases of flanking homology on either side of desired change (also see *UNIT 15.1*)
- Bacterial strain expressing the defective lambdoid prophage recombination system λ Red (Table 1.16.1; strains are available from the Court Laboratory; court@ncifcrf.gov)
- LB medium and plates (*UNIT 1.1*), without antibiotic
- Medium lacking carbon source: M9 medium (*UNIT 1.1*) or 1 × TM buffer (*APPENDIX 2*)
- Selective plates—minimal plates (*UNIT 1.1*) if selecting for prototrophy *or* rich plates (also *UNIT 1.1*) containing the following concentrations of antibiotic (depending on drug cassette used):
 - 30 μ g/ml ampicillin
 - 30 μ g/ml kanamycin
 - 10 μ g/ml chloramphenicol
 - 12.5 μ g/ml tetracycline
 - 50 μ g/ml spectinomycin
- 30° to 32°C incubator
- 32° and 42°C shaking water baths
- 125- and 250-ml Erlenmeyer flasks, preferably baffled
- Refrigerated low-speed centrifuge with Sorvall SA-600 rotor (or equivalent)
- 35- to 50-ml plastic centrifuge tubes
- 0.1-cm electroporation cuvettes (Bio-Rad), chilled
- Electroporator (Bio-Rad *E. coli* Pulser is used in authors' laboratory)
- Additional reagents and equipment for PCR (*UNIT 15.1*), gel electrophoresis of DNA (*UNIT 10.2*), purification of DNA by ethanol precipitation (*UNIT 2.1*; optional; commercially available PCR cleanup kit may be substituted), electroporation (*UNIT 1.8*), isolation of bacterial colonies by streaking (*UNIT 1.3*), restriction enzyme digestion (*UNIT 3.1*), and DNA sequencing (Chapter 7).

Table 1.16.2 PCR Primers and Suggested Source of Template for Amplifying Drug Cassettes (from Yu et al., 2000)

Gene	Source	Primer sequence

Kanamycin	<i>Tn5</i>	5' TATGGACAGCAAGCGAACCG 5' TCAGAAGAACTCGTCAAGAAG
Spectinomycin	DH5 α PRO (Clontech)	5' ACCGTGGAAACGGATGAAGGC 5' AGGGCTTATTATGCACGCTTAA

Prepare DNA for transformation

1. Design and procure the oligos to use for PCR-mediated generation of a dsDNA product, or for use in single-stranded oligo engineering.

The sequences of the primers used to amplify the common drug cassettes are listed in Table 1.16.2. Remember to add the homologous targeting sequence to the 5' ends of the oligos.

UNIT 15.1 describes general considerations for primer design.

2. Make the PCR product (UNIT 15.1), examine it by gel electrophoresis (UNIT 10.2), and gel purify by isolating the desired band if unwanted products are obtained.

If the DNA is gel purified, avoid exposing it to ultraviolet light, which will damage it and result in lower recombination frequencies.

3. Clean up the PCR product by ethanol precipitation (UNIT 2.1) or using a commercially available kit to remove salt.

If a plasmid template is used to construct a PCR-amplified drug cassette, any intact circular plasmid remaining will transform the cells efficiently and give unwanted background. This background can be minimized by using a linear plasmid template for the PCR and by digesting the completed PCR reaction with DpnI before using it for electroporation. Always include a control reaction of uninduced cells transformed with the PCR product, to give a measure of any unwanted intact plasmid background.

Prepare bacterial cultures

4. Inoculate the suitable bacterial strain (Table 1.16.1) from frozen glycerol stock or a single colony into 3 to 5 ml LB medium. Shake at 30° to 32°C overnight.

Most of the authors' strains containing the defective lambdaoid prophage are W3110 derivatives; however the prophage can be moved into other backgrounds. See Commentary for details. Plasmids expressing the recombination functions can be put into any strain of choice.

Either 30° or 32°C is acceptable for the low temperature throughout the procedure, since either temperature allows good repression by the cI857 repressor. The cultures will grow more rapidly at 32°C.

5. Equilibrate two shaking water baths to 32°C and 42°C, respectively. Add ~0.5 ml of the overnight culture to 35 ml of LB medium in a 250-ml (baffled) Erlenmeyer flask.

This is a 70-fold dilution. One must make sure that one's dilution is at least 50-fold. Higher dilutions will also work, but the cells will take longer to grow to the appropriate density.

***Escherichia coli,
Plasmids, and
Bacteriophages***

1.16.5

If targeting the recombineering to a plasmid, or expressing from a plasmid, add antibiotic as appropriate to maintain selection during growth. If an alternate method of inducing the recombination functions is used (i.e., addition of arabinose), the inducer should be added to the medium. In this case remember to include an additional flask containing an uninduced culture as a negative control. The authors have found that expression of the λ Red functions from the plasmids of Datsenko and Wanner (2000) is enhanced by use of 10 mM arabinose (for Ara⁺ strains).

6. Place the flask in the 32°C shaking water bath and grow cells at 32°C with shaking for ~2 hr (the time will vary with different strains and dilutions).

The cells are ready when the A₆₀₀ is between 0.4 and 0.6. It is important not to over-grow the cells, since stationary phase cells do not express the recombination functions well.

Induce recombination functions

7. Transfer half the culture to a 125-ml (baffled) Erlenmeyer flask and place that flask in the 42°C water bath. Shake 15 min at 220 rpm to induce. Leave the remainder of the culture at 32°C; this will be used as the uninduced control that lacks recombination activity. While the cells are inducing, fill an ice bucket with an ice-water slurry.
8. Immediately after inducing for 15 min at 42°C, rapidly cool the flask in the ice-water slurry with gentle swirling. Leave on ice for ≥ 5 min. Follow the same cooling protocol with the uninduced 32°C culture. While the cells are on ice, precool the centrifuge to 4°C and chill the necessary number of 35- to 50-ml plastic centrifuge tubes, labeled for induced and uninduced cells.

The temperature shift is unnecessary when a chemical inducer like arabinose is used.

Make electrocompetent cells

9. Transfer both the induced and uninduced cultures to the appropriately labeled chilled 35- to 50-ml centrifuge tubes. Centrifuge 7 min at $4600 \times g$ (6700 rpm in a Sorvall SA-600 rotor), 4°C. Aspirate or pour off supernatant.
10. Add 1 ml ice-cold distilled water to the cell pellet in the bottom of each tube and gently resuspend cells with a large pipet tip (do not vortex). Add another 30 ml ice-cold distilled water to each tube, seal, and gently invert to mix, again without vortexing. Centrifuge tubes again as in step 9.

All subsequent resuspensions of cells through step 16 should be done gently and without vortexing. Preparation of the cells for electroporation washes out any added chemical inducing agent.

11. Decant the 30-ml supernatant very carefully from the soft pellet in each tube and resuspend each cell pellet in 1 ml ice-cold distilled water.

Remove tubes from the centrifuge promptly. The pellet is very soft and care should be taken not to dislodge it, especially when processing multiple tubes.

12. Transfer resuspended cells to microcentrifuge tubes. Microcentrifuge 30 to 60 sec at maximum speed, 4°C. Carefully aspirate supernatant. In each of the tubes, resuspend the cell pellet in 200 μ l cold distilled water, which will provide enough material for four or five electroporations.

For routine procedures when optimal recombination frequency is not necessary, e.g., when selection is used to find recombinants, electrocompetent cells can be stored at -80°C after resuspending the cell pellet in 15% (v/v) glycerol. For highest efficiency, use freshly processed cells.

Introduce DNA by electroporation

13. Chill the desired number of 0.1-cm electroporation cuvettes on ice. Turn on the electroporator and set to 1.80 kV.

Brands of cuvettes and electroporator other than Bio-Rad may work, but have not been tested in the authors' laboratory. 0.2-cm cuvettes may require different electroporation conditions (consult electroporator instruction manual) and standardization to obtain optimal recombination frequencies.

14. In microcentrifuge tubes on ice, mix 100 to 150 ng of salt-free PCR fragment (from step 3) or 10 to 100 ng of single-stranded oligonucleotide with 50 to 100 μ l of the suspension of induced or uninduced cells (from step 12). Do the mixing and subsequent electroporation rapidly; do not leave the DNA-cell mixes on ice for extended periods. Be sure to include the following electroporation reactions and controls:

- a. Induced cells plus DNA.

This is the culture that should yield the designed recombinants.

- b. Induced cells without DNA.

This is a control to identify contamination, determine the reversion frequency, and obtain some idea of the efficiency of the selection.

- c. Uninduced cells plus DNA.

This control tells whether there is some contaminating factor in the DNA that is contributing to the selected colonies (for example, intact plasmid template from the PCR reaction will give rise to drug-resistant colonies here).

15. Introduce the DNA into the cells by electroporation (UNIT 1.8).

The time constant should be greater than 5 msec for optimal results. Low time constants indicate problems with the cells, the DNA, or even the equipment.

16. Immediately after electroporation, add 1 ml LB medium to the cuvette using a micropipettor with a 1000- μ l pipet tip. If transforming with a drug cassette, transfer the electroporation mix to sterile culture tubes and incubate the tubes with shaking at 30° to 34°C for 1 to 2 hr to allow expression of the antibiotic resistance gene.

Even if not selecting for drug resistance, it is still recommended that the cells outgrow to recover from the shock of electroporation. It has been observed in the authors' laboratory that omitting the outgrowth reduces the cell viability ~10-fold.

An alternative, and in the author's experience more reliable, method for outgrowth is to spread appropriate dilutions of cells (see step 18 below) on a sterile 82-mm diameter nitrocellulose filter atop a rich (LB) plate. Incubate this plate for 3 hr at 30° to 34°C. After the incubation, transfer the filter to the appropriate selective drug plate using sterile forceps. This method is preferable because the cells are less dense and more efficient outgrowth is achieved.

Determine cell titers

17. Make serial 1:10 dilutions of the electroporation mix through 10^{-6} using M9 medium or 1 \times TM (Tris Magnesium) buffer, dispensing 0.9 ml M9 or TMG and 0.1 ml of the cell suspension per tube.

The dilutions can be made in rich medium if a selection for antibiotic resistance is applied.

18. To determine total viable cell count, spread 100 μ l of 10^{-5} and 10^{-6} dilutions on LB plates (rich plates without drug). Incubate the plates at 30° to 34°C for 1 to 2 days, depending on the growth requirements of the recipient strain.

19. To determine recombinant cell count, plate cells on selective plates as follows depending on the anticipated recombinant frequency.
 - a. If efficient recombination is expected, spread both 10 and 100 μl of the 10^{-1} and 10^{-2} dilutions.
 - b. If low numbers of recombinants are expected, spread 100 μl each of a 1:5 and 1:10 dilution.

The authors routinely obtain ten-fold or higher recombinant yields with the prophage system than with the Datsenko and Wanner plasmids.

For the no-DNA and uninduced controls, plate 200 μl directly on selective plates.

Since targeting to the chromosome results in a lower copy number of the drug cassette than is present with a multicopy plasmid, antibiotic concentrations must be adjusted accordingly. The authors routinely use the drug concentrations recommended above for chromosomal constructs. Minimal plates are used for selection based on prototrophy.

20. Incubate plates at the appropriate temperature (30° to 34°C).

At 30°C, colonies may take two days to come up on LB plates and 3 to 4 days on minimal plates. Candidates should be purified by streaking for single colonies and retested for the appropriate phenotype.

Analyze recombinants

21. Once recombinant clones are identified, confirm the presence of the desired mutation(s) by PCR analysis (UNIT 15.1) followed by DNA sequencing (Chapter 7) or restriction digestion analysis, if appropriate.

The design of the PCR primers depends on the changes made. For an antibiotic cassette or other insertion, the primer pair used to amplify the insertion can also be used to confirm its presence. These primers will not determine whether the cassette has integrated at the desired location, however. The recombinant junctions can be confirmed with the help of two additional primers (all four should have compatible annealing temperatures) pointing outwards from the cassette; use one primer flanking the cassette and one internal cassette primer to amplify the unique junctions created by the recombination reaction. A primer pair that hybridizes to the external flanking sequences on each side rather than the insertion itself can also be used to demonstrate loss of the target sequences and presence of the insertion. Unwanted mutations can be introduced by heterologies (variations) in the synthetic primer population (Oppenheim et al. 2004); therefore, it is important to confirm the final construct by sequence analysis, especially the regions derived from the original primers.

SUPPORT PROTOCOL 1

MANIPULATING *cat-sacB* FOR COUNTER-SELECTION AND GENE REPLACEMENT

This protocol describes a two-step method to create precise genetic changes without otherwise altering the DNA sequence. First, *cat-sacB* (or another counter-selectable cassette) is placed on the DNA; this is then replaced with the desired alteration in a second recombineering. The final construct will not have a drug marker.

Additional Materials (also see Basic Protocol 1)

Template for amplification of *cat-sacB*: bacterial strain DY441 (DY329 with a *cat-sacB* insertion on the *E. coli* chromosome) or the plasmid pEL04 (Lee et al., 2001). pEL04 has previously been called both pK04 and *pcat-sacB*. Both DY441 and pEL04 are available from the Court Laboratory; court@ncifcrf.gov

SpeI and *DpnI* restriction endonucleases (UNIT 3.1)

Primer L *sacB*: 5'-homology sequence- ATC AAA GGG AAA ACT GTC CAT
AT -3'

Primer R *cat*: 5'- homology sequence- TGT GAC GGA AGA TCA CTT CG -3'

Invitrogen Platinum High Fidelity enzyme
 LB-Cm plates: LB plates (*UNIT 1.1*) containing 10 µg/ml chloramphenicol
 M63 minimal glycerol plates with sucrose (see recipe) or LB plates (*UNIT 1.1*)
 lacking NaCl but containing 6% (w/v) sucrose
 Medium lacking carbon source: e.g., M9 medium (*UNIT 1.1*)
 Thermal cycler (MJ Research PTC-100)
 Additional reagents and equipment for PCR (*UNIT 15.1*) and purification of DNA
 (*UNIT 2.1*)

Amplify the *cat-sacB* element for recombineering

1. If using pEL04, completely cleave *pcat-sacB* with *SpeI*.

This step is unnecessary if the chromosomal insertion of cat-sacB is used as template for PCR. Failure to digest when the plasmid is used as template will give a high background of intact plasmid transformants.

2. Amplify *cat-sacB*, either from the cleaved pEL04 or from DY441 with the Invitrogen Platinum High Fidelity enzyme and an MJ Research thermal cycler, using 50 pmol of each primer and the following cycling program:

1 cycle:	2 min	94°C	(denaturation)
9 cycles:	15 sec	94°C	(denaturation)
	30 sec	55°C	(annealing)
	3.5 min	68°C	(extension)
19 cycles:	15 sec	94°C	(denaturation)
	30 sec	55°C	(annealing)
	3.5 min		
	(adding 5 sec/cycle)	68°C	(extension)
1 cycle:	7 min	68°C	(extension)
1 cycle:	indefinite	4°C	(hold)

The PCR primers used to amplify the cat-sacB element are at the 3' end of chimeric primers that include 5' segments of bacterial target homology ~40 to 50 nt in length. Hence each primer is 60 to 70 nt long.

Since the PCR product is greater than 3 kb, it can be difficult to amplify. The above conditions have been used successfully in the authors' laboratory.

3. If pEL04 was used as template, digest the completed PCR reaction with *DpnI* to specifically eliminate the methylated plasmid template. Purify the PCR product to remove salt (*UNIT 2.1*).

Perform electroporation and recombination to insert *cat-sacB* at the desired location

4. Insert the *cat-sacB* cassette into the chromosome as described above (see Basic Protocol 1, steps 4 to 21; also see Background Information for important tips) using the following techniques specific for the *cat-sacB* cassette.
 - a. Select chloramphenicol-resistant (Cm^R) colonies and purify on LB-Cm plates to isolate single colonies.
 - b. Test several Cm^R isolates for sensitivity to sucrose, either on minimal glycerol plates containing 5% sucrose or on LB plates lacking NaCl but containing 6% sucrose (Blomfield et al., 1991). Use the parental transformation strain as a sucrose-resistant control. Determine that the insertion is correct before proceeding with the next step of the procedure.

*The sucrose-resistant parent serves as a control for growth in the presence of sucrose. Sucrose sensitivity needs to be tested because the PCR process generates mutations that inactivate *sacB* in a fraction of the clones.*

Perform electroporation and recombination to replace *cat-sacB* with chosen allele

5. Use a confirmed Cm^R/sucrose-sensitive candidate from step 4 as the starting bacterial strain for a second round of recombineering by carrying out Basic Protocol 1, steps 1 to 21; however, suspend the electroporated cells at step 16 of Basic Protocol 1 in a final volume of 10 ml instead of 1 ml of LB medium, and incubate with aeration (applied via shaking in a shaking water bath) at 30° to 32°C for 4 hr to overnight for outgrowth following electroporation.

*The higher dilution promotes better cell recovery and allows complete segregation of recombinant chromosomes that no longer carry the *cat-sacB* cassette from nonrecombinant sister chromosomes that still contain it. If outgrowth is inadequate and sister chromosomes are not fully segregated, the presence of the cassette on one chromosome will confer sucrose sensitivity to the entire cell, thus preventing recovery of recombinants. This is generally true in counter-selection experiments and illustrates a common problem encountered with them.*

6. Centrifuge cells 7 min at 4600 × g, 4°C. Remove supernatant, then wash the cells twice, each time by resuspending in 1 ml minimal medium lacking a carbon source, such as M9, centrifuging again as before, and removing the supernatant. Resuspend and dilute the cells for plating, and spread appropriate dilutions of the cells on either LB sucrose plates or minimal glycerol plates (if the defective prophage was moved to another strain, the metabolic requirements of that strain must be considered). In parallel, be sure to include a control of electroporated cells to which no PCR product was added, to determine the frequency of spontaneous sucrose-resistant mutants; these spontaneous mutants will retain the Cm^R cassette.

*The frequency of spontaneous sucrose-resistant cells is normally ~1 in 10⁴. Thus, in the recombination experiment, the sucrose-resistant colonies that arise are of two types, spontaneous mutants like those found in the control, and deletions caused by replacing *cat-sacB* by recombination with the PCR product. The frequency of the latter is optimally 10- to 100-fold greater than that of spontaneous mutation.*

7. Purify ~10 sucrose-resistant colonies by streaking to isolate single colonies (UNIT 1.3) and then test for chloramphenicol sensitivity (Cm^S)—spontaneous mutants will be Cm^R while the recombinants will be Cm^S. Screen the Cm^S/sucrose-resistant colonies by PCR (see Basic Protocol 1, step 21), then sequence to confirm the presence of the desired change.

Screen a minimum of ten colonies. If high-efficiency recombination is not achieved, more colonies will need to be screened. Note that the frequency of spontaneous mutants remains relatively constant and provides an internal control for determining the efficiency of the recombination.

RETRIEVAL OF ALLELES ONTO A PLASMID BY GAP REPAIR

Often it is desirable to retrieve a DNA sequence from the bacterial chromosome, either to clone and amplify a gene, to express a gene under a given promoter, or to create a gene or operon fusion. To do this with recombineering, a PCR product with homology to the target at the ends is made from a linearized plasmid DNA and introduced into cells expressing the Red system. This homology will allow recombination with the sequence to be retrieved, yielding a circular plasmid containing the sequence. It is important to linearize the plasmid DNA used as template. This retrieval method works with ColEI and p15A (pACYC) replicons, but not with pSC101 (Lee et al., 2001).

**SUPPORT
PROTOCOL 2**

**Genetic
Engineering in
Bacteria Using
Homologous
Recombination**

1.16.10

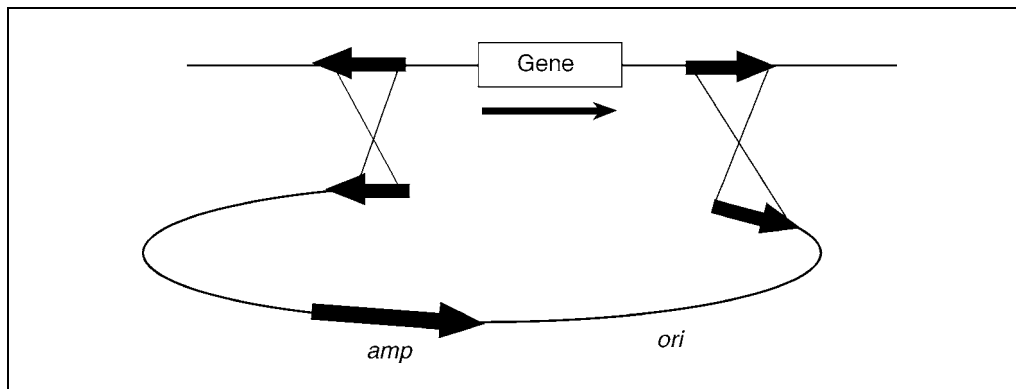

Figure 1.16.2 Cloning genes by gap repair of a plasmid. A linear plasmid with flanking homology to the target at the ends (indicated by dark arrows) is generated by PCR. The plasmid is introduced by electroporation into cells expressing the Red functions, which catalyze recombination of the vector with the target site, resulting in incorporation of the gene onto the plasmid.

If the desired gene is not present on the chromosome, it can be provided as PCR product and introduced into the cells along with the PCR-amplified vector DNA by coelectroporation. Always remember to provide flanking homology so that the plasmid can recombine with the additional PCR product (it is easier to provide the homology on the short product to be cloned rather than on the vector).

Additional Materials (also see *Basic Protocol 1*)

- Plasmid onto which sequence of choice is to be rescued
- Restriction enzyme(s) (*UNIT 3.1*) that do not cut within plasmid region to be amplified
- Synthetic chimeric primers providing homology to sequence flanking gene of choice and to the plasmid sequence to be amplified
- Additional reagents and equipment for PCR (*UNIT 15.1*)

Amplify linear plasmid PCR product with homology to the target

1. Design primers with homology that flanks the desired target.

Drawing a sketch of the plasmid as a gapped circle interacting with the target sequence will help one visualize the recombination reaction (see Fig. 1.16.2), since the plasmid template has the linear ends pointing toward each other. Both of the primers will have ~50-nt of bacterial sequence homology at the 5' ends linked to 3' plasmid sequence. It is not necessary to amplify the entire plasmid. Any portion can be amplified as long as the minimal requirements of a selectable marker and an origin of DNA replication are met. If the DNA to be retrieved is adjacent to an antibiotic resistance gene, only a plasmid replication origin need be amplified; the origin can be used to retrieve both the desired sequence and the nearby drug marker. Avoid having other regions of the plasmid that are homologous to the bacterial chromosome (e.g., lac); these can lead to unwanted rearrangements.

2. To minimize background, digest the plasmid with one or more restriction enzyme(s) that do not cut within the region to be amplified. Amplify the linear plasmid by PCR using the primers (reaction conditions will need to be established empirically).

The amplified product will be a linear gapped plasmid with flanking homology to either side of the allele to be rescued from the chromosome.

Use the least amount of plasmid DNA possible for the PCR template, to minimize the background of false positives. Digestion of the completed PCR reaction mix with DpnI will help remove the template plasmid. Purify the PCR product to remove salt before proceeding.

Transform induced cells with the linear plasmid and select recombinants

3. Introduce the linear plasmid PCR product into the strain (see Basic Protocol 1, steps 4 to 21). If necessary, also add the PCR product to be co-electroporated. Select for the marker on the plasmid, and transform the uninduced cells with the linear plasmid PCR product, to determine the background of intact plasmid present. Purify candidate colonies and screen them with PCR. Isolate the recombinant plasmids and use them to retransform a standard cloning strain such as DH5 α or XL2 Blue, to generate pure clones.

Transformation into a recA mutant host ensures that the newly engineered plasmid does not undergo additional rearrangement.

If the DNA of interest is linked to a drug marker and it is retrieved with a replication origin lacking a drug marker, dilute the electroporation mix into 10 ml LB medium and grow the culture overnight nonselectively. The next day, isolate plasmid DNA and transform into a high-efficiency cloning strain, selecting for the drug resistance of the rescued marker. The transformation should be done with a low concentration of DNA, to minimize uptake of multiple plasmids into the same cell. The advantage of using only the plasmid origin for retrieval is that any possible background of religated vector is eliminated.

Gap repair is less efficient than targeting to the chromosome. The maximal yield achieved in the authors' laboratory is ~ 1000 recombinants/ 10^8 cells. A possible side reaction is joining of the plasmid ends without incorporation of the chromosomal marker. This is caused by small (>5 base) repeats near the linear ends (Zhang et al., 2000); it is likely that the Red functions facilitate the short repeat recombination that generates this background. The short repeat recombination can be reduced or eliminated by designing primers that are free of such repeated sequences.

SCREENING FOR UNSELECTED RECOMBINANTS

When recombinant frequencies approach 1/1000, direct screening can often be used to find recombinant colonies from total viable cells plated out nonselectively on LB. The authors have successfully used the nonradioactive Roche DIG (digoxigenin) system for colony hybridization to detect the recombinant bacterial colonies (L. Thomason, unpub. observ.). For this method to be feasible, the sequence inserted by recombineering must be unique to the recombinant and absent in the starting strain. The authors have used a 21-nt long DIG-labeled oligonucleotide probe to detect insertion of the same sequence. For larger insertions or fusion proteins such as GFP derivatives, a labeled PCR product or gel-purified fragment could also be used as a probe. Both oligo probes and larger DNA fragments could be radioactively labeled with ^{32}P .

The authors have also successfully isolated unselected recombinants when the genetic change confers a slow growth phenotype by simply looking for colonies that grow more slowly than the majority class. Another useful method is the mismatch amplification mutation assay-PCR (MAMA-PCR; Cha et al., 1992; Swaminathan et al., 2001). MAMA-PCR is capable of identifying single base changes by screening colonies.

Additional Materials (also see Basic Protocol 1)

Flanking primers for PCR analysis of mutation of interest (also see UNIT 15.1)
Additional reagents and equipment for colony hybridization (e.g., UNIT 6.6)

1. Introduce the genetic change of interest (see Basic Protocol 1, steps 1 to 18).

Possible changes include small in-frame deletions or a protein tag. For subtle changes, it is helpful to engineer a restriction-site change that can be detected in a PCR product. For detection by hybridization, confirm beforehand that the sequence does not exist in the parental bacterial strain—e.g., using a BLAST search (UNIT 19.3; Altschul et al., 1990).

2. Assuming an expected viable cell count in the transformation mix of $\sim 10^8$, plate the cells nonselectively on rich plates so that the expected number of colonies per plate is ~ 500 .

Six plates should be adequate if the recombination is efficient. More crowded plates will mean that fewer plates must be screened, but if the plates are too crowded it will be more difficult to locate positive clones.

3. Screen for recombinants by performing colony hybridization using established procedures (e.g., UNIT 6.6). If using a nonradioactive labeling method, follow the conditions suggested by the manufacturer.

The required length of oligonucleotide probes will depend on the sensitivity of the system.

The authors have detected positive colonies at frequencies of as low as 5×10^{-2} to 1×10^{-3} .

4. Streak positive candidates to obtain pure clones and retest.

Since the recombination only alters one of several copies of the chromosome existing in a single cell, the colony from that cell will be heterozygous for the allele. Thus, on re-streaking, some fraction of the colonies will not give a positive signal. The signal can again be detected by colony hybridization, or if a new restriction site has been designed into the construct, perform PCR and cut the product with the appropriate restriction enzyme to detect the recombinant (also see UNIT 3.1).

SCREENING FOR UNSELECTED PLASMID RECOMBINANTS

With the extremely high oligonucleotide recombination frequencies obtainable in the absence of mismatch repair (20% to 25% of total viable cells), direct sequencing of unselected plasmid clones can be used to find recombinants. If the oligonucleotide carrying the mutation to be introduced creates a C-C mismatch when paired at the target site, the recombination can be done in wild-type cells containing the defective prophage, since a C-C mismatch is not repaired. Otherwise, a bacterial strain with prophage and mutant for the mismatch repair system can be used. It is helpful if the mutation to be inserted creates a restriction site change that can be monitored by digestion of a PCR amplified fragment covering the region of interest.

Additional Materials (also see Basic Protocol 1)

Cells expressing Red but mutant for host mismatch repair system *or* oligonucleotide that creates C-C mismatch when annealed to target DNA strand: e.g., HME63 and/or HME64 (see Table 1.16.1)
High-efficiency cloning strain (lacking the Red system)

1. Perform Basic Protocol 1, introducing both the plasmid and the oligonucleotide by co-electroporation into cells mutant for the host mismatch repair system, or using an oligo that creates a C-C mismatch when annealed to the target DNA strand.
2. After the outgrowth, dilute the electroporation mix into 10 ml broth containing the appropriate antibiotic for plasmid selection and grow the culture overnight.
3. Isolate plasmid DNA from this culture.
4. Using a low DNA concentration, transform the engineered plasmid into a high efficiency cloning strain (lacking the Red system), selecting for drug resistance. Purify colonies.

Use a low DNA concentration to minimize uptake of more than one molecule/cell.

SUPPORT PROTOCOL 4

Escherichia coli,
Plasmids, and
Bacteriophages

1.16.13

5. Screen to find the mutation, either by direct sequencing or, if there is a restriction site change, by amplifying a fragment with PCR and digesting it with the appropriate enzyme(s).

The authors recommend looking at 25 to 50 colonies. This procedure has been successfully used for plasmid mutagenesis (L.Thomason, unpub. observ.).

REMOVAL OF THE PROPHAGE BY RECOMBINEERING

Once the mutational changes are introduced, the defective λ prophage can be removed if necessary. This is done by another Red-mediated recombination reaction. Alternatively, the prophage can be removed by P1 transduction. In both cases, the desired recombinant can be selected on minimal plates since it will grow in the absence of biotin.

Materials

Oligonucleotide primers for amplifying the bacterial *attB* site:

5' GAGGTACCAGGCGCGGTTTGATC 3'

5' CTCCGGTCTTAATCGACAGCAAC 3'

E. coli K12 strain lacking the prophage (e.g., W3110), but containing the *attB* and biotin (*bio*) genes

M63 minimal glucose plates with and without biotin (see recipe)

Additional reagents and equipment for recombineering (see Basic Protocol 1)

1. Amplify the bacterial *attB* site by PCR using 50 pmol of each of the primers listed above, with an *E. coli* K12 strain lacking the prophage (e.g., W3110) as template (the PCR product is \sim 2.5 kb), and the following program:

1 cycle:	2 min	94°C	(denaturation)
9 cycles:	15 sec	94°C	(denaturation)
	30 sec	65°C	(annealing)
	3 min	68°C	(extension)
19 cycles:	15 sec	94°C	(denaturation)
	30 sec	65°C	(annealing)
	3 min		
	(adding 5 sec/cycle)	68°C	(extension)
1 cycle:	7 min	68°C	(extension)
1 cycle:	indefinite	4°C	(hold)

*The technique used here is "colony PCR" in which the PCR reaction is prepared without allowing any volume for the template DNA; a fresh colony of the *E. coli* K12 strain is then touched with a sterile inoculating loop and mixed into the PCR reaction.*

2. Delete the prophage by recombineering (see Basic Protocol 1, steps 1 to 18). using the *attB* PCR product for recombination.
3. Wash the cells in minimal salts twice and resuspend them in the same medium for plating. Select for the desired recombinant on minimal glucose plates lacking biotin but containing vitamin B1 by incubating 2 hr at 32°C then shifting to 42°C until colonies appear.

*LB has trace amounts of biotin, enough to complement a *bio* mutant for growth; therefore the cells must be washed free of LB for this selection to be successful. Those cells in which the prophage has been deleted will be *bio*⁺, since the PCR product brings in a wild-type (wt) biotin gene, and will grow at 42°C, since the removal of the prophage makes the cells temperature resistant. As a control, confirm that the prophage-containing strain, subjected to the same washes, does not plate on minimal glucose plates lacking biotin, but does plate when biotin is present.*

The 32°C incubation allows time for the recombinant chromosomes to segregate away from those still containing the prophage, which expresses a killing function at high temperature (see Commentary). Streak the recombinant colonies to purify them. As an additional confirmation that the prophage has been deleted, the same PCR primers can be used to confirm the presence of the 2.5-kb band in the purified strain.

RECOMBINEERING WITH AN INTACT λ PROPHAGE

Basic Protocol 1 describes a method for recombineering using a defective lambdoid prophage. It is also possible to recombineer using an intact λ prophage (Court et al., 2003). If the phage of interest has a temperature-sensitive *cI857* repressor, intact *exo*, *beta*, and *gam* genes, and is able to lysogenize the host, it can exist in the prophage state and can be induced by high temperature to express the recombination functions. Such a phage will provide the necessary functions for recombineering; it can also itself serve as a target for such engineering. Since the recombineering efficiency is lower with this method than with the defective prophage, a selection for the recombinants should be applied. To recombineer using an intact phage, construct and confirm a bacterial lysogen (Arber et al., 1983) with the phage of choice. Once the phage exists in the prophage state, it can be induced by a temperature shift, as described below, and PCR product or oligo containing the desired genetic change can be introduced by electroporation.

Additional Materials (also see Basic Protocol 1)

Bacterial lysogen carrying the λ *cI857* bacteriophage of choice as a prophage

Chloroform

1 × TM buffer (APPENDIX 2)

82-mm nitrocellulose filters, sterile

39°C water bath

Additional reagents and equipment for plating λ phage to generate plaques (plaque purification; UNIT 1.11)

1. Grow the host bacterial strain (lysogen) to mid-log phase at 32°C (see Basic Protocol 1, step 6).
2. Induce recombination functions, electroporate cells, and plate to determine viable cell counts (see Basic Protocol 1, steps 7 to 18), except at step 7 of Basic Protocol 1, transfer half the culture to 42°C and shake vigorously for 4 to 5 min at 220 to 225 rpm, instead of 15 min, before chilling both flasks rapidly in an ice-water slurry for ≥ 5 min.

The induction time must be shorter to prevent phage lytic replication and resultant cell killing. The shorter induction time means that lower levels of the recombination functions are produced. The only situation in which the 15-min induction time should be used is when changes are being targeted to the bacteriophage chromosome itself (steps 3b and 4b).

If the mutation of interest is targeted to the bacterial chromosome

- 3a. Select for recombinants by plating an entire electroporation mix on one selective plate (because recombinant levels are reduced by the lower induction time). Use a sterile 82-mm diameter nitrocellulose filter atop a rich (LB) plate and incubate > 3 hr at 30° to 32°C, then transfer the filter to the appropriate drug plate using sterile forceps.

The number of recombinants is generally less than 500 per electroporation mix. Usually, approximately half of the surviving cells will have spontaneously lost the prophage. It is possible to screen for non-lysogens by testing candidate colonies for their ability to plate λ , since the prophage renders the cells immune to phage infection; the cured cells will also be viable at 42°C while those containing the prophage will not (see Commentary).

ALTERNATE PROTOCOL 1

Escherichia coli,
Plasmids, and
Bacteriophages

1.16.15

- 4a. Use PCR (*UNIT 15.1*) and subsequent DNA sequencing (Chapter 7) to confirm the mutation.

If mutations have been targeted to the bacteriophage itself

In this case, the 15-min induction time can be used.

- 3b. Dilute the electroporation mix into 5 ml LB medium and aerate by shaking in a shaking water bath 90 min at 39°C. Add 0.25 ml chloroform to complete cell lysis and release the phage particles. Dilute the lysate and plate for single plaques (see *UNIT 1.11*).
- 4b. Plaque-purify the positive candidates (*UNIT 1.11*). Resuspend a plaque in 50 µl of sterile water and use 20 µl of this suspension as template for a PCR reaction (*UNIT 15.1*; reduce the amount of water accordingly). Resuspend another plaque from the same plate in 1 mM of 1× TM buffer to grow a stock. Reconfirm the mutation after growing the stock.

ALTERNATE PROTOCOL 2

TARGETING AN INFECTING PHAGE λ WITH THE DEFECTIVE PROPHAGE STRAINS

Sometimes it may be useful to target genetic changes to bacteriophage λ derivatives. A strain carrying the Red system on the prophage or a plasmid can be infected with a phage and recombineering can then be targeted to the incoming phage chromosome. A procedure for this method follows. Ideally the construction should be designed so that the plaque morphology of the recombinant phage will differ from that of the parent. For example, a PCR product able to both introduce the mutation of interest and correct a known mutation (such as an amber or temperature-sensitive allele) can be recombined onto a phage containing the known mutation. Select for correction of the known mutation and screen among these recombinants for the mutation of interest. If no selection exists, plaque hybridization can sometimes be used to identify recombinant phages. While the authors have only tested this method for phage λ , theoretically it may be possible to introduce genetic changes onto the chromosome of any phage able to propagate in the defective prophage host (Oppenheim et al., 2004).

Additional Materials (also see Basic Protocol 1)

- 10% (w/v) maltose stock solution, filter sterilized
- Tris-magnesium (TM) buffer: 10 mM Tris·Cl, pH 7.4 (*APPENDIX 2*)/10 mM MgSO₄
- High-titer lysate of the bacteriophage to be engineered
- PCR product with desired sequence changes and flanking homology to the target on the phage chromosome
- Lambda plates and lambda top agar (see *UNIT 1.1*, adjust NaCl to 5 g per liter in both the plates and the top agar)
- Chloroform
- Appropriate bacterial indicator strain
- Additional reagents and equipment for working with λ bacteriophages (*UNITS 1.9-1.13*)

Grow host strain

1. Grow strain with defective prophage to mid-log phase at 32°C (see Basic Protocol 1, step 6), except supplement the LB medium with 0.4% maltose (added from 10% w/v maltose stock solution).

Maltose induces the phage receptor on the bacterial cell surface, ensuring efficient adsorption of the phage to the host cells.

Adsorb bacteriophage

2. Harvest the cells by centrifuging 7 min at $4600 \times g$, 4°C . Resuspend pellet in 1 ml Tris-magnesium (TM) buffer. Infect the cells with the phage to be engineered at a multiplicity of 1 to 3 phages per cell.

The cells will be at $\sim 1 \times 10^8/\text{ml}$ before concentration. UNITS 1.9-1.13 contain protocols for working with λ bacteriophages.

3. Let the phage adsorb to the cells for 15 min at room temperature.

Phages other than λ may require different adsorption conditions.

Induce recombination functions and phage DNA entry; electroporate cells

4. Transfer the infected cells to 5 ml of 42°C LB medium and shake vigorously for 15 min. At end of incubation, chill rapidly on ice.

This serves to both induce the Red functions and allow phage infection to proceed.

5. Make electrocompetent cells and introduce transforming DNA (i.e., introduce PCR product with mutation of interest; see Basic Protocol 1, steps 8 to 14).

Outgrow infected cells to allow phage production

6. Dilute electroporation mix into 5 ml warm LB medium and shake vigorously for 90 min at 42°C to allow the phage to complete a lytic cycle. Add 0.25 ml chloroform to completely lyse infected cells. Plate phage on lambda plates with lambda top agar (see UNIT 1.11) using the appropriate bacterial indicator strain as a host; apply a selection if possible; or plate non-selectively and screen for the desired mutation with plaque hybridization.

Amber mutations can be specifically selected (Oppenheim et al., 2004).

REAGENTS AND SOLUTIONS

Use Milli-Q purified water or equivalent in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

M63 minimal glucose plates with biotin

Per liter:

3 g KH_2PO_4

7 g K_2HPO_4

2 g $(\text{NH}_4)_2\text{SO}_4$

0.5 ml of 1 mg/ml FeSO_4

0.2% (v/v) glucose

0.001% (w/v) biotin (omit for control)

1 ml 1% (w/v) vitamin B1 (thiamine)

1 ml 1 M MgSO_4

15 g agar

Pour 40 ml of the agar-containing medium per plate.

Store up to several months at 4°C .

M63 minimal glycerol plates with sucrose

Per liter:

3 g KH_2PO_4

7 g K_2HPO_4

2 g $(\text{NH}_4)_2\text{SO}_4$

0.5 ml of 1 mg/ml FeSO_4

0.2% (v/v) glycerol

continued

***Escherichia coli,
Plasmids, and
Bacteriophages***

1.16.17

5% (w/v) sucrose
 0.001% (w/v) biotin
 1 ml 1% (w/v) vitamin B1 (thiamine)
 1 ml 1 M MgSO₄
 15 g agar
 Pour 40 ml of the agar-containing medium per plate.
 Store up to several months at 4°C.

COMMENTARY

Background Information

Bacteriophage λ encodes three genes important for recombineering. The *exo* and *bet* genes, respectively, encode a 5' to 3' double-strand exonuclease, Exo, and a single strand annealing protein, Beta, which together can recombine a double-stranded PCR product with short flanking homologies into the desired genetic target. The λ *gam* gene encodes a protein, Gam, that inhibits the RecBCD enzyme, which will otherwise degrade linear DNA introduced into the bacterial cell. Only the Beta single-strand annealing function is required to recombine single-stranded oligos containing the desired alterations. A cryptic lambdoid prophage, *rac*, is present in some strains of *E. coli*, and encodes RecE and RecT functions that are analogous to Exo and Beta, respectively. Unlike some other in vivo genetic engineering methods (Russell et al., 1989), recombineering does not require the host *recA* function. A strain mutant for *recA* provides more controllable recombination, since the strain is recombination proficient only when the phage functions are induced. A more detailed discussion of the molecular mechanism of recombineering can be found in Court et al. (2002).

Recently the Red genes have been moved to several plasmids (Table 1.16.3; S. Datta, manuscript in preparation) having different DNA replication origins. Here, the essential control elements of the prophage system are retained and recombination functions are

induced by a temperature shift as in Basic Protocol 1. The plasmids are especially useful when one wants to create a mutation in a particular bacterial strain, rather than create the mutations in the prophage-containing strains and subsequently move them into a different background.

Critical Parameters and Troubleshooting

Induction times

When inducing the recombination functions from the defective prophage, the proper induction time is essential. Longer induction times will cause decreased cell viability, since the prophage Kil function is also induced by the temperature shift. The Gam function, necessary for efficient transformation of ds-DNA, is also toxic to the cells (Sergueev et al., 2001).

Storage of induced cells

It is also important to use the induced cells promptly, since the induced phage functions will decay over time, especially at 32°C. Although one pioneering laboratory member reports that induced cells can be successfully stored on ice for several hours before electroporation, the authors do not recommend this procedure. As detailed in the Basic Protocol 1, competent cells may be frozen in 15% glycerol, although their recombineering efficiency has been less than that of the freshly prepared cells.

Table 1.16.3 Plasmids Containing the Red System Under *cl857* Control

Plasmid designation	Plasmid origin	Approximate copy number/cell
pSIM5(Cm ^R) pSIM6(Amp ^R)	pSC101 <i>ts</i>	16
pSIM7(Cm ^R) pSIM8(Amp ^R)	pBBR1	30-40
pSIM9(Cm ^R)	pRK2 <i>ts</i>	20-40

Amplification of drug cassettes

The authors strongly recommend that each drug cassette be amplified with only one standard set of primers. Confusion has arisen in the authors' laboratory when individuals have designed their own primers for the drug cassettes. Remember that it is best to have a promoter, the open reading frame, and a transcriptional terminator on each cassette. Standard priming sequences for the commonly used cassettes are listed in Table 1.16.2.

The *cat-sacB* element

The *cat-sacB* DNA segment described in Support Protocol 1 is amplified from plasmid pEL04, previously known as both pKO4 and *pcat-sacB*, or from the strain DY441, using colony PCR. If a different antibiotic resistance gene is required, the *cat* gene on *pcat-sacB* can be replaced with another drug marker. Use 50 bases of homology upstream of the 5' *cat* primer and downstream of the 3' *cat* primer to cross in the other marker. The sequence of pEL04 is available from the Court Laboratory (court@ncifcrf.gov). Since the *cat-sacB* PCR product is 3264 bp, it is not always easy to amplify. The authors have used the PCR conditions detailed above, but other conditions and any other high-fidelity enzyme should also work. This is really an empirical problem, and, in the opinion of the authors, the biggest factors, if sufficient extension times and appropriate temperatures are used, are the PCR machine itself and the polymerase. An MJ Research PTC-100 machine is used in the authors' laboratory. Adjusting the Mg²⁺ concentration may also improve yield. There has been some confusion regarding the primers for amplification of the *cat-sacB* cassette. The authors have now settled on an optimal primer pair for amplification of this DNA, and strongly recommend that only this set of primers be used. Please note that both primer sequences are different than those previously given in this protocol.

Detecting recombinants

If one has engineered a drug marker into the DNA, drug resistance will serve as the selection. The two-step *cat-sacB* replacement allows precise modification without leaving an antibiotic-resistance cassette or other marker behind. The authors have also had success using colony hybridization with a labeled oligo probe, although a unique sequence hybridizing only to the probe must be inserted (or a unique sequence must be created by a deletion) for this method to be an option.

Mismatch repair minus conditions for oligonucleotide recombination

The authors have recently found (Costantino and Court, 2003) that extremely high levels of recombinants can be obtained when recombineering with oligos if the bacterial strain is mutant for the host methyl-directed mismatch repair system (the *mut HLS* system). Under these conditions ~20% to 25% of the total viable cells are recombinant. Strains with the prophage and mutations in the mismatch repair system are available from the Court laboratory: these are HME63 and HME64 and contain a *mutS* <> *amp* and an *uvrD* <> *kan* mutation, respectively. Either mutation will eliminate mismatch repair; the latter strain can be used for engineering onto plasmids expressing ampicillin resistance. The same elevated level of recombination is obtained in mismatch repair proficient strains if the incoming oligo creates a C-C mismatch when annealed to the target DNA, since C-C mispairs are not subject to mismatch repair.

Counter-selections

The *cat-sacB* cassette is a counter-selection; it can be selected either for (by chloramphenicol resistance) or against (sucrose sensitivity). Several such counter-selections are available and may prove useful for one's particular situation; tetracycline resistance is another example (Bochner et al., 1980; Maloy and Nunn, 1981). If removing a bacteriostatic drug marker (such as tetracycline), enrichment for recombinants is possible using ampicillin. Nonrecombinant bacteria will still express resistance to the *tet* marker encoded on the chromosome; when the electroporated culture is propagated in the presence of both tetracycline and ampicillin, only nonrecombinant cells will grow; these will be killed by the ampicillin (Murphy et al., 2000). Recombinant cells will not grow but will not be killed. 2-deoxy D-galactose is a toxic analog of galactose on which only mutants of galactokinase, the product of the *galK* gene, will grow (Alper and Ames, 1975). Other counter-selections may be devised.

In vivo assembly with overlapping oligos

Complementary oligos will anneal in vivo when introduced by electroporation into cells expressing Exo and Beta protein (Yu et al., 2003). Multiple overlapping oligos can be used to build moderately sized DNA products (100 to 150 bp) in an in vivo reaction similar to PCR assembly (Stemmer et al., 1995). By adding

flanking homologies to chromosomal targets, these overlapping oligos are restored to linear dsDNA *in vivo* and recombined into the target.

Anticipated Results

As discussed above, ideally, transformation with dsDNA and ssDNA can approach frequencies of 0.1%, and 25%, respectively. Because of this high efficiency, there should rarely if ever be experiments where no recombinants are found. However, in practice, recombineering frequency may be partially context dependent; certain areas of the chromosome appear “hotter” for recombination than others (Ellis et al., 2001). If recombinants are not obtained, check the construct design and redesign primers if necessary, as this is one reason for failure. If the recombineering reaction does not work, the authors strongly recommend doing a control experiment using known strains and oligos or PCR products, as described in Yu et al. (2000), Ellis et al. (2001), and Costantino and Court (2003) to verify that the predicted number of recombinants are obtained in these control reactions. It has been the authors’ experience that most recombineering failures occur because the protocol is not executed carefully or properly.

Recombineering onto plasmids

Genetic alterations can also be targeted to intact circular plasmids. If the desired change can be engineered with an oligonucleotide, the mismatch repair-deficient strains can be used and unselected clones screened for the mutation. Otherwise, it is helpful to have a selection for the desired recombinant. If one has a selection, the plasmid may either be already resident in the bacterial cell or may be introduced by co-electroporation. The former method is less optimal, because expression of the λ Gam function can lead to formation of linear multimers of some plasmid replicons (Cohen and Clark, 1986). Hence, co-electroporation is preferable. If introducing an unselected mutation, co-electroporation is essential, since it is unlikely that more than one resident plasmid in a cell will become modified. In either case, the recombinant plasmid clones should be purified and the DNA isolated, characterized, and used to transform a new host.

Engineering onto BACs

Red recombineering has also been optimized for engineering bacterial artificial chromosomes (Copeland et al., 2001; Lee et al., 2001; Swaminathan and Sharan, 2004), which are able to accommodate hundreds of kilobases

of foreign DNA. DY380 is the bacterial host of choice for use with BACs; it is a DH10B derivative containing the defective prophage. The plasmids listed in Table 1.16.3 may also be useful in manipulating BACs.

Mutating essential genes

Mutation of an essential gene usually results in cell death. Such a mutation can be recovered in a diploid state; however, the cell will maintain a wild-type copy of the gene as well as a mutant version. This diploid state can usually be detected by PCR analysis.

Moving the prophage to a different background

If a different host is required for recombineering, the defective prophage can be moved by P1 transduction (Miller, 1972; Yu et al., 2000). Grow a P1 lysate on DY329 and transduce the strain of choice. Select for tetracycline resistance and screen for temperature sensitivity or an inability to grow in the absence of biotin. Check the genotype of the strain first and supplement the minimal plates to complement any additional auxotrophies when performing the biotin screen.

Time Considerations

The basic recombineering protocol can be executed in one day, with bacterial cultures started the evening before. The recombinants may take several days to grow on the selective plates, and it may take another day or so to confirm the recombinants.

CHAPTER 2

Preparation and Analysis of DNA

INTRODUCTION

The ability to prepare and isolate pure DNA from a variety of sources is an important step in many molecular biology protocols. Indeed, the isolation of genomic, plasmid, or DNA fragments from restriction digests and polymerase chain reaction (PCR) products has become a common everyday practice in almost every laboratory. This chapter therefore begins with protocols for purification of genomic DNA from bacteria, plant cells, and mammalian cells (*UNITS 2.1-2.4*). These protocols consist of two parts: a technique to lyse the cells gently and solubilize the DNA, followed by one of several basic enzymatic or chemical methods to remove contaminating proteins, RNA, and other macromolecules. The basic approaches described here are generally applicable to a wide variety of starting materials. A brief collection of general protocols for further purifying and concentrating nucleic acids is also included.

The last decade has shown a dramatic departure from the use of traditional DNA purification methods outlined in *UNITS 2.2-2.4*, with a concomitant increase in the use of purpose-specific kits for the isolation and purification of DNA. For example, kits for purification of DNA using pre-made anion-exchange columns packaged with all necessary solutions to lyse the cells and solubilize the DNA are available from many molecular biology companies. A variety of kits based on binding of DNA to glass beads are also available. The uses of both types of kits are discussed in *UNIT 2.1B*.

The use of kits has two main advantages: it saves time and makes the process of DNA purification a relatively easy and straightforward process. The purification of DNA by anion-exchange chromatography (*UNIT 2.1B*) is readily becoming the accepted standard for quick and efficient large-scale (more than 100 μg of DNA) production of DNA from bacteria, mammalian tissue, and plant tissue. In most cases, the cell lysis and solubilization of DNA is relatively unchanged compared to traditional methods, with anion-exchange chromatography columns having replaced labor and time-intensive techniques such as cesium chloride centrifugation for the isolation of relatively pure DNA. Purification kits are usually available in several sizes and configurations, allowing the researcher to have variability concerning the processing and purification of their DNA.

A variety of techniques exist for the isolation of small amounts of plasmid DNA from minipreps and for DNA fragments from restriction digests/PCR products from agarose gels (with removal of unincorporated nucleoside triphosphates, reaction products, and small oligonucleotides from PCR reactions). These are detailed in *UNITS 2.1A, 2.1B, 2.6 & 2.7*. Likewise, kits are available from several molecular biology companies, usually based on silica-gel technology, for each of these applications (*UNIT 2.1B*). As with large-scale DNA isolation and purification, these kits provide a quick and efficient means to recover purified DNA that can be used for subsequent cloning or other modifications.

Virtually all protocols in molecular biology require, at some point, fractionation of nucleic acids. Chromatographic techniques are appropriate for some applications and may be used for separation of plasmid from genomic DNA as well as separation of genomic DNA from debris in a cell lysate (*UNIT 2.1B*). Gel electrophoresis, however, has much greater

resolution than alternative methods and is generally the fractionation method of choice. Gel electrophoretic separations can be either analytical or preparative, and can involve fragments with molecular weights ranging from less than 1000 Daltons to more than 10^8 . A variety of electrophoretic systems have been developed to accommodate such a large range of applications.

In general, the use of electrophoresis to separate nucleic acids is simpler than its application to resolve proteins. Nucleic acids are uniformly negatively charged and, for double-stranded DNA, reasonably free of complicating structural effects that affect mobility. A variety of important variables affect migration of nucleic acids on gels. These include the conformation of the nucleic acid, the pore size of the gel, the voltage gradient applied, and the salt concentration of the buffer. The most basic of these variables is the pore size of the gel, which dictates the size of the fragments that can be resolved. In practice, this means that larger-pore agarose gels are used to resolve fragments >500 to 1000 bp (*UNITS 2.5A & 2.6*) and smaller-pore acrylamide or sieving agarose gels (*UNIT 2.7*) are used for fragments <1000 bp. A protocol for resolution of very large pieces of DNA may also be resolved on agarose gels using pulsed-field gel electrophoresis (*UNIT 2.5B*). Finally, the powerful analytical technique of capillary electrophoresis of DNA (*UNIT 2.8*) may be used to assess the purity of synthetic oligonucleotides, analyze quantitative PCR results, and compare DNA fragment lengths from restriction fragment length polymorphism (RFLP) and variable number of tandem repeat (VNTR) analyses.

Frequently it is desirable to identify an individual fragment in a complex mixture that has been resolved by gel electrophoresis. This is accomplished by a technique termed Southern blotting, in which the fragments are transferred from the gel to a nylon or nitrocellulose membrane and the fragment of interest is identified by hybridization with a labeled nucleic acid probe. Section IV of this chapter gives a complete review of methods and materials required for immobilization of fractionated DNA (*UNIT 2.9*) and associated hybridization techniques (*UNIT 2.10*). These methods have greatly contributed to the mapping and identification of single and multicopy sequences in complex genomes, and facilitated the initial eukaryotic cloning experiments.

Other commonly encountered applications of gel electrophoresis include resolution of single-stranded RNA or DNA. Polyacrylamide gels containing high concentrations of urea as a denaturant provide a very powerful system for resolution of short (<500-nucleotide) fragments of single-stranded DNA or RNA. Such gels can resolve fragments differing by only a single nucleotide in length, and are central to all protocols for DNA sequencing (see *UNIT 7.6*). Such gels are used for other applications requiring resolution of single-stranded fragments, particularly including the techniques for analyzing mRNA structure by S1 analysis (*UNIT 4.6*), ribonuclease protection (*UNIT 4.7*), or primer extension (*UNIT 4.8*). Denaturing polyacrylamide gels are also useful for preparative applications, such as small-scale purification of radioactive single-stranded probes and large-scale purification of synthetic oligonucleotides (*UNIT 2.12*).

Resolution of relatively large single-stranded fragments (>500 nucleotides) can be accomplished using denaturing agarose gels. This is of particular importance to the analysis of mRNA populations by northern blotting and hybridization. A protocol for use of agarose gels containing formaldehyde in resolution of single-stranded RNA is presented in *UNIT 4.9*. The use of denaturing alkaline agarose gels for purification of labeled single-stranded DNA probes is described in *UNIT 4.6*.

Gels and Electric Circuits

Gel electrophoresis units are almost always simple electric circuits and can be understood using two simple equations. Ohm's law, $V = IR$, states that the electric field, V (measured in volts), is proportional to current, I (measured in milliamps), times resistance, R (measured in ohms). When a given amount of voltage is applied to a simple circuit, a constant amount of current flows through all the elements and the decrease in the total applied voltage that occurs across any element is a direct consequence of its resistance. For a segment of a gel apparatus, resistance is inversely proportional to both the cross-sectional area and the ionic strength of the buffer. Usually the gel itself provides nearly all of the resistance in the circuit, and the voltage applied to the gel will be essentially the same as the total voltage applied to the circuit. For a given current, decreasing either the thickness of the gel (and any overlying buffer) or the ionic strength of the buffer will increase resistance and, consequently, increase the voltage gradient across the gel and the electrophoretic mobility of the sample.

A practical upper limit to the voltage is usually set by the ability of the gel apparatus to dissipate heat. A second useful equation, $P = I^2R$, states that the power produced by the system, P (measured in watts), is proportional to the resistance times the square of the current. The power produced is manifested as heat, and any gel apparatus can dissipate only a particular amount of power without increasing the temperature of the gel. Above this point small increases in voltage can cause significant and potentially disastrous increases in temperature of the gel. It is very important to know how much power a particular gel apparatus can easily dissipate and to carefully monitor the temperature of gels run above that level.

Two practical examples illustrate applications of the two equations. The first involves the fact that the resistance of acrylamide gels increases somewhat during a run as ions related to polymerization are electrophoresed out of the gel. If such a gel is run at constant current, the voltage will increase with time and significant increases in power can occur. If an acrylamide gel is being run at high voltage, the power supply should be set to deliver constant power. The second situation is the case where there is a limitation in number of power supplies, but not gel apparatus. A direct application of the first equation shows that the fraction of total voltage applied to each of two gels hooked up in series (one after another) will be proportional to the fraction of total resistance the gel contributes to the circuit. Two identical gels will each get 50% of the total voltage and power indicated on the power supply.

Finally, it should be noted that some electrophoretic systems employ lethally high voltages, and almost all are potentially hazardous. It is very important to use an adequately shielded apparatus, an appropriately grounded and regulated power supply, and most importantly, common sense when carrying out electrophoresis experiments.

David D. Moore and Dennis Dowhan

MANIPULATION OF DNA

SECTION I

This section begins with a protocol describing basic techniques for purifying and concentrating DNA samples by extraction and precipitation (*UNIT 2.1A*) and anion-exchange chromatography (*UNIT 2.1B*), followed by similar protocols for purifying DNA from mammalian tissue (*UNIT 2.2*), plant tissue (*UNIT 2.3*), and bacteria (*UNIT 2.4*). Various properties and useful measurements of DNA are presented in *APPENDIX 1* (see Tables A.1B.1 and A.1B.2 and Fig. A.1B.1).

IMPORTANT NOTE: The smallest amount of contamination of DNA preparations by recombinant phages or plasmids can be disastrous. Many person-years have been wasted reisolating previously cloned sequences that contaminated preparations of DNA used to create recombinant DNA libraries (see Hall, 1987, for an account of such a mistake) and many researchers have been embarrassed to find that the “extra” genes they found on their Southern blots were actually contaminating plasmid DNA. All materials used for preparation of plasmid or phage DNA should be kept separate from those used for preparation of genomic DNA, and disposable items should be used wherever possible. Particular care should be taken to avoid contamination of commonly used rotors.

Purification and Concentration of DNA from Aqueous Solutions

UNIT 2.1A

This unit presents basic procedures for manipulating solutions of single- or double-stranded DNA through purification and concentration steps. These techniques are useful when proteins or solute molecules need to be removed from aqueous solutions, or when DNA solutions need to be concentrated for reasons of convenience. The Basic Protocol, using phenol extraction and ethanol precipitation, is appropriate for the purification of DNA from small volumes (<0.4 ml) at concentrations ≤ 1 mg/ml. Isopropanol may also be used to precipitate DNA, as described in Alternate Protocol 1. Three support protocols outline methods to buffer the phenol used in extractions (see Support Protocol 1), concentrate DNA using butanol (see Support Protocol 2), and extract residual organic solvents with ether (see Support Protocol 3). An alternative to these methods is nucleic acid purification using commercially available silica membrane spin columns, presented in Alternate Protocol 2. These protocols may also be used for purifying RNA.

The final two alternate protocols provide modifications to the basic protocol that are used for concentrating RNA and extracting and precipitating DNA from larger volumes and from dilute solutions (see Alternate Protocol 3), and for removing low-molecular-weight oligonucleotides and triphosphates (see Alternate Protocol 4).

PHENOL EXTRACTION AND ETHANOL PRECIPITATION OF DNA

BASIC PROTOCOL

This protocol describes the most commonly used method of purifying and concentrating DNA preparations. The DNA solution is first extracted with a phenol/chloroform/isoamyl alcohol mixture to remove protein contaminants, and then precipitated with 100% ethanol. The DNA is pelleted after the precipitation step, washed with 70% ethanol to remove salts and small organic molecules, and resuspended in buffer at a concentration suitable for further experimentation.

Preparation and Analysis of DNA

2.1.1

Materials

≤1 mg/ml DNA to be purified
25:24:1 (v/v/v) phenol/chloroform/isoamyl alcohol (made with buffered phenol; see Support Protocol 1)
3 M sodium acetate, pH 5.2 (APPENDIX 2)
100% ethanol, ice cold
70% ethanol, room temperature
TE buffer, pH 8.0 (APPENDIX 2)
Speedvac evaporator (Savant)

1. Add an equal volume of phenol/chloroform/isoamyl alcohol to the DNA solution to be purified in a 1.5-ml microcentrifuge tube.

DNA solutions containing ≤0.5 M monovalent cations can be used. Extracting volumes ≤100 μl is difficult; small volumes should be diluted to obtain a volume that is easy to work with.

High salt concentrations can cause the inversion of the aqueous and organic phases. If this happens, the organic phase can be identified by its yellow color.

2. Vortex vigorously for 10 sec and microcentrifuge 15 sec at maximum speed, room temperature.

Phases should be well separated. If DNA solution is viscous or contains a large amount of protein, it should be microcentrifuged longer (1 to 2 min).

3. Carefully remove the top (aqueous) phase containing the DNA using a 200-μl pipettor and transfer to a new tube. If a white precipitate is present at the aqueous/organic interface, repeat steps 1 to 3.

If starting with a small amount of DNA (<1 μg), recovery can be improved by reextracting the organic phase with 100 μl TE buffer, pH 8.0. This aqueous phase can be pooled with that from the first extraction.

4. Add $\frac{1}{10}$ vol of 3 M sodium acetate, pH 5.2, to the solution of DNA. Mix by vortexing briefly or by flicking the tube several times with a finger.

If the solution contained a high concentration of NaCl or sodium acetate (0.3 to 0.5 M) prior to the phenol extraction step, then no additional salt should be added. It is advisable to make appropriate dilutions to keep NaCl and sodium acetate concentrations below 0.5 M.

For high concentrations of DNA (>50 to 100 μg/ml), precipitation is essentially instantaneous at room temperature. If ethanol precipitation is not desirable, residual organic solvents can be removed by ether extraction (see Support Protocol 3). In this case, no salt should be added.

To prevent carryover of residual phenol, the aqueous phase can be reextracted with 24:1 (v/v) chloroform/isoamyl alcohol. However, this should not be necessary if the final pellet is washed well with 70% ethanol, or if an additional ethanol precipitation step is included.

5. Add 2 to 2.5 vol (calculated after salt addition) of ice-cold 100% ethanol. Mix by vortexing and place in crushed dry ice for 5 min or longer.

This precipitation step can also be done in a -70°C freezer for 15 min or longer, or in a -20°C freezer for at least 30 min. A slurry of dry ice and ethanol may also be used, but tube labels are less often lost when crushed dry ice is used.

6. Microcentrifuge 5 min at maximum speed and remove the supernatant.

For large pellets the supernatant can simply be poured off. For small pellets (<1 μg), aspirate off the ethanol supernatant with a pipetting device such as a Pasteur pipet or mechanical pipettor. This is best accomplished by drawing off liquid from the side of the

tube opposite that against which the DNA precipitate was pelleted. Start at the top and move downward as the liquid level drops.

7. Add 1 ml room-temperature 70% ethanol. Invert the tube several times and microcentrifuge as in step 6.

If the DNA molecules being precipitated are very small (<200 bases), use 95% ethanol at this step.

8. Remove the supernatant as in step 6. Dry the pellet in a desiccator under vacuum or in a Speedvac evaporator.

The DNA pellet will not stick well to the walls of the tube after the 70% ethanol wash and care must be taken to avoid aspirating the pellet out of the tube.

9. Dissolve the dry pellet in an appropriate volume of water if it is going to be used for further enzymatic manipulations requiring specific buffers. Dissolve in TE buffer, pH 8.0, if it is going to be stored indefinitely.

DNA pellets will not dissolve well in high-salt buffers. To facilitate resuspension, the DNA concentration of the final solution should be kept at <1 mg/ml.

If DNA is resuspended in a volume of TE buffer or water to yield a DNA concentration of <1 mg/ml, small quantities (<25 µg) of precipitated plasmids or restriction fragments should dissolve quickly upon gentle vortexing or flicking of the tube. However, larger quantities of DNA may require vortexing and brief heating (5 min at 65°C) to resuspend. High-molecular-weight genomic DNA may require one to several days to dissolve and should be shaken gently (not vortexed) to avoid shearing, particularly if it is to be used for cosmid cloning or other applications requiring high-molecular-weight DNA. Gentle shaking on a rotating platform or a rocking apparatus is recommended.

PRECIPITATION OF DNA USING ISOPROPANOL

Equal volumes of isopropanol and DNA solution are used in precipitation. Note that the isopropanol volume is half that of the given volume of ethanol in precipitations. This allows precipitation from a large starting volume (e.g., 0.7 ml) in a single microcentrifuge tube. Isopropanol is less volatile than ethanol and takes longer to remove by evaporation. Some salts are less soluble in isopropanol (compared to ethanol) and will be precipitated along with nucleic acids. Extra washings may be necessary to eliminate these contaminating salts.

PREPARATION OF BUFFERED PHENOL AND PHENOL/CHLOROFORM/ISOAMYL ALCOHOL

For some purposes, fresh liquefied phenol (88% phenol) can be used without further purification. However, for purification of DNA prior to cloning and other sensitive applications, phenol must be redistilled before use, because oxidation products of phenol can damage and introduce breaks into nucleic acid chains. Redistilled phenol for use in nucleic acid purification is commercially available, but must be buffered before use. Appropriately buffered phenol is also commercially available, but is somewhat more expensive and should not be stored for long periods of time (e.g., >6 months).

CAUTION: Phenol can cause severe burns to skin and damage clothing. Gloves, safety glasses, and a lab coat should be worn whenever working with phenol, and all manipulations should be carried out in a fume hood. A glass receptacle should be available exclusively for disposing of used phenol and chloroform.

**ALTERNATE
PROTOCOL 1**

**SUPPORT
PROTOCOL 1**

**Preparation and
Analysis of DNA**

2.1.3

Materials

8-hydroxyquinoline
Liquefied phenol
50 mM Tris base (unadjusted pH ~10.5)
50 mM Tris·Cl, pH 8.0 (APPENDIX 2)
Chloroform
Isoamyl alcohol

1. Add 0.5 g of 8-hydroxyquinoline to a 2-liter glass beaker containing a stir bar.
2. Gently pour in 500 ml liquefied phenol or melted crystals of redistilled phenol (melted in a water bath at 65°C).

The phenol will turn yellow due to the 8-hydroxyquinoline, which is added as an antioxidant.

3. Add 500 ml of 50 mM Tris base.
4. Cover the beaker with aluminum foil. Stir 10 min at low speed with magnetic stirrer at room temperature.
5. Let phases separate at room temperature. Gently decant the top (aqueous) phase into a suitable waste receptacle. Remove what cannot be decanted with a 25-ml glass pipet and a suction bulb.
6. Add 500 ml of 50 mM Tris·Cl, pH 8.0. Repeat steps 4 to 6 so that two successive equilibrations with Tris·Cl are performed, ending with removal of the second Tris·Cl phase.

The pH of the phenol phase can be checked with indicator paper and should be 8.0. If it is not, the Tris·Cl equilibration should be repeated until this pH is obtained.

7. Add 250 ml of 50 mM Tris·Cl, pH 8.0, or TE buffer, pH 8.0, and store at 4°C in brown glass bottles or clear glass bottles wrapped in aluminum foil.

Phenol prepared with 8-hydroxyquinoline as an antioxidant can be stored ≤ 2 months at 4°C.

8. For use in DNA purification procedure (see Basic Protocol), mix 25 vol phenol (bottom yellow phase of stored solution) with 24 vol chloroform and 1 vol isoamyl alcohol. Store up to 2 months at 4°C wrapped in foil or in a dark glass bottle.

SUPPORT PROTOCOL 2

CONCENTRATION OF DNA USING BUTANOL

It is generally inconvenient to handle large volumes or dilute solutions of DNA. Water molecules (but not DNA or solute molecules) can be removed from aqueous solutions by extraction with *sec*-butanol (2-butanol). This procedure is useful for reducing volumes or concentrating dilute solutions before proceeding with the Basic Protocol.

Additional Materials (also see Basic Protocol)

sec-Butanol
25:24:1 (v/v/v) phenol/chloroform/isoamyl alcohol (made with buffered phenol;
see Support Protocol 1)
Polypropylene tube

1. Add an equal volume of *sec*-butanol to the sample and mix well by vortexing or by gentle inversion (if the DNA is of high molecular weight). Perform extraction in a polypropylene tube, as butanol will damage polystyrene.

2. Centrifuge 5 min at $1200 \times g$ (2500 rpm), room temperature, or in a microcentrifuge for 10 sec at maximum speed.
3. Remove and discard the upper (*sec*-butanol) phase.
4. Repeat steps 1 to 3 until the desired volume of aqueous solution is obtained.
5. Extract the lower, aqueous phase with 25:24:1 phenol/chloroform/isoamyl alcohol and ethanol precipitate (see Basic Protocol, steps 1 to 9) or remove *sec*-butanol by two ether extractions (see Support Protocol 3).

Addition of too much sec-butanol can result in complete loss of the water phase into the sec-butanol layer. If this happens, add 1/2 vol water back to the sec-butanol, mix well, and spin. The DNA can be recovered in this new aqueous phase and can be further concentrated with smaller amounts of sec-butanol.

The salt concentration will increase in direct proportion to the volume decrease. The DNA can be precipitated with ethanol to readjust the buffer conditions.

REMOVAL OF RESIDUAL PHENOL, CHLOROFORM, OR BUTANOL BY ETHER EXTRACTION

SUPPORT PROTOCOL 3

DNA solutions that have been purified by extraction with phenol and chloroform (see Basic Protocol) or concentrated with *sec*-butanol (see Support Protocol 2) can often be used without ethanol precipitation for enzymatic manipulations or in gel electrophoresis experiments if the organic solvents are removed by extraction with ether. Traces of ether are subsequently removed by evaporation. This procedure is useful only if the solute concentrations in the starting solution are compatible with what is needed in later steps. It is quite useful in purifying high-molecular-weight DNA, as mechanical shearing of large nucleic acid molecules can occur during precipitation with ethanol.

CAUTION: Ether is highly flammable and its vapors can cause drowsiness. All manipulations with ether should be carried out in a well-ventilated fume hood.

Materials

Diethyl ether
TE buffer, pH 8.0 (APPENDIX 2)
Polypropylene tube

1. Mix diethyl ether with an equal volume of water or TE buffer, pH 8.0, in a polypropylene tube. Vortex vigorously for 10 sec and let the phases separate.

Ether is the top phase.

2. Add an equal volume of hydrated ether to the DNA sample. Mix well by vortexing or by gentle inversion (if the DNA is of high molecular weight).
3. Microcentrifuge 5 sec at maximum speed or let the phases separate by setting the tube upright in a test tube rack.
4. Remove and discard the top (ether) layer. Repeat steps 2 and 3.
5. Remove ether by leaving the sample open under a fume hood for 15 min (small volumes, <100 μ l), or under vacuum for 15 min (larger volumes).

The DNA solution will be free of organic solvents and will have salt concentrations that are roughly three-fourths of those that were in the aqueous solution before phenol extraction (solute concentrations are lowered in the two phenol/chloroform/isoamyl alcohol extractions steps).

Preparation and Analysis of DNA

2.1.5

DNA PURIFICATION USING SILICA MEMBRANE SPIN COLUMNS

The use of glass beads or silica gel particles has become a popular method for isolating DNA. The evolution of this principle has resulted in the introduction of silica membrane spin columns. The basic principle of silica gel solid support spin columns is fairly simple. DNA is bound to the silica membrane spin column in the presence of a high concentration of chaotropic salt, contaminants are washed away, and the DNA is then eluted from the silica membrane in water or a low-salt buffer. The procedure below includes steps for when a bacterial lysate is used as the starting material.

The major advantage of silica membrane spin columns is the fact that the silica is bound to a solid support, which eliminates the problem of glass-bead contamination of the DNA sample. This method of DNA purification is quick and convenient, and can produce a high yield of pure DNA. Silica membrane spin columns are available from many companies, including Qiagen, Promega, Invitrogen, and Novagen, as kits including the columns and all appropriate buffers necessary for DNA purification.

Materials

- 1 × 10⁹ cell/ml bacterial culture containing DNA of interest *or* 0.1 to 1 mg/ml DNA to be purified (5 to 10 µg DNA total)
- 6 M sodium iodide (NaI) solution (filter through filter paper, store up to 3 months in the dark at 4°C)
- Resuspension buffer (see recipe)
- Lysis solution: 0.2 M NaOH/1.0% (w/v) SDS (store indefinitely at room temperature)
- Neutralization/binding solution (see recipe)
- Wash buffer (see recipe)
- TE buffer, pH 8.5 (*APPENDIX 2*) *or* nuclease-free H₂O
- Silica membrane spin columns (e.g., Qiagen, Promega, Invitrogen, Novagen)
- 1.5-ml microcentrifuge tubes

Prepare DNA solution

1. Harvest 1 to 5 ml of bacterial culture by centrifuging 1 min at 10,000 × *g*, room temperature, then discard the supernatant.

To clean a DNA solution not generated from bacterial lysates, add 3 vol of 6 M NaI solution to DNA in a 1.5-ml microcentrifuge tube, mix, and proceed to step 6.
2. Add 250 µl cell resuspension buffer, resuspend the cell pellet by vortexing or pipetting, and transfer to 1.5-ml microcentrifuge tube.
3. Add 250 µl lysis solution and mix by inversion (do not vortex). Allow lysis to proceed 3 to 5 min; do not allow lysis reaction to proceed for more than 5 min.
4. Add 350 µl neutralization/binding solution and mix by inversion.
5. Microcentrifuge 10 min at maximum speed (a white pellet will form in the bottom of the tube).

Purify DNA on silica membrane spin column

6. Apply the supernatant to the silica membrane spin column.
7. Microcentrifuge spin column inside its collection tube for 1 min at maximum speed. Remove the spin column from the collection tube and discard the flowthrough. Reinsert the spin column into the collection tube.

8. Wash the spin column by adding 750 μ l of wash buffer and microcentrifuging 1 min at maximum speed. Remove the spin column from the collection tube and discard the flowthrough.
9. Reinsert the spin column in the collection tube and microcentrifuge for an additional 1 min to remove any residual wash buffer (ethanol) from the column membrane.
10. Transfer the spin column to a 1.5-ml microcentrifuge tube and add 75 to 100 μ l nuclease-free water or TE buffer, pH 8.5, to the center of the membrane. Let stand for 2 to 10 min, then microcentrifuge 1 min at maximum speed.
11. Collect DNA and store at 4°C until use.

PURIFICATION AND CONCENTRATION OF RNA AND DILUTE SOLUTIONS OF DNA

*ALTERNATE
PROTOCOL 3*

The following adaptations to the purification procedure (see Basic Protocol) are used if RNA or dilute solutions of DNA are to be purified.

Purification and Concentration of RNA

The procedure outlined in the Basic Protocol is identical for purification of RNA, except that 2.5 vol ethanol should be used routinely for the precipitation (step 5). It is essential that all water used directly or in buffers be treated with diethylpyrocarbonate (DEPC) to inactivate RNase (see *UNIT 4.1*, reagents and solutions, for instructions).

Dilute Solutions of DNA

When DNA solutions are dilute (<10 μ g/ml) or when <1 μ g of DNA is present, the ratio of ethanol to aqueous volume should be increased to 3:1 and the time on dry ice (step 5) extended to 30 min. Microcentrifugation should be carried out for 15 min in a cold room to ensure the recovery of DNA from these solutions.

Nanogram quantities of labeled or unlabeled DNA can be efficiently precipitated by the use of carrier nucleic acid. A convenient method is to add 10 μ g of commercially available tRNA from *E. coli*, yeast, or bovine liver to the desired DNA sample. The DNA will be co-precipitated with the tRNA. The carrier tRNA will not interfere with most enzymatic reactions, but will be phosphorylated efficiently by polynucleotide kinase and should not be added if this enzyme will be used in subsequent radiolabeling reactions.

Recovery of small quantities of short DNA fragments and oligonucleotides can be enhanced by adding magnesium chloride to a concentration of <10 mM before adding ethanol (step 4). However, DNA precipitated from solutions containing >10 mM magnesium or phosphate ions is often difficult to redissolve and such solutions should be diluted prior to ethanol precipitation.

DNA in Large Aqueous Volumes (>0.4 to 10 ml)

Larger volumes can be accommodated by simply scaling up the amounts used in the basic protocol or by using butanol concentration (see Support Protocol 2). For the phenol extraction (see Basic Protocol, steps 1 through 3), tightly capped 15- or 50-ml polypropylene tubes should be used as polystyrene tubes cannot withstand the phenol/chloroform mixture. Centrifugation steps should be performed for 5 min at speeds not exceeding $1200 \times g$ (2500 rpm), room temperature. The ethanol precipitate (step 6) should be centrifuged in thick-walled Corning glass test tubes (15- or 30-ml capacity) for 15 min in fixed-angle rotors at $8000 \times g$ (10,000 rpm), 4°C. Glass tubes should be silanized (*APPENDIX 3B*) to facilitate recovery of small amounts of DNA (<10 μ g).

**Preparation and
Analysis of DNA**

2.1.7

REMOVAL OF LOW-MOLECULAR-WEIGHT OLIGONUCLEOTIDES AND TRIPHOSPHATES BY ETHANOL PRECIPITATION

The use of ammonium acetate in place of sodium acetate allows the preferential precipitation of longer DNA molecules. Thus, small single- or double-stranded oligonucleotides (less than ~30 bp) and unincorporated nucleotides used in radiolabeling or other DNA modification reactions can be effectively removed from DNA solutions by two rounds of ethanol precipitation in the presence of ammonium acetate. This approach is not sufficient to completely remove large quantities of linkers as used in cloning procedures (UNIT 3.16). If the nucleic acid is to be phosphorylated, this protocol should not be used because T4 polynucleotide kinase is inhibited by ammonium ions. Although the removal of unincorporated nucleoside triphosphates, reaction products, and small oligonucleotides is effective, it is not absolute and the procedure should not be used to purify DNA from these small molecules prior to detailed biochemical or analytical studies.

Additional Materials (also see Basic Protocol)

4 M ammonium acetate, pH 4.8

1. Add an equal volume of 4 M ammonium acetate, pH 4.8, to the DNA solution. Mix well.
2. Add 2 vol (calculated *after* salt addition) of ice-cold 100% ethanol. Vortex and set tube in crushed dry ice for 5 min.

This precipitation step can also be done in a -70°C freezer for 15 min or longer, or in a -20°C freezer for at least 30 min. A slurry of dry ice and ethanol may also be used, but tube labels are less often lost when crushed dry ice is used.

3. Microcentrifuge 5 min at high speed, room temperature. Carefully remove supernatant and redissolve pellet in 100 µl TE buffer, pH 8.0.
4. Repeat steps 1 to 3.

Reprecipitation is required, particularly if the DNA solution from step 1 contained Mg²⁺ or other divalent or polyvalent cations that will facilitate the precipitation of the oligonucleotides.

5. Proceed with steps 7 to 9 in Basic Protocol.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Neutralization/binding solution

Add 477.65 g guanidine HCl and 49.09 g potassium acetate to 500 ml water and stir to dissolve. Adjust pH to ~4.2 with acetic acid, dilute solution to 1 liter with water, and filter sterilize. Store indefinitely at 4°C.

Resuspension buffer

50 mM Tris·Cl, pH 8.0 (APPENDIX 2)
10 mM EDTA (APPENDIX 2)
100 mg RNase A
Store indefinitely at 4°C.

Wash buffer

1 part 10 mM Tris·Cl, pH 7.5 (APPENDIX 2)
1 part 100 mM NaCl (APPENDIX 2)
4 parts 100% ethanol (final 80%)
Store indefinitely at room temperature

COMMENTARY

Background Information

It is often necessary to purify or concentrate a solution of DNA prior to further enzymatic manipulations or analytical studies. The most commonly used method for deproteinizing DNA is extraction with phenol, which efficiently denatures proteins and probably dissolves denatured protein (Kirby, 1957). Chloroform is also a useful protein denaturant with somewhat different properties—it stabilizes the rather unstable boundary between an aqueous phase and a pure phenol layer. The phenol/chloroform mixture reduces the amount of aqueous solution retained in the organic phase (compared to a pure phenol phase), maximizing the yield (Penman, 1966; Palmiter, 1974). Isoamyl alcohol prevents foaming of the mixture upon vortexing and aids in the separation of the organic and aqueous phases (Marmur, 1961). Denatured protein forms a layer at the interface between the aqueous and organic phases and is thus isolated from the bulk of the DNA in the aqueous layer. This procedure is rapid, inexpensive, and easy to perform.

Ethanol precipitation is useful for concentrating DNA solutions and for removing residual phenol and chloroform from the deproteinized aqueous solution. It is also useful for providing DNA that is relatively free of solute molecules when buffer conditions need to be changed. In the presence of relatively high (0.1 to 0.5 M) concentrations of monovalent cations, ethanol induces a structural transition in nucleic acid molecules which causes them to aggregate and precipitate from solution (Eickbush and Moudrianakis, 1978). However, because most salts and small organic molecules are soluble in 70% ethanol, ethanol precipitation and washing of the pellet will effectively desalt DNA. Although sodium chloride, sodium acetate, and ammonium acetate are each capable of inducing precipitation, it is more difficult to remove sodium chloride due to its lower solubility in 70% ethanol.

The silica membrane spin column protocol, modified from principles originally described in Vogelstein and Gillespie (1979), provides a simple, nontoxic method for removing DNA from contaminating impurities (UNIT 2.6). In the presence of high chaotropic salt concentrations, DNA binds to a silica membrane inside a spin column. The resulting precipitate is washed to remove NaI (or other chaotropic salts like guanidine HCl or sodium perchlorate) along with impurities from the original sample, and

subsequent suspension in water or TE buffer causes dissociation (elution) of the DNA from the silica membrane. Because fewer manipulations are required, this method is faster and easier to perform than organic-based extraction methods. However, the yields may somewhat lower, generally ranging from 50% to 75% of the starting material. The procedure seems to work best with DNA fragments larger than 500 bp, as some shorter fragments may bind tightly and irreversibly to the silica membrane. An advantage of silica membrane spin columns relative to glass beads (Vogelstein and Gillespie, 1979) is that they help to decrease shearing of DNA fragments that are larger than 3 to 10 kb.

One alternative for purifying DNA from residual protein is the use of StrataClean Resin (Stratagene), a nontoxic slurry of hydroxylated silica particles. Acidic hydroxy groups on the resin appear to bind proteins in a manner similar to phenolic hydroxyls, and at or near neutral pH display a high affinity for protein and low affinity for DNA. Protein bound to the resin is separated by centrifugation from nucleic acids remaining in solution; two or three extractions with the resin may be required to completely remove protein from a nucleic acid sample. Another product, Phase Lock Gel (an inert silica-based blend of intermediate density available from 5 Prime → 3 Prime; APPENDIX 4) improves recoveries in standard organic extractions by reducing loss of sample at the interface. During centrifugation, the normally fuzzy interface is compacted tightly below or within the gel. The gel/interface complex migrates discretely between the organic and aqueous phases, thus creating a tight partition which allows recovery of virtually all of the aqueous phase.

Critical Parameters

The oxidation products of phenol can damage nucleic acids and only redistilled phenol should be used. For complete deproteinization, extractions should be repeated until no protein precipitate remains at the aqueous/organic interface.

In general, alcohol precipitation of nucleic acids requires the presence of at least 0.1 M monovalent cation in the starting aqueous solution. Precipitation of nucleic acids at low concentrations requires cooling to low temperatures to give good recovery. Precipitation of nucleic acids at high concentrations (>0.25

mg/ml after addition of ethanol) is very rapid at room temperature. Formation of a visible precipitate after adding alcohol and mixing well indicates complete precipitation, and no chilling or further incubation is needed.

In organic extraction, loss of nucleic acid at the interface and into the organic phase is minimized by back-extracting the organic phase. The most critical parameter in the purification of DNA using silica membrane spin columns is the pH of the chaotropic salt solution. For efficient binding to the silica membrane, the salt solution should be at pH 6.5. Many different companies sell silica membrane spin columns as kits supplied with all necessary reagents and buffers. One variable is the type of chaotropic salt solution supplied with the kit (NaI, guanidine HCl, or guanidine isothiocyanate). For the most part, these salt solutions are only a variation on the same theme and may be interchangeable between kits or columns from different vendors.

Anticipated Results

These procedures should result in virtually complete removal of proteins and quantitative recovery of nucleic acids. However, sequential extractions or precipitations require care and attention to detail to prevent accumulation of small losses at each step. It is particularly important to carefully recover the aqueous phase and reextract the organic phase to ensure full recovery of small amounts of DNA from phenol/chloroform extractions.

The yield of nucleic acids resulting from the silica membrane spin column procedure can be similarly improved (to $\leq 80\%$ recovery) by subjecting supernatants to an additional binding step and increasing the amount of elution buffer to 100 μ l or more.

Time Considerations

Approximately 90 min should be allowed for carrying out steps 1 through 9 of the Basic Protocol on twelve DNA samples in microcentrifuge tubes. Phenol buffering should be started ≥ 1 hr before equilibrated phenol is needed. Nucleic acids should not be left in the presence of phenol, but can be indefinitely precipitated in alcohol or dried after precipitation. The silica membrane spin column protocol can be performed on twelve samples in 15 to 20 min.

Purification of DNA by Anion-Exchange Chromatography

Column chromatography has recently evolved to provide a rapid and effective alternative to more laborious methods for preparing high-quality DNA, such as CsCl-gradient centrifugation. This protocol describes the use of a column made of a unique anion-exchange resin that selectively binds nucleic acids, allowing rapid separation of DNA from contaminating RNA, proteins, carbohydrates, and metabolites. The procedure below employs columns supplied by QIAGEN; other preparation methods are available from other suppliers. A crude nucleic acid sample (usually a cleared cell lysate) is applied to the QIAGEN-tip under conditions that favor binding. Contaminants in the sample are washed from the column with a moderate-salt buffer, and DNA is eluted using a high-salt buffer.

Materials

Plasmid- or phage-bearing bacterial culture or mammalian, plant, or bacterial cell culture

Buffer QBT (equilibration buffer; see recipe)

QIAGEN-tip of appropriate size (Table 2.1B.1)

Buffer QC (washing buffer; see recipe)

Buffer QF (eluting buffer; see recipe)

TE buffer, pH 8.0 (APPENDIX 2)

Isopropanol, room temperature

70% (v/v) ethanol, ice cold

Beckman JS-13, Sorvall HB-4 or HB-6, or equivalent rotor

Additional reagents and equipment for preparation of mammalian, plant, or bacterial genomic DNA (cell lysate; UNITS 2.2-2.4), alkaline lysis preparation of plasmid DNA (UNIT 1.7), or preparation of phage lysates (UNIT 1.13)

1. To isolate plasmid, cosmid, or phage DNA, prepare a cell lysate from a strain harboring the appropriate vector. To isolate genomic DNA, prepare cell lysate from mammalian, plant, or bacterial culture. Remove a sample from the cleared lysate and

Table 2.1B.1 Recommended Loading Volumes, DNA Capacities, and Culture Volumes for QIAGEN-tips

	QIAGEN-tip 100	QIAGEN-tip 500	QIAGEN-tip 2500	QIAGEN-tip 10000
<i>Column DNA capacity</i>				
Plasmid or ds phage	100 µg	500 µg	2500 µg	10000 µg
Cosmid or λ phage	60 µg	300 µg	1500 µg	6000 µg
Mammalian or <i>B. subtilis</i> genomic	80 µg	400 µg	2000 µg	8000 µg
<i>Culture volume for plasmid DNA</i>				
High-copy-number plasmid	25 ml	100 ml	500 ml	2.5 liters
Low-copy-number plasmid	100 ml	500 ml	2.5 liters	5 liters
<i>Culture volume for genomic DNA</i>				
<i>B. subtilis</i>	8 ml	40 ml	200 ml	800 ml
Mammalian (no. cells)	2×10^7	1×10^8	5×10^8	2×10^9

save for an analytical gel to determine whether growth and lysis conditions were optimal.

For plasmid preps, lysozyme treatment is not necessary. Plasmid and phage preps should include RNase A treatment, because the long RNA molecules can compete with DNA for binding sites on the resin. When the sample is loaded on the QIAGEN-tip, it must have a salt concentration of 750 mM and a pH of 7.0, and should be free of particulate matter, which will clog the column.

Bacterial lysates can be cleared by a conventional centrifugation or by filtration through a special filter unit available from QIAGEN. The QIAfilter is available in syringe or cartridge format and is suitable for small to large bacterial culture volumes. It has been designed to rapidly clear bacterial lysates and completely remove SDS precipitates without centrifugation.

For endotoxin-free DNA, QIAGEN offers EndoFree Plasmid Kits containing an endotoxin-removal buffer that is briefly incubated with the cleared lysate prior to loading on the QIAGEN-tip. Plasmid DNA purified using EndoFree Plasmid Kits contains only negligible amounts of endotoxin.

Anionic detergents such as SDS will inhibit DNA binding to the resin; thus, their use in preparing these cell lysates should be avoided if possible (see Tables 10.15.1 and 10.15.2 for physical and chemical properties of commonly used detergents). If anionic detergents must be included in any of the extraction or lysis buffers, they may be removed by precipitation with acidic potassium acetate (UNIT 1.7) followed by centrifugation. Small SDS precipitates that cannot be separated by conventional centrifugation are completely removed by the QIAfilter process.

2. Equilibrate an appropriately sized QIAGEN-tip with Buffer QBT by applying 2 bed volumes of buffer and allowing it to empty by gravity flow.

The flow of buffer will stop when the meniscus reaches the upper column frit. Do not force out the remaining buffer.

3. Apply cleared lysate from step 1 to the equilibrated column and allow it to enter the resin by gravity flow. Remove a small sample of flowthrough (50 to 500 μ l, depending on the column size) and save for analytical gel electrophoresis.
4. Wash column twice with 3 to 6 bed volumes of Buffer QC (depending on column size) and allow the buffer to move through the QIAGEN-tip by gravity flow. Remove a small sample of flowthrough and save for analytical gel electrophoresis.

This step removes cellular contaminants and any remaining RNA from the DNA.

5. Elute pure DNA by applying 1 to 2 bed volumes of Buffer QF (depending on column size) and allowing it to flow through by gravity flow. Remove a small sample of eluate and save for analytical gel electrophoresis.
6. Add 0.7 vol isopropanol to eluate and immediately centrifuge 30 min at 15,000 \times g (\geq 9500 rpm in Beckman JS-13), 4°C, to precipitate DNA. Remove and discard supernatant.
7. Wash pellet with ice-cold 70% ethanol, air dry 10 min, and redissolve in a suitable volume of TE buffer, pH 8.0.

Overdrying will make the pellet difficult to dissolve. Do not pipet high-molecular-weight DNA up and down when dissolving, as this may cause shearing.

8. *Optional:* To analyze the purification procedure, precipitate the samples taken in steps 1, 3, 4, and 5 with 0.7 vol isopropanol. Rinse pellets with 70% ethanol, drain well, and resuspend in 10 μ l TE buffer, pH 8.0. Use 2 μ l of each for analysis on a 1% agarose gel (UNIT 2.5A; see Critical Parameters and Troubleshooting).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Buffer QBT

750 mM NaCl
50 mM 3-(*N*-morpholino)propanesulfonic acid (MOPS)
Adjust pH to 7.0 with HCl
15% (v/v) isopropanol
0.15% (v/v) Triton X-100
Store indefinitely at room temperature

Buffer QC

1.0 M NaCl
50 mM MOPS
Adjust pH to 7.0 with HCl
15% (v/v) isopropanol
Store indefinitely at room temperature

Buffer QF

1.25 M NaCl
50 mM Tris·Cl
15% isopropanol
Adjust pH to 8.5 with HCl
Store indefinitely at room temperature

COMMENTARY

Background Information

For many routine applications in molecular biology, DNA used as starting material must be very pure. Until recently, traditional CsCl/ethidium bromide gradients (for plasmid and phage DNA; *UNITS 1.7 & 1.13*) or organic extraction (for genomic DNA; *UNIT 2.1A*) have been widely used. Although they provide a highly purified product, these methods are generally time-consuming, may involve the use of hazardous amounts of toxic reagents, and do not yield endotoxin-free plasmid DNA. A simple and time-saving alternative to these methods, without sacrifice in quality, is provided by ion-exchange chromatography. This technique was originally used for protein purification (see *UNIT 10.10* for a complete discussion), but is now also widely used for nucleic acid separation.

The general principles of ion-exchange purification hold true for nucleic acid separations: negatively charged nucleic acids are applied to an oppositely charged chromatographic matrix. The best choice for these separations is an anion-exchange resin carrying positively charged groups that adsorb negatively charged molecules in buffers near neutral pH and of medium ionic strength. In particular, the high surface density of anion-exchange (DEAE)

groups—together with the large pore size of the commercially available QIAGEN Anion-Exchange Resin—permits attachment and retention of the highly charged nucleic acid molecules on the column. Subsequent washing of the column to remove impurities contained in the lysate results in a very high degree of purification of the DNA.

The separation range of conventional anion exchangers for nucleic acids extends only up to ~0.5 M salt. Because binding and elution of the components of a lysate are limited to a narrow range of salt concentrations, the elution peaks of proteins, RNA, and DNA overlap with one another, preventing effective separation of DNA from contaminants. Because of the extremely high charge density (QIAGEN Resin contains ~5-fold more DEAE groups per unit surface area of resin than do conventional anion exchangers), the resin described here separates various nucleic acid forms over a broader range of salt concentration (up to 1.6 M, the elution point for double-stranded DNA; Fig. 2.1B.1). Because the charge density of the resin is inversely proportional to the pH of the buffer, the binding, washing, and elution profiles are strongly affected by the pH of the relevant buffers (Fig. 2.1B.2).

Anion-exchange methods have been used in conjunction with a variety of applications whose success depends critically upon the purity of the nucleic acid sample, including transfection of mammalian cells (Chen et al., 1991), DNA sequencing (Hall et al., 1989; Voss et al., 1990), PCR (Jones and Winistorfer, 1992; Jung

et al., 1992), and runoff transcription (Kayne et al., 1988; Luytjes et al., 1989). In addition, the method has been used to recover plasmid and viral DNA from mammalian cells (Lutze and Winegar, 1990).

Further alternatives to traditional purification procedures include gel filtration as well as

Figure 2.1B.1 Separation of nucleic acids at neutral pH on QIAGEN Anion-Exchange Resin (reproduced with permission from QIAGEN, 1997).

Figure 2.1B.2 Elution points of different nucleic acids from QIAGEN Anion-Exchange Resin as a function of pH (reproduced with permission from QIAGEN, 1997).

Table 2.1B.2 Troubleshooting Guide for DNA Purification by Anion-Exchange Chromatography (adapted from QIAGEN, 1997)

Problem	Possible cause(s)	Solution
No DNA in sample lysate before loading	Plasmid failed to propagate	Check that conditions for optimum plasmid growth were met
	Lysate was incorrectly prepared	Check age of buffers and prepare fresh if necessary
DNA in flowthrough fraction	Column overloaded with DNA	Check yield against capacity of column (see Table 2.1B.1). Purify excess DNA by passing through new tip.
	SDS or other ionic detergent in the DNA sample	Ensure that SDS is removed from lysate before column loading by dialyzing or precipitating with cold potassium acetate
High-molecular-weight RNA in eluate	RNase A digestion insufficient	Check culture volume against recommended volumes in Table 2.1B.1 and reduce if necessary. Check effectiveness of RNase A solution.
		Recover DNA by precipitating the eluate, digesting with RNase A, and purifying on a new tip
DNA found in wash fraction	Column overloaded with DNA	Check the culture volume and yield against the capacity of the respective QIAGEN-tip. Reduce culture volume accordingly.
	Wash buffer incorrect	Check pH and salt concentration of Buffer QC. Recover DNA by precipitation and purify on another column.
No DNA in eluate	Elution buffer incorrect	Check pH and salt concentration of Buffer QF. Recover DNA by eluting with fresh buffer.
Little or no DNA upon precipitation	DNA failed to precipitate	Check isopropanol batch. Make sure that precipitate is centrifuged at $>15,000 \times g$ for 30 min; if necessary, centrifuge longer at higher speeds.
	DNA pellet lost (isopropanol pellets are glassy and may be difficult to see)	Mark expected location of pellet before centrifugation
	DNA poorly resuspended	Check that DNA was completely resuspended. Wash any DNA off walls, particularly if glass tubes are used, as up to half of total DNA may be smeared on walls. Use a swinging-bucket rotor so that the pellet will be localized at very bottom of tube.
DNA difficult to resuspend	Pellet overdried	Air dry pellet; do not use a vacuum. Warm DNA solution slightly to dissolve.
	Residual isopropanol in pellet	Wash pellet in 70% ethanol
	Too much salt in pellet	Use isopropanol at room temperature. Increase volume of TE buffer.
RNA in eluate	RNase A digestion insufficient	Check culture volume against recommended volumes in Table 2.1B.1 and reduce if necessary. Increase volume of wash buffer, recover DNA by precipitating eluate, digest with RNase A, and purify.
Genomic DNA contamination in eluate (for plasmid preps)	Mixing too vigorous	Lysate must be handled gently to prevent shearing. Reduce culture volume if lysate is too viscous for gentle mixing.
	Lysis time too prolonged	Make sure that lysis step does not last longer than 5 min

continued

Preparation and Analysis of DNA

2.1.15

Table 2.1B.2 Troubleshooting Guide for DNA Purification by Anion-Exchange Chromatography (adapted from QIAGEN, 1997), continued

Problem	Possible cause(s)	Solution
DNA is nicked, sheared, or degraded	Endonuclease-containing host	Consider changing <i>E. coli</i> host strain
	Nuclease contamination present	Check buffers for nuclease contamination and replace if necessary. Use autoclaved glass and plastic and wear gloves.
	DNA poorly buffered	Resuspend DNA in TE, pH 8.0, to inhibit nuclease activity and maintain stable pH during storage
	Shearing during resuspension	Resuspend DNA gently without vortexing or vigorous pipetting
DNA does not perform well in later experiments	DNA nicked	Check percentage of nicked DNA on agarose gel
	Too much salt	Make sure isopropanol is at room temperature for precipitation and pellet is washed with 70% ethanol
	Residual protein	Check culture volume against recommended volumes in Table 2.1B.1 and reduce if necessary. Increase volume of wash buffer.

additional separation methods (e.g., G-25/G-50, Select, and pZ spin columns, available from 5 Prime → 3 Prime, and Wizard DNA purification resin, available from Promega; also see *UNIT 1.13*). Gel-filtration columns purify DNA by allowing large nucleic acid molecules to pass through while retarding the migration of contaminants (small RNAs and oligonucleotides) through the gel. In general, these alternatives are comparable in terms of the purity of the sample obtained, although some may permit carryover of residual impurities from the starting sample. Opinions vary, however, regarding the relative values of the different methods. For example, recent reports assert that plasmid DNA purified by QIAGEN Anion-Exchange Resin is at least comparable (and may be superior) to preparations purified using CsCl. Determinations were made by measuring transfection efficiencies (Ehlert et al., 1993) and by observations of plasmid preparations using electron microscopy (Schleef and Heilmann, 1993). In a series of biological assays, various purified preparations of plasmid DNA injected into *Drosophila* embryos were subsequently analyzed for the ability to generate germline-transformed flies. No significant differences were observed among CsCl-, PEG-, QIAGEN-, or pZ-purified plasmids, although PEG-derived preparations appeared to be slightly less toxic to the cells (Joseph Heilig, pers. comm.).

Critical Parameters and Troubleshooting

QIAGEN Anion-Exchange Resin has different binding capacities for different classes of nucleic acids: the binding capacity for RNA, for example, is roughly twice that for plasmid DNA. Larger DNA molecules (e.g., phage, cosmid, BACs, P1s, and genomic DNAs) are bound at an even lower capacity than plasmid DNA. Therefore, when selecting a column size, the type of nucleic acid to be purified should be taken into account. It is also important to choose a column with the appropriate binding capacity for the culture volume used, to avoid overloading (see Table 2.1B.1). For plasmid, phage, and cosmid preparations, this is achieved by careful control of culture conditions and inclusion of an RNase treatment in the lysate preparation. While the use of super-rich medium such as Superbroth (*UNIT 1.1*) or Terrific broth (Tartoff and Hobbs, 1987; *UNIT 1.7*) can be advantageous for culturing cosmids and plasmids maintained at low copy number, high-copy-number plasmids do not require growth in super-rich medium to give a reasonable yield. In these cases, use of super-rich medium can result in extraordinarily high cell densities with a corresponding increase in lysate viscosity due to the presence of large amounts of nucleic acid or protein. Before loading the column, ensure that the lysate is clear and free of particulate matter and adjust the loading volume as indicated in Table 2.1B.1.

Another critical factor is the pH of the column buffers used for binding, washing, and eluting (Fig. 2.1B.2). For optimal recovery, the final pH should be adjusted as recommended in the recipes (see Reagents and Solutions); changes in pH may lead to loss of DNA.

Many factors may cause low or no yield or incomplete purification of DNA. Checking an aliquot of each fraction on an analytical gel (Fig. 2.1B.3) can help locate the source of the problem. Table 2.1B.2 describes various problems that may be encountered and provides suggestions for how to deal with them.

Anticipated Results

The expected yield for a preparation of genomic DNA from mammalian cell culture is ~30 to 40 μg per 10^7 cells. Low-copy-number plasmid and cosmid preparations from cells grown overnight in LB medium yield 0.2 to 1 μg DNA per milliliter of overnight culture, while high-copy-number plasmids prepared under these conditions yield 3 to 5 $\mu\text{g}/\text{ml}$. When grown in super-rich medium, the yield of cosmids and low-copy-number plasmids is in-

creased to 2.5 to 5 μg DNA/ml, and that of high-copy-number plasmids to 5 to 25 $\mu\text{g}/\text{ml}$.

Time Considerations

With most types of cells, preparing the original DNA sample (lysate) and running the column (including equilibration time, sample loading, washing, and elution) should take 1.5 to 4 hr, depending upon the volume of lysate and the corresponding column size.

Preparation of Genomic DNA from Mammalian Tissue

UNIT 2.2

**BASIC
PROTOCOL**

Tissue is rapidly frozen and crushed to produce readily digestible pieces. The processed tissue is placed in a solution of proteinase K and SDS and incubated until most of the cellular protein is degraded. The digest is deproteinized by successive phenol/chloroform/isoamyl alcohol extractions, recovered by ethanol precipitation, and dried and resuspended in buffer.

Materials

Tissues, whole or cultured cells
Liquid nitrogen
Digestion buffer (see recipe)
PBS (*APPENDIX 2*), ice cold
7.5 M ammonium acetate
70% and 100% ethanol
TE buffer, pH 8 (*APPENDIX 2*)
Incubator or water bath at 50°C, with shaker

Additional reagents and equipment for trypsinizing adherent cells (*APPENDIX 3F*) and phenol/chloroform/isoamyl alcohol extraction (*UNIT 2.1A*)

Prepare cells

Beginning with whole tissue:

1a. As soon as possible after excision, quickly mince tissue and freeze in liquid nitrogen.

If working with liver, remove the gallbladder, which contains high levels of degradative enzymes.

2a. Starting with between 200 mg and 1 g, grind tissue with a prechilled mortar and pestle, or crush with a hammer to a fine powder (keep the tissue fragments, if crushing is incomplete).

3a. Suspend the powdered tissue in 1.2 ml digestion buffer per 100 mg tissue. There should be no clumps.

Beginning with tissue culture cells:

1b. Pellet suspension culture out of its serum-containing medium. Trypsinize adherent cells and collect cells from the flask. Centrifuge 5 min at $500 \times g$, 4°C, and discard supernatant.

2b. Resuspend cells with 1 to 10 ml ice-cold PBS. Centrifuge 5 min at $500 \times g$ and discard supernatant. Repeat this resuspension and centrifugation step.

3b. Resuspend cells in 1 vol digestion buffer. For $<3 \times 10^7$ cells, use 0.3 ml digestion buffer. For larger numbers of cells use 1 ml digestion buffer/ 10^8 cells.

Lyse and digest cells

4. Incubate the samples with shaking at 50°C for 12 to 18 hr in tightly capped tubes.

The samples will be viscous. After 12 hr incubation the tissue should be almost indiscernible, a sludge should be apparent from the organ samples, and tissue culture cells should be relatively clear.

**Preparation and
Analysis of DNA**

2.2.1

Extract nucleic acids

5. Thoroughly extract the samples with an equal volume of phenol/chloroform/isoamyl alcohol.

CAUTION: *Phenol is extremely caustic.*

6. Centrifuge 10 min at $1700 \times g$ in a swinging bucket rotor.

If the phases do not resolve well, add another volume of digestion buffer, omitting proteinase K, and repeat the centrifugation.

If there is a thick layer of white material at the interface between the phases, repeat the organic extraction.

Purify DNA

7. Transfer the aqueous (top) layer to a new tube and add $\frac{1}{2}$ vol of 7.5 M ammonium acetate and 2 vol (of original amount of top layer) of 100% ethanol. The DNA should immediately form a stringy precipitate. Recover DNA by centrifugation at $1700 \times g$ for 2 min.

This brief precipitation in the presence of high salt reduces the amount of RNA in the DNA. For long-term storage it is convenient to leave the DNA in the presence of ethanol.

Alternatively, to prevent shearing of high-molecular-weight DNA, omit steps 7 to 9 and remove organic solvents and salt from the DNA by at least two dialysis steps against at least 100 vol TE buffer. Because of the high viscosity of the DNA, it is necessary to dialyze for a total of at least 24 hr.

8. Rinse the pellet with 70% ethanol. Decant ethanol and air dry the pellet.

It is important to rinse well to remove residual salt and phenol.

9. Resuspend DNA at ~ 1 mg/ml in TE buffer until dissolved. Shake gently at room temperature or at 65°C for several hours to facilitate solubilization. Store indefinitely at 4°C .

From 1 g mammalian cells, ~ 2 mg DNA can be expected.

If necessary, residual RNA can be removed at this step by adding 0.1% sodium dodecyl sulfate (SDS) and 1 $\mu\text{g/ml}$ DNase-free RNase (UNIT 3.13) and incubating 1 hr at 37°C , followed by organic extraction and ethanol precipitation, as above.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Digestion buffer

100 mM NaCl
10 mM Tris·Cl, pH 8 (APPENDIX 2)
25 mM EDTA, pH 8 (APPENDIX 2)
0.5% SDS
0.1 mg/ml proteinase K
Store at room temperature

The proteinase K is labile and must be added fresh with each use.

COMMENTARY

Background Information

There are a number of different procedures for the preparation of genomic DNA. They all start with some form of cell lysis, followed by deproteination and recovery of DNA. The main differences between various approaches lie in the extent of deproteination and in molecular weight of the DNA produced. The isolation procedure described here is relatively brief and relies on the powerful proteolytic activity of proteinase K combined with the denaturing ability of the ionic detergent SDS. Use of proteinase K for DNA purification was described by Gross-Bellard et al. (1973) and Enrietto et al. (1983). EDTA is included in the digestion buffer to inhibit DNases.

Critical Parameters

To minimize the activity of endogenous nucleases, it is essential to rapidly isolate, mince, and freeze tissue. Tissue culture cells should be cooled and washed quickly. As soon as the tissue is frozen or the tissue culture cells are added to the lysis buffer, DNA is protected from action of nucleases throughout this protocol. It is important that the tissue be well dispersed, and not left in large lumps, to permit rapid and efficient access to proteinase K and SDS.

It is crucial to generate high-molecular-weight DNA for construction of phage (>60 kb) or cosmid (>120 kb) genomic libraries. Two main precautions should be taken to maximize molecular weight: (1) minimize shearing forces by gentle (but thorough) mixing during extraction steps, and (2) after the extraction, remove organic solvents and salt from the DNA by dialysis, rather than by ethanol precipitation. Additional precautions must be taken to prepare very high-molecular-weight DNA for the construction of P1 or BAC libraries.

The absence of both cellular proteins and proteinase K in the final DNA solution is important for susceptibility of the genomic DNA to restriction enzyme action; therefore, care should be exercised in deproteination. To remove protein completely it may be necessary to repeat the proteinase K digestion. In general, highly pure DNA has an A_{260}/A_{280} ratio >1.8, while 50% protein/50% DNA mixtures have A_{260}/A_{280} ratios of ~1.5.

Troubleshooting

Failure of the organic phase to separate cleanly from the aqueous phase is generally due to a very high concentration of DNA and/or cellular debris in the aqueous phase. Dilution with more digestion buffer and reextraction can remedy this problem.

Upon addition of the room-temperature ethanol to the extracted DNA solution, the DNA should precipitate in long, stringy fibers. If there is no precipitate or if the precipitate is flocculent, the DNA is either degraded or not purified away from cellular debris. Improper handling of the tissue before digestion or too much tissue in the digestion reaction are possible causes of such problems.

Anticipated Results

Approximately 2 mg DNA should be obtained from 1 g tissue or 10^9 cells. The DNA should be at least 100 kb long and should be digestible with restriction enzymes.

Time Considerations

This protocol involves effort on 2 days: tissue preparation on the first day followed by overnight lysis, and extraction/precipitation on the second day. Actual time spent on the procedure, however, will be less than 1 hr each day. The DNA can be stored indefinitely in the presence of ethanol at 4° or in TE buffer at -20°C.

Preparation of Genomic DNA from Plant Tissue

UNIT 2.3

This unit describes two methods for preparing genomic DNA from plant tissue. In the first method, plant cells are lysed with ionic detergent, treated with protease, and subsequently purified by cesium chloride (CsCl) density gradient centrifugation. The second method is based upon a series of treatments with the nonionic detergent cetyltrimethylammonium bromide (CTAB) to lyse cells and purify nucleic acid. Nucleic acid is recovered from the final CTAB solution by isopropanol or ethanol precipitation. The first method, although somewhat more lengthy, results in highly purified nucleic acid. The second method requires fewer manipulations, results in very high yields (~10-fold higher per gram fresh tissue depending on species and condition of starting material), and produces DNA that is less pure but nonetheless suitable in quality for use in many molecular biology manipulations.

PREPARATION OF PLANT DNA USING CSCL CENTRIFUGATION

Plant cells are lysed by the detergent *N*-lauroylsarcosine (Sarkosyl), and the lysate is digested with proteinase K. After clearing insoluble debris from the lysate, nucleic acids are precipitated and DNA is purified on a cesium chloride (CsCl) density gradient.

**BASIC
PROTOCOL**

Materials

For recipes, see **Reagents and Solutions** in this unit (or cross-referenced unit); for common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.

Plant tissue, fresh
Liquid nitrogen
Extraction buffer (see recipe)
10% (w/v) *N*-lauroylsarcosine (Sarkosyl)
Isopropanol
TE buffer, pH 8.0
Cesium chloride
10 mg/ml ethidium bromide
CsCl-saturated isopropanol (equilibrate over a CsCl-saturated aqueous phase)
Ethanol
3 M sodium acetate, pH 5.2
250-ml centrifuge bottle
55°C water bath
Beckman JA-14, JA-20 or JA-21, and VTi80 rotors (or equivalents)
5-ml quick-seal ultracentrifuge tubes
15-G needle and 1-ml syringe

Prepare plant tissue

1. Harvest 10 to 50 g fresh plant tissue.

Plants may be placed in the dark for 1 to 2 days prior to harvest to reduce the starch content in the tissues.

Younger plants are the preferred source of tissue because they have a lower polysaccharide content.

2. Rinse tissue with deionized water to remove adhering debris and blot dry.
3. Freeze tissue with liquid nitrogen and grind to a fine powder in a mortar and pestle.

Keep the tissue frozen throughout this procedure by occasionally adding liquid nitrogen.

**Preparation and
Analysis of DNA**

Supplement 27

Lyse and digest cells

4. Transfer frozen powder to a 250-ml centrifuge bottle and immediately add 5 to 10 ml extraction buffer per gram fresh plant tissue. Stir gently to disperse tissue.
5. Add 10% *N*-lauroylsarcosine to a final concentration of 1%. Incubate 1 to 2 hr at 55°C.

*It is important to add N-lauroylsarcosine **after** the tissue is resuspended in extraction buffer. If N-lauroylsarcosine is included in extraction buffer, premature lysis of the plant cells will interfere with tissue dispersal and lead to unwanted shearing of DNA.*

The lysate should be clear, green, and slightly viscous. From this point on solutions should be handled gently to reduce shearing of the DNA—use a wide-bore pipet and do not vortex or mix vigorously.

6. Centrifuge lysate 10 min at $5500 \times g$ (6000 rpm in a Beckman JA-14 rotor), 4°C, to pellet debris. Save the supernatant and centrifuge again if necessary to remove undigested debris.

Precipitate the DNA

7. Add 0.6 vol isopropanol to the supernatant and gently mix. A nucleic acid precipitate should be visible; if not, incubate 30 min at -20°C .
8. Centrifuge 15 min at $7500 \times g$ (8000 rpm in a Beckman JA-14 rotor), 4°C. Discard supernatant.

Do not let the nucleic acid pellet dry or it will become extremely difficult to dissolve.

Carry out CsCl centrifugation

9. Resuspend pellet in 9 ml TE buffer. If necessary, incubate at 55°C to aid resuspension. Add 9.7 g of solid CsCl and mix gently until dissolved.

To minimize depurination, limit 55°C incubation to ≤ 2 hr.

10. Incubate 30 min on ice. Centrifuge 10 min at $7500 \times g$ (8000 rpm in a JA-20 rotor), 4°C, and save supernatant.

This clearing spin removes some of the insoluble debris remaining in the lysate. In addition, a small separate phase may form on the top of the solution after centrifugation; this is due to residual Sarkosyl in the lysate. The Sarkosyl phase can be removed by filtering the supernatant through two layers of cheesecloth. Collect the supernatant but discard the Sarkosyl phase.

11. Add 0.5 ml of 10 mg/ml ethidium bromide and incubate 30 min on ice.

CAUTION: Ethidium bromide is a mutagen. Be careful and wear gloves.

12. Centrifuge 10 min at $7500 \times g$, 4°C.

A large RNA pellet should form. At this point much of the unwanted constituents in the lysate—RNA, protein, and carbohydrates—have been removed.

13. Transfer the supernatant to two 5-ml quick-seal ultracentrifuge tubes and seal tubes.

Make sure tubes are full, balanced, and well-sealed.

14. Centrifuge 4 hr at $525,000 \times g$ (80,000 rpm in a Beckman VTi80 rotor), 20°C, or overnight at $300,000 \times g$ (60,000 rpm in VTi80 rotor), 20°C.

Collect and purify DNA

15. Gently remove the tube. Punch a hole in the top (to provide an air inlet) with a large-bore (15-G) collecting needle. Recover the DNA band by inserting needle, attached to a 1-ml syringe, through tube wall directly below the band (see Fig. 1.7.1).

This operation is identical to that used during plasmid purification, except that only one band should be visible.

CAUTION: If UV illumination is used to visualize the DNA, wear UV protective glasses or a face shield. Minimize exposure of gradient to visible light to reducing nicking of DNA caused by ethidium bromide.

16. Remove the ethidium bromide by repeatedly extracting the collected DNA with CsCl-saturated isopropanol.
17. Add 2 vol water and 6 vol ethanol to the DNA solution and mix. Incubate 1 hr at -20°C .

DNA may precipitate immediately as a single white mass; it can be collected using a Pasteur pipet with a hook introduced at the tip or by brief centrifugation.

18. Centrifuge 10 min at $7500 \times g$, 4°C .
19. Resuspend pellet in TE buffer and reprecipitate DNA by adding $\frac{1}{10}$ vol of 3 M sodium acetate and 2 vol ethanol. Incubate at -20°C if precipitate is not visible and collect DNA by centrifugation.
20. Briefly air dry the final pellet and resuspend in 0.5 to 2 ml TE buffer.

A DNA concentration of 100 ng/ μl is generally convenient for most purposes.

PREPARATION OF PLANT DNA USING CTAB

Alternatively, the nonionic detergent cetyltrimethylammonium bromide (CTAB) is used to liberate and complex with total cellular nucleic acids. This general procedure has been used on a wide array of plant genera and tissue types. Many modifications have been published to optimize yields from particular species. The protocol is relatively simple, fast, and easily scaled from milligram to grams of tissue; it requires no cesium chloride density gradient centrifugation.

Additional Materials

*For recipes, see **Reagents and Solutions** in this unit (or cross-referenced unit); for common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.*

CTAB extraction solution (see recipe)

CTAB/NaCl solution (*UNIT 2.4*)

CTAB precipitation solution (see recipe)

2% (v/v) 2-mercaptoethanol (2-ME)

High-salt TE buffer (see recipe)

24:1 (v/v) chloroform/octanol or chloroform/isoamyl alcohol

80% ethanol

Pulverizer/homogenizer: mortar and pestle, blender, Polytron (Brinkmann),
or coffee grinder

Organic solvent-resistant test tube or beaker

65°C water bath

Beckman JA-20 rotor or equivalent *or* microcentrifuge

ALTERNATE PROTOCOL

Preparation and Analysis of DNA

2.3.3

Extract nucleic acids

1. Add 2-ME to the required amount of CTAB extraction solution to give a final concentration of 2% (v/v). Heat this solution and CTAB/NaCl solution to 65°C.

Approximately 4 ml of 2-ME/CTAB extraction solution and 0.4 to 0.5 ml CTAB/NaCl solution are required for each gram of fresh leaf tissue. With lyophilized, dehydrated, or dry tissues such as seeds, 2-ME/CTAB extraction solution should be diluted 1:1 with sterile water. 2-ME should be used in a fume hood.

2. Chill a pulverizer/homogenizer with liquid nitrogen (−196°C) or dry ice (−78°C). Pulverize plant tissue to a fine powder and transfer the frozen tissue to an organic solvent-resistant test tube or beaker.

Use young tissue and avoid larger stems and veins to achieve the highest DNA yield with minimal polysaccharide contamination.

3. Add warm 2-ME/CTAB extraction solution to the pulverized tissue and mix to wet thoroughly. Incubate 10 to 60 min at 65°C with occasional mixing.

A 60-min incubation results in larger DNA yields. If maximum yield is not important, 10 min should be adequate. If the tissue contains large amounts of phenolic compounds, 1% (v/v) polyvinylpyrrolidone (mol. wt. = 40,000) may be added to absorb them.

4. Extract the homogenate with an equal volume of 24:1 chloroform/octanol or chloroform/isoamyl alcohol. Mix well by inversion. Centrifuge 5 min at 7500 × g (8000 rpm in JA-20; ~10,000 rpm in a microcentrifuge, for smaller samples), 4°C. Recover the top (aqueous) phase.

Octanol, rather than isoamyl alcohol, is used because it may enhance isolation of nuclei. Slower centrifugation speeds are possible if centrifugation time is increased accordingly; a microcentrifuge may be used for small-scale preparations (≤150 mg starting tissue). After centrifugation, two phases should be evident with tissue debris at the interface.

5. Add 1/10 vol 65°C CTAB/NaCl solution to the recovered aqueous phase and mix well by inversion.
6. Extract with an equal volume of chloroform/octanol. Mix, centrifuge, and recover as in step 4 above.

The aqueous phase may still be light yellow-brown in color.

Precipitate nucleic acids

7. Add exactly 1 vol CTAB precipitation solution. Mix well by inversion. If precipitate is visible, proceed to step 8. If not, incubate mixture 30 min at 65°C.
8. Centrifuge 5 min at 500 × g (2000 rpm in JA-20; ~2700 rpm in microcentrifuge), 4°C.

Do not increase the speed or time of centrifugation as the pellet may become very difficult to resuspend. If there is no pellet, add more CTAB precipitation solution (up to 1/10 the total volume). Incubate 1 hr to overnight at 37°C. Centrifuge 5 min at 500 × g, 4°C.

9. Remove but do not discard the supernatant and resuspend pellet in high-salt TE buffer (0.5 to 1 ml per gram of starting material). If the pellet is difficult to resuspend, incubate 30 min at 65°C. Repeat until all or most of pellet is dissolved.

Polysaccharide contamination may make it excessively difficult to resuspend the pellet. Read the A₂₆₀ of the supernatant and discard pellet if nucleic acids are present in the supernatant.

10. Precipitate the nucleic acids by adding 0.6 vol isopropanol. Mix well and centrifuge 15 min at $7500 \times g$, 4°C .

Ethanol can be used for the precipitation, but isopropanol may yield cleaner pellets.

11. Wash the pellet with 80% ethanol, dry, and resuspend in a minimal volume of TE (0.1 to 0.5 ml per gram of starting material).

Residual CTAB is soluble and is removed by the 80% ethanol wash. Further purification of the DNA with RNase A and proteinase K may be done using standard methods (UNITS 2.4 & 3.13).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

CTAB extraction solution

2% (w/v) CTAB
100 mM Tris·Cl, pH 8.0
20 mM EDTA, pH 8.0
1.4 M NaCl
Store at room temperature (stable several years)

CTAB precipitation solution

1% (w/v) CTAB
50 mM Tris·Cl, pH 8.0
10 mM EDTA, pH 8.0
Store at room temperature (stable several years)

Extraction buffer

100 mM Tris·Cl, pH 8.0
100 mM EDTA, pH 8.0
250 mM NaCl
100 $\mu\text{g}/\text{ml}$ proteinase K (add fresh before use)
Store indefinitely at room temperature without proteinase K

High-salt TE buffer

10 mM Tris·Cl, pH 8.0
0.1 mM EDTA, pH 8.0
1 M NaCl
Store at room temperature (stable for several years)

COMMENTARY

Background Information

CsCl gradient purification

This protocol is an adaptation of common DNA isolation procedures—cell lysis by detergent, protease treatment, and CsCl gradient purification. Because whole cells are lysed, DNA purified using this protocol will correspond to both the nuclear genome and cytoplasmic (mitochondrial and chloroplast) genomes. Methods for purifying nuclear DNA—free of plastid and mitochondrial DNA contamination—have been described by Watson and Thompson (1986). In addition, a miniprep pro-

tol for isolation of total plant DNA has been described by Dellaporta et al. (1983); the miniprep protocol is similar to the protocol described here, except that it omits the CsCl gradient centrifugation.

CTAB purification

The alternate protocol, cetyltrimethylammonium bromide (CTAB) DNA isolation, was initially used in bacteria (Jones, 1953; UNIT 2.4) and later modified to obtain DNA from plants (Murray and Thompson, 1980). CTAB forms an insoluble complex with nucleic acids when the initial NaCl concentration is lowered to

~0.5 M (Rogers and Bendich, 1985). Polysaccharides, phenolic compounds, and other enzyme-inhibiting contaminants found in plant cells are efficiently removed in the supernatant because most do not precipitate under the conditions described. The nucleic acid-CTAB complex is only soluble in high salt; detergent is removed by raising the NaCl concentration and precipitating the nucleic acids. The residual CTAB is removed by washing the nucleic acid pellet with 80% ethanol; CTAB is more soluble in ethanol and is discarded with the wash solution.

The CTAB method of DNA isolation is widely used on plants because of its versatility. Total genomic DNA has been isolated from many genera of monocotyledons and dicotyledons (Murray and Thompson, 1980; Rogers and Bendich, 1985). Various types of tissue can be used, including whole seedlings, leaves, cotyledons, seeds/grains, endosperm, embryos, tissue culture callus, and pollen. In addition, milligram amounts of tissue can be used when sample size is limiting. The starting material can be lyophilized, dehydrated (even mummified), frozen, or fresh.

The authors' (M.R. and S.R.) laboratory has successfully used this protocol to isolate DNA from *Arabidopsis thaliana*, *Zea mays*, *Gossypium hirsutum*, *Flaveria* sp., *Linum usitatissimum*, *Petunia hybrida*, *Glycine* sp., *Nicotiana tabacum*, and *Lycopersicon esculentum*. In addition, each year *The Plant Molecular Biology Reporter* publishes several modifications to this general protocol optimized for species from which nucleic acid extraction is difficult.

Critical Parameters

The aim of any genomic DNA preparation technique is to isolate high-molecular-weight DNA of sufficient purity. Two factors affect the size of the DNA isolated: shear forces and nuclease activity. As noted in the protocols, lysates should be treated gently to minimize shear forces. Plant cells are rich in nucleases. To reduce nuclease activity, the tissue should be frozen quickly and thawed only in the presence of an extraction buffer that contains detergent and a high concentration of EDTA.

Plant DNA isolated using the basic protocol should be in the range of 50 kb in length, which is quite acceptable for most applications. *Arabidopsis* DNA isolated using this protocol can be digested with restriction enzymes and ligated efficiently into cloning vectors. However, in some cases it may be necessary to modify the steps in order to reduce contamination by poly-

saccharides, phenolics, and other compounds that interfere with DNA isolation. Polysaccharides pose the most common problem affecting plant DNA purity. These carbohydrates are difficult to separate from the DNA itself, and they inhibit many enzymes commonly used in cloning procedures. The recommended procedure for polysaccharide removal is chloroform extraction of lysates in the presence of 1% CTAB and 0.7 M NaCl, as described by Murray and Thompson (1980) and in the alternate protocol. If the DNA pellet obtained using the alternate protocol is excessively difficult to resuspend, it may be due to the presence of polysaccharides that were not removed during CTAB precipitation. The DNA should be soluble in TE buffer; passage of the solution over an anion-exchange column should remove much of the contamination (Fang et al., 1992; UNIT 2.1B). If phenolic compounds are a problem, 1% polyvinylpyrrolidone (mol. wt. = 40,000; Sigma) can be included during tissue homogenization to absorb them. Chloroform/octanol is preferred over chloroform/isoamyl alcohol for organic extractions because it has been reported to isolate nuclei more efficiently (Watson and Thompson, 1986). Finally, RNase A and proteinase K digestion followed by phenol extraction can be performed if further purification is required.

Anticipated Results

***CsCl* gradient purification.** Yields should be in the range of 10 to 40 μ g DNA (50-kb length) per gram of fresh plant tissue. Isolated DNA should digest well with restriction enzymes and be ligated efficiently into cloning vectors.

CTAB purification. Yields should be in the range of 100 to 500 μ g DNA per gram of fresh plant tissue. The greatest yields will always be obtained using the youngest, freshest tissue available. DNA \geq 50 kb can be obtained if care is taken not to shear it (by using wide bore pipettes and gentle mixing) and if nucleases are avoided (by keeping tissue frozen or lyophilized and thawing or rehydrating only in the presence of CTAB extraction solution). In addition to DNA, RNA is also efficiently liberated and purified by this method and can be separated from the DNA if desired (e.g., see UNIT 4.3 and Taylor and Powell, 1982).

Time Considerations

***CsCl* gradient purification.** Approximately 4 to 6 hr are required to work through the protocol to the point where the lysate is loaded

onto the CsCl gradient. The gradient can be centrifuged overnight at $300,000 \times g$ or 4 hr at $525,000 \times g$. Approximately 3 to 4 hr are required to process the banded DNA.

CTAB purification. This procedure should take between 2 and 6 hr depending on the quantity of starting material, desired purity, and yield.

Preparation of Genomic DNA from Bacteria

MINIPREP OF BACTERIAL GENOMIC DNA

Bacteria from a saturated liquid culture are lysed and proteins removed by digestion with proteinase K. Cell wall debris, polysaccharides, and remaining proteins are removed by selective precipitation with CTAB, and high-molecular-weight DNA is recovered from the resulting supernatant by isopropanol precipitation.

Materials

- TE buffer (APPENDIX 2)
- 10% sodium dodecyl sulfate (SDS)
- 20 mg/ml proteinase K (stored in small single-use aliquots at -20°C)
- 5 M NaCl
- CTAB/NaCl solution
- 24:1 chloroform/isoamyl alcohol
- 25:24:1 phenol/chloroform/isoamyl alcohol (UNIT 2.1)
- Isopropanol
- 70% ethanol

1. Inoculate a 5-ml liquid culture with the bacterial strain of interest. Grow in conditions appropriate for that strain (i.e., appropriate medium, drug selection, temperature) until the culture is saturated. This may take several hours to several days, depending on the growth rate.
2. Spin 1.5 ml of the culture in a microcentrifuge for 2 min, or until a compact pellet forms. Discard the supernatant.
3. Resuspend pellet in 567 μl TE buffer by repeated pipetting. Add 30 μl of 10% SDS and 3 μl of 20 mg/ml proteinase K to give a final concentration of 100 $\mu\text{g/ml}$ proteinase K in 0.5% SDS. Mix thoroughly and incubate 1 hr at 37°C .

The solution should become viscous as the detergent lyses the bacterial cell walls. There should be no need to predigest the bacterial cell wall with lysozyme.

4. Add 100 μl of 5 M NaCl and mix thoroughly.

This step is very important since a CTAB–nucleic acid precipitate will form if salt concentration drops below about 0.5 M at room temperature (Murray and Thompson, 1980). The aim here is to remove cell wall debris, denatured protein, and polysaccharides complexed to CTAB, while retaining the nucleic acids in solution.

5. Add 80 μl of CTAB/NaCl solution. Mix thoroughly and incubate 10 min at 65°C .
6. Add an approximately equal volume (0.7 to 0.8 ml) of chloroform/isoamyl alcohol, mix thoroughly, and spin 4 to 5 min in a microcentrifuge.

This extraction removes CTAB–protein/polysaccharide complexes. A white interface should be visible after centrifugation.

7. Remove aqueous, viscous supernatant to a fresh microcentrifuge tube, leaving the interface behind. Add an equal volume of phenol/chloroform/isoamyl alcohol, extract thoroughly, and spin in a microcentrifuge for 5 min.

With some bacterial strains the interface formed after chloroform extraction is not compact enough to allow easy removal of the supernatant. In such cases, most of the interface can be fished out with a sterile toothpick before removal of any supernatant. Remaining CTAB precipitate is then removed in the phenol/chloroform extraction.

8. Transfer the supernatant to a fresh tube. Add 0.6 vol isopropanol to precipitate the nucleic acids (there is no need to add salt since the NaCl concentration is already

high). Shake the tube back and forth until a stringy white DNA precipitate becomes clearly visible. At this point it is possible to transfer the pellet to a fresh tube containing 70% ethanol by hooking it onto the end of a micropipet that has been heat-sealed and bent in a Bunsen flame. Alternatively, the precipitate can be pelleted by spinning briefly at room temperature.

If no stringy DNA precipitate forms in the above step, this implies that the DNA has sheared into relatively low-molecular-weight pieces. If this is acceptable, i.e., if DNA is to be digested to completion with restriction endonucleases for Southern blot analysis, chromosomal DNA can often still be recovered simply by pelleting the precipitate in a microcentrifuge.

9. Wash the DNA with 70% ethanol to remove residual CTAB and respin 5 min at room temperature to repellet it. Carefully remove the supernatant and briefly dry the pellet in a lyophilizer.
10. Redissolve the pellet in 100 μ l TE buffer.

This may take some time (up to 1 hr) since the DNA is of high molecular weight. 15 μ l of this DNA will typically digest to completion with 10 U EcoRI in 1 hr, which is sufficient to be clearly visible on an agarose gel, or to give a good signal during Southern hybridization.

REMOVAL OF POLYSACCHARIDES FROM EXISTING GENOMIC DNA PREPS

Steps 4 through 10 of the basic protocol can be adapted for removing polysaccharides and other contaminating macromolecules from existing bacterial chromosomal DNA preparations. Simply adjust the NaCl concentration of the DNA solution to 0.7 M and add 0.1 vol CTAB/NaCl solution. A white interface after the chloroform/isoamyl extraction indicates that contaminating macromolecules have been removed. The CTAB extraction step (steps 5 and 6) can be repeated several times until no interface is visible.

**SUPPORT
PROTOCOL**

MINIPREP OF BACTERIAL GENOMIC DNA

1. Grow bacterial strain to saturation.
2. Spin 1.5 ml for 2 min in microcentrifuge.
3. Resuspend in 567 μ l TE buffer, 3 μ l of 10% SDS, 3 μ l of 20 mg/ml proteinase K. Mix and incubate 1 hr at 37°C.
4. Add 100 μ l of 5 M NaCl. Mix thoroughly.
5. Add 80 μ l of CTAB/NaCl solution. Mix. Incubate 10 min at 65°C.
6. Extract with an equal volume of chloroform/isoamyl alcohol. Spin 5 min in microcentrifuge.
7. Transfer aqueous phase to a fresh tube. Extract DNA with phenol/chloroform/isoamyl alcohol. Spin 5 min in microcentrifuge.
8. Transfer aqueous phase to a fresh tube. Extract DNA with 0.6 vol isopropanol. Wash precipitate with 70% ethanol. Remove supernatant and briefly dry pellet in lyophilizer.
9. Resuspend pellet in 100 μ l TE buffer.

Analysis of DNA**

2.4.2

LARGE-SCALE CsCl PREP OF BACTERIAL GENOMIC DNA

This procedure is essentially a scale-up of the chromosomal miniprep described in the basic protocol, followed by additional purification on a cesium chloride gradient. This procedure may be used if large amounts of exceptionally clean genomic DNA are required, e.g., for the construction of genomic libraries.

Additional Materials

Cesium chloride
10 mg/ml ethidium bromide
CsCl-saturated isopropanol or H₂O-saturated butanol
3 M sodium acetate, pH 5.2

Beckman JA-20 rotor or equivalent
50-ml Oak Ridge centrifuge tubes
Wide-bored pipet
4-ml sealable centrifuge tubes
Beckman VTi80 rotor
3-ml plastic syringe with 15-G needle

Preparation and lysis of cells

1. Grow 100 ml culture of bacterial strain to saturation.
2. Pellet cells for 10 min at 4000 × g (e.g., in a Beckman JA-20 rotor at 6000 rpm). Discard supernatant.

This, and the following steps, can be conveniently carried out using 50-ml Oak Ridge centrifuge tubes.

3. Resuspend cells gently in 9.5 ml TE buffer. Add 0.5 ml of 10% SDS and 50 μl of 20 mg/ml proteinase K. Mix thoroughly and incubate 1 hr at 37°C.

Precipitation and purification of DNA

4. Add 1.8 ml of 5 M NaCl and mix thoroughly.
5. Add 1.5 ml CTAB/NaCl solution. Mix thoroughly and incubate 20 min at 65°C.
6. Add an equal volume of chloroform/isoamyl alcohol. Extract thoroughly. Spin 10 min at 6000 × g (JA-20 rotor at 7000 rpm), room temperature, to separate phases.
7. Transfer aqueous supernatant to a fresh tube using a wide-bored pipet.

The supernatant will probably be very viscous if the yield is high. An additional chloroform/isoamyl alcohol extraction, or a phenol/chloroform/isoamyl alcohol extraction, is optional but should not be necessary if the material is to be purified on a cesium chloride gradient.

8. Add 0.6 vol isopropanol and mix until a stringy white DNA pellet precipitates out of solution and condenses into a tight mass. Transfer the precipitate to 1 ml of 70% ethanol in a fresh tube, by hooking it on the end of a Pasteur pipet that has been bent and sealed in a Bunsen flame.
9. Spin the pellet 5 min at 10,000 × g (JA-20 rotor at 9900 rpm). Remove supernatant and redissolve the pellet in 4 ml TE buffer. This may take several hours to overnight—the DNA can be placed at 60°C to hasten the process.
10. Measure the DNA concentration on a spectrophotometer. Adjust concentration to 50 to 100 μg/ml. This will give 200 to 400 μg chromosomal DNA per 4 ml gradient.

It is not advisable to spin larger quantities of chromosomal DNA on such a small gradient.

11. Add 4.3 g CsCl per 4 ml TE buffer. Dissolve. Add 200 μ l of 10 mg/ml ethidium bromide. Transfer to 4-ml sealable centrifuge tubes. Adjust volume and balance tubes with CsCl in TE buffer (1.05 g/ml). Seal tubes. Spin 4 hr in a Beckman VTi80 rotor at 70,000 rpm, 15°C, or overnight at 55,000 rpm, 15°C.
12. Visualize gradient under longwave UV lamp. A single band should be visible. Remove band using a 15-g needle and a 3-ml plastic syringe.

If the DNA is intact high-molecular-weight chromosomal DNA it will appear very viscous as the band is withdrawn from the gradient; hence, it is important to use a wide-bore needle to avoid mechanical shearing of the DNA. If the band appears right at the top of the gradient, then the gradient is too dense. Reduce the amount of CsCl added in step 11.
13. Remove the ethidium bromide by sequential extractions with CsCl-saturated isopropanol or water-saturated butanol, as described in *UNIT 1.7*.
14. Dialyze overnight against 2 liters TE buffer to remove CsCl.
15. Transfer DNA solution to a fresh tube. If required, precipitate chromosomal DNA as described above (steps 8 and 9) by adding $\frac{1}{10}$ vol of 3 M sodium acetate and 0.6 vol isopropanol, and resuspend at desired concentration.

LARGE-SCALE CsCl PREP OF BACTERIAL GENOMIC DNA

1. Grow 100 ml culture of bacterial strain to saturation.
2. Spin 10 min at 4000 \times g.
3. Resuspend pellet in 9.5 ml TE buffer, 0.5 ml of 10% SDS, and 50 μ l of 20 mg/ml proteinase K. Mix and incubate 1 hr at 37°C.
4. Add 1.8 ml of 5 M NaCl. Mix thoroughly.
5. Add 1.5 ml CTAB/NaCl solution and mix. Incubate 20 min at 65°C.
6. Extract with an equal volume of chloroform/isoamyl alcohol. Spin 10 min at 6000 \times g, room temperature.
7. Transfer aqueous phase to a fresh tube. Extract with phenol/chloroform/isoamyl alcohol if necessary. Spin as in step 6.
8. Transfer aqueous phase to a fresh tube. Precipitate DNA with 0.6 vol isopropanol. Wash precipitate with 70% ethanol. Remove supernatant and resuspend pellet in 4 ml TE buffer.
9. Measure DNA concentration. Adjust concentration to give 50 to 100 μ g/ml. Add 4.3 g CsCl per 4 ml TE buffer. Add 200 μ l of 10 mg/ml ethidium bromide. Transfer to sealable centrifuge tubes. Spin 4 hr at 70,000 rpm, 15°C.
10. Visualize gradient with UV light. Remove band.
11. Extract ethidium bromide with CsCl-saturated isopropanol.
12. Dialyze overnight against 2 liters TE buffer.

SHORT PROTOCOL

Preparation and Analysis of DNA

2.4.4

REAGENTS AND SOLUTIONS

CTAB/NaCl solution (10% CTAB in 0.7 M NaCl)

Dissolve 4.1 g NaCl in 80 ml water and slowly add 10 g CTAB (hexadecyltrimethyl ammonium bromide) while heating and stirring. If necessary, heat to 65°C to dissolve. Adjust final volume to 100 ml.

COMMENTARY

Background Information

Most commonly used protocols for the preparation of bacterial genomic DNA consist of lysozyme/detergent lysis, followed by incubation with a nonspecific protease and a series of phenol/chloroform/isoamyl alcohol extractions prior to alcohol precipitation of the nucleic acids (Meade et al., 1984; Silhavy et al., 1982). Such procedures effectively remove contaminating proteins, but are not effective in removing the copious amounts of exopolysaccharides that are produced by many bacterial genera, and which can interfere with the activity of molecular biological enzymes such as restriction endonucleases and ligases. In this procedure, however, the protease incubation is followed by a CTAB extraction whereby CTAB complexes both with polysaccharides and with residual protein; both groups of contaminating molecules are effectively removed in the subsequent emulsification and extraction with chloroform/isoamyl alcohol. This procedure is effective in producing digestible chromosomal DNA from a variety of gram-negative bacteria, including those of the genera *Pseudomonas*, *Agrobacterium*, *Rhizobium*, and *Bradyrhizobium*, all of which normally produce large amounts of polysaccharides. If large amounts of exceptionally clean DNA are required, the procedure can be scaled up and the DNA purified on a cesium chloride gradient, as described in the alternate protocol. The method can also be used to extract high-molecular-weight DNA from plant tissue (Murray and Thompson, 1980).

Critical Parameters

The most critical parameter is the salt (NaCl) concentration of the solution containing the

lysed bacteria prior to adding CTAB. If the NaCl concentration is <0.5 M then the nucleic acid may also precipitate; indeed, CTAB is frequently used for just this process (Murray and Thompson).

It is also important to maintain all solutions above 15°C, as the CTAB will precipitate below this temperature.

Anticipated Results

The typical yield from both the miniprep and the large-scale prep is 0.5 to 2 mg DNA per 100 ml starting culture (10^8 to 10^9 cells/ml).

Time Considerations

The miniprep takes ~2 hr, including the 1-hr incubation. The large-scale prep takes slightly longer to reach the point where the CsCl gradients loaded. Subsequent steps will spread over 1 to 2 days, depending on the time of the CsCl gradient spin.

RESOLUTION AND RECOVERY OF LARGE DNA FRAGMENTS

This section describes the application of agarose gel electrophoresis to both analytical and preparative separation of DNA fragments. Standard agarose gels separate DNA fragments from ~0.5 to 25 kb, whereas pulsed-field agarose gels resolve molecules from ~10 to >2000 kb. Descriptions of standard and pulsed-field agarose gel electrophoresis as well as parameters affecting resolution of large DNA fragments are presented in *UNITS 2.5A* and *2.5B*. Three different protocols that employ agarose gels to prepare DNA fragments are described in *UNIT 2.6*. A general description of gels as electric circuits can be found in the introduction to this chapter.

Agarose Gel Electrophoresis

UNIT 2.5A

Agarose gel electrophoresis is a simple and highly effective method for separating, identifying, and purifying 0.5- to 25-kb DNA fragments (see *UNIT 2.5B* for larger fragments). The protocol can be divided into three stages: (1) a gel is prepared with an agarose concentration appropriate for the size of DNA fragments to be separated; (2) the DNA samples are loaded into the sample wells and the gel is run at a voltage and for a time period that will achieve optimal separation; and (3) the gel is stained or, if ethidium bromide has been incorporated into the gel and electrophoresis buffer, visualized directly upon illumination with UV light.

RESOLUTION OF DNA FRAGMENTS ON STANDARD AGAROSE GELS

BASIC PROTOCOL

Materials

- Electrophoresis buffer (TAE or TBE; *APPENDIX 2*)
- Ethidium bromide solution (see recipe)
- Electrophoresis-grade agarose
- 10× loading buffer (see recipe)
- DNA molecular weight markers (see Fig. 2.5A.3)
- 55°C water bath
- Horizontal gel electrophoresis apparatus
- Gel casting platform
- Gel combs (slot formers)
- DC power supply

Preparing the gel

1. Prepare an adequate volume of electrophoresis buffer (TAE or TBE; see Critical Parameters, Electrophoresis buffers) to fill the electrophoresis tank and prepare the gel.

To facilitate visualization of DNA fragments during the run, ethidium bromide solution can be added to the electrophoresis buffer to a final concentration of 0.5 µg/ml. If buffer is prepared for the electrophoresis tank and the gel separately, be sure to bring both to an identical concentration of ethidium bromide.

CAUTION: *Ethidium bromide is a mutagen and potential carcinogen. Gloves should be worn and care should be taken when handling ethidium bromide solutions.*

2. Add the desired amount of electrophoresis-grade agarose to a volume of electrophoresis buffer sufficient for constructing the gel (see Table 2.5A.1). Melt the agarose in

Preparation and Analysis of DNA

Table 2.5A.1 Appropriate Agarose Concentrations for Separating DNA Fragments of Various Sizes

Agarose (%)	Effective range of resolution of linear DNA fragments (kb)
0.5	30 to 1
0.7	12 to 0.8
1.0	10 to 0.5
1.2	7 to 0.4
1.5	3 to 0.2

a microwave oven or autoclave and swirl to ensure even mixing. Gels typically contain 0.8 to 1.5% agarose (see Critical Parameters, Agarose Concentration).

Melted agarose should be cooled to 55°C in a water bath before pouring onto the gel platform. This prevents warping of the gel apparatus. Gels are typically poured between 0.5 and 1 cm thick. Remember to keep in mind that the volume of the sample wells will be determined by both the thickness of the gel and the size of the gel comb.

3. Seal the gel casting platform if it is open at the ends. Pour in the melted agarose and insert the gel comb, making sure that no bubbles are trapped underneath the combs and all bubbles on the surface of the agarose are removed before the gel sets.

Most gel platforms are sealed by taping the open ends with adhesive tape. As an added measure to prevent leakage, hot agarose can be applied with a Pasteur pipet to the joints and edges of the gel platform and allowed to harden.

Loading and running the gel

4. After the gel has hardened, remove the tape from the open ends of the gel platform and withdraw the gel comb, taking care not to tear the sample wells.

Most gel platforms are designed so that 0.5 to 1 mm of agarose remains between the bottom of the comb and the base of the gel platform. This is usually sufficient to ensure that the sample wells are completely sealed and to prevent tearing of the agarose upon removal of the comb. Low percentage gels and gels made from low gelling/melting temperature agarose should be cooled at 4°C to gain extra rigidity and prevent tearing.

5. Place the gel casting platform containing the set gel in the electrophoresis tank. Add sufficient electrophoresis buffer to cover the gel to a depth of about 1 mm (or just until the tops of the wells are submerged). Make sure no air pockets are trapped within the wells.
6. DNA samples should be prepared in a volume that will not overflow the gel wells by addition of the appropriate amount of 10× loading buffer. Samples are typically loaded into the wells with a pipettor or micropipet. Care should be taken to prevent mixing of the samples between wells.

Be sure to include appropriate DNA molecular weight markers (see Fig. 2.5.3).

7. Be sure that the leads are attached so that the DNA will migrate into the gel toward the anode or positive lead. Set the voltage to the desired level, typically 1 to 10 V/cm of gel, to begin electrophoresis. The progress of the separation can be monitored by the migration of the dyes in the loading buffer.

CAUTION: To prevent electrical shocks, the gel apparatus should always be covered and kept away from heavily used work spaces.

- Turn off the power supply when the bromphenol blue dye from the loading buffer has migrated a distance judged sufficient for separation of the DNA fragments. If ethidium bromide has been incorporated into the gel, the DNA can be visualized by placing on a UV light source and can be photographed directly (see Support Protocol 2).

Gels that have been run in the absence of ethidium bromide can be stained by covering the gel in a dilute solution of ethidium bromide (0.5 $\mu\text{g}/\text{ml}$ in water) and gently agitating for 10 to 30 min. If necessary, gels can be destained by shaking in water for an additional 30 min. This serves to remove excess ethidium bromide which causes background fluorescence and makes visualization of small quantities of DNA difficult.

MINIGELS AND MIDIGELS

Small gels—minigels and midigels—can generally be run faster than larger gels and are often employed to expedite analytical applications. Because they use narrower wells and thinner gels, minigels and midigels also require smaller amounts of DNA for visualization of the separated fragments. Aside from a scaling down of buffer and gel volumes, the protocol for running minigels or midigels is similar to that described above for larger gels. Similarly, the parameters affecting the mobility of DNA fragments, discussed below, are the same for both large and small gels.

A number of manufacturers offer smaller versions of their large electrophoresis models. An important feature to consider when selecting a mini- or midigel apparatus is the volume of buffer held by the gel tank. As smaller gels are typically run at high voltages (>10 V/cm), electrophoresis buffers are quickly exhausted, and it is therefore advantageous to choose a gel apparatus with a relatively large buffer reservoir. Minigel boxes can also be easily constructed from a few simple materials (Maniatis et al., 1982). A small (e.g., 15 cm long \times 8 cm wide \times 4 cm high) plastic box can be equipped with male connectors and platinum wire electrodes at both ends to serve as a minimal gel tank (see Fig. 2.5A.1).

Figure 2.5A.1 Minigel apparatus.

SUPPORT PROTOCOL 1

Preparation and Analysis of DNA

2.5A.3

Although trays for casting small gels are commercially available, gels can also be poured onto glass lantern slides or other small supports without side walls. Such gels are held on the support simply by surface tension. After pouring the gel (e.g., 10 ml for a 5 cm × 8 cm gel), the comb is placed directly onto the support and held up by metal paper-binding clamps placed to the side.

Since there is no agarose at the bottom of such wells, extra care must be taken to prevent separation of the gel from the support when removing the comb.

PHOTOGRAPHY OF DNA IN AGAROSE GELS

DNA can be photographed in agarose gels stained with ethidium bromide by illumination with UV light ($>2500 \mu\text{W}/\text{cm}^2$). A UV transilluminator is typically used for this purpose, and commercial models are available designed specifically for DNA visualization and photography (e.g., UVP, Bio-Rad, Stratagene).

CAUTION: UV light is damaging to eyes and exposed skin. Protective eyewear should be worn at all times while using a UV light source.

The traditional means for photographing agarose gels uses a bellows-type camera equipped with a Polaroid film holder. An orange filter (Kodak Wratten #23A) is required to achieve a desirable image of light transmitted by fluorescing DNA. Polaroid type 667 film (ASA 3000) offers ideal sensitivity, allowing as little as several nanograms of DNA to be detected on film after making adjustments of exposure time. Gel photography systems can be set up by purchasing and assembling the individual components (e.g., camera, film holder, filters, and UV transilluminator). Alternatively, complete photography systems are commercially available (Bio-Rad, UVP).

A major disadvantage of traditional photography is the high cost of film. This can have a significant impact on a laboratory budget, particularly if large numbers of gels are processed on a routine basis. Because of this, traditional photography systems have been largely replaced with video imaging systems (e.g., Alpha Innotech Corp., Bio-Rad, Stratagene, and UVP; also see *UNIT 10.5*). Such systems use a CCD camera to capture the gel image and a video monitor to adjust focus and exposure time. A thermal printer generates inexpensive prints suitable for data documentation. A second advantage of imaging systems over traditional photography is that many systems come with video-processing computers and analysis software. This enables the degree of DNA fluorescence to be quantified (and thereby the relative amount of nucleic acid), and images can be stored for documentation and publication. Although the commercially available imaging systems are convenient, they can also be assembled on a less costly basis by purchasing the individual components and using public domain or commercially available software (Griess et al., 1995; Harriman and Wabl, 1995; Sutherland et al., 1987).

REAGENTS AND SOLUTIONS

Agarose gel

Gels typically contain ~1% agarose in 1× TAE or TBE (see *APPENDIX 2* for recipes; see Critical Parameters for choice of buffer). Electrophoresis-grade agarose powder is added to 1× gel buffer and melted by boiling for several minutes. Be sure all agarose particles are completely melted. To facilitate visualization of DNA fragments during the run, ethidium bromide can be added to 0.5 $\mu\text{g}/\text{ml}$ in the gel.

Ethidium bromide solution

1000× stock solution, 0.5 mg/ml:

50 mg ethidium bromide

100 ml H₂O

Working solution, 0.5 µg/ml:

Dilute stock 1:1000 for gels or stain solution

Protect from light.

10× loading buffer

20% Ficoll 400

0.1 M disodium EDTA, pH 8 (*APPENDIX 2*)

1.0% sodium dodecyl sulfate

0.25% bromphenol blue

0.25% xylene cyanol (optional; runs ~50% as fast as bromphenol blue and can interfere with visualization of bands of moderate molecular weight, but can be helpful for monitoring very long runs)

COMMENTARY

Background Information

Virtually all scientific investigations involving nucleic acids use agarose gel electrophoresis as a fundamental tool. Two papers that offer detailed descriptions of this technique and its practical use for DNA analysis are McDonnell et al. (1977) and Southern (1979).

Voltage applied at the ends of an agarose gel generates an electric field with a strength defined by the length of the gel and the potential difference at the ends (V/cm). DNA molecules exposed to this electric field migrate toward the anode due to the negatively charged phosphates along the DNA backbone. The migration velocity is limited by the frictional force imposed by the gel matrix. While charge and/or size can affect the rate at which macromolecules will pass through a gel, the charge to mass ratio is the same for DNA molecules of different lengths. It is the size of the DNA, therefore, that determines the rate at which it passes through the gel, thereby allowing an effective separation of DNA fragment-length mixtures by electrophoresis.

Critical Parameters

While agarose gel electrophoresis is straightforward and easy to perform, several factors should be considered before undertaking an electrophoretic separation. Parameters affecting the mobility of the DNA (i.e., applied voltage and agarose concentration) should be chosen for optimal resolution of the desired DNA fragment(s). The protocol should be designed such that the progress of the electrophoretic separation can be monitored and the

results accurately interpreted. This includes using such tools as tracking dyes and molecular weight markers.

Parameters affecting the migration of DNA through agarose gels

Agarose concentration. Molecules of linear, duplex DNA (form III) travel through gel matrices at a rate that is inversely proportional to the log₁₀ of their molecular weight (Helling et al., 1974). The molecular weight of a fragment of interest can therefore be determined by comparing its mobility to the mobility of DNA standards of known molecular weight. This is the most valuable feature of agarose gel electrophoresis, as it provides a reproducible and accurate means of characterizing DNA fragments by size.

Agarose concentration plays an important role in electrophoretic separations, as it determines the size range of DNA molecules that can be adequately resolved. Figure 2.5A.2A shows the effects of agarose concentration on mobility of fragments of different molecular weights. For most analyses, concentrations of 0.5% to 1.0% agarose are used to separate 0.5- to 30-kb fragments. However, low agarose concentrations (0.3 to 0.5%) are used to separate large DNA fragments (20 to 60 kb), and high agarose concentrations (1 to 1.5%) can resolve small DNA fragments (0.2 to 0.5 kb). See also Table 2.5A.1.

Applied voltage. In general, DNA fragments travel through agarose at a rate that is proportional to the applied voltage. With increasing voltages, however, large DNA molecules mi-

Figure 2.5A.2 Effect of (A) agarose concentration, (B) applied voltage, (C) electrophoresis buffer, and (D) ethidium bromide on migration of DNA through agarose gels.

grate at a rate proportionately faster than small DNA molecules. Consequently, higher voltages are significantly less effective in resolving large DNA fragments, as shown in Figure 2.5A.2B. For separating large DNA molecules, it is best to run gels at both low agarose concentrations and low applied voltages (~1 V/cm, 0.5% agarose).

Electrophoresis buffers. The two most widely used electrophoresis buffers are Tris/acetate (TAE) and Tris/borate (TBE). While these buffers have slightly different effects on DNA mobility (Figure 2.5A.2C), the predominant factor that should be considered in choosing between the two is their relative buffering capacity. Tris/acetate is the most commonly used buffer despite the fact that it is more easily exhausted during extended or high-voltage electrophoresis. Tris/borate has a significantly greater buffering capacity, but should be

avoided for purification of DNA from gels (see gel purification protocols).

DNA conformation. Closed circular (form I), nicked circular (form II), and linear duplex (form III) DNA of the same molecular weight migrate at different rates through agarose gels (Thorne, 1967). In the absence of ethidium bromide, closed circular supercoiled DNAs such as plasmids migrate faster than their linear counterpart DNAs (Fig. 2.5A.2D). Supercoiling essentially winds the molecules up, giving them a smaller hydrodynamic radius and allowing them to pass more readily through the gel matrix. Nicked or relaxed circular molecules that have lost all of their superhelicity migrate appreciably slower than either supercoils or linear molecules (Fig. 2.5A.2D; Johnson and Grossman, 1977).

The intercalating dye (ethidium bromide) is commonly incorporated into the gel and run-

ning buffer. The dye reduces the mobility of linear duplexes (Fig. 2.5A.2D) and has a particularly pronounced effect on the mobility of closed circular DNA. Ethidium bromide changes the superhelical density of closed circular molecules by inducing positive supercoils. With increasing concentrations of ethidium bromide, negative supercoils are gradually removed, causing a concomitant decrease in the mobility of the DNA molecule. This occurs until a critical free-dye concentration is reached where no more superhelical turns remain (usually between 0.1 to 0.5 $\mu\text{g}/\text{ml}$). As still more ethidium bromide is bound, positive superhelical turns are generated which, like negative supercoils, cause an increase in the electrophoretic mobility of the molecules (i.e., Fig. 2.5A.2D). By running gels at different concentrations of ethidium bromide, therefore, form I DNAs can easily be distinguished from other topoisomers.

Monitoring and interpreting separations of DNA through agarose gels

The DNA sample. In choosing the amount of DNA to be loaded, the width of the well plus the depth of the gel and the number and size of DNA fragments should be considered. Between 5 and 200 ng of a single DNA fragment can be loaded into a 0.5-cm-wide \times 0.2-cm-deep sample well; 5 ng approaches the minimal amount of an individual DNA fragment that can be detected by ethidium bromide staining, and 200 ng approximates the most that can be resolved before overloading occurs (the trailing and smearing characteristic of overloading become more pronounced with DNA fragments above 10 kb). For samples of DNA containing several fragments, between 0.1 and 0.5 μg of DNA is typically loaded per 0.5 cm sample well. Up to 10 μg of DNA can be adequately resolved for samples containing numerous fragments of different sizes (e.g., restriction digests of genomic DNA).

Tracking dyes. The most common means of monitoring the progress of an electrophoretic separation is by following the migration of tracking dyes that are incorporated into the loading buffer. Two widely used dyes displaying different electrophoretic mobilities are bromphenol blue and xylene cyanol. Xylene cyanol typically migrates with DNA fragments around 5 kb (Fig. 2.5A.2A) and bromphenol blue usually comigrates with DNA molecules around 0.5 kb (Fig. 2.5A.2A). Bromphenol Blue therefore provides an index of the mobility of the fastest fragments and is particularly

valuable in determining the length of the gel over which the separation of DNA has occurred. Xylene cyanol is useful for monitoring the progress of longer runs. Both dyes can interfere with the visualization of the fragments that comigrate with them.

Ethidium bromide. Ethidium bromide is commonly used for direct visualization of DNA in gels. The dye intercalates between the stacked bases of nucleic acids and fluoresces red-orange (560 nm) when illuminated with UV light (260 to 360 nm). This allows very small quantities of DNA to be detected (<5 ng) (Sharp et al., 1973).

Ethidium bromide is frequently added to the gel and running buffer prior to electrophoresis. While this has a slight effect on the mobility of the DNA (Fig. 2.5A.2D), it eliminates the need to stain the gel upon completion of the separation. An added advantage to running gels with ethidium bromide is that the mobility of the DNA can be monitored throughout the run until the desired separation is achieved.

Molecular weight markers. Among the samples loaded onto a gel, at least one lane should contain a series of DNA fragments of known sizes so that a standard curve can be constructed to allow the calculation of the sizes of unknown DNA fragments. The most commonly used molecular weight markers are restriction digests of phage λ DNA or, for smaller fragments, the plasmid pBR322. Figure 2.5A.3 shows the migration pattern and fragment sizes for restriction digests of λ DNA and pBR322 that are frequently used as molecular weight markers.

Aside from λ restriction fragments, many commercial preparations of molecular weight markers are also available. These products usually cover a wide range of DNA sizes, and some manufacturers also offer supercoiled (form I) markers for calculating plasmid sizes.

Troubleshooting

Common problems encountered in agarose gel electrophoresis are described below, along with several possible causes.

Poor resolution of DNA fragments. The most frequent cause of poor DNA resolution is improper choice of agarose concentration. Low percentage agarose gels should be used to resolve high-molecular-weight DNA fragments and high percentage gels for low-molecular-weight DNAs (see Table 2.5A.1). Fuzzy bands, encountered particularly with small DNA fragments, result from diffusion of the DNA through

the gel. This is especially true when gels are run for long periods of time at low voltages.

Band smearing. Trailing and smearing of DNA bands is most frequently observed with high-molecular-weight DNA fragments. This is often caused by overloading the DNA sample or running gels at high voltages. DNA samples loaded into torn sample wells will also cause extensive smearing, as the DNA will tend to run in the interface between the agarose and the gel support.

Melting of the gel. Melting of an agarose gel during an electrophoretic separation is a sign that either the electrophoresis buffer has been omitted in the preparation of the gel or has become exhausted during the course of the run. For high-voltage electrophoresis over long time periods, TBE should be used instead of TAE as it has a greater buffering capacity. Also, minigel and midigel boxes, which typically have small buffer reservoirs, tend to exhaust buffers more readily than larger gel boxes.

Anticipated Results

DNA fragments of ~0.5 to 25 kb are well resolved using the Basic Protocol. See following description of pulsed-field gel electrophoresis (UNIT 2.5B) for resolving molecules from ~10 to >2000 kb.

Time Considerations

Among the parameters that influence the length of time required to complete an electrophoretic separation, the one that has the greatest effect is the applied voltage. Most large agarose gels are run overnight (~16 hr) at voltages between 1 and 1.5 V/cm. While gels can be run much faster, particularly if the gel apparatus is cooled, resolution of larger DNA fragments is lost when higher voltages are used. Because the resolution required depends on the relative molecular weights of the fragments of interest, the time required for adequate separation is best determined empirically. As described above, this is most easily done by including ethidium bromide in the gel and then monitoring the progress of the run directly by visualization with UV light.

Mini- and midigels are typically run at high voltages relative to gel size (>10 V/cm) and are often completed in less than 1 hr. Two consequences of high-voltage runs should be kept in mind: First, as mentioned above, buffers become quickly exhausted and therefore TBE should be used, or gel tanks with large buffer capacities. Second, high voltages provide poor resolution of high-molecular-weight DNA fragments (see previous discussion). If large DNA fragments are to be separated, it may be advisable to use larger gels and/or lower applied voltages.

Figure 2.5A.3 Migration pattern and fragment sizes of common DNA molecular weight markers.

Pulsed-Field Gel Electrophoresis

UNIT 2.5B

DNA molecules longer than 25 kb are poorly resolved by standard agarose gel electrophoresis (UNIT 2.5A). These longer molecules can be resolved using several techniques that periodically change the direction of the electric field in the gel. The simplest and most generally useful of the pulsed-field techniques is field inversion electrophoresis (see Basic Protocol), which can be tuned to resolve molecules from ~10 to 2000 kb (or more with specialized equipment). To resolve molecules beyond the range of field inversion, it is necessary to use some sort of field-angle alternation electrophoresis such as CHEF (contour-clamped homogeneous electric field; see Alternate Protocol). High-molecular-weight DNA samples and size markers to be resolved by these techniques can be prepared while embedded in agarose blocks (see Support Protocol).

FIELD-INVERSION ELECTROPHORESIS

**BASIC
PROTOCOL**

Materials

1% agarose gel, standard or pulsed-field grade (e.g., SeaKem FastLane; FMC Bioproducts)

GTBE buffer (see recipe) *or* 0.5× TBE buffer (APPENDIX 2)

Samples embedded in agarose (Support Protocol), or liquid samples

Peristaltic pump (Cole-Parmer Masterflex or equivalent)

Programmable switching device (MJ Research PPI-200 or equivalent)

Additional reagents and equipment for agarose gel electrophoresis (UNIT 2.5A)

NOTE: Some power supplies have pulsed-DC rather than constant-voltage output and are unacceptable for pulsed-field gels. These can usually be recognized because their output is fixed, or adjustable in steps, rather than continuously variable.

1. Prepare a 1% agarose gel for a horizontal gel apparatus using GTBE or 0.5× TBE buffer.

Make the gel only as thick as necessary for the samples so that it will consume little power and heat up as little as possible.

Ethidium bromide can be incorporated into the gel, but is recommended only for gels resolving fragments <100 kb (see Critical Parameters).

2. Allow gel to set, then carefully remove comb. Insert into wells any samples that have been prepared in agarose blocks (see Support Protocol).

If blocks fit tightly into wells, it may be easiest to draw them down into the wells by inserting a pipettor with a 0.4-mm (or thinner) gel-loading tip into the back of the well to remove the air from under the blocks. If the blocks do not fit tightly, add melted agarose (55°C in gel buffer) to the well to hold the block in place.

3. Place gel into gel box, cover with buffer to a depth of 2 to 3 mm, and load any samples that are in liquid. To avoid shearing DNA >100 kb, cut ~5 mm off ends of pipet tips with a razor blade and pipet gently. At least one lane should contain bromphenol blue.
4. Adjust peristaltic pump for an appropriate flow (5 to 10 ml/min for a minigel and 20 to 50 ml/min for a large gel). Connect tubing ends to recirculation ports of gel box or place directly in buffer tanks.
5. Paying careful attention to polarity, connect programmable switching device to a constant-voltage DC power supply and connect gel apparatus to switching device.

Supplement 51

Set switching device for an appropriate switching regime but don't begin switching yet. Start gel running.

See Critical Parameters, including Table 2.5B.2, for a guide to time intervals, voltage, and other parameters. The most commonly used ratio of forward to reverse time is 3:1.

6. Allow bromphenol blue to migrate 1 cm, then start switching device and peristaltic pump.
7. Complete run and stain gel with ethidium bromide (UNIT 2.5A). Photograph as for a standard agarose gel (Fig. 2.5B.1).

The gel may be Southern blotted (UNIT 2.9A); note that the acid depurination step is essential for transfer.

ALTERNATE PROTOCOL

CHEF ELECTROPHORESIS

It is possible to resolve DNA molecules several million bases in length by periodically changing the angle of the electric field in the gel. There are a number of variations to the basic setup but all require specially constructed gel boxes, which can be quite expensive. In addition, some types of alternating-angle electrophoresis setups dissipate so much power in the gel that special cooling equipment must be used, adding to the expense.

Running CHEF or other alternating-angle gels, described here, is very similar to running field-inversion gels, so the factors to be considered in that protocol apply to this one, as well. See Critical Parameters for a guide to estimating optimal conditions for running alternating-angle gels.

Additional Materials (also see Basic Protocol)

CHEF electrophoresis voltage-divider circuitry and gel box (see Background Information).

1. Prepare a 1% agarose gel for a CHEF gel apparatus using GTBE or 0.5× TBE buffer.
2. Allow gel to set, then carefully remove comb. Insert into wells any samples that have been prepared in agarose blocks (see Support Protocol).
3. Place gel into gel box, cover with buffer to a depth of 2 to 3 mm, adjust recirculation to ≥ 100 ml/min, and monitor buffer temperature. Wait 15 min after buffer has reached

Figure 2.5B.1 Chromosomes of *Saccharomyces cerevisiae* separated by field inversion.

desired running temperature to ensure that the gel has equilibrated at the correct temperature.

4. Load any samples that are in liquid.
5. Paying careful attention to polarity, connect programmable switching device to constant-voltage DC power supply, voltage divider circuitry, and gel apparatus. Set the switching device for an appropriate switching regime and start gel.
6. Complete run and stain gel with ethidium bromide (*UNIT 2.5A*). Photograph as for a standard agarose gel.

PREPARATION OF HIGH-MOLECULAR-WEIGHT DNA SAMPLES AND SIZE MARKERS

SUPPORT PROTOCOL

Very long DNA molecules are extremely fragile and cannot survive the standard manipulations of molecular biology. These molecules can, however, be prepared and manipulated easily while embedded in agarose blocks. This protocol describes the preparation of very high-molecular-weight DNA.

Materials

1% agarose

Sample to be prepared (e.g., tissue culture cells, nematode worms, nuclei, yeast, bacteria, or phage; Table 2.5B.1)

Lysis buffer (see recipe)

Storage buffer (see recipe)

400 mM phenylmethylsulfonyl fluoride (PMSF) in ethanol

10 mM Tris-Cl, pH 8.0 (*APPENDIX 2*)

Appropriate restriction enzyme and buffer (*UNIT 3.1*)

Block molds or petri plates

1. Prepare block molds (see Fig. 2.5B.2) by sealing one end with tape. If block molds are unavailable, samples can be prepared in agarose poured as a puddle on the bottom of a petri dish and blocks cut to size using a razor blade.
2. Suspend sample at room temperature in water or an appropriate buffer or medium at twice the desired final concentration.

Figure 2.5B.2 Block molds for high-molecular-weight DNA samples. These can be made in the laboratory, or may be purchased from pulsed-field gel box manufacturers.

Preparation and Analysis of DNA

2.5B.3

Table 2.5B.1 Preparation of High-Molecular-Weight DNA Samples and Size Markers

Starting material	Preparation
Bacteria and phage	Resuspend bacteria (<i>UNIT 1.2</i>) or phage particles (<i>UNIT 1.13</i>) at a concentration calculated to yield the desired amount of DNA per lane; e.g., 5×10^8 <i>E. coli</i> per ml will yield ~100 ng DNA in an average lane.
Lambda ladders for size markers	Start with a concentrated stock of phage λ particles (<i>UNIT 1.13</i>). This procedure does not work well with some lots of commercial λ DNA, possibly because of damaged cohesive ends. Try several dilutions of phage stock to see which works best. The second incubation in lysis buffer should be done at 25° rather than 37°C; during this incubation, the cohesive ends of the molecules will anneal, giving multimers of varying lengths. These concatemers will stay together during electrophoresis provided that the gel is run at <25°C.
Nematodes	Anesthetize worms by resuspending in 10 mM NaN ₃ , then place in agarose.
Nuclei	Isolate as in <i>UNIT 4.10</i> . Approximately 1 μ g DNA is contained in 10 ⁵ mammalian nuclei.
Tissue culture cells	Cells should be washed several times in a medium containing no serum, as serum may inhibit proteinase K.
Yeast	<i>Saccharomyces cerevisiae</i> cells must have their cell walls removed before being embedded in agarose as described in <i>UNIT 13.13</i> , Basic Protocol.

The samples may also be suspended in the buffer in which they were originally prepared, or in a buffer such as TE buffer (APPENDIX 2). See Table 2.5B.1 for guidelines to preparing specific starting materials.

3. Add equal volume of 1% agarose, melted and cooled to 50°C. Quickly mix and aliquot solution into block mold. Let agarose solidify on ice.
4. Remove tape from mold and carefully push hardened blocks into a 50-ml conical tube containing at least 20 vol lysis buffer. Incubate overnight at 50°C, preferably with gentle agitation.
5. Pour off lysis buffer, add fresh lysis buffer, and incubate overnight at 37°C.
6. Pour off lysis buffer and replace with 20 vol storage buffer. Store at 4°C or proceed with steps 7 to 9 for sample to be digested with restriction enzymes.
7. Wash sample three times, 1 hr at room temperature each time, with at least 10 vol storage buffer supplemented with 1 mM PMSF.

CAUTION: PMSF is a powerful covalent inhibitor of proteases. It is both toxic and volatile and should always be handled in a hood. It is unstable in aqueous solution, so solutions should always be freshly prepared from a stock of 400 mM in ethanol stored at -20°C (PMSF will precipitate at -20°C and redissolve when warmed).

8. Wash sample three times, 30 min at room temperature each time, in at least 10 vol of 10 mM Tris·Cl, pH 8.0.

- Place sample in 1.5-ml microcentrifuge tube and remove excess liquid. Add an amount of 3× restriction buffer (containing the restriction enzyme) equal to half the volume of the block. Incubate at appropriate temperature.

For particular batches of samples and lots of enzyme, it may be necessary to titrate the amount of enzyme and digestion time to minimize DNA degradation.

REAGENTS AND SOLUTIONS

GTBE buffer

50 ml 10× TBE buffer (*APPENDIX 2*; 0.5× final)

50 ml 2 M glycine (0.1 M final)

900 ml H₂O

Store at room temperature

Lysis buffer

100 mM EDTA, pH 8.0 (*APPENDIX 2*)

10 mM Tris·Cl, pH 8.0 (*APPENDIX 2*)

1% (w/v) N-lauroylsarcosine sodium salt (Sarkosyl)

100 μg/ml proteinase K (add just before use from a 20 mg/ml stock)

Store at room temperature, *without proteinase K*

Storage buffer

10 mM Tris·Cl, pH 8.0 (*APPENDIX 2*)

10 mM EDTA, pH 8.0 (*APPENDIX 2*)

Store at room temperature

COMMENTARY

Background Information

In DNA gel electrophoresis, negatively charged DNA molecules are pulled through a gel by an electric field. An agarose gel presents a DNA molecule with a set of pores of varying sizes. Small molecules pass easily through most pores and move rapidly through the gel. Larger molecules have to “squeeze,” or change conformation, to get through the smaller pores and are slowed more than smaller molecules. The mobility of a molecule is related to the fraction of pores that it can easily move through, a process known as “sieving.”

DNA molecules larger than a certain size must squeeze to get through even the largest pores and cannot be sieved by the gel. Molecules in this size range all migrate at about the same rate, called “limiting mobility.” For ordinary agarose gel electrophoresis (*UNIT 2.5A*), limiting mobility generally occurs between 20 and 40 kb, depending on the exact conditions of the gel run. Schwartz and Cantor (1984) showed that it was possible to resolve molecules that would otherwise run at limiting mobility by cyclically varying the orientation of the electric field in the gel during the run.

The principle involved in alternating-angle electrophoresis is relatively simple. As a large molecule squeezes through a pore, it is forced into an extended conformation. It takes some time (from milliseconds to minutes, depending on the molecule’s size) to squeeze through the first pore but once the extended conformation is attained, the molecule can continue to squeeze rapidly through successive pores, moving at limiting mobility. If a large molecule moving through a gel is suddenly forced to change direction by a change in the orientation of the electric field, it must first change to a new conformation that will allow it to move in the new direction. The larger a molecule is, the longer it will take to change to the new conformation, and this time difference can be used to separate molecules. For example, although a 100-kb and a 200-kb molecule move through the gel matrix at the same rate in the steady state of limiting mobility, every time the direction of the field changes the 100-kb molecule will get a “head start” on the 200-kb molecule.

There are a number of implementations of alternating-angle electrophoresis. Schwartz and Cantor (1984) originally used an apparatus

that resulted in nonuniform electric fields. Nonuniform fields can focus bands, making them very sharp, but inevitably cause the lanes to run in various crooked shapes.

More practical systems use uniform electric fields, which result in gel lanes that run straight. Several methods of achieving uniform fields have been invented, including CHEF (contour-clamped homogeneous electric fields; Chu et al., 1986), and simply running the gel in a rectangular box and periodically rotating it. The angle between the two fields must be somewhat greater than 90° , and may be much greater.

In CHEF electrophoresis, the gel is surrounded by a set of electrodes whose voltages can be fixed in such a way that a uniform electric field is set up in the gel. Thus CHEF gels require two pieces of equipment not necessary for field inversion electrophoresis: a voltage-divider circuit to set the electrode voltages, and a multi-electrode gel box. Both are available commercially and plans have been published (Chu, 1989). Figure 2.5B.3 shows a popular version of CHEF voltage divider circuitry.

Alternating-angle electrophoresis using a fixed switching time gives optimum resolution in a single size range, but does separate DNA outside this size range, albeit with reduced resolution (see critical parameters). It is there-

fore advantageous to vary the pulse durations during a run.

Field-inversion electrophoresis employs the limiting value for the angle between two uniform fields, 180° (Carle et al., 1986). Analysis of field-inversion electrophoresis is somewhat more complicated than that of alternating-angle electrophoresis because different pulse times are used in the forward and reverse directions. Like alternating-angle electrophoresis, field inversion slows molecules that would otherwise run at limiting mobility by taking advantage of the time required for molecules to change conformation.

One difference between the two techniques is that in field inversion a single pulse duration separates only a relatively narrow range of sizes. To get resolution over a broad size range, it is necessary to use a range of reverse times; this is accomplished with a time ramp—i.e., progressively increasing the forward and reverse intervals from a lower limit to an upper limit. It is preferable to cycle repeatedly through the range of times rather than to use one long time ramp, as there is some hysteresis in the behavior of large molecules (the largest molecules will move more slowly during short intervals if they immediately follow longer intervals).

Varying the reverse interval also prevents a possible artifact of field inversion. If the reverse

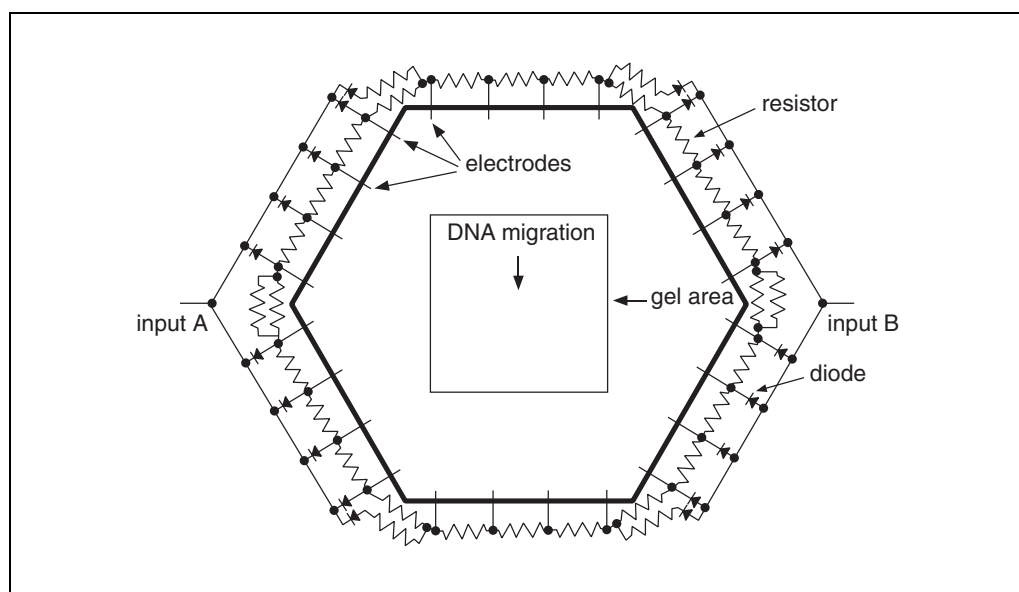

Figure 2.5B.3 Circuitry for clamping electrode voltages of a 24-electrode hexagonal CHEF gel (redrawn from Chu, 1989). Positions of the 24 electrodes are shown schematically, as well as the direction of the resulting DNA migration. This circuitry can be driven directly by an inverting gel controller connected to input A and input B. Power dissipation in the resistors limit this circuit to ~ 250 V input. All resistors are 470Ω , 1% tolerance, 3 W and diodes are type 1N4004 (1 A, 400 V).

time is not long enough, large molecules may not be sufficiently disrupted by the reversal, and may actually migrate faster than shorter molecules. This effect can be completely overcome by using a time ramp whose longest reverse time is long enough to disrupt all molecules of interest.

A phenomenon that affects all forms of pulsed-field electrophoresis is “trapping” of the largest molecules, preventing them from entering the gel. Trapping is dependent on both voltage and temperature. At high temperatures and field strengths, molecules as small as 1 Mb may be trapped; at low temperatures and field strengths, molecules >5 Mb will enter the gel.

Critical Parameters

All forms of pulsed-field electrophoresis depend on differences in the time it takes for molecules of various sizes to change directions in a gel; these times are affected by a number of factors. The effects of some of these factors have been investigated in detail (Birren et al., 1988) and are discussed below.

Voltage. Voltage is measured in V/cm of gel length. It is best to measure this directly by dipping the two probes of a voltmeter into the buffer at the ends of a running gel, and dividing the reading by the length of the gel in centimeters. Most horizontal submarine gel boxes apply ~80% of the power-supply voltage to the gel (the rest is lost in the buffer tanks), so voltage can be estimated by multiplying the

power supply readout by 0.8 and dividing the result by the length of the gel. Sizes resolved by pulsed-field gels can be changed over a wide range merely by changing the voltage. Higher voltage increases the sizes separated, but also may result in trapping the largest molecules. Pulsed-field gels are generally run at 5 to 10 V/cm.

Temperature. Pulsed-field gels can be run over a broad range of temperatures. A given time interval will separate larger molecules at 30°C than at 10°C. Choose a temperature that is convenient and adjust times for best resolution. The upper limit of resolution field-inversion gels is affected by trapping, and at 8 V/cm varies from 2000 kb at 4°C to ~1000 kb at 30°C.

Although different temperatures may be used, it is critical that the entire gel be at the same temperature to prevent the “smile” effect. This is best accomplished by recirculating the buffer using a peristaltic pump. In many cases, pulsed-field gels can be run on the benchtop with no cooling. Gels that generate a lot of heat can often be run in a cold room.

Buffer. Because pulsed-field gels are usually run at higher voltages than standard gels, they have the potential to generate quite a bit of heat. For this reason, they are often run in 0.5× TBE buffer, which carries little current. This works well, especially for molecules less than a few hundred kilobases.

DNA has higher mobility in TAE buffer, but TAE carries a lot of current, causing gels to heat

Table 2.5B.2 Empirical Equations for Fragment Resolution and Velocity Using Pulsed-Field Gels^{a,b}

Field-inversion gels

Maximum resolved size ^c (kb)	$0.13 \times (T + 40) \times V^{1.1} \times (3 - A)^{0.6} \times t^{0.875}$
Minimum resolved size (kb)	0.75 × maximum size
Velocity of 10-kb fragment (cm/hr)	$\frac{0.0016 \times (T + 25) \times V^{1.6} \times (R - 1)}{A \times (R + 1)}$

CHEF or other alternating-angle gels

Maximum well-resolved size ^c (kb)	$0.034 \times (T + 40) \times V^{1.1} \times (3 - A)^{0.6} \times t^{0.875}$
Minimum well-resolved size (kb)	0.75 × maximum size
Velocity of 10-kb fragment (cm/hr)	$\frac{0.0012 \times (T + 25) \times V^{1.6} \times \cos(\theta/2)}{A}$

^aEquations assume use of 0.5× TBE buffer; for GTBE and TAE buffers, sizes separated will be slightly larger and gels will run ~20% and 30% faster, respectively.

^bVariables: *T*, temperature in °C; *V*, field strength, volts/cm; *A*, % agarose (multiply by 0.8 for pulsed-field grade agarose); *t*, pulse time (reverse time for field-inversion gels) in sec; *R*, forward-to-reverse time ratio; *θ*, reorientation angle.

^cField inversion does not resolve fragments outside this range; alternating-angle gels will resolve fragments outside this range, but not as well.

up. A good compromise is GTBE buffer, which is 0.5× TBE with 100 mM glycine added. GTBE increases the mobility of the DNA without significantly increasing the current.

Ethidium bromide. Ethidium slows the re-orientation of molecules, possibly by making DNA stiffer. Addition of ethidium bromide to the gel can help resolve molecules <100 kb, but is not recommended for larger molecules.

Agarose. Low agarose concentration shifts the sizes of molecules resolved toward the larger range, and also speeds the migration of all molecules. Special pulsed-field grade agarose is available from several companies. These agaroses make gels with large pore sizes, so that larger molecules can be resolved, and with high gel strength, so that low-percentage gels can be used. A gel poured with 1% pulsed-field grade agarose will give similar results to a gel poured with 0.8% regular agarose, but will be much stronger.

Pulse times. For alternating-angle electrophoresis, best resolution is obtained by using pulse times just long enough to resolve the largest molecules of interest (or better yet, using a time ramp with a maximum that is just long enough).

Pulse times are much more critical for field-inversion electrophoresis, because a given reverse pulse time resolves a narrower range of sizes. Use a range of reverse times broad enough to separate all molecules of interest. The ratio between forward and reverse times is generally in the range of 2.5:1 to 3.5:1. Lower ratios give better separation but make gels run more slowly. The most commonly used ratio is 3:1.

Table 2.5B.2 lists equations predicting the sizes resolved and the speed of gel runs for field-inversion and alternating-angle gels. For example, for a field inversion gel run at 12° at 8 V/cm in 0.8% agarose with reverse pulses of 10 sec and forward pulses of 30 sec:

$$\begin{aligned} \text{Size} &= 0.13 \times (12 + 40) \times 8^{1.1} \times \\ &\quad (3 - 0.8)^{0.6} \times 10^{0.875} \\ &= 0.13 \times 52 \times 9.85 \times 1.6 \times 7.5 = 800 \text{ kb} \end{aligned}$$

$$\text{Minimum size} = 0.75 \times 800 = 600 \text{ kb}$$

$$\begin{aligned} \text{Velocity} &= \frac{0.0016 \times (12 + 25) \times 8^{1.6} \times (3 - 1)}{0.8 \times (3 + 1)} \\ &= \frac{0.0016 \times 37 \times 27.9 \times 2}{0.8 \times 4} = 1.0 \text{ cm/hr} \end{aligned}$$

Thus, the gel will resolve fragments from 600 to 800 kb, and a 10-kb fragment will move at 1 cm/hr.

Troubleshooting

Size range resolved too high or too low. Refer to Table 2.5B.2 and adjust whatever parameter is convenient (typically voltage or pulse times) to change the sizes resolved.

Bands broadening or disappearing at top of gel. Decrease trapping by decreasing temperature or voltage.

Bands smeared. Run samples into gel for longer time, at lower voltage, or both.

Excessive smile. More heat is being produced than can be dissipated effectively. Either reduce the heating by decreasing voltage, gel thickness, or buffer depth, or increase buffer recirculation.

Anticipated Results

Molecules of interest should be well resolved in straight lanes (see Fig. 2.5B.2).

Time Considerations

The time required for running a gel can be estimated from Table 2.5B.2. The support protocol on sample preparation requires two overnight incubations, and restriction enzyme digestion (if desired) takes most of another day.

Isolation and Purification of Large DNA Restriction Fragments from Agarose Gels

UNIT 2.6

This unit describes methods for recovering and purifying DNA restriction fragments from agarose gels. The first Basic Protocol involves electroelution of the fragment of interest from standard agarose gels using buffer-filled dialysis bags, followed by concentration and purification using an Elutip column (see Basic Protocol 1). This approach can be used effectively for fragments of all sizes from 50 to 20,000 bp. Electrophoresis directly onto NA-45 paper (see Basic Protocol 2) provides relatively high yields for fragments ≤ 2000 bp. Fragments ≥ 1000 bp can also be separated on low gelling/melting agarose gels and purified by phenol extraction (see Basic Protocol 3), β -agarase digestion of the gel (Alternate Protocol 1), or via silica membrane spin columns (Alternate Protocol 2). Removing linkers from a fragment using a column rather than a gel (Alternate Protocol 3) is included, followed by a method for estimating DNA concentrations in solution (Support Protocol).

ELECTROELUTION FROM AGAROSE GELS

**BASIC
PROTOCOL**

Following digestion with appropriate restriction enzymes, the DNA of interest is electrophoresed on a preparative agarose gel. The portion of the gel containing the restriction fragment to be purified is then physically removed from the remainder of the gel. This agarose slice is placed into a buffer-filled piece of dialysis tubing and again subjected to electrophoresis. The restriction fragment migrates out of the gel slice into the buffer, and the DNA is further purified and concentrated using an Elutip-d column. This procedure is effective with fragment sizes ranging from 50 to 20,000 bp, although for eluting fragments ≤ 2000 bp, the use of one of the other protocols (e.g., elution from NP-45 paper; see Basic Protocol 2) is recommended.

Materials

- DNA encoding sequence of interest
- Appropriate restriction enzymes and buffers (*UNIT 3.1*)
- Ethidium bromide solution (*UNIT 2.5A*)
- TAE buffer (*APPENDIX 2*)
- Elutip high-salt solution (see recipe)
- 2.5 M NaCl
- Elutip low-salt solution (see recipe)
- 100% and 70% ethanol
- TE buffer, pH 8.0 (*APPENDIX 2*)
- Spectrapor 3 dialysis membrane tubing (11.5-mm diameter with MWCO of 3500; Baxter)
- Elutip-d columns (Schleicher & Schuell)
- Small syringe (e.g., 5-ml)
- Additional reagents and equipment for restriction enzyme digestion (*UNIT 3.1*) and agarose gel electrophoresis and photography (*UNIT 2.5A*)

Choose and electrophorese a preparative agarose gel

1. Digest 0.1 to 25 μ g DNA to completion with appropriate restriction enzyme(s).

The relative abundance of the DNA fragment to be isolated in the sample to be electrophoresed and the use to which this fragment will be put are the most important factors in determining the amount of DNA to be digested. For frequently used cloning

**Preparation and
Analysis of DNA**

2.6.1

vectors and fragments for nick translation, enough sample should be digested to give ~10 μg of DNA in the target band. For preparation of fragments to be used in a single cloning experiment, 1 μg of DNA in the target band is more than sufficient. It is worthwhile to electrophorese a small aliquot of the preparative digest on a minigel before loading the preparative gel—this will allow the efficiency of the digestion to be ascertained as well as verify the existence of the relevant restriction sites.

2. Load sample onto the appropriate agarose gel and electrophorese.

The molecular weight of the DNA fragment to be isolated, as well as the weights of other fragments in the sample, should be considered when choosing the dimensions and percentage of the gel to be poured and the rate at which the gel will be electrophoresed. Using a wide slot (e.g., 4 to 5 cm) on a large gel (e.g., 20 \times 20 cm) is best when large amounts of DNA are to be separated or when the DNA fragment of interest is somewhat difficult to resolve from other fragments. Using a minigel is best when a small amount of a well-separated DNA fragment is to be isolated. It is best to load only a single sample on a preparative gel and to minimize or eliminate markers—this will avoid contamination of the fragment of interest.

3. After electrophoresis, stain the gel with ethidium bromide solution and photograph the gel.

Do not be surprised to see a few extra bands on the preparative gel. Because so much more DNA is loaded onto the gel, minor products of the restriction digest are sometimes visible. If the gel was electrophoresed too rapidly or if too much DNA was loaded into the preparative slot, a “flame” of DNA running from the bands back up to the slot will be visible. When this flame is present, it is likely that trapping has occurred (i.e., that small amounts of DNA of several different molecular weights migrated with the target band).

Electroelute the DNA

4. Using UV light for visualizing bands, carefully cut out the target band with a scalpel.

Cut the narrowest gel slice possible that allows the removal of the bulk of the target band. Occasionally, it is worthwhile to cut out only the heart of the target band if it has migrated close to another band on the gel. Be sure to minimize exposure of eyes, skin, and the DNA to UV light.

CAUTION: *Wear safety goggles or full face mask—UV burns of the cornea (which will occur with even brief exposure of unprotected eyes) are extremely painful and can result in infections and loss of vision. A strong UV source can also “sunburn” sensitive skin in exposed areas such as the face and hands in <1 min.*

5. Rinse dialysis tubing with TAE buffer.

It is not necessary to store the tubing in buffer for long periods of time—5 min in TAE buffer is sufficient.

6. Tightly tie off one end of the tubing with two knots. Slide the gel slice into the tubing. Fill the tubing with TAE buffer until it is almost completely expanded. Knot or clip the top of the tubing closed.

It is essential that no leakage from the sealed tubing occur. Spectra/Por closures (e.g., Thomas Scientific) are often used to clip the ends of the bags.

7. Place the sealed dialysis bag in a horizontal gel electrophoresis apparatus (any box with two wires connected to electrodes). Fill the apparatus with 1 \times TAE buffer until the dialysis bag is just covered with solution.

If too much buffer is added, the dialysis bag will float freely and not always be in the proper orientation for efficient electroelution.

8. Electroelute at a constant voltage of ~2 V/cm between the two wires. For a 50- to 500-bp target fragment, electroelute 30 to 45 min. For a 500- to 2000-bp fragment, electroelute 2 hr. For a 2000- to 4000-bp fragment, electroelute 4 hr. For larger fragments, electroelute at 1 V/cm overnight.

Under no circumstances should the running buffer heat up—the yield will be severely reduced if this occurs.

9. After electroelution is complete, reverse the polarity of the electrodes and turn on voltage at 100 V for 30 sec.

This will free any DNA that has stuck to the dialysis tubing.

10. Carefully open the top of the dialysis bag and collect TAE buffer with a Pasteur pipet. Massage gel slice out of the bag and wash the bag with a pipet of TAE buffer.

It is worthwhile to stain the gel slice with ethidium bromide to ensure that all the DNA has been eluted from the gel. If some DNA remains in the gel, repeat electroelution (step 4). Depending on size of gel slice, the final volume of TAE buffer will range from 2 and 25 ml.

Concentrate and purify electroeluted DNA with Elutip-d

11. Wet the Elutip-d column with Elutip high-salt solution. Place 2 ml high-salt solution in a small syringe. Attach the syringe to an Elutip-d column and push the high-salt solution through the column.

Elutip-d miniature affinity columns contain a reverse-phase resin. Do not cut off the tip of the column (as recommended in some protocols), as this will cause solutions to pass through the column too rapidly. Also, do not allow any solutions to flow in the reverse direction (i.e., toward the wide portion of the column), and do not allow the column to dry out during the procedure.

12. Equilibrate the column with Elutip low-salt solution. Place 5 ml low-salt solution in the syringe and push the solution through the column.

13. Adjust salinity of the DNA sample to be purified to 0.2 M NaCl with 2.5 M NaCl. Take up the DNA solution in the syringe and load onto the column.

The DNA is loaded onto the column in low salt. Loading is conveniently done by placing a weight on the syringe such that ~20 drops per minute of the DNA-containing solution pass through the column. If the flow rate is too high, the DNA will flow through too quickly and severe reduction in yield will occur. If the DNA solution being applied to the column appears to contain particulates (which it should not), a disposable 0.45- μ m cellulose acetate filter can be placed between the syringe and the column.

14. Wash the column with 5 ml low-salt solution.

The flow rate through the column during this step should be approximately twice as fast as during the DNA loading step.

15. Elute the DNA with 400 μ l high-salt solution. Collect the solution in a 1.5-ml microcentrifuge tube.

The flow rate should be the same as during the DNA loading step. It is worthwhile to elute a second time with 400 μ l high-salt solution.

16. Add 1 ml of 100% ethanol to 400 μ l eluted DNA. Precipitate at -20°C . Pellet DNA, wash in 70% ethanol, and dry. Resuspend in desired amount of TE buffer, pH 8.0, and use for further manipulations and quantitation (support protocol).

For fragments >1 kb, the yield after electroelution and purification should be 80% to 90%. For smaller fragments, the yield is generally 50% to 60%.

ELECTROPHORESIS ONTO NA-45 PAPER

This procedure is simpler than Basic Protocol 1, as it does not require the manipulation of gel slices and dialysis bags. It is particularly suitable for small DNA fragments (i.e., <2000 bp). After preparative gel electrophoresis in a gel containing ethidium bromide, a piece of NA-45 paper is inserted into the gel ahead of the fragment of interest. Further electrophoresis results in migration of the fragment onto the paper, which then is removed from the gel. The fragment is eluted from the paper with high salt.

Materials

Ultrapure agarose (e.g., SeaKem GTG agarose, FMC Bioproducts)

NA-45 paper (Schleicher & Schuell)

TE buffer, pH 8.0 (*APPENDIX 2*)

NA-45 elution buffer (see recipe)

Buffered phenol (*UNIT 2.1*)

25:24:1 (v/v/v) phenol/chloroform/isoamyl alcohol (*UNIT 2.1*)

95% and 70% ethanol, ice cold

Flat forceps, two pairs

Additional reagents and equipment for agarose gel electrophoresis (*UNIT 2.5A*) and DNA extraction and precipitation (*UNIT 2.1*)

1. Digest DNA to completion with appropriate restriction enzymes and load onto gel prepared with ultrapure agarose (see Basic Protocol 1, steps 1 and 2).

Ethidium bromide is added to the gel at a final concentration of 0.5 µg/ml.

2. Electrophorese at appropriate voltage until DNA fragment of interest is well resolved from contaminants, as assessed by visualization with hand-held UV lamp.
3. Stop electrophoresis and, with a clean scalpel or razor blade, cut slits just above and below the fragment.
4. Insert a small piece of NA-45 paper into each of the slits by carefully separating the opening with a flat forceps while placing the paper in the slit with another set of forceps.

The NA-45 paper is cut to the size of a rectangle as wide as the gel band of interest and as long as the depth of the gel. Do not touch the paper with your hands!

5. Gently push on the top and bottom of the gel to ensure that the slits are in contact with the paper. Electrophorese 10 min at the same voltage and current as the prior run, or until the DNA has migrated onto the paper.

The paper below the band will bind the DNA fragment of interest, while the paper above will capture any higher-molecular-weight contaminants.

6. Carefully remove the paper containing the DNA fragment of interest with forceps. Wash paper gently three times in TE buffer, pH 8.0.

A 12-well microtiter plate is convenient for this; simply move the paper from one well to the next.

7. Remove the washed paper to a 1.5-ml microcentrifuge tube containing 400 µl NA-45 elution buffer. Heat to 70°C—15 min for short fragments (<500 bp) or 1 hr for larger fragments (>1500 bp).

Intermediate times are appropriate for intermediate-length fragments.

8. Extract once with 400 µl buffered phenol. Reextract aqueous phase twice with phenol/chloroform/isoamyl alcohol, then extract twice with chloroform.

9. Add 1 ml of 95% ethanol and precipitate overnight at -20°C .
10. Microcentrifuge at high speed and wash pellet with 70% ethanol chilled to -20°C . Resuspend DNA in TE buffer, pH 8.0.

ISOLATION OF DNA FRAGMENTS USING LOW GELLING/MELTING TEMPERATURE AGAROSE GELS

BASIC PROTOCOL 3

Following preparative gel electrophoresis using low gelling/melting temperature agarose, the gel slice containing the band of interest is removed from the gel. This agarose slice is then melted and subjected to phenol extraction or to an Elutip-d column.

For some applications (including restriction enzyme digestions, *UNIT 3.1*, and ligations, *UNIT 3.16*) the melted gel slice containing the fragment can be used directly, without further purification by extraction or Elutip-d purification.

Materials

DNA to be isolated

Appropriate restriction enzymes and buffers (*UNIT 3.1*)

Low gelling/melting temperature agarose (SeaPlaque; FMC Bioproducts)

Ethidium bromide solution (*UNIT 2.5A*)

TE buffer, pH 8.0 (*APPENDIX 2*)

Buffered phenol (*UNIT 2.1*)

Elutip high-salt and low-salt solutions (see recipe)

Scalpel

Elutip-d column (Schleicher & Schuell)

Beckman JS-13 swinging-bucket rotor (or equivalent)

Additional reagents and equipment for restriction enzyme digestion (*UNIT 3.1*), agarose gel electrophoresis (*UNIT 2.5A*), and ethanol precipitation (*UNIT 2.1*)

1. Digest DNA sample to completion with appropriate restriction enzymes. Pour, load, and electrophorese on a 1% low gelling/melting temperature agarose gel.

Both the quantity of DNA that can be loaded and the quality of resolution are less on a low gelling/melting temperature gel than on a standard agarose gel.

2. Stain the gel using ethidium bromide solution and cut out the target band with a scalpel. Melt the gel slice at 65°C and add enough TE buffer, pH 8.0, to decrease the agarose percentage to $\leq 0.4\%$.

3. If DNA is to be used for ligation (*UNIT 3.16*), transformation (*UNIT 1.12*), or restriction endonuclease digestion (*UNIT 3.1*), use the molten solution directly. To isolate a fragment directly using an Elutip-d column, proceed to steps 8 and 9. To remove agarose by phenol extraction, proceed to step 4.

Fragments separated by low gelling/melting temperature agarose gels can also be isolated by β -agarase digestion of the agarose (see Alternate Protocol 1) or using a silica membrane spin column (see Alternate Protocol 2).

4. Add an equal volume of buffered phenol (*not* phenol/chloroform) and mix vigorously for 5 to 10 min. Centrifuge 10 min at $15,800 \times g$ (10,000 rpm in a Beckman JS-13 rotor), room temperature.

After centrifugation, a thick white interface will be visible.

5. Collect the aqueous phase and set aside. Reextract the phenol phase and interface with an equal volume of TE buffer, pH 8.0. Centrifuge as in step 4.

Preparation and Analysis of DNA

2.6.5

6. Collect second aqueous phase. If a large interface still appears, reextract a third time.
7. Ethanol precipitate the combined aqueous phase. Further purify the DNA solution via an Elutip-d column (steps 8 and 9) or use directly after resuspending in the appropriate buffer.

Generally, the resulting pellet will be rather large, as it contains a fair amount of agarose. If the DNA is not further purified, it is helpful to add BSA to 500 µg/ml final concentration. This helps reduce the inhibition of enzymatic reactions that is characteristic of agarose-containing DNA solutions.
8. Add 10 to 20 vol Elutip low-salt solution.
9. Purify the DNA fragment using an Elutip-d column (see Basic Protocol, steps 11 to 16), maintaining all solutions at 37°C. Ethanol precipitate and quantitate as described in the support protocol.

**ALTERNATE
PROTOCOL 1**

**RECOVERY OF DNA FROM LOW GELLING/MELTING TEMPERATURE
AGAROSE GELS USING β-AGARASE DIGESTION**

The following protocol is an alternative method for recovery of DNA from low gelling/melting temperature agarose. A gel slice containing the DNA of interest is treated with β-agarase, which digests the long-chain polysaccharides in the agarose to monosaccharides and short oligosaccharides. The resulting DNA in solution can be directly subjected to many further manipulations such as ligation (UNIT 3.16), transformation (UNIT 1.12) and restriction endonuclease digestion (UNIT 3.1). Alternatively, ethanol precipitation may be used to remove oligosaccharide digestion products. This protocol may also be used in conjunction with purification via Elutip-d columns (second basic protocol) and for purifying small DNA fragments from sieving agarose gels (UNIT 2.8).

Additional Materials (also see Basic Protocol 3)

β-agarase I (New England Biolabs or Calbiochem)
β-agarase buffer (see recipe)

Additional reagents and materials for dialysis (APPENDIX 3D) and isopropanol precipitation of DNA (UNIT 2.1)

1. Prepare a low gelling/melting temperature agarose gel (see Basic Protocol 3, steps 1 and 2).
2. Transfer gel slice to a clean tube. Wash twice for 30 min each on ice with 2 vol of 1× β-agarase buffer. Add an approximately equal volume of β-agarase buffer to the washed gel slice.

Alternatively, if trying to keep volumes low, add 1/10 vol β-agarase buffer to the gel slice and proceed directly to step 3.
3. Melt the gel completely by heating 10 min at 65°C.
4. Equilibrate molten agarose to 40°C (allow ~10 min). Add 1 U β-agarase for every 200 µl of 1% agarose and continue incubation for 1 hr.

If equilibration of the gel slice in β-agarase buffer was bypassed in step 2, double the amount of β-agarase added here. β-agarase exhibits 50% activity in TBE buffer and 80% activity in TAE buffer.

5. If DNA is to be used for ligation (*UNIT 3.16*), transformation (*UNIT 1.12*), or restriction endonuclease digestion (*UNIT 3.1*), use the molten β -agarase/DNA solution directly. To further purify large (>50 kb) DNA fragments, dialyze the DNA solution to remove carbohydrates and β -agarase. To purify smaller fragments, follow steps 6 to 9.

This gentle treatment will avoid mechanical shearing of large DNA molecules.

6. To purify small (<50 kb) fragments, adjust the salt concentration of the β -agarase/DNA solution to 0.5 M NaCl and add an equal volume of isopropanol. Chill 15 min on ice.

Sodium acetate (0.3 M final) or LiCl (0.8 M final) may also be used for this precipitation step.

7. Centrifuge 15 min at $15,000 \times g$ to pellet any undigested carbohydrates and transfer supernatant to a clean tube.
8. Add 2 to 3 vol isopropanol, mix thoroughly, and chill 30 min at 0°C.

Carrier RNA (1 μ g) may be added to ensure recovery of small quantities of DNA. Large volumes of isopropanol are needed to dilute salt concentrations and ensure DNA precipitation.

9. Centrifuge 15 min at $15,000 \times g$, discard supernatant, and dry pellet. Resuspend in TE buffer, pH 8.0, or appropriate buffer required for subsequent manipulation.

RECOVERY OF DNA FROM AGAROSE USING SILICA MEMBRANE SPIN COLUMNS

ALTERNATE PROTOCOL 2

The following rapid approach is based on the silica membrane column purification method described in *UNIT 2.1*. A gel slice containing DNA fractionated through an agarose gel is melted and passed through a silica membrane column in the presence of high salt. Under these conditions, DNA is adsorbed onto the silica membrane. The gel contaminants are subsequently washed away and DNA is eluted in low-salt buffer. This procedure is suitable for fragments >100 bp. It is actually intended for recovering DNA from gels made from standard agarose, but can also be used with low gelling/melting temperature agarose. Although it is more rapid than standard electroelution or organic extraction methods, this approach may result in somewhat lower yields. Silica membrane spin columns for purification from agarose gels are available from many companies (including Qiagen, Promega, Invitrogen, and Novagen) as kits which include silica membrane spin columns and all appropriate buffers necessary for DNA purification.

Additional Materials (also see Basic Protocol 3)

6.0 M NaI solution (filter through filter paper, store up to 3 months in the dark at 4°C)

Binding buffer (see recipe)

Wash buffer (*UNIT 2.1A*)

TE buffer, pH 8.0 (*APPENDIX 2*) or nuclease-free H₂O

1.5-ml microcentrifuge tubes

45° to 50°C water bath

Silica membrane spin columns (e.g., Qiagen, Promega, Invitrogen, Novagen)

1. Digest DNA sample to completion, pour, load, and electrophorese through a 1% agarose gel, and stain gel using ethidium bromide (see Basic Protocol 3, steps 1 and 2). Cut out the target band with a clean scalpel and transfer to a 1.5-ml microcentrifuge tube.

Preparation and Analysis of DNA

2.6.7

2. Estimate the volume of the agarose (usually ~100 μ l) and add 2.5 to 3.0 vol of 6.0 M sodium iodide (250 to 300 μ l).

When using either this procedure or kits with NaI as the chaotropic salt, recovery may be reduced if the agarose gel was run with TBE rather than TAE buffer; TBE may inhibit the binding of DNA to silica membranes. To resolve this problem, reduce the pH of the buffer by the addition of 1/10 vol of sodium phosphate, pH 6 (APPENDIX 2). Sodium perchlorate or guanidine isothiocyanate can be used as the chaotropic salt to dissolve the agarose gel. It is important keep the pH of the gel/salt solution at pH 6.5 for the DNA to bind the silica membrane efficiently.

3. Incubate 5 min at 45° to 50°C to dissolve the agarose.

Mix the contents once or twice during this incubation. If all agarose has not completely dissolved after 5 min, return the tube to the water bath for 1 to 2 min, but do not leave the mixture heating longer than required to dissolve all agarose.

4. Place the tube at room temperature, add 2 vol binding buffer (700 to 800 μ l), and mix well.
5. Apply the supernatant to the silica membrane spin column.
6. Microcentrifuge the spin column inside its collection tube for 1 min at maximum speed. Remove the spin column from the collection tube and discard the flowthrough. Reinsert the spin column into the collection tube.
7. Wash the spin column by adding 750 μ l of wash buffer and microcentrifuging 1 min at maximum speed. Remove the spin column from the collection tube and discard the flow-through.
8. Reinsert the spin column in the collection tube and microcentrifuge for an additional 1 min to remove any residual wash buffer (ethanol) from the column membrane.
9. Transfer the spin column to a 1.5-ml microcentrifuge tube and add 75 to 100 μ l nuclease-free water or TE buffer, pH 8.5, to the center of the membrane. Let stand 2 to 10 min, then microcentrifuge 1 min at maximum speed.
10. Collect DNA and store at 4°C until use.

Typical yields are 60% to 80%, but may be lower for smaller fragments (e.g., ~50% for a fragment <500 bp).

ALTERNATE PROTOCOL 3

REMOVAL OF OLIGONUCLEOTIDE FRAGMENTS USING A SEPHACRYL S-300 COLUMN

In this protocol, DNA samples are passed over a Sephacryl S-300 column and the eluted fractions that contain the DNA of interest are recovered. This provides a rapid, nonelectrophoretic method for isolating a DNA fragment from linkers or other synthetic oligonucleotides.

Additional Materials (also see Basic Protocol 3)

- 50% (v/v) Sephacryl S-300 (Pharmacia Biotech) in TE buffer, pH 8.0 (Sephacryl/TE), stored covered at 4°C
- 0.3 M NaCl in TE buffer, pH 8.0 (NaCl/TE solution)
- DNA sample in NaCl/TE solution
- Glass wool plug and 6-in. Pasteur pipet, silanized (APPENDIX 3B)

1. Pour ~10 ml of a resuspended 50% Sephacryl S-300/TE buffer mixture into a tube. Allow the Sephacryl to settle.

2. Remove the TE buffer and add ~10 ml NaCl/TE solution. Mix, allow the Sephacryl to settle, and repeat.
3. Place a silanized glass wool plug inside a 6-in. silanized Pasteur pipet. Pour the equilibrated Sephacryl into the column. Continue adding mixture until the level of Sephacryl is up to the indentation on the pipet (~1 in. from the top). After the column is packed, wash with 2 ml NaCl/TE solution.
4. Load 200 μ l DNA sample onto the column and collect the first 200 μ l that elutes—this is fraction 1.
5. Add 100- μ l aliquots of NaCl/TE solution to the column and collect twelve to fourteen 100- μ l fractions.
6. Combine fractions 8 to 11. Add 2.5 vol ethanol and precipitate. Centrifuge and recover the pellet, which contains the oligonucleotide-free DNA fragment of interest.

It is worthwhile to calibrate the batch of Sephacryl using a plasmid on hand. Collect and ethanol precipitate each 100- μ l fraction individually so that the plasmid-containing fractions can be identified by electrophoresis.

RAPID ESTIMATION OF DNA CONCENTRATION BY ETHIDIUM BROMIDE DOT QUANTITATION

SUPPORT PROTOCOL

In this protocol, the sample DNA is mixed with ethidium bromide and spotted on a piece of plastic wrap next to DNA standards. Comparison of the fluorescence of the sample to these standards provides an estimate of the DNA concentration in the sample. This is a simple method to estimate the concentration of DNA in dilute solution, and is useful for determining recovery of isolated fragments.

Materials

DNA: purified DNA for standards and isolated DNA to be quantitated
(previous protocols)

TE buffer, pH 8.0 (*APPENDIX 2*)

1 μ g/ml ethidium bromide (store wrapped in foil at 4°C)

Plastic wrap

UV transilluminator

Additional reagents and equipment for gel photography (*UNIT 2.5A*)

CAUTION: Ethidium bromide is a mutagen and should be handled with care.

1. Prepare the following DNA standards in TE buffer, pH 8.0, using any solution of pure DNA: 0, 1, 2.5, 5, 7.5, 10, and 20 μ g/ml.

These standards can be stored for several months at 4°C.

2. Add 4 μ l of each standard DNA solution to 4 μ l of 1 μ g/ml ethidium bromide. Prepare 4 μ l of the DNA solution of unknown concentration in the same way. Mix well.
3. Place a piece of plastic wrap on a UV transilluminator. Spot the standard and unknown DNA/ethidium bromide solutions side-by-side on the plastic wrap. Photograph under UV light. Estimate DNA concentration of the unknown sample by comparison to the fluorescence of the standards.

The linear range of the assay is from 0 to 20 μ g/ml. If the fluorescence of the DNA sample exceeds that of the standards, dilute the unknown DNA solution until it can be estimated.

Preparation and Analysis of DNA

2.6.9

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see *APPENDIX 2*; for suppliers, see *APPENDIX 4*.

***β*-agarase buffer, 10×**

100 mM bis-Tris, pH 6.5

10 mM EDTA

Filter sterilize and store indefinitely at room temperature

Binding buffer (6 M guanidine HCl)

Add 0.75 g Na₂SO₃ and 57.3 g guanidine HCl (Sigma) to 35 ml H₂O and stir until dissolved. Adjust volume to 100 ml with water, sterilize, and store 3 to 4 months in the dark (in aluminum foil) at 4°C. Discard if precipitate is observed.

Elutip high-salt solution

1 M NaCl

20 mM Tris-Cl, pH 7.5 (*APPENDIX 2*)

1 mM EDTA

Filter sterilize and store indefinitely at room temperature

Elutip low-salt solution

0.2 M NaCl

20 mM Tris-Cl, pH 7.5 (*APPENDIX 2*)

1 mM EDTA

Filter sterilize and store indefinitely at room temperature

NA-45 elution buffer

1 M NaCl

0.05 M arginine (free base)

Filter sterilize and store indefinitely at room temperature

COMMENTARY

Background Information

There are probably as many approaches to the isolation and purification of DNA fragments as there are molecular biologists. Not surprisingly, many of these approaches actually work. In the 1970s, the first successful protocols for isolating DNA fragments from agarose gels were developed—these included the freeze-squeeze method (Thuring et al., 1975), gel dissolution using potassium iodide (Blin et al., 1975), and electroelution (Wienand et al., 1978). One of the most intriguing purification techniques involved specific binding of DNA fragments to powdered glass. Because only certain types of glass worked for this procedure and because the reasons why they worked were uncharacterized, it was not uncommon to see scientists crushing every piece of glassware they could get their hands on. The glass bead dilemma was resolved by Vogelstein and Gillespie (1979), and has been improved upon by the introduction of silica membrane spin columns to replace glass beads.

The most important considerations in choosing an isolation/purification system (whether it is based on physical or chemical properties of DNA) are speed of the technique, yield of purified DNA, and ability of the DNA to be further manipulated. Many protocols, including those presented here, satisfy all three criteria. The basic electroelution/Elutip protocol described here (Weinand et al., 1978) is particularly reproducible and reliable, and the resulting DNA is suitable for a wide range of enzymatic reactions as well as several biological applications (including the production of transgenic mice by single-cell embryo microinjection).

The major objection to the electroelution procedure is that it requires manipulating a small gel fragment with forceps, and introducing this into a dialysis bag. Occasionally the geometry of the gel slice and the orientation of the electric field work against each other and it is difficult to know when all of the fragment has eluted; this uncertainty can result in poor quan-

titative recovery. Two of the other methods described—electrophoresis onto NA-45 paper and purification with low gelling/melting agarose—eliminate the difficulties of getting the gel slice into the dialysis bag and often give better yields.

Electrophoresis onto NA-45 paper, using paper at both the leading and trailing edges of the band, is most effective for eliminating contamination with higher-molecular-weight fragments. It does, however, give lower yields for fragments >2 kb. In contrast, low gelling/melting agarose is effective for DNA fragments of virtually all sizes. A major advantage of using low gelling/melting agarose is the ability to perform subsequent ligations (*UNIT 3.16*) in the gel slice without removing the DNA fragment. If desired, DNA fragments in low gelling/melting temperature agarose gels may be treated with β -agarase I, an agarose-digesting enzyme isolated from *Pseudomonas atlantica*. β -agarase I cleaves carbohydrate bonds, reducing agarose to a mixture of monosaccharides and short oligosaccharides which can no longer gel. Many further enzymatic reactions can be subsequently carried out directly without interference from contaminating carbohydrate residues.

A related compound, the agarose-digesting enzyme mixture GELase (Epicentre Technologies), has somewhat different properties and can be used with denaturing gels or regular agarose as well as with low gelling/melting agarose; see manufacturer's specifications for using these gels.

An alternative for isolating relatively large DNA fragments (>500 bp) is the silica membrane spin column method (see Alternate Protocol 2). This is a very rapid method that has the advantage of concentrating purified DNA from agarose gels without the need for ethanol precipitation. Commercial kits for this procedure are now widely available (e.g., Qiagen, Promega, Invitrogen, Novagen).

Critical Parameters and Troubleshooting

The quality of the preparative DNA digest and the resolution of the preparative gel are critical for obtaining optimal yields of fragments from all protocols. If the preparative gel is overloaded, cross-contamination will occur as a small amount of each fragment becomes "trapped" in the other bands. This low level of contamination can be significant if the fragment is to be used for some cloning procedures, or as a probe in some hybridizations. If it is

necessary to obtain a large amount of highly pure fragment, the first preparation should be re-electrophoresed and repurified.

For the Elutip purification used in the electroelution or low gelling/melting temperature agarose protocols, it is essential that the DNA solution be passed through the column slowly to adsorb it completely. For the phenol extraction purification from low gelling/melting temperature agarose, it is essential to use straight buffered phenol and not phenol/chloroform/isomyl alcohol mixtures.

Transfer to NA-45 paper works well as long as the paper is carefully introduced in front of the band of interest, so that air bubbles are not trapped between the paper and the gel. It is convenient to examine the gel under UV illumination with a hand-held lamp prior to removing the NA-45 paper, to ensure that the fragment has migrated into the paper. If the fragment of interest is <2000 bp, another method should be employed, because the yields can be poor (because of inefficient elution) with small fragments.

Low gelling/melting temperature agarose does not have the integrity of regular agarose. Extreme care should be taken when pulling the combs out of the gel, as wells tear easily. Because low gelling/melting temperature agarose remelts at 65°C, a low voltage (6 to 7 V/cm of gel) should be maintained to keep the gel from overheating. In 4% gels using a TAE buffer system, the bromphenol blue marker migrates at ~50 bp.

The β -agarase treatment is straightforward and reliable. Incomplete digestion can be remedied in most cases by adding more enzyme (up to double the amount recommended). If difficulties are encountered when using the Sephacryl column to purify DNA fragments away from small oligonucleotides, the column must be calibrated using plasmid DNA as described in the protocol.

The most critical parameters in purification of DNA using silica membrane spin columns are the molar concentration and pH of the chaotropic salt solution. For efficient binding to the silica membrane, the salt solution should be at pH 6.5 with the chaotropic salt (NaI, NaClO₄, guanidine HCl, guanidine isothiocyanate) at 2 M. Some companies recommend that the agarose gel be made with TAE and not TBE. This problem may be overcome by reducing the pH of the gel/salt solution with the addition of 1/10 volume of 1.0 M sodium phosphate, pH 6.5.

Anticipated Results

Electroelution, although more tedious and time-consuming to perform than the other methods, provides the most efficient recoveries of highly purified DNA: 80% to 90% for fragments ≥ 1000 bp and 50% to 60% for smaller fragments. Electrophoresis onto NA-45 paper is appropriate for fragments ≤ 2000 bp, giving yields of 50% to 90%. Recovery from conventional or sieving low gelling/melting temperature agaroses is generally 70% for fragments ≤ 1000 bp.

Typical yields for silica membrane spin column purification are 60% to 80% for large DNA fragments. The procedure seems to work best with DNA fragments > 500 bp; smaller-length fragments apparently bind tightly and irreversibly to the silica membrane.

Time Considerations

The gel slice containing the target band should be cut out as soon as possible after the preparative gel has been electrophoresed—this will minimize diffusion of the DNA in the band. The gel slice can be stored for hours to days by wrapping the damp gel slice in a piece of plastic wrap and refrigerating. Depending on the size of the fragment to be isolated, electroelution should take 2 to 4 hr. After electroelution, the DNA solution can be stored for days at 4°C before purifying. Once Elutip purification has been started, however, it should be carried to the stage of ethanol precipitation. The Elutip-d column itself is completed in ~ 15 min.

NA-45 elution takes ~ 1 hr for fragments < 500 bp and longer (≤ 2 to 3 hr) for those > 1500

bp. Purification of fragments separated on low gelling/melting temperature agarose, using either phenol extraction or β -agarase digestion, will take ~ 1 hr. Purification via silica membrane spin column requires 20 to 40 min. Linker removal using Sephacryl S-300 takes ~ 30 min.

RESOLUTION AND RECOVERY OF SMALL DNA FRAGMENTS

This section describes the use of polyacrylamide gels and sieving agarose gels for analytical or preparative separation of small double-stranded DNA fragments. Polyacrylamide gels provide somewhat better resolution as well as significantly higher capacity. Sieving agarose gels are much easier to pour and run, however, and are particularly useful for simple analytical applications.

The use of denaturing polyacrylamide gels to separate single-stranded polynucleotides is described in *UNITS 2.12 & 7.6*.

Separation of Small DNA Fragments by Conventional Gel Electrophoresis

Large amounts of small (<1000-bp) DNA fragments can be separated by conventional electrophoretic means. The purified fragments can then be used for cloning, sequencing, and labeling. In this unit, the techniques of DNA separation via both nondenaturing polyacrylamide and sieving agarose electrophoresis are discussed.

Basic Protocol 1 outlines the pouring and electrophoresis of nondenaturing polyacrylamide gels. Elution of the labeled or unlabeled separated DNA fragments from the gels by either passive diffusion (see Basic Protocol 1) or electroelution (see Alternate Protocol) is described.

Sieving agarose (see Basic Protocol 2) is a specially treated type of agarose designed to be used at high concentrations. Poured and run like conventional agarose gels, this matrix can resolve small DNA fragments much like a nondenaturing polyacrylamide gel.

NONDENATURING POLYACRYLAMIDE GEL ELECTROPHORESIS

This protocol describes the preparation of polyacrylamide gels for separation of small double-stranded DNA fragments. After gel setup, DNA samples are loaded, electrophoresed through the gel, and finally purified away from the gel slices.

Materials

- 10× and 1× TBE electrophoresis buffer, pH 8.0 (*APPENDIX 2*)
- 29:1 (w/w) acrylamide/bisacrylamide (see recipe; solutions are also available commercially from National Diagnostics)
- TEMED (*N,N,N',N'*-tetramethylethylenediamine; store at 4°C)
- 10% (w/v) ammonium persulfate (APS) in water (store ≤1 month at 4°C)
- 5× loading buffer (see recipe)
- DNA samples
- DNA-molecular-weight markers: e.g., pBR322 restriction digested with *Hin*FI or M13 digested with *Hpa*II
- 0.5 µg/ml ethidium bromide
- Elution buffer, pH 7.5 (see recipe)
- 100% and 70% ethanol
- TE buffer, pH 7.5 (*APPENDIX 2*)
- 3 M sodium acetate, pH 5.2 (*APPENDIX 2*)

Glass plates, spacers, and combs for casting gels
 Acrylamide gel electrophoresis apparatus
 DC power supply
 Thin-layer chromatography (TLC) plate with fluorescent indicator (e.g., Silica Gel F-254 or IB-F; for UV shadowing)
 Longwave UV transilluminator
 3-ml small-bore disposable syringe
 Syringe equipped with silanized glass wool plug (UNIT 5.6) or 2- μ m filter
 Centrifuge with Beckman JA-20 rotor or equivalent
 Additional reagents and equipment for ethanol precipitation (UNIT 2.1A)

Prepare the gel

1. Assemble the gel casting apparatus.

Gel spacer and casting systems have been developed to avoid leakage. Those that avoid sealing the gel with tape are best, and recently gel casting boots that lack bottom spacers have become available (Life Technologies). Greasing the side and/or bottom spacers or pouring an agarose plug for the gel is not necessary if some care is taken to ensure that the bottom of the plate assembly is completely sealed. The gel plates should be thoroughly cleaned by washing them with warm soapy water and then rinsing with 70% ethanol. However, if the plates are particularly dirty or if complete removal of any residual nucleic acids is required, the plates may be soaked in 0.1 M NaOH for 30 min prior to washing. When the gel is particularly thin (<1 mm), silanizing one or both plates (APPENDIX 3B) facilitates post-electrophoretic separation of the gel from the plate.

2. Prepare the gel solution in a flask that has a wide mouth and a spout for pouring (see Table 2.7.1 for appropriate acrylamide concentrations for resolving DNA fragments of different sizes). For a nondenaturing 5% polyacrylamide gel of 20 cm \times 16 cm \times 1.6 mm, 60 ml of gel solution is sufficient; this can be made by mixing the following:

6 ml 10 \times TBE buffer
 10 ml 29:1 acrylamide/bisacrylamide
 44 ml H₂O.

CAUTION: Acrylamide is a neurotoxin; always wear gloves, safety glasses, and a surgical mask when working with acrylamide powder.

The migration distance (D) of double-stranded DNA through a nondenaturing gel is inversely proportional to the log of its molecular weight: i.e., $D \approx -\log(MW)$. Pick a concentration of acrylamide that will allow the desired DNA fragments to have migrated approximately one-half to three-fourths of the way through the gel when the loading dye has reached the bottom of the gel. Also, note that the base composition of a sequence affects its electrophoretic mobility and may cause aberrant migration.

Commercially prepared polyacrylamide solutions (National Diagnostics) are available and highly recommended, since they have long shelf lives and avoid manipulation of the neurotoxic acrylamide powder.

Table 2.7.1 Concentrations of Acrylamide Giving Maximum Resolution of DNA Fragments^a

Acrylamide (%)	Size of fragments separated (bp)	Migration of bromphenol blue marker (bp)	Migration of xylene cyanol marker (bp)
3.5	100 to 1000	100	460
5.0	100 to 500	65	260
8.0	60 to 400	45	160
12.0	50 to 200	20	70
20.0	5 to 100	12	45

^aData are compiled from articles by Maniatis and Ptashne (1973a,b) and Maniatis et al. (1975).

3. Vigorously agitate the solution ~1 min with magnetic stirring to ensure complete mixing.
4. Add 34 μl TEMED and swirl the flask to ensure thorough mixing. Immediately add 250 μl of 10% (w/v) APS and mix thoroughly. Pour the acrylamide between the gel plates and insert the comb. Clamp the comb in place at the top of the gel to avoid separation of the gel from the plates as the acrylamide polymerizes. Allow the gel to polymerize for ~30 min.

IMPORTANT NOTE: Polymerization begins as soon as APS is added to the mixture, so all succeeding actions must be performed promptly.

CAUTION: Be sure to wear safety glasses while pouring the gel since splashing of the neurotoxic, unpolymerized acrylamide is common.

For thick gels, the acrylamide should be poured directly from the mixing flask, but for thinner ones, a syringe fitted with a needle is useful. By pouring the gel slowly with a tilt 45° relative to the bench top and starting from one corner, bubbles may be largely avoided. Also, the gel should be polymerized lying flat to avoid undesirable hydrostatic pressure on the gel bottom.

TEMED may be stored indefinitely at 4°C, but the ability of APS solution to efficiently initiate the free radical-induced acrylamide polymerization diminishes greatly over time. A new APS stock should be prepared each month and stored at 4°C.

Run the gel

5. After polymerization is complete, remove the comb and any bottom spacers from the gel. Wash the gel plates free of spilled acrylamide and be sure that the spacers are properly seated and clean.
6. Fill the lower reservoir of the electrophoresis tank with 1× TBE buffer. Initially, place the gel into the lower tank at an angle to avoid the formation of air bubbles between the plates and the gel bottom. Clamp the gel plates to the top of the electrophoresis tank and fill the upper reservoir with 1× TBE so that the wells are covered.

A syringe with a bent needle may be used to remove air bubbles trapped under the gel, which will disrupt the current flow.

7. Use a DC power supply to prerun and warm the gel for at least 30 min at 5 V/cm (constant voltage).
8. Add 5× loading buffer to DNA samples and molecular-weight markers (to 1× final) and load on gel.

Load an amount of DNA that correlates with the visualization technique to be used. If the sample is to be UV shadowed (UNIT 2.12), then 2 μg of DNA will be required per band in a 2 cm \times 2 cm \times 1.6 mm well. With ethidium bromide staining, the detection limit is only 15 ng DNA per band; for good resolution using this method, only 25 μg of material should be loaded per 2 cm \times 2 cm \times 1.6 mm well.

Plastic disposable pipet tips are available in a variety of styles and sizes. Choose one that fits the application for use in loading the gel. Alternatively, particularly for larger volumes, use a micropipet or pulled plastic capillary, made as follows: Break a 1-ml disposable plastic (polystyrene) pipet in half and heat the center portion over a Bunsen burner until it is just soft (barely melted). Remove from heat for 1 to 2 sec and, holding vertically, quickly pull to generate a thin capillary. After the plastic has cooled, cut as desired. To calibrate, draw up a premeasured volume of water and mark capillary.

9. Run the gel at ~5 V/cm, taking care to avoid excessive heating. Run the gel until the desired resolution has been obtained as determined empirically or from Table 2.7.1.

From 2 to 10 V/cm is acceptable. If the gel is noticeably warm to the touch, the samples in the middle will run faster or may even be denatured.

Shorter electrophoresis times may be achieved by running the gel at higher voltage in a cold room so long as the temperature of the gel remains below the denaturation temperature of the sample.

10. Turn off the power supply and detach the gel plates from electrophoresis apparatus. Carefully pry apart the plates so that the gel is still attached to one plate.
- 11a. If desired (but only for samples $\geq 2 \mu\text{g}$), visualize the DNA with UV shadowing, using a TLC plate with a fluorescent indicator (see *UNIT 2.12*).
- 11b. Alternatively, stain the gel while still attached to the plate by submerging it for 5 to 10 min in 0.5 $\mu\text{g/ml}$ ethidium bromide. If necessary, soak the gel and plate in water for 10 to 30 min to remove nonintercalated ethidium bromide to lower the background absorption.
12. Carefully wrap the gel and plate with plastic wrap. Invert, place the gel onto a UV transilluminator, and photograph.

Longwave UV light transmits through plastic wrap. Alternatively, the gel can be put directly on the transilluminator. If a photograph is not required, a longwave UV light may be shined onto the stained preparative gel to locate the DNA fragment of interest. It is important to avoid unnecessarily long UV exposure, which will damage the nucleic acids. Unpolymerized acrylamide absorbs strongly at 211 nm and may also cause shadowing that is confined to the edges and wells of the gel.

Recover the DNA

13. Cut out the desired DNA band with a scalpel or razor blade.
14. Crush the gel into many fine pieces by pushing it through a 3-ml small-bore disposable syringe to aid the diffusion of the DNA from the matrix.

If planning to use electroelution, omit this step and proceed to the Alternate Protocol.

15. Collect the pieces in an appropriately sized tube.
16. Add 2 vol elution buffer for every volume of gel. Incubate the tube with rotation or in a shaking air incubator at room temperature until desired level of elution is obtained.

Since elution is a diffusion-controlled process, increasing the amount of buffer will improve elution efficiency. Also, note that larger DNAs will take longer to diffuse from the gel. If speed is essential and high yields are dispensable, enough sample can be obtained for most experiments in only a few hours of extraction. Increasing the temperature to 37°C will also speed the process. Yield may be increased upon repeated elutions. Small fragments (<300 bp) should be mostly eluted in 4 hr, but large fragments (>750 bp) will need to be eluted overnight.

17. Depending on the volume of the elution, pellet the gel fragments at room temperature for 10 min in a tabletop centrifuge or 1 min in a microcentrifuge. Pipet off the supernatant solution, taking care to avoid the polyacrylamide pieces.
18. Recover any residual DNA by rinsing the gel with a small volume of elution buffer. Recentrifuge if necessary and combine the two supernatant solutions.

If necessary, remove any remaining acrylamide pieces by filtering the supernatant through a syringe equipped with a disposable 0.2- μm filter.

Also, if the volume of elution buffer is too large to allow for convenient precipitation, it may be reduced by successive extractions against equal volumes of butanol to concentrate the sample. About $\frac{1}{5}$ vol of the aqueous layer is extracted into the organic butanol layer for every volume of butanol used. If too much butanol is added and the water is completely extracted into the butanol, simply add more water and concentrate again.

- Precipitate the DNA by adding 2 vol of 100% ethanol and chilling 30 min at -20°C or 10 min at -70°C . Pellet DNA by centrifuging 10 min at $12,000 \times g$.

It is generally not necessary to add carrier to aid precipitation since the small acrylamide polymers released from the gel slice will suffice. If carrier is necessary, then use 10 μg of a carrier such as tRNA or glycogen, depending on the application.

- Redissolve the DNA pellet in 100 μl TE buffer, pH 7.5. If necessary, transfer to a microcentrifuge tube. Add 10 μl of 3 M sodium acetate, pH 5.2, reprecipitate the DNA with 2 vol of 100% ethanol, and chill 30 min at -20°C or 10 min at -70°C . Recover the DNA by centrifugation as in step 19.
- Rinse the pellet twice with 70% ethanol. Allow pellet to dry, and resuspend in TE buffer, pH 7.5, if appropriate.

ELECTROELUTION OF SMALL DNA FRAGMENTS FROM POLYACRYLAMIDE GELS

**ALTERNATE
PROTOCOL**

When working with small DNAs (<300 bp), if time is at a premium, the passive elution by diffusion described in Basic Protocol 1 (steps 15 to 19) may be replaced with the following electroelution procedure. Recovery of DNA fragments should be similar to that obtained with passive elution.

Additional Materials (also see Basic Protocol 1)

0.5 \times TBE electrophoresis buffer, pH 8.0 (APPENDIX 2)

Small dialysis bag

Additional reagents and equipment for agarose gel electrophoresis (UNIT 2.5A)

1. Prepare and run the gel as described in the previous protocol (see Basic Protocol 1, steps 1 to 12). Cut out the DNA band of interest but do not crush.

The gel slabs are not crushed to allow easy monitoring of the electroelution process and to speed the elution of the DNA.

2. Place the gel slab in a small dialysis bag with an appropriate molecular weight cutoff, and add enough 0.5 \times TBE buffer to surround and immerse the slab.

Many commercial electroelution apparatuses with less cumbersome handling procedures are also available (e.g., from Schleicher & Schuell and Sialomed).

3. Place bag in a small horizontal electrophoresis apparatus containing 0.5 \times TBE buffer.
4. Electrophorese the DNA out of the polyacrylamide gel at ~ 4 V/cm across the apparatus for 2 hr for small DNAs (<300 bp) or 6 hr for longer DNAs.

Because elution times are variable and especially if near-complete recovery is required, the gel should be UV shadowed and stained again after elution to ensure that the DNA has been quantitatively removed. Should some DNA remain in the gel, elution should be continued.

5. Recover the 0.5 \times TBE buffer, now containing the eluted DNA, from the electrophoresis apparatus. Reverse the polarity of the apparatus for ~ 1 min to free any bound DNA, and rinse the gel slab and inner surface of the dialysis bag to recover residual DNA.
6. Add 0.1 vol of 3 M sodium acetate and ethanol precipitate (see Basic Protocol 1, steps 20 and 21).

A second ethanol precipitation may be done if desired.

**Preparation and
Analysis of DNA**

2.7.5

SIEVING AGAROSE GEL ELECTROPHORESIS

Sieving agarose is agarose chemically modified to give low gelling ($\leq 35^{\circ}\text{C}$) and melting ($\leq 65^{\circ}\text{C}$) temperatures. Sieving agarose gels are poured and run like conventional agarose gels, but resolve small DNA fragments like nondenaturing polyacrylamide gels. They finely resolve nucleic acid fragments <1000 bp and can distinguish fragments as small as 8 bp.

Materials

Sieving agarose (NuSieve GTG agarose)
TAE or TBE electrophoresis buffer, pH 8.0 (*APPENDIX 2*)

Additional reagents and equipment for agarose gel electrophoresis (*UNIT 2.5A*) and isolating DNA using low gelling/melting temperature agarose (*UNIT 2.6*)

1. Melt 2% to 4% sieving agarose in the appropriate buffer as outlined by the manufacturer. Pour gel of desired size for ordinary agarose gel apparatus.

Sieving gels generally resolve DNA more slowly and with sharper resolution in TBE than in TAE. Smaller fragments (<300 bp) are best separated in TBE and larger ones in TAE.

2. Load sample and run gel as for an ordinary agarose gel (*UNIT 2.5A*).

In a 4% NuSieve GTG agarose gel in TBE buffer, bromphenol blue will migrate at a rate equal to DNA fragments of <20 bp and xylene cyanol at a rate equal to 150 bp.

The gel can be run with ethidium bromide (0.5 mg/ml) included; this will cause only a slight decrease in DNA mobility, due to unwinding of the helix as a result of intercalation of the dye.

CAUTION: Ethidium bromide is a mutagen.

3. Isolate the fragment (see *UNIT 2.6*, Alternate Protocol for low gelling/melting temperature agarose, steps 2 to 9).

Various manufactures have developed methods for the removal of ethidium bromide from agarose gel slices. Spin columns (Supelco) made of a negatively charged matrix that attracts ethidium bromide and repels DNA offer quick, easy handling along with high recovery.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Acrylamide/bisacrylamide 29:1 (w/w)

29 g acrylamide
1 g bisacrylamide
H₂O to 100 ml
Store ≤ 1 month at 4°C

CAUTION: Acrylamide is a neurotoxin. Always wear gloves when working with the unpolymerized monomer.

Elution buffer, pH 7.5

10 mM Tris-Cl, pH 7.5
50 mM NaCl
1 mM EDTA, pH 8.0

Loading buffer for nondenaturing PAGE, 5 \times

50 mM EDTA, pH 8.0
50 mM Tris-Cl, pH 8.0
50% (v/v) glycerol

COMMENTARY

Background Information

Polyacrylamide gel electrophoresis (PAGE) offers high resolution of low-molecular-weight nucleic acids. In particular, small DNA fragments (<500 bp) that are poorly resolved by ordinary agarose gels are easily separated on polyacrylamide gels. Depending on the pore size of the gel (3.5% to 20% polyacrylamide), a separation from 10 to 1000 bp can be achieved. The concentrations of acrylamide that give the maximum resolution of DNA fragments of different sizes have been empirically determined, as shown in Table 2.7.1.

Polyacrylamide gels have a much higher capacity for DNA than agarose gels. Up to 15 μg of material can be loaded per 2 cm \times 2 cm \times 1.6 mm well. This is particularly important for preparation of significant amounts of small fragments. Elution of fragments from polyacrylamide gels yields DNA that is generally devoid of contaminating material that could interfere with enzymes used in cloning, sequencing, or labeling DNA. These two qualities make polyacrylamide gels the preferred means for purifying significant quantities of small fragments.

A polyacrylamide gel is formed by the polymerization of acrylamide monomers into long chains, which are further covalently attached by a cross-linking agent, most commonly *N,N'*-methylenebisacrylamide. Polymerization of a polyacrylamide gel is initiated by free radicals provided by ammonium persulfate and stabilized by TEMED. The reaction takes ~10 to 20 min to go to completion, but the reaction rate can be varied by adjusting the TEMED and ammonium persulfate concentrations.

The pore size of a polyacrylamide gel is determined by the total percentage of acrylamide (the sum of the weights of the acrylamide monomer and cross-linker). Historically, this has been expressed as %T. For example, the 5%T gel described above would contain 5% (w/v) of acrylamide plus bisacrylamide. As the %T increases, the pore size decreases. An appropriate %T for various ranges of fragment sizes can be determined from Table 2.7.1. The migration distance (*D*) of double-stranded DNA through a nondenaturing gel is inversely proportional to the log of its molecular weight—that is, $D \approx -\log(\text{MW})$. The base composition of a sequence also affects its electrophoretic mobility and may cause aberrant migration with respect to what would be expected

based on size alone; hence, size markers of similar composition should be used to confirm the size of the fragment of interest. To separate fragments over a wide range of molecular weights, a pore-gradient gel can be used. In such a gel the pore size is larger at the top than at the bottom, and becomes more restrictive as the fragment runs down the gel. Such gradient gels are difficult to pour, however, and are not commonly used. A general description of gels as electric circuits can be found in the introduction to this chapter.

The unique pore size of sieving agarose allows separation of much smaller fragments than ordinary agarose. Sieving agarose gels in the range of 2% to 4% separate in the range of 8 to 1000 bp and provide an alternative to polyacrylamide gels. Although the bands on sieving gels are somewhat more diffuse and the resolution is slightly poorer, sieving gels are easier and faster to pour and run, making them useful for a variety of applications, such as checking ligation of linker monomers into ladders (UNIT 3.16). Like low gelling/melting temperature agarose, sieving agarose is used to purify DNA fragments because of its unique properties of melting at 65°C and remaining liquid at $\leq 35^\circ\text{C}$. However, DNA fragments prepared from polyacrylamide gels are generally cleaner than those prepared from sieving agarose and can be more reproducibly used as substrates for a variety of enzymes.

Critical Parameters and Troubleshooting

The most important parameter for the successful separation of small DNA fragments by polyacrylamide gels is the polymerization reaction itself. It is important to use only high-quality electrophoresis-grade reagents when running the gels. Acrylamide and bisacrylamide both break down in solution to acrylic acid, which affects the mobility of molecules through the gel matrix. Acrylamide solutions should be protected from light and should not be stored for more than a few months. Commercially prepared polyacrylamide solutions with long shelf lives (due to the incorporation of a gaseous inhibitor that prevents the initiation of polymerization) are available (National Diagnostics) and highly recommended. Ammonium persulfate is stable for ~1 month at 4°C. Clean plates are also essential in order to avoid the introduction of bubbles into the gel when pouring.

One of the most common problems encountered in polyacrylamide gels is "smiling," in which the lanes in the center of an overheated gel run faster than the lanes at the sides. This is caused by uneven dissipation of heat by the gel: the sides are cooler than the center and samples run faster at higher temperatures. There are several ways to avoid smiling, the simplest of which is to run the gel at lower voltage. An alternative is to use an apparatus that incorporates a mechanism such as a metal plate to disperse heat evenly throughout the gel, or an active cooling mechanism.

Sieving agarose does not have the integrity of regular agarose and is even more fragile than the common low gelling/melting temperature agaroses. The manufacturers recommend against using sieving agarose concentrations of <2%. Extreme care should be taken when pulling the combs out of the gel, as wells tear easily. It is usually best to remove the comb after the gel has been submerged in the electrophoresis tank. Because this type of agarose melts at 65°C, a low voltage (6 to 7 V/cm of gel) should be maintained to keep the gel from heating too much. In a 4% NuSieve GTG agarose gel in TBE buffer, bromphenol blue will migrate at a rate equal to DNA fragments of <20 bp and xylene cyanol at a rate equal to 150 bp.

Anticipated Results

Because of the high capacity of acrylamide relative to agarose, up to 2 µg of a fragment >250 bp and up to 5 µg of a smaller fragment can be purified on a 2 cm × 2 cm × 1 mm lane by the method presented in Basic Protocol 1. Up to 25 µg of material can be purified on the larger 2 cm × 2 cm × 1.6 mm preparative gels. After several hours of shaking at 37°C, the eluted yield should be 60% to 75% for larger fragment and >85% for smaller fragments. Essentially quantitative recovery will be obtainable by overnight elution. Similar recoveries can be obtained using the faster but slightly more cumbersome electroelution alternate method (Alternate Protocol).

Yields from sieving agarose gels (Basic Protocol 2) are similar to those from conventional low gelling/melting temperature agarose (≥70%) as long as fragments are <1000 bp. These gels resolve best below 500 bp.

Time Considerations

Although a polyacrylamide gel is less convenient than an agarose gel to set up and polymerize, this process should take <1 hr in

either case. After polymerization, gels can be stored overnight or even for several weeks, provided precautions are taken to prevent the slots from drying out: for instance, using a paper towel soaked with buffer and encased in plastic wrap to keep the gel hydrated. In general, the comb should be left in the gel and the top should be covered with plastic wrap. The limiting factor in polyacrylamide gel electrophoresis is heating of the gel, which results in smiling. Inclusion of a mechanism to disperse the heat and/or actively cool the gel can minimize this problem and greatly shorten electrophoresis times. If the Alternate Protocol for electroelution of fragments is followed, purified fragments can be obtained in <8 hr after pouring the gel.

The sieving agarose procedure is short, especially for minigels, and can be completed in 2 hr. After the addition of ethanol to the extracted fragment, the protocol can be interrupted for as long as desired.

Capillary Electrophoresis of DNA

DNA fragments are traditionally separated and analyzed by slab gel electrophoresis. The gel matrices are usually either polyacrylamide (UNIT 10.2A) or agarose (UNIT 2.5A), and separations are achieved in the presence (for ssDNA) or the absence (for dsDNA) of dissociating agents such as urea or formamide. The slab gel systems have the advantage of analyzing multiple samples in the same separation at low cost, but normally take several hours to complete. The DNA is typically visualized with stains, UV shadowing, intercalating dyes such as ethidium bromide, and on occasion by radioactivity. Capillary electrophoresis (CE), an alternative to conventional slab gel electrophoresis, has developed over the past few years into a very powerful tool for the separation of DNA fragments. CE offers a number of advantages over slab gel separations in terms of speed, resolution, sensitivity, and data handling. This is partly because the CE separation occurs inside a small-diameter (50- to 100- μm) quartz capillary in the presence of high (kilovolt-level) separating voltages. Separation times are generally only a few minutes. The DNA is detected either by UV absorption or by fluorescent labeling, both of which eliminate the need to use mutagenic substances (e.g., ethidium bromide) or dispose of radioactive waste. The quantity of DNA required for the separation is in the nanogram range. Single-base resolution can be readily obtained on fragments up to several hundred base pairs in size. In the presence of appropriate standards, fragments can be accurately sized, based on relative electrophoretic mobility.

The separation of DNA fragments by CE occurs within the walls of a fused-silica capillary. Since the negatively charged nature of this surface has a dramatic impact on the resolution achieved during the separations, the vast majority of CE separations are done in “coated” capillaries whose surface has been modified to be chemically inert to the DNA. The capillaries are filled with a sieving matrix, and the DNA fragments are separated on the basis of size, analogously to standard slab gel separations. The matrix is either a chemically cross-linked gel, such as polyacrylamide, or a flowable polymer, such as modified cellulose or non-cross-linked polyacrylamide. Single-stranded DNA (ssDNA) fragments as small as 5 bases are readily separated with single-base resolution. The analysis of synthetic oligonucleotides in a flowable matrix is described in this unit (see Basic Protocol 1) as an example of this type of application. Fragments of double-stranded DNA (dsDNA) as large as 20 kb are also separated, although not with single-base-pair resolution. The only difference between these separations is the separation matrix.

CE has found increasing use in a number of analytical applications where DNA separations are required. These include assessment of the purity of synthetic oligonucleotides and their modifications, analysis of PCR products, sequencing of fluorescent DNA, analysis of restriction maps, accurate sizing of restriction fragments for genetic analysis, forensic analysis of biological samples, genotyping (see Alternate Protocol), and analysis of conformational polymorphisms. Additional applications continue to be developed. An area of growing interest is the ability to analyze low levels of PCR products in biological fluids, as presented below (see Basic Protocol 2). Rapid progress is also being made in the development of multicapillary automated DNA sequencing instruments using laser fluorescence detection.

CE is an analytical technique rarely used in preparative mode. This is largely because only small quantities of DNA can be loaded onto a capillary. Amplifying DNA by PCR after separation can circumvent this problem. In general, however, preparative separation of DNA fragments is best achieved by slab gel electrophoresis (UNITS 2.5A, 2.7, & 2.12) or high-performance liquid chromatography (HPLC) methods (UNITS 10.12–10.14).

INSTRUMENTATION

CE separation in its simplest form can be achieved by passing a high voltage between two buffer reservoirs that are joined by a fused silica capillary filled with liquid or gel. This results in an electric field that drives the molecules of interest from one end of the capillary to the other. The capillaries are generally 20 to 80 cm long and 50 to 100 μm in internal diameter, with total volumes in the 1- to 2- μl range. For comparison, the volume of a slab gel lane is ~ 1000 μl . The capillaries are thin walled, which allows for dissipation of the Joule heating resulting from the high voltages (10 to 30 kV) that are necessary for high-performance electrophoretic separations. This minimizes convective effects that could result in band broadening during electrophoresis. The fused-silica capillary is coated on the outside with a polyimide layer that eliminates oxidation of the fused-silica glass and confers excellent tensile strength to the otherwise fragile capillary. The polyimide sheathing is carefully burned from a small portion of the capillary to expose a section of the silica. This clear section of the capillary is inserted into the light path of a UV or fluorescence detector and becomes the on-column flow cell. As the DNA molecules migrate through the capillary as a result of the electric field, they pass through the detector light path and are measured by UV or fluorescence detection. In effect, the separation column itself becomes a very-low-volume flow cell.

IMPORTANT NOTE: Removal of the polyimide coating makes the capillaries susceptible to breakage. Capillaries that are not provided in cartridges by the manufacturer should be handled with care to avoid breakage.

The combination of high field strength and large surface-area-to-volume ratio of the capillaries results in rapid and very efficient separations of both ssDNA and dsDNA. Sample loading can be accomplished from as little as 1 μl , with starting sample concentrations of ~ 1 $\mu\text{g}/\text{ml}$ for UV detection and ~ 1 pg/ml or less for laser-induced fluorescence detection. Clearly, with respect to sensitivity, speed, and versatility, CE offers significant advantages over gel electrophoresis for the separation of nucleic acids.

Figure 2.8.1 Schematic of a CE instrument configured for DNA separations.

Table 2.8.1 Capillary Electrophoresis Systems

Manufacturer	Model number ^a	Autosampler	Detection method ^b	Column temperature
Agilent	CE System	48-position, 10° to 40°C	Diode array UV-vis	15° to 60°C
Amersham	MegaBACE 500 16, 32 or 48-capillary DNA sequencer	96-well plate, no cooling	4-color scanning LIF detection	27° to 44°C
	MegaBACE 1000 96-capillary DNA sequencer	Single 96-well plate, no cooling	4-color scanning LIF detection	27° to 44°C
	MegaBACE 4000 384-capillary DNA sequencer	Single 384-well plate, no cooling	4-color scanning LIF detection	27° to 44°C
Applied Biosystems	Prism 310	482- or 96-sample position, cooled 96-well	4-color LIF with CCD	30° to 60°C
	Prism 3100 16-capillary DNA sequencer	96-well plate with sample cooling	CCD	26° to 65°C
	Prism 3730 96-capillary DNA sequencer	96-well plates with autoloader	CCD	18° to 70°C
Beckman Coulter	P/ACE MDQ DNA System	Up to 96-well plate	UV and diode array detection	15° to 60°C
	CEQ 8000 8-capillary DNA sequencer	96-well plate with cooling and heating to 90°C	4-color CCD	30° to 60°C

^aAll units listed have a single capillary unless otherwise noted.

^bLIF, laser-induced fluorescence detector, used with either a PMT (photomultiplier tube) or a CCD (charge-coupled device) camera for visualization; UV, ultraviolet detector.

As stated previously, in its simplest form capillary electrophoretic separation can be achieved by passing a current between cathodic and anodic buffer reservoirs via a liquid-filled glass capillary. In practice, the basic CE instrument also requires a suitable sample injection module, a detector, adequate temperature control, and isolation for the user from the high voltages used for the separations. A schematic of the basic instrument is shown in Figure 2.8.1. There have been a number of changes recently in the features of commercially available instruments; these instruments and their capabilities are summarized in Table 2.8.1.

SEPARATION THEORY

CE is part of the family of electrophoretic techniques that separate species based upon their size and ionic properties. An ion (*i*) placed in an electric field will move in the direction parallel to the field towards the oppositely charged electrode with a velocity (v_i) defined as follows:

$$v_i = \mu_i E = \mu_i V / L$$

where μ_i is the mobility of the ion, E is the electric field in volts per centimeter, V is the voltage across the column, and L is the total column length. The electrophoretic mobility of a given ion is equal to:

$$m_i = q_i / 6\pi\eta a_i$$

where q_i is the charge on the ion, η is the viscosity of the buffer or gel matrix, and a_i is the radius of the ion.

Since DNA has a constant size-to-charge ratio, a sieving matrix must be added to the capillary in order to discriminate based only on size, rather than charge and size. In CE there are two types of gels employed in DNA separations: cross-linked gels (static gels) and non-cross-linked gels (flowable polymers or polymer networks). Cross-linked gels are fixed gels that are polymerized inside the capillary, usually covalently bound to the capillary surface, and are not removed from the capillary between runs. Flowable polymers are viscous hydrophilic polymer solutions that can be pumped into the capillary. The same flowable polymer matrix can be used repeatedly when small molecules such as synthetic oligonucleotides are being analyzed. The time between injections is sufficient for the preceding sample to clear the detector. Alternatively, the polymer can be used once, discarded, and replaced with fresh matrix prior to the next injection. This approach is preferred where larger DNA molecules are present in the samples—e.g., for fragment analysis and DNA sequencing analysis. Usually, a coated capillary is utilized to eliminate the charge effects that are contributed by the native silica surface. With cellulose-derived polymers or some specially modified acrylamides, however, uncoated capillaries may be used, because of the strong interaction of the polymer with the inner surface of the bare fused-silica capillary, in essence forming its own coating.

With either a cross-linked or non-cross-linked gel in the capillary, the matrix offers a frictional resistance to the movement of the DNA through the gel medium that is proportional to the size of the species. The frictional resistance can vary with the molecular weight, concentration, and chemical composition of the flowable gel polymer or the pore size in the cross-linked gel, and must be optimized for the particular size of the DNA to be separated. A detailed description of the theory of DNA motility in entangled polymer solutions can be found in Grossman (1991).

STRATEGIC PLANNING

The most common approach to the separation of both ssDNA and dsDNA by CE uses a coated capillary and an uncharged sieving matrix. This is very similar to slab gel electrophoresis, but in a silica capillary. The separation matrix, as mentioned, can take the form of a cross-linked polyacrylamide gel or flowable polymer such as hydroxypropyl methyl cellulose (HPMC), hydroxyethylcellulose (HEC), polyethylene oxide (PEO), or non-cross-linked linear polyacrylamide. The cross-linked gel is polymerized directly inside the capillary and can be reused for 30 to 100 separations before losing resolution. The capillary is then discarded, since the polyacrylamide gel cannot be regenerated. The flowable polymer has the advantage that it can be expelled from the capillary by pressure at the end of each electrophoretic separation; fresh matrix is then reloaded into the capillary prior to the next separation. These capillaries have lifetimes of several hundred injections. The eventual loss of the surface coating is the major reason for replacement; another common reason is mechanical breakage.

The selection of the appropriate matrix can significantly affect the quality of the separation. Cross-linked polyacrylamide is best used for the separation of synthetic oligonucleotides—both native and modified versions. However, flowable polymers can also be used for oligonucleotide analysis and for the separations of automated sequencing ladders. Where dsDNA fragment analysis is required, only flowable polymers are routinely used. The general rule for matrix selection is that the larger the DNA fragment, the weaker the sieving capabilities of the matrix.

Separation buffers frequently are variants of Tris/borate/EDTA (TBE) mixtures and are buffered at alkaline pH. Urea is often included in the buffer, as a denaturant, when analyzing ssDNA (e.g., synthetic oligonucleotides). Samples are loaded onto the capillary by electrokinetic, or pressure, injection. Separation times range from 10 to 45 min, at

voltages between 1 and 10 kV. DNA fragments are detected in the UV spectrum at 260 nm, either in the presence or absence of ethidium bromide. Sensitivity can be increased by at least two orders of magnitude through the use of fluorescence detection. Since DNA possesses no native fluorescence, intercalating dyes such as cyanine derivatives (Zhu et al., 1994) or rhodamine derivatives must be added to the electrophoresis buffer, or covalently attached to the DNA prior to the electrophoretic separation. In addition to increasing the sensitivity of detection, these intercalating dyes can improve resolution and sharpening of the bands by physically disrupting the DNA structure. The selection of specific dyes is dictated by their excitation and emission spectra and the compatibility with the detection systems of individual instruments. Specific examples of intercalating dyes are: thiazole orange (Aldrich), YO-PRO-1, YOYO-1, and SYBR Green (Molecular Probes). The added sensitivity is particularly useful when analyzing PCR products that have been amplified from biological fluids. Targets of interest are frequently present in small amounts, and the presence of salts and proteins make their direct analysis by CE impractical. However, after completion of the PCR reaction, the sample can be diluted with water and an aliquot analyzed using fluorescent detection.

The mobility of a given DNA fragment may not be constant over a series of injections. This variability can have a variety of causes: aging of the polymer (polyacrylamide), loss of capillary coating, or depletion of the conductivity of the running buffers. The absolute mobility of DNA in a given sample will be dependent upon the salt content (and hence the conductance) of that sample. The presence of high salt will significantly reduce the electrophoretic mobility of the DNA. One solution is to dilute the sample in water and load for longer times; alternatively, the sample can be desalted (*UNIT 10.9*) prior to injection. Where accurate sizing is important, it is essential to incorporate sizing standards into the sample prior to electrophoresis.

The CE analysis of synthetic oligonucleotides requires the selection of a matrix that optimizes resolution of low-molecular-weight oligonucleotides. The separation of fluorescently labeled fragments from an automated sequencing ladder represents a specialized CE application and requires the selection of a matrix with a greater resolution range. These ladders range in size from 20 to more than 1000 bases and can be separated with single-base resolution to a high degree of accuracy. Currently, three automated CE instruments are commercially available as DNA sequencers (see Table 2.8.1). A detailed discussion of the general principles associated with dideoxy sequencing can be found in *UNIT 7.4*.

SEPARATION OF OLIGONUCLEOTIDES

In this protocol synthetic oligonucleotides are analyzed for purity by CE using a replaceable, flowable polymer as the separation matrix. The running buffer and separation matrix contain 7 M urea to keep the DNA in its single-stranded configuration. The sample is loaded onto the capillary at the cathode by electrochemical injection. After loading, the sample vial is replaced by the cathode buffer reservoir, and the electrophoresis is continued. The matrix does not need to be replaced between each separation, but should be replaced at the beginning of each series of separations, e.g., at the beginning of each day. Each time fresh matrix is loaded, the capillary must be equilibrated before samples are run. No further equilibration is required between samples. The electrophoretic separation should provide single-base resolution for DNAs of at least 100 bases. A poly(A)₄₀₋₆₀ size ladder (see Fig. 2.8.2) should be analyzed initially in order to confirm that resolution is optimal.

NOTE: The filled capillary can be stored on the instrument overnight, but if >1 day elapses between runs, the capillary should be stored at 4°C with both ends capped.

BASIC PROTOCOL 1

Preparation and Analysis of DNA

2.8.5

Figure 2.8.2 CE separation of a standard poly(A)₄₀₋₆₀ mixture of synthetic oligonucleotides.

NOTE: The following protocol demonstrates the use of a P/ACE 5510 CE instrument from Beckman Coulter. However, other instruments (Table 2.8.1) are capable of comparable separations when operated in accordance with manufacturers' instructions.

NOTE: The selection of a matrix is often instrument-dependent. It is recommended that a kit be used initially for a reference separation. Linear polyacrylamide is frequently used for oligonucleotide separations.

Materials

ssDNA 100-R separation kit (Beckman Coulter) including:

60-cm, 100- μ m-i.d. coated capillary

ssDNA 100-R separation gel solution

Running buffer: Tris-borate electrophoresis buffer (reconstitute and store up to 30 days at 4°C)

Poly(A)₄₀₋₆₀ sizing standard (dissolve at 100 μ g/ml [3 OD₂₆₀ units/ml] in water and store indefinitely at -20°C)

Dried ssDNA oligonucleotide sample

CE instrument (e.g., Beckman Coulter P/ACE 5510 or equivalent; see Table 2.8.1)

1. Reverse standard polarity of the CE instrument electrodes (see manufacturer's instructions).
2. Rinse capillary on-instrument with deionized water for 5 min.
3. Fill the capillary with ssDNA 100-R gel solution using a 20-min pressure rinse from the matrix vial (based on a 20-psi rinse pressure).

This solution can be stored on-instrument for 5 days, but should then be discarded.

4. Equilibrate the capillary in running buffer by running a voltage ramp from 0 to 8.1 kV over 20 min and holding at 8.1 kV for 10 min.

5. Replace the inlet reservoir with a container of water and inject for 1 sec at 7.5 kV.
6. Position the sizing standard vial at the inlet and inject for 10 sec at 7.5 kV.
7. Replace with running buffer reservoir and carry out the electrophoresis at 8.1 kV for 40 min at 30°C.
8. At completion of run, confirm that the separation of the standards is satisfactory by comparison with the example provided in the kit.
9. Prepare samples to be analyzed by dissolving in water to ~10 µg/ml.
10. Load samples onto autosampler and inject for 10 sec at 7.5 kV.
11. Carry out the electrophoresis at 8.1 kV for 40 min at 30°C.
12. Repeat steps 10 and 11 until resolution begins to deteriorate (at least 15 runs); then replace separation gel by returning to step 2.

QUANTITATIVE PCR ANALYSIS

Quantitative PCR can be used in conjunction with CE separation to amplify and quantitate any DNA target sequence—by the use of either an intercalating dye (coinjected with the samples) or a covalently modified, fluorescently labeled oligonucleotide primer. The size of the expected product is determined by coinjection of sizing standards. Quantitation is achieved by the coamplification of a second target sequence of known concentration, or by the addition of a known quantity of DNA to each sample.

Another application of this method is the direct measurement of viral load by reverse transcription (RT)-PCR of the viral RNA. This is achieved by the procedure known as competitive PCR analysis (Piatak, 1993). A known amount of a standard DNA template is included in the reaction mixture to compete for amplification with the target DNA. The sequence of the competing DNA is designed such that the PCR product is similar, but not identical, in size to the target DNA. The small quantities of DNA that are produced by this process require coinjection of an intercalating dye (e.g., YO-PRO-1 or SYBR Green I) as well as fluorescence detection.

Since dsDNA is being analyzed in these applications, it is not necessary to include denaturant in the electrophoresis buffer.

Materials

LIFluor dsDNA 1000 kit (Beckman Coulter) containing:

- Gel buffer mixture (containing separating gel and Tris/borate/EDTA buffer)
- Enhance intercalating dye
- 65-cm, 100-µm-i.d. coated capillary
- Standard sizing ladder: *Hae*III restriction digest of ϕ X-174 DNA (dissolve at 10 µg/ml in deionized water and store at –20°C)
- PCR reaction mixes containing amplicon
- CE instrument with fluorescent detection (e.g., Beckman Coulter P/ACE 5510 or equivalent)

1. Prepare gel buffer mixture according to manufacturer's instructions and add 0.4 µg/ml intercalating dye.

Store up to 30 days at 4°C.

2. Reverse standard polarity of CE instrument electrodes (see manufacturer's instructions).

Figure 2.8.3 A sizing ladder from a *Hae*III digest of ϕ X-174 DNA. Fragment size in bp is indicated.

3. If the capillary is new, rinse with gel buffer for 10 min at high (20 psi) pressure.
This step is not necessary between runs.
4. Place standard sizing ladder in inlet position and load for 10 sec at low (0.5 psi) pressure.
See Figure 2.8.3 for a chromatogram of this standard.
The buffer ions become depleted over a series of injections. Consequently the inlet gel reservoir should be replaced after 30 injections.
5. Perform electrophoresis at 9.4 kV for 30 min at 25°C.
6. At the completion of the separation, replace the gel matrix using a 3-min high-pressure wash.
7. Assess the resolution and the linearity of area quantitation of the electrophoretic separation, and compare with the expected profile.
8. Dilute the PCR reaction mixes 10-fold with water and analyze by repeating steps 4 to 6, as with the sizing ladder.

Some applications may require the coinjection of the sizing ladder with the sample. In these instances the sizing ladder is loaded for 10 sec, followed by the sample for 10 sec.

Figure 2.8.4 An example of VNTR analysis with (A) the D1S80 locus PCR products and (B) the D1S80 allelic ladder with a repeat unit of 16 bp and a range of 14 to 38 copies (as labeled on peaks).

GENOTYPING

The use of capillary gel electrophoresis in genotyping can be viewed as an extension of the fragment-sizing application of RT-PCR analysis (Basic Protocol 2). Two major differences are the source of the target DNA and the analysis method used. Genotyping procedures begin with genomic DNA, which is either assessed directly by restriction fragment length polymorphism (RFLP; Jarcho, 1994) analysis or amplified and then subjected to variable number of tandem repeat (VNTR; Sozer et al., 1998) analysis. The fragments can be detected by using either UV or fluorescence detectors. The same Beckman Coulter dsDNA 1000 analysis kit that is used for quantitative PCR can be used for genotyping, since the fragment size ranges are similar.

In the case of VNTR analysis, where the number of repeats is being measured, it is important to select standards whose size corresponds approximately to the expected number of repeats. Standards can be obtained from a number of suppliers. For example, a D1S80 allelic ladder, with a range of 300 to 700 bp (see Fig. 2.8.4) and a 16-bp repeating unit, is available from Lifecodes. It is advisable to coinject the sizing standards with the sample for the greatest accuracy. RFLP analysis simply requires pattern matching. However, size standards are required for the alignment of multiple analyses.

The CE setup, sample loading, and running conditions for this method are identical to those for quantitative PCR (see Basic Protocol 2).

COMMENTARY

Background Information

The application of capillary electrophoresis to the separation of DNA fragments is a relatively recent development. The inherent

advantages of this technology—high resolution, excellent sensitivity, and rapid separation times—provide significant improvements over the conventional slab gel electrophoresis

ALTERNATE PROTOCOL

Preparation and Analysis of DNA

2.8.9

technology. This has led to rapid acceptance of CE as an essential tool for the analysis of DNA fragments of all sizes.

When applied to the analysis of synthetic oligonucleotides (see Basic Protocol 1), the technique's ability to obtain single-base resolution has proven extremely useful in diagnosing synthesis problems and in obtaining overall purity estimates for the final products (Cohen et al., 1988). The chemistry of DNA synthesis involves sequential addition of bases to the growing oligonucleotide chain in a prescribed order (UNIT 2.11). After each addition, the growing chain is "capped" in order to terminate the portion of the oligonucleotide that has not completed the coupling reaction. This yields a truncation series. If present in sufficient quantity, these species will compete with the full-length oligonucleotide in some applications. Since they are shorter than the full-length oligonucleotide they can readily be resolved and quantitated by CE.

After synthesis has been completed, the bases have to be deprotected. If deprotection is incomplete it can interfere with the base-pairing properties of the oligonucleotide. These species, which appear larger than the

full-length oligonucleotide, can also be readily resolved by CE. Figure 2.8.5 illustrates a crude oligonucleotide containing coupling failures (shorter migration times) and incompletely deprotected species (longer migration times). The resolution capacity of CE using a matrix optimized for oligonucleotides can extend to the analysis of oligonucleotides in excess of 100 bases. An example of the separation of a standard oligonucleotide mixture ranging from 40 to 60 bases is presented in Figure 2.8.2. Single-base resolution is readily observed.

An increasing number of oligonucleotide applications require modification of the basic oligonucleotide probe—e.g., biotinylation, fluorescent dye modification, phosphorylation, base modification, addition of phosphorothioate (antisense) backbones, DNA-RNA hybridization, and 5'-amino- or 5'-thiol-modification—prior to conjugation to other molecular species. In all instances, the extent of modification to produce these unique oligonucleotides can be readily assessed by CE due to its high resolution. Recent developments in the area of quantitative gene expression measurements (Freeman et al., 1999) and single nucleotide polymorphism

Figure 2.8.5 CE separation of a synthetic 20-mer oligonucleotide. The coupling failure products (shorter migration times) and incomplete deprotection products (longer migration times) are clearly visible.

(SNP) detection have utilized the principle of fluorescence energy transfer via oligonucleotide probes. Assays based on quantitative RT-PCR have been developed—e.g., TaqMan (Applied Biosystems), Invader (Third Wave), and Black Hole Quenchers (BioSearch Technologies)—that require either paired single-labeled or dual-labeled oligonucleotides. These reagents are readily analyzed for purity by CE using Basic Protocol 1. CE is particularly useful in this instance since MALDI mass spectrometry (*UNIT 10.21*), a commonly used alternative, fragments the fluorescent label, resulting in multiple molecular species.

Small interfering RNAs (siRNA) can be used for the down-regulation of individual genes (Chapter 26; Elbashir et al., 2001). These molecules all share the same features: 2 thymidine deoxynucleotides at the 3' end followed by 19 ribonucleotides, terminating in a 5'-hydroxyl. These siRNA probes are readily characterized for purity by CE using Basic Protocol 1.

The development of matrices to extend this single-base resolution to ssDNA that ranges in size from 20 to 1000 bases has allowed for development of important applications in the field of automated fluorescence-based DNA sequencing. The most commonly performed sequencing chemistry is the “dye terminator” chemistry, in which the sequence-terminating dideoxy nucleotide also contains the fluorescent reporter group. Consequently, the sequence ladder is labeled in the 3'-hydroxyl position. This means that sequencing reactions can be performed using a primer of any

sequence. The alternate “dye primer” chemistry employs a primer that is labeled at the 5'-hydroxyl and is restricted to a small number of commonly used vector sequences—e.g., M13 forward and reverse, T3, T7, and SP6 sequences. An example of this type of application is shown in Figure 2.8.6. Significant effort is being directed towards the development of matrix formulations that will further extend the length of the current sequence reads. Commercial CE sequencing instruments all have shorter run times than slab gel-based automated sequencers and retain comparable sensitivity and accuracy. Each of these applications requires the analysis of ssDNA and is performed under dissociating conditions in the presence of a flowable matrix.

The sizing of larger fragments that have been amplified from genomic DNA has proven to be a very effective method for studying genetic variability in populations. These fragments can be analyzed by capillary gel electrophoresis either under dissociating conditions (short fragments, high size accuracy) or as dsDNA (large fragments, lower resolution). Genomic DNA from eukaryotes contains a large number of tandem-repeating sequences that vary in size from 2 to several dozen bp in size. This polymorphism can be used to advantage when studying human identity or individual heredity. The smaller repeats, commonly referred to as microsatellite or short tandem repeats (STR), are best analyzed as ssDNA (Butler et al., 1994). To determine identity or heredity it is necessary to accurately determine the number of copies of (2- to 5-bp-long) identical sequence repeats in the

Figure 2.8.6 A portion of the chromatographic output from a PE Biosystems model 373A DNA sequencer using dye terminator sequencing chemistry. Although shown in black and white here, the direct output is color-coded to more clearly illustrate the peaks corresponding to each base in the sequence.

selected fragment. Fragment lengths are usually <300 bp and require single-nucleotide resolution.

Larger repeats are commonly referred to as variable number of tandem repeats (VNTR) and produce larger-sized fragments that are analyzed as dsDNA. The sizes of the repeats are 10 to 12 nucleotides and up, and fragment sizes can exceed 4000 bp. An example of this type of separation was presented in Figure 2.8.4 and explained in the Alternate Protocol. The required resolution for this type of separation is on the order of 4%.

In contrast to the accurate sizing of DNA, fragment pattern matching can also be a very useful analytical tool. The loss or gain of a restriction site between individuals is sufficiently common that restriction fragment length polymorphism (RFLP) analysis can demonstrate individual identity to a high degree of certainty (Ulfelder et al., 1992). These patterns are readily analyzed by CE. RFLP has found application in the fields of forensic medicine and pedigree testing. Where a polymorphic mutation produces a detectable phenotype, it can also be used as a diagnostic for inherited diseases. It requires the separation of dsDNA in the presence of an intercalating dye for visualization. The matrix is generally a flowable polymer, and fragment lengths are from hundreds to thousands of bp in size.

Mutation detection can also be performed using ssDNA. A denatured DNA fragment can adopt a sequence-specific conformation upon refolding, which will affect its electrophoretic mobility. This property is taken advantage of in single-stranded conformational polymorphism (SSCP) separations (Ren et al., 1997). The DNA region of interest is PCR-amplified from genomic or cDNA to give sufficient copies of a small (<300-bp) fragment. The strands are separated and allowed to refold. The wild-type and mutant fragments adopt different conformations and are resolved with single-base-pair resolution by CE using a nondissociating medium and a flowable polymer matrix.

CE can accurately quantitate and size DNA fragments (Rossomando et al., 1991; Fasco et al., 1995). This can be of considerable value when used to quantitate levels of viruses and pathogenic bacteria. The difficulty arises when quantitation is attempted in the presence of high levels of other DNA, RNA, and proteins. Fluorescence detection coupled with PCR—which can amplify very low levels of DNA in a highly specific manner—can be used to surmount this problem. This amplification can be

combined with the inherent sensitivity of CE through the incorporation of fluorescently labeled primers into the amplified DNA. In this fashion samples such as blood can be analyzed at high dilution, thereby reducing the levels of interfering substances to manageable levels. RNA can be amplified by RT-PCR to give the dsDNA fragment that is subsequently quantitated. This is ideal for measuring low levels of viral messenger RNA, i.e., viral load. The fragments are <1000 bp and separations are usually performed under nondenaturing conditions. The use of appropriate quantitative calibration standards is essential. One such standard, a sizing ladder, is shown in Figure 2.8.3, and an example of this technique is presented in Basic Protocol 2.

A majority of CE separations are performed at the standard alkaline pH in the presence of borate, which is an effective buffer in this pH range. The buffer may also contain 6 to 8 M urea, a denaturant that keeps the DNA in its simple single-stranded conformation when required. The urea is omitted from the buffer for analyses where secondary structure plays an important role in the separation, e.g., single-nucleotide polymorphisms or conformational polymorphisms.

The type of matrix that is selected for the actual separation can dramatically influence the quality of the separation that is achieved for a given application. Instrument manufacturers frequently supply kits that have been optimized for a particular application (see Table 2.8.2). These can be very helpful as a first, and maybe the only step required for optimizing individual applications. In general, cross-linked polyacrylamide that is polymerized inside, and covalently attached to, the capillary is best suited for smaller-fragment separations. However, since the column is reused multiple times, many things can reduce resolution—for example, capillary plugging, bubble formation, or drying of the capillary end—and require that the capillary be discarded. In the absence of such external parameters, the lifetime of the capillary is ultimately dependent on the breakdown of the polyacrylamide (or other hydrophilic polymer) matrix.

Flowable polymers have the advantage of wide fragment-separation ranges. These polymers can have a variety of chemical origins (see Table 2.8.2) and have the advantage of being replaced after each separation. This is achieved by applying pressure to the inlet end of the capillary. However, some of these polymers are quite viscous and require considerable pressure within the instrument

Table 2.8.2 Supplies and Kits for CE Systems

Manufacturer	Part number	Supplies and kits	Application information

(up to 1600 psi) to load the capillary. Linear polyacrylamide, which contains no crosslinker, is a flowable polymer that can produce a very effective sieving matrix. The sieving properties are dependent upon both the polymer concentration and the average chain length (molecular weight). In general, lower polymer concentrations of higher average molecular weight are preferred for the separation of high molecular weight DNA, the reverse being true for lower molecular weight DNA. The selection of an optimal combination of these conditions must be balanced by viscosities that are compatible with the pumping capabilities of the CE instrumentation. It is essential to avoid purchasing incompatible components by matching the instrument capabilities to the matrix that has been selected for the given application.

With bare fused silica, either cellulose-based gels (e.g., hydroxyethylcellulose; Aldrich) or acrylamide-based gels (PE Biosystems) can be used. Replacing coated or gel-filled capillaries can be quite expensive; as premature failure of the capillary can normally be attributed to excessive voltage during separation or to inappropriate storage, it is worthwhile to take precautions for avoiding these problems. All manufacturers of CE instrumentation offer UV absorbance detection systems that will work for most general applications. Beckman Coulter and Bio-Rad offer laser-based fluorescence detectors for high-sensitivity CE applications. PE Biosystems offers a single-capillary laser fluorescence instrument for genetic analysis and DNA sequencing, while Beckman Coulter offers similar instrumentation in an eight-capillary format.

Preparation and Analysis of DNA

2.8.13

Critical Parameters

Oligonucleotide purity

The most common size of synthetic oligonucleotide probes is in the range of 20 to 30 bases. However, some applications require synthetic probes that are 100 bases or more in length. Single-base resolution over this range is essential in order to obtain an accurate assessment of purity. The salt content of the oligonucleotide should be kept to a minimum (<50 mM) in order to obtain optimal resolution. The oligonucleotide should be dissolved in water, or serially diluted in water from the stock TBE solution, prior to electrophoresis. Concentrations should be in the 1 µg/20 ml range for UV absorbance detection. The presence of alkaline-pH buffers and urea in the separation matrix and electrophoresis buffer are essential for single-stranded separations. It is important to run a standard—poly(A)₄₀₋₆₀—at the beginning of each set of analyses in order to confirm that the electrophoretic resolution is optimal (see Fig. 2.8.2).

DNA sequencing

In addition to the items above, this application requires single-base resolution over the range of 20 to 1000 bases. Automated, DNA sequencing instruments rigidly control the separation conditions to minimize temperature and power fluctuations and to eliminate variability in the matrix loading protocols. Consequently, most of the critical parameters are associated with template and primer quality and quantity issues. High-quality, salt-free plasmid, cosmid, or PCR-derived DNA is essential. The optimal molar ratio of template to primer is 1:1 and an imbalance of either component outside a ratio of 4:1 will give unusable sequences. Template concentrations should be in the 1 µg/20 µl range. The presence of proteins, salts, detergents, etc. in the template can inhibit the DNA polymerase and kill the reaction. It is essential to remove the excess fluorescent primers or dideoxynucleotides before separating the sequencing ladder on the CE. Further details on the essential parameters of the sequencing reaction itself can be found in Ausubel et al. (2003).

Fragment sizing

Selection of an appropriate separation matrix is probably the most important issue when analyzing microsatellite repeats. Resolution of the smaller fragments at the one to two nucleotide level is required. The DNA should be single-stranded and separated with denaturants. The use of internal size standards is es-

sential since the absolute mobilities can change from run to run and from sample to sample. When analyzing the VNTR fragments, which have larger repeating units (see Alternate Protocol), base pair resolution in the 3% to 6% range is required. These fragments are analyzed as double-stranded DNA without denaturants. Since the fragments are longer, lower matrix concentrations are preferred. Again, internal standards are essential.

The fragments are either obtained directly from genomic DNA, or PCR-amplified DNA. Considerable care has to be taken to remove particulate matter and salts from these samples prior to CE separation. The internal diameter of most capillaries is only 50 to 100 µm, and they are sensitive to plugging. Sometimes plugged capillaries can be salvaged by high-pressure back-flushing, but replacement is usually necessary. Salt concentrations should be <50 mM to minimize sample loading problems.

RFLP mutation screening

The same criteria for VNTR analysis are applied to mutation screening—the major exception being that the application requires pattern matching between control and mutant DNA, rather than absolute sizing. The double-stranded fragments must assume their sequence-dependent conformations. The addition of 10% glycerol to the flowable polymer significantly improves the discrimination of the electrophoretic separation.

Quantitation (RT-PCR)

The readout from this application is the absolute level of viral RNA in a biological sample. The PCR amplification is specific, but the target is present in a mixture of other nucleic acids, proteins and salts. The use of a fluorescent label or the addition of an intercalating dye, such as YO-PRO-1 or SYBR Green I, as well as the ability to dilute out the interfering substances, are essential features of this application. The fragments are separated as double-stranded PCR products and are quantitated by peak height on the electropherogram. The presence of salts in the starting material and in the PCR reaction can cause variable sample loading if electrokinetic sample injection is used. Sample loading by pressure injection bypasses these problems.

Absolute quantitation of the PCR product has to take into account both the length of the DNA and the degree of incorporation of the intercalating dye. This is achieved by coinjecting a standard of known concentration with the sample. If this standard contains a ladder

of fragments of known length then the quantity of the amplicon can be accurately determined. This procedure carries the added advantage of confirming the correct fragment size.

The difficulties encountered with this type of quantitation are not associated with the CE quantitation but with the PCR amplification step. It is essential that a dilution series is performed on the PCR mix to ensure that the reaction is linear with respect to cycle number. In the case of competitive PCR, it is essential that the competing template concentration approximates that of the target template. Alternatively, expression levels can be quantitated relative to a “housekeeping” gene. This is a gene, such as β -actin, that is constitutively expressed in the cells of interest. In this procedure the β -actin gene is coamplified with the gene of interest prior to quantitation by CE. As indicated previously, this field has recently undergone major expansion. The introduction of automated PCR-based instrumentation and the availability of high-quality fluorescently labeled oligonucleotides has produced a number of robust RT-PCR-based kits. They have superseded the intercalating dye approach for some applications.

Troubleshooting

Mechanical and electrical problems that might be encountered during instrument use are addressed in the troubleshooting sections of the manufacturers’ manuals. One difficulty is the loss of electrical continuity during a run. This loss of current can be caused if a small bubble forms in the column during injection or if the power generated by the run is so great that the solution boils or outgasses. Purging the column after a failed run removes any bubbles in the column. The vial containing the sample must have sufficient liquid to cover the end of the column during injection to prevent introduction of air into the column. On the autosampler, the vials can dry out during a long run, so sample temperature control or the use of the correct cap on the vial is required to slow evaporation. Reducing the buffer concentration or the run voltage can eliminate bubble formation during a run. Degassing the buffer is also useful if the outgassing problems continue.

On occasion capillaries can become plugged. This is normally due to the capillary matrix being allowed to dry out. When not in use, the capillary can remain installed on the CE instrument, but both ends must remain submerged in buffer. If it is removed from the instrument the capillary should be stored refrigerated, with both ends capped to prevent evapo-

ration. The capillary can also become plugged from insoluble material that is present in the sample. Sometimes it is possible to apply pressure to the anode outlet and blow out the plug. More likely, however, the capillary will need to be replaced.

Loss of resolution on a separation of standards can have several causes: e.g., the buffer, the separation matrix, or the capillary. A process of elimination should follow the course of first trying fresh buffer, then new matrix, and finally changing out the capillary. Where separation of standards is normal, but resolution or signal strength is poor, the cause is likely excess salts and/or buffers in the samples. Examining the behavior of the electrical current during the run will probably assist in troubleshooting. Most CE instruments simultaneously monitor both detector output and current flow throughout the electrophoresis run.

A drop in sensitivity or signal strength can be observed when multiple injections are made from a single standard vial (especially if the standard is dissolved in deionized water). This phenomena can be due to salt contamination of the sample by residual matrix buffer on the outside of the capillary (Guttman and Schwartz, 1995). Keep in mind that any source of additional ions to the sample (e.g., salt, buffer, or other ion species) will affect an electrokinetic injection. The ions of the sample will be effectively diluted by the ions from the contaminant. Sample preparation to remove variable salt contamination will improve the consistency of injections (Ruiz-Martinez et al., 1998).

Anticipated Results

The separation of oligonucleotides should show single-base resolution from 5 bases to > 100 bases. The synthetic efficiency of the assembly process is in excess of 99% (Pon et al., 1996), such that the yield of full-length product for a 100-mer should still exceed 30% of the total DNA present. For a 25-mer the yield of full-length product should exceed 80%. The addition of various functional moieties to the oligonucleotide will normally be seen as an increase in size (or decrease in mobility). The addition of a group as small as a phosphate group at the 5'-hydroxyl will make the oligonucleotide appear longer by a single base. The size increase, however, is insufficient proof of successful modification. This must be verified by obtaining a molecular weight by mass spectrometry (e.g., MALDI-TOF; UNIT 10.21).

The DNA-sequencing application (as stated previously) can have single-base resolution up

to 1000 bases or more, though performance today on commercial multicapillary instruments is ~600 bases or more in 2 hr. The smallest sequencing fragments will be detected as sharp, tight bands usually ~1 to 3 sec in width. The larger (slower-moving) fragments will show considerable band broadening due to diffusion as well as reduced separation efficiency of the matrix.

The microsatellite and VNTR analyses will show well-resolved peaks for the various multimers that are reflective of the number of repeats in the sample. These should be well resolved from the sizing control that has been added to, or coinjected with, the sample of interest.

The variability of these repeats at a given locus should give sufficient information to clearly identify relatedness between individuals. The expression levels of various isotypes should be sufficiently well discriminated to use this technique as a potential diagnostic test for disease states.

Quantitative PCR data should be sufficiently accurate to detect a 3- to 5-fold change in viral load level. The linearity of response of the standard and target DNAs should extend to the low to sub-nanogram level.

Time Considerations

These will vary dependent upon the type of separations that are required. Preparation of the stock solutions can take up to 1 hr. Filling the capillaries with fresh gel can take 1 hr. The analysis of synthetic oligonucleotides is normally completed within 30 min and sample preparation time is minimal. The DNA sequencing application probably requires the longest separation times. A 2-hr cycle time from injection to injection is normally sufficient to obtain 500 to 600 bases of high-quality sequence. Regeneration and loading times are <15 min. Preparing the stock solutions from the kit takes 24 hr. Filling the capillary with gel takes 30 min. Analysis of microsatellite fragments can take as little as 15 min, whereas the analysis of VNTR fragments takes up to 30 min. Regeneration times are <10 min. The analysis component of quantitative PCR is similar. However, this application requires multiple runs in order to obtain linearity curves for the PCR products and the calibration standards.

ANALYSIS OF DNA SEQUENCES BY BLOTTING AND HYBRIDIZATION

UNIT 2.9A

Southern Blotting

Southern blotting is the transfer of DNA fragments from an electrophoresis gel to a membrane support. The transfer or a subsequent treatment results in immobilization of the DNA fragments, so the membrane carries a semipermanent reproduction of the banding pattern of the gel. After immobilization, the DNA can be subjected to hybridization analysis (UNIT 2.10), enabling bands with sequence similarity to a labeled probe to be identified.

When setting up a Southern transfer, choices must be made between different types of membrane, transfer buffer, and transfer method. The most popular membranes are made of nitrocellulose, uncharged nylon, or positively charged nylon. Although these materials have different properties, the three types of membrane are virtually interchangeable for many applications. The main advantage of nylon membranes is that they are relatively robust and so can be reprobbed ten or more times before falling apart. Nitrocellulose membranes are fragile and can rarely be reprobbed more than three times; however, these are still extensively used, as they give lower backgrounds with some types of hybridization probe. The properties and advantages of the different membranes are discussed more fully in the commentary.

The basic protocol describes Southern blotting via upward capillary transfer of DNA from an agarose gel onto a nylon or nitrocellulose membrane, using a high-salt transfer buffer to promote binding of DNA to the membrane. With the high-salt buffer, the DNA becomes bound to the membrane during transfer but not permanently immobilized. Immobilization is achieved by UV irradiation (for nylon) or baking (for nitrocellulose). A support protocol describes how to calibrate a UV transilluminator for optimal UV irradiation of a nylon membrane.

The first alternate protocol details transfer using nylon membranes and an alkaline buffer, and is primarily used with positively charged nylon membranes. The advantage of this combination is that no post-transfer immobilization step is required, as the positively charged membrane binds DNA irreversibly under alkaline transfer conditions. The method can also be used with neutral nylon membranes but less DNA will be retained.

The second alternate protocol describes a transfer method based on a different transfer-stack setup. The traditional method of upward capillary transfer of DNA from gel to membrane described in the first basic and alternate protocols has certain disadvantages, notably the fact that the gel can become crushed by the weighted filter papers and paper towels that are laid on top of it. This slows down the blotting process and may reduce the amount of DNA that can be transferred. The downward capillary method described in the second alternate protocol is therefore more rapid than the basic protocol and can result in more complete transfer.

Although the ease and reliability of capillary transfer methods makes this far and away the most popular system for Southern blotting with agarose gels, it unfortunately does not work with polyacrylamide gels, whose smaller pore size impedes the transverse movement of the DNA molecules. The third alternate protocol describes an electroblotting procedure that is currently the most reliable method for transfer of DNA from a polyacrylamide gel.

Southern Blotting**2.9.1**

SOUTHERN BLOTTING ONTO A NYLON OR NITROCELLULOSE MEMBRANE WITH HIGH-SALT BUFFER

BASIC PROTOCOL

The procedure is specifically designed for blotting an agarose gel onto an uncharged or positively charged nylon membrane. With the minor modifications detailed in the annotations, the same protocol can also be used with nitrocellulose membranes.

The protocol is divided into three stages. First, the agarose gel is pretreated by soaking in a series of solutions that depurinate, denature, and neutralize the DNA and gel matrix. The second stage is the transfer itself, which occurs by upward capillary action. Finally, the DNA is immobilized on the membrane by UV irradiation (for nylon) or baking (for nitrocellulose).

Materials

- DNA samples to be analyzed
- 0.25 M HCl
- Denaturation solution: 1.5 M NaCl/0.5 M NaOH (store at room temperature)
- Neutralization solution: 1.5 M NaCl/0.5 M Tris·Cl, pH 7.0 (store at room temperature)
- 20× and 2× SSC (APPENDIX 2)
- Oblong sponge slightly larger than the gel being blotted
- Whatman 3MM filter paper sheets
- Nylon *or* nitrocellulose membrane (see Table 2.9.1 for suppliers)
- UV-transparent plastic wrap (e.g., Saran Wrap) for nylon membranes
- UV transilluminator (UNIT 2.5) or UV light box (e.g., Stratagene Stratalink) for nylon membranes
- Additional reagents and equipment for restriction endonuclease digestion (UNIT 3.1) and agarose gel electrophoresis (UNIT 2.5)

Table 2.9.1 Properties of Materials used for Immobilization of Nucleic Acids^a

	Nitrocellulose	Supported nitrocellulose	Uncharged nylon	Positively charged nylon	Activated papers
Application	ssDNA, RNA, protein	ssDNA, RNA, protein	ssDNA, dsDNA, DNA, protein	ssDNA, dsDNA, RNA, protein	ssDNA, RNA
Binding capacity (μg nucleic acid/cm ²)	80-100	80-100	400-600	400-600	2-40
Tensile strength	Poor	Good	Good	Good	Good
Mode of nucleic acid attachment ^b	Noncovalent	Noncovalent	Covalent	Covalent	Covalent
Lower size limit for efficient nucleic acid retention	500 nt	500 nt	50 nt or bp	50 nt or bp	5 nt
Suitability for reprobing	Poor (fragile)	Poor (loss of signal)	Good	Good	Good
Commercial examples	Schleicher & Schuell BA83, BA85; Amersham Hybond-C; PALL Biodyne A	Schleicher & Schuell BA-S; Amersham Hybond-C extra	Amersham Hybond-N; Stratagene Duralon-UV; Du Pont NEN GeneScreen	Schleicher & Schuell Nytran; Amersham Hybond-N ⁺ ; Bio-Rad ZetaProbe; PALL Biodyne B; Du Pont NEN GeneScreen Plus	Schleicher & Schuell APT papers

^bAfter suitable immobilization procedure (see text).

Preparation and Analysis of DNA

2.9.2

CAUTION: Wear gloves from step 2 of the protocol onward to protect your hands from the acid and alkali solutions and to protect the membrane from contamination.

Prepare the gel

1. Digest the DNA samples with appropriate restriction enzyme(s), run in an agarose gel with appropriate DNA size markers, stain with ethidium bromide, and photograph with a ruler laid alongside the gel so that band positions can later be identified on the membrane.

The gel should contain the minimum agarose concentration needed to resolve bands in the area of interest (see commentary to UNIT 2.5A) and should be ≤ 7 mm thick, preferably less. The amount of DNA that must be loaded depends on the relative abundance of the target sequence that will subsequently be sought by hybridization probing (see recommendations in commentary to this unit and UNIT 2.10).

2. Rinse the gel in distilled water and place in a clean glass dish containing ~10 gel volumes of 0.25 M HCl. Shake slowly on a platform shaker for 30 min at room temperature.

This step results in partial depurination of the DNA fragments, which in turn leads to strand cleavage. The length reduction improves the transfer of longer molecules. The step is not necessary with PCR products < 4 kb in length, or if efficient transfer of molecules > 5 kb is not required. The time needed for the acid treatment depends on the concentration and thickness of the gel. To check that the treatment has been sufficient, watch the xylene cyanol and bromophenol blue dyes. When these change color to green and yellow respectively, the gel has equilibrated with the acid. Adequate depurination takes a further 10 min.

3. Pour off the HCl and rinse the gel with distilled water. Add ~10 vol denaturation solution and shake as before for 20 min. Replace with fresh denaturation solution and shake for a further 20 min.

Denaturation unzips the DNA to give single-stranded molecules that have unpaired bases and are suitable for subsequent hybridization analysis.

4. Pour off the denaturation solution and rinse the gel with distilled water. Add ~10 vol neutralization solution, shake as before for 20 min, then replace with fresh neutralization solution and shake for a further 20 min.

The aim of the neutralization step is to bring the gel pH down to < 9.0 . At higher pH, the transferred DNA will not bind to nitrocellulose. After neutralization, the gel pH can be checked using a pH meter. If the pH is > 9.0 , carry out a third washing in neutralization solution. Neutralization is less critical with a nylon membrane but should still be carried out.

Set up the transfer

5. Using Figure 2.9.1 as a guide, place an oblong sponge, slightly larger than the gel, in a glass or plastic dish (if necessary, use two or more sponges placed side by side). Fill the dish with enough 20 \times SSC to leave the soaked sponge about half-submerged in buffer.

The sponge forms the support for the gel. Any commercial sponge will do; before a sponge is used for the first time, it should be washed thoroughly with distilled water to remove any detergents that may be present. As an alternative, use a solid support with wicks made out of Whatman 3MM filter paper (see Fig. 2.9.1). An electrophoresis tank should not be used, as the high-salt transfer buffer will corrode the electrodes.

6. Cut three pieces of Whatman 3MM paper to the same size as the sponge. Place these on the sponge and wet them with 20 \times SSC.

7. Place the gel on the filter paper and squeeze out air bubbles by rolling a glass pipet over the surface.
8. Cut four strips of plastic wrap and place over the edges of the gel.

This is to prevent the buffer from “short-circuiting”—i.e., so that it flows through rather than around the gel.
9. Cut a piece of nylon membrane just large enough to cover the exposed surface of the gel. Pour distilled water ~0.5 cm deep in a glass dish and wet the membrane by placing it on the surface of the water. Allow the membrane to submerge, then leave for 5 min.

If a nitrocellulose membrane is being used, submerge in distilled water; replace the water with 20× SSC and leave for 10 min. Avoid handling nylon and nitrocellulose membranes even with gloved hands—use clean blunt-ended forceps instead.
10. Place the wetted membrane on the surface of the gel. Try to avoid getting air bubbles under the membrane; remove any that appear by carefully rolling a glass pipet over the surface.

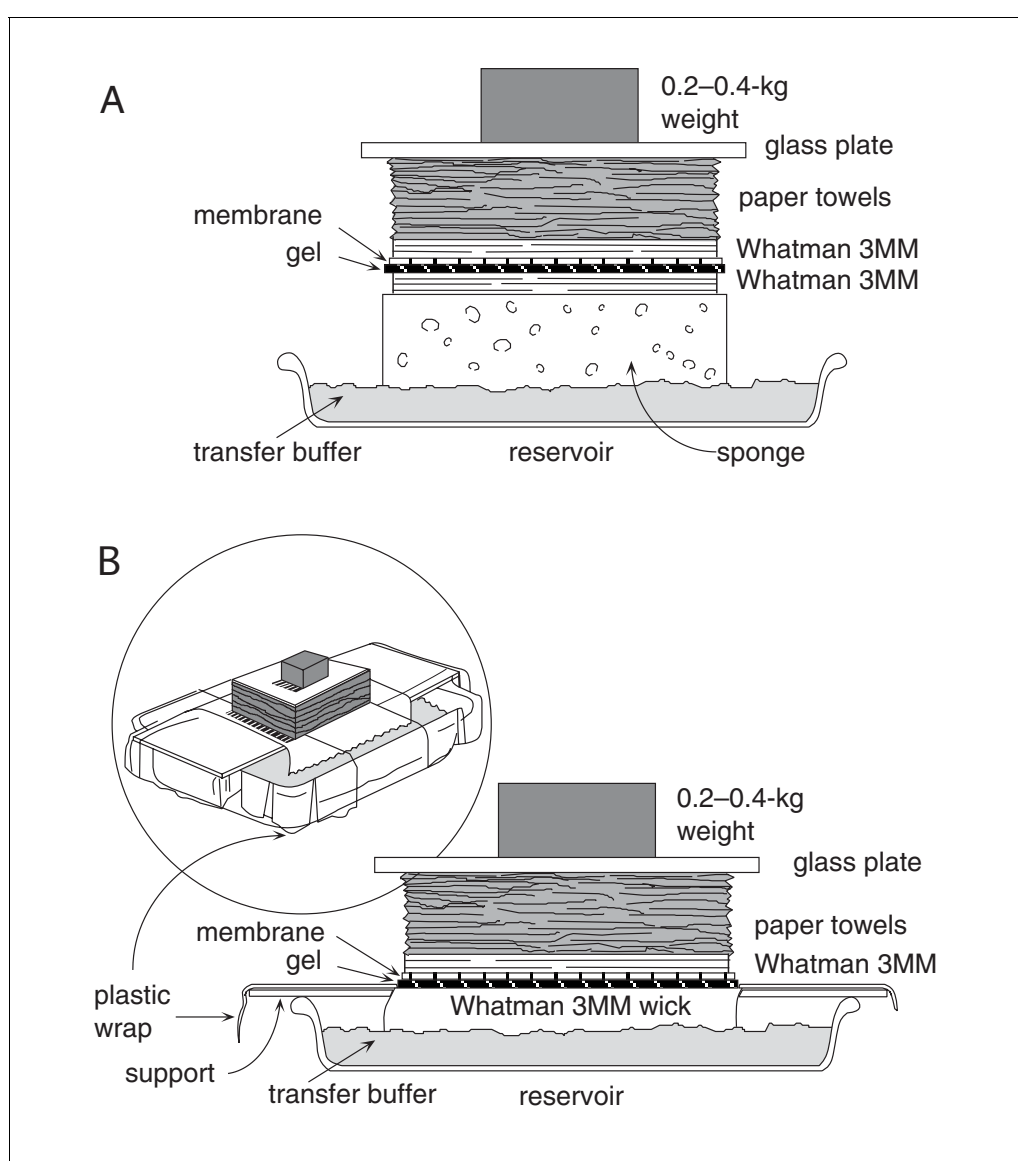

Figure 2.9.1 Two alternative transfer pyramid setups for Southern blotting via upward capillary transfer. (A) Sponge method. (B) Whatman 3MM filter paper wick method.

For blots of substantial amounts of plasmid or other very-low-complexity DNA, it is important to lay the membrane down precisely the first time, as detectable transfer can take place almost immediately, and moving the membrane may cause “mobile” bands as streaks on the autoradiograph.

11. Flood the surface of the membrane with 20× SSC. Cut five sheets of Whatman 3MM paper to the same size as the membrane and place these on top of the membrane.
12. Cut paper towels to the same size as the membrane and stack these on top of the Whatman 3MM papers to a height of ~4 cm.
13. Lay a glass plate on top of the structure and place a weight on top to hold everything in place. Leave overnight.

The weight should be sufficient to compress the paper towels to ensure good contact throughout the stack. Excessive weight, however, will crush the gel and retard transfer.

An overnight transfer is sufficient for most purposes. Extend the transfer time if the gel concentration is >1%, or transfer of fragments >20 kb is desired. Make sure that the reservoir of 20× SSC does not run dry during the transfer. If the gel contains large amounts of DNA (see annotation to step 10), high transfer efficiencies may not be required and shorter transfer times (~1 hr) may be used.

Disassemble the transfer pyramid

14. Remove the paper towels and filter papers and recover the membrane. Mark in pencil the position of the wells on the membrane and ensure that the up-down and back-front orientations are recognizable.

Pencil is preferable to pen, as ink marks may wash off the membrane during hybridization. An alternative for a nylon membrane only is to cut slits with a razor blade to mark the positions of the wells (do not do this before transfer or the buffer will short-circuit). The best way to record the orientation of the membrane is by making an asymmetric cut at one corner.

15. Rinse the membrane in 2× SSC, then place it on a sheet of Whatman 3MM paper and allow to dry.

The rinse has two purposes: to remove agarose fragments that may adhere to the membrane and to leach out excess salt. The gel can be retained with ethidium bromide to assess the efficiency of transfer.

Immobilize the DNA

16. Wrap the membrane UV-transparent plastic wrap, place DNA-side-down on a UV transilluminator (254-nm wavelength) and irradiate for the time determined from the support protocol.

CAUTION: Exposure to UV irradiation is harmful to the eyes and skin. Wear suitable eye protection and avoid exposure of bare skin.

Nitrocellulose membranes should not be UV irradiated. Instead, place between two sheets of Whatman 3MM paper and bake under vacuum for 2 hr at 80°C. This results in noncovalent attachment of the DNA to the membrane; the vacuum is needed to prevent the membrane from igniting.

UV crosslinking is recommended for a nylon membrane as this leads to covalent attachment and enables the membrane to be reprobed several times. The membrane must be completely dry before UV crosslinking; check the manufacturer’s recommendations. A common procedure is to bake for 30 min at 80°C prior to irradiation. Plastic wrap is used to protect the membrane during irradiation, but it must be UV-transparent. A UV light box can be used instead of a transilluminator (follow manufacturer’s instructions).

17. Store membranes dry between sheets of Whatman 3MM paper for several months at room temperature. For long-term storage, place membranes in a desiccator at room temperature or 4°C.

CALIBRATION OF A UV TRANSILLUMINATOR

When immobilizing DNA on a nylon membrane by UV crosslinking as described in the basic protocol, the intensity of irradiation is critical. Too little results in submaximal immobilization, and too much causes DNA degradation. UV transilluminators must therefore be calibrated to determine their output. The calibration should be repeated from time to time as the output of the lights changes with age. If a UV exposure meter (e.g., Baxter Scientific Blak-Ray) is available, it can be used to calculate the period of irradiation needed to produce the optimal exposure described in the manufacturer's support literature for the membrane (see also *UNIT 3.19*). Alternatively, the optimal exposure time can be determined experimentally as described in this protocol.

UV light boxes designed specifically for crosslinking are now commercially available. Most have automatic devices that vary output according to the age of the lights, but it is still a good idea to calibrate them regularly.

Additional Materials

DNA probe labeled to a specific activity of 10^8 dpm/ μ g

Additional reagents and equipment for DNA dot blotting (*UNIT 2.9B*) and hybridization analysis (*UNIT 2.10*)

CAUTION: Exposure to UV irradiation is harmful to the eyes and skin. Wear suitable eye protection and avoid exposure of bare skin.

1. Prepare five identical series of DNA dot blots (*UNIT 2.9B*) on nylon membrane strips, each with a range of DNA quantities from 1 to 100 pg.

The dot blots should be prepared on nylon membrane from the batch that is being used for Southern transfers.

2. Dry the nylon strips, wrap each one in UV-transparent plastic wrap, and place on the UV transilluminator, DNA-side-down.
3. Put on eye protection and cover exposed skin, then switch on the transilluminator. Remove individual strips after 30 sec, 45 sec, 1 min, 2 min, and 5 min.
4. Hybridize the strips with a suitable DNA probe labeled to a specific activity of 10^8 dpm/ μ g and prepare autoradiographs (*UNIT 2.10*).
5. Determine which nylon strip gives the most intense hybridization signals; the exposure time used for that strip is the optimal exposure time.

Note that the optimal exposure time depends on the dryness of the membrane. The test membrane strips should therefore be dried in exactly the same way as the Southern blots.

At no or low UV dose, the signal will be weak; with increasing dose, it will reach a plateau. At long exposures the signal will again decline, as the radiation will damage the DNA so that it hybridizes poorly.

**ALTERNATE
PROTOCOL**

**SOUTHERN BLOTTING ONTO A NYLON MEMBRANE WITH AN
ALKALINE BUFFER**

With a positively charged nylon membrane, the transferred DNA becomes covalently linked to the membrane if an alkaline transfer buffer is used. The protocol can also be carried out with uncharged nylon membranes using the minor modifications detailed in the annotations to the protocol steps below, but the transfer will be less complete. However, this transfer technique is not suitable for nitrocellulose membranes, as these do not retain DNA at pH >9.0 and fall apart after long exposure to alkali. The resistance of the nylon membrane to alkali should be checked before use, as some types of nylon membrane are less resistant than others.

Additional Materials

- 0.4 M (for charged membrane) *or* 0.25 M (for uncharged membrane) NaOH
- 0.25 M NaOH/1.5 M NaCl for uncharged membrane
- Positively charged *or* uncharged nylon membrane (see Table 2.9.1 for suppliers)

CAUTION: Wear gloves to protect your hands from the acid and alkali solutions and to protect the membrane from contamination.

1. Prepare a gel and treat with 0.25 M HCl as described in steps 1 and 2 of the basic protocol.
2. Rinse the gel with distilled water. Pour 10 gel volumes of 0.4 M NaOH into the dish and shake slowly on a platform shaker for 20 min.

This is the denaturation step. If an uncharged nylon membrane is being used, use 0.25 M NaOH in place of 0.4 M NaOH.

3. Follow steps 5 to 14 of the basic protocol to carry out the transfer, using 0.4 M NaOH as the transfer solution in place of 20× SSC. Leave to transfer ≥2 hr.

Alkaline transfer is quicker than high-salt transfer, so the blot can be taken apart any time after 2 hr.

A positively charged nylon membrane does not have to be prewetted, but can be placed directly onto the gel. If uncharged nylon is being used, use 0.25 M NaOH/1.5 M NaCl as the transfer solution. Check that the paper towels are resistant to the alkali solution; some types go brown and should not be used.

4. Remove the paper towels and filter paper and recover the membrane. Rinse the membrane in 2× SSC, place on a sheet of Whatman 3MM filter paper, and allow to air dry. Store as described in step 17 of the basic protocol.

The rinse has two purposes: to remove agarose fragments that may adhere to the membrane and to neutralize the membrane. Baking or UV crosslinking is not needed with a positively charge membrane; in fact, UV crosslinking is detrimental. With an uncharged membrane, immobilize as described in step 16, basic protocol.

**ALTERNATE
PROTOCOL**

SOUTHERN BLOTTING BY DOWNWARD CAPILLARY TRANSFER

One disadvantage with the upward capillary method (basic protocol) is that the gel can become crushed by the weighted filter papers and paper towels that are laid on top of it, reducing capillary action. The problem worsens as the transfer proceeds, as the paper towels become soaked in transfer buffer, increasing the pressure on the gel. This retards the blotting process and as a result the transfer must be carried out for 16 to 24 hr.

This alternate protocol describes a simple downward capillary transfer system that does not cause excessive pressure to be placed on the gel. Transfer from a 4-mm-thick 1% agarose gel is complete in just 1 hr. The protocol is suitable for all types of membrane and

Figure 2.9.2 Transfer pyramid setup for Southern blotting via downward capillary transfer. Adapted with permission from Academic Press.

can be used with either high-salt or alkaline transfer buffers.

CAUTION: Wear gloves to protect your hands from the acid and alkali solutions used in gel preparation and transfer and to protect the membrane from contamination.

1. Prepare a gel as described in steps 1 to 4 of the basic protocol (high-salt transfer) or steps 1 to 2 of the first alternate protocol (alkaline transfer).
2. Make a stack of paper towels 2 to 3 cm high in a glass dish. The towels should be slightly wider than the gel.
3. Using Figure 2.9.2 as a guide, place four pieces of Whatman 3MM filter paper on top of the paper towels. Wet a fifth filter paper with transfer buffer and place on top.
4. Wet the membrane as described in step 9 of the basic protocol.

The membrane can be slightly larger than the gel.
5. Place the membrane on the top filter paper. Remove bubbles by rolling a glass pipet over the surface of the membrane.

Plastic wrap should be placed around the gel to prevent short-circuiting, as in step 8 of the basic protocol.
6. Place the gel on the membrane and remove bubbles.

No part of the gel should extend over the edge of the membrane.
7. Soak three pieces of Whatman 3MM paper cut to the same size as the gel with transfer buffer and place on top of the gel.
8. Place two larger pieces of Whatman 3MM paper together and soak in transfer buffer. As shown in Figure 2.9.2, place the glass dish containing transfer buffer on a support and use the two pieces of soaked Whatman 3MM paper to form a bridge between the gel and the reservoir.
9. Place a light plastic cover (e.g., a gel plate) over the top of the stack to reduce evaporation. Leave for 1 hr.
10. Remove the paper towels and filter papers and recover the membrane. Treat the membrane as described in steps 16 and 17 of the basic protocol (high-salt transfer) or step 4 of the first alternate protocol (alkaline transfer).

**ELECTROBLOTTING FROM A POLYACRYLAMIDE GEL
TO A NYLON MEMBRANE**

Capillary transfer, although reliable and needing no special equipment, has the disadvantage that it does not work with polyacrylamide gels, whose pore sizes are too small for effective transverse diffusion of DNA. Polyacrylamide gels must therefore be blotted by electrophoretic transfer. This requires a transfer buffer of low ionic strength, so nylon membranes are generally used, with uncharged nylon being slightly preferable to positively charged.

In conjunction with UV crosslinking (support protocol), this method transfers small DNA fragments and retains them quantitatively on the membrane; complete transfer and retention is crucial to the success of many procedures, including genomic sequencing and polymerase chain reaction (PCR) methods for quantitation of rare DNAs (Chapter 15). The polyacrylamide gel containing the samples of interest is placed in contact with an appropriately prepared membrane. These are then sandwiched into an electroblotting apparatus and the DNA is transferred out of the gel onto the membrane using electric current. After a buffer rinse, the membrane is ready to be UV-crosslinked.

There are several types of electroblotting apparatus on the market and the precise details of the procedure depend on the equipment being used. This protocol refers specifically to the Trans-Blot electroblotter (Bio-Rad). With a different piece of equipment, modify the procedure in accordance with the manufacturer's instructions.

Additional Materials

- 0.5× TBE electrophoresis buffer (*APPENDIX 2*)
- Scotch-Brite pads (supplied with Trans-Blot apparatus)
- Trans-Blot electroblotting cell (Bio-Rad) with cooling coil, or other electroblotting apparatus (*UNIT 10.8*)
- Additional reagents and equipment for nondenaturing (*UNIT 2.7*) or denaturing (*UNIT 2.12*) polyacrylamide gel electrophoresis and for electroblotting (*UNIT 10.8*)

CAUTION: Wear gloves to protect the membrane from contamination.

1. Run DNA samples in a nondenaturing or denaturing polyacrylamide gel.
2. When electrophoresis is almost complete, cut a piece of nylon membrane sufficient in size to cover the relevant parts of the gel. Pour distilled water ~0.5 cm deep in a glass dish. Wet the membrane by floating it on the surface of the water, then submerge it. Leave for 5 min.

The membrane need not be exactly the same size as the gel. Ensure that the membrane is large enough to cover all the DNA bands, but do not worry if not all parts of the gel are in contact with the membrane. Avoid handling the membrane even with gloved hands—use clean blunt-ended forceps instead.

3. When electrophoresis is complete, remove one glass plate from the electrophoresis apparatus and stain and photograph the gel (if nondenaturing). Cut a piece of Whatman 3MM filter paper slightly larger than the gel. Lay the filter paper on the surface of the gel and remove trapped air bubbles by rolling a glass pipet over the surface. The gel should adhere to the filter paper. Lift the gel off the glass plate by peeling the filter paper away.

This manipulation is designed to prevent breakage of a thin polyacrylamide gel. If the gel is sufficiently sturdy, it can instead be lifted directly onto a piece of Whatman 3MM paper that has been soaked in 0.5× TBE electrophoresis buffer.

4. Soak two Scotch-Brite pads in 0.5× TBE and remove air pockets by repeated

squeezing and agitation. Cut seven pieces of Whatman 3MM paper to the same size as the gel and soak these for 15 to 30 min in 0.5× TBE.

5. Place the opened gel holder of the Trans-Blot cell in a shallow tray, with the grey panel resting flat on the bottom, and place one of the saturated Scotch-Brite pads on the inner surface of the grey panel. Place three soaked filter papers on the pad. To ensure that there are no trapped air bubbles, build up the stack of filter papers one by one, carefully searching for trapped bubbles and removing them by rolling a glass pipet over the surface of the top paper.

Removing air bubbles is crucial to the success of electroblotting. It is also important that the filter papers be totally saturated with buffer. If heat build-up and bubble formation during transfer are a problem, the filters were probably not completely saturated.

6. Flood the filter paper carrying the gel with 0.5× TBE and place on top of the filter-paper stack. Flood the surface of the gel with 0.5× TBE and place the prewetted membrane onto the gel.

Again, it is important to remove air bubbles. Placing the stack on a light box makes trapped bubbles stand out more clearly.

7. Flood the surface of the membrane with 0.5× TBE and place the remaining four sheets of saturated Whatman 3MM paper on top, followed by the second saturated Scotch-Brite pad. Close the gel holder.

8. Half-fill the Trans-Blot cell with 0.5× TBE and place the gel holder in the cell with the grey panel facing towards the cathode. Fill the cell with 0.5× TBE and electroblot at 30 V (~125 mA) for 4 hr under the conditions recommended by the manufacturer.

Higher voltages can be used to reduce the transfer time (e.g., 40 V for 2 hr).

Some protocols suggest using precooled 0.5× TBE when filling the cell as well as performing the electroblotting in a cold room. This may not provide sufficient cooling to prevent heat build up and bubble formation, especially if a voltage >30 V is used. For more efficient transfer, the temperature must be kept at 4°C using the cooling coil. With other makes of equipment, it may be possible to control the temperature of the blot by circulating water from a cooling water bath.

9. Switch off the power and remove the gel holder. Take the assembly apart, marking the orientation of the membrane in pencil or by cutting a corner as in step 14 of the basic protocol.
10. If the gel was nondenaturing, denature the membrane by placing it for 10 min, DNA-side-up, on three pieces of Whatman 3MM paper soaked in 0.4 M NaOH.

This denaturation step is required for subsequent rehybridization. If the gel was run under denaturing conditions, this step is not required.

11. Rinse the membrane in 2× SSC, place on a sheet of Whatman 3MM paper, and allow to dry. Immobilize the DNA and store membranes as in steps 16 and 17 of the basic protocol.

COMMENTARY

Background Information

Southern blotting has been one of the cornerstones of DNA analysis since its first description by E.M. Southern (1975). Immobilization of DNA by binding to nitrocellulose, either powdered or in sheet form, had been utilized in biochemistry and molecular biology for several years (Hall and Spiegelman, 1961; Nygaard and Hall, 1963), but Southern was the first to show how immobilization of size-fractionated DNA fragments could be carried out in a reliable and efficient manner. The advent of Southern transfer and the associated hybridization techniques (UNIT 2.10) made it possible for the first time to obtain information about the physical organization of single and multicopy sequences in complex genomes. This expedited the first successful cloning experiments with eukaryotic genes and was directly responsible for breakthroughs such as the discovery of introns (Doel et al., 1977). The later application of Southern transfer and hybridization to the study of restriction fragment length polymorphisms (RFLPs) opened up new possibilities such as genetic fingerprinting (Jeffreys et al., 1985) and prenatal diagnosis of genetic disease (Davies, 1986).

The term Southern blotting, now used to describe any type of DNA transfer from gel to membrane, originally referred solely to capillary transfer onto nitrocellulose. The fragility of nitrocellulose membranes prompted the search for alternative types of support matrix, resulting in the introduction of nylon membranes in the early 1980s. In comparison with nitrocellulose, nylon membranes have less stringent requirements regarding the composition of the transfer buffer, and in recent years several novel buffer formulations have been devised. The most important innovation has been the use of alkaline transfer buffers with positively charged nylon membranes, resulting in immediate covalent attachment of the DNA to the membrane and thereby eliminating the need for the post-transfer immobilization steps required with nitrocellulose and uncharged nylon. Attempts have also been made to reduce the time needed for transfer by either changing the architecture of the transfer assembly (Lichtenstein et al., 1990; Chomczynski, 1992) or using noncapillary methods such as electroblotting, first described for protein transfers (Towbin et al., 1979; UNIT 10.8).

Critical Parameters

The amount of DNA that must be loaded depends on the relative abundance of the target sequence to which hybridization will take place (UNIT 2.10). The detection limit for a radioactive probe with a specific activity of 10^8 to 10^9 dpm/ μ g is about 0.5 pg DNA. Thus, for human genomic DNA, 10 μ g—equivalent to 1.5 pg of a single-copy gene 500 bp in length—is a reasonable minimum quantity to load. For more information about appropriate DNA quantities, see the commentary to UNIT 2.10.

Optimization of the parameters that influence Southern blotting must be carried out in conjunction with hybridization analysis, as the efficiency of transfer can be assessed only from the appearance of the autoradiograph obtained after the membrane is probed. It can therefore take a considerable amount of time to identify the precise conditions needed for optimal transfer, and there is often a temptation to make do with a suboptimal setup, so long as it works sufficiently well. This is understandable, but quality control of Southern transfers should not be neglected, as quite dramatic improvements can sometimes be achieved simply by using a more appropriate membrane or transfer system. The following paragraphs describe the most important factors that should be considered.

Choice of membrane

Nylon and nitrocellulose membranes have very different properties (Table 2.9.1). It is generally accepted that the main advantage of a nylon membrane is its greater tensile strength and the fact that the DNA can be bound covalently by UV crosslinking (Li et al., 1987) or, in the case of positively charged nylon, by transfer with an alkaline buffer (Reed and Mann, 1985). Nylon membranes can therefore be reprobbed up to about 12 times without becoming broken or losing their bound DNA. In contrast, nitrocellulose membranes are fragile and do not bind DNA covalently; baking to immobilize the DNA leads to a relatively weak hydrophobic attachment through exclusion of water. After about three rounds of hybridization, a nitrocellulose membrane is usually in pieces, with most of the DNA leached off (Haas et al., 1972). If reprobbing is important, then a nylon membrane (charged or uncharged) should be used.

The most clearly recognized disadvantage of nylon membranes (both charged and uncharged) is the amount of background signal

seen after hybridization. This can be a problem with any type of hybridization probe but is especially bad with some nonradioactive DNA probes (*UNITS 3.18 & 3.19*). There are several ways of reducing background hybridization signals (see *UNIT 2.10*, troubleshooting), but these may not be fully effective with a nylon membrane; if background is a problem, the only answer may be to change to nitrocellulose.

Nylon membranes are able to bind about five times more DNA per cm² than nitrocellulose (Table 2.9.1), but this is not a factor in Southern blotting, as the maximum binding capacity of the membrane is never approached. Size limits for efficient DNA retention are more important. Nylon retains DNA fragments down to 50 nucleotides in length, but nitrocellulose is inefficient with molecules <500 nucleotides. The only reason that PCR products shorter than 500 bp give reasonable hybridization signals after transfer to nitrocellulose is because there is normally a lot of DNA in the band to start with. Nitrocellulose is not a good choice for restriction-digested genomic DNA if the target band for hybridization probing is likely to be <500 bp.

In addition to nitrocellulose, uncharged nylon, and positively charged nylon, there are several other transfer matrices that are used less frequently (Table 2.9.1). Supported nitrocellulose membranes, an interesting innovation of the late 1980s, attempt to improve the tensile strength of nitrocellulose by supporting the matrix on a more rigid platform. In practice these membranes tend to combine the worst feature of nitrocellulose (loss of bound DNA) with elevated background caused by the support material. A second alternative to the “traditional” types of membrane are the activated cellulose papers, ABM- (Noyes and Stark, 1975) and APT-papers (Seed, 1982). The cellulose matrix of these papers carries aromatic groups that, after chemical activation, bind DNA covalently. These papers have relatively low binding capacities and for routine work offer no advantages over nylon (which they predated). They can, however, bind oligonucleotides down to just 2 nucleotides in length, considerably below the lower limit for nylon or nitrocellulose.

Many commercial suppliers market transfer membranes of one type or another. Quality is variable, especially with charged nylon membranes. The products listed in Table 2.9.1 reflect the author’s experiences and do not necessarily include all the reliable brands.

Transfer buffer

With nitrocellulose, the transfer buffer must provide a high ionic strength to promote binding of the DNA to the membrane (Southern, 1975; Nagamine et al., 1980). Several formulations exist, but 20× SSC is recommended because it is easy to make up and can be stored for several months at room temperature. The solution does not need to be filtered prior to use as a transfer buffer, but will need filtering if the same stock is to be used to prepare hybridization solutions (*UNIT 2.10*). Lower SSC concentrations (e.g., 10×) should not be used with nitrocellulose membranes, as the lower ionic strength may result in loss of smaller DNA fragments during transfer. In addition, alkaline transfer is not suitable for nitrocellulose membranes, as they do not retain DNA at pH 9.0 and fall apart after long exposure to alkali (Dyson, 1991).

Nylon membranes are able to bind DNA under a variety of conditions (acid, neutral, alkaline, high or low ionic strength), but a high-salt buffer such as 20× or 10× SSC appears to be beneficial (Khandjian, 1987). The addition of 2 mM *N*-laurylsarcosine (Sarkosyl) to the buffer may aid transfer to certain brands of nylon membrane (Chomczynski, 1992). Positively charged nylon membranes can be used with SSC buffers as described in the basic protocol, but this does not exploit their full potential. The ability of these membranes to bind DNA covalently after transfer in an alkaline buffer (0.4 M NaOH) is a major advantage, and the technique is well worth assessing if low efficiency is suspected with high-salt transfers. The only real problem with alkaline blotting is that high backgrounds may result if a chemiluminescent detection system (*UNIT 3.19*) is used. Alkaline transfer can also be carried out with uncharged nylon, but less DNA is retained than with charged nylon (Dyson, 1991).

Duration of transfer

The most difficult parameter to evaluate is duration of transfer. In a capillary system, rate of transfer depends on the size of the DNA, thickness of the gel, and agarose concentration. Upward capillary transfer is slow, as the architecture of the blot crushes the gel and retards diffusion of the DNA. With a high-salt buffer, it takes ~18 hr to obtain acceptable transfer of a 15-kb molecule from a 5-mm-thick 0.7% agarose gel; with the same gel 90% of the 1-kb molecules will be transferred in 2 hr. This problem is partially alleviated by the depurination step in the basic protocol, which breaks

larger molecules into fragments 1 to 2 kb in length, thereby reducing the time needed for their transfer. Even so, the blot should be left for at least 12 hr. If the gel is thicker than 5 mm or has an agarose concentration >1.0%, it cannot be assumed that the larger fragments will have transferred to a sufficient extent after 12 hr and a longer blotting period (up to 24 hr) may be necessary. The required blotting period can be assessed only by trial and error: if it is possible that the target band for the hybridization probe is >10 kb and a clear signal is not seen, the blot should be repeated using a longer transfer period.

Alkaline blots are more rapid, with most of the DNA being transferred during the first 2 hr. Therefore, if transfer of large bands is essential, alkaline transfer onto positively charged nylon should be considered as an alternative to a high-salt blot. Prolonging the alkaline transfer beyond 2 hr apparently does no harm (Chomczynski, 1992), and often these blots are left overnight.

More rapid transfers can be achieved with the downward capillary blot procedure developed by Chomczynski, described in the second alternate protocol. Variables in this system have been comprehensively evaluated (Chomczynski, 1992) and a downward blot is recommended if maximal transfer efficiency is required. If speed is more important than efficiency (e.g., if the gel being blotted contains a restriction-digested plasmid with few bands, each containing a relatively large amount of DNA) then any one of several quick-blot techniques can be used (e.g., Smith and Summers, 1980). These are not described in the protocols because in practice an overnight blot is usually just as convenient—everyone has to sleep sometime.

Transfer method

Capillary transfer is still the most popular method of Southern blotting. Its advantages are simplicity, reliability, and the lack of special equipment requirements. Alternative transfer methods have not yet achieved widespread use but are gaining prominence for certain applications.

Electroblotting, originally developed for protein transfers (see *UNIT 10.8*), does not work well with high-salt buffers and so is less appropriate for nitrocellulose membranes; it is worth attempting with nitrocellulose only if there is a really good reason for using this type of membrane (Smith et al., 1984). The technique has been applied to both nylon membranes and

activated papers (Bittner et al., 1980; Stellwag and Dahlberg, 1980), but problems often arise with overheating, which leads to bubble formation between the layers of the sandwich enclosing the gel, in turn leading to uneven transfer. Electroblotting is therefore only recommended for polyacrylamide gels, which cannot be blotted by capillary transfer.

The second alternative to capillary transfer is vacuum blotting, which was likewise first used with protein gels (Peferoen et al., 1982). The transfer buffer is drawn through the gel by vacuum pressure, enabling a 5-mm-thick 1% agarose gel to be blotted onto nitrocellulose (in 20× SSC) or nylon (in water) in as little as 30 min. The vacuum pressure must be controlled carefully to avoid compressing the gel and retarding transfer, but once mastered, the technique is very efficient. In a side-by-side comparison, a vacuum-blotted gel usually gives a significantly higher hybridization signal than a capillary blot. Reliable vacuum blotters are the StrataVac (Stratagene), VacuGene (Pharmacia Biotech), Model 785 (Bio-Rad), and TransVac (Hoefer). A protocol for their use is not provided here, as each device has its own special features; the individual manufacturer's instructions should be followed. Vacuum blotting should be seriously considered in any laboratory where Southern transfers are the rate-limiting step in the research program.

Immobilization technique

The aim of immobilization is to attach as much of the transferred DNA as possible to the membrane as tightly as possible. The standard procedures for the three common types of membranes, in increasing order of desirability, are as follows: for nitrocellulose, baking in a vacuum (leading to relatively weak noncovalent interactions), for uncharged nylon, UV irradiation (leading to covalent crosslinking), and for positively charged nylon, immobilization during alkaline transfer (giving covalent linkages).

Baking and alkaline transfer are straightforward procedures that cannot be improved on if carried out according to the instructions. UV crosslinking is more variable. Calibration of the UV source (see support protocol) is essential even if a light box rather than a transilluminator is used. Calibration should be repeated from time to time to check that the performance of the lights has not declined, and should also be carried out with each new batch of membrane, especially if the supplier has been

changed. Before irradiation, a nylon membrane must be thoroughly dried. Some manufacturers recommend air drying; others suggest a 30-min bake at 80°C. The manufacturer's recommendations should also be consulted if UV crosslinking is to be carried out after a nonalkaline transfer to a positively charged nylon membrane; with some brands, UV treatment can result in a loss of DNA.

Troubleshooting

Troubleshooting Southern blotting can be difficult and laborious, as transfer efficiency cannot be assessed accurately until the membrane has been subjected to hybridization analysis. The gel can be restained with ethidium bromide immediately after blotting in order to determine if a large quantity of DNA remains in the gel, which indicates a major problem with the transfer; however, the absence of DNA on the gel does not mean that all of it has become bound to the membrane. Bound DNA can sometimes be visualized by staining the membrane with methylene blue, but this is unreliable. Often a problem is only recognized when a less-than-perfect autoradiograph is obtained after probing, and even then it may be difficult to decide whether the transfer or hybridization technique is to blame. Discussion of how to troubleshoot Southern transfer is therefore provided in more detail in the commentary of *UNIT 2.10*.

Early warning signs of problems may be provided by the appearance of the membrane before and during transfer. Membranes should be pure white when removed from their wrapping and should remain white during the transfer and immobilization procedures. Membranes that are discolored, dusty, or dirty should not be used, and a membrane that is difficult to wet should be treated with suspicion. Yellow patches on a nitrocellulose membrane after transfer indicate inadequate neutralization. The only permissible color changes are a slight pinkness after transfer, from ethidium bromide staining of the DNA, or blue marks from transfer of the gel dye markers.

Anticipated Results

The Southern transfer procedures described in this unit should all yield a clear white membrane, possibly with pink and blue patches as described above. No data is generated until the membrane is subjected to autoradiography; anticipated results of autoradiography are discussed in the commentary to *UNIT 2.10*.

Time Considerations

The time required for Southern blotting is variable, as discussed in critical parameters. The basic protocol can be carried out in 24 hr as follows: restricting the DNA and running the agarose gel, 4 hr; preparing the gel, 2 hr; setting up the transfer, 30 min; transfer, overnight; taking the blot apart and drying the membrane, 30 min; immobilization, 2 hr for nitrocellulose, 5 min for nylon. More rapid transfer systems allow the procedure to be completed in a working day, mainly by reducing transfer time.

UNIT 2.9B

Dot and Slot Blotting of DNA

Dot and slot blotting are simple techniques for immobilizing bulk unfractionated DNA on a nitrocellulose or nylon membrane. Hybridization analysis (UNIT 2.10) can then be carried out to determine the relative abundance of target sequences in the blotted DNA preparations. Dot and slot blots differ only in the geometry of the blot, a series of spots giving a hybridization pattern that is amenable to analysis by densitometric scanning.

Samples are usually applied to the membrane using a manifold attached to a suction device. The basic protocol describes such a procedure for dot or slot blotting on an uncharged nylon membrane; annotations to the steps detail the minor modifications that are needed if blotting onto nitrocellulose. The first alternate protocol describes the more major changes required for blotting with a positively charged nylon membrane. A second alternate protocol describes preparation of dot blots by spotting the samples onto the membrane by hand.

CAUTION: In all of the protocols, wear gloves to protect your hands from the alkali solution and to protect the membrane from contamination. Avoid handling nitrocellulose and nylon membranes even with gloved hands—use clean blunt-ended forceps instead.

UNIT 2.9B

Dot and Slot Blotting of DNA

Dot and slot blotting are simple techniques for immobilizing bulk unfractionated DNA on a nitrocellulose or nylon membrane. Hybridization analysis (UNIT 2.10) can then be carried out to determine the relative abundance of target sequences in the blotted DNA preparations. Dot and slot blots differ only in the geometry of the blot, a series of spots giving a hybridization pattern that is amenable to analysis by densitometric scanning.

Samples are usually applied to the membrane using a manifold attached to a suction device. The basic protocol describes such a procedure for dot or slot blotting on an uncharged nylon membrane; annotations to the steps detail the minor modifications that are needed if blotting onto nitrocellulose. The first alternate protocol describes the more major changes required for blotting with a positively charged nylon membrane. A second alternate protocol describes preparation of dot blots by spotting the samples onto the membrane by hand.

CAUTION: In all of the protocols, wear gloves to protect your hands from the alkali solution and to protect the membrane from contamination. Avoid handling nitrocellulose and nylon membranes even with gloved hands—use clean blunt-ended forceps instead.

DOT AND SLOT BLOTTING OF DNA ONTO UNCHARGED NYLON AND NITROCELLULOSE MEMBRANES USING A MANIFOLD

Dot and slot blots are usually prepared with the aid of a manifold and suction device. This is quicker and more reproducible than manual blotting and is the method of choice if a number of blots are to be prepared at any one time. Many commercial manifolds are available, most of them with interchangeable units that provide a choice of dot- and slot-blot geometries (Fig. 2.9.3).

In this protocol, the DNA to be transferred is heat-denatured and applied to the membrane in a salt buffer. After blotting, the membrane is treated with denaturation and neutralization solutions and the DNA immobilized by UV irradiation (for nylon) or baking (for nitrocellulose).

Materials

6× and 20× SSC (APPENDIX 2)

DNA samples to be analyzed

Denaturation solution: 1.5 M NaCl/0.5 M NaOH (store at room temperature)

Neutralization solution: 1 M NaCl/0.5 M Tris·Cl, pH 7.0 (store at room temperature)

Uncharged nylon *or* nitrocellulose membrane (see Table 2.9.1, UNIT 2.9A, for suppliers)

Whatman 3MM filter paper sheets

Dot/slot blotting manifold (e.g., Bio-Rad Bio-Dot SF *or* Schleicher and Schuell Minifold II)

UV-transparent plastic wrap (e.g., Saran Wrap)

UV transilluminator (UNIT 2.5A) for nylon membranes

1. Cut a piece of nylon membrane to the size of the manifold. Pour 6× SSC to a depth of ~0.5 cm in a glass dish; place the membrane on the surface and allow to submerge. Leave for 10 min.

A nitrocellulose membrane should be wetted in 20× rather than 6× SSC.

2. Cut a piece of Whatman 3MM filter paper to the size of the manifold. Wet in 6× SSC.

Use 20× SSC if transferring onto nitrocellulose.

3. Place the Whatman 3MM paper in the manifold and lay the membrane on top of it. Assemble the manifold according to the manufacturer's instructions, ensuring that there are no air leaks in the assembly.

4. To each DNA sample, add 20× SSC and water to give a final concentration of 6× SSC in a volume of 200 to 400 μl. Denature the DNA by placing in a water bath or oven for 10 min at 100°C, then place in ice.

Figure 2.9.3 Dot (left) and slot (right) blot manifold architectures.

The amount of DNA that should be blotted will depend on the relative abundance of the target sequence that will subsequently be sought by hybridization probing (see commentaries to UNITS 2.9A & 2.10).

If using a nitrocellulose membrane, add an equal volume of 20× SSC to each sample after placing in ice.

5. Switch on the suction to the manifold device, apply 500 µl of 6× SSC to each well, and allow the SSC to filter through, leaving the suction on.

For a nitrocellulose membrane, use 20× SSC. The suction should be adjusted so that 500 µl of buffer takes ~5 min to pass through the membrane, as higher suction may damage the membrane.

Wells that are not being used can be blocked off by placing masking tape over them or by applying 500 µl of 3% (w/v) gelatin to each one (the former method is preferable, as gelatin may lead to a background signal after hybridization). Alternatively, keep all wells open and apply 6× or 20× SSC instead of sample to the extra wells.

6. Spin the DNA samples in a microcentrifuge for 5 sec. Apply to the wells being careful to avoid touching the membrane with the pipet. Allow the samples to filter through.

If any of the samples contain particulate material, blockage of the wells can be a major problem. If this occurs, add additional 6× SSC (20× SSC for nitrocellulose) and try to remove the blockage by resuspending the particles. The extra SSC must filter through the membrane, so often the blockage recurs. Increasing suction is not advisable, as it risks damaging the membrane. The best solution is to troubleshoot the DNA preparative method to avoid carryover of particles.

7. Dismantle the apparatus and place the membrane on a piece of Whatman 3MM paper soaked in denaturation solution. Leave for 10 min.
8. Transfer the membrane to a piece of Whatman 3MM paper soaked in neutralization solution. Leave for 5 min.
9. Place the membrane on a piece of dry Whatman 3MM paper and allow to dry.
10. Wrap the dry membrane in UV-transparent plastic wrap, place DNA-side-down on a UV transilluminator, and immobilize the DNA by irradiating for the appropriate time (determined as described in UNIT 2.9A support protocol).

CAUTION: Exposure to UV irradiation is harmful to the eyes and skin. Wear suitable eye protection and avoid exposure of bare skin.

UV irradiation causes DNA to become covalently bound to the nylon membrane. The membrane must be completely dry before UV crosslinking; check the manufacturer's recommendations. A common procedure is to bake for 30 min at 80°C prior to irradiation. Plastic wrap is used to protect the membrane during irradiation, but it must be UV transparent. A UV light box (e.g., Stratagene Stratalinker) can be used instead of a transilluminator (follow manufacturer's instructions).

Nitrocellulose membranes should not be UV irradiated. Instead, place between two sheets of Whatman 3 MM paper and bake under vacuum for 2 hr at 80°C.

11. Store the membrane dry between sheets of Whatman 3MM filter paper for several months at room temperature. For long-term storage, place the membrane in a desiccator at room temperature or 4°C.

DOT AND SLOT BLOTTING OF DNA ONTO A POSITIVELY CHARGED NYLON MEMBRANE USING A MANIFOLD

ALTERNATE
PROTOCOL

Positively charged nylon membranes bind DNA covalently at high pH (see UNIT 2.9A). Samples for dot or slot blotting can therefore be applied in an alkaline buffer, which promotes both denaturation of the DNA and binding to the membrane. The procedure is therefore quicker than blotting in salt buffer, as the post-blotting denaturation, neutralization, and immobilization steps are omitted.

Additional Materials

Positively charged nylon membrane (see Table 2.9.1, UNIT 2.9A, for suppliers)
0.4 M and 1 M NaOH (APPENDIX 2)
200 mM EDTA, pH 8.2 (APPENDIX 2)
2× SSC (APPENDIX 2)

1. Cut a piece of positively charged nylon membrane to the appropriate size. Pour distilled water to a depth of ~0.5 cm in a glass dish; place the membrane on the surface and allow to submerge. Leave for 10 min.
2. Prepare the blotting manifold as described in steps 2 and 3 of the basic protocol, using distilled water instead of SSC.
3. Add 1 M NaOH and 200 mM EDTA, pH 8.2, to each sample to give a final concentration of 0.4 M NaOH/10 mM EDTA. Heat for 10 min in a water bath or oven at 100°C. Microcentrifuge each tube for 5 sec.

The alkali/heat treatment denatures the DNA. The amount of DNA that should be blotted will depend on the relative abundance of the target sequence that will subsequently be sought by hybridization probing (see commentaries to UNITS 2.9A & 2.10).

4. Apply the samples to the membrane as described in steps 5 and 6 of the basic protocol, but prewash the membrane with 500 µl distilled water per well.
5. After applying the samples, rinse each well with 500 µl of 0.4 M NaOH and dismantle the manifold.
6. Rinse the membrane briefly in 2× SSC and air dry.
7. Store membrane as described in step 11 of the basic protocol.

MANUAL PREPARATION OF A DNA DOT BLOT

ALTERNATE
PROTOCOL

Dot blots can also be set up by hand simply by spotting small aliquots of each sample on to the membrane and waiting for the blot to dry. Repeated applications enable a sufficiently large volume of a dilute DNA sample to be blotted, but applying more than 30 µl is tedious and leads to untidy dots. In fact, manual application rarely produces results of publishable quality. It should be used only if no manifold is available. The protocol below details the procedure used for uncharged nylon membranes; annotations describe the changes needed to blot nitrocellulose and positively charged nylon membranes.

CAUTION: Wear gloves to protect your hands from the alkali solution and to protect the membrane from contamination. Avoid handling nitrocellulose and nylon membranes even with gloved hands—use clean blunt-ended forceps instead.

1. Cut a strip of uncharged nylon membrane to the desired size and mark out a grid of 0.5-cm × 0.5-cm squares with a blunt pencil. Pour 6× SSC to a depth of ~0.5 cm in a glass dish; place membrane on the surface and allow to submerge. Leave 10 min.

A nitrocellulose membrane should be wetted in 20× instead of 6× SSC, and a positively

Preparation and
Analysis of DNA

2.9.18

charged nylon membrane should be wetted in distilled water.

2. To each DNA sample, add $\frac{1}{2}$ vol of 20× SSC to give a final concentration of 6× SSC in the minimum possible volume. Denature the DNA by placing in a water bath or oven for 10 min at 100°C, then place in ice.

The amount of DNA that should be blotted will depend on the relative abundance of the target sequence that will subsequently be sought by hybridization probing (see commentaries to UNITS 2.9A & 2.10). The sample volume should be no more than 30 μ l and if possible much less. If necessary, reduce volume by ethanol precipitation (UNIT 2.1) before adding SSC.

If using positively charged nylon, add 1 M NaOH and 200 mM EDTA, pH 8.2, to each sample to give a final concentration of 0.4 M NaOH/10 mM EDTA, then heat as described.

If using a nitrocellulose membrane, add an equal volume of 20× SSC to each sample after placing on ice.

3. Place the wetted membrane over the top of an open plastic box so that the bulk of the membrane is freely suspended.
4. Spin each sample in a microcentrifuge for 5 sec, spot onto the membrane using a pipet, and allow to dry.

Do not touch the membrane with the pipet when applying the samples. Up to 2 μ l can be spotted in one application. If the sample volume is >2 μ l, it should be applied in successive 2- μ l aliquots, with each spot being allowed to dry before the next aliquot is applied on top. Drying can be aided with a hair dryer, but be careful that the blower does not spread the sample over the surface of the membrane. Try to keep the diameter of each dot to <4 mm.

5. For an uncharged nylon or nitrocellulose membrane, denature, neutralize, and immobilize as described in steps 7 to 10 of the basic protocol.

For a positively charged nylon membrane, rinse and dry as described in step 6 of the first alternate protocol.

6. Store membrane as described in step 11 of the basic protocol.

COMMENTARY

Background Information

Dot or slot blotting followed by hybridization analysis (UNIT 2.10) was first developed by Kafatos et al. (1979). The procedure is used to determine the relative abundance of a target sequence in a series of DNA samples. If a manifold is used, a large number of samples can be applied at once, enabling many different DNAs to be screened in a single hybridization experiment. The technique has found many applications over the years. For instance, in genome analysis, information on the genetic significance of a DNA sequence can often be obtained by using the sequence as a hybridization probe to dot blots of DNA prepared from related species. The rationale is that most genes have homologs in related organisms; for example, a coding sequence from the human genome will probably hybridize to related sequences in

dot blots prepared from DNA of various mammals. An intergenic or intronic region, which is less likely to have homologs in the other species, will probably not show widespread hybridization. This is the so-called “zoo blot” approach; blots containing DNA from a variety of related species are available ready-made from a number of suppliers.

Critical Parameters

The key requirement with dot blotting is that the DNA be fully denatured after transfer, or at least that all the samples be denatured to the same extent. The underlying assumption of dot blot analysis—that it can be used for meaningful comparisons of sequence abundance in different DNA samples—holds only if denaturation is precisely controlled. Variations in denaturation result in different samples having

different amounts of hybridizable DNA; if this occurs, the relative intensities displayed by two dots after hybridization will not be representative of the amount of target DNA that each contains.

The protocols for blotting uncharged nylon and nitrocellulose membranes attempt to ensure complete denaturation through the use of two denaturation steps—a heat denaturation before application to the membrane and an alkaline denaturation after application. Heat denaturation on its own is rarely adequate, as the DNA can renature fairly extensively before application to the membrane, even if plunged into ice on removal from the incubator. Blotting, whether manual or with a manifold, takes time, with some samples being blotted more quickly than others, so differential renaturation is a possibility. The second denaturation step, when the membrane is placed on a filter paper soaked in alkali, is intended to bring all the DNA back to an equal standing. Note that these problems do not arise with alkaline blotting onto positively charged nylon, as the high pH of the blotting solution maintains the DNA in a denatured state. Alkaline blotting is therefore the method of choice for DNA dot and slot blots where comparisons between different samples are to be made.

A second variable results from the purity of the DNA samples. With a Southern transfer, the gel electrophoresis step helps to fractionate away impurities, so the DNA that is transferred is relatively clean. Dot/slot blotting with bulk DNA lacks the benefit of a gel fractionation step, and the resulting co-blotted impurities can have unpredictable effects on hybridization, possibly reducing signal by blocking access to the hybridization sites, or increasing signal by trapping the probe. This must be taken into account if the signal intensity is to be used to estimate the absolute amount of target DNA, through comparison with a control dilution series. Copy number reconstruction by dot blot analysis is particularly suspect, as comparison between blots of cellular and plasmid DNA are reliable only if both types of DNA are scrupulously purified.

Troubleshooting

As with Southern blotting (*UNIT 2.9A*), most

problems with dot and slot blots become apparent only after hybridization analysis. The warning signs detailed in the commentary to *UNIT 2.9A* also hold for dot/slot blotting; other problems are described in *UNIT 2.10* (see Table 2.10.4 for troubleshooting).

Anticipated Results

The procedures yield a clear white membrane carrying applied DNA in amounts up to the carrying capacity of the matrix (Table 2.9.1, *UNIT 2.9A*). No data is generated until the membrane is subjected to autoradiography; anticipated results of autoradiography are discussed in *UNIT 2.10*.

Time Considerations

A manifold or manual blot can be set up and ready for sample application in as little as 15 min. After sample application, it takes about 3 hr to complete the protocol with a nitrocellulose membrane (most of this being the baking step), 60 min with an uncharged nylon membrane, and 30 min with a positively charged nylon membrane. The rate-determining step is sample application. Manifold application of clean samples (where no blockages occur) takes 5 min, but application by hand can take several hours if the sample volume is large and multiple additions have to be made.

Hybridization Analysis of DNA Blots

The principle of hybridization analysis is that a single-stranded DNA or RNA molecule of defined sequence (the “probe”) can base-pair to a second DNA or RNA molecule that contains a complementary sequence (the “target”), with the stability of the hybrid depending on the extent of base pairing that occurs. Experimentally, the analysis is usually carried out with a probe that has been labeled and target DNA that has been immobilized on a membrane support. Hybridization analysis is sensitive and permits detection of single-copy genes in complex genomes. The technique has widespread applications in molecular biology.

The first stage in a hybridization experiment is to immobilize the denatured nucleic acids on a suitable solid support. Methods for achieving this with gel-fractionated and bulk DNA are described in *UNITS 2.9A & 2.9B*. The labeled probe is then applied in a solution that promotes hybridization. After a suitable incubation, the membrane is washed so that any nonspecifically bound probe is removed, leaving only probe that is base-paired to the target DNA. By controlling the stringency of the washing conditions, decisions can be made about whether to target sequences that are 100% complementary to the probe, or allow some mismatching so that sequences with lower degrees of similarity are also detected. The latter approach (heterologous probing) is used to study related sequences in a single or more than one genome.

Hybridization analysis was originally carried out with long (100 to 1000 bp), radioactively labeled DNA probes. Other types of probe (RNA, oligonucleotide) have more recently been introduced, as have nonradioactive labeling and detection strategies. In addition, improvements in understanding of the factors that influence hybrid stability and hybridization rate have led to a proliferation of reagents and protocols for hybridization analysis. Finding one’s way through the maze can be a daunting task, especially as protocols that work well with one probe-target combination may not work so well if either member of the partnership is changed. The approach taken here is to present as the basic protocol an unsophisticated procedure for hybridization analysis with a radiolabeled DNA probe. Despite its lack of embellishments, the protocol gives acceptable results with Southern and dot blots on nitrocellulose and nylon (uncharged and charged) membranes. The alternate protocol describes a similar method for probing DNA blots with a radiolabeled RNA probe. A support protocol for stripping blots to ready them for reprobing is also provided.

Relevant units elsewhere in the manual include the following: *UNITS 3.18 & 3.19* describe the preparation of nonradioactive probes and their use in hybridization analysis; *UNIT 4.9* covers hybridization analysis of immobilized RNA; *UNIT 6.3* describes hybridization analysis of recombinant clone libraries; and *UNIT 6.4* explains how to use labeled oligonucleotides as hybridization probes.

These hybridization protocols should not be read in isolation. The commentary describes various modifications that can be introduced, including changes to prehybridization, hybridization, and wash solution formulations, and alterations to incubation times and conditions, the latter including a discussion of the wash conditions compatible with different degrees of stringency. The intention is provide the reader with sufficient data to make well-informed decisions about how to modify the basic and alternate protocols for specific applications.

CAUTION: Investigators should wear gloves for all procedures involving radioactivity and should be careful not to contaminate themselves and their clothing. When working with ^{32}P , investigators should frequently check themselves and the working area for

radioactivity using a hand-held monitor. Any radioactive contamination should be cleaned up using appropriate procedures. Radioactive waste should be placed in appropriately designated areas for disposal. Follow the guidelines provided by your local radiation safety adviser.

HYBRIDIZATION ANALYSIS OF A DNA BLOT WITH A RADIOLABELED DNA PROBE

BASIC PROTOCOL

This protocol is suitable for hybridization analysis of Southern transfers (*UNIT 2.9A*) and dot and slot blots (*UNIT 2.9B*) with a radioactively labeled DNA probe 100 to 1000 bp in length. The steps employ nylon membranes (uncharged or positively charged) but are suitable for nitrocellulose if modified as described in the annotations. The commentary describes how to tailor the protocol for individual requirements.

A hybridization experiment can be divided into three stages. First, the membrane is incubated in a prehybridization solution containing reagents that block nonspecific DNA binding sites on its surface, thereby reducing background hybridization. In this protocol, the blocking agents are Denhardt solution and denatured salmon sperm DNA; alternatives are described in the commentary. In the second stage, the prehybridization solution is replaced by fresh buffer containing the labeled probe, and an overnight incubation is carried out to allow the probe to bind to target sequences in the immobilized DNA. During this hybridization step, the probe pairs not only with target sites that have 100% complementarity with the probe, but also with related sequences. In the final stage of the experiment the membrane is washed with a series of solutions that gradually remove bound probe molecules until only highly matched hybrids remain.

Materials

DNA to be used as probe

Aqueous prehybridization/hybridization (APH) solution, room temperature and 68°C

2× SSC/0.1% (w/v) SDS

0.2× SSC/0.1% (w/v) SDS, room temperature and 42°C

0.1× SSC/0.1% (w/v) SDS, 68°C

2× and 6× SSC (*APPENDIX 2*)

Hybridization oven (e.g., Hybridiser HB-1, Techne) *or* 68°C water bath *or* incubator

Hybridization tube *or* sealable bag and heat sealer

Additional reagents and equipment for DNA labeling by nick translation or random oligonucleotide priming (*UNIT 3.5*), measuring the specific activity of labeled DNA and separating unincorporated nucleotides from labeled DNA (*UNIT 3.4*), and autoradiography (*APPENDIX 3*)

1. Label the probe DNA to a specific activity of $>1 \times 10^8$ dpm/μg by nick translation or random oligonucleotide priming. Measure the specific activity and remove unincorporated nucleotides.

The probe should be a double-stranded DNA fragment, ideally 100 to 1000 bp in length. Usually the probe DNA is obtained as a cloned fragment (Chapter 1) which is purified from the vector by restriction digestion (UNIT 3.1) followed by recovery from an agarose gel (UNIT 2.6).

2. Wet the membrane carrying the immobilized DNA in 6× SSC.

The membrane is blotted as described in UNIT 2.9A. Do not handle the membrane: use clean blunt-ended forceps.

Preparation and Analysis of DNA

2.10.2

3. Place the membrane, DNA-side-up, in a hybridization tube and add ~1 ml APH solution per 10 cm² of membrane.

Prehybridization and hybridization are usually carried out in glass tubes in a commercial hybridization oven. Alternatively, a heat-sealable polyethylene bag can be used. The membrane should be placed in the bag, all edges sealed using a heat sealer, and a corner cut off. The APH solution is then pipetted into the bag through the cut corner and resealed.

4. Place the tube in the hybridization oven and incubate 3 hr with rotation at 68°C.

If using a bag, shake slowly in a suitable incubator or water bath.

If using a nylon membrane, reduce the prehybridization period to 15 min, but warm the prehybridization/hybridization solution to 68°C before adding to the membrane.

5. Denature the probe DNA by heating for 10 min in a water bath or incubator at 100°C. Place in ice.

Step 5 should be done immediately before step 6, with a minimum delay between them.

6. Pour the APH solution from the hybridization tube and replace with an equal volume of prewarmed (68°C) APH solution. Add denatured probe and incubate with rotation overnight at 68°C.

The probe concentration in the hybridization solution should be 10 ng/ml if the specific activity is 10⁸ dpm/μg, or 2 ng/ml if the specific activity is 1 × 10⁹ dpm/μg. If using a bag, cut off a corner, pour out the prehybridization solution, add the hybridization solution plus probe, and reseal. It is very difficult to avoid contaminating the bag sealer with radioactivity; furthermore, the sealing element (the part that gets contaminated) is often difficult to clean. Hybridization bags are therefore not recommended.

7. Pour out the APH solution, using the appropriate disposal method for radioactive waste, and add an equal volume of 2× SSC/0.1% SDS. Incubate with rotation for 10 min at room temperature, changing the wash solution after 5 min.

CAUTION: *All wash solutions must be treated as radioactive waste and disposed of appropriately.*

To reduce background, it may be beneficial to increase the volume of the wash solutions by 100%. If using a bag, transfer the membrane to a plastic box for the washes.

8. Replace the wash solution with an equal volume of 0.2× SSC/0.1% SDS and incubate with rotation 10 min at room temperature, changing the wash solution after 5 min (this is a low-stringency wash; see commentary).

9. If desired, carry out two further washes as described in step 8 using prewarmed (42°C) 0.2× SSC/0.1% SDS for 15 min each at 42°C (moderate-stringency wash).

10. If desired, carry out two further washes using prewarmed (68°C) 0.1× SSC/0.1% SDS for 15 min each at 68°C (high-stringency wash).

11. Pour off the final wash solution, rinse the membrane in 2× SSC at room temperature, and blot excess liquid. Wrap in plastic wrap.

Do not allow the membrane to dry out if it is to be reprobbed.

12. Set up an autoradiograph (APPENDIX 3).

HYBRIDIZATION ANALYSIS OF A DNA BLOT WITH A RADIOLABELED RNA PROBE

ALTERNATE PROTOCOL

Purified RNA polymerases from bacteriophages such as SP6, T3, and T7 (*UNIT 3.8*) are very efficient at synthesizing RNA *in vitro* from DNA sequences cloned downstream of the appropriate phage promoter (Little and Jackson, 1987). Several micrograms of RNA can be obtained from 1 μg of DNA template in a 10-min reaction. If a radiolabeled ribonucleotide is added to the reaction mixture, the polymerase synthesizes uniformly labeled RNA with specific activities up to and beyond 10^9 dpm/ μg . The fact that RNA probes are single-stranded gives them certain advantages over DNA probes. RNA probes do not need to be denatured before being added to the hybridization solution, and remain fully available for hybridization during the course of the incubation. In contrast, the “potency” of a double-stranded DNA probe gradually declines as the complementary strands of the probe reanneal during the hybridization reaction, reducing the amount of probe available to hybridize to the target.

The hybridization protocol for an RNA probe is not greatly different from that with labeled DNA. Formamide is usually included in the prehybridization/hybridization solutions, because in the presence of formamide an RNA-DNA hybrid is more stable than the equivalent DNA-DNA hybrid. Carrying out the hybridization with formamide also permits the incubation to be at a lower temperature without loss of stringency. Single-strand-specific RNases are added to one or more of the wash solutions to remove nonhybridized probe molecules, considerably reducing background.

The protocol includes details of probe preparation (Mundy et al., 1991). The hybridization procedure is suitable for both nitrocellulose and nylon membranes, though backgrounds may be higher with nylon.

Additional Materials

- TE buffer, pH 8.0 (*APPENDIX 2*)
 - Labeling buffer
 - Nucleotide mix
 - 200 mM dithiothreitol (DTT), freshly prepared
 - 20 U/ μl human placental ribonuclease inhibitor
 - [α - ^{32}P]UTP: 20 mCi/ml (800 Ci/mmol) or 10 mCi/ml (400 Ci/mmol)
 - SP6 or T7 RNA polymerase (*UNIT 3.8*)
 - RNase-free DNase I (*UNIT 3.12*)
 - 0.25 M EDTA, pH 8.0 (*APPENDIX 2*)
 - Formamide prehybridization/hybridization (FPH) solution
 - 2 \times SSC (*APPENDIX 2*) containing 25 $\mu\text{g}/\text{ml}$ RNase A + 10 U/ml RNase T1 (*UNIT 3.13*)
- Additional reagents and equipment for cloning and purifying plasmid DNA (Chapter 1), phenol extraction and ethanol precipitation (*UNIT 2.1*), restriction digestion of DNA (*UNIT 3.1*), measuring the specific activity of and separating unincorporated nucleotides from labeled RNA (*UNIT 3.4*), and autoradiography (*APPENDIX 3*)

Prepare the RNA probe

1. Clone into a suitable vector (Table 2.10.1) the DNA fragment that will be transcribed into the RNA probe.

DNA must be of high purity, so use a method that includes a CsCl/ethidium bromide equilibrium centrifugation step (UNIT 1.7).

2. Linearize the DNA by restriction digestion immediately downstream of the cloned fragment.

Preparation and Analysis of DNA

2.10.4

Linearization introduces an endpoint for RNA synthesis. This ensures that enzymes and substrates are not wasted by transcribing downstream vector DNA, and also increases the specificity of the probe by excluding unwanted sequences.

3. Purify the DNA from the restriction enzyme by phenol extraction and ethanol precipitation. Resuspend in TE buffer, pH 8.0, at a concentration of 1 mg/ml.

4. Mix the following at room temperature:

- 4 μ l labeling buffer
- 1.5 μ l nucleotide mix
- 1 μ l 200 mM DTT
- 1 μ l (20 U) human placental ribonuclease inhibitor
- 2 μ g purified plasmid DNA from step 3
- 100 to 200 μ Ci [α -³²P]UTP
- H₂O to a final volume of 20 μ l.

These are mixed at room temperature, as the spermidine in the labeling buffer may precipitate on ice.

5. Add 5 U SP6 or T7 RNA polymerase. Incubate for 1 hr at 40°C for SP6 or at 37°C for T7.

6. Add 2 U RNase-free DNase I and incubate at 10 min 37°C. Stop the reaction by adding 2 μ l of 0.25 M EDTA, pH 8.0.

DNase treatment degrades the template. This step may not be necessary for probes to be used in hybridization analysis, but is worth doing to be on the safe side.

7. Measure the specific activity of the RNA by acid precipitation and remove unincorporated nucleotides by the spin-column procedure.

The specific activity should be at least 7×10^8 dpm/ μ g, preferably $>10^9$ dpm/ μ g.

The labeled probe can be stored at -20°C for 2 days before use.

Carry out hybridization analysis

8. Carry out the prehybridization incubation as described in steps 2 to 4 of the basic protocol, but use FPH solution and incubate at 42°C.

9. Replace the FPH solution with an equal volume of fresh prewarmed solution. Add the labeled probe and incubate overnight with rotation at 42°C.

The probe concentration in the hybridization solution should be 1 to 5 ng/ml. Hybridizations in formamide solutions are carried out at lower temperatures than aqueous hybridizations. However, if background hybridization is a problem, raise the incubation temperature to 65°C.

10. Wash the membrane as described in steps 7 to 8 of the basic protocol.

11. Replace the wash solution with an equal volume of 2 \times SSC containing 25 μ g/ml RNase A + 10 U/ml RNase T1; incubate with rotation for 30 min at room temperature.

The RNase wash decreases background hybridization.

12. Carry out moderate- and high-stringency washes as desired, rinse the membrane in 2 \times SSC, and set up autoradiograph as in steps 9 to 12 of the basic protocol.

Table 2.10.1 Selection of Cloning Vectors Incorporating Promoters for Bacteriophage RNA Polymerases

REMOVAL OF PROBES FROM HYBRIDIZED MEMBRANES

If the DNA has been immobilized on the membrane by UV crosslinking (for uncharged nylon membranes) or by alkaline transfer (for positively charged nylon), the matrix-target DNA interaction (which is covalent in nature) is much stronger than the target-probe interaction (which results from hydrogen bonding). It is therefore possible to remove (or “strip off”) the hybridized probe DNA without removing the membrane-bound target DNA. Nylon membranes can therefore be reused several times—a dozen reprobings are routinely possible. Hybridized probe DNA can also be stripped from nitrocellulose membranes, but the weakness of the hydrophobic interactions that bind the target DNA to the matrix, plus the fragility of nitrocellulose, limits the lifetime of these membranes to three reprobings at most.

This protocol describes three methods for probe stripping, in order of increasing harshness. The treatment that is needed depends on how tightly the probe anneals to the target, which in turn depends on the GC content of the probe and the number of base pairs that are formed. To start with, use the least harsh treatment, monitoring the results by autoradiography of the stripped membrane. If a hybridization signal can still be seen, move up to a harsher method. To strip probe from a northern membrane (with immobilized RNA), use the mild treatment only. Do not add NaOH to RNA; it will be destroyed.

Additional Materials

Mild stripping solution
Moderate stripping solution
0.4 M NaOH
0.1% (w/v) SDS, 100°C

CAUTION: Although the stripping solutions may not become highly radioactive, they should still be disposed of as radioactive waste.

- 1a. *Mild treatment:* Wash the membrane in several hundred milliliters of mild stripping solution for 2 hr at 65°C.
- 1b. *Moderate treatment:* Wash the membrane in 0.4 M NaOH for 30 min at 45°C. Then rinse twice in several hundred milliliters of moderate stripping solution for 10 min at room temperature.

SUPPORT PROTOCOL

Preparation and Analysis of DNA

2.10.6

- 1c. *Harsh treatment:* Pour several hundred milliliters of boiling 0.1% SDS onto the membrane. Cool to room temperature.

If a membrane is to be reprobbed, it must not be allowed to dry out between hybridization and stripping. If it becomes dry, the probe may bind to the matrix.

2. Place membrane on a sheet of dry Whatman 3MM filter paper and blot excess liquid with a second sheet. Wrap the membrane in plastic wrap and set up an autoradiograph.

If signal is still seen after autoradiography, rewash using harsher conditions.

3. The membrane can now be rehybridized. Alternatively, it can be dried and stored for later use.

Membranes can be stored dry between Whatman 3MM paper for several months at room temperature. For long-term storage, place the membranes in a desiccator at room temperature or 4°C.

REAGENTS AND SOLUTIONS

Aqueous prehybridization/hybridization (APH) solution

- 5× SSC (APPENDIX 2)
- 5× Denhardt solution (APPENDIX 2)
- 1% (w/v) SDS

Add 100 µg/ml denatured salmon sperm DNA (see below) just before use

Alternatives to Denhardt solution and denatured salmon sperm DNA as blocking agents are listed in Table 2.10.5 (see discussion in critical parameters).

Denatured salmon sperm DNA

Dissolve 10 mg Sigma type III salmon sperm DNA (sodium salt) in 1 ml water. Pass vigorously through a 17-G needle 20 times to shear the DNA. Place in a boiling water bath for 10 min, then chill. Use immediately or store at -20°C in small aliquots. If stored, reheat to 100°C for 5 min and chill on ice immediately before using.

Formamide prehybridization/hybridization (FPH) solution

- 5× SSC (APPENDIX 2)
- 5× Denhardt solution (APPENDIX 2)
- 50% (w/v) formamide
- 1% (w/v) SDS

Add 100 µg/ml denatured salmon sperm DNA (see above) just before use

Alternatives to Denhardt solution and denatured salmon sperm DNA as blocking agents are listed in Table 2.10.5 (see discussion in critical parameters).

Commercial formamide is usually satisfactory for use. If the liquid has a yellow color, deionize as follows: add 5 g of mixed-bed ion-exchange resin [e.g., Bio-Rad AG 501-X8 or 501-X8(D) resins] per 100 ml formamide, stir at room temperature for 1 hr, and filter through Whatman no. 1 paper.

CAUTION: Formamide is a teratogen. Handle with care.

Labeling buffer

- 200 mM Tris·Cl, pH 7.5
- 30 mM MgCl₂
- 10 mM spermidine

Mild stripping solution

- 5 mM Tris·Cl, pH 8.0
- 2 mM EDTA
- 0.1× Denhardt solution (APPENDIX 2)

Moderate stripping solution

200 mM Tris·Cl, pH 7.0
0.1× SSC (APPENDIX 2)
0.1% (w/v) SDS

Nucleotide mix

2.5 mM ATP
2.5 mM CTP
2.5 mM GTP
20 mM Tris·Cl, pH 7.5
Store at −20°C

COMMENTARY

Background Information

Hybridization between complementary polynucleotides was implicit in the Watson-Crick model for DNA structure and was initially exploited, via renaturation kinetics, as a means of studying genome complexity. In these early applications, the two hybridizing molecules were both in solution—an approach that is still utilized in “modern” techniques such as nuclease protection transcript mapping (UNITS 4.6 & 4.7) and oligonucleotide-directed mutagenesis (Chapter 8). The innovative idea of immobilizing one hybridizing molecule on a solid support was first proposed by Denhardt (1966) and led to methods for identification of specific sequences in genomic DNA (dot blotting; UNIT 2.9B) and recombinant clones (UNITS 6.3 & 6.4). A second dimension was subsequently introduced by Southern (1975), who showed how DNA molecules contained in an electrophoresis gel could be transferred to a membrane (UNIT 2.9A), enabling genetic information relating to individual restriction fragments to be obtained by hybridization analysis.

Since the pioneering work of Denhardt and Southern, advances in membrane hybridization have been technical rather than conceptual. As reviewed by Dyson (1991), the detailed protocols have become more sophisticated, largely because of advances in understanding of the factors that influence hybrid stability and hybridization rate.

Hybrid stability is expressed as the melting temperature or T_m , which is the temperature at which the probe dissociates from the target DNA. For DNA-DNA hybrids, the T_m can be approximated from the equation of Meinkoth and Wahl (1984):

$$T_m = 81.5^\circ\text{C} + 16.6 (\log M) + 0.41(\%GC) - 0.61 (\%form) - 500/L$$

and for RNA-DNA hybrids from the equation of Casey and Davidson (1977):

$$T_m = 79.8^\circ\text{C} + 18.5(\log M) + 0.58(\%GC) - 11.8(\%GC)^2 - 0.56(\%form) - 820/L$$

where M is the molarity of monovalent cations, %GC is the percentage of guanosine and cyto-

sine nucleotides in the DNA, %form is the percentage of formamide in the hybridization solution, and L is the length of the hybrid in base pairs. The practical considerations that arise from these two equations are summarized Table 2.10.2A.

The second important consideration in hybridization analysis is the rate at which the hybrid is formed. Hybrid formation cannot occur until complementary regions of the two molecules become aligned, which occurs purely by chance; however, once a short nucleating region of the duplex has formed, the remaining sequences base-pair relatively rapidly. The rate at which the probe “finds” the target, which is influenced by a number of factors (Table 2.10.2B), is therefore the limiting step in hybrid formation (Britten and Davidson, 1985). However, in practical terms hybridization rate is less important than hybrid stability, as in most protocols hybridization is allowed to proceed for so long that factors influencing rate become immaterial.

Critical Parameters

To be successful, a hybridization experiment must meet two criteria:

(1) *Sensitivity*. Sufficient probe DNA must anneal to the target to produce a detectable signal after autoradiography.

(2) *Specificity*. After the last wash, the probe must be attached only to the desired target sequence (or, with heterologous probing, family of sequences).

Parameters influencing these two criteria are considered in turn, followed by other miscellaneous factors that affect hybridization.

Factors influencing sensitivity

The sensitivity of hybridization analysis is determined by how many labeled probe molecules attach to the target DNA. The greater the number of labeled probe molecules that anneal, the greater the intensity of the hybridization signal seen after autoradiography.

Probe specific activity. Of the various factors that influence sensitivity, the one that most

frequently causes problems is the specific activity of the probe. Modern labeling procedures, whether nick translation, random oligonucleotide priming (UNIT 3.5), or in vitro RNA synthesis (alternate protocol), routinely provide probes with a specific activity of $>10^8$ dpm/ μ g. This is the minimum specific activity that should be used in hybridization analysis of genomic DNA, even if the target sequences are multicopy. If the specific activity is $<10^8$ dpm/ μ g, hybridization signals will be weak or possibly undetectable, and no amount of adjusting the hybridization conditions will compensate. If there is a problem in obtaining a specific activity of $>10^8$ dpm/ μ g, it is important to troubleshoot the labeling protocol before attempting to use the probe in hybridization analysis.

If the probe is labeled to 10^8 to 10^9 dpm/ μ g, it will be able to detect as little as 0.5 pg of target DNA. Exactly what this means depends on the size of the genome being studied and the copy number of the target sequence. For human genomic DNA, 0.5 pg of a single-copy sequence 500 bp in length corresponds to 3.3 μ g

of total DNA. This is therefore the minimum amount of human DNA that should be used in a dot blot or Southern transfer if a single-copy gene is being sought.

Amount of target DNA. There is, however, a second argument that dictates that rather more than 3.3 μ g of DNA should be loaded with each dot or Southern blot. During hybridization, genuine target sequences (100% homologous to the probe) and heterologous target sequences (related but not identical to the probe) compete with one another, with the homologous reactions always predominant. Ideally this competition should be maintained until the end of the incubation period so that maximum discrimination is seen between homologous and heterologous signals. This occurs only if the membrane-bound DNA is in excess, so that target sequences are continually competing for the available probe (Anderson and Young, 1985). If the probe is in excess then the homologous reaction may reach completion (i.e., all genuine target sites become filled) before the end of the incubation, leaving a period when only

Table 2.10.2 Factors Influencing Hybrid Stability and Hybridization Rate^a

Factor	Influence
A. Hybrid stability^b	
Ionic strength	T_m increases 16.6°C for each 10-fold increase in monovalent cations between 0.01 and 0.40 M NaCl
Base composition	AT base pairs are less stable than GC base pairs in aqueous solutions containing NaCl
Destabilizing agents	Each 1% of formamide reduces the T_m by about 0.6°C for a DNA-DNA hybrid. 6 M urea reduces the T_m by about 30°C
Mismatched base pairs	T_m is reduced by 1°C for each 1% of mismatching
Duplex length	Negligible effect with probes >500 bp
B. Hybridization rate^b	
Temperature	Maximum rate occurs at 20-25°C below T_m for DNA-DNA hybrids, 10-15°C below T_m for DNA-RNA hybrids
Ionic strength	Optimal hybridization rate at 1.5 M Na^+
Destabilizing agents	50% formamide has no effect, but higher or lower concentrations reduce the hybridization rate
Mismatched base pairs	Each 10% of mismatching reduces the hybridization rate by a factor of two
Duplex length	Hybridization rate is directly proportional to duplex length
Viscosity	Increased viscosity increases the rate of membrane hybridization; 10% dextran sulfate increases rate by factor of ten
Probe complexity	Repetitive sequences increase the hybridization rate
Base composition	Little effect
pH	Little effect between pH 5.0 and pH 9.0

^aThis table is based on Brown (1991) with permission from BIOS Scientific Publishers.

^bThere have been relatively few studies of the factors influencing membrane hybridization. In several instances extrapolations are made from what is known about solution hybridization. This is probably reliable for hybrid stability, less so for hybridization rate.

heterologous hybridization is occurring and during which discrimination between the homologous and heterologous signals becomes reduced. The problem is more significant with a double-stranded rather than a single-stranded probe, as with double-stranded probe reannealing between the two probe polynucleotides gradually reduces the effective probe concentration to such an extent that it always becomes limiting towards the end of the incubation.

In practical terms it is difficult to ensure that the membrane-bound DNA is in excess. The important factor is not just the absolute amount of DNA (which is dependent on the efficiency of immobilization and how many times the membrane has been reprobed) but also the proportion of the DNA that is composed of sequences (homologous and heterologous) able to hybridize to the probe. Rather than attempting complex calculations whose results may have factor-of-ten errors, it is advisable simply to blot as much DNA as possible: 10 μ g is sufficient with most genomes. Assuming that the probe is labeled adequately and used at the correct concentration in the hybridization solution, a clear result will be obtained after autoradiography for a few hours with a simple genome (e.g., yeast DNA) or a few days with a more complex one (e.g., human DNA).

Labels other than ^{32}P . The discussion so far has assumed that the probe is labeled with ^{32}P . The lower emission energy of ^{35}S results in reduced sensitivity, and this isotope is in general unsuitable for hybridization analysis of genomic DNA. ^{35}S can be used only if the blotted DNA is exceptionally noncomplex (e.g., restricted plasmid DNA), or if the DNA is highly concentrated (e.g., colony and plaque blots; *UNIT 6.3*). Note that a membrane hybridized to a ^{35}S -labeled probe has to be dried before autoradiography, so probe stripping is not possible.

Nonradioactive probes are a more realistic option for hybridization analysis of genomic DNA and are becoming increasingly popular as the problems involved in their use are gradually ironed out. Their advantages include greater safety, the fact that large amounts of probe can be prepared in one batch and stored for years, and the rapidity of the detection protocols. Their main disadvantage is that the sensitivity of most nonradioactive detection systems is lower than that of ^{32}P autoradiography, which means that the blot and hybridization have to be carried out at maximum efficiency if a satisfactory signal is to be seen. For details on hybridization analysis with nonra-

dioactive probes, see *UNITS 3.18 & 3.19* and Mundy et al. (1991).

Using an inert polymer to increase sensitivity. In addition to adjusting the parameters discussed above, an improvement in sensitivity can also be achieved by adding an inert polymer such as 10% (w/v) dextran sulfate (molecular weight 500,000) or 8% (w/v) PEG 6000 to the hybridization solution. Both induce an increase in hybridization signal, 10-fold with a single-stranded probe and as much as 100-fold if the probe is double-stranded (Wahl et al., 1979; Amasino, 1986). The improvement is thought to arise from formation of interlocked meshes of probe molecules, which anneal en masse at target sites. Increased hybridization signals are a major bonus in detecting single-copy sequences in complex genomes, but this must be balanced with the fact that the polymers make the hybridization solutions very viscous and difficult to handle.

Factors influencing specificity

Ensuring specificity in homologous hybridization experiments. The hybridization incubation is carried out in a high-salt solution that promotes base-pairing between probe and target sequences. In $5\times$ SSC, the T_m for genomic DNA with a GC content of 50% is about 96°C . Hybridization is normally carried out at 68°C , so the specificity of the experiment is not determined at this stage. Specificity is the function of post-hybridization washes, the critical parameters being the ionic strength of the final wash solution and the temperature at which this wash is carried out.

The highly stringent wash conditions described in the basic and alternate protocols should destabilize all mismatched heteroduplexes, so that hybridization signals are obtained only from sequences that are perfectly homologous to the probe. For DNA and RNA probes (as opposed to oligonucleotides), problems with lack of specificity after the highly stringent wash occur only if the hybridizing sequences are very GC-rich, resulting in a relatively high T_m . If the high-stringency wash does not remove all nonspecific hybridization, temperature can be increased by a few degrees. The equations above for calculating T_m can be used as a guide for selecting the correct temperature for the final wash, but trial and error is more reliable. Note that a membrane that has been autoradiographed can be rewashed at a higher stringency and put back to expose again, the only limitation being decay of the label and the need for a longer exposure the second time.

Table 2.10.3 High-Salt Solutions Used in Hybridization Analysis

Stock solution	Composition
20× SSC	3.0 M NaCl/0.3 M trisodium citrate
20× SSPE ^a	3.6 M NaCl/0.2 M NaH ₂ PO ₄ /0.02 M EDTA, pH 7.7
Phosphate solution ^b	1 M NaHPO ₄ , pH 7.2 ^c

^aSSC may be replaced with the same concentration of SSPE in all protocols.

^bPrehybridize and hybridize with 0.5 M NaHPO₄ (pH 7.2)/1 mM EDTA/7% SDS [or 50% formamide/0.25 M NaHPO₄ (pH 7.2)/0.25 M NaCl/1 mM EDTA/7% SDS]; perform moderate-stringency wash in 40 mM NaHPO₄ (pH 7.2)/1 mM EDTA/5% SDS; perform high-stringency wash in 40 mM NaHPO₄ (pH 7.2)/1 mM EDTA/1% SDS.

^cDissolve 134 g Na₂HPO₄·7H₂O in 1 liter water, then add 4 ml 85% H₃PO₄. The resulting solution is 1 M Na⁺, pH 7.2.

Designing washes for heterologous hybridization. Calculations of T_m become more critical if heterologous probing is being attempted. If the aim is to identify sequences that are merely related, not identical, to the probe (e.g., members of a multigene family, or a similar gene in a second organism), then it is useful to have an idea of the degree of mismatching that will be tolerated by a “moderate-” or “low-” stringency wash. The best way to approach this is to first establish the lowest temperature at which only homologous hybridization occurs with a particular SSC concentration. Then assume that 1% mismatching results in a 1°C decrease in the T_m (Bonner et al., 1973) and reduce the temperature of the final wash accordingly (for example, if sequences with ≥90% similarity with the probe are being sought, decrease the final wash temperature by 10°C). If the desired degree of mismatching results in a wash temperature of <45°C, then it is best to increase the SSC concentration so that a higher temperature can be used. Doubling the SSC concentration results in a ~17°C increase in T_m , so washes at 45°C in 0.1× SSC and 62°C in 0.2× SSC are roughly equivalent. Note that in these extreme cases it may also be necessary to reduce the hybridization temperature to as low as 45°C (aqueous solution) or 32°C (formamide solution).

This approach sometimes works extremely well (as shown when the heterologous targets are eventually sequenced), but the assumption that a 1% degree of mismatching reduces the T_m of a heteroduplex by 1°C is very approximate. Base composition and mismatch distribution influence the actual change in T_m , which can be anything between 0.5° and 1.5°C per 1% mismatch (Hyman et al., 1973). Unfortunately trial and error is the only alternative to the “rational” approach described here.

Other parameters relevant to hybridization analysis

Length of prehybridization and hybridization incubations. The protocols recommend prehybridization for 3 hr with nitrocellulose and 15 min for nylon membranes. Inadequate prehybridization can lead to high backgrounds, so these times should not be reduced. They can, however, be extended without problem.

Hybridizations are usually carried out overnight. This is a rather sloppy aspect of the procedure, because time can have an important influence on the result, especially if, as described above, an excess amount of a single-stranded probe is being used. The difficulties in assigning values to the parameters needed to calculate optimum hybridization time has led to the standard “overnight” incubation, which in fact is suitable for most purposes. The exception is when hybridization is being taken to its limits, for instance in detection of single-copy sequences in human DNA, when longer hybridization times (up to 24 hr) may improve sensitivity if a single-stranded probe is being used. Note that this does not apply to double-stranded probes, as gradual reannealing results in only minimal amounts of a double-stranded probe being free to hybridize after ~8 hr of incubation.

Formamide hybridization buffers. Formamide destabilizes nucleic acid duplexes, reducing the T_m by an average of 0.6°C per 1% formamide for a DNA-DNA hybrid (Meinkoth and Wahl, 1984) and rather less for a DNA-RNA hybrid (Casey and Davidson, 1977; Kafatos et al., 1979). It can be used at 50% concentration in the hybridization solution, reducing the T_m so that the incubation can be carried out at a lower temperature than needed with an aqueous solution. Originally formamide was used with nitrocellulose membranes as a means of prolonging their lifetime, as the

lower hybridization temperature results in less removal of target DNA from the matrix. More recently formamide has found a second use in reduction of heterologous background hybridization with RNA probes. RNA-DNA hybrids are relatively strong, and heterologous duplexes remain stable even at high temperatures. The destabilizing effect of formamide is therefore utilized to maximize the discrimination between homologous and heterologous hybridization with RNA probes.

Formamide probably confers no major advantage on DNA-DNA hybridization with a nylon membrane. In fact it introduces two problems, the hazardous nature of the chemical itself, and an apparent reduction in hybridization rate. The latter point is controversial (Hutton, 1977), but for equivalent sensitivity a formamide hybridization reaction usually has to incubate for longer than an aqueous one.

Alternatives to SSC. Although SSC has been used in hybridization solutions for many years, there is nothing sacrosanct about the formulation, and other salt solutions can be employed (Table 2.10.3). There is little to choose between these alternatives. SSPE and phosphate solutions have a greater buffering power and may confer an advantage in formamide hybridization solutions. Alternatively, the buffering power of SSC can be increased by adding 0.3% (w/v) tetrasodium pyrophosphate.

Probe length. Probe length has a major influence on the rate of duplex formation in solution hybridization (Wetmur and Davidson, 1986), but the effect is less marked when the target DNA is immobilized. In membrane hybridization a more important factor is the specificity of the probe. The probe should never be too long (>1000 bp), as this increases the chance of heterologous duplexes remaining stable during a high-stringency wash. Neither should the probe contain extensive vector sequences, as these can hybridize to their own target sites, wrecking the specificity of the experiment.

Mechanics of hybridization. Traditionally hybridization has been carried out in plastic bags. This technique is messy, radiochemical spills being almost unavoidable, and can lead to detrimental contact effects if too many membranes are hybridized in a single bag. Hybridization incubators are now available from a number of companies and are recommended as a distinct advance over the plastic bag technology. Rotation of the hybridization tube results in excellent mixing, reducing hot spots caused by bubbles and dust and leading to very evenly

hybridized membranes. Good-quality results are possible even when ten or more minigel Southern are hybridized in a single 8.5 × 3.0-inch tube.

If bags are used, they should be of stiff plastic to prevent the sides collapsing on to the membrane, which will lead to high background. The volume of hybridization solution should be sufficient to fill the bag, and no more than two membranes should be hybridized in each bag.

Troubleshooting

Problems in blotting and hybridization reveal themselves when the autoradiograph is developed. A guide to the commonest problems and how to solve them is given in Table 2.10.4 (based on Dyson, 1991).

A particularly troublesome problem is high background signal across the entire membrane. This is due to the probe attaching to nucleic acid binding sites on the membrane surface, the same sites that bind DNA during the blotting procedure. Prehybridization/hybridization solutions contain reagents that block these sites and hence reduce background hybridization. The most popular blocking agent is Denhardt solution, which contains three polymeric compounds (Ficoll, polyvinylpyrrolidone, and BSA) that compete with nucleic acids for the membrane-binding sites. The formulations used in the basic and alternate protocols also include denatured salmon sperm DNA (any complex DNA that is nonhomologous with the target is acceptable) which also competes with the probe for the membrane sites. Blocking agents are included in the prehybridization solution to give them a head start over the probe. With a nylon membrane, the blocking agents may have to be left out of the hybridization solution, as they can interfere with the probe-target interaction. When the membranes are washed, the Denhardt solution and salmon sperm DNA are replaced with SDS, which acts as a blocking agent at concentrations ≥1%.

Other blocking agents can also be used (Table 2.10.5). With DNA blots, the main alternatives to Denhardt are heparin (Singh and Jones, 1984) and milk powder (BLOTTO; Johnson et al., 1984), although Denhardt is generally more effective, at least with nylon membranes. Note that BLOTTO contains RNases and so can be used only in DNA-DNA hybridizations. With an RNA probe, denatured salmon sperm DNA is sometimes replaced by 100 µg/ml yeast tRNA, which has the advantage that it does not need to be sheared before

Table 2.10.4 Troubleshooting Guide for DNA Blotting and Hybridization Analysis^a

Problem	Possible cause ^b	Solution
Poor signal	Probe specific activity too low	Check labeling protocol if specific activity is $<10^8$ dpm/ μ g.
	Inadequate depurination	Check depurination if transfer of DNA >5 kb is poor.
	Inadequate transfer buffer	1. Check that 20 \times SSC has been used as the transfer solution if small DNA fragments are retained inefficiently when transferring to nitrocellulose. 2. With some brands of nylon membrane, add 2 mM Sarkosyl to the transfer buffer. 3. Try alkaline blotting to a positively charged nylon membrane.
	Not enough target DNA	Refer to text for recommendations regarding amount of target DNA to load per blot.
	Poor immobilization of DNA	See recommendations in <i>UNIT 2.9A</i> commentary.
	Transfer time too short	See recommendations in <i>UNIT 2.9A</i> commentary.
	Inefficient transfer system	Consider vacuum blotting as an alternative to capillary transfer.
	Probe concentration too low	1. Check that the correct amount of DNA has been used in the labeling reaction. 2. Check recovery of the probe after removal of unincorporated nucleotides. 3. Use 10% dextran sulfate in the hybridization solution. 4. Change to a single-stranded probe, as reannealing of a double-stranded probe reduces its effective concentration to zero after hybridization for 8 hr.
	Incomplete denaturation of probe	Denature as described in the protocols.
	Incomplete denaturation of target DNA	When dot or slot blotting, use the double denaturation methods described in <i>UNIT 2.9B</i> , or blot onto positively charged nylon.
	Blocking agents interfering with the target-probe interaction	If using a nylon membrane, leave the blocking agents out of the hybridization solution.
	Final wash was too stringent	Use a lower temperature or higher salt concentration. If necessary, estimate T_m as described in <i>UNIT 6.4</i> .
	Hybridization temperature too low with an RNA probe	Increase hybridization temperature to 65°C in the presence of formamide (see alternate protocol).
	Hybridization time too short	If using formamide with a DNA probe, increase the hybridization time to 24 hr.
Inappropriate membrane	Check the target molecules are not too short to be retained efficiently by the membrane type (see Table 2.9.1).	

continued

Table 2.10.4 Troubleshooting Guide for DNA Blotting and Hybridization Analysis^a, continued

Problem	Possible cause ^b	Solution
	Problems with electroblotting	Make sure no bubbles are trapped in the filter-paper stack. Soak the filter papers thoroughly in TBE before assembling the blot. Used uncharged rather than charged nylon.
Spotty background	Unincorporated nucleotides not removed from labeled probe	Follow protocols described in <i>UNIT 3.4</i> .
	Particles in the hybridization buffer	Filter the relevant solution(s).
	Agarose dried on the membrane	Rinse membrane in 2× SSC after blotting.
Patchy or generally high background	Baking or UV crosslinking when membrane contains high salt	Rinse membrane in 2× SSC after blotting.
	Insufficient blocking agents	See text for of discussion of extra/alternative blocking agents.
	Part of the membrane was allowed to dry out during hybridization or washing	Avoid by increasing the volume of solutions if necessary.
	Membranes adhered during hybridization or washing	Do not hybridize too many membranes at once (ten minigel blots for a hybridization tube, two for a bag is maximum).
	Bubbles in a hybridization bag	If using a bag, fill completely so there are no bubbles.
	Walls of hybridization bag collapsed on to membrane	Use a stiff plastic bag; increase volume of hybridization solution.
	Not enough wash solution	Increase volume of wash solution to 2 ml/10 cm ² of membrane.
	Hybridization temperature too low with an RNA probe	Increase hybridization temperature to 65°C in the presence of formamide (see alternate protocol).
	Formamide needs to be deionized	Although commercial formamide is usually satisfactory, background may be reduced by deionizing immediately before use.
	Labeled probe molecules are too short	1. Use a ³² P-labeled probe as soon as possible after labeling, as radiolysis can result in fragmentation. 2. Reduce amount of DNase I used in nick translation (<i>UNIT 3.5</i>).
Probe concentration too high	Check that the correct amount of DNA has been used in the labeling reaction.	
Inadequate prehybridization	Prehybridize for at least 3 hr with nitrocellulose or 15 min for nylon.	
Probe not denatured	Denature as described in the protocols.	
Inappropriate membrane type	If using a nonradiocative label, check that the membrane is compatible with the detection system.	
Hybridization with dextran sulfate	Dextran sulfate sometimes causes background hybridization. Place the membrane between Schleicher and Schuell no. 589 WH paper during hybridization, and increase volume of hybridization solution (including dextran sulfate) by 2.5%.	

continued

Table 2.10.4 Troubleshooting Guide for DNA Blotting and Hybridization Analysis^a, continued

Problem	Possible cause ^b	Solution
Extra bands	Not enough SDS in wash solutions	Check the solutions are made up correctly.
	Final wash was not stringent enough	Use a higher temperature or lower salt concentration. If necessary, estimate T_m as described in <i>UNIT 6.4</i> .
	Probe contains nonspecific sequences (e.g., vector DNA)	Purify shortest fragment that contains the desired sequence.
	Target DNA is not completely restriction digested	Check the restriction digestion (<i>UNIT 3.1</i>).
Nonspecific background in one or more tracks	Formamide not used with an RNA probe	RNA-DNA hybrids are relatively strong but are destabilized if formamide is used in the hybridization solution.
	Probe is contaminated with genomic DNA	Check purification of probe DNA. The problem is more severe when probes are labeled by random printing. Change to nick translation.
	Insufficient blocking agents	See text for of discussion of extra/alternative blocking agents.
	Final wash did not approach the desired stringency	Use a higher temperature or lower salt concentration. If necessary, estimate T_m as described in <i>UNIT 6.4</i> .
Cannot remove probe after hybridization	Probe too short	Sometimes a problem with probes labeled by random priming. Change to nick translation.
	Membrane dried out after hybridization	Make sure the membrane is stored moist between hybridization and stripping.
	Poor retention of target DNA during probe stripping	1. Check calibration of UV source if cross-linking on nylon. 2. Use a less harsh stripping method (support protocol).
Decrease in signal intensity when reprobbed		

^aBased on Dyson (1991).

^bWithin each category, possible causes are listed in decreasing order of likelihood.

use. If a cDNA clone is used as the probe, or for the *in vitro* synthesis of an RNA probe, then blockage of sites with high affinity for poly(A)⁺ sequences often reduces background. This is achieved by using 10 µg/ml of poly(A) DNA as the blocking agent.

Anticipated Results

Using either a nitrocellulose or nylon membrane and a probe labeled to $\geq 10^8$ dpm/µg, there should be no difficulty in detecting 10 pg of a single copy sequence in human DNA after 24 hr autoradiography.

Time Considerations

The hybridization experiment can be completed in 24 hr, the bulk of this being taken up by the overnight incubation. Prehybridization takes 3 hr for a nitrocellulose membrane or 15 min for nylon. Post-hybridization washing to high stringency can usually be completed in 1.5 hr. If a single-copy sequence in human DNA is being probed, the hybridization step may be extended to 24 hr, with a concomitant increase in the length of the experiment as a whole.

The length of time needed for autoradiography depends on the abundance of the target sequences in the blotted DNA. Adequate exposure can take anything from overnight to several days.

Table 2.10.5 Alternatives to Denhardt/Denatured Salmon Sperm DNA as Blocking Agents in DNA Hybridization^a

Blocking agent	Composition	Storage and use
BLOTTO	5% (w/v) nonfat dried milk/0.02% (w/v) NaN ₃ in H ₂ O	Store at 4°C; use at 4% final concentration
Heparin (porcine grade II)	50 mg/ml in 4× SSC	Store at 4°C. Use at 500 µg/ml with dextran sulfate or 50 µg/ml without
Yeast tRNA	10 mg/ml in H ₂ O	Store at 4°C; use at 100 µg/ml
Homopolymer DNA	1 mg/ml poly(A) or poly(C) in H ₂ O	Store at 4°C; use at 10 µg/ml in water; appropriate targets: poly(A) for AT-rich DNA, poly(C) for GC-rich DNA

SYNTHESIS AND PURIFICATION OF OLIGONUCLEOTIDES

Synthesis and Purification of Oligonucleotides

Avery's realization that DNA carries the genetic information lead chemists on a 40-year search that has culminated in efficient, automated oligonucleotide synthesis on solid-phase supports. Modern nucleic acid synthesizers utilize phosphite triester chemistries that employ stable phosphoramidite monomers to build the growing polymer. These robust reactions allow both chemists and molecular biologists to easily generate specific ribo- and deoxyribo oligonucleotides with a variety of labels, modified linkages, and nonstandard bases attached throughout the chain. The synthesis of short (less than 40-nucleotide) probes and primers requires no more special expertise than the ability to read the synthesizer operator's manual, and longer oligonucleotides (up to 150 nucleotides) can be synthesized with a little more care.

The introductory section of this unit provides strategies on the maximization of synthetic yield, the generation of sequences containing site specific modifications, and the isolation of synthetic oligonucleotides. Protocols describe monitoring the progress of synthesis via the trityl assay (see Basic Protocol 1 and Support Protocol) and methods for deprotection of DNA (see Basic Protocol 2) and RNA (see Basic Protocol 3) oligonucleotides.

This unit augments the detailed instructions provided by the manufacturers of oligonucleotide synthesizers. A functional understanding of the synthesis chemistries coupled to insights on the mechanical operation of the synthesizer will allow the user to minimize input time and maximize oligonucleotide output.

INTRODUCTION TO CHEMICAL NUCLEIC ACID SYNTHESIS

Many hydroxyl and amine moieties make nucleic acids very animated molecules with rich chemistries of their own that can interfere with the phosphite triester reactions used to couple the nucleotide monomers; therefore, protection strategies are necessary in chemical synthesis to mask the functional groups on the monomers so that the only significant reaction is the desired 3' to 5' sequential condensation of monomers to the growing oligonucleotide. (Note that enzymatic polymerizations occur with the opposite directionality and require no masking of monomer functionality.) These synthetic protecting groups must be chosen so that they can be removed easily to expose the natural nucleotides.

The fully protected monomers for nucleic acid synthesis are generally called phosphoramidites (Fig. 2.11.1). In traditional protection schemes the nucleophilic amino moieties on the bases are protected with either isobutyryl (N-2 of guanine) or benzoyl (N-6 of adenine and N-4 of cytidine) groups, both of which can be removed at the completion of synthesis by ammoniolysis. However, recent advances have led to the wide spread use of phenoxyacetyl (PAC) protection of adenosine, dimethylformamide (DmF) protection of guanosine, and acyl protection of cytosine to yield oligonucleotides that can be deprotected rapidly under very mild conditions (Reddy et al., 1994). The 5' primary hydroxyl of the ribose sugar is protected with a dimethoxytrityl (DMT) ether moiety which is removed by mild protic acids at the beginning of each coupling cycle. The efficiency of synthesis at each coupling cycle can be monitored by detecting the release of the chromophore trityl cation. To synthesize nucleic acids with the natural phosphodiester backbone, the 3' secondary hydroxyl function of the ribose sugar is

derivatized with a highly reactive phosphitylating agent. The phosphate oxygen on this moiety is usually masked by β -cyanoethoxy and diisopropylamine protecting groups. By insulating the phosphate oxygen with alternative groups, modified phosphate backbones may be accessed. Finally, for ribonucleic acids the secondary 2' hydroxyl of the ribose is shielded throughout the chemical synthesis by the *tert*-butyldimethylsilyl group.

The genius of using these protecting groups for automated nucleic acid synthesis is that they yield nearly lesion-free natural nucleic acids with high efficiency through simple hydrolysis, nucleophilic displacement, and redox chemistries. In a standard synthesis cycle, the nucleotide chain grows from an initial protected nucleoside bound via its terminal 3' hydroxyl to a solid support. Reagents and solvents are pumped through the support to induce the consecutive removal and addition of sugar protecting groups in order

Figure 2.11.1 Structure of nucleoside phosphoramidite units, showing traditional protection groups for 2' hydroxyl, phosphate, and base moieties. For DNA, Z = H (no protection required); for RNA, Z = O-protection group.

to isolate the reactivity of a specific chemical moiety on the monomer and affect its stepwise addition to the growing oligonucleotide chain. This design eliminates the need to purify synthetic intermediates or unreacted reagents, because they are simply rinsed off the column at the end of each chemical step. Assembly of the protected oligonucleotide chain is carried out in four chemical steps: deblocking, activation/coupling, oxidation, and capping (Fig. 2.11.2). Cleavage and deprotection then reveal the single-stranded nucleic acid.

Deblocking

The synthesis cycle begins with the removal of the acid-labile DMT ether from the 5' hydroxyl of the 3' terminal nucleoside. This is usually accomplished by using dichloroacetic acid (DCA) in dichloromethane. The resulting trityl cation chromophore can be quantitated to determine coupling efficiency (see Basic Protocol 1). After deblocking, the 5' hydroxyl is the only reactive nucleophile capable of participating in the subsequent coupling step. Since the nitrogenous bases of the growing DNA chain are susceptible to acid-catalyzed depurination, the deblocking step is short, and an acetonitrile rinse thoroughly removes the deblocking agent from the support. Also, coupling efficiency and accuracy are increased by this wash, since premature detritylation of the incoming phosphoramidite monomer is prevented.

Activation/Coupling

Following deblocking of the 5' hydroxyl group, the next protected phosphoramidite is delivered to the reaction column along with the weakly acidic activator tetrazole ($pK_a = 4.8$). Nucleophilic attack of the previously freed 5' hydroxyl upon the incoming monomer's diisopropylamine-protected phosphorus, which was activated via protonation by tetrazole, elongates the nucleic acid chain. Because this protonated phosphoramidite is so reactive, the coupling reaction is usually complete within 30 sec. A molar excess of tetrazole over the phosphoramidite ensures complete activation, and a molar excess of phosphoramidite over free 5' hydroxyls of the growing chain promotes efficient coupling. To optimize the coupling efficiency, the amounts of reagents injected and the coupling time can be varied (see Synthesizing Long Oligonucleotides).

Capping

In spite of these efficiency measures, a small percentage of the support-bound nucleoside's 5' hydroxyls do not couple to the incoming activated monomer. They must be rendered inactive to minimize deletion products and simplify the purification process. Usually, acetic anhydride and *N*-methylimidazole dissolved in pyridine and tetrahydrofuran (THF) act to create an acylating agent that "caps" the unextended 5' hydroxyls. The 5' acetyl ester cap is unreactive in all subsequent cycles and is removed during the final ammonia deprotection step. Additional acetonitrile washing subsequent to capping can increase synthetic yield. After coupling and capping, the internucleotide linkage is a trivalent phosphite triester that is extremely unstable and must be oxidized to a phosphotriester which will ultimately yield natural DNA.

Oxidation

In the last step of the cycle, the unstable phosphite triester linkages are oxidized to a more stable phosphotriester by 0.02 M iodine dissolved in water/pyridine/THF. An iodine-pyridine adduct forms to the phosphite triester and is subsequently displaced by water to yield phosphorus oxidized to the pentavalent state. Pyridine also neutralizes the hydrogen iodide byproduct. Because the oxidizer contains water, the support is rinsed several times with acetonitrile following this reaction. One cycle of monomer addition is then complete, and another cycle begins with the removal of the 5' DMT from the previously added monomer.

Figure 2.11.2 Steps in the assembly of the protected oligonucleotide chain.

Cleavage/Deprotection

At the end of the synthesis, the final trityl can either be removed with a final acid wash (“trityl-off”), or be left on for purification purposes (“trityl-on”). The oligonucleotide itself is removed from the support with concentrated ammonium hydroxide. Additionally, this treatment deprotects the phosphorus by β -elimination of the cyanoethyl group and removes the protecting groups from the heterocyclic bases to yield a single-stranded nucleic acid.

RNA Synthesis

RNA chemical synthesis is identical to that used for DNA except for the need for an additional protecting group at the 2' hydroxyl of ribose. This position is usually protected with *tert*-butyldimethyl silyl groups, which are stable throughout the synthesis (Fig. 2.11.1). They are removed at the final deprotection step by the basic fluoride ion. The remaining positions on both the sugar and the bases are protected in the same fashion as for DNA. By adjusting several parameters in the DNA synthesis protocol—including the coupling times, monomer delivery rate, frequency of washing steps, and types of capping reagents—stepwise coupling efficiencies of up to 99% can be obtained (Wincott et al., 1995; G. Glick, pers. comm.). However, for the casual user this yield represents the exception rather than the norm, and only shorter oligoribonucleotides (<20 bases) should initially be attempted.

STRATEGIES FOR NUCLEIC ACID SYNTHESIS

A Checklist for Nucleic Acid Synthesis

Consistency and planning are the keys to reliable nucleic acid synthesis. Organizing these repetitive tasks into a standard operating protocol will streamline efficiency and produce better-quality oligonucleotides.

1. Plan syntheses to optimize machine use. Oligonucleotides of similar size should be combined in parallel runs, since synthesizing many short oligonucleotides followed by a longer one is faster than mixing the sets on dual-column synthesizers.
2. Determine the total number of bases to be incorporated. Be sure there are enough of the required reagents and phosphoramidites available for the entire synthesis. Consult the synthesizer manual for the amount of reagent needed for each coupling (also see Troubleshooting). Remember that different synthetic scales (e.g., 0.25 μ mol versus 1 μ mol) require different amounts of reagents. Syntheses should be planned so that a phosphoramidite is almost completely exhausted. Also, phosphoramidites that have been dissolved for >2 weeks should be replaced.
3. Consider special programming requirements. Many synthesis options pertaining to the scale of the synthesis, backbone composition, and presence of protecting groups can be modified. Create a log for users to fill out detailing exact synthesis requirements, and check the log prior to synthesis. A computerized log book is especially useful and allows for an organized oligonucleotide nomenclature (e.g., R20.17 may refer to Rebecca's 20-mer, the 17th 20-mer made on the system).
4. If the synthesizer lacks a trityl monitor, set up a fraction collector to monitor the chromophoric trityl cation release (see Basic Protocol 1).
5. Initialize the system. If previous oligonucleotides were cleaved from their supports automatically, rinse the columns for 30 sec with acetonitrile to remove any remaining traces of ammonium hydroxide. If the machine has been at rest for >6 hr, immediately

before starting the synthesis (and following the addition of fresh reagents) remove any stale reagents or moisture from the lines by priming them. This will maximize the first coupling step's efficiency. Check the reagent and phosphoramidite flow rates to ensure that reagents are being properly delivered.

6. Start the synthesis. Confirm that the flow through the lines and columns is not obstructed and monitor the first few trityl releases. An abortive synthesis of a 60-mer sequence wastes much more material than a failed 3-mer run.

Synthesizing Long Oligonucleotides (≥ 100 Bases)

Modern synthesizers can routinely produce sequences of 150 or more nucleotides in usable amounts ($\geq 10 \mu\text{g}$). Several strategies can be employed to enhance the yield from syntheses longer than 100 bases.

1. Exclude water from the system (the importance of this cannot be overstated; see Critical Parameters, Excluding water from solvents). Replace reagents on the machine with fresh ones before all long syntheses. This is particularly important for the phosphoramidites and especially for guanosine phosphoramidite, since it decomposes more quickly than the other two protected bases (Zon et al., 1985).
2. Monitor trityl releases for shorter runs prior to attempting the synthesis of long oligonucleotides to limit wastage of expensive reagents. In general, if the stepwise efficiency of synthesis is $<99\%$, alter parameters to increase the efficiency on shorter sequences before attempting to synthesize a long oligonucleotide (see Basic Protocol 1).
3. Use dichloroacetic acid (DCA) rather than trichloroacetic acid (TCA) for deblocking if the synthesizer is compatible with this reagent. Depurination (cleavage of the glycosidic bond) under acidic conditions is a prominent side reaction that ultimately limits DNA synthesis. DCA tends to show much better synthetic yields than trichloroacetic acid, especially for longer oligonucleotides (R. Pon, pers. comm.). Use a 2% (v/v) DCA/1,2-dichloroethane mixture.
4. Modify the synthesis protocol to increase the coupling time of the phosphoramidite. Also, additional methylene chloride wash steps included prior and subsequent to deblocking, along with increased acetonitrile washing subsequent to capping, lead to increased yields (G. Glick, pers. comm.).
5. Increase the phosphoramidite concentration to enhance the coupling efficiency—e.g., use a concentration of 50 mg/ml (double the normal concentration; 20-fold molar excess over the synthetic polynucleotide chain) for longer sequences.
6. Using a support matrix such as control pore glass (CPG) with a loading capacity of $<40 \mu\text{mol/g}$ can greatly increase yields of long oligonucleotide. Furthermore, the pore size of the support should be 1000 Å for >100 -mers and 2000 Å for 200-mers (Gait, 1984) to alleviate molecular crowding and steric effects. For a typical 1- μmol scale synthesis of a 150-mer, 20 mg of a support with a loading capacity of 5 mmol/g is used.

If it is too difficult to synthesize the desired sequence in a reasonable yield, or if oligomers >150 bases are desired, the nucleic acids may be made in segments and ligated (Bartel and Szostak, 1993) following PCR with a proofreading polymerase such as *Pfu* or *Tth*. Note, however, that since PCR is an inherently mutagenic procedure, any products generated should be checked by sequencing. Also, very long synthetic oligonucleotides (300 to 600 bases) have also been synthesized directly, and in spite of incredibly low

yields, rare full-length products have been successfully amplified by PCR (Ciccarelli et al., 1991). Finally, mutually primed synthesis (UNIT 8.2) can also be a suitable option for oligomers >150 bases.

Synthesizing RNA

Since many structural and mechanistic studies are underway concerning catalytic RNAs, the catalog of commercially available modified RNA monomers has recently bloomed (Table 2.11.1). RNA chemical synthesis has become as routine as that of DNA and typically uses identical 5'-dimethoxytrityl- β -cyanoethyl-protected phosphoramidites except for an additional protecting group on the 2' hydroxyl. *tert*-Butyldimethylsilyl protection of the 2'-hydroxyl group is the basis of most commercially available RNA phosphoramidites, since the silyl group is stable to both acid and base and can be removed with fluoride ion. Recently, however, RNA monomers with 2'-acetyl groups (FPMP, CEE) have appeared; these have the advantage of being conveniently removed at pH 2 just prior to use of the particular sample of RNA. Strategies for ribophosphoramidite protection are an active area of research, and recent work with 5'-silyl ethers in conjunction with 2'-orthoester protection has proven particularly interesting (S. Scaaringe, pers. comm.). For the casual user of RNA, it is often easier just to purchase small quantities of the required sequence from a ribo-oligonucleotide synthesis company such as Baron Consulting, Dharmacon Research, Genosys, or Peninsula Labs (see APPENDIX 4).

Isomeric purity of the phosphoramidites is often variable because of the difficulties inherent in distinguishing between the vicinal hydroxyls of ribose. If a homogeneous population of 5'-to-3'-linked oligoribonucleotides is required (as in most cases), then a thin-layer chromatography (TLC) or ^{31}P nuclear magnetic resonance (NMR) analysis of the starting phosphoramidites should be performed to establish their isomeric composition. While phosphorus NMR facilities are not generally available to molecular biologists, TLC is both inexpensive and straightforward. Recommended solvent systems to separate the 2' and 3' ribonucleotide phosphoramidites are 1:1 ether/chloroform, or 40:58:2 or 50:46:4 dichloromethane/hexane/triethylamine (Usman et al., 1987).

With a few slight modifications, the procedures and precautions described for DNA synthesis chemistry apply to RNA as well. Since stepwise coupling efficiency is lower than that of DNA, even greater care should be taken to exclude water completely from the closed system. Because the 2' hydroxyl is often protected with sterically hindering protecting groups, reaction times for RNA reagents tend to be longer, and adjustments should be made to phosphoramidite concentrations and coupling times, as detailed below. As is true for all RNA work, equipment and reagents that will contact unprotected oligonucleotides should be RNase free (UNITS 3.12 & 4.1) to avoid degradation of the synthesized material.

Depending on the synthesizer and coupling program used, RNA phosphoramidites are suspended in dry acetonitrile at a concentration of 0.1 to 1.0 M with a 6- to 10-fold excess of reagents delivered per 300 sec coupling. *S*-ethyltetrazole and DCI have also been found to be a more effective activators than the traditional tetrazole (Sproat et al., 1995; Vargeese et al, 1998). Also, additional methylene chloride washing steps included prior to and subsequent to deblocking, along with increased acetonitrile washing subsequent to capping, lead to increased yields (G. Glick, pers. comm.).

Incorporation of Modified Nucleosides

Chemical nucleic acid synthesis allows for the incorporation of unnatural or modified bases, as well as a variety of labeling moieties, into an oligonucleotide. This can be extremely useful for testing models of structural interactions between enzymes and nucleic acids, selecting labeled molecules from a population of unlabeled ones, or gaining insights into the parameters which govern nucleic acid structure and chemistry. Modified backbone chemistries such as phosphorothioates, phosphoramidates, and phosphotriesters are also readily available. In general, the bases themselves can be obtained commercially and are handled like any other phosphoramidite; however, consult the company which supplies the analog about necessary modifications to programs or reagents (see Table 2.11.1). Typically, the only adjustment needed is to dissolve the modified base at a somewhat higher concentration than normal to overcome problems associated with reactivity. Most of the methods used to increase the yield of long and ribo-oligonucleotides may be applied to the synthesis of modified nucleic acids.

When synthesizing modified oligonucleotides, compatibilities of the chemistries, placement of modifications relative to other chemical groups, and 5' to 3' directionality are all factors to consider. Generally when an oligonucleotide is end-labeled/modified, a long flexible tether is added to allow greater accessibility. Stretches of four deoxythymines are often used for this purpose. Also, adding deoxythymines 5' to the label (5'-TTTT-label-3') can aid in separating labeled molecules from unlabeled ones by size. Note that some tagging phosphoramidites allow for the enzymatic extension or kinasing of the modified oligonucleotide, while others do not. Finally, oligonucleotides may also be synthesized directly on solid glass supports (Cohen et al., 1997).

Terminal transferase can be used as an alternative means of incorporating modified bases at the 3' end of an oligonucleotide (Ratliff, 1982; *UNIT 3.6*). This enzyme is tolerant of a variety of substrates, and has been used to add deoxynucleotide triphosphates derivatized at virtually every position (C-8 on adenine, any of the amino groups, C-5 on cytosine, O-6 on guanosine) to DNA. It also functions, though less well, with RNA bases. It can use any DNA oligonucleotide that is at least 2 bases long [d(pXpX)] and contains a free 3' hydroxyl as a primer. A potential problem in preparing homogeneous polynucleotides using terminal transferase is that a statistically random number of bases is added to the 3' end of the template (with the exception of molecules such as cordycepin, which act as chain terminators due to the absence of 3' hydroxyl). If a single species is desired, it can be gel purified (see *UNIT 2.12*). Polynucleotide phosphorylase may also be used to incorporate modified bases at the 3' end (Gillam and Smith, 1980).

A more controlled means of introducing modified nucleotides relies on T4 RNA ligase and substrates of the form A(5')ppX (where X can be virtually any molecule, including for example ribose or amino acids, in a pyrophosphate linkage with adenosine; Uhlenbeck and Gumpert, 1982). The minimal template for reactions of this form is a trinucleoside containing a free 3' hydroxyl. RNA reacts much better than DNA, and single-strand molecules act as better templates than double-stranded ones. Since 3' hydroxyl groups are required, substrates of the form A(5')ppXp will undergo only a single round of addition, unlike the similar reaction with terminal transferase. In some cases, the compound A(5')ppXp can be generated directly by RNA ligase from pXp and ATP, although the substrate requirements for the X moiety are much more strict than in the ligation reaction. Thus, while virtually any dinucleotide of the form A(5')ppX can be added to an oligonucleotide, only a few compounds (primarily sterically "small" derivatives of natural bases) can be used by the enzyme to form A(5')ppXp from pXp.

T4 RNA ligase can catalyze the ligation of single-stranded oligonucleotides in the presence of ATP and various analogs (Kinoshita et al., 1997). Templates prepared by terminal transferase or by T4 RNA ligase that contain modified nucleotides (or other adducts) at their 3' termini may be able to act as substrates in this reaction. This would allow modified nucleotides to be introduced into the middle of a longer chain. However, the substrate specificity of the enzyme for the 3' hydroxyl donor is highly substrate dependent and will have to be determined empirically.

Synthesizing Degenerate Oligonucleotides

Current combinatorial and “irrational” nucleic acid design methodologies focus on the ability to create large pools of random sequences from which useful sequences may be culled (Szostak, 1992). Also, random mutagenesis using degenerate oligonucleotides allows for the exploration of “sequence space” surrounding a given protein or RNA structure. Sequences can be produced that give a completely random distribution of nucleotides at a given position or, alternatively, the sequence can be biased or “doped” toward a particular base with only a low level of randomization.

Most synthesizers can be programmed for in-line degenerate mixing of bases, which is useful if only a few positions are to be randomized. A potential problem with this method is that if mixing is incomplete, the sequence will be skewed toward whichever phosphoramidite enters the column first, since the reaction of the activated phosphoramidite with the free 5' hydroxyl is extremely fast. Therefore, while in-line mixing will generate all base substitutions at a given position, the distribution of these substitutions may not be uniform. If a statistically random distribution of nucleotides is required or if long stretches of random sequence are to be made, it is better to manually mix the phosphoramidites together and use this mixture for the degenerate position. A true random distribution may be obtained by mixing A, C, G, and T phosphoramidites in a 3:3:2:2 molar ratio to compensate for the faster coupling times of G and T phosphoramidites (D. Bartel, pers. comm.). On synthesizers where phosphoramidites are loaded without detaching the bottle, the mixing generated by sequential loading of each phosphoramidite into the extra bottle is sufficient to generate randomized sequences.

Oliphant and Struhl (Oliphant et al., 1986; Oliphant, 1989) have constructed degenerate oligonucleotides using mixed phosphoramidites, but have modified the synthesis protocol by deleting the capping step during the random additions. This increases the overall yield of long oligonucleotides, since sequences that fail to elongate are not terminated, and the size of the final product is more heterogeneous. This method is particularly useful if deletions, as well as randomized bases, in a given sequence are required.

Hermes et al. (unpub. observ.) have developed a detailed protocol for producing statistically mutated oligonucleotides. This method employs in-line mixing between pure phosphoramidite contained in separate bottles and equimolar mixtures of the four bases contained in an additional bottle. The obvious advantage of such a method is that doped and clean sequences can be synthesized on the same oligonucleotide. Whether or not this method is employed, it is an example of how to dissect the chemistry of mixed-site oligonucleotide synthesis. Hermes et al. (1989) have shown that mutations introduced by this method are indeed statistically random.

Regardless of the strategy employed, the level of misincorporation of an oligonucleotide should be decided in advance by the mutagenesis frequency desired. Quantitatively, this level is given by the probability distribution:

$$P(n, m, x) = [m! / (m - n)! n!] [x]^n [1 - x]^{m \times n}$$

where P is the probability of finding n errors in an oligonucleotide m in length with x level of misincorporation (fraction “wrong” nucleotides delivered). This equation describes a Poisson distribution. If primarily single mutations are desired, then x should be maximized for $n = 1$; if multiple mutations (e.g., doubles, or triples in a single oligonucleotide) are necessary, x should be correspondingly higher. If the mix is optimized for n mutations, then $n - 1$ and $n + 1$ mutations will occur in roughly equal amounts and n mutations will be the most frequent.

Cloning randomized oligonucleotides can be difficult, since a complementary wild-type sequence will generate mismatches that may result in biased correction *in vivo*. To avoid this problem, second-strand synthesis can be primed from a nonrandom portion of the sequence, or mutually primed synthesis (UNIT 8.2) can be utilized. Alternatively, Derbyshire et al. (1986) describe the direct cloning of doped single-strand material with “sticky ends” into a double-stranded cloning vector. Finally, Reidhaar-Olson and Sauer (1988) describe the synthesis of complementary oligonucleotides containing inosine (which can pair with any of the four natural bases) directly across from randomized codons. This method resulted in the successful introduction of a wide variety of mutations into the gene for lambda repressor, although there was a slight compositional bias in cloned sequences.

STRATEGIES FOR OLIGONUCLEOTIDE PURIFICATION

Deprotected nucleic acids may be purified and isolated by a variety of methods. The method of choice will depend on the availability of resources, the purity required—some methods cannot separate ($n-1$)-mers from n -mers—and time considerations. Any of the methods described below can be used to clean up crude material.

Isolation Methods

Precipitation

Direct precipitation of the nucleic acids constitutes a fast and efficient purification from contaminating small molecules such as urea and phenol, but does not allow for purification of abortive synthesis products from the full-length one. If oligonucleotide size separation is required, this method should be used in conjunction with some of the other methods described. After deprotection, resuspend the whitish pellet obtained in water. Add $MgCl_2$ to a final concentration of 10 mM and mix along with 5 vol ethanol. Precipitation should be immediate. Freeze the sample briefly at -20° or $-70^\circ C$. Centrifuge the precipitated material, wash with 95% ethanol, dry, and resuspend in water.

Precipitated deoxyoligonucleotides can be used for sequencing or cloning. They can also be used in PCR reactions, although the efficiency of amplification may be reduced as compared to gel-purified oligonucleotides. If the DNA is to be phosphorylated, a more thorough purification procedure is necessary, since T4 polynucleotide kinase is inhibited by lingering ammonium ions.

Sizing columns

Size-exclusion chromatography is extremely useful as a final purification step, especially when small-molecule contamination occurs with otherwise pure oligonucleotides, but (like precipitation) does not effect purification of abortive synthesis products from the full-length one. If oligonucleotide size separation is required, this method should be used in conjunction with some of the other methods described. Oligonucleotides purified by PAGE (UNIT 2.12) might contain small amounts of low-molecular-weight contaminants such as urea or phenol that might inhibit enzymatic reactions; sizing columns are a simple way to decontaminate these samples. Spin columns (UNIT 3.4) are simple to prepare

and use, but gravity-flow columns give better, more reproducible separation. The type of resin used should be adjusted based on the size of the oligonucleotide being purified (e.g., Sephadex G-25 for 25-mers or less, G-50 for longer sequences).

Reversed-phase cartridges

A hydrophobic matrix may be used to separate full-length from abortive synthesis products if the final trityl group is left on following the final monomer coupling reaction. The resulting hydrophobically tagged full-length “trityl-on” oligonucleotide can be separated easily from failure sequences, which lack trityl groups and do not efficiently bind the hydrophobic matrix. Several companies supply columns designed specifically for the purification of “trityl-on” oligonucleotides (e.g., Applied Biosystems oligonucleotide purification cartridges). The procedure is simple and can be performed on a number of samples in parallel within only a few minutes. The yield from such columns is excellent, often >80% of the applied sample. However, although a majority of failure sequences are removed using this method, many shorter sequences are co-purified with the desired full-length material. Some of these fragments are due to cleavage of depurinated DNA. These apurinic molecules can be eliminated prior to cleavage from the column by treatment with lysine (Horn and Urdea, 1988). In addition, if care is not taken to wash and elute samples from these columns slowly, some inhibitors (particularly of ligation reactions) may co-elute.

Denaturing PAGE

Denaturing polyacrylamide gel electrophoresis separates oligonucleotides with single-residue resolution and is the method of choice for purifying full-length oligonucleotides (see *UNIT 2.12*). However, the compatibility of the chemistries of modified nucleotides incorporated into the nucleic acids and acrylamide matrix should be checked (thiolated oligonucleotides seem to undergo Michael addition to the acrylamide, which renders them irreversibly capped).

HPLC

Liquid chromatography can also separate oligonucleotides with single-residue resolution, but its chief advantage is speed. Total run time can be as short as 30 min. The use of alkali perchlorate salts has made ion exchange the HPLC method of choice given that long oligonucleotide (>40 residues) may be easily purified in large scales ($\geq 25 \mu\text{mol}$; Sproat et al., 1995; Warren and Vella, 1994). However, secondary structural migration anomalies are generally more severe than those found with PAGE. Depending on the system employed, the amount of oligonucleotide that can be purified in a single chromatographic run can be comparable to PAGE, and sample recovery is typically >70%. For labs with an HPLC system and a need to routinely purify short oligonucleotides with no secondary structure, this method is ideal.

Oligonucleotides can be purified with HPLC by charge differences through ion exchange or hydrophobicity if the final trityl group is left on following the ultimate monomer coupling reaction. Only the “trityl-on” systems use buffers that can be lyophilized. A more complete treatment of the complexities of oligonucleotide purification by HPLC can be found in Applied Biosystems User Bulletin no. 13 on oligonucleotide purification (Applied Biosystems, 1988).

Confirming the Oligonucleotide Sequence

Most oligonucleotides that are used for cloning need not be checked immediately after synthesis, since the clones themselves will be checked after biological or enzymatic amplification. However, in cases where a sequence will be used in a structural application such as mobility-shift assays (*UNIT 12.1*), filter-binding assays (*UNIT 12.8*), or crystallography,

it is desirable to confirm the sequence. For almost all oligonucleotides, this usually requires chemical sequencing (*UNIT 7.5*). Although sequencing will confirm that the correct product was made, it cannot determine the homogeneity. How unnatural or protected bases will react during chemical sequencing, or how they will affect mobility on a sequencing gel, is not predictable. In order to determine what fraction of molecules contain only the natural bases (A, T, C, and G), it is necessary to digest the DNA enzymatically to completion and to examine its composition by a comparison with standard bases separated by HPLC. At least one HPLC buffer system has been developed specifically for examining modified nucleosides in chemically synthesized oligonucleotides (Eadie et al., 1987). The insertion and deletion rates for chemical nucleic acid synthesis are non-negligible. The rate of insertions (presumably due to DMT cleavage via tertrazole) has been measured to be as high as 0.4% per position, and the rate of deletions (presumably due to incomplete capping) has been found to be as high as 0.5% per position (A. Keefe and D. Wilson, pers. comm.). Therefore, for an oligonucleotide 100 bases in length and assuming a random, noncorrelated mechanism of action, only about 40% of the sequences will be the intended one. Finally, matrix-assisted laser desorption/ionization mass spectrometry (MALDI-MS; *UNITS 10.20 & 10.21*), which has recently emerged as a new biotechnology tool, may be used to determine the sequence of deoxy and ribo-oligonucleotides of up to 60 bases (Zhu et al., 1997).

BASIC PROTOCOL 1

MONITORING DNA SYNTHESIS USING THE TRITYL ASSAY

A trityl cation is released from the 5' end of the growing oligonucleotide during each synthesis cycle, and the yield of each step of the synthesis can be determined by spectrophotometrically measuring the amount of trityl cation liberated. This procedure is the simplest and most rapid means available for the identification of problems with synthesized oligonucleotides prior to deprotection and purification. Also, in-line quantitative trityl monitors can be interfaced to most synthesizers (Ana-Gen Technologies).

Materials

0.1 M *para*-toluene sulfonic acid (TSA; monohydrate) in acetonitrile
15-ml glass tubes (graduated, if possible)

1. Collect the trityl cation solution in 15-ml glass tubes after each step.

It is helpful to use graduated tubes so that a uniform final volume of acetonitrile can be attained before assay.

2. Dilute the first three and last three fractions to 10 ml with 0.1 M TSA in acetonitrile. Mix thoroughly.

CAUTION: Handle the solution consisting of dichloroacetic acid (or trichloroacetic acid) in dichloromethane and acetonitrile with gloves, because it is corrosive as well as toxic. Avoid prolonged contact with toxic acetonitrile fumes. Do not pipet by mouth.

Although 2.5 ml of deblocking solution is initially released, because acetonitrile is a volatile liquid the volume may change during the course of a synthesis. Fractions may sit for several days before being assayed without affecting the results. Samples that have evaporated to dryness must be thoroughly redissolved. The acid ensures protonation of the trityl groups, making them more strongly colored. It is misleading merely to visualize the yellow/orange color of the fractions, however, since variable volumes of differing acidity are often released.

3. Dilute each sample 20- to 50-fold in the same solution. Measure the absorbance at 498 nm versus acetonitrile/TSA.

These dilutions are necessary because most spectrophotometers cannot accurately measure absorbances >2.

4. Calculate the stepwise coupling efficiency and absolute yield for the synthesis as a whole. The stepwise efficiency is given by:

$$(\text{stepwise efficiency})^n = \frac{\text{average absorbance of last three fractions}}{\text{average absorbance of first three fractions}}$$

where n is the number of trityl nucleotides in the oligonucleotide (equal to the length of the oligonucleotide for trityl-off syntheses).

The absolute yield of product is given by:

$$\mu\text{mol DMT} = \frac{(\text{absorbance of last fraction}) \times (\text{dilution factor}) \times (10 \text{ ml})}{70 \text{ ml}/\mu\text{mol}}$$

where 70 μmol is the extinction coefficient of DMT.

The average stepwise efficiency is useful in determining the relative efficiency of each cycle of the synthesis. The absolute yield is useful for determining how many milligrams of product are present for subsequent purifications, although not all of the product will be of the desired length.

The average absorbance of the first and last few steps is used to avoid discrepancies in individual trityl assays. Clearly, if the synthesis was performed on a 1- μmol column, the absolute yield in the first few fractions should be close to 1 μmol . A low absolute yield (absorbance) in the first trityl release, followed by higher absolute yields (absorbances) in the next few fractions, is sometimes observed. This is because some spontaneous detritylation occurs during storage of the columns and the trityls are subsequently rinsed off during the prime lines program. In this case, the average stepwise efficiency should be calculated with fractions 2 through 4. It should be noted that visual assessment of the trityl fractions cannot begin to detect subtle differences (<5%) which may be critical in terms of overall yield.

5. Perform troubleshooting assay (see Support Protocol) if average stepwise efficiency is low.

USING THE TRITYL ASSAY FOR TROUBLESHOOTING

If the average stepwise efficiency for the oligonucleotide synthesis is low, each fraction should be assayed in order to diagnose the problem (what counts as a “low” yield depends on the length and quantity of oligonucleotide desired). In general, synthetic efficiency should be >99% per step, although lower stepwise efficiencies can be tolerated for short oligonucleotides (<40 bases) or where yield is not critical.

Three classes of failures can be detected by trityl assays. A low absolute yield at the first step followed by similarly low absorbances that results in a low overall yield is commonly due to inefficient purging of activator or phosphoramidite lines prior to the synthesis. Such a problem frequently occurs when a synthesizer has not been used for several days. Purge the lines with dry reagents prior to starting the run to avoid inefficient synthesis. Most machines have a priming program precisely for this purpose.

If the stepwise efficiency of each step is low, there is a systematic problem with one of the common reagents, such as the acetonitrile. Often this is due to moisture in one or more of the reagents, and it is more likely if reagents have not been recently replaced. The phosphoramidites should be used until they are almost completely exhausted during a series of syntheses, so that fresh chemicals will be diluted as little as possible by older, potentially wet material (see Critical Parameters, Excluding water from solvents).

SUPPORT PROTOCOL

Preparation and Analysis of DNA

2.11.17

Finally, individual trityl assays are most useful in determining when phosphoramidites have become defective. In this case, drops in stepwise efficiency will only be seen at the coupling steps involving the phosphoramidites in question.

Many problems, such as inefficient oxidation or product depurination, cannot be detected by the trityl cation assay. Therefore, the trityl assay procedure should be used in conjunction with HPLC or gel electrophoresis for product analysis, especially if a homogenous population of oligonucleotides is essential.

DEPROTECTION OF DNA OLIGONUCLEOTIDES

After synthesis is complete, the DNA may be cleaved from the column and protecting groups removed by treatment with ammonia. Although very extended treatment in base can harm DNA, hours of ammoniolysis are still preferred to ensure complete deprotection, since a homogeneous population of “natural” oligonucleotides at slightly lower yield is better than a mixed population of partially deprotected, “unnatural” molecules.

To cleave the DNA from the support matrix and remove protecting groups completely, the support bound product must be treated with concentrated ammonia at 55° to 60°C overnight (≥ 12 hr). Even with such extended treatment, deoxyguanosine may not be completely deprotected (Schulhof et al., 1987). Raising the temperature at which oligonucleotides are deprotected has been reported to speed up the process (≥ 5 hr at 70°C).

Phosphoramidites with more labile protecting groups such as phenoxyacetyl or dimethylformamide masking adenosine and guanosine have recently become commercially available (Table 2.11.1). These allow essentially complete deprotection within 30 to 60 min at 70°C (Reddy et al., 1994). Also, by replacing the traditional benzyl protection of cytosine with acetyl and using a 1:1 mixture of aqueous ammonium hydroxide and aqueous methylamine, oligonucleotides synthesized with traditional purine protections may be completely deprotected in 5 min at 65°C (Reddy et al., 1995). Finally, anhydrous ammonia gas-phase deprotection of oligonucleotides has recently been described; this provides a convenient method for parallel deprotection of as many columns will fit in a reactor. Since no water is present, the fully deprotected oligonucleotides remain adsorbed to the column matrix, thereby guaranteeing that no cross-contamination will occur. The oligonucleotides can then be eluted with water and desalted or further purified. Using PAC-protected monomers, the cleavage and deprotection processes can be completed in ~30 min (Boal et al., 1996).

Materials

Concentrated (14.8 N) ammonium hydroxide (see recipe)
Triethylamine
3:1 (v/v) concentrated ammonium hydroxide/ethanol
n-Butanol

Screw-cap plastic vial (preferably fitted with rubber O ring)
Heat block or oven, 55° to 60°C
0.2- μ m filter

1. In a screw-cap plastic vial, suspend the synthesis support matrix or the already support-cleaved oligonucleotide in ~1.0 ml concentrated ammonium hydroxide for a 1- μ mol synthesis.

Depending on the synthesizer or nucleic acid provider, the oligonucleotide may come attached to a support matrix or free in an ammonium hydroxide solution. The volume of ammonium hydroxide in which product is eluted from the synthesizer is variable. The ammonium hydroxide used should not have been diluted by excessive vapor loss.

2. Place the sample in heat block or oven for ≥ 12 hr at 55° to 60°C .
Seal vial tightly with Parafilm (if not fitted with a rubber O ring).
3. After cleavage from the support and deprotection are complete, spin the sample briefly in a tabletop centrifuge to pool the ammonia and support that may have collected in the cap. Let the vial cool to room temperature before opening it to avoid sample boil-over.
4. Filter off the support by passing the liquid through an $0.2\text{-}\mu\text{m}$ filter and wash the filter with 0.3 ml of $3:1$ (v/v) ammonium hydroxide/ethanol.
5. Precipitate the oligonucleotide from the resulting supernatant by adding 10 vol n -butanol and vortexing for 15 sec. Centrifuge 10 min at $16,000 \times g$, 4°C .
6. Remove and discard the single aqueous n -butanol phase to reveal the white oligonucleotide pellet.

Oligonucleotides 20 residues or shorter with good trityl responses are typically suitable for use directly in DNA sequencing, PCR amplification, and gel-shift analysis. However, if more assuredly homogenous material is required, methods such as denaturing PAGE and HPLC may be employed to further purify the full length product.

7. If a yellowish liquid or crusty pellet remains, rather than a white powder, resuspend the pellet in 0.1 ml distilled water and precipitate again with n -butanol as described above.

Generally, it is not necessary to add additional salt for precipitation.

Further extraction will aid in removing any residual ammonia or volatile organics. If the yellow color does not disappear, it will ultimately be removed by almost any of the standard purification methods.

8. Lyophilize the sample to dryness in a Speedvac evaporator.

This deprotection is primarily intended for oligonucleotides with the trityl group off. When the trityl group is left on, care must be taken that it is not prematurely hydrolyzed from the DNA by acid conditions. During lyophilization, a drop of triethylamine must be added regularly to the sample in order to maintain its basicity (Applied Biosystems, 1988). Heating of the samples should be avoided.

DEPROTECTION OF RNA OLIGONUCLEOTIDES

Techniques and recommendations for deprotecting RNA are similar to those for DNA. Ammoniolysis cleaves the RNA from the support and frees the bases of their protecting groups. Additionally, the $2'$ hydroxyl protecting group must be removed to reveal a functional RNA sequence. Reagents, water, and plasticware to which RNA is exposed must be sterile. The protocol detailed below is for use with nucleosides bearing the standard isobutyryl and benzyl protection on the bases and $2'$ silyl protection. Protection options are becoming available that both increase yield and streamline deprotection time (Table 2.11.1).

Materials

100% ethanol
 $3:1$ (v/v) concentrated (14.8 N) ammonium hydroxide/ethanol
 3 M sodium acetate, pH 5.2 (APPENDIX 2)
 Triethylamine trihydrofluoride
 Screw-cap plastic vial (preferably fitted with rubber O ring)
 Heat block or oven, 55° to 60°C
 $0.2\text{-}\mu\text{m}$ filter
 Sephadex G-25 column (Amersham Pharmacia Biotech)

BASIC PROTOCOL 3

Preparation and Analysis of DNA

2.11.19

1. In a screw-cap plastic vial, suspend the synthesis support matrix or the already support-cleaved oligonucleotide in ~1.2 ml of 3:1 (v/v) ammonium hydroxide/ethanol for up to a 1- μ mol scale.

Depending on the synthesizer or nucleic acid provider, the oligo may come attached to a support matrix or free in an ammonium hydroxide solution. The volume of ammonium hydroxide in which product is eluted from the synthesizer is variable. The ammonium hydroxide used should not have been diluted by excessive vapor loss.

2. Place the sample in a heat block or oven for 12 to 16 hr at 55° to 60°C.

Seal vial tightly with Parafilm (if not fitted with a rubber O ring). If fast-cleaving phosphoramidites such as PAC-protected purines and acyl-protected cytosine are used, the deprotection time of the bases can be a little as 10 min in methylamine at 65°C (Wincott et al., 1995).

3. After cleavage from the support and base deprotection are complete, spin the sample briefly in a tabletop centrifuge to pool the ammonia and support that may have collected in the cap. Let the vial cool to room temperature before opening it to avoid sample boil-over.

4. Filter off the support by passing the liquid through an 0.2- μ m filter and wash the filter with 0.3 ml of 3:1 (v/v) ammonium hydroxide/ethanol.

5. Evaporate the combined solutions to dryness in the Speedvac evaporator without heating. Resuspend the pellet in 0.2 ml of 100% ethanol and evaporate to dryness without heating.

6. Treat the dried residue with triethylamine trihydrofluoride (0.3 ml for a 0.2- μ mol or 0.5 ml for a 1- μ mol synthesis). Allow to rotate in a foil-covered screw-cap vial in the dark for at least 24 but no more than 48 hr.

Alternative methods exist to remove the 2' silyl protecting groups either under dilute acidic conditions (Kawahara et al., 1996) or with anhydrous triethylamine/hydrogen fluoride in N-methylpyrrolidinone (Wincott et al., 1995).

7. To desalt via ethanol precipitation, add an equal volume of water to the triethylamine trihydrofluoride solution and immediately dilute with $\frac{1}{10}$ vol of 3.0 M sodium acetate, pH 5.2. Precipitate by adding 3 vol of 100% ethanol and chilling for ~20 min at -80°C. Centrifuge 10 min at 16,000 \times g, 4°C.

8. Remove and discard the single ethanol layer to reveal the white oligonucleotide pellet.

9. If a yellowish liquid or crusty pellet remains, rather than a white powder, resuspend the pellet in 0.1 ml distilled water and repeat the sodium acetate/ethanol precipitation as described in step 7. If desired, desalt the RNA on a desalting matrix such as Sephadex G-25 (UNIT 3.4).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Acetonitrile, dry

Since large volumes are used for rinsing lines and dissolving other reagents, acetonitrile is one of the most costly reagents in nucleic acid synthesis. If the DNA synthesizer is used infrequently, it may be useful to produce small amounts of dry acetonitrile immediately prior to synthesis since the acetonitrile will accumulate water after the bottle has been opened. Moisture greatly diminishes synthetic yield. In this case acetonitrile can be prepared in any laboratory equipped for routine

continued

distillations. However, the time and effort involved in setting up and maintaining a still should be balanced against the cost of obtaining dry acetonitrile. The use of molecular sieving pouches that do not release metal ions is recommended; they are often available from the synthesizer manufacturer and should keep the acetonitrile to <20 ppm water. Some commercial suppliers now market bulk solvents specifically for nucleic acid synthesis (e.g., Baker “low-water” acetonitrile, 0.002% or 20 ppm water; Burdick and Jackson acetonitrile, 0.001% or 10 ppm water). The cost of these special dry reagents is about the same as that of HPLC-grade acetonitrile (which typically contains 0.01% or 100 ppm water), which is the starting material for a laboratory distillation.

CAUTION: *Acetonitrile vapor is poisonous.*

Ammonium hydroxide

Purchase concentrated (14.8 N) ammonium hydroxide in 0.5- to 1.0-liter bottles, and store it at 4°C to reduce the ammonia gas found in the vapor phase above the liquid.

CAUTION: *Concentrated ammonium hydroxide is extremely caustic. Breathing the vapors is harmful. Always use this compound in the fume hood, as it is possible to be quickly overcome by ammonia fumes and blinded.*

Ammonia is volatile and its concentration will decrease on repeated opening, until it is no longer completely functional as a deprotecting reagent. When this occurs, obtain a fresh supply.

Oxidizer

Prepare 0.02 M iodine in 7:2:1 (v/v/v) THF/pyridine/water. Store ≤6 months at room temperature.

CAUTION: *Pyridine is toxic in both liquid and vapor forms.*

CAUTION: *Iodine is harmful if inhaled. Beware of spills containing both iodine and ammonia since explosive compounds can be formed.*

Most commercial sources of THF contain BHT, a free-radical scavenger that prevents the buildup of explosive peroxides. This compound has no effect on synthesis chemistry. Any commercial grade of pyridine is acceptable; use resublimed iodine.

Phosphoramidites

Prepare phosphoramidites in extremely dry, commercially sealed acetonitrile according to the procedure recommended by the synthesizer manufacturer. Store ≤6 months at 4°C and discard after 2 weeks.

Some companies recommend dissolving phosphoramidites to give equal molarities of the four bases, while others recommend a standard weight/volume ratio that will give slightly different final molar concentrations. The actual phosphoramidite concentration may matter for some applications—e.g., when making mixed-site oligonucleotides.

COMMENTARY

Critical Parameters

By optimizing the reagents and protocols used in oligonucleotide synthesis, it is reliably possible to make products of greater length and yield, while minimizing the costs associated with unproductive runs.

Excluding water from solvents

The most critical factor in any synthesis is how the reagents are handled to excluded water

from the system. From the moment a bottle is opened, it is in contact with water in the air, and all the solvents used are hygroscopic and will absorb water vapor, which reduces yields. This problem is so severe that it is advisable to avoid large-scale, lengthy, or important runs on rainy or highly humid days.

Special anhydrous reagents can be purchased from most manufacturers of nucleic acid synthesizers. Additionally, some chemical

suppliers are now beginning to market solvents specifically for DNA synthesis. Adding molecular sieving pouches to the activator and acetonitrile used before oxidation is extremely useful in preserving the anhydrous environment of the phosphoramidite coupling reaction.

Phosphoramidites are the most sensitive to water contamination because they are easily hydrolyzed, which renders them unreactive. Precautions must be taken to avoid exposing them to even small amounts of water. Very dry acetonitrile (<0.003% water), kept as a separate stock and sealed under argon, should be used to dissolve the phosphoramidites. The acetonitrile should be introduced through the septum on the amidite bottles via a syringe. Glass syringes can be dried in a 300°C drying oven, then cooled in a desiccator prior to use. Plastic syringes can be dried in a 45°C vacuum oven. Disposable plastic syringes from air-tight sterile casings are dry enough to use with acetonitrile to be dispensed into phosphoramidites with no additional precautions. The syringe should be filled with argon or helium prior to drawing up the acetonitrile, so that wet air is not introduced into the system. On some synthesizers, this can be done directly via the phosphoramidite ports. Otherwise, an argon line should be used.

An argon line is generally a helpful tool for DNA synthesis chemistry. It consists of an argon tank with a regulator connected to a piece of plastic (Tygon) tubing. The tubing is then fitted with either a Pasteur pipet or a syringe and needle. Gas flow can be roughly determined via an in-line “bubbler” (e.g., Aldrich). Argon from a tank is dry enough so that an in-line desiccator is unnecessary. It is necessary to flush the line for several seconds prior to use. Empty bottles can be dried under an argon stream, which will help to exclude condensation from the air. Partially used reagents should be sealed under an argon layer to prevent equilibration with water vapor in the air (the heavier argon will exclude air from the containers).

Choosing synthesis columns

Automated DNA synthesis generally takes place on a solid support made of controlled-pore glass (CPG). This is a porous, nonswelling particle, 125 to 177 μm in diameter, that is derivatized with a terminal nucleotide attached to a long spacer arm. The accessibility of the growing end of the oligonucleotide chain is influenced by the pore size of the particle. It has been recommended that oligonucleotides up to 50 bases in length should be synthesized

on CPG with $\sim 500\text{-\AA}$ pores, while longer oligonucleotides should be synthesized on CPG with $\sim 1000\text{-\AA}$ or larger pores. Be sure that the column geometry is compatible with the trityl monitor. Also, when packing columns be sure to purge the column first with dry acetonitrile and then with dry argon to ensure that all CPG particles are caught between the filters, since loose particles can damage the synthesizer.

CPG columns are available that contain ~ 0.2 to $10.0\ \mu\text{mol}$ of linked nucleotides. In general larger loadings are used for larger oligonucleotides since as the size of the oligonucleotide increases, the overall yield decreases. Also, subsequent purification steps invariably involve losses, and the amount of product of correct length must be kept high to ensure that there is enough material. Oligonucleotides >35 bases should be synthesized on $1.0\text{-}\mu\text{mol}$ CPG columns. See Synthesizing Long Oligonucleotides for discussion of choosing a column when synthesizing ≥ 100 -base oligonucleotides.

Alternatively, columns that are more heavily derivatized with the 3' terminal nucleotide are available as solid supports (e.g., Fractosil, from Merck), and a higher yield of product per column (and per amount of reagent delivered) can be obtained using these columns. However, Fractosil is not recommended for synthesizing oligonucleotides >20 bases long.

Synthesis chemistry

Regardless of reagent and final product purity, there are inherent limitations in the chemistry used for the synthesis of oligonucleotides. Therefore, it is necessary to understand the differences between chemically synthesized and biologically derived DNA.

Failure to produce “natural” DNA can be due to the synthesis chemistry used. Methylation of some bases can occur during deprotection with thiophenol in methyl phosphoramidite-based syntheses. Under standard synthesis conditions, these methylated bases can account for up to 7% of the nucleotides present, with *N*-3-methyl-dT being the primary modified base (Farrance et al., 1989). However, this problem does not always occur—some such syntheses have been reported to contain 99.9% dA, dG, dT, and dC. In general, this problem can be avoided by increasing the time of the thiophenol deprotection step to between 60 and 90 min.

With both methyl and β -cyanoethyl chemistries, the glycosidic bond of *N*-protected purine phosphoramidites is subject to hydroly-

sis during DMT removal with acid. Such depurination eventually leads to strand cleavage during the ammonia deprotection step. N-protected adenosine is more sensitive to depurination than guanosine, and it is most sensitive when located at the 5' end of an oligonucleotide chain (Tanaka and Letsinger, 1982).

In order to maintain low levels of depurination, the deblocking step should not be longer than ~1 min. Additionally, the mildest effective acid (DCA rather than TCA) should be used. Occasionally, however, protected nucleotides are supplied as monomethoxytrityl (MMT) esters, which are 10-fold more resistant to acidic detritylation. Oligonucleotides synthesized with MMT as a protecting group are more susceptible to depurination, since the deblocking step must be correspondingly lengthened to achieve complete detritylation and high yields. In cases where only one base is being added as the MMT compound, it is recommended that this step be performed manually, so that the nucleotides are subjected to only one lengthy acid treatment.

Advances in oligonucleotide synthesis chemistry may mitigate the problems associated with depurination. Recently, nucleotides derivatized with protecting groups that render synthesized material less sensitive to depurination have become commercially available (Schulhof et al., 1987; Pharmacia, 1989).

Reagents

Most reagents may be purchased from the synthesizer manufacturer or from companies that specialize in reagents for nucleic acid synthesis; however, some labs choose to make their own reagents to reduce costs. Notes on the preparation and storage of certain reagents are provided above. Other reagents should probably be purchased from commercial sources, as the preparation of anhydrous materials is more difficult and expensive than most molecular biology labs can support. An appropriate text should be consulted on the medical dangers of all solutions and reagents used in DNA synthesis (see Key References). Most suppliers of materials have a fairly extensive list of products available on-line.

Troubleshooting

Rescue after reagent depletion

Most synthesizer problems require a visit from the service engineer. However, syntheses during which reagent or solvent bottles run empty can sometimes be rescued. Certain in-

struments respond to depleted reagents during a synthesis by continuing the synthesis or stopping. For instruments that stop, it may be possible to recover oligonucleotides, depending on which reservoir was depleted. It is important that the lines be rinsed after an empty reservoir has been detected (some machines perform this step automatically). Otherwise, the oligonucleotide should be resynthesized. Many machines have the capacity to restart in the middle of a cycle, and if not, the cycle can be finished manually. The exact procedure will vary depending on which reagent has been exhausted.

Acetonitrile. This is quite serious. The lines cannot be rinsed of whatever reagent they last contained; thus, determine whether to continue with the synthesis based on the reactivity of the last reagent in the lines.

Deblocking reagent. Refill the reservoir. The machine can continue at the beginning of the cycle that was interrupted, but full-length yield will greatly suffer.

Phosphoramidites. Refill the reservoir and perform manual coupling. In this way, the chains that did elongate will not form $n + 1$ products, and those that did not will have a chance to elongate. Programmed synthesis can be resumed with the next cycle.

Capping reagent. Perform a manual capping and complete the cycle manually, at which point programmed synthesis can resume. This ensures that capping is efficient for this cycle and avoids accumulation of $n - 1$ sequences.

Oxidizer. Running out of oxidizer is particularly dangerous, because the unstable phosphite linkages remain on the column for long periods. It is best to discard the material; otherwise, perform a manual oxidation and continue with the synthesis.

Ammonium hydroxide. Some material may be left on the column if ammonium hydroxide runs out during the course of synthesis. Refill the bottle and pump more ammonium hydroxide through the column, or remove the column and treat with ammonium hydroxide.

Thiophenol. Refill the thiophenol reservoir. Restart from the deprotection step. At worst, a small amount of product may have cleaved because of inefficient methyl deprotection.

Routine maintenance

To avoid other purely mechanical problems with a DNA synthesizer, create a regular maintenance schedule to perform a few minor maintenance tasks. Change the various frits and filters that remove debris before they enter the system; furthermore, remove the deposits of

salt and debris as these may affect flow rates and decrease volumes delivered. Change the filters on the acetonitrile bottle more often, because the flow of this reagent is much greater than any other. Also, change any rubber O rings every few months. Rinse all the instrument's lines with base and organic solvents thoroughly every 500 hr of machine use or approximately every 3 months. Finally, rinse the lines extensively with dry acetonitrile. Finish the general maintenance by checking the flow rates of the instrument after cleaning and then synthesize a small oligonucleotide. Monitor the trityls carefully in order to confirm that the cleaning did not affect any aspect of the synthesis cycle. If this regimen is followed, many minor delays encountered in the synthesis schedule can be avoided.

Anticipated Results

When the synthesizer is working properly (>98% coupling efficiency), typical yields of deoxyoligonucleotides 20 bases in length at the 1- μ mol scale, as measured from the trityl response, are nearly 60%. Also, these shorter deoxyoligonucleotides are typically suitable for DNA sequencing, PCR amplification, and gel-shift analysis without extensive purification. However, if very homogenous material is required, further purification must be done, because many sequences will be truncated (*UNIT 2.12*). Longer DNA sequences are generally obtained in lesser yield and quality and should be purified. Sequences of >120 bases are generally obtained in \leq 10% yield as measured by the trityl response. Yields for RNA sequences are typically much lower than for their DNA counterparts of a given length, and the products must be extensively purified.

Time Considerations

On a typical day when most of the bottles on the synthesizer need refilling, it may take 30 to 60 min to fill the bottles, empty waste, install columns, and rinse and prime the lines prior to starting a synthesis. The most time-consuming syntheses are those involving doped oligonucleotides, which require a high level of precision in distributing the various phosphoramidites to the appropriate bottles. A computer interfaced with the instrument can increase synthesis accuracy and throughput. Instruments take varying amounts of time to synthesize oligonucleotides depending on the number of columns in use, the length of the oligonucleotide, and the synthesis program. Deprotection and isolation of a standard DNA oligonu-

cleotide will probably take one working day, while RNA oligonucleotides take longer because of the extra deprotection and desalting steps.

Purification of Oligonucleotides Using Denaturing Polyacrylamide Gel Electrophoresis

UNIT 2.12

**BASIC
PROTOCOL**

Several methods exist for the purification of oligonucleotides following chemical synthesis (UNIT 2.11). The advantages of purification on denaturing polyacrylamide gels are speed, simplicity, and high resolution. These gels can resolve oligonucleotides from 2 to 300 bases long, depending on the percentage of polyacrylamide used (see Table 2.12.1). This method is thus useful for isolating not only chemically synthesized deoxyribonucleotides (UNIT 2.11) but also small RNAs or other single-stranded oligonucleotides. After gel setup, samples are loaded onto a urea-based denaturing gel, separated by electrophoresis, and finally recovered from the crushed gel slice by freeze/thaw and elution.

Materials

Nucleic acid samples

Urea

10× and 1× TBE buffer, pH 8 (APPENDIX 2)

40% acrylamide/2% bisacrylamide (UNIT 7.6)

TEMED (*N,N,N',N'*-tetramethylethylenediamine)

10% ammonium persulfate (APS) in water (store ≤1 month at 4°C)

Urea loading buffer (see recipe)

3 M sodium acetate, pH 5.2 (APPENDIX 2)

TE buffer, pH 7.5 (APPENDIX 2)

Acrylamide gel electrophoresis apparatus

Glass plates, spacers, and combs for pouring gels

50°, 60° and 90°C water baths

DC power supply

Thin-layer chromatography (TLC) plate with fluorescent indicator (e.g., Silica Gel F-254 or IB-F, Merck)

Hand-held short-wave (254-nm) UV lamp

Small-bore (5-ml) syringe (e.g., Becton Dickinson)

15-ml centrifuge tube capable of withstanding high temperatures

Rotary shaker

0.2-μm filter (Gelman Sciences)

Additional reagents and equipment for oligonucleotide deprotection (UNIT 2.11), gel electrophoresis (UNIT 2.7), phenol extraction, and ethanol and butanol precipitation (UNIT 2.1)

Prepare the sample

1. Follow the appropriate deprotection protocol (UNIT 2.11) to prepare the nucleic acid sample for electrophoresis.

Be sure to lyophilize the sample to dryness. The samples will generally appear as an off-white powder following deprotection and lyophilization. If a yellowish liquid or crusty pellet remains, rather than an off-white powder, resuspend the pellet in 0.5 ml distilled water and add $\frac{1}{10}$ vol of 3.0 M sodium acetate, pH 5.2. Add 3 vol of 100% ethanol and chill ~20 min at -80°C to precipitate. Centrifuge 10 min at 16,000 × g, 4°C. Decant and save the supernatant. Wash the pellet in 70% ethanol and lyophilize to dryness.

Supplement 42

Table 2.12.1 Concentrations of Acrylamide Giving Optimum Resolution of DNA Fragments Using Denaturing PAGE^a

Acrylamide (%)	Fragment sizes separated (bases)	Migration of bromphenol blue (bases)	Migration of xylene cyanol (bases)
30	2-8	6	20
20	8-25	8	28
10	25-35	12	55
8	35-45	19	75
6	45-70	26	105
5	70-300	35	130
4	100-500	~50	~230

^aData, from Maniatis et al. (1975), are for single-stranded DNA; RNA will migrate slightly more slowly than DNA of the same sequence and length.

Prepare the gel

2. Assemble the gel-casting apparatus.

Gel spacer and casting systems have been developed to avoid leakage. Those that avoid the need to seal the gel with tape are best, and recently gel casting boots that lack bottom spacers have become available (GIBCO/BRL). Greasing the side/bottom spacers or pouring an agarose plug for the gel is not necessary if some care is taken to ensure that the bottom of the plate assembly is completely sealed. The gel plates should be thoroughly cleaned by washing them with warm soapy water and then rinsing them in 70% ethanol/water. However, if the plates are particularly dirty or if the complete removal of any residual nucleic acids is required, the plates may be soaked in 0.1 M NaOH for 30 min prior to washing. If the gel is particularly thin (<1 mm), silanizing one or both plates (APPENDIX 3B) facilitates post-electrophoretic separation of the gel from the plate.

3. Prepare the gel solution (see Table 2.12.1 for appropriate acrylamide concentrations for resolving single-stranded DNAs). For a denaturing acrylamide gel of 20 cm × 16 cm × 1.6 mm, 60 ml of gel solution is sufficient, made by mixing the following:

25.2 g urea (7 M final)
6 ml 10× TBE buffer
Desired amount of 40% acrylamide/2% bisacrylamide needed for resolution
H₂O to 60 ml final.

CAUTION: Acrylamide is a neurotoxin; always wear gloves, safety glasses, and a surgical mask when working with acrylamide powder.

Commercially prepared polyacrylamide solutions (National Diagnostics) are available and highly recommended since they have long shelf lives and avoid manipulation of the neurotoxic acrylamide powder.

Pick a concentration of acrylamide that will allow the single-stranded nucleic acid to migrate approximately one-half to three-fourths of the way through the gel when the loading dye has reached the bottom of the gel. This allows for good separation of non-full-length and full-length products.

Use a flask that has a wide mouth and a spout for pouring.

4. Heat the mixture to speed its dissolution by immersing the flask in a 60°C water bath or under hot running tap water. Once most of the urea and acrylamide have dissolved, vigorously agitate the solution for ~20 min with magnetic stirring to ensure complete mixing.

5. Add 40 μl TEMED and swirl the flask to ensure thorough mixing. Immediately add 300 μl of 10% APS and mix thoroughly. Pour the acrylamide between the gel plates and insert the comb. Clamp the comb in place at the top of the gel to avoid separation of the gel from the plates as the acrylamide polymerizes. Allow the gel to polymerize for ~ 30 min.

IMPORTANT NOTE: *Polymerization begins as soon as the TEMED and APS are mixed, so all succeeding steps must be performed promptly.*

CAUTION: *Be sure to wear safety glasses while pouring the gel, since it is easy to splash the neurotoxic unpolymerized acrylamide.*

For thick gels, the acrylamide can be poured directly from the mixing flask, but for thinner ones, a large syringe fitted with a needle is useful. By pouring the gel slowly with a tilt of 45° relative to the bench top and starting from one corner, bubbles may largely be avoided. Also, letting the gel polymerize while it is lying flat helps minimize undesirable hydrostatic pressure on the gel bottom.

TEMED may be stored indefinitely at 4°C , but the ability of APS to efficiently initiate the free radical-induced acrylamide polymerization diminishes greatly over time. Make a new APS stock every month and store at 4°C .

Run the gel

6. After polymerization is complete, remove the comb and any bottom spacers from the gel. Wash the gel plates free of spilled acrylamide, and be sure that the spacers are properly seated and clean.
7. Fill the lower reservoir of the electrophoresis tank with $1\times$ TBE. Initially, place the gel into the lower tank at an angle to avoid formation of air bubbles between the plates and the gel bottom. Clamp the gel plates to the top of the electrophoresis tank and fill the upper reservoir with $1\times$ TBE so that the wells are covered.

A syringe with a bent needle may be used to remove air bubbles trapped under the gel, which will disrupt the current flow.

8. Using a DC power supply, prerun and warm the gel for at least 30 min at 20 to 40 V/cm (constant voltage).
9. Add $1\times$ urea loading buffer to the oligonucleotide pellet from step 1 and resuspend it by heating it 5 min at 90°C .

The amount of sample that can be loaded depends on the efficiency of the synthesis reaction. At least 10 μg of material in a single band 2 cm wide is required to cast a clear UV shadow. The longer the oligonucleotide, the less full-length product will be obtained.

Use an amount of loading buffer that is consistent with loading $\sim 25\%$ of a 0.2- μmol synthesis of a 20-mer oligonucleotide per $2\text{ cm} \times 2\text{ cm} \times 1.6\text{ mm}$ well. This will give sharp bands with good resolution. Up to 4-fold more may be added, but the resolution will suffer.

10. Rinse the wells thoroughly with $1\times$ TBE solution immediately prior to gel loading.

The 7 M urea dissolved in the gel will start to diffuse from the wells, creating a dense layer at the bottom of the wells that prevents sample loading and decreases resolution. Rinsing eliminates this problem.

11. Load the samples.

Tracking dyes such as bromphenol blue and xylene cyanol may be added to the samples or in empty lanes to monitor migration (see Table 2.12.1 for migration data).

12. Electrophorese the gel at 20 to 40 V/cm (constant voltage) until the positions of the tracking dye(s) from the loading buffer indicate that the oligonucleotide has migrated one-half to three-fourths of the way through the gel.

The speed of electrophoresis is directly proportional to the voltage gradient across the gel. The current in the circuit and the heat generated for higher-percentage gels (>15% acrylamide) are corresponding smaller; since the increased acrylamide concentration leads to greater resistance. While some heating of the gel during electrophoresis is desirable since it helps to denature the sample, temperatures >65°C should be avoided. All gels should be monitored to make sure that they do not generate so much heat that the plates crack. For example, while a 20% gel can be electrophoresed at 800 V with few problems, an 8% gel run under the same conditions would likely generate too much heat for the apparatus to dissipate.

13. When the oligonucleotide is sufficiently resolved, turn off the power supply and detach the plates from the electrophoresis tank. Pry off the top plate. Cover the gel with plastic wrap (taking care to avoid bubbles and folds) and invert the plate onto a TLC plate with a fluorescent indicator. Using a spatula, peel a corner of the gel away from the plate and onto the plastic wrap. Pry off the remaining plate and place another sheet of plastic wrap on top of the gel.

Recover the oligonucleotide

14. Visualize the bands on the gel by briefly exposing them to short-wave (254 nm) radiation from a handheld lamp. The bands will appear as black shadows on a green background. Outline the bands using a marking pen.

Avoid unnecessarily long UV exposure, which will damage the nucleic acids.

The desired band is generally the darkest one on the gel (excluding material that runs at the dye front); it should also be the slowest-migrating band unless deprotection was incomplete. Lighter bands containing partially protected oligonucleotides, if present, will migrate considerably above the major fully deprotected band. If the stepwise efficiency of the synthesis is low, a smear may be seen instead of a clear band. The top of the smear should be cut out of the gel.

Unpolymerized acrylamide absorbs strongly at 211 nm and may also cause shadowing that is confined to the edges and wells of the gel.

15. Cut out the bands directly with a clean scalpel or razor blade.
16. Chop the gel slabs into fine particles by forcing the gel through a small-bore syringe to aid the diffusion of the oligonucleotide from the matrix. Place the crushed gel slab in a 15-ml centrifuge tube capable of withstanding high temperatures.
17. Add 3 ml TE buffer for every 0.5 ml of gel slab. Freeze the sample for 30 min at -80°C or until frozen solid. Quickly thaw it in a hot water bath (-50°C) and let soak 5 min at 90°C. Elute on a rotary shaker overnight at room temperature.

This freeze/rapid thaw approach (Chen and Ruffner, 1996) greatly decreases elution time and increases yield by allowing ice crystals to break apart the acrylamide matrix. Recovery of a 20-mer oligonucleotide is typically 80% after 3 hr of rotary shaking, making this technique comparable in yield to electroelution (UNIT 2.7).

Since elution is a diffusion-controlled process, using more buffer will aid in elution efficiency. Also, note that longer oligonucleotides will take longer to diffuse from the gel. If speed is essential and high yields are dispensable, enough sample can be obtained for most experiments in only a few hours of extraction. Increasing the temperature to 37°C will also speed the process. Yield may be increased by repeated elutions.

18. Centrifuge the tube 2 min at 1000 × g, room temperature, to pellet the gel fragments. Use a syringe to remove the supernatant, then filter off any remaining acrylamide

fragments by passing the suspension through an 0.2- μ m filter and into a fresh 15-ml centrifuge tube.

19. Concentrate the sample by extracting against 1 vol *n*-butanol. Remove the upper butanol layer and repeat until the volume of the lower, aqueous layer is convenient for precipitation.

About 1/5 vol of the aqueous layer is extracted into the organic butanol layer for every volume of butanol used. If too much butanol is added and the water is completely extracted into the butanol, simply add more water and concentrate again.

20. Add 3.0 M sodium acetate, pH 5.2 (to a final concentration of 0.3 M). Add 2 vol of 100% ethanol to precipitate DNA or 3 vol for RNA. Chill 20 min at -20°C . Pellet the oligonucleotide by centrifuging 10 min at $12,000 \times g$, 4°C .

Do not attempt to precipitate small oligonucleotides (20 bases) in the presence of ammonium ions. If the samples prove refractory to precipitation, use a 1:1 (v/v) mix of ethanol/acetone or 6 vol of acetone for precipitation. A rinse with 95% ethanol will remove undesired salts.

21. Redissolve the oligonucleotide in TE buffer if appropriate.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Urea loading buffer

- 8 M urea
- 20 mM EDTA
- 5 mM Tris·Cl, pH 7.5 (APPENDIX 2)
- 0.5% (w/v) xylene cyanol, bromphenol blue, or both

Add 1 vol loading buffer to sample if a solution, or enough to dissolve a dry sample.

COMMENTARY

Background Information

The traditional alternative to gel purification of oligonucleotides has been high-performance liquid chromatography (HPLC). Although alkali perchlorate salts HPLC systems can achieve very high resolution of small and medium-sized oligonucleotides (<60 bases), electrophoresis provides superior capacity and resolution over a greater range of sizes and is simpler to set up and operate. Separation times using HPLC may be faster (<30 min) than for gels, but the time required for initialization of the system and product workup tend to negate this advantage.

Purification of oligonucleotides on low-pressure reverse-phase cartridges is technically simpler than gel electrophoresis, and faster (<2 hr). However, these cartridges offer no separation of desired product from failed sequences and, if not used properly, allow contamination of the final product with low-molecular-weight compounds that often inhibit subsequent enzy-

matic manipulation of oligonucleotides. For short oligonucleotides synthesized in high yield, very simple purification methods (e.g., gel filtration or ethanol precipitation) are adequate for some applications, such as sequencing or PCR primers, that do not require absolutely homogeneous material.

The high resolution and capacity of polyacrylamide gels makes them the method of choice for the purification of oligonucleotides. Urea disrupts hydrogen bonding between bases and thus allows oligonucleotides to be resolved almost exclusively on the basis of molecular weight as opposed to secondary structure. However, it should be noted that oligonucleotides of equivalent length but different sequence will still migrate slightly differently. Thus, mixed sequences will appear as broader bands than homogeneous sequences (Applied Biosystems, 1984). Also, RNA electrophoreses through the gel more slowly than does DNA of comparable size. Finally, when modified nu-

cleotides have been incorporated into the nucleic acids, the compatibility of their chemistries with that of the acrylamide matrix should be checked before PAGE purification (in particular, oligonucleotides bearing thio groups seem to undergo Michael addition to the acrylamide, which renders them irreversibly capped).

Critical Parameters

For most applications, the separation of oligonucleotides from mononucleotides and protecting groups provides adequate purification. In those cases where separation of oligonucleotides from nearby failure sequences is essential, however, the most critical parameters to be considered are the percentage of acrylamide and the amount of sample loaded. If maximum resolution is desired, then only 50 to 100 μg of material should be loaded per 2 cm \times 2 cm \times 1.6 mm well. The percentages of acrylamide that will give optimal resolution for different-sized oligonucleotides are given in Table 2.12.1, and can also be determined empirically by running a small portion of the starting material on trial gels and staining with ethidium bromide. By running long (20- to 30-cm) gels, oligonucleotides of lengths (n) up to 100 bases can be cleanly separated from the $n - 1$ and $n + 1$ products. If an oligonucleotide contains extensive self-complementary sequences or polyguanosine tracts, it may not be completely denatured in 7 M urea, and thus it may not be possible to separate it cleanly from failed synthesis products. To overcome this difficulty, samples can be electrophoresed on gels containing 20 M formamide instead of urea (Frank et al., 1981).

Troubleshooting

All of the problems that apply to non-denaturing PAGE are relevant here (see *UNIT 2.7*, Commentary). However, most failures in purification will occur because the initial synthesis reaction has been inefficient. In almost all cases, it is better to resynthesize a poor-yielding oligonucleotide than to attempt to isolate a small amount of full-length product from a starting material seriously contaminated with failure sequences. If the oligonucleotide cannot be resynthesized, relatively small amounts of product can be visualized by autoradiography providing the starting material is end-labeled with polynucleotide kinase and [γ - ^{32}P]ATP (the starting material should not contain residual ammonium, which inhibits the enzyme; see

UNIT 3.10). It is convenient to end label a small amount of starting material with radioactive ATP; the remainder should be phosphorylated using nonradioactive ATP so that it will not migrate differently from the labeled tracer. Smaller amounts of starting material should be loaded on thinner (~ 0.75 - to 1.0-mm) gels in narrower lanes (~ 1.0 cm).

Anticipated Results

In general, the yield of purified oligonucleotides from denaturing PAGE decreases as the percentage of acrylamide increases. With crushed gel slices, an average yield of 50% may be expected.

Greater recoveries can be obtained by increasing the volume of elution solution added to the gel slice or by performing serial elutions from the same gel slice. Methods employing more active transfers (e.g., electroelution; Smith, 1980; Vorndam and Kerschner, 1986) may give more efficient recoveries. Also, samples (especially large synthetic RNAs) that prove particularly refractory to elution with aqueous buffers may be eluted easily with 6 vol formamide (for >5 hr at room temperature) followed by a brief (~ 1 hr) elution with an aqueous buffer. Isoamyl alcohol may be used to concentrate the formamide/aqueous buffer extracts to a convenient precipitation volume (J. Urbach, pers. comm.).

Time Considerations

It is usually most convenient to set up and run the gel on one day, elute the oligonucleotide overnight, then phenol extract and ethanol precipitate the sample the following day. However, a deprotected oligonucleotide can be ready for molecular biology applications in as little as 6 hr: setup and polymerization of gel, 1 hr; running of gel, 2 hr; fragment elution, 2 hr; product recovery, 1 hr.

CHAPTER 3

Enzymatic Manipulation of DNA and RNA

INTRODUCTION

Many of the revolutionary changes that have occurred in the biological sciences over the past few years can be directly attributed to the ability to manipulate DNA in defined ways. The major tools for this genetic engineering are the enzymes that catalyze specific reactions on DNA molecules. This chapter reviews the properties of the principal enzymes that are critical for carrying out most of the important reactions involved in recombinant DNA technology. In addition, it describes protocols for many of the basic techniques such as restriction mapping, radioactive labeling of nucleic acids, and construction of hybrid DNA molecules (cloning). The protocols are described in a manner that includes all the necessary individual components. For convenience, commercial suppliers offer self-contained kits in which many of the components are combined.

From a historical perspective, the discovery of restriction enzymes that cleave DNA at discrete nucleotide sequences was probably the breakthrough that ushered in the rest of the technology. First, the cleavage sites provide specific landmarks for obtaining a physical map of the DNA. Second, the ability to produce specific DNA fragments by cleavage with restriction enzymes makes it possible to purify these fragments by molecular cloning. Third, DNA fragments generated by restriction endonuclease treatment are basic substrates for the wide variety of enzymatic manipulations of DNA that are now possible.

This chapter begins with a protocol for cleaving DNA with restriction endonucleases. In addition to the basic reaction, it includes methods for cleavage with multiple enzymes, for partial digestion of DNA, and for analysis of multiple samples. Structural maps of DNA are generated by restriction mapping that involves digestion with multiple enzymes. This section also contains basic information about all the enzymes that are commercially available. For each enzyme the recognition sequence, type of termini that are produced upon cleavage, buffer conditions, and conditions for thermal inactivation are described.

Another major section of this chapter describes the properties and reaction conditions for other enzymes that are used to manipulate DNA molecules. These include the following: DNA polymerases which synthesize DNA from double-stranded or primed, single-stranded templates; exonucleases which degrade DNA stepwise from the 5' and/or 3' ends; ligases which join double-stranded segments of DNA; RNA polymerases which synthesize RNA from double-stranded DNA templates; phosphatases which remove 5' terminal phosphate residues from nucleic acids; kinases which phosphorylate 5' terminal hydroxyl residues; and several other enzymes that have more specialized applications. The major uses of these enzymes are described, as are some specific protocols for radioactively labeling RNA or DNA.

General techniques for constructing hybrid DNA molecules are presented in the fourth section. Because there are numerous tricks of the trade, this section deals with the general principles for designing the best strategy for any particular cloning experiment. Some specific examples are discussed in more detail, e.g., subcloning restriction fragments via cohesive or blunt ends, directional cloning, joining DNA fragments with incompatible ends, and ligations involving oligonucleotide linkers (*UNIT 3.16*). The polymerase chain

Digestion of DNA with Restriction Endonucleases

Restriction endonucleases recognize short DNA sequences and cleave double-stranded DNA at specific sites within or adjacent to the recognition sequences. Restriction endonuclease cleavage of DNA into discrete fragments is one of the most basic procedures in molecular biology. The first method presented in this unit is the cleavage of a single DNA sample with a single restriction endonuclease (see Basic Protocol). A number of common applications of this technique are also described. These include digesting a given DNA sample with more than one endonuclease (see Alternate Protocol 1), digesting multiple DNA samples with the same endonuclease (see Alternate Protocol 2), and partially digesting DNA such that cleavage only occurs at a subset of the restriction sites (see Alternate Protocol 3). A protocol for methylating specific DNA sequences and protecting them from restriction endonuclease cleavage is also presented (see Support Protocol). A collection of tables describing restriction endonucleases and their properties (including information about recognition sequences, types of termini produced, buffer conditions, and conditions for thermal inactivation) is given at the end of this unit (see Table 3.1.1, Table 3.1.2, Table 3.1.3, and Table 3.1.4).

DIGESTING A SINGLE DNA SAMPLE WITH A SINGLE RESTRICTION ENDONUCLEASE

Restriction endonuclease cleavage is accomplished simply by incubating the enzyme(s) with the DNA in appropriate reaction conditions. The amounts of enzyme and DNA, the buffer and ionic concentrations, and the temperature and duration of the reaction will vary depending upon the specific application.

Materials

- DNA sample in H₂O or TE buffer (*APPENDIX 2*)
- 10× restriction endonuclease buffers (see recipe)
- Restriction endonucleases (Table 3.1.1 and Table 3.1.3)
- 10× loading buffer (*UNIT 2.5*)
- 0.5 M EDTA, pH 8.0 (optional; *APPENDIX 2*)

Additional reagents and equipment for agarose or polyacrylamide gel electrophoresis (*UNIT 2.5* or *UNIT 2.7*), DNA extraction (optional; *UNIT 2.1*), and ethanol precipitation (optional; *UNIT 2.1*)

1. Pipet the following into a clean microcentrifuge tube:

- x μ l DNA (0.1 to 4 μ g DNA in H₂O or TE buffer)
- 2 μ l 10× restriction buffer (Table 3.1.1)
- 18 – x μ l H₂O.

A 20- μ l reaction is convenient for analysis by electrophoresis in polyacrylamide or agarose gels. The amount of DNA to be cleaved and/or the reaction volume can be increased or decreased provided the proportions of the components remain constant.

2. Add restriction endonuclease (1 to 5 U/ μ g DNA) and incubate the reaction mixture 1 hr at the recommended temperature (in general, 37°C).

In principle, 1 U restriction endonuclease completely digests 1 µg of purified DNA in 60 min using the recommended assay conditions. However, crude DNA preparations, such as those made by rapid procedures (UNIT 1.6), often require more enzyme and/or more time for complete digestion (see Critical Parameters). The volume of restriction endonuclease added should be less than 1/10 the volume of the final reaction mixture, because glycerol in the enzyme storage buffer may interfere with the reaction.

3. Stop the reaction and prepare it for agarose or acrylamide gel electrophoresis (UNIT 2.5 or UNIT 2.7) by adding 5 µl (20% of reaction vol) 10× loading buffer.

The reaction can also be stopped by chelating Mg²⁺ with 0.5 µl of 0.5 M EDTA (12.5 mM final concentration). If the digested DNA is to be used in subsequent enzymatic reactions (e.g., ligation or “filling-in” reactions), addition of EDTA should be avoided. Alternatively, many enzymes can be irreversibly inactivated by incubating 10 min at 65°C (see Table 3.1.1). Some enzymes that are partially or completely resistant to heat inactivation at 65°C may be inactivated by incubating 15 min at 75°C. When the enzyme(s) is completely resistant to heat inactivation, DNA may be purified from the reaction mixture by extraction with phenol and precipitation in ethanol (UNIT 2.1).

Alternatively, DNA may be purified conveniently using a silica matrix suspension as described in UNIT 2.1 (also commercially available as GeneClean from Bio101.)

ALTERNATE PROTOCOL 1

DIGESTING DNA WITH MULTIPLE RESTRICTION ENDONUCLEASES

It is often desirable to cleave a given DNA sample with more than one endonuclease. Two or more enzymes may be added to the same reaction mixture if all are relatively active in the same buffer and at the same temperature. Many enzymes are active in a wide variety of buffer solutions. It is frequently possible to choose a standard buffer solution in which two or more enzymes will retain activity (see Commentary and Table 3.1.2). Alternatively, most restriction endonucleases and some DNA-modifying enzymes are active to some extent in potassium glutamate- and potassium acetate-based buffers (see recipe for 10× restriction endonuclease buffers). Hence, these buffers may be useful for digesting DNA with multiple enzymes. However, if the reaction conditions needed are too dissimilar, follow the procedure below.

1. Digest the DNA with the enzyme(s) that is active at the lower NaCl concentration (see Basic Protocol, steps 1 and 2).

If optimal digestion conditions differ only in incubation temperature, cleave the DNA with one enzyme, then shift the temperature and add the second enzyme (the order of cleavage does not matter; Table 3.1.1). However, many enzymes with optimal activity at high temperatures are also active at 37°C. In these cases, the enzymes can be added simultaneously and the reaction mixture incubated at 37°C (it may be necessary to add more of the “high-temperature” enzyme than usual).

2. For enzymes active at higher salt concentrations, add 1 M NaCl (1 to 3 µl for a 20-µl reaction) so that the final concentration is suitable for digestion by the next enzyme(s). Add enzyme(s) for the second reaction and incubate appropriately.

Purification of the DNA fragments between digestions is the most reliable method to ensure complete, multiple digestions. However, it is much more laborious and is rarely necessary.

3. Stop the reaction for electrophoretic analysis or further enzymatic treatment (see Basic Protocol, step 3).

Digestion of DNA with Restriction Endonucleases

3.1.2

DIGESTING MULTIPLE SAMPLES OF DNA

This procedure minimizes the number of pipetting steps when multiple samples are to be digested with the same enzyme(s) and, hence, saves time. More importantly, by minimizing the number of transfers from the tube containing the restriction enzyme, the potential for contamination of the enzyme is reduced.

1. For each sample to be tested, add a constant *volume* of DNA to a separate microcentrifuge tube.

It is critical to use a different pipet tip for each DNA sample in order to prevent cross-contamination.

2. Prepare a “premix solution” containing sufficient 10× restriction endonuclease buffer and water for digesting all the samples. Place solution on ice.

For example, if ten 3- μ l samples of DNA are each to be digested in a 20- μ l reaction mixture, the premix will contain 20 μ l of 10× restriction buffer and 150 μ l water. It is prudent to make up enough solution for at least one more sample than is to be tested.

3. Add sufficient restriction endonuclease(s) for digesting all the samples. Mix quickly by flicking the tube and replace on ice.

The solution to which the enzyme is added should not be more concentrated than 3× buffer.

4. Add the appropriate amount of solution containing the restriction endonuclease (17 μ l for above example) to each tube of DNA and incubate the reactions 1 hr at the appropriate temperature.

For most analytical purposes, the same pipet tip can be used to dispense the restriction endonuclease solution provided that care is taken to avoid direct contact with the DNA at the bottom of the tubes. For preparative purposes, it is advisable to use a different pipet tip for each sample.

5. Stop the reactions for electrophoretic analysis or further enzyme digestion (see Basic Protocol, step 3).

PARTIAL DIGESTION OF DNA WITH RESTRICTION ENDONUCLEASES

For some purposes, it is useful to produce DNA that has been cleaved at only a subset of the restriction sites. This is particularly important for cloning segments of DNA in which the site(s) used for cloning is also present internally within the segment, and is also useful for restriction mapping (UNIT 3.3). Partial cleavage is accomplished using reduced (and therefore limiting) concentrations of restriction enzyme. Here a set of serial dilutions of enzyme is set up so that one or more of the conditions used is likely to produce the appropriate partial digestion product. If necessary, the procedure can be used for analytical purposes, and the reaction can be repeated and/or scaled up using digestion conditions that have been empirically determined. Partial cleavage can also be achieved by varying the time of digestion, but this is more tedious and less reliable.

1. Make up a 100- μ l reaction mixture containing DNA in 1× restriction enzyme buffer.
2. Divide up reaction mixture such that tube 1 contains 30 μ l, tubes 2 to 4 contain 20 μ l, and tube 5 contains 10 μ l. Place tubes on ice.
3. Add the selected restriction endonuclease (3 to 10 U/ μ g DNA) to tube 1, mix quickly by flicking the tube, and place the tube back on ice.

**ALTERNATE
PROTOCOL 2**

**ALTERNATE
PROTOCOL 3**

**Enzymatic
Manipulation of
DNA and RNA**

3.1.3

- Using a different pipet tip, add 10 μl from tube 1 into tube 2, mix quickly, and place back on ice. Continue the serial dilution process by successively pipetting 10 μl from tube 2 to 3, 3 to 4, and 4 to 5. When finished, all five tubes should contain 20 μl and be on ice.

Figure 3.1.1 illustrates the serial dilution process.

It is critical to use a new pipet tip for each dilution step.

- Incubate all five tubes for 15 min at the appropriate temperature for the restriction endonuclease and stop the reactions for electrophoretic analysis or further enzymatic treatment (see Basic Protocol, step 3).

By virtue of the serial dilution process, the amount of enzyme per microgram of DNA has been varied over a 54-fold range. The extent of digestion is determined by gel electrophoresis of the samples. For most purposes, the desired partial digestion products can be obtained directly.

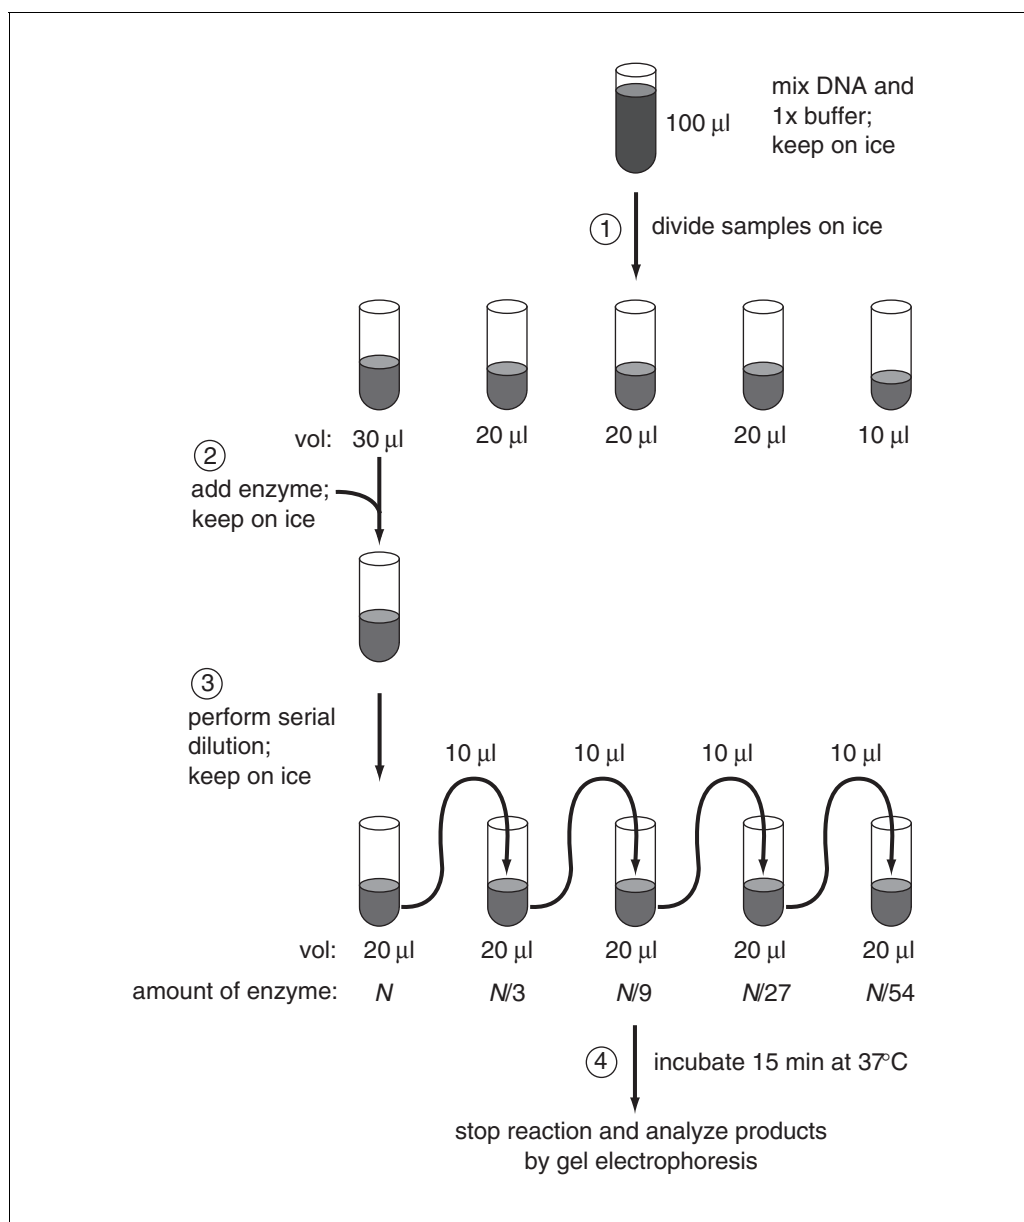

Figure 3.1.1 Partial digestion by serial dilution.

METHYLATION OF DNA

A number of commercially available methylases covalently join methyl groups to adenine or cytosine residues within specific target sequences (i.e., the *EcoRI* methylase methylates an A residue within the *EcoRI* recognition sequence). Methylation of these sites renders them resistant to cleavage by the corresponding restriction endonuclease.

Additional Materials (also see Basic Protocol)

10× methylase buffer (see recipe)
S-adenosylmethionine (SAM)

1. Set up a reaction (typically 20 μ l) containing DNA (at a final concentration of ~20 to 200 μ g/ml) in 1× methylase buffer (Table 3.1.3).
2. Add SAM to achieve a final concentration of 80 μ M.

SAM is the methyl group donor.

3. Add a sufficient amount of methylase to completely protect the DNA from cleavage by the corresponding restriction endonuclease.

A unit of methylase protects 1 μ g bacteriophage λ DNA under the recommended conditions from cleavage by the corresponding restriction endonuclease.

4. Incubate the reaction mixture 1 hr at the appropriate temperature (usually 37°C).

Methylase reactions frequently contain EDTA, which may inhibit subsequent endonuclease reactions. Methylated DNA may be purified from the reaction mixture by extraction with phenol/chloroform and precipitation in ethanol (UNIT 2.1).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Methylase buffer, 10×

NaCl
Tris·Cl, pH 7.5 (APPENDIX 2)
EDTA
2-mercaptoethanol (2-ME) or dithiothreitol (DTT)
S-adenosylmethionine (SAM)

The concentrations of buffer components depend upon the methylase (Table 3.1.3)

Restriction endonuclease buffers

10× sodium chloride–based buffers
100 mM Tris·Cl, pH 7.5 (APPENDIX 2)
100 mM MgCl₂
10 mM dithiothreitol (DTT)
1 mg/ml bovine serum albumin (BSA)
0, 0.5, 1.0, or 1.5 M NaCl

The concentration of NaCl depends upon the restriction endonuclease (Table 3.1.1). The four different NaCl concentrations listed above are sufficient to cover the range for essentially all commercially available enzymes except, those requiring a buffer containing KCl instead of NaCl (see recipe below). Autoclaved gelatin (at 1 mg/ml) can be used instead of BSA. See Critical Parameters.

continued

Note that most restriction enzymes are provided by the suppliers with the appropriate buffers.

10× potassium acetate–based buffer

660 mM potassium acetate
330 mM Tris·acetate, pH 7.9
100 mM magnesium acetate
5 mM DTT
1 mg/ml BSA (optional)

10× potassium chloride–based buffer

60 mM Tris·Cl, pH 8.0 (APPENDIX 2)
60 mM MgCl₂
200 mM KCl
60 mM 2-mercaptoethanol (2-ME)
1 mg/ml BSA

2× potassium glutamate–based buffer

200 mM potassium glutamate
50 mM Tris·acetate, pH 7.5
100 µg/ml BSA
1 mM 2-ME

COMMENTARY

Background Information

Restriction endonucleases are enzymes that cleave DNA in a sequence-dependent manner. Such cleavage is used for a wide number of applications in molecular biology, including (a) establishment of an endonuclease map of a plasmid or bacteriophage clone; (b) fragmentation of genomic DNA prior to electrophoretic separation and Southern blotting; (c) generation of fragments that can be subcloned in appropriate vectors; and (d) generation of fragments to be used as labeled probes in both Southern (UNIT 2.9) and northern (UNIT 4.9) blotting, as well as in nuclease protection analysis (UNIT 4.7).

Members of a large subgroup of these enzymes (type II restriction endonucleases) recognize short nucleotide sequences and cleave double-stranded DNA at specific sites within or adjacent to the sequences. The recognition sequences are generally, but not always, 4 to 6 nucleotides in length and are usually characterized by dyad symmetry (the 5' to 3' nucleotide sequence of one DNA strand is identical to that of the complementary strand). Two enzymes, *NotI* and *SfiI*, recognize an 8-bp sequence found infrequently in genomic DNA and hence are extremely useful for cleaving DNA into large fragments. More than 600 type II restriction endonucleases have been isolated.

Some type II restriction endonucleases cleave at the axis of symmetry, yielding “flush” or “blunt” ends. Others make staggered cleavages, yielding overhanging single-stranded 3'

or 5' ends known as cohesive termini or “sticky ends.”

*Bam*HI cleavage generates cohesive 5' overhanging ends:

*Kpn*I cleavage generates cohesive 3' overhanging ends:

*Dra*I cleavage generates blunt ends:

Endonucleases with the same recognition sequences are called isoschizomers. Isoschizomers may or may not cleave DNA identically to produce the same ends. Conversely, two or more restriction endonucleases recognizing identical or different sequences may generate identical DNA fragment termini (Table 3.1.4). These endonucleases are said to produce compatible ends. DNA fragments with compatible termini may be ligated with DNA ligases to produce hybrid DNA molecules (UNIT 3.16).

For example, *Bgl*II recognizes a different six-nucleotide sequence from *Bam*HI, but generates cohesive termini compatible with those of *Bam*HI. *Bgl*II cleaves:

The hybrid sites generated by joining *Bam*HI and *Bgl*II cohesive ends cannot be cleaved by either enzyme.

Restriction endonucleases, generally found in prokaryotic organisms, are probably important for degrading foreign DNA (particularly bacteriophage DNA). Organisms that produce restriction endonucleases protect their own genomes by methylating nucleotides within the endonuclease recognition sequences. A specific methylase covalently links methyl groups to adenine or cytosine nucleotides within target sequences, thus rendering them resistant to cleavage by the restriction enzyme.

Several sources provide comprehensive and up-to-date listings of restriction endonucleases, including their restriction sites, isoschizomers, and reaction conditions. One source is the catalogs of commercial suppliers of enzymes. The *Biotech Buyers' Guide* (ACS, 1995) provides free of charge an annually updated list of restriction enzymes and their suppliers. Another comprehensive source listing all known restriction endonucleases is a special annual supplement to *Nucleic Acids Research* (e.g., Roberts, 1994). This provides an additional listing of all commercial suppliers of each enzyme. The most complete and up-to-date version of Roberts' information is maintained as a text file database called REBASE, available online from a variety of electronic mail and network servers (see UNIT 19.1 for a complete listing of sources).

Critical Parameters

Purity of DNA

The efficiency of the restriction endonuclease reaction is very dependent upon the purity of the DNA. Contaminants found in some DNA preparations (e.g., protein, phenol, chloroform, ethanol, EDTA, SDS, high salt concentration) may inhibit restriction endonuclease activity. Such impurities are often present in DNA samples prepared by miniprep procedures (UNIT 1.6). The decreased reaction efficiency associated with impure DNA preparations may be overcome by increasing the number of enzyme units added to the reaction mixture (up to 10 to 20 U per microgram DNA), increasing the reaction volume to dilute potential inhibitors, or increasing the duration of incubation. Some preparations of DNA (particularly minipreps) are contaminated by DNases. Because DNases require Mg²⁺ for enzyme activity, DNA in such preparations is stable in its storage buffer (which contains EDTA), but is rapidly degraded upon addition

of restriction endonuclease buffer. This problem can be overcome only by repurifying the DNA.

Digestion of genomic DNA (prepared as in UNITS 2.2-2.4) can be facilitated by the addition of the polycation spermidine (final concentration 1 to 2.5 mM), which acts by binding negatively charged contaminants. However, as spermidine will precipitate DNA at 4°C, it should be added after the other components of the reaction mixture have been incubated at the appropriate temperature for a few minutes. Finally, some preparations of DNA require repurification (phenol and chloroform extractions and ethanol precipitation) prior to digestion with restriction enzymes.

Degree of methylation

Some restriction endonucleases are inhibited by methylation of nucleotides within their recognition sequences (Table 3.1.1). In general, *Escherichia coli* host strains from which plasmids are harvested contain two nucleotide-sequence-specific methylases: *dam*, which methylates adenine in the sequence GATC, and *dcm*, which methylates the internal cytosine residue in the sequences CC(A/T)GG (Table 3.1.3). Thus, plasmid DNA from normal strains may be cleaved partially or not at all by restriction endonucleases that are sensitive to methylation. This can be avoided by preparing plasmid DNA from strains that lack these methylases (UNIT 1.4).

Mammalian DNA contains occasional 5-methylcytosine residues, usually at the 5' side of guanosine residues. The degree of methylation varies from site to site, and is strongly influenced by the cell type from which the DNA is isolated. Methylation patterns in eukaryotic genomic DNA can be investigated by using the different methylation sensitivities of isoschizomers. For example, *Msp*I cleaves CCGG even when the internal cytosine is methylated, whereas *Hpa*II, which also cleaves CCGG, is very sensitive to such methylation.

In some situations, it is useful to take advantage of a restriction enzyme's inability to cleave methylated nucleotide sequences. Methylases recognizing sequences close to a restriction enzyme's recognition sequences can inhibit cleavage at those sites, thereby altering the enzyme's apparent sequence specificity. Alternatively, when using synthetic linkers to modify the termini of a DNA fragment (UNIT 3.16), it may be important to protect internal restriction enzyme sites by methylation prior to enzyme cleavage of linkers.

Other factors influencing DNA cleavage

Larger amounts (up to 20-fold more) of some enzymes are necessary to cleave supercoiled plasmid or viral DNA as compared to the amount needed to cleave linear DNA (Fuchs and Blakesley, 1983). In addition, some enzymes cleave their defined sites with different efficiency, presumably due to differences in flanking nucleotides. In general, cleavage rates for different sites recognized by a given enzyme differ by less than a factor of 10. Although such variability is usually irrelevant, it can be significant in experiments involving partial digestion. It may be difficult to cleave DNA at a particular site without extensive cleavage at other sites. A few restriction endonucleases such as *NarI*, *NaeI*, *SacII*, and *XmaIII* show extreme variability such that some sites are very difficult to cleave.

Buffer conditions

The typical restriction endonuclease buffer contains magnesium chloride, sodium or potassium chloride, Tris-Cl, 2-mercaptoethanol (2-ME) or dithiothreitol (DTT), and bovine serum albumin (BSA). A divalent cation, usually Mg^{++} , is an absolute requirement for enzyme activity. Buffer, typically Tris-Cl, is necessary to maintain the optimal pH for enzyme function. Sulfhydryl reagents may be useful for stabilization of some restriction enzymes, but may also stabilize potential contaminants. Some restriction endonucleases are very sensitive to the concentration of sodium or potassium ion, while others are active over a wide range of ionic strengths.

For each restriction endonuclease, optimal reaction conditions are recommended by the manufacturer. However, strict adherence to these recommendations would require the investigator to stock a large number of buffers. Because many enzymes retain most of their activity over a wide range of reaction conditions (Table 3.1.2), most manufacturers have begun to recommend a panel of four buffers for use with their restriction endonucleases. These buffers may be provided with the purchase of enzymes or may be purchased separately, or they may be prepared in the laboratory and stored at $-20^{\circ}C$, as 10 \times concentrates, for more than a year. The buffer systems typically include a core buffer with varying NaCl concentrations, pH, and specific ion requirements. Manufacturers' catalogs include descriptions of these buffers and indicate enzyme activities in each buffer. Unfortunately, these buffers

have not been standardized among the various companies; different manufacturers may recommend different buffers for the same endonuclease. In general, we recommend purchasing restriction endonucleases from a single company based upon price and using the buffers that are provided with the enzymes.

As an alternative to the four-buffer system described above, many laboratories use potassium glutamate-based (McClelland et al., 1988) and potassium acetate-based (O'Farrell et al., 1980) buffers (known as "universal" buffers) for digestion of DNA with restriction endonucleases. The key features of these buffers is that they include potassium glutamate or potassium acetate instead of sodium chloride and Tris-acetate instead of Tris-Cl. Most restriction endonucleases are active in these buffers, although some enzymes are less active (sometimes only 20%) than under optimal conditions specified by the manufacturer. Several DNA-modifying enzymes are also active in these buffers, including T4 DNA polymerase and T4 DNA ligase. "Universal" buffers are useful for digestion of DNA with multiple restriction endonucleases, particularly when the endonucleases are incompatible in any one of the standard buffers.

Some restriction endonucleases "relax" their recognition sequence specificity in "nonoptimal" reaction conditions (including high endonuclease concentrations, high glycerol concentrations, low ionic strength, Mn^{2+} instead of Mg^{2+} , and high pH). This "star" activity cleaves DNA at other sites besides those containing the "correct" sequence. For example, *EcoRI* star activity cleaves some but not all sequences of the form AATT (usually sites with a 5 out of 6 match to GAATTC are cleaved better than sites with a 4 out of 6 match). The cleavage products all contain cohesive ends identical to those generated by the true *EcoRI* activity.

Additional comments

Enzymes should be stored at $-20^{\circ}C$. While in use, enzymes should be carefully maintained on ice.

Be extremely careful to avoid contaminating enzyme solutions, particularly with plasmid DNA, other restriction endonucleases, or DNase I.

Some restriction enzymes are expensive, others relatively inexpensive. Their use is dictated in part by their cost. Ironically, expensive enzymes are often of lower quality.

Anticipated Results

Complete cleavage of the DNA by a restriction endonuclease should generate a set of discrete DNA fragments that are bounded by the restriction sites. Upon analysis by gel electrophoresis (UNITS 2.5 & 2.7), the cleavage products should be visualized as sharp bands.

Time Considerations

In principle, if 1 U of restriction endonuclease digests 1 μ g of DNA in 1 hr, then incubations for longer durations might be expected to permit conservation of expensive enzymes. In practice, however, some restriction endonucleases have only limited stability in the reaction mixture. Thus, enzyme reactions are usually carried out for 30 min to 2 hr unless very large amounts of DNA or expensive enzymes are involved. In addition, be aware that extended incubations often reveal low levels of contaminating nuclease activities, which may confound experimental results.

^aCompiled from Amersham (1994-95), Boehringer Mannheim (1994), GIBCO/BRL (1994), New England Biolabs (1995), Pharmacia Biotech (1994), Promega (1994), Stratagene (1995). See APPENDIX 4 for addresses and phone numbers of suppliers.

^bAbbreviations: N, any nucleotide (G, A, T, C); Pu, either purine (G or A); Py, either pyrimidine (C or T).

^cRecommended concentrations of NaCl (or KCl, indicated by parenthetical K) where L is <50 mM, M is 50-100 mM, and H is >100 mM (see recipe for restriction endonuclease buffers).

^dReaction temperature is the temperature (°C) at which the reaction should be performed; inactivation temperature indicates the temperature (°C) at which the enzyme is inactivated after 15 min of incubation.

^eAbbreviations and other terminology: *dam*, activity blocked by *dam* or overlapping *dam* methylation; *dcm*, activity blocked by *dcm* or overlapping *dcm* methylation; difficult ligation, the enzyme has single-bp 5' overhanging ends that are difficult to ligate with T4 DNA ligase; SAM, S-adenosylmethionine; site-dependent activity refers to marked differences in rates of cleavage at various sites by a particular enzyme (probably determined by the surrounding sequence); star activity refers to altered specificity of a restriction enzyme that causes it to cleave sequences that are similar but not identical to its defined recognition sequence—conditions that may provoke this altered specificity include elevated pH, high glycerol concentration, low ionic strength, and high enzyme to DNA ratio; *t*_{1/2}, half-life.

^fRefer to manufacturer's recommendations and Table 3.1.2 for information on salt requirements.

^gRefer to manufacturer's recommendations for reaction temperature.

^aReprinted by permission of New England Biolabs. The activity of each enzyme listed is compared at specified NaCl concentrations to its activity in recommended assay buffer. Recommended assay buffers in some cases differ widely in terms of pH and specific ion requirements. The conditions here varied only the NaCl concentration. All buffers contained 10 mM Tris·Cl (pH 7.5) and 100 µg/ml bovine serum albumin. All incubations were done for 60 min at the optimum temperature for each enzyme. Scoring is as follows:

+ <10% of the activity can be obtained using these conditions compared to the recommended conditions.

++ between 100% and 20% of the activity can be obtained using these conditions compared to the recommended conditions.

+++ between 30% and 100% of the activity can be obtained using these conditions compared to the recommended conditions.

^bNot recommended because of star activity, which refers to cleavage at sites other than the usual recognition sequence. Star activity occurs under nonoptimal reaction conditions, such as low ionic strength, high endonuclease concentrations, high glycerol concentrations, high pH, and when Mn²⁺ is used in place of Mg²⁺.

^bSequences at the top of each column are written 5' to 3'. Asterisks at the left of each row are place holders for nucleotides within a recognition sequence, and arrows indicate the point of cleavage. Sequences of complementary strands and their cleavage sites are implied. Enzymes written in bold type recognize only one sequence, while those in light type have multiple recognition sequences.

^cSequence cleaved identically by two or more enzymes that are affected differently by DNA modification at that site (see Table 3.1.1).

reaction (PCR) provides additional versatility for constructing recombinant DNA molecules. *UNIT 3.17* gives a general approach and discusses particular scenarios for incorporating specific sequences onto the ends of DNA fragments, for creating in-frame fusion proteins, and for creating deletions and insertions using inverse PCR.

A final section on specialized applications describes the labeling and various means of detecting nonisotopically labeled probes. Biotinylated and digoxigenin-labeled probes are becoming more widely used in place of their radioactive counterparts for the hybridization applications described in *UNITS 2.9, 4.9 & 14.3*. Aside from eliminating the concerns of working with hazardous materials, the use of these probes offers increased stability and reasonable sensitivity to colorimetric (*UNIT 3.18*) or chemiluminescent (*UNIT 3.19*) detection techniques.

Kevin Struhl

RESTRICTION MAPPING

Construction of an accurate map of the sites where restriction endonucleases cleave DNA—restriction mapping—is critical for almost all subsequent manipulations of genetic material. Restriction mapping is based upon the cleavage of DNA at or near specific nucleotide sequences with restriction endonucleases and the determination of the sizes of the resulting DNA fragments by gel electrophoresis (see *UNITS 2.5* and *2.7*).

Restriction maps are often determined by digesting recombinant DNA molecules in which the DNA of interest is cloned into plasmid or phage vectors. The most common approach is to deduce the map after digesting the DNA of interest with a variety of restriction enzymes, either individually or in combination. This method requires the fewest experimental manipulations, and it is easy to use for cloned DNA segments up to 20 kb in length. Restriction mapping of larger unknown regions gets progressively more difficult. This method is best used for generating an initial restriction map with enzymes that cleave the DNA relatively infrequently.

In an alternative method, DNA fragments are end labeled (*UNITS 3.5* and *3.10*), purified by electrophoresis (*UNITS 2.6* and *2.7*), and subjected to partial endonucleolytic cleavage. This method defines the position of restriction sites with respect to a single defined position, the site of labeling. It is valuable in situations where a restriction endonuclease cleaves the DNA in many positions, or in mapping very large DNA molecules.

It is important to note that careful restriction mapping is critical for subcloning (*UNIT 3.16*) and is useful for nucleotide sequence analysis (*UNIT 7.4*). Conversely, nucleotide sequence data can predict restriction endonuclease cleavage sites and thereby generate a complete restriction map.

Mapping by Multiple Endonuclease Digestions

UNIT 3.2

The DNA of interest is cleaved with a variety of restriction endonucleases, either individually or in combination, and the resulting products are separated by agarose or acrylamide gel electrophoresis. By determining the sizes of DNA fragments produced by endonuclease cleavage, the restriction map is deduced progressively from simple situations where enzymes cleave the DNA once or twice to more complex situations where cleavage occurs more frequently.

BASIC
PROTOCOL

Materials

Restriction endonucleases (Table 3.1.1)

10× restriction endonuclease buffers (*UNIT 3.1*)

Additional reagents and equipment for agarose or polyacrylamide gel electrophoresis (*UNITS 2.5* or *2.7*) and DNA molecular weight markers (*UNITS 2.5A*)

1. In each of several separate tubes, cleave the DNA of interest (up to 20 kb in length) with a restriction endonuclease that can be expected to cleave infrequently.

In general, inexpensive restriction endonucleases with six base-pair recognition sequences are used first (e.g., EcoRI, HindIII, BamHI, PstI, KpnI, XbaI, Sall, and XhoI). DNA fragments produced by cleavage with these enzymes are also easily subcloned into standard plasmid or phage vectors.

2. After cleavage, remove a small portion of each reaction mixture and separate the products by agarose or polyacrylamide gel electrophoresis. Store the remainders of the reaction mixtures on ice.

It is essential that the DNA is completely cleaved by the restriction endonuclease. See critical parameters.

3.2.1

- Using DNA fragments of known lengths for comparison (see *UNIT 2.5* for the preparation of size standards), calculate the lengths of all the fragments. Determine the number of cleavage sites for each restriction endonuclease.

A restriction endonuclease cleaving a DNA molecule N times will generate N restriction fragments if the molecule is circular and $N + 1$ fragments if the molecule is linear.

- For each sample from step 1, transfer an aliquot into separate tubes and add a different restriction endonuclease to each tube. In this way, the DNA in each tube will be digested by two enzymes. One aliquot from each sample should not be cleaved with a second enzyme.

Obviously, it is wasteful and unnecessary to perform secondary digestions with enzymes that do not cleave the DNA (as determined from step 3).

- Using agarose gel electrophoresis, compare DNA fragments resulting from digestion with the two restriction enzymes with the fragments resulting from digestion with the first enzyme alone and with the second enzyme alone. Calculate the lengths of all the restriction fragments.
- As more restriction enzymes are used to digest the DNA and the resulting restriction fragments are analyzed, an unambiguous, internally consistent map of restriction endonuclease cleavage sites can be determined. See commentary and examples.

COMMENTARY

Critical Parameters

Completeness of digestion

When digestion is complete, the cleavage products should be present in equimolar quantities. If DNA is visualized by staining with ethidium bromide (*UNIT 2.5*), band intensity is proportional to fragment length. For example, an 8-kb fragment stains twice as intensely as a 4-kb fragment. Bands that appear fainter than expected for their molecular weight are probably the result of incomplete cleavage. Bands that appear more intense than expected are probably due to the presence of two (or more) DNA fragments of similar length. If DNA is end labeled at the 5' (*UNIT 3.10*) or 3' (*UNIT 3.5*) termini and visualized by autoradiography, all radiolabeled restriction fragments should produce bands of equal intensity. If DNA is uniformly labeled (such as by nick translation as described in *UNIT 3.5*), band intensities are proportional to fragment length.

Internal consistency of the results

Sum of fragment lengths. It is obvious that the sum of the lengths of the restriction fragments should equal the total length of the DNA molecule. In other words, for each enzyme that is tested, the sum of all the fragments should be equal.

If, for a given digestion, the sum is lower than expected, check carefully for fragments of similar length. Such “comigrating” fragments can be identified by their increased band intensity (two comigrating fragments should produce a band that is twice as intense as expected from the molecular weight) or by band “broadening” or “fuzziness” (due to similar but distinct electrophoretic mobilities of two fragments). Alternatively, a low sum of fragment lengths could be due to the existence of several small fragments, which may be difficult to visualize in the agarose gel or which may have “run off” the bottom of the gel.

If the sum is larger than expected, the most likely explanation is that some of the bands arise from incomplete digestion. Another possibility, less likely in general, is that the DNA being tested is actually a mixture of DNAs. Finally, some DNA fragments have anomalous electrophoretic mobilities (especially in acrylamide gels), usually because of unusual bending properties dictated by specific DNA sequences.

Number of bands. As mentioned, the number of DNA fragments produced in a given reaction is directly related to the number of times that the restriction enzyme cleaves the DNA. Thus, it follows that when DNA is cleaved

by two (or more) enzymes, the number of fragments should be the sum of the fragments generated by the individual enzymes. For example, if cleavage of a circular molecule by enzyme A generates three fragments (indicative of three sites) and cleavage by enzyme B generates five fragments (indicative of five sites), cleavage by enzymes A + B should generate eight fragments. If fewer fragments are seen, it means either that some fragments are comigrating or that very small DNA fragments have been generated due to the proximity of A and B sites.

Additional comments

If the DNA to be studied is subcloned into a plasmid or phage vector for which the restriction map is known, restriction mapping of the DNA insert is facilitated by digestion with a series of restriction endonucleases that cleave the vector at least once. In this way, restriction sites in the DNA are mapped with respect to known sites in the vector (see Example 3.2.2).

Utilization of nucleic acid hybridization probes (UNIT 3.5) and of the Southern transfer technique (UNIT 2.9) permits restriction mapping of a small segment of DNA within a larger fragment or even within total cellular DNA.

Anticipated Results

When sufficient enzyme digestions are performed, it should be possible to obtain an unambiguous and internally consistent map.

Time Considerations

Depending on the resolution that is desired, it will take 1 to 10 days to generate a restriction map. Additional mapping can be done at any time.

EXAMPLES

Example 3.2.1: Restriction Mapping a Plasmid of Unknown Structure

Consider a 9-kb circular plasmid DNA, pPROTO, with an unknown restriction map. Cleavage with restriction endonuclease A or with enzyme B generates a 9-kb linear DNA molecule, thus indicating that each enzyme recognizes a single site in pPROTO. To determine the location of enzyme A's cleavage site with respect to enzyme B's cleavage site, pPROTO is digested with both enzymes. Two restriction fragments, 4 kb and 5 kb in size, are generated. Therefore, these endonucleases cleave sequences that are located 4 kb apart.

Restriction endonuclease C cleaves

Figure 3.2.1 Restriction mapping of pPROTO (see Example 3.2.1).

pPROTO DNA at three sites. Gel electrophoresis reveals three fragments that are 1 kb, 2 kb, and 6 kb in length. When pPROTO is digested with enzymes A and C, four bands are seen, as expected. The 6-kb fragment generated by enzyme C alone “disappears” and is replaced by two more rapidly migrating fragments 1.5 and 4.5 kb in size, whereas the 1- and 2-kb fragments produced by endonuclease C are unchanged. Thus, the A site is localized within the 6-kb enzyme C fragment.

At this stage, there are four possible restriction maps (Fig. 3.2.1). Within the 6 kb fragment generated by enzyme C, the A site could be located in two possible positions (1.5 kb from either of the two possible ends), and the 1- and 2-kb C fragments could be located in two possible orders with respect to the 6-kb fragment. The correct map can be determined from the results obtained upon cleavage with enzymes B + C. The predictions for each of the possible maps are shown in Figure 3.2.1.

To map restriction sites for endonuclease D, the same logic is followed. The process is greatly simplified once the restriction sites for endonucleases A, B, and C have been mapped as described above. In some cases, ambiguities

in positions of D sites can be resolved by appropriate triple digests.

The general rule is to build up the restriction map from simple situations where enzymes cleave once or twice in the DNA to more complex situations where cleavage occurs more frequently.

Example 3.2.2: Restriction Mapping a Cloned DNA Insert within a Plasmid of Known Structure

Frequently, restriction mapping is performed on a region of DNA within the context of surrounding DNA for which the nucleotide sequence and/or restriction map is known. Consider the following approach to mapping pCDNA, which contains an insert of cDNA that has been ligated into the plasmid pBR322 at the *Pst*I site. pBR322, a 4363-bp *E. coli* plasmid vector, is cleaved once by *Pst*I at a site that is 754 bp from the unique *Eco*RI cleavage site (UNIT 1.5). Utilization of the known restriction map for pBR322 permits rapid restriction mapping of the cDNA insert.

Cleavage of pBR322 with *Pst*I generates a single 4363-bp DNA fragment. Cleavage of single pCDNA with *Pst*I generates two fragments,

Figure 3.2.2 Restriction mapping pCDNA (see Example 3.2.2).

4363 and 1000 bp in size, demonstrating that the cDNA insert is 1 kb in size (Fig. 3.2.2).

Cleavage of pBR322 with *EcoRI* generates a single 4363-bp DNA molecule. Cleavage of pCDNA generates three fragments, 300, 900, and 4163 bp in size. Knowledge of the location of the cDNA insert (cloned into the *PstI* site) with respect to the vector *EcoRI* site allows one to conclude that the cDNA insert has two *EcoRI* cleavage sites that are located 146 and 446 bp from one end of the cDNA.

Similarly, parallel digestions of the recombinant DNA molecule and the cloning vector, using a panel of restriction endonucleases, permit efficient restriction mapping of the DNA of interest.

Mapping by Partial Endonuclease Digestions

BASIC PROTOCOL

A DNA fragment radiolabeled at one of its two ends is purified by gel electrophoresis and subjected to partial cleavage by a restriction endonuclease. Analysis of the resulting products by polyacrylamide (or agarose) gel electrophoresis enables one to define the distance of restriction sites from the labeled end.

Materials

Reagents and equipment for digesting DNA with restriction enzymes (UNIT 3.1), labeling DNA (UNIT 3.5 or 3.10), agarose or polyacrylamide gel electrophoresis (UNIT 2.5 or 2.7), and autoradiography (APPENDIX 3)

1. Cleave the DNA fragment of interest with a restriction endonuclease that can be expected to cleave infrequently.
2. "End label" the products of digestion with ^{32}P . 5' termini can be labeled by successive treatment with calf intestine phosphatase and T4 polynucleotide kinase (UNIT 3.10), and 3' termini can be labeled with the Klenow fragment of *E. coli* DNA polymerase I (UNIT 3.5) or with T4 DNA polymerase (UNIT 3.5).

Each restriction fragment is labeled at both ends.

3. Cleave fragments with a second restriction endonuclease and fractionate the products by gel electrophoresis.
4. Purify the DNA fragments that are now radiolabeled at one end. See UNIT 2.7 and 2.6, respectively, for methods of isolating DNA from acrylamide or agarose gels.

Only the fragments generated by cleavage with both restriction endonucleases will be labeled at one end. Fragments from step 2 that are not cleaved by the second enzyme will retain the label at both ends and hence be useless for the subsequent analysis.

5. Partially digest one of the isolated DNA fragments with a restriction enzyme which cleaves relatively frequently (usually with a 4-bp recognition site).

Because some sites are cleaved more readily than others, it is useful to generate a series of enzyme reactions in which the DNA is cleaved to various extents. This is easily accomplished by serially diluting the enzyme, as described in UNIT 3.1.

6. Separate the products of the partial digestion by gel electrophoresis (usually polyacrylamide) and visualize the bands by autoradiography.
7. Determine the size of the restriction fragments by comparison with radiolabeled DNA fragments of known size.

MspI-cleaved pBR322 DNA (UNIT 1.5) that has been end labeled is an excellent size standard for fragments less than 650 bp in length.

COMMENTARY

Background Information

This technique for partial digestion of DNA fragments radiolabeled at one end is rapid and relatively simple for fine structure restriction mapping. Unlike restriction mapping by multiple endonuclease cleavage (UNIT 3.2), the analysis is not complicated by the presence of many cleavage sites for a given enzyme. However, it can be complicated if

some sites are cleaved much better than others.

If the restriction fragment to be mapped has been generated by two restriction endonucleases with different cohesive termini, it may be possible to radiolabel one end of the fragment by "filling in" with the appropriate [α - ^{32}P]NTP. For example, a fragment that has been generated by *EcoRI* (5' overhang, AATT) and *BamHI* (5' overhang, GATC) can

be radiolabeled, exclusively, at the *Bam*HI site by using [α - 32 P]GTP in the reaction.

Critical Parameters

High salt concentrations can alter the electrophoretic mobility of DNA fragments (especially small fragments). When performing fine structure restriction mapping, it may be necessary to “desalt” the sample by ethanol precipitation and by washing with 70% ethanol.

The major artifact associated with this method is that recognition sites for a given restriction endonuclease are not always cleaved with equal efficiency. This problem becomes more severe with increased distance of the “inefficient” site to the labeled site because cleavage at more “efficient” sites becomes more likely to eliminate the diagnostic fragment. Thus, restriction maps generated by this method are occasionally “missing” a site. A standard restriction digest using unlabeled DNA is very useful for confirming the positions of cleavage.

It is relatively difficult to map cleavage sites that are located close to either of the two ends. Sites near the unlabeled end will be very similar in size to the undigested fragment, whereas sites near the labeled end will be extremely small. These problems can be resolved by choosing different fragments and/or by using appropriate gels to visualize small DNA fragments.

Anticipated Results

By varying the amount of enzyme to produce different degrees of partial digestion, a series of bands should be generated. Each band represents the location of a restriction site with respect to the labeled site.

Time Considerations

Preparation of the labeled DNA fragment should take about 1 to 2 days, and the remainder of the procedure (partial cleavage, gel electrophoresis, and autoradiography) should take an additional 1 to 5 days. The locations of restric-

tion sites for 5 to 20 different enzymes can easily be determined from the same preparation of the labeled DNA fragment.

EXAMPLES

Example 3.3.1: Mapping Restriction Sites by Partial Cleavage of End-Labeled DNA.

Plasmid pPROTO (see sketch below) is digested with enzyme A, and the ends of the linearized molecule are radiolabeled. The DNA is then digested with enzyme B, and the 5-kb fragment is isolated.

The uniquely end-labeled fragment is partially digested with enzyme D, and the products are fractionated by agarose gel electrophoresis. A “ladder” of radiolabeled DNA fragments, 2.7, 4.0, and 5.0 kb in size, is evident by autoradiography. This demonstrates conclusively that enzyme D cleaves pPROTO DNA at sites that are 2.7 and 4 kb from enzyme A’s cleavage site as shown below.

This result can be confirmed by reversing the order of restriction enzyme cleavage. When the 32 P label is at the B cleavage site, partial digestion should produce bands of 1.0, 2.3, and 5.0 kb.

ENZYMES FOR MODIFYING AND RADIOACTIVELY LABELING NUCLEIC ACIDS

This section describes enzymes other than restriction endonucleases that are used to manipulate nucleic acids. An increasing number of DNA polymerases, RNA polymerases, and exonucleases, each with unique properties, are becoming available to the molecular biologist. A basic knowledge of these differences helps one to choose the optimal enzyme for a given procedure.

Increasingly, commercially produced enzymes are purified from strains containing cloned genes that have been designed to overproduce the enzyme. These enzymes offer several advantages. First, they are significantly less expensive. Second, enzyme purification procedures are less extensive and more rapid, resulting in more homogenous enzymes with higher specific activities. Finally, for enzymes normally encoded by bacteriophages, the use of cloned genes eliminates contamination by other nucleic acid-metabolizing enzymes that are encoded by the phage genome.

IMPORTANT NOTE: Enzymes are expensive and sensitive reagents that are easily inactivated or destroyed by careless use. Enzymes should always be stored at -20°C in freezers that maintain a constant temperature. For use, the tube containing the enzyme should be placed quickly on ice, and the enzyme should be removed with a clean pipet tip (sterility is not essential, but can be helpful). After the enzyme is removed, the tube should be immediately returned to -20°C . Do not let enzymes stay for extended periods on ice and do not expose them to temperatures greater than 0°C .

UNIT 3.4

Reagents and Radioisotopes Used to Manipulate Nucleic Acids

STOCK SOLUTIONS

It is convenient to have preparations of the following stock solutions on hand for the enzyme reactions and applications described in *UNITS 3.5 through 3.15* and in subsequent chapters of the manual. See *APPENDIX 2* for recipes.

Solutions should be prepared in deionized water and stored in aliquots. Most of the solutions are stable for years at -20°C or at room temperature if kept sterile. Dithiothreitol should be stored at -20°C and is stable for months. DTT should not be autoclaved, and it should be kept at 0°C during use.

Acid precipitation solution	1 M NaCl
10 mg/ml autoclaved gelatin	5 M NaCl
10 mg/ml bovine serum albumin (BSA), Pentax Fraction V	10 mg/ml sonicated salmon or herring sperm DNA
Buffered phenol (<i>UNIT 2.1</i>)	500 $\mu\text{g}/\text{ml}$ sonicated salmon or herring sperm DNA
0.1 M dithiothreitol (DTT)	Standard enzyme diluent (SED; <i>APPENDIX 2</i>)
10 mg/ml <i>E. coli</i> tRNA	TE buffer (<i>APPENDIX 2</i>)
0.5 M EDTA, pH 8.0	1 M Tris-Cl, pH 7.5
Ethanol	1 M Tris-Cl, pH 8.0
Glycerol	
1 M KCl	
0.2 M MgCl_2

50 mM DTT
0.5 mg/ml BSA or gelatin

T4 DNA polymerase

0.5 M Tris·Cl, pH 8.0
50 mM MgCl₂
50 mM DTT
0.5 mg/ml BSA or gelatin

T4 polynucleotide kinase

0.5 M Tris·Cl, pH 7.5 (forward reaction) or 500 mM imidazole·Cl, pH 6.6 (exchange reaction)
0.1 M MgCl₂
50 mM DTT
0.5 mg/ml BSA or gelatin

T4 RNA ligase

0.5 M HEPES, pH 8.3
100 mM MgCl₂
50 mM DTT
0.5 mg/ml BSA

T7 DNA polymerase (native and modified)

0.4 M Tris·Cl, pH 8.0
0.1 M MgCl₂ (native or chemically modified; or 50 mM MgCl₂, genetically modified)
50 mM DTT
0.5 M NaCl
0.5 mg/ml BSA or gelatin

T7 gene 6 exonuclease (see exonuclease III)

T7 RNA polymerase (see SP6 polymerase)

Taq DNA polymerase

0.1 M Tris·Cl, pH 8.4
x MgCl₂
500 mM KCl
1 mg/ml gelatin

The concentration (x) of MgCl₂ depends upon the sequence and primer set of interest. The optimal concentration is first determined empirically using a 10× amplification buffer minus MgCl₂. Based upon these results, a 10× amplification buffer containing MgCl₂ at the optimal concentration is prepared (UNIT 15.1).

Terminal transferase

1 M sodium cacodylate, pH 7.0
10 mM CoCl₂
1 mM DTT
0.5 mg/ml BSA or gelatin

ENZYME REACTION CONDITIONS AND APPLICATIONS

General guidelines for enzyme reaction conditions are provided in Table 3.4.1. Because many parameters vary depending on the application, *UNITS 3.5-3.15*, which describe specific classes of enzymes, should be consulted for further details.

Some applications of nucleic acid-modifying enzymes are indicated in Table 3.4.2. For some applications, more than one enzyme can be used to carry out the reaction. More detailed information is provided in *UNITS 3.5-3.15*.

Table 3.4.1 General Guidelines for Enzyme Reaction Conditions

Many parameters, including reaction volume, dNTP concentration, time, and temperature, will vary depending on application. Dilute appropriate 10× or 5× enzyme buffer (see recipes preceding this section) to 1× and set up reactions as described in table. Stop reactions at 75°C for 10 min, or by adding 2 μl of 0.5 M EDTA (except where indicated otherwise under “Comments”). Enzymes are described in further detail in the units indicated in parentheses.

^fBAP and CIP—pmol DNA termini; terminal transferase—pmol DNA as 3′ termini.

^gRNA polymerases—use DNA with a promoter; T4 RNA ligase—use single-stranded DNA or RNA.

^hAdd 1 mM spermidine for SP6.

ⁱAdd 100 μCi [α-³²P]dNTP, specific activity >400 Ci/mmol, and 1 μg oligo(dT)₁₂₋₁₈.

3.4.4

Table 3.4.2 Applications of Nucleic Acid–Modifying Enzymes
Enzymes are described in further detail in the units indicated in parentheses.

Application	Enzyme
Blunt-end generation	
by removal of 3' protruding ends	T4 and T7 DNA polymerase (3.5)
by filling in 3' recessed ends	T4 and T7 DNA polymerase (3.5); Klenow fragment (3.5)
cDNA synthesis	
from RNA	Reverse transcriptase (3.7)
of second strand	Klenow fragment (3.5)
Cloning of DNA fragments	CIP (3.10); T4 DNA ligase (3.14); Klenow fragment (3.5); restriction endonucleases (3.1)
Degradation of DNA	
Exonucleases—double strand	
5'→3'	T7 gene 6 and λ exonuclease (3.11)
3'→5'	Exonuclease III (3.11)
5'→3' and 3'→5'	<i>Bal</i> 31 nuclease (3.12)
Exonuclease—single strand (3' & 5')	Exonuclease VII (3.11)
Endonucleases—double strand	
nonspecific	DNase I and micrococcal nucleases (3.12)
specific	Restriction endonucleases (3.1)
Endonucleases—single strand	S1, <i>Bal</i> 31, and mung bean nucleases (3.12)
Degradation of RNA	Ribonuclease A and/or T1 (3.13); micrococcal nuclease (3.12)
Degradation of RNA in RNA:DNA duplexes	Ribonuclease H (3.13) BAP and CPI (3.10)
DNA sequencing	Modified T7 DNA polymerase (3.5); <i>Taq</i> polymerase (3.5); Klenow fragment (3.5); T4 polynucleotide kinase (3.10); reverse transcriptase (3.7)
Intron mapping	Exonuclease VII (3.11); S1 nuclease (3.12 & 4.6)
Labeling DNA at 5' ends	T4 polynucleotide kinase (3.10)
Labeling DNA at 3' ends	Modified T7 DNA polymerase (3.5); Klenow fragment (3.5); reverse transcriptase (3.7); terminal transferase (3.6)
Labeling RNA at 3' ends	Poly(A) polymerase (3.9); T4 RNA ligase (3.15)
Ligations of DNA	<i>E. coli</i> and T4 DNA ligase (3.14)
Ligations of RNA	T4 RNA ligase (3.15)
Mapping mRNA 5' ends	S1 or mung bean nuclease (3.12 & 4.6); reverse transcriptase (3.7 & 4.8); ribonuclease A (4.8)
Methylation of DNA	Methylases (3.1)
Nested deletion construction	<i>Bal</i> 31 (3.12 & 7.2); exonuclease III (3.11 & 7.2) + S1 or mung bean nuclease (3.12 & 7.2)
Nick translation	DNase I (3.12); <i>E. coli</i> DNA polymerase I (3.5)
Oligonucleotide extension	T7 DNA polymerase (3.5); Klenow fragment (3.5)
Phosphorylation	T4 polynucleotide kinase (3.10)
Poly(A) tailing of RNA	Poly(A) polymerase (3.9)
Polymerase chain reaction (PCR)	<i>Taq</i> DNA polymerase (3.5 & 3.17)
Primed synthesis	Klenow fragment (3.5)
Replacement synthesis	T4 and T7 DNA polymerase (3.5)
Restriction mapping	Restriction endonucleases (3.1)
Tailing DNA	Terminal transferase (3.6)
Tailing RNA	Poly(A) polymerase (3.9)
Transcription, promoter-specific	<i>E. coli</i> , SP6, T3, and T7 RNA polymerase (3.8)

3.4.5

NUCLEOSIDE TRIPHOSPHATES

Nucleoside triphosphates (also referred to as *ribonucleoside* triphosphates) have a limited shelf life in solution and hence should be stored as aliquots at -20°C , where they are stable for up to 1 year. They should be HPLC-(or comparably) purified. Pharmacia is the recommended supplier. Deoxyribonucleoside triphosphates (dNTPs) or ribonucleoside triphosphates (NTPs) can be purchased as ready-made 100 mM solutions, which is the preferred method of shipping and storage. Alternatively, they can be purchased in lyophilized form and prepared in deionized water as follows:

1. Dissolve in water to an expected concentration of 30 mM; adjust to pH 7 with 1 M NaOH.

dNTPs and NTPs will undergo acid catalyzed hydrolysis unless they are neutralized.

2. Determine the actual concentration of each dNTP and NTP spectrophotometrically, using the extinction coefficients given in Table 3.4.3 (see also APPENDIX 3).
3. Prepare 5 mM working solutions for each NTP and dNTP from concentrated stocks of nucleoside triphosphates.
4. Prepare NTP and dNTP solutions (mixes) containing equimolar amounts of all four RNA or DNA precursors as follows:

5 mM 4NTP mix: 5 mM each of ATP, UTP, CTP, GTP

5 mM 4dNTP mix: 5 mM each of dATP, dTTP, dCTP, dGTP

0.5 mM 4dNTP mix: 0.5 mM each of dATP, dTTP, dCTP, dGTP

5. For radioactive labeling purposes, prepare stocks lacking one particular NTP or dNTP but containing equimolar amounts of the remaining three precursors:

5 mM 3NTP mix (minus UTP): 5 mM of ATP, GTP, CTP for radiolabeling RNA with radioactive UTP

5 mM and 0.5 mM 3dNTP mixes (minus dATP): 5 mM and 0.5 mM each of dTTP, dCTP, dGTP for radiolabeling DNA with radioactive ATP.

Other 3NTP or 3dNTP mixes are made by omitting the precursor corresponding to the selected radiolabel. Various alternate nomenclatures exist for identifying the precursors that are present (or absent) in these solutions. For example, in the instances above, 5 mM 3NTP mix (minus UTP) might be referred to as 5 mM (A,C,G)TP mix. Similarly, 5 mM 3dNTP mix (minus dATP) might be named 5 mM d(C,G,T)TP mix. Whatever the nomenclature, remember that the molarity of the mix refers to the concentration of each precursor present in the solution.

Table 3.4.3 Properties of the Nucleoside Triphosphates

Nucleoside triphosphate	λ max (pH 7.0)	ϵ max $\times 10^{-3}$ (pH 7.0)	Absorbance ratio (280/260) (pH 7.0)	pK _a of base
ATP	259	15.4	0.15	4.0
CTP	271	12.8 ^a	0.97	4.8
GTP	252	13.7	0.66	3.3

				9.7
dTTP	267	9.6	0.73	9.3

^aPerform the spectral analysis at pH 2.0.

RADIOISOTOPES FOR LABELING NUCLEIC ACIDS

^{32}P is the most common isotope used to radioactively label nucleic acids. It emits energetic β particles, it has the highest specific activity (9200 Ci/mmol in pure form), and it has a fairly short half-life (14 days). ^{32}P -labeled NTP or dNTP precursors can be purchased at various specific activities. In general, α -labeled precursors are purchased at 400 to 800 Ci/mmol, whereas γ -labeled precursors are purchased at 3000 to 7000 Ci/mmol. ^{32}P is preferred for preparation of highly radioactive probes and for most autoradiographic procedures. Its strong energy gives optimal sensitivity, especially when autoradiography is carried out with intensifying screens. In addition, enzymes are not inhibited by ^{32}P -labeled nucleoside triphosphates because their structures are virtually identical to nonradioactive nucleoside triphosphates.

^{35}S emissions are less energetic, the specific activity is several-fold lower (1500 Ci/mmol in pure form), and it has a longer half-life (87 days; see Table A.1E.2). ^{35}S -labeled nucleoside triphosphates have a thio moiety replacing one of the oxygens covalently bound to the phosphate. This is a significant perturbation that inhibits many enzymes. Because the lower energy of ^{35}S does not cause extensive damage to nucleic acids, it is used for the preparation of more stable, but lower specific activity, probes. Recently, ^{35}S has replaced ^{32}P as the preferred isotope for the dideoxy sequencing procedure because its lower energy results in sharper images in autoradiography. Exposure to ^{35}S is less dangerous to laboratory workers than exposure to ^{32}P , but ^{35}S is more difficult to detect with a standard radioactivity monitor.

^3H has the lowest specific activity (29 Ci/mmol in pure form) and the longest half-life (12 years). Its emission is too weak for most autoradiographic procedures, although it is used for in situ hybridizations. Its primary use is for quantitative analysis of nucleic acid synthesis and degradation. For some specific purposes, ^{14}C and ^{125}I are used for radiolabeling nucleic acids.

CAUTION: Investigators should wear gloves for all procedures involving radioactivity and should be careful about contaminating themselves or their clothing. All experiments involving ^{32}P should be performed behind lucite screens to minimize exposure. When working with ^{32}P , investigators should frequently check themselves and the working area for radioactivity with a hand-held minimonitor. When finished, radioactive waste should be placed in appropriately designated areas (not public garbage cans!) for eventual disposal. The working area should be checked for radioactivity and, if any is found, cleaned up to protect other laboratory workers and other unsuspecting people.

BASIC PROTOCOL

Measuring Radioactivity in DNA and RNA by Acid Precipitation

For many of the radioactive labeling procedures discussed in this chapter, it is useful to quantitate the amount of radioactive precursors that have been incorporated into nucleic acid. The amount of radioactivity for a known amount of DNA is called the specific activity (usually given in units of cpm/ μg of nucleic acid). The most common method for the measurement of radioactivity in nucleic acids is based on the fact that DNA or RNA molecules greater than 20 nucleotides in length are quantitatively precipitated in strong acids, whereas dNTP or NTP precursors remain in solution. The precipitated nucleic acids are easily separated from the radioactive precursors by filtration on discs of glass microfiber paper.

Materials

500 $\mu\text{g}/\text{ml}$ sonicated salmon sperm DNA in TE buffer
Ice-cold acid precipitation solution (APPENDIX 2)
100% ethanol

Reagents and
Radioisotopes Used
to Manipulate
Nucleic Acids

3.4.7

Glass microfiber filters (2.4-cm diameter, Whatman GF/A)
Filtration device
Heat lamp (optional)
Scintillation fluid and vials

1. Add a known volume (typically 1 μ l) of a reaction mixture containing radioactive precursors to a disposable glass tube containing 100 μ l of salmon sperm DNA (500 μ g/ml in TE buffer).
2. Spot 10 μ l of the mixture onto a glass microfiber filter.
3. To the remaining 90 μ l, add 1 ml of ice-cold acid precipitation solution and incubate on ice 5 to 10 min. The solution should appear cloudy due to the precipitated nucleic acid.
4. Collect the precipitate by filtering the solution through a second glass microfiber filter. Rinse the tube with 3 ml acid precipitation solution and pour through the filter. Wash the filter four more times with 3 ml acid precipitation solution, followed by 3 ml ethanol.
5. Dry both filters under a heat lamp, and place them in separate vials containing 3 ml of a toluene-based scintillation fluid. Measure the radioactivity in a liquid scintillation counter.

Drying the filters is unnecessary with scintillation fluids that can accommodate aqueous samples.

6. Determine the incorporation of radioactivity into nucleic acid from the ratio of cpm on the second filter (which measures radioactivity in nucleic acid) to cpm on the first filter (which measures total radioactivity in the sample).

For example, if both filters contain an equal number of cpm, the incorporation is 11% because only 10% of the original mixture (step 1) was placed on filter 1 whereas 90% of the original mixture was subjected to acid precipitation.

Separating Radioactively Labeled DNA from Unincorporated dNTP Precursors by Column Chromatography

After most radioactive labeling procedures, it is desirable to separate the DNA from unincorporated dNTPs. Removal of the radioactive precursors helps to reduce the background in hybridization experiments and protects investigators from unnecessary exposure to radioactivity. Gel filtration, which separates DNA and dNTPs by virtue of the large difference in molecular weight, is the most efficient method. It is also possible to perform the separation by ethanol precipitation, especially if ammonium acetate is used instead of sodium chloride (*UNIT 2.1*). However, ethanol precipitation is less efficient at removing the dNTPs and is more likely to result in radioactive contamination of the microcentrifuge and the investigator.

For DNA that is greater than 100 nucleotides, the two most common materials for column chromatography are Sephadex G-50 and Bio-Gel P-60. Other resins may be more useful for specialized applications (e.g. Bio-Gel P-2 is useful for separating oligonucleotides from dNTPs). Before carrying out the separation procedure described below, it is important to “swell the resin.” This is accomplished by adding 30 g of either resin to 300 ml TE buffer in a 500-ml screw-capped bottle and then heating to 65°C for a few hours (overnight at room temperature is also sufficient). After cooling to room temperature, excess TE buffer is removed and replaced by fresh TE buffer ($\frac{1}{2}$ volume of the resin). Store at room temperature or 4°C.

**BASIC
PROTOCOL**

**Enzymatic
Manipulation
of DNA and RNA**

3.4.8

Figure 3.4.1 Separating DNA from dNTPs by column chromatography.

Materials

TE buffer (*APPENDIX 2*)

6 1/2-in. Pasteur pipet

Silanized glass wool (*APPENDIX 3*)

Swelled column resin (e.g., Sephadex G-50 or Bio-Gel P-60 from Bio-Rad)

1. Plug the bottom of a 6 1/2-in. Pasteur pipet with clean glass wool.

The easiest method is to push the glass wool down to the bottom with a 9-in. Pasteur pipet. A small amount of glass wool is sufficient to plug the bottom.

2. Swirl the bottle containing the column resin to make an even suspension, and fill the pipet with the suspension. Repeat until the pipet is almost completely filled with packed column resin, leaving enough space for the addition of 200 µl (see Fig. 3.4.1). This should take about 5 min.

Several columns can be prepared and processed simultaneously.

3. After placing the column behind a lucite shield to protect against exposure to radioactivity, apply the DNA sample (in a volume no greater than 200 μ l) to the column, while collecting the drops in a microcentrifuge tube. After the sample has run in, wash the column with two 200- μ l additions of TE buffer.

It takes 1 to 2 min for each 200- μ l addition to run into the column. At this time, the DNA should be nearing the bottom of the column, while the dNTPs should be near the top of the column. This can be ascertained with a hand-held "minimonitor."

4. Place a new microcentrifuge tube beneath the column, and add 200 μ l TE buffer to the top of the column. Repeat four times, thus generating five fractions each containing 200 μ l.
5. Determine the amount of radioactivity in each tube with a hand-held minimonitor. Almost all of the DNA should be in the first two fractions that contain high amounts of radioactivity. The amount of radioactivity in subsequent fractions, which represents a variety of products including degraded DNA (most often seen in nick translation reactions containing too much DNase I), should be less than in the "peak" fractions. The unincorporated dNTPs should still be on the column.

With experience, the investigator will know when the radioactive DNA will come through the column. By following the progress of the chromatography with a minimonitor, fewer fractions need be collected.

6. For many applications, the fractions containing the DNA can be used directly. If necessary, the DNA can be ethanol precipitated (UNIT 2.1). The column and the unused radioactive fractions should be disposed of properly as radioactive waste.

Spin-Column Procedure for Separating Radioactively Labeled DNA from Unincorporated dNTP Precursors

**ALTERNATE
PROTOCOL**

This method involves the same principle as described in the basic protocol above for conventional column chromatography. It differs in that the packing and running of the column is accomplished by centrifugation rather than by gravity. This method is more rapid than conventional chromatography and is useful when many samples are involved; however, removal of the dNTPs may be less quantitative. Spin columns can be purchased commercially at moderate expense.

CAUTION: Use extreme care that centrifuge and work area do not become contaminated with radioactivity. Whenever possible, place samples behind a lucite shield.

Additional Materials

5-ml disposable syringe

1. Plug the bottom of a 5-ml disposable syringe with clean, silanized glass wool.
2. Swirl the column resin to make an even suspension, and fill the syringe with the suspension.

Several columns can be prepared and processed simultaneously.

3. Place the syringe containing the resin into a polypropylene tube that is suitable for centrifugation in a desktop centrifuge (see Fig. 3.4.2). Spin 2 to 3 min at a setting of 4 in order to pack the column.

Centrifugation should be carried out in a swinging-bucket rotor, not fixed-angle rotors. This ensures that the sample passes uniformly through the column. In addition, do not use Sorvall or Beckman floor-model centrifuges that are meant for higher speed centrifugation.

**Enzymatic
Manipulation
of DNA and RNA**

3.4.10

Figure 3.4.2 Preparation of a spin column. A 5-ml syringe containing the column resin is placed upside down in a polypropylene centrifuge tube.

The most convenient equipment for this purpose is a desktop centrifuge.

The resin should not be packed too tightly or too loosely. Therefore, adjust the time and speed in the tabletop centrifuge according to individual laboratory conditions. A general guideline for speed is ~1200 rpm.

4. Dilute the radioactive sample with TE buffer to a final volume of 100 μ l and load the sample in the center of the column.

If sample is loaded on the side of the column resin, some dNTPs may pass around the gel and elute with the DNA.

5. Place the syringe containing the loaded column into a new polypropylene tube, and spin 5 min at a setting of 5 to 6.
6. Save the liquid at the bottom of the tube containing the labeled DNA. Discard the syringe, which retains the unincorporated dNTPs, into a radioactive waste unit.

DNA-Dependent DNA Polymerases

All DNA polymerases add deoxyribonucleotides to the 3'-hydroxyl terminus of a primed double-stranded DNA molecule (Kornberg, 1980), as shown in Figure 3.5.1.

Figure 3.5.1 DNA polymerase 5'→3' polymerase activity.

Synthesis is exclusively in a 5'→3' direction with respect to the synthesized strand. Each nucleotide that is incorporated during polymerization is complementary to the one opposite to it in the template (dA pairs with dT, dC with dG). The reaction requires the four deoxyribonucleoside triphosphates (dNTPs) and magnesium ions.

Many DNA polymerases have a 3'→5' exonuclease inherently associated with the polymerase activity, as shown in Figure 3.5.2.

The 3'→5' exonuclease activity removes a single nucleotide at a time, releasing a nucleoside 5' monophosphate. In the absence of dNTPs, this activity will catalyze

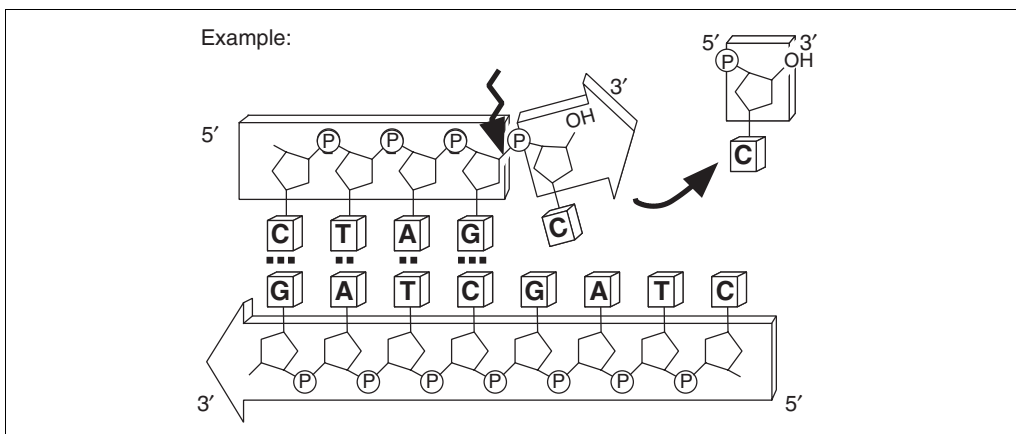

Figure 3.5.2 DNA polymerase 3'→5' exonuclease activity.

stepwise degradation from a free 3'-hydroxyl end of both single- and double-stranded DNA. In the presence of dNTPs, the exonuclease activity on double-stranded DNA is inhibited by the polymerase activity. During DNA synthesis, the exonuclease activity performs a proofreading function by removing misincorporated nucleotides.

In addition to the 3'→5' exonuclease activity, some DNA polymerases (e.g., *E. coli* DNA polymerase I) also have an associated 5'→3' exonuclease activity. This activity degrades double-stranded DNA from a free 5'-hydroxyl end (Fig. 3.5.3).

Figure 3.5.3 DNA polymerase 5'→3' exonuclease activity.

The 5'→3' exonuclease activity removes from one to several nucleotides at a time, releasing predominantly nucleoside 5' phosphates, but also some larger oligonucleotides up to 10 nucleotides in length. The 5'→3' exonuclease activity of *E. coli* DNA polymerase I enables it to initiate synthesis from nicks in duplex DNA. The 5'→3' exonuclease degrades the DNA ahead of the synthesizing polymerase, resulting in translocation of the nick (Kelley et al., 1970). This reaction, known as nick translation, is important for uniformly labeling duplex DNA molecules (Rigby et al., 1977; see Fig. 3.5.4). The 5'→3' exonuclease activity of *E. coli* DNA polymerase I, which is located at the N-terminus of the molecule, can be removed either by protease treatment or by deletion of the relevant part of the gene. The resulting DNA polymerase, which retains the 3' to 5' exonuclease, is referred to as the *E. coli* DNA polymerase I large fragment, or the Klenow fragment.

An important property of DNA polymerases is their processivity. Processivity is the ability of a polymerase molecule to incorporate nucleotides continuously on a given primer without dissociating from the primer template. Most DNA polymerases (e.g., *E. coli* DNA polymerase I, Klenow fragment, T4 DNA polymerase) have low processivity; they dissociate from a primer template after incorporating fewer than 10 nucleotides. In contrast, T7 DNA polymerase is highly processive; it can incorporate thousands of nucleotides from a given primer without dissociating from the primer template. This is a useful property when long stretches of DNA are being synthesized. See Table 3.5.1 for a summary of properties of DNA polymerases.

Table 3.5.1 Properties of DNA Polymerases

Enzyme	3'→5' exonuclease	5'→3' exonuclease	Polymerase rate	Processivity
<i>E. coli</i> DNA polymerase	Low	Present	Intermediate	Low
Klenow fragment	Low	None	Intermediate	Low
Reverse transcriptase	None	None	Slow	Intermediate
T4 DNA polymerase	High	None	Intermediate	Low
Native T7 DNA polymerase	High	None	Fast	High
Chemically modified T7 DNA polymerase	Low	None	Fast	High
Genetically modified T7 DNA polymerase ($\Delta 28$)	None	None	Fast	High
<i>Taq</i> DNA polymerase	None	Present	Fast	High

***ESCHERICHIA COLI* DNA POLYMERASE I** (Lehman, 1981)**ENZYME**

The enzyme is the product of the *E. coli polA* gene. The *polA* gene has been cloned in bacteriophage λ , and the enzyme is overproduced after temperature induction of a lysogenic strain. DNA polymerase I is a single polypeptide of molecular weight 109,000. In addition to its DNA-dependent DNA polymerase activity, it also has both a 3'→5' exonuclease activity and a 5'→3' exonuclease activity. The 3'→5' exonuclease activity is much less active than that of T4 or T7 DNA polymerase.

Reaction Conditions

For 25- μ l reaction:

50 mM Tris·Cl, pH 7.5

10 mM MgCl₂

1 mM DTT

50 μ g/ml BSA

20 μ M 4dNTP mix (one or more [α -³²P]dNTPs; UNIT 3.4)

1 μ g DNA

3 U *E. coli* DNA polymerase I

The volume of reaction, concentration of the 4 dNTPs, and amount of DNA will vary, depending upon the specific application. Stop the reaction by adding 1 μ l of 0.5 M EDTA or by heating to 75°C for 10 min.

Nick translation reactions should be carried out at 15°C (typically for 1 to 3 hr) to prevent the synthesis of “snapback” DNA that occurs at higher temperatures. Other reactions involving DNA polymerase I are performed at 20° to 37°C for 15 to 30 min.

For preparing radioactively labeled DNA of high specific activity, the concentration of one (or more) of the dNTP precursors is reduced to 1 to 2 μ M. For example, in a 25- μ l reaction, 25 μ Ci of ³²P-labeled dATP at 400 to 800 Ci/mmol, or 100 μ Ci at 3000 Ci/mmol, can be used instead of 20 μ M dATP. For efficient synthesis of DNA, the concentration of any of the dNTPs should not go below 1 μ M, the approximate K_m . If dNTP precursors of higher specific activity (3000 to 5000 Ci/mmol) are used, the reaction volume should be decreased or the amount of radioactive dNTP should be increased to maintain the 1 μ M concentration. Reactions with two radioactive precursors (both at 1 μ M) are frequently inefficient because the reaction rate is slowed by the low concentrations of the labeled precursors.

Uniform Labeling of DNA by Nick Translation

The nick translation reaction is a rapid, easy, and relatively inexpensive method for producing uniformly radioactive DNA of high specific activity. It is frequently used for the preparation of sequence-specific probes for screening libraries (UNIT 6.3), for genomic DNA blots (UNIT 2.9), and for RNA blots (UNIT 4.9). A typical nick translation reaction is carried out with a DNA fragment that has been purified by gel electrophoresis; for some applications, it is unnecessary to purify the fragment away from the plasmid or phage vector DNA sequences.

The mechanism of nick translation involves the combined activities of the 5'→3' polymerase and 5'→3' exonuclease activities of *E. coli* DNA polymerase I. Given a nicked duplex DNA molecule, the polymerase will translocate the nick, removing nucleotides ahead of it using its 5'→3' exonuclease activity, while simultaneously synthesizing DNA at the 3' end. The nicks in the DNA template are generally produced by adding trace amounts of DNase I to the reaction mixture (UNIT 3.12) (Fig. 3.5.4).

1. Prepare reaction mix for 0.25 µg of DNA as follows:

2.5 µl 0.5 mM 3dNTP mix (minus dATP; UNIT 3.4)
 2.5 µl 10× *E. coli* DNA polymerase I buffer (UNIT 3.4)
 10 µl 3000 Ci/mmol [α -³²P]dATP (100 µCi)
 1 µl DNase I [diluted 10,000-fold into standard enzyme diluent (APPENDIX 2)
 from a 1 mg/ml stock solution; refer to critical parameters]
 1 µl *E. coli* DNA polymerase I (5 to 15 U)

Keep ice-cold until all additions are made.

For generating probes with slightly lower specific activity, 2.5 µl (25 µCi) of 800 Ci/mmol [α -³²P]dATP can be used (an additional 7.5 µl water must be added to reaction mixture to maintain a constant volume). Lower-specific-activity probes are useful for most purposes, and are less expensive to prepare.

The reaction can be scaled up or down depending on the amount of probe that is desired. However, it is critical to maintain the above concentrations of DNA, [α -³²P]dATP, and enzymes for an efficient reaction.

The amount of DNase I is critical for optimal nick translation (refer to critical parameters). A molten gel slice of DNA in low gelling/melting temperature agarose can be added directly to the reaction mixture. For reproducible results, it is best to prepare and store the 1 mg/ml DNase I solution as described in UNIT 3.12.

2. Add 0.25 µg DNA in a total volume of 8 µl (add water if necessary). The total reaction volume should be 25 µl. Immediately incubate the reaction mixture at 12° to 14°C for 15 to 45 min, depending on the DNase calibration curve (refer to critical parameters).

If the DNA of interest is purified by electrophoresis in a low gelling/melting temperature agarose gel (UNIT 2.6), 8 µl of a molten gel slice (at 37°C) can be added directly to the reaction mixture without purification of the DNA fragment from the agarose. Although the resulting mixture will solidify, the nick translation reaction will take place (sometimes at a reduced efficiency).

3. After the time determined for the particular batch of DNase I, stop the reaction by adding 1 µl of 0.5 M EDTA, 3 µl of 10 mg/ml tRNA, and 100 µl TE buffer.

If DNA was added as a molten gel slice, the stopped reaction mixture must be remelted by incubating 10 min at 70°C.

4. Phenol extract the reaction mixture as described in UNIT 2.1. Transfer the aqueous (top) phase into a fresh tube.

If the volume of the mixture exceeds 400 μl , a small amount may seep around the cap and contaminate the microcentrifuge with ^{32}P .

5. Separate the labeled DNA from the unincorporated radioactive precursors by chromatography on a small Sephadex G-50 or Bio-Gel P-60 column as described in UNIT 3.4.

Alternatively, this separation can be achieved by ethanol precipitation; however, the separation is not as good and the procedure is more likely to lead to radioactive contamination of the investigator and equipment.

6. If desired, remove a 1- μl aliquot and determine the amount of ^{32}P incorporation (UNIT 3.4). A specific activity of 10^8 cpm/ μg should be easily obtained.

Commercial kits are available which can be used to produce nick translated DNA fragments. However, they do not produce very high-specific-activity probes because they do not optimize the DNase to DNA polymerase I activities as described below in critical parameters. Furthermore, they are expensive.

Figure 3.5.4 Nick translation activity of *Escherichia coli* DNA polymerase I.

Critical Parameters of Nick Translation

1. For production of high-specific-activity probes by nick translation, it is crucial to optimize the amount of DNase I and the time of reaction. If the reaction time is too short or the amount of DNase I is too low, insufficient label will be incorporated. In contrast, if the reaction time is too long or the amount of DNase I is too high, the DNA will be degraded. To optimize the nick translation reaction for a given preparation of the 1 mg/ml DNase I stock solution, parallel reactions should be set up in which the amount of DNase I and the time of reaction are varied. By measuring the incorporation of ^{32}P dATP into DNA by acid precipitation (*UNIT 3.4*), optimal conditions can be selected. At the appropriate concentration of DNase I (typically 1 μl of a 10^4 dilution of a 1 mg/ml solution), a maximum incorporation of 30 to 40% should occur between 15 and 45 min. Once the DNase I stock solution is “calibrated,” nick translations are carried out routinely by using the optimal DNase I dilution and reaction time.
2. Nick-translation can be carried out on DNA fragments purified by gel electrophoresis or on intact DNA molecules. Gel-purified DNA fragments are usually essential for screening genomic or cDNA libraries because vector or *E. coli* DNA sequences in the probe will hybridize to every clone in the library. The purification of DNA fragments also leads to the production of more specific probes, which is helpful for increasing the signal and reducing the background in hybridization experiments. For example, consider a 1-kb DNA fragment cloned into a 4-kb plasmid vector or a 39-kb bacteriophage λ vector. If intact DNA molecules are nick translated, only 20% or 2.5% of the labeled DNA will represent the DNA region of interest; in contrast, if the purified fragment is used, 100% of the labeled DNA will represent the region of interest.
3. For nick translation of very short fragments (<500 bp), it may be necessary to increase the amount of DNase I in order to ensure that most of the molecules are nicked at least once.
4. Nick translations of electrophoretically separated DNA fragments can be carried out without purification of the DNA away from the gel matrix provided that low gelling/melting temperature agarose is used. The gel slice containing the DNA fragment is melted, and the reaction occurs in the resolidified gel. This procedure saves time, but radioactive labeling of the DNA may not be as efficient.

Other Applications of *E. Coli* DNA Polymerase I

1. Labeling 3' ends of DNA molecules. This procedure is generally performed with the Klenow fragment of *E. coli* DNA polymerase I (see following section).
2. Repairing overhanging 3' or 5' ends to generate blunt ends. This procedure is generally performed with the Klenow fragment of *E. coli* DNA polymerase I (see following section). For repairing overhanging 3' ends, T4 DNA polymerase is usually preferred because its 3'→5' exonuclease is more active.

KLENOW FRAGMENT OF *ESCHERICHIA COLI* DNA POLYMERASE I

The Klenow fragment, molecular weight 76,000, consists of the C-terminal, 70% of *E. coli* DNA polymerase I. It retains the DNA polymerase and 3'→5' exonuclease activity of *E. coli* DNA polymerase I, but lacks the 5'→3' exonuclease activity.

Originally, the Klenow fragment was generated by proteolytic digestion of intact *E. coli* DNA polymerase I (Jacobsen et al., 1974). However, now it is overproduced directly from the cloned gene for DNA polymerase I modified to delete the N-terminal 323 amino acid residues of the polymerase (Joyce and Grindley, 1983).

The reaction conditions for the Klenow fragment are the same as those described earlier in this unit for the intact DNA polymerase I. The protocols that follow below describe procedures for labeling 3' ends of DNA, for repairing 3' or 5' overhanging ends to blunt ends, and for uniformly labeling DNA by random-sequence oligonucleotide-primed synthesis.

Labeling the 3' Ends of DNA

1. In a 20- μ l reaction mixture, digest 0.1 to 4 μ g DNA with a restriction endonuclease that generates 5' overhanging ends (UNIT 3.1).

DNA fragments with blunt ends can be labeled inefficiently by replacement of the nucleotide at the 3'-hydroxyl terminus. For endonucleases that produce 3' overhanging ends, labeling of 3' termini must be carried out by replacement synthesis using T4 DNA polymerase (see Fig. 3.5.5 and accompanying text).

2. Add 20 μ Ci of the desired [α -³²P]dNTP (400 to 800 Ci/mmol) and 1 μ l of appropriate 5 mM 3dNTP mix (UNIT 3.4). If higher specific activities are required, add 80 μ Ci of the radioactive dNTP at 3000 Ci/mmol.

Since the Klenow fragment incorporates nucleotides that are complementary to the single-stranded, 5' extensions, the choice of ³²P-labeled dNTP depends on the restriction endonuclease used to cleave the DNA. For example, labeling of BamHI ends (GATC) can be accomplished with any of the radioactive precursors, whereas labeling of EcoRI ends (AATT) requires either radioactive dATP or dTTP.

3. Add 1 U of the Klenow fragment and incubate 15 min at 30°C.

It is unnecessary to inactivate the restriction endonuclease, to change buffers, or to repurify the DNA prior to adding the Klenow fragment.

4. Stop the reaction with 1 μ l of 0.5 M EDTA or by heating to 75°C for 10 min. If desired, remove unincorporated dNTP precursors from labeled DNA (UNIT 3.4).

Critical Parameters of Labeling 3' Ends

For DNA fragments that are 500 bp in length, the above procedure will generate DNA with a specific activity of 10⁷ cpm/ μ g. For situations where higher specific activities are desired (e.g., for hybridization probes), use radioactive dNTPs of higher specific activity (3000 to 5000 Ci/mmol). When the specific activity is relatively unimportant (e.g., restriction mapping or preparation of size standards), add 1 μ l of a mixture containing all four unlabeled dNTPs (0.5 mM each dNTP) to the ³²P-labeled dNTP.

This procedure is extremely useful for visualizing small DNA molecules after gel electrophoresis. Unlike staining with ethidium bromide where band intensity is proportional to fragment length, all end-labeled fragments will have the same band intensity.

This is the method of choice for generating ³²P-labeled size standards for autoradiography. Besides the fact that band intensities are independent of fragment length, end-labeled

DNAs are stable for several months. Although radioactive decay reduces the specific activity and increases exposure time, DNA is not broken internally, as is the case for uniformly labeled molecules.

DNA can be labeled selectively at one end by cleaving with two different restriction endonucleases and labeling with a ^{32}P -labeled dNTP that is complementary to only one of the two 5' extensions. For example, if DNA is cleaved with *Eco*RI (AATT) and *Bam*HI (GATC), the *Bam*HI ends can be selectively labeled by using ^{32}P -labeled dGTP. Alternatively, DNA can be cleaved with one enzyme, radiolabeled, and then cleaved with the second enzyme. In this case, it is important to inactivate the Klenow fragment by heating to 75°C for 15 min prior to addition of the second restriction enzyme.

For some applications, e.g., DNA sequencing by the Maxam-Gilbert method (UNIT 7.5) or preparation of hybridization probes for S1 analysis (UNIT 4.6), it is important that all molecules are of identical length. To accomplish this, carry out steps 1 to 3 as above,

Figure 3.5.5 T4 DNA polymerase replacement synthesis.

but after the initial incubation, add 1 μ l of the 5 mM solution containing all four dNTP and incubate for an additional 15 min. This “cold chase” ensures that the Klenow fragment will extend to the end of every molecule.

Repairing 3' or 5' Overhanging Ends to Generate Blunt Ends

For many cloning experiments, it is necessary to convert the ends generated by restriction endonucleases into blunt ends (UNIT 3.16).

1. In a 20- μ l reaction, digest 0.1 to 4 μ g DNA with a restriction endonuclease.

DNA can be treated with exonucleases such as Bal 31, λ exonuclease, exonuclease III, or endonucleases such as S1 or mung bean nuclease if desired.

2. Add 1 μ l of 0.5 mM each dNTP.

It is unnecessary to inactivate the restriction endonuclease, to change buffers, or to repurify the DNA prior to adding the Klenow fragment.

3. Add 1 to 5 U of the Klenow fragment and incubate at 30°C for 15 min.

Repair of 5' extensions is carried out by polymerase activity, whereas repair of 3' extensions is carried out by 3' to 5' exonuclease activity. Due to the relative inactivity of exonuclease, this method is not desirable in cases where extensive repair of overhanging 3' ends is required. In such situations, T4 DNA polymerase (a much more expensive enzyme) or native T7 DNA polymerase are better choices.

4. Stop the reaction by heating to 75°C for 10 min or by adding 1 μ l of 0.5 M EDTA.

For restriction fragments produced by cleavage with different endonucleases, it is possible to repair one end selectively. This is done by cleaving with enzyme 1, repairing the ends, inactivating the Klenow fragment by heat (75°C for 10 min), and cleaving with enzyme 2.

Labeling of DNA by Random Oligonucleotide-Primed Synthesis

Random oligonucleotide-primed synthesis is an alternative to nick translation for producing uniformly radioactive DNA of high specific activity (Feinberg and Vogelstein, 1983). To carry out the labeling procedure, cleave the DNA with a restriction endonuclease, and, if desired, purify the DNA fragment containing the sequence of interest by gel electrophoresis. Denature the resulting linear DNA molecule(s) by boiling; anneal to random-sequence oligodeoxynucleotides (typically six bases in length); and then incubate with the Klenow fragment in the presence of dNTPs. In this way, the hexanucleotides prime the DNA of interest at various positions along the template, and are extended to generate double-stranded DNA that is uniformly labeled on both strands.

1. Cleave the DNA of interest with an appropriate restriction endonuclease (UNIT 3.1).

It is very useful, though not absolutely essential, to linearize the DNA for the subsequent denaturation step.

2. If desired, purify the DNA fragment of interest by gel electrophoresis using any of the procedures described in UNIT 2.6. If gel purification is unnecessary, ethanol precipitate the DNA (UNIT 2.1) and resuspend in TE buffer.

It is essential to remove the restriction endonuclease buffer from the DNA because the Mg^{++} ions will make it difficult to denature the DNA.

If low gelling/melting temperature agarose is used for the gel, it is usually unnecessary to purify the DNA away from the gel matrix.

3. Prepare the following reaction mix on ice:

- 2.5 μ l 0.5 mM 3dNTP mix (minus dATP; *UNIT 3.4*)
- 2.5 μ l 10 \times Klenow fragment buffer (*UNIT 3.4*)
- 5 μ l 3000 Ci/mmol [α -³²P]dATP (50 μ Ci)
- 1 μ l Klenow fragment (3 to 8 U)

For generating probes with slightly lower specific activity, 2.5 μ l (25 μ Ci) of 800 Ci/mmol [α -³²P]dATP can be used (an additional 2.5 μ l of water must be added to reaction mixture to maintain a constant volume). Lower-specific-activity probes are useful for most purposes, and are less expensive to prepare.

4. Combine the DNA of interest (30 to 100 ng) with the random hexanucleotides (1 to 5 μ g) in a total volume of 14 μ l. Boil the DNA mixture for 2 to 3 min and then place on ice.

If the DNA has not been purified from the gel matrix, place the boiled DNA at 37°C. Random hexanucleotides can be purchased from Pharmacia.

5. Add 11 μ l of the reaction mix from step 3 to the denatured DNA (final volume is 25 μ l), and immediately incubate the mixture 2 to 4 hr at room temperature.

6. Stop the reaction by adding 1 μ l of 0.5 M EDTA, 3 μ l of 10 mg/ml tRNA, and 100 μ l TE buffer.

If DNA was added as a molten gel slice, the stopped reaction mixture must be remelted by incubation at 70°C for 10 min.

7. Phenol extract the reaction mixture as described in *UNIT 2.1*. Transfer the aqueous (top) phase into a fresh tube.

8. Separate the labeled DNA from the unincorporated radioactive precursors by chromatography on a small Sephadex G-50 or Bio-Gel P-60 column as described in *UNIT 3.4*.

Alternatively, this separation can be achieved by ethanol precipitation; however, the separation is not as good and the procedure is more likely to lead to radioactive contamination of the investigator and equipment.

9. If desired, remove a 1- μ l aliquot and determine the amount of ³²P incorporation by acid precipitation (*UNIT 3.4*). A specific activity of 10⁸ cpm/ μ g should be easily obtained.

Other Applications of Klenow Fragment

1. DNA sequencing by the dideoxy method (*UNIT 7.4*).
2. Synthesis of the second strand for the cloning of cDNAs (*UNIT 5.5*).
3. Extension of oligonucleotide primers on single-stranded templates. Some specific applications include dideoxy DNA sequencing (mentioned above), synthesis of hybridization probes, and in vitro mutagenesis (*UNITS 8.1 & 8.3*).
4. Converting single-stranded oligonucleotides to double-stranded DNA by mutually primed synthesis (*UNIT 8.2*).

T4 DNA POLYMERASE

T4 DNA polymerase, the product of gene 43 of bacteriophage T4, is either prepared from cells of *E. coli* that have been infected with the phage or has been overproduced from its cloned gene. T4 DNA polymerase is a single polypeptide of molecular weight 112,000. In addition to its DNA-dependent DNA polymerase activity, it has a very active single-stranded and double-stranded 3'→5' exonuclease. It lacks a 5'→3' exonuclease activity. T4 DNA polymerase by itself has low processivity; however, in the presence of several T4 accessory proteins, it becomes very processive (Nossal, 1984). This polymerase has been produced from a clone that overexpresses its gene (gene 43) (Lin et al., 1987).

Reaction Conditions

For 50- μ l reaction:

50 mM Tris·Cl, pH 8.0

5 mM MgCl₂

5 mM DTT

2 μ g DNA

100 μ M 4dNTP mix (*UNIT 3.4*)

50 μ g/ml BSA

10 U T4 DNA polymerase

Incubate 20 min at 11°C. Stop reaction by adding 2 μ l of 0.5 M EDTA or by heating to 75°C for 10 min. The volume of reaction, concentration of 4 dNTPs, and the temperature of the reaction will vary, depending upon the individual application.

Effect of Triphosphate Concentration

For reaction conditions that do not require radioactive labeling of the DNA, high concentrations (100 μ M) of dNTPs are used to maximize the ratio of polymerase to exonuclease activity. In labeling experiments, the concentration of the labeled dNTP is reduced to 1 to 2 μ M; this maximizes the specific activity of the DNA. Levels lower than 1 μ M labeled dNTP should not be used because once the dNTPs are exhausted the exonuclease activity will degrade the DNA.

Effect of Temperature

For labeling 3' termini with T4 DNA polymerase, the temperature of the reaction should be maintained at 11°C. At higher temperatures, if only a subset of the four deoxyribonucleoside triphosphates are added, the exonuclease will degrade the template beyond the nucleotide which the polymerase could replace.

Buffer Compatibility

For most applications, T4 DNA polymerase is used following digestion with restriction endonucleases. For many restriction enzymes, cleavage can be carried out in T4 DNA polymerase buffer, and T4 DNA polymerase can be used directly. If buffers for the restriction enzyme and T4 DNA polymerase are incompatible, the DNA should be digested with the restriction enzyme and then repurified by phenol extraction, ethanol precipitation, and resuspension in TE buffer (*UNIT 2.1*) prior to treatment with T4 DNA polymerase.

Applications

1. Radioactive labeling of the 3' termini of DNA fragments (Goulian et al., 1968). DNA fragments containing 5' protruding ends are incubated with the appropriate [α -³²P]dNTPs at 1 to 2 μ M at 11°C for 20 min. The Klenow fragment of *E. coli* DNA polymerase I carries out the same reaction and is considerably less expensive.

2. Selective and extensive labeling of the 3' termini of a linear duplex DNA molecule (Challberg and Englund, 1980). This technique, known as "replacement synthesis" (Fig. 3.5.5), involves first incubating the duplex DNA fragment with T4 DNA polymerase in the absence of dNTPs. Under these conditions, the strong 3'→5' exonuclease activity will degrade selectively from the 3' ends. After an empirically determined period of time, the four dNTPs are added (including one radioactively labeled [α -³²P]dNTP). The polymerase activity of T4 DNA polymerase then extends the 3' ends the length of the template. Optimal labeling is achieved when the 3'→5' exonuclease activity removes 30 to 40% of the nucleotides from each end. If exonuclease action proceeds further, the strands will separate and hence not serve as substrates for the polymerase activity.

The resulting molecules are selectively labeled at their 3' ends to an extent determined by the length of time of the exonuclease reaction. To obtain a DNA fragment labeled from only one of its 3' ends, the molecules are subsequently cut with an appropriate restriction enzyme, and the resulting fragments are resolved by electrophoresis.

3. Converting the ends of any duplex DNA fragment to blunt-ended structures suitable for blunt-end ligation for cloning. Although the Klenow fragment of *E. coli* DNA polymerase I can also catalyze this reaction, T4 DNA polymerase is the enzyme of choice for removing 3' protruding ends because of its strong 3'→5' exonuclease activity. In the presence of high concentrations of all four dNTPs, the degradation will stop when the enzyme reaches the duplex region. Similarly, if the termini have a 5' protruding region, the enzyme will simply extend the recessed 3' termini until the end is blunt. For these applications, the DNA is incubated with T4 polymerase and 100 μ M each of the four dNTPs at 11°C for 20 min.

ENZYME

NATIVE T7 DNA POLYMERASE (Tabor et al., 1987)

This enzyme was originally isolated from bacteriophage T7-infected *E. coli*. The purified T7 DNA polymerase is a complex of two proteins in a one-to-one stoichiometry: the T7-encoded gene 5 protein (molecular weight 80,000), and the *E. coli*-encoded thioredoxin (molecular weight 12,000). Both proteins have been overproduced in *E. coli* from genes cloned into plasmid vectors.

Purified T7 gene 5 protein has a 3'→5' exonuclease activity and a nonprocessive DNA polymerase activity. Thioredoxin acts as an accessory protein to increase the affinity of T7 gene 5 protein for the primer template, rendering DNA synthesis processive for thousands of nucleotides. The high processivity of the T7 gene 5/thioredoxin complex (T7 DNA polymerase) is in marked contrast to the low processivity of *E. coli* DNA polymerase I, Klenow fragment, or T4 DNA polymerase.

Native T7 DNA polymerase (T7 gene 5 protein/thioredoxin complex) has a very active single-stranded and double-stranded DNA 3'→5' exonuclease activity in addition to its polymerase activity. This activity is a detriment to the use of this enzyme for DNA sequence analysis, and must be reduced or eliminated (modified T7 DNA polymerase) to be used for this application.

Reaction Conditions

For 50- μ l reaction:

40 mM Tris·Cl, pH 7.5
10 mM MgCl₂
5 mM DTT
50 mM NaCl
2 μ g DNA
300 μ M 4dNTP mix (*UNIT 3.4*)
50 μ g/ml BSA
5 U T7 DNA polymerase

Incubate at 37°C for 20 min. Stop reaction by adding 2 μ l of 0.5 M EDTA or by heating to 75°C for 10 min. The volume of reaction, concentration of 4 dNTPs, and temperature of the reaction will vary, depending upon the individual application.

Applications

1. Since T7 DNA polymerase is highly processive, it can be used for extensive synthesis of DNA on long templates (e.g., M13). It will extend thousands of nucleotides from the same primer template without dissociating and is largely unaffected by secondary structures that impede *E. coli* DNA polymerase I, T4 DNA polymerase, or reverse transcriptase.
2. Native T7 DNA polymerase is the enzyme of choice for the synthesis of the complementary strand during site-directed mutagenesis (Tabor and Richardson, 1989; Bebenek and Kunkel, 1989; see *UNIT 8.1*).
3. Native T7 DNA polymerase can be used analogously to T4 DNA polymerase for labeling 3' termini either by simple extension or by replacement synthesis. T7 and T4 DNA polymerases have comparably strong 3'→5' exonuclease activities.
4. Native T7 DNA polymerase can be used analogously to T4 DNA polymerase to convert the ends of any duplex DNA fragment (either 5' or 3' protruding) to blunt-ended structures.

MODIFIED T7 DNA POLYMERASE (Tabor and Richardson, 1987a, 1989)

Native T7 DNA polymerase has a very active 3'→5' exonuclease activity in addition to its polymerase activity. In modified T7 DNA polymerase, this exonuclease activity has either been reduced selectively by a chemical reaction or inactivated completely by genetic modification that deletes 28 amino acid residues from the exonuclease domain of the enzyme. Inactivation of the 3'→5' exonuclease activity increases the T7 DNA polymerase activity by 3- to 9-fold, by increasing the processivity of the enzyme and its ability to synthesize through regions of secondary structure.

Reaction Conditions

For 50- μ l reaction:

40 mM Tris·Cl, pH 7.5
5 or 10 mM MgCl₂ (see below)
5 mM DTT
50 mM NaCl
2 μ g DNA
300 μ M 4dNTP mix (*UNIT 3.4*)
50 μ g/ml BSA
10 U modified T7 DNA polymerase

ENZYME

**Enzymatic
Manipulation
of DNA and RNA**

3.5.13

Incubate at 37°C for 20 min. Stop reaction by adding 2 µl of 0.5 M EDTA or by heating to 75°C for 10 min. The volume of reaction, concentration of 4 dNTPs, amount of DNA and enzyme, and temperature of the reaction will vary, depending upon the individual application. Genetically modified T7 DNA polymerase has a lower MgCl₂ optimum (5 mM) than the chemically modified polymerase (10 mM).

Applications

1. Modified T7 DNA polymerase has the ideal characteristics for a DNA sequencing enzyme: high processivity, lack of 3'→5' exonuclease, and the lack of discrimination against deoxynucleotide analogs (dideoxynucleotides, [α -³⁵S]deoxynucleotides, and deoxyinosine nucleotides; see *UNIT 7.4* and Tabor and Richardson, 1987b).
2. Modified T7 DNA polymerase efficiently incorporates dNTPs that are present at very low levels (<0.1 µM) (Tabor and Richardson, 1987b). This is useful for the preparation of labeled substrates.
3. Because of its high specific activity and lack of associated 3'→5' exonuclease activity, modified T7 DNA polymerase is useful for labeling the 3' termini of DNA fragments with 5' protruding ends. It should not be used to make blunt-end fragments because it leaves a one-base overhang at the 5' end.

ENZYME

TAQ DNA POLYMERASE

Native *Taq* DNA polymerase is isolated from the extreme thermophile *Thermus aquaticus* (Lawyer et al., 1989). The enzyme is a double-stranded DNA polymerase with a molecular mass of 94 kDa. It has a temperature optimum for polymerization of 75° to 80°C and does not appear to have any 3'→5' exonuclease activity (D.H. Gelfand and S. Stoffel, unpublished results; Tindall and Kunkel, 1988). The enzyme is a single polypeptide chain with high turnover number and high processivity.

For Conditions for Polymerase Chain Reaction (PCR) see *UNIT 15.1*

Applications

1. *Taq* polymerase is active over a broad temperature range and has a high optimum temperature of polymerization, which makes it ideal for use in the polymerase chain reaction (see Chapter 15). The high temperature allows more specific pairing of oligonucleotide primers, which increases the efficiency and specificity and hence the sensitivity of PCR. The fact that the enzyme withstands repeated cyclings from the annealing temperatures used in PCR to the temperature required to separate the strands affords the advantage of adding the enzyme only once to a sample prior to running the amplification cycles.
2. *Taq* polymerase has a high turnover number, high processivity, and the capability to use deoxynucleoside triphosphate analogs, which makes it an excellent enzyme for DNA sequencing (Innis et al., 1988). These qualities—combined with its high temperature optimum—allow sequencing on templates that may exhibit strong secondary structure at lower temperatures, obviating use of conventional sequencing enzymes (see *UNIT 15.2*).

Template-Independent DNA Polymerases

UNIT 3.6

TERMINAL DEOXYNUCLEOTIDYLTRANSFERASE (Terminal Transferase)

ENZYME

This enzyme, purified from calf thymus, catalyzes the incorporation of deoxynucleotides to the 3'-hydroxyl termini of DNA accompanied by the release of inorganic phosphate (Fig. 3.6.1).

Figure 3.6.1 Terminal transferase activity.

A template is not required and will not be copied. Divalent cations are required, and the preference for the nucleotide to be incorporated will vary depending upon the divalent cation used. Single-stranded DNA is preferred as a primer; for double-stranded DNA, the extensions are most efficient when the ends have 3' protruding termini. However, in the presence of Co^{2+} , terminal transferase will prime any 3' terminus (protruding, blunt, or recessed) although not with uniform efficiency. The presence of Co^{2+} will also allow terminal transferase to catalyze the limited polymerization of ribonucleotides (Deng and Wu, 1983).

Reaction Conditions

For 50- μl reaction:

100 mM sodium cacodylate, pH 7.0

1 mM CoCl_2

0.1 mM DTT

4 pmol DNA (as 3' termini)

20 μM dNTPs (UNIT 3.4)

50 $\mu\text{g/ml}$ BSA

10 U terminal transferase

Incubate at 37°C for 30 min. Stop reaction by adding 2 μl of 0.5 M EDTA or by heating to 75°C for 10 min. The selection of which dNTPs to use and its concentration will vary, depending upon the individual application. Under the conditions outlined above, using dCTP, terminal transferase will add approximately 10 deoxycytidines to each 3' end in 30 min.

Applications

1. Cloning DNA fragments. It is used to synthesize a homopolymer “tail” at each end of the DNA to be cloned and a complementary homopolymer tail at each end of a linearized vector. The vector and insert DNAs are subsequently annealed by virtue of their complementary tails.
2. Labeling the 3' termini of DNA with ^{32}P . For DNA sequence analyses, incorporation can be limited to a single nucleotide by using [α - ^{32}P]cordycepin triphosphate (3'-deoxyribonucleoside triphosphate). This analog is a chain terminator; without a free 3' hydroxyl group, no additional nucleotides can be incorporated (Tu and Cohen, 1980).
3. Incorporating nonradioactive tags onto the 3' termini of DNA fragments. With use of biotin-11-dUTP [8-(2,4-dinitrophenyl-2,6-aminoethyl)aminoadenosine-5'-triphosphate or 2'-deoxyuridine-5'-triphosphate-5'-allylaminebiotin], these nucleotides serve as receptor sites for either fluorescent dyes or avidin conjugates (Vincent et al., 1982).
4. Synthesizing model polydeoxynucleotide homopolymers.

RNA-Dependent DNA Polymerases

UNIT 3.7

ENZYME

REVERSE TRANSCRIPTASE

Reverse transcriptases are derived from retroviruses such as avian myeloblastosis virus (AMV) or Moloney murine leukemia virus (MMLV), which use them to make DNA copies of their RNA genomes. The AMV enzyme is purified from isolated AMV virus (Verma, 1977), whereas the MMLV enzyme is purified from overproducing *E. coli* cells containing the cloned gene (Roth et al., 1985). AMV and MMLV reverse transcriptases are multifunctional enzymes, but they are mainly used as RNA-directed DNA polymerases. Specifically, deoxyoligonucleotides (either oligo(dT) polymers, a collection of random DNA sequences, or a specific sequence) are used as primers for extension on RNA (usually messenger RNA) templates (UNIT 5.5). The DNA synthesized from the RNA template is referred to as complementary DNA (cDNA).

Reverse transcriptase also has a DNA-directed DNA polymerase activity (Fig. 3.7.1). The incorporation of dNTPs is very slow (~5 nucleotides/sec), nearly 100 times slower than the rate of T7 DNA polymerase (Tabor and Richardson, 1987). The DNA polymerase activity of reverse transcriptase lacks a 3'→5' exonuclease activity.

A third activity of reverse transcriptase will degrade the RNA in an RNA:DNA hybrid (Fig. 3.7.2). This so-called RNase H activity is an exonuclease acting processively from either the 5' or 3' terminus. This activity is useful for selectively destroying parts of an RNA molecule to which DNA molecules (typically sequence-specific oligonucleotides) have been hybridized.

Figure 3.7.2 Reverse transcriptase 5'→3' and 3'→5' exonuclease activity (RNase H activity).

Reaction Conditions

For 50- μ l reaction:

50 mM Tris-Cl, pH 8.2

5 mM MgCl₂

5 mM DTT

50 mM KCl

1 μ g mRNA

1 μ g oligo(dT)₁₂₋₁₈

40 μ M 4 dNTPs (UNIT 3.4)

100 μ Ci [α -³²P]dNTP (specific activity >400 Ci/mmol)

50 μ g/ml BSA

40 U reverse transcriptase

Incubate at 37°C for 30 min. Stop reaction by adding 2 μ l of 0.5 M EDTA or by heating to 75°C for 10 min. If necessary, the RNA template can be destroyed by adding 10 μ l of 5 M NaOH and incubating at 37°C overnight. The volume of reaction, concentration of 4 dNTPs, and temperature of the reaction will vary, depending upon the individual application.

Applications

1. Synthesizing cDNA for insertion into bacterial cloning vectors (see UNIT 5.5). Two different types of primers are used for the synthesis of cDNA: oligo(dT) primers and a population of randomly generated oligodeoxyribonucleotides. Oligo(dT) primers bind exclusively to the poly(A) tracts of mRNA; as a result, the synthesis of cDNA is biased towards the region corresponding to the 3' end of an mRNA template. In contrast, a mixed population of oligonucleotides will anneal at random positions on the RNA; consequently, the DNA synthesized will be complementary to all parts of the RNA template at a similar frequency (Taylor et al., 1976).
2. Filling in and labeling the 3' termini of DNA fragments with 5' protruding ends. Reverse transcriptase is useful for this reaction because, unlike *E. coli* DNA polymerase I or the Klenow fragment, it lacks a 3'→5' exonuclease activity.
3. For DNA sequencing, in place of Klenow fragment (UNIT 7.4). Due to its lack of a 3'→5' exonuclease, reverse transcriptase will often synthesize through regions that impede the progress of the Klenow fragment (Zagursky et al., 1985).

DNA-Dependent RNA Polymerases

There are two types of DNA-dependent RNA polymerases commonly used for nucleic acid research. One class is represented by *E. coli* RNA polymerase. This is a large, multisubunit enzyme which recognizes two DNA sequences, the -10 and -35 elements, within a large (~40 bp) promoter region. *E. coli* RNA polymerase was the DNA-dependent RNA polymerase used originally for the synthesis of transcripts *in vitro*. However, its use has several problems. It terminates prematurely *in vitro*; therefore, transcripts over 500 bases are difficult to obtain. Also, it has a relatively low specificity for promoter sequences; transcripts frequently initiate from other sequences, such as the 5' ends of the templates.

More recently, a different class of DNA-dependent RNA polymerases has become available. They are the bacteriophage T7, T3, and SP6 RNA polymerases, which are encoded by members of a related family of bacteriophages. Each is a single subunit enzyme that recognizes specific, 20 bp promoter sequences. Each initiates transcription specifically and exclusively from its own promoter sequence.

The phage RNA polymerases have a number of advantages over *E. coli* RNA polymerase for the synthesis of high levels of specific transcripts. First, they are extremely processive enzymes; transcripts thousands of bases in length are readily obtained without the enzyme dissociating from the template. Second, transcription is both extensive and rapid; from 2 µg of template DNA, 60 µg of specific transcripts can be generated in 30 min. Third, initiation is extremely specific for the individual promoter sequence. This allows the generation of radioactive RNA probes that are strand specific. Finally, the T7 and T3 RNA polymerases have been purified from cells overexpressing their genes. This results in homogeneous enzyme preparations that are inexpensive and have extremely high specific activities.

ENZYME

ESCHERICHIA COLI RNA POLYMERASE

The *E. coli* holoenzyme has five subunits (structure $\alpha_2\beta\beta'\omega$) and a total molecular weight of ~450,000. It will transcribe a given DNA template, native or denatured, into an RNA copy utilizing ribonucleoside triphosphates as precursors. Transcription is initiated preferentially from promoters that contain conserved sequences located 10 and 35 bp upstream from the start of transcription, and usually ceases *in vivo* at sequences called terminators. The specificity and extent of transcription will depend strongly on the quality of the DNA preparation, the strength of the promoter and terminator sequences, and the kind and concentration of mono- and divalent cations in the reaction mixture. The core enzyme, which lacks the ω subunit, does not recognize promoter sequences and hence initiates transcription randomly on the template.

Reaction Conditions for Promoter-Specific Transcription

For 50-µl reaction:

40 mM Tris·Cl, pH 8.0

10 mM MgCl₂

5 mM DTT

50 mM KCl

2 µg double-stranded DNA containing a promoter

300 µM 4 NTPs (UNIT 3.4)

50 µg/ml BSA

10 U *E. coli* RNA polymerase

Incubate 30 min at 37°C. Stop reaction by adding 2 µl of 0.5 M EDTA or by heating to 75°C for 10 min. The volume of reaction and concentration of DNA and 4 NTPs will vary, depending upon the individual application.

Applications

For most purposes, *E. coli* RNA polymerase is used for synthesizing transcripts only when it is not possible to clone the DNA into a vector containing a phage RNA polymerase promoter. *E. coli* RNA polymerase holoenzyme is useful for determining which segments of cloned DNA contain promoter sequences for expression in *E. coli*. The core enzyme, which lacks the σ subunit, synthesizes short transcripts relatively uniformly on the DNA template in the presence of high concentrations of random primers and low ribonucleoside triphosphate concentrations. The transcripts using native DNA (<500 nucleotides) are longer than those on denatured DNA (<100 nucleotides).

PHAGE RNA POLYMERASES: SP6, T7, T3

T7 and T3 RNA polymerases, the gene 1 products of the respective bacteriophage, were originally purified from infected *E. coli* cells. Now, both polymerases are purified from *E. coli* cells that are overexpressing the cloned genes (Davanloo et al., 1984; Tabor and Richardson, 1985; Morris et al., 1986). SP6 RNA polymerase is purified from bacteriophage SP6-infected *Salmonella typhimurium* (strain LT2) (Butler and Chamberlin, 1982).

All three of these homologous bacteriophage RNA polymerases are single polypeptides of molecular weight 90,000 to 100,000. Each is highly specific for its own promoter, which consists of a specific 20-bp sequence. Transcription is both very rapid (10 times the rate of *E. coli* RNA polymerase in vitro) and extremely processive.

Reaction Conditions

For 50-µl reaction:

40 mM Tris-Cl, pH 7.5

10 mM MgCl₂

5 mM DTT

2 µg DNA template containing appropriate phage promoter

400 µM 4 NTPs (UNIT 3.4)

50 µg/ml BSA

1 mM spermidine (for SP6 reaction mixture only)

10 U RNA polymerase (T7, T3, or SP6)

Incubate at 37°C for 30 min. Stop reaction by adding 2 µl of 0.5 M EDTA or by heating to 75°C for 10 min. The volume of reaction and concentration of DNA and 4 dNTPs will vary, depending upon the individual application. The reaction conditions given above are used to synthesize large amounts of unlabeled transcripts; over 60 µg of transcripts can be generated under these conditions. For producing labeled transcripts of high specific activity, the concentration of labeled ribonucleoside triphosphate should be reduced to 10 µM. Spermidine, which is helpful for SP6 RNA polymerase, should be added to the reaction mixture at room temperature in order to prevent precipitation of DNA.

Applications

Phage T7, T3, and SP6 RNA polymerases are used for extensive, highly specific transcription of DNA sequences inserted downstream from the appropriate T7, T3, or SP6 promoter (Fig. 3.8.1). Plasmids have been constructed with polylinker cloning sites

ENZYME

Enzymatic
Manipulation
of DNA and RNA

3.8.2

adjacent to these promoters (see *UNIT 1.5*). Often the plasmid is cleaved with a restriction enzyme prior to transcription, resulting in the synthesis of “runoff” transcripts that terminate at the end of the DNA template.

1. Phage polymerases are used to generate homogeneous single-stranded RNA probes that are uniformly labeled to a high specific activity. These are useful for detection of homologous DNA or RNA sequences by standard hybridization techniques. With use of [α - 32 P]UTP, over 90% of the radioactivity can be incorporated into the transcripts. For hybridization experiments, RNA probes, because they are single stranded, result in a greater sensitivity as compared to nick-translated DNA probes, which are double-stranded and hence can self-anneal.
2. Uniformly labeled transcripts are used to map the ends of RNA or DNA (*UNIT 4.7*). After hybridization is allowed to proceed to completion, the products are cleaved with ribonucleases under conditions where double-stranded RNA is not cleaved. This procedure is similar to mapping the ends of RNA and DNA using end-labeled DNA fragments and S1 nuclease (*UNIT 4.6*).
3. Uniformly labeled transcripts are used for genomic DNA sequencing.
4. Transcripts synthesized by phage polymerases are used as precursor RNAs for studies of RNA splicing and processing.
5. The RNA transcripts can be translated *in vitro* in the presence of radioactively labeled amino acids to generate radiopure proteins. Proteins generated in this manner can be tested for their functional activity and are useful for substrates for a variety of *in vitro* systems (Hope and Struhl, 1985).
6. T7 RNA polymerase can be used *in vivo* to express cloned genes at very high levels exclusively under the control of a T7 RNA polymerase promoter (Tabor and Richardson, 1985; Studier and Moffatt, 1986).

DNA-Independent RNA Polymerases

ENZYME

POLY(A) POLYMERASE

The enzyme, purified from *E. coli*, catalyzes the incorporation of AMP residues onto the free 3'-hydroxyl terminus of RNA, utilizing ATP as a precursor (Fig. 3.9.1; Edmonds, 1982).

Figure 3.9.1 Poly(A) polymerase activity.

Reaction Conditions

For 50- μ l reaction:
 40 mM Tris-Cl, pH 8.0
 10 mM MgCl₂
 2.5 mM MnCl₂
 250 mM NaCl
 250 μ g/ml RNA
 250 μ M ATP (UNIT 3.4)
 50 μ g/ml BSA
 5 U poly(A) polymerase

Incubate at 37°C for 30 min. Stop reaction by adding 2 μ l of 0.5 M EDTA or by heating to 75°C for 10 min. The volume of reaction and concentration of ATP will vary, depending upon the individual application.

Applications

1. Labeling the 3' ends of RNA with [α^{32} P]ATP. Labeled RNA prepared by this procedure has been used for hybridization probes. For cloned genes, however, the synthesis of RNA probes using phage RNA polymerases is much more efficient and produces RNA with a much higher specific activity. For labeling of cellular RNA, cDNA synthesis using reverse transcriptase is the preferred method.
2. Cloning RNA that lacks a poly(A) tail (Gething et al., 1980). A poly(A) tail is synthesized using a poly(A) polymerase, and subsequently a cDNA copy is made by using oligo(dT) as a primer.

Phosphatases and Kinases

ENZYME

ALKALINE PHOSPHATASES: BACTERIAL ALKALINE PHOSPHATASE AND CALF INTESTINE PHOSPHATASE

Bacterial alkaline phosphatase (BAP) from *E. coli* and calf intestine phosphatase (CIP) from veal are commonly used in nucleic acid research. Both enzymes catalyze the hydrolysis of 5'-phosphate residues from DNA, RNA, and ribo- and deoxyribonucleoside triphosphates (Fig. 3.10.1). The dephosphorylated products possess 5'-hydroxyl termini which can subsequently be radioactively labeled using [γ - 32 P]ATP and T4 polynucleotide kinase (p. 3.10.3).

Figure 3.10.1 Phosphatase activity.

Both phosphatases require Zn^{2+} for activity. The primary difference between them is the stability of the two enzymes. CIP is readily inactivated by heating to 70°C for 10 min and/or extraction with phenol. On the other hand, BAP is much more resistant to these treatments. Thus, for most purposes, CIP is the enzyme of choice. Furthermore, CIP has a 10- to 20-fold higher specific activity than BAP.

BAP Reaction Conditions for Dephosphorylation of DNA

For 50- μ l reaction:

- 50 mM Tris-Cl, pH 8.0
- 1 mM $ZnCl_2$
- 1 to 20 pmol DNA termini
- 0.1 U BAP

Incubate at 60°C for 30 min. Stop reaction by adding 0.1% SDS and 100 μ g/ml proteinase K and incubating at 37°C for 30 min. Then, extract twice with phenol and precipitate the DNA with ethanol (UNIT 2.1).

CIP Reaction Conditions for Dephosphorylation of DNA

For 50- μ l reaction:

- 20 mM Tris-Cl, pH 8.0
- 1 mM $MgCl_2$
- 1 mM $ZnCl_2$
- 1 to 20 pmol DNA termini
- 0.1 U CIP

Incubate at 37°C for 30 min. Stop reaction by heating to 75°C for 10 min or extracting with phenol, and then precipitate with ethanol. *NOTE: CIP is heat labile; 10 min at 75°C effectively inactivates CIP.*

The volume of reaction and concentration of DNA will vary, depending upon the individual application. In general, phosphatase treatment can be done directly following cleavage by a restriction endonuclease, thus minimizing the number of manipulations. A useful conversion factor is that 1 µg of a 3-kb linear DNA contains 1 pmol of 5' termini.

Applications

1. Dephosphorylation of 5' termini of nucleic acids prior to labeling with [γ - 32 P]ATP and T4 polynucleotide kinase. 5'- 32 P end-labeled DNA is used for sequencing by the Maxam-Gilbert procedure (UNIT 7.5), RNA sequencing by specific RNase digestions, and in mapping studies using specific DNA or RNA fragments.
2. Dephosphorylation of 5' termini of vector DNA in order to prevent self-ligation of vector termini (UNIT 3.16).

T4 POLYNUCLEOTIDE KINASE

T4 polynucleotide kinase, the product of the phage T4 *pseT* gene, was originally purified from T4-infected *E. coli* cells (Richardson, 1981). Recently, the *pseT* gene has been cloned into *E. coli*, and the enzyme has been overproduced from this strain (Midgley and Murray, 1985).

The forward reaction of T4 polynucleotide kinase catalyzes the transfer of the terminal (γ) phosphate of ATP to the 5'-hydroxyl termini of DNA and RNA (Fig. 3.10.2). This reaction is very efficient and hence is the general method for labeling 5' ends or for phosphorylating oligonucleotides.

Figure 3.10.2 Kinase activity.

The exchange reaction of T4 polynucleotide kinase catalyzes the exchange of 5'-terminal phosphates. In this reaction, which requires an excess of ADP, the 5'-terminal phosphate is transferred to ADP and subsequently rephosphorylated by the transfer from the γ phosphate of [γ - 32 P]ATP (Fig. 3.10.3). The exchange reaction is less efficient than the forward reaction; thus, it is rarely used.

ENZYME

Figure 3.10.3 Kinase exchange activity.

Finally, polynucleotide kinase is a 3' phosphatase. Some commercial preparations of polynucleotide kinase are prepared from the phage T4 strain am N81 *pseT1*, which has a mutated *pseT* gene. This derivative lacks the 3' phosphatase activity.

**BASIC
PROTOCOL**

Labeling 5' Ends by the Forward Reaction

For 30- μl reaction:

50 mM Tris-Cl pH 7.5

10 mM MgCl_2

5 mM DTT

1 to 50 pmol dephosphorylated DNA, 5' ends

50 pmol (150 μCi) $[\gamma\text{-}^{32}\text{P}] \text{ATP}$ (specific activity $>3000 \text{ Ci/mmol}$)

50 $\mu\text{g/ml}$ BSA

20 U T4 polynucleotide kinase

Incubate at 37°C for 60 min. Stop reaction by adding 1 μl of 0.5 M EDTA or by heating to 75°C for 10 min. Extract with phenol/chloroform. Separate the labeled DNA from the unincorporated labeled nucleotides by filtration on Sephadex G-100 (UNIT 3.4) or by centrifugation through a spin column containing Sephadex G-50 (UNIT 3.4).

The volume of reaction and the concentration of DNA and $[\gamma\text{-}^{32}\text{P}] \text{ATP}$ will vary, depending upon the application.

Phosphorylating Synthetic Oligonucleotides by the Forward Reaction

For 30- μ l reaction:

50 mM Tris·Cl, pH 7.5
10 mM MgCl₂
5 mM DTT
1 to 10 μ g oligonucleotide linker
1 mM ATP
50 μ g/ml BSA
20 U T4 polynucleotide kinase

Incubate at 37°C for 60 min. Stop reaction by adding 1 μ l of 0.5 M EDTA. If desired, [γ -³²P]ATP can be added to trace the reaction.

Labeling 5' Termini by the Exchange Reaction

For 30- μ l reaction:

50 mM imidazole·Cl, pH 6.6
10 mM MgCl₂
5 mM DTT
1 to 50 pmol phosphorylated DNA, 5' ends
5 mM ADP
60 pmol (180 μ Ci) [γ -³²P]ATP (specific activity >3000 Ci/mmol)
50 μ g/ml BSA
20 U T4 polynucleotide kinase

Incubate at 37°C for 60 min. Stop reaction by adding 1 μ l of 0.5 M EDTA. Extract with buffered phenol. Separate the labeled DNA from the unincorporated labeled nucleotides by either Sephadex G-100 gel filtration (UNIT 3.4), or centrifugation through a spin column containing Sephadex G-50 (UNIT 3.4).

The volume of reaction and the concentration of DNA and [γ -³²P]ATP will vary, depending upon the application.

Critical Parameters

1. The ATP concentration should be at least 1 μ M for the forward reaction and 2 μ M for the exchange reaction.
2. T4 polynucleotide kinase prepared from an *E. coli* strain overproducing the enzyme should be used. This enzyme has a higher purity, specific activity, concentration, and is less expensive than that obtained from T4 infected cells.
3. The DNA should be well purified. Contamination by small oligonucleotides or tRNA (often used for the purification of small DNA fragments) can significantly lower the efficiency with which the desired DNA is labeled. This is because oligonucleotides can contribute a large number of 5' ends even if they constitute a small percentage of the total weight of the preparation.
4. The enzyme is inhibited by low levels of phosphate buffer or ammonium salts. In addition, the enzyme works extremely poorly on DNAs that have been purified from agarose gels (even the more purified low gelling/melting temperature agarose). To radioactively label such DNA, it is necessary to perform further purification procedures such as chromatography on DEAE cellulose (UNIT 2.6) or hydroxylapatite. DNAs purified by electrophoresis in polyacrylamide gels also sometimes require further purification for effective labeling.
5. For linear pBR322, 1 pmol of 5' ends = 1.6 μ g DNA.

**BASIC
PROTOCOL**

**BASIC
PROTOCOL**

**Enzymatic
Manipulation
of DNA and RNA**

3.10.4

6. 5' protruding ends are phosphorylated more efficiently than blunt ends, and labeling of 5' recessed ends is very inefficient. Labeling of blunt or recessed ends can be improved by denaturing the DNA (by boiling or by NaOH treatment) and then immediately carrying out the reaction. However, if alternative strategies are possible, it is preferable to avoid labeling of 5' recessed ends by T4 polynucleotide kinase.
7. Recently, it has been shown that macromolecular exclusion molecules (e.g., PEG 8000) greatly improve the rate and overall efficiency of all the kinase reactions. For example, PEG 8000 caused a 1000-fold increase in the rate of labeling of a *Pst*I restriction fragment with recessed 5' termini, and the overall efficiency was increased from 20 to 70% using much lower enzyme levels (Harrison and Zimmerman, 1986).

Applications

1. DNA sequencing by the chemical degradation (Maxam-Gilbert) technique.
2. Defining specific protein–DNA interactions by DNase I footprinting or protection from DNA-damaging chemicals such as dimethyl sulfate or methidiumpropyl-EDTA (MPE).
3. Mapping of restriction sites by partial digestion of 5' end-labeled DNA fragments (*UNIT 3.3*).
4. Mapping the termini of RNA transcripts (*UNIT 4.6*).
5. Mapping the position of introns in DNA.
6. Synthesis of substrates for the assay of DNA and RNA ligases.
7. Labeling oligonucleotides for purification by gel electrophoresis (*UNIT 2.7*).
8. Ligation of oligonucleotides into DNA vectors; when oligonucleotides are chemically synthesized, they have 5'-hydroxyl termini; for cloning purposes, it is often desirable to phosphorylate them (*UNIT 3.16*).

Exonucleases

SINGLE-STRANDED 5'→3' and 3'→5' EXONUCLEASES

Exonuclease VII (exo VII) (Vales et al., 1982)

ENZYME

Exonuclease VII from *E. coli* consists of two subunits, the products of the *xseA* and *xseB* genes. It is a processive single-stranded exonuclease that acts from both the 3' and 5' ends of single-stranded DNA (Fig. 3.11.1). The products of exo VII are small oligonucleotides. Exo VII is unique among the nucleases discussed here in that it does not require Mg^{2+} ; it retains full activity in the presence of 10 mM EDTA.

Figure 3.11.1 Exonuclease VII activity.

Reaction conditions

- For 50- μ l reaction:
- 70 mM Tris·Cl, pH 8
 - 8 mM EDTA
 - 10 mM β -mercaptoethanol
 - 1 μ g DNA
 - 50 μ g/ml BSA
 - 0.2 U exo VII

Incubate at 37°C for 30 min. Stop reaction by extraction with phenol and precipitation with ethanol. Note that exo VII is not inhibited by EDTA.

Applications

1. For mapping the positions of introns in genomic DNA (Berk and Sharp, 1977) (UNIT 4.6).
2. To excise segments of DNA that have been inserted into plasmid vectors by the poly(dA-dT) tailing method (Goff and Berg, 1978).

DOUBLE-STRANDED 5'→3' EXONUCLEASES

ENZYME

Lambda Exonuclease (λ exo) (Little, 1981)

This exonuclease, which is purified from *E. coli* cells that have been infected with bacteriophage λ , catalyzes the stepwise and processive hydrolysis of duplex DNA from 5'-phosphoryl termini liberating 5' mononucleotides (Fig. 3.11.2). λ exo will not degrade 5'-hydroxyl termini.

Figure 3.11.2 5'→3' exonuclease activity: T7 gene 6 exonuclease and λ exonuclease.

Reaction conditions

For 50- μ l reaction:

67 mM glycine·KOH, pH 9.4

2.5 mM MgCl₂

2 μ g DNA

50 μ g/ml BSA

10 U λ exo

Incubate at 37°C for 1 to 30 min, depending upon extent of digestion required. Stop reaction by adding 2 μ l of 0.5 M EDTA or by heating to 75°C for 10 min.

Applications

1. Converting double-stranded DNA into single-stranded DNA that can be subjected to the dideoxy sequencing method (UNIT 7.4).
2. Removing 5' protruding ends from duplex DNA for tailing with terminal transferase.

ENZYME

T7 Gene 6 Exonuclease (Kerr and Sadowski, 1972)

This enzyme is the product of gene 6 of bacteriophage T7. Gene 6 has been cloned onto a plasmid, and the enzyme is purified from overexpressing *E. coli* cells. The gene 6 exonuclease is similar to λ exo in that it catalyzes the stepwise hydrolysis of duplex DNA from the 5' termini liberating 5' mononucleotides. However, unlike λ exo, the enzyme has low processivity and it will remove both 5'-hydroxyl and 5'-phosphoryl termini (Thomas and Olivera, 1978).

Reaction conditions

For 50- μ l reaction:

50 mM Tris·Cl, pH 7.5

5 mM MgCl₂

5 mM DTT

20 mM KCl

2 μ g DNA

50 μ g/ml BSA

5 U T7 gene 6 exo

Incubate at 37°C for 1 to 30 min, depending upon extent of digestion required. Stop reaction by adding 2 μ l of 0.5 M EDTA or by heating to 75°C for 10 min.

Applications

T7 gene 6 exonuclease is used for the same purposes as described for λ exonuclease. However, the T7 enzyme, because it is less processive than λ exonuclease, is preferred for the controlled and uniform digestion from 5' ends. In addition, the T7 enzyme can degrade from 5'-phosphoryl termini. Finally, the T7 enzyme is available from an over-producing strain; thus, it is more homogeneous and less expensive than enzyme from T7 infected cells. It is currently available from U.S. Biochemical.

DOUBLE-STRANDED 3'→5' EXONUCLEASES

Exonuclease III (exo III) (Rogers and Weiss, 1980)

Exonuclease III, the product of the *E. coli xthA* gene, is made from *E. coli* cells overproducing the protein. Exo III is a multifunctional enzyme that catalyzes hydrolysis of several types of phosphodiester bonds in double-stranded DNA. The main application of exo III is as a 3'→5' double-strand specific exonuclease that catalyzes release of 5' nucleotides from the 3'-hydroxy end of double-stranded DNA (Fig. 3.11.3).

Figure 3.11.3 Exonuclease III activity.

The exonuclease activity is nonprocessive, which is ideal for generating uniform single-stranded regions in double-stranded DNA. Its rate of degradation is dependent on the base composition of the DNA: C>>A~T>>G. As a result, different termini will be degraded at different rates.

In addition to the 3'→5' exonuclease, exo III has three other activities: a 3' phosphatase, an RNase H, and an endonuclease specific for apurinic or apyrimidinic sites.

ENZYME

Enzymatic
Manipulation
of DNA and RNA

3.11.3

Reaction conditions

For 50- μ l reaction:

50 mM Tris-Cl, pH 7.5

5 mM MgCl₂

5 mM DTT

2 μ g DNA

50 μ g/ml BSA

10 U exo III

Incubate at 37°C for 1 to 30 min, depending upon the extent of digestion required. Stop the reaction by adding 2 μ l of 0.5 M EDTA or by heating to 75°C for 10 min. One unit of exo III will remove ~ 200 nucleotides from each 3' recessed end of 1 μ g of a 5000-bp linear double-stranded DNA template in 10 min at 37°C.

Applications

All of the applications described below utilize the nonprocessive 3'→5' double-stranded exonuclease activity of exo III to generate uniform single-stranded regions in double-stranded DNA.

1. Preparing strand-specific radioactive probes, in conjunction with the Klenow fragment; this procedure is analogous to replacement synthesis using the exonuclease and polymerase functions of T4 DNA polymerase (Fig. 3.5.5).
2. Preparing single-stranded DNA templates for sequencing by the dideoxy technique (Sanger et al., 1977) (UNIT 7.4).
3. Constructing unidirectional deletions; since exo III is double-strand specific, it will degrade preferentially from duplex DNA having a 3'-recessed end as opposed to one with a 5'-recessed end (Henikoff, 1984). This property is useful for constructing a set of unidirectional deletions from a given position in cloned DNA, that are used for DNA sequencing without prior restriction site mapping.

Endonucleases

BAL 31 NUCLEASE

ENZYME

Bal 31 nuclease from *Alteromonas espejiana* is a single strand-specific endodeoxyribonuclease (Gray et al., 1981; Wei et al., 1983) (Fig. 3.12.1). On duplex circular DNA, it degrades at nicks or at transient single-stranded regions created by supercoiling (Lau and Gray, 1979). On duplex linear DNA, it degrades from both the 5' and 3' termini at both ends, resulting in a controlled shortening of the DNA.

Bal 31 also acts as a ribonuclease, catalyzing the hydrolysis of ribosomal and tRNA (Gray et al., 1975). *Bal 31* nuclease requires both Ca^{++} and Mg^{++} . Digestions can be terminated with EGTA, a specific chelator of Ca^{++} , without affecting the Mg^{++} concentration. *Bal 31* nuclease is active in SDS and urea (Gray et al., 1975).

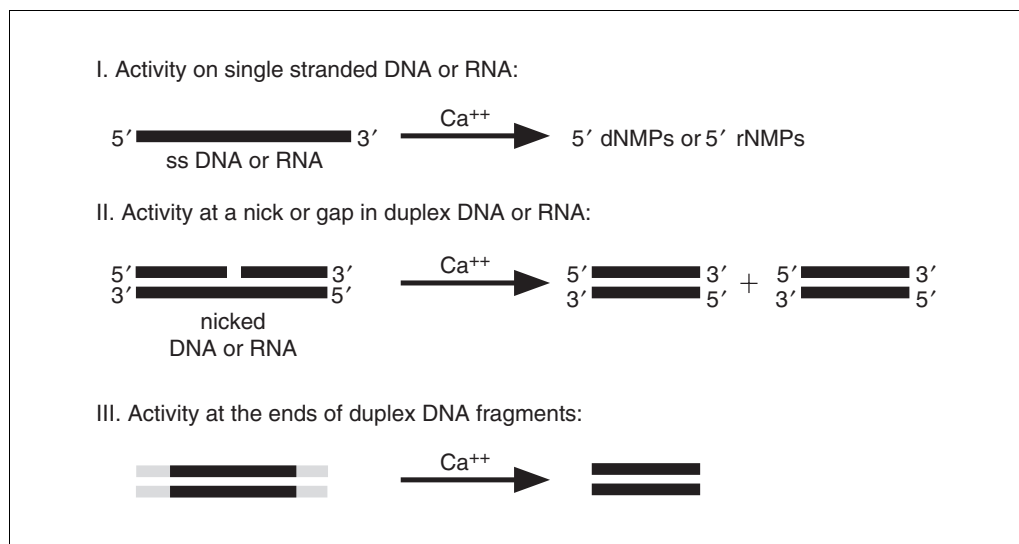

Figure 3.12.1 *Bal 31* activities.

Reaction Conditions

For 50- μl reaction:

50 mM Tris-Cl, pH 7.5

10 mM CaCl_2

10 mM MgCl_2

600 mM NaCl

2 μg DNA

50 $\mu\text{g/ml}$ BSA

10 U *Bal 31* nuclease

Incubate at 30°C for 1 to 30 min, depending upon extent of digestion required. Stop the reaction by adding 5 μl of 0.5 M EDTA or by heating to 75°C for 10 min, and analyze products by agarose gel electrophoresis (UNIT 2.5). Due to the high NaCl concentration in the *Bal 31* buffer, small volumes of the reaction mixture should be loaded. For subsequent enzymatic treatments, it is usually necessary to remove the NaCl by precipitating the DNA with ethanol (UNIT 2.1).

One unit is defined as the amount of enzyme that catalyzes the removal of 200 bp from each end of linearized pBR322 in 10 min at 30°C using a DNA concentration of 50 $\mu\text{g/ml}$ in a 50- μl reaction.

Critical Parameters

1. *Bal* 31 activity is inhibited by RNA that contaminates crude DNA preparations. Thus, DNA should be purified using CsCl gradients or PEG precipitation (UNIT 1.7), or gel-purified (UNIT 2.6).
2. The unit definition for *Bal* 31 nuclease should be used only as a rough estimate. For each preparation of DNA, the extent of digestion should be monitored by agarose gel electrophoresis (UNIT 2.5).
3. To reduce the rate of digestion, lower the temperature of the reaction. A temperature of 20°C reduces the rate of *Bal* 31 nuclease 3-fold from that observed at 30°C.
4. *Bal* 31 activity will vary with different DNA templates. GC-rich regions are degraded more slowly than AT-rich regions. Consequently, the two ends of a given DNA fragment can be degraded at different rates. Also, a series of deletions of a given DNA fragment will be nonuniform at the nucleotide level; some sequences will have a very low frequency of appearance at the junction of the deletion.
5. *Bal* 31-digested DNA fragments can be ligated directly at low frequency. To increase the efficiency of ligation, digested DNA should be extracted with phenol and precipitated with ethanol (UNIT 2.1). Then the ends of the DNA should be repaired with Klenow fragment or T4 DNA polymerase (UNIT 3.5), prior to the ligation reaction with T4 DNA ligase (UNIT 3.16).

Applications

1. Cloning for creating deletions of different sizes in a controlled manner. The cloned DNA is resected at specific sites with a restriction enzyme, and the resulting linear DNA is digested with *Bal* 31 nuclease for various intervals of time (UNIT 7.3).
2. Mapping restriction sites in a DNA fragment (Legerski et al., 1978).
3. Investigating secondary structure of supercoiled DNA (Lau and Gray, 1979) and alterations in the helix structure of duplex DNA caused by treatment with mutagenic agents (Legerski et al., 1977).
4. Creating successive deletions needed for linker-scanning mutagenesis (UNIT 8.4).

ENZYME

S1 NUCLEASE

S1 nuclease from *Aspergillus oryzae* is a highly specific single-stranded endonuclease (Vogt, 1980; Fig. 3.12.2). The rate of digestion of single-stranded DNA is 75,000 times faster than that of double-stranded DNA.

Figure 3.12.2 S1 nuclease activities.

The pH optimum is 4.0 to 4.3, and the rate drops 50% at pH 4.9. Reactions are normally run at pH 4.6 to avoid depurination of the DNA. The enzyme requires low levels of Zn⁺⁺, and it is largely unaffected by NaCl concentrations in the range of 10 to 300 mM. It is stable to urea, SDS, and formamide.

Reaction Conditions

For 100- μ l reaction:

50 mM sodium acetate, pH 4.6

1 mM zinc acetate

250 mM NaCl

2 μ g DNA

50 μ g/ml BSA

10 U S1 nuclease

Incubate at 37°C for 30 min. Stop reaction by adding 1 μ l of 0.5 M EDTA. The volume of reaction, amount of DNA, units of S1 nuclease, temperature, and time of reaction will vary with different applications of S1 nuclease.

Applications

Most applications of S1 nuclease make use of its ability to trim protruding single-stranded ends of DNA and RNA without significant nibbling of blunt duplex ends.

1. Mapping the 5' and 3' ends of RNA transcripts by the analysis of S1-resistant RNA:DNA hybrids (*UNIT 4.6*).
2. Mapping the location of introns by digesting a hybrid of mature mRNA with ³²P-labeled genomic DNA. S1 will cleave at the single-stranded loops created by introns within these hybrid molecules.
3. Digesting the hairpin structures formed during the synthesis of cDNA by reverse transcriptase (*UNIT 5.5*).
4. Removing single-stranded termini of DNA fragments to produce blunt ends for ligation (*UNIT 3.16*).
5. Creating small deletions at restriction sites. It will nibble at the ends of a linear duplex fragment at a very slow rate.
6. Rendering the ends flush after successive deletions by exo III for linker-scanning mutagenesis (*UNIT 8.4*).

MUNG BEAN NUCLEASE

Mung bean nuclease (from sprouts of mung bean) is a highly specific single-stranded endonuclease with properties similar to those of S1 nuclease (Kroeker et al., 1976). Reactions are normally performed at pH 5.0, which is optimal for degrading single-stranded DNA. Activity against double-stranded DNA is essentially negligible at pH 5.0, but it increases as the pH is reduced below this point. Mung bean nuclease activity is significantly decreased at NaCl concentrations >200 mM.

One unit is defined as the amount of enzyme that produces 1 μ g of acid-soluble material in 1 min at 37°C using single-stranded salmon sperm DNA as the substrate.

ENZYME

Reaction Conditions

For 100- μ l reaction:

30 mM sodium acetate, pH 5.0

50 mM NaCl

1 mM zinc acetate

5% (vol/vol) glycerol

1 μ g DNA

50 μ g/ml BSA

15 U mung bean nuclease

Incubate 30 min at 37°C. Stop reaction by adding 1 μ l of 0.5 M EDTA. The volume of reaction, amount of DNA, units of enzyme, temperature, and time of reaction will vary depending on the application.

Applications

Mung bean nuclease is used for most of the same purposes as described for S1 nuclease. However, mung bean nuclease is more precise than S1 nuclease for cleaving immediately adjacent to the last hybridized base pair without removing any of the base-paired nucleotides. For this reason, mung bean nuclease will typically generate single bands in transcript mapping experiments (UNIT 4.6), whereas S1 often results in multiple bands. In addition, mung bean nuclease is preferred over S1 for precisely deleting overhanging bases that result from restriction endonuclease cleavage. Unlike S1 nuclease, mung bean nuclease will not cleave the strand opposite a nick in duplex DNA. The disadvantages of mung bean nuclease are that it is more expensive than S1, and that its activity is more sensitive to reaction conditions.

ENZYME

MICROCOCCAL NUCLEASE

Micrococcal nuclease from *Staphylococcus aureus* is a relatively nonspecific nuclease that cleaves single- and double-stranded DNA and RNA to oligo- and mononucleotides with 3' phosphates (Alexander et al., 1961). The enzyme is more active on single-stranded nucleic acids. Cleavage of DNA or RNA occurs preferentially at AT- or AU-rich regions although all sequences are ultimately cleavable. The enzyme is strictly dependent on calcium for activity and hence can be inactivated by Ca⁺⁺-specific chelating agents such as EGTA.

One unit is defined as the amount of enzyme that hydrolyzes 1 μ mol of acid-soluble oligonucleotides from native DNA per minute at 37°C, pH 8.8.

Reaction Conditions

Typical micrococcal nuclease digestions are performed in solutions containing 10 mM Tris-Cl, pH 8.0, and 1 mM CaCl₂. However, the enzyme is somewhat more active at higher pH. The volume of reaction, amount and source of nucleic acid, units of enzyme, temperature, ionic strength, and time of reaction will vary greatly depending on the application. The reactions can be stopped by EDTA or the Ca⁺⁺-specific chelator EGTA.

Applications

1. Studies of chromatin structure (Kornberg, 1977).
2. Removing nucleic acid from crude cell-free extracts without destroying enzyme activities. Digestion of nucleic acid is performed under mild buffer and ionic conditions in the presence of CaCl₂. When digestion is complete, micrococcal nuclease is inactivated with EGTA (Pelham and Jackson, 1976). Such treated extracts are generally active for all processes except those requiring calcium.

Endonucleases

3.12.4

DEOXYRIBONUCLEASE I (DNase I)

DNase I from bovine pancreas is an endonuclease that degrades double-stranded DNA to produce 3'-hydroxyl oligonucleotides (Moore, 1981; Fig. 3.12.3). The enzyme requires divalent cations; the specificity of the reaction differs depending upon which divalent cation is present (Campbell and Jackson, 1980). In the presence of Mg^{++} , DNase I produces nicks in duplex DNA, while in the presence of Mn^{++} the enzyme produces double-stranded breaks in the DNA.

Figure 3.12.3 DNase I activities.

Reaction Conditions

For 100- μ l reaction:

50 mM Tris-Cl, pH 7.5

10 mM $MgCl_2$ (for single-strand nicks; to create double-strand breaks, replace with 10 mM $MnCl_2$)

2 μ g DNA

50 μ g/ml BSA

1 μ l DNase I (the concentration depends on the application)

Incubate at $37^\circ C$ for 1 to 30 min, depending upon the degree of digestion desired. Stop the reaction by adding 5 μ l of 0.5 M EDTA. For nick translations, the DNase I reaction is carried out simultaneously with the DNA polymerase I reaction (UNIT 3.5).

Preparation and Storage of DNase I Solutions

DNase I is usually purchased as a lyophilized powder at a concentration of 2000 to 3000 U/mg protein. For almost all applications, it is useful to make up a solution containing DNase I that can be stored for long periods of time without loss of enzyme activity. One method is to dissolve 1 mg DNase I in 1 ml of a 50% (wt/vol) solution of glycerol containing 20 mM Tris-Cl, pH 7.5, plus 1 mM $MgCl_2$; this solution can be stored in liquid form at $-20^\circ C$. Alternatively, 1 mg DNase I can be dissolved in 1 ml of a solution containing 20 mM Tris-Cl, pH 7.5, plus 1 mM $MgCl_2$, then aliquotted into small microcentrifuge tubes (100 10- μ l aliquots are convenient). The aliquots should be quick-frozen on dry ice, then stored at $-80^\circ C$. For use, an aliquot of DNase I is thawed on ice and an appropriate amount is added to the reaction mixture (for nick translations, the enzyme must first be diluted; see UNIT 3.5). Aliquots are not refrozen; they are simply discarded after use. DNase I solutions prepared by either method are stable for at least 1 year. It is important that DNase I be dissolved without vortexing (to minimize denaturation) and at a concentration of at least 1 mg/ml (to improve long-term stability).

RNase-Free DNase I

For many purposes, DNase I should be free of RNase. High-grade commercial preparations such as Worthington grade DPRF can be satisfactory. Alternatively, DNase I can be dissolved at 1 mg/ml in 0.1 M iodoacetic acid plus 0.15 M sodium acetate at a final pH of 5.3. The solution is then heated 40 min at 55°C and cooled. Finally, 1 M CaCl₂ is added to the solution to 5 mM. This homemade preparation of RNase-free DNase I should be stored frozen in small aliquots.

Applications

1. Nick translation (*UNIT 3.5*). Introduces nicks in duplex DNA which then serve as primer sites to initiate DNA synthesis by *E. coli* DNA polymerase I.
2. Cloning random DNA fragments by catalyzing double-stranded cleavage of DNA in the presence of Mn⁺⁺ (Anderson, 1981).

Boston, Massachusetts

Ribonucleases (RNases) with different sequence specificities are used for a variety of analytical purposes, including RNA sequencing, mapping, and quantitation. One very common application for RNase A (see below) is hydrolyzing RNA that contaminates DNA preparations. Two other commonly used RNases, RNase H and RNase T1, are also described below.

Many commercially available RNases are sequence-specific endoribonucleases. This property has been used for enzymatic sequencing of RNA. For example, a combination of three different RNases and *Staphylococcus aureus* nuclease can be used in RNA sequence determination (see Table 3.13.1).

Table 3.13.1 RNases Used in RNA Sequencing^a

RNase	Sequence specificity
T1	Gp↓N
U2	Ap↓N
CL3	C(A/G)p↓N
<i>S. aureus</i> nuclease ^b	Np↓A/U

^aAdapted from Boehringer Mannheim.

^b*Staphylococcus aureus* nuclease cleaves both RNA and DNA.

RIBONUCLEASE A

Ribonuclease A (RNase A) from bovine pancreas is an endoribonuclease that specifically hydrolyzes RNA after C and U residues (Richards and Wyckoff, 1971). Cleavage occurs between the 3'-phosphate group of a pyrimidine ribonucleotide and the 5'-hydroxyl of the adjacent nucleotide. The reaction generates a 2':3' cyclic phosphate which then is hydrolyzed to the corresponding 3'-nucleoside phosphates. RNase A activity can be inhibited specifically by an RNase inhibitor (e.g., RNasin from Promega), a protein isolated from human placenta.

Reaction Conditions

RNase A is active under an extraordinarily wide range of reaction conditions, and it is extremely difficult to inactivate. At low salt concentrations (0 to 100 mM NaCl), RNase A cleaves single-stranded and double-stranded RNA as well the RNA strand in RNA:DNA duplexes. However, at NaCl concentrations of 0.3 M or above, RNase A becomes specific for cleavage of single-stranded RNA. Removal of RNase A from a reaction solution generally requires treatment with proteinase K followed by multiple phenol extractions and ethanol precipitation.

DNase-Free RNase A

To prepare RNase A free of DNase, dissolve RNase A in TE buffer at 1 mg/ml, and boil 10 to 30 min. Store aliquots at -20°C to prevent microbial growth.

Applications

1. Mapping and quantitating RNA species using the ribonuclease protection assay (UNIT 4.7). It is used in conjunction with RNase T1.
2. Hydrolyzing RNA that contaminates DNA preparations (UNITS 1.6 & 1.7).
3. RNA sequencing.

ENZYME

4. Blunt-ending double-stranded cDNA (*UNIT 5.5*). It is used in conjunction with RNase H.

ENZYME

RIBONUCLEASE H

Ribonuclease H (RNase H) from *E. coli* is an endoribonuclease that specifically hydrolyzes the phosphodiester bonds of RNA in RNA:DNA duplexes to generate products with 3' hydroxyl and 5' phosphate ends (Berkower et al., 1973). It will not degrade single-stranded or double-stranded DNA or RNA. RNase H cleavage can be directed to specific sites by hybridizing short deoxyoligonucleotides to the RNA (Donis-Keller, 1979).

One unit is defined as the amount of enzyme that produces 1 nmol of acid-soluble ribonucleotides from poly(A)-poly(dT) in 20 min at 37°C.

Reaction Conditions

For 100- μ l reaction:

- 20 mM HEPES·KOH, pH 8.0
- 50 mM KCl
- 4 mM MgCl₂
- 1 mM DTT
- 2 μ g RNA:DNA duplex
- 50 μ g/ml BSA
- 1 U ribonuclease H

Incubate 20 min at 37°C. Stop reaction by adding 1 μ l of 0.5 M EDTA. The volume of reaction, amount of DNA, units of enzyme, temperature, time, and method of stopping the reaction will vary depending on the application.

Applications

1. Facilitating the synthesis of double-stranded cDNA by removing the mRNA strand of the RNA:DNA duplex produced during first strand synthesis of cDNA (*UNIT 5.5*). It is also used later in the protocol to degrade residual RNA in conjunction with RNase A.
2. Creating specific cleavages in RNA molecules by using synthetic deoxyoligonucleotides to create local regions of RNA:DNA duplexes (Donis-Keller, 1979).

ENZYME

RIBONUCLEASE T1

Ribonuclease T1 (RNase T1) from *Aspergillus oryzae* is an endoribonuclease that specifically hydrolyzes RNA after G residues (Uchida and Egami, 1971). Cleavage occurs between the 3'-phosphate group of a guanine ribonucleotide and the 5'-hydroxyl of the adjacent nucleotide. The reaction generates a 2':3' cyclic phosphate which then is hydrolyzed to the corresponding 3'-nucleoside phosphates.

Reaction Conditions

The enzyme is active under a wide range of reaction conditions, and it is difficult to inactivate. At low salt concentrations (0 to 100 mM NaCl), it cleaves single-stranded and double-stranded RNA as well as the RNA strand in RNA:DNA duplexes. However, at NaCl concentrations of 0.3 M or above, it becomes specific for cleavage of single-stranded RNA. Removal of RNase T1 from a reaction solution generally requires treatment with proteinase K followed by multiple phenol extractions and ethanol precipitation.

Ribonucleases

3.13.2

Applications

1. Mapping and quantitating RNA species using the ribonuclease protection assay (*UNITS 4.7 & 9.8*). It is used in conjunction with RNase A.
2. RNA sequencing.
3. Determining the level of RNA transcripts synthesized in vitro from DNA templates containing a “G-less cassette.” Because accurately initiated transcripts contain no G residues, treatment of the reaction products with RNase T1 preferentially destroys all nonspecific transcripts (Sawadogo and Roeder, 1985).

DNA Ligases

DNA ligases catalyze the formation of phosphodiester bonds between juxtaposed 5' phosphate and a 3'-hydroxyl terminus in duplex DNA. This activity can repair single-stranded nicks in duplex DNA (Fig. 3.14.1) and join duplex DNA restriction fragments having either blunt ends (Fig. 3.14.2) or homologous cohesive ends (Fig. 3.14.3). Two ligases are used for nucleic acid research—*E. coli* ligase and T4 ligase. These enzymes differ in two important properties. One is the source of energy: T4 ligase uses ATP, while *E. coli* ligase uses NAD. Another important difference is their ability to ligate blunt ends; under normal reaction conditions, only T4 DNA ligase will ligate blunt ends.

Figure 3.14.1 DNA ligase activity at a nick.

ENZYME

T4 DNA LIGASE

T4 DNA ligase, the product of gene 30 of phage T4, was originally purified from phage-infected cells of *E. coli*. The phage T4 gene 30 has been cloned, and the enzyme is now prepared from overproducing strains. Using ATP as a cofactor, T4 DNA ligase catalyzes the repair of single-stranded nicks in duplex DNA and joins duplex DNA restriction fragments having either blunt or cohesive ends. It is the only ligase that efficiently joins blunt-end termini under normal reaction conditions. It appears that T4 DNA ligase activity may be stimulated by T4 RNA ligase (UNIT 3.15). See UNIT 3.16 for a detailed ligation protocol.

Reaction Conditions

For 50- μ l reaction:

40 mM Tris·Cl, pH 7.5

10 mM MgCl₂

10 mM DTT

1 μ g DNA

0.5 mM ATP

50 μ g/ml BSA

1 “Weiss” U T4 DNA ligase

Incubate at 12° to 30°C for 1 to 16 hr. Stop reaction by adding 2 μ l of 0.5 M EDTA or by heating to 75°C for 10 min. The volume of reaction, concentration of DNA, and the temperature and time of the reaction will vary, depending upon the individual application. One Weiss unit is equivalent to 60 cohesive-end units.

Ligation of cohesive ends is usually carried out at 12° to 15°C to maintain a good balance between annealing of the ends and activity of the enzyme. Higher temperatures make it difficult for the ends to anneal, whereas lower temperatures diminish ligase activity. Blunt-end ligations are typically performed at room temperature since annealing is not a factor (the enzyme is not particularly stable above 30°C). Blunt-end ligations require about 10 to 100 times more enzyme than cohesive-end ligations to achieve an equal efficiency. T4 DNA ligase is not inhibited by tRNA, but it is strongly inhibited by NaCl concentrations >150 mM. Macromolecular exclusion molecules (e.g., PEG 8000) have been shown to greatly increase the rate of both cohesive-end and blunt-end joining by T4 DNA ligase (Pfeiffer and Zimmerman, 1983). An inherent consequence of macromolecular crowding is that all ligations are intermolecular; thus, this technique is not suitable for the ligation and circularization of inserts and vectors that are required for most cloning experiments.

Figure 3.14.2 DNA ligase activity at blunt ends.

(e.g., DTT) in the reaction. PEG 8000 greatly increases the rate of cohesive end joining by *E. coli* DNA ligase (Harrison and Zimmerman, 1983). Interestingly, the presence of macromolecular exclusion molecules also enables *E. coli* DNA ligase to efficiently join blunt-end termini, a reaction it is unable to carry out in their absence.

Modrich-Lehman units measure the ability to form poly d(A-T) circles. One Modrich-Lehman unit is equivalent to 6 Weiss units (Modrich and Lehman, 1975).

Applications

E. coli DNA ligase can be used as an alternative to T4 DNA ligase when blunt-end ligations are not required. Transformation using DNA ligated with *E. coli* DNA ligase has a lower background that results from aberrant ligations compared with T4 DNA ligase, since T4 DNA ligase has a much lower specificity for the structure of the termini.

RNA Ligases

ENZYME

T4 RNA LIGASE (Uhlenbeck and Gumport, 1982)

T4 RNA ligase, the product of the phage gene 63, is purified from phage-infected cells. It catalyzes the ATP-dependent covalent joining of single-stranded 5'-phosphoryl termini of DNA or RNA to single-stranded 3'-hydroxyl termini of DNA or RNA (Fig. 3.15.1).

Figure 3.15.1 RNA ligase activity.

Reaction Conditions

For 50- μ l reaction:

- 50 mM HEPES, pH 8.3
- 10 mM MgCl₂
- 5 mM DTT
- 2 μ g single-stranded DNA or RNA
- 2 mM ATP
- 50 μ g/ml BSA
- 1 U T4 RNA ligase

Incubate at 17°C for 10 hr. Stop the reaction by adding 2 μ l of 0.5 M EDTA.

Applications

1. Radioactive labeling of 3' termini of RNA (Uhlenbeck and Gumport, 1982). The reaction contains the RNA molecule as the acceptor, a [5'-³²P]nucleoside 3', 5'-bis(phosphate) (e.g., 5'-³²P-Cp) as the donor, and ATP as the energy source. The product formed by this reaction is the RNA molecule containing one additional nucleotide at the 3' terminus and a ³²P-labeled phosphate in the last internucleotide linkage.
2. Circularizing deoxy- and ribo-oligonucleotides (Brennan et al., 1983).
3. Ligating oligomers for oligonucleotide synthesis (Romaniuk and Uhlenbeck, 1983). One such use is to synthesize oligomers that contain internally labeled oligomers at specific residues.
4. Stimulating the blunt-end ligation activity of T4 DNA ligase (Sugino et al., 1977).

CONSTRUCTION OF HYBRID DNA MOLECULES

Given the large number of restriction endonucleases and other enzymes for manipulating DNA, it is possible to create any DNA molecule of interest. As it is impossible to cover all possible ways of manipulating DNA molecules, this section will discuss the general principles involved along with several specific techniques that are frequently used. Chapter 8 describes methods for creating point mutations in DNA.

UNIT 3.16

BASIC PROTOCOL

Subcloning of DNA Fragments

In order to construct new DNA molecules, the starting DNAs are treated with appropriate restriction endonucleases and other enzymes if necessary. The individual components of the desired DNA molecule are purified by agarose or polyacrylamide gel electrophoresis, combined, and treated with DNA ligase. The products of the ligation mixture (along with control mixtures) are introduced into competent *E. coli* cells, and transformants are identified by an appropriate genetic selection. DNA is prepared from the colonies or plaques and subjected to restriction endonuclease mapping in order to determine if the desired DNA molecule was created. All cloning experiments follow the steps outlined below.

Materials

Calf intestine phosphatase (CIP) and buffer (optional; *UNIT 3.10*)
 dNTP mix (0.5 mM each; *UNIT 3.4*)
 Klenow fragment of *E. coli* DNA polymerase I or T4 DNA polymerase (optional; *UNIT 3.5*)
 Oligonucleotide linkers (optional)
 10 mM ATP
 0.2 mM dithiothreitol (DTT)
 T4 DNA ligase (measured in cohesive-end units; *UNIT 3.14*)
 2× T4 DNA ligase buffer

Additional reagents and equipment for restriction endonuclease digestions (*UNIT 3.1*), transformation of *E. coli* cells (*UNIT 1.8*), DNA minipreps (*UNIT 1.6*), and agarose or polyacrylamide gel electrophoresis (*UNIT 2.5* or *2.7*).

1. In a 20- μ l reaction mixture, cleave the individual DNA components with appropriate restriction endonuclease. After the reaction is complete, inactivate the enzymes by heating 15 min to 75°C. If no further enzymatic treatments are necessary, proceed to step 6.

Reaction mixtures can be done in any volume; 20 μ l is convenient for gel electrophoresis (step 6). Many of the subsequent enzymatic manipulations (steps 2 to 5) can be carried out sequentially without further buffer changes.

2. If the 5' phosphates of one of the DNAs are to be removed (see Example 3.16.1), add 2 μ l of 10× CIP buffer and 1 U CIP; incubate 30 to 60 min at 37°C as described in *UNIT 3.10*. After the reaction is complete, inactivate CIP by heating 15 min to 75°C. If no further enzymatic treatments are necessary, proceed to step 6.
3. If one or both ends generated by a restriction endonuclease must be converted to blunt ends (see Example 3.16.4), add 1 μ l of a solution containing all 4 dNTPs (0.5 mM each) and an appropriate amount of the Klenow fragment of *E. coli* DNA polymerase I or T4 DNA polymerase; carry out the filling-in or trimming reaction as described in *UNIT 3.5*. After the reaction is complete, inactivate the enzymes by

heating 15 min to 75°C. If oligonucleotide linkers are to be added (see Example 3.16.6), proceed to step 4. If a DNA fragment containing only one blunt end is desired, cleave the reaction products with an appropriate restriction endonuclease. If no further enzymatic treatments are necessary, proceed to step 6.

4. Add 0.1 to 1.0 µg of an appropriate oligonucleotide linker, 1 µl of 10 mM ATP, 1 µl of 0.2 M DTT, and 20 to 100 cohesive-end units of T4 DNA ligase; incubate overnight at 15°C. Inactivate the ligase by heating 15 min to 75°C.

In general, the oligonucleotide linkers are phosphorylated prior to ligation (UNIT 3.10). However, the linkers do not have to be phosphorylated, in which case the products will contain only one linker on each end.

5. Cleave the products from step 4 with the restriction endonuclease recognizing the oligonucleotide linker, adjusting the buffer conditions if necessary. If only one of the two ends is to contain a linker, cleave the products with an additional restriction enzyme (see Examples 3.16.2 and 3.16.6).
6. Isolate the desired DNA segments by gel electrophoresis, or by other methods if appropriate.

Electrophoresis in agarose gels is the most common method. Purification is not essential for many cloning experiments, but it is usually very helpful. See critical parameters.

7. Using longwave UV light for visualization of the DNA, cut out the desired band(s) and purify the DNA away from the gel material using the procedures described in UNIT 2.6.

It is critical to use longwave UV light sources to prevent damage to the DNA. If low gelling/melting temperature agarose is used, ligation reactions can usually be performed directly in the gel slice (see alternate protocol).

8. Set up the following ligation reaction:

9 µl component DNAs (0.1 to 5 µg)
10 µl 2× ligase buffer
1 µl 10 mM ATP
20 to 500 U (cohesive end) T4 DNA ligase

Incubate 1 to 24 hr at 15°C.

Simple ligations with two fragments having 4-bp 3' or 5' overhanging ends require much less ligase than more complex ligations or blunt-end ligations. The quality of the DNA will also affect the amount of ligase needed.

Controlled cloning experiments usually involve several different ligation reactions. For simplicity, appropriate DNAs should be added to each tube (adding water if necessary) so that the volume is 9 µl. Immediately prior to use, pre-mix on ice the remaining ingredients (2× buffer, ATP, enzyme) in sufficient amounts for all the reactions. To start the ligation reactions, add 11-µl aliquots of the pre-mix to each tube containing DNA. The amounts and ratios of the component DNAs and the controls for these ligation reactions are discussed below.

9. Introduce 1 to 10 µl of the ligated products into competent *E. coli* cells and select for transformants by virtue of the genetic marker present on the vector.
10. From individual *E. coli* transformants, purify plasmid or phage DNAs by miniprep procedures and determine their structures by restriction mapping.

If the frequency of transformants containing the desired hybrid DNA molecule is too low, initial screening by filter hybridization to immobilized colonies (UNIT 6.2) or plaques (UNIT 6.1) or by genetic techniques is necessary.

LIGATION OF DNA FRAGMENTS IN GEL SLICES

This alternate protocol saves considerable time in comparison to the basic protocol because it eliminates purification of the DNA fragments away from the gel matrix (Struhl, 1985). It is suitable for most simple cloning experiments and is particularly valuable for carrying out a set of hybrid constructions involving a variety of different DNA fragments. However, as the cloning efficiency may be reduced, this method should be employed only when it is desired to make one (or relatively few) specific molecules.

Additional Materials

Low gelling/melting temperature agarose (SeaPlaque, FMC Marine Colloids)
TAE buffer (*APPENDIX 2*)

1. Treat the starting DNAs with appropriate restriction endonucleases and other enzymes, as described in steps 1 to 6 of the basic protocol.
2. Subject the treated DNAs to electrophoresis in low gelling/melting temperature agarose using TAE buffer.

It is critical that the agarose be of high quality. SeaPlaque is a good choice. The agarose concentration should be kept as low as possible (0.7% is suitable for most applications).

3. Cut out the desired band(s) in the smallest possible volume (20 to 50 μ l) using a clean razor blade, and place the gel slice in a microcentrifuge tube.
4. Melt the gel slices containing DNA at 70°C for at least 10 min.

This temperature is hot enough to melt the agarose without denaturing the DNA.

5. In separate tubes for each ligation reaction, combine the gel slices containing appropriate DNAs (and water if necessary) for a total volume of 9 μ l. Place the tubes at 37°C for a few minutes.

The gel slices should remain molten at 37°C.

6. To each tube containing DNA, add 11 μ l of an ice-cold mixture containing 2 \times buffer, ATP, and T4 DNA ligase. Mix immediately by flicking the tube and place on ice. Then incubate the reaction mixtures 1 to 48 hr at 15°C.

DNA fragments can still be ligated even though the reaction mixture has resolidified into a gel.

7. After the ligation reaction is complete, remelt the gel slices 5 to 10 min at 73°C and add 5 μ l of the ligated products to 200 μ l of competent *E. coli* cells (*UNIT 1.8*).

The remelted gel must be diluted at least 30-fold so that it does not resolidify when the cells are placed on ice.

8. Carry out steps 9 and 10 of the basic protocol.

*Ligation in gel slices is suitable for most cloning applications. If the method does not work, DNA fragments can be purified from the gel by various techniques discussed in *UNIT 2.6*. Ligations are then carried out by the basic protocol.*

REAGENTS AND SOLUTIONS

2 \times T4 DNA ligase buffer

100 mM Tris·Cl, pH 7.5
20 mM MgCl₂
20 mM DTT

COMMENTARY

Background Information

The essence of recombinant DNA technology is the joining of two or more separate segments of DNA to generate a single DNA molecule that is capable of autonomous replication in a given host. The simplest constructions of hybrid DNA molecules involve the cloning of insert sequences into plasmid or bacteriophage cloning vectors. The insert sequences can derive from essentially any organism, and they may be isolated directly from the genome (UNITS 5.3 and 5.4), from mRNA (UNIT 5.5), or from previously cloned DNA segments (in which case, the procedure is termed subcloning). Alternatively, insert DNAs can be created directly by DNA synthesis.

Critical Parameters

Many different factors must be considered before embarking on any specific DNA manipulation. These include the number, type, and concentration of DNA fragments, the preparation and purification of DNA fragments, and the selection or screening systems that might be necessary for identifying the DNA molecule of interest. Another practical consideration is the number of hybrid DNA molecules that are desired for any particular experiment. For example, when generating genomic or cDNA libraries, it is critical to obtain the maximum number of recombinants. Strategies for producing large libraries are discussed elsewhere (UNITS 5.1 and 5.2).

On the other hand, when it is desired to make one (or relatively few) specific DNA molecule, it is important to maximize the frequency of generating the “correct” molecule rather than the absolute cloning efficiency. In other words, it is better to obtain a low number of colonies, mostly containing the desired DNA rather than a large number of colonies few of which contain the desired DNA. In this way, screening for the correct colonies or plaques is unnecessary, and preparation and analysis of DNA from *E. coli* transformants is minimized; these represent the major time-consuming steps in the overall cloning process.

Although it is obvious that the experimental conditions should be designed to favor the desired ligation events, the crucial factor for optimizing the frequency of correct molecules is to reduce the “background” of undesired events that will result in transformable DNA molecules. One major cause of background involves

“errors” in the preparation of the starting DNA components (e.g., incomplete digestion by restriction endonucleases). Such errors can be significantly reduced, but never entirely eliminated. The other major source of background is undesired ligation between molecules in the reaction mixture. This problem is addressed by considering all possible ways in which the starting components (and probable contaminants) can be joined to produce DNA molecules that can transform *E. coli* via the genetic selection being imposed. By appropriate “tricks,” the major “side reactions” can often be minimized; these are discussed below.

DNA preparation and the purification of specific fragments. The efficiency of obtaining the desired recombinant DNA molecule is greatly improved by purifying the individual components by electrophoresis in agarose gels. The extra effort involved is more than compensated by the elimination (in most cases) of the need to screen the recombinants and the resulting preparation and analysis of fewer DNAs. Equally importantly, gel purification makes it possible to use crude miniprep DNAs (UNIT 1.6) as the initial starting material instead of CsCl-purified DNAs, thus eliminating time, expense, and tedium.

Purified DNA fragments are relatively free of minor contaminants that can cause major background problems. For example, if a circular plasmid vector is cleaved at 99% efficiency with a single restriction enzyme, the uncleaved 1% of the molecules are fully infectious even though they cannot be visualized by ethidium bromide staining. This background, which is unacceptably high for many experiments, can be greatly reduced by gel purification of the linearized DNA. Gel purification is extremely useful in situations where only one of several fragments is needed or where fragments are generated by partial digestion. It is also useful for removal of small oligonucleotide linkers or other low-molecular-weight contaminants.

Electrophoretically separated DNA fragments should be isolated in the smallest possible volume of gel slice. Purity is more important than yield. DNA fragments can be purified away from the agarose (or acrylamide) by any of the procedures described in UNIT 2.6. It is important to use high-quality agarose such as SeaKem or SeaPlaque, since other preparations may contain inhibitors of DNA ligase that are hard to remove. DNA purified from acrylamide

gels does not usually contain such inhibitors. Finally, for most applications, ligation reactions can be performed directly in slices of low gelling/melting temperature agarose (Struhl, 1985; see alternate protocol on p. 3.16.3). By eliminating the need to purify the DNA away from the agarose, considerable time and effort is saved.

Intramolecular versus intermolecular ligation of DNA fragments. The absolute and relative concentrations of the input DNA fragments influence the frequencies of specific ligation events. The first consideration is whether the end of a particular DNA molecule will be joined to the other end of the same molecule (intramolecular ligation) or to a separate DNA molecule (intermolecular ligation). The second consideration is whether intermolecular events will be between molecules of the same type (vector–vector or insert–insert) or between molecules of a different type (vector–insert). Most hybrid constructions involve one or more intermolecular events followed by a final intramolecular event to generate a circular plasmid molecule.

Intramolecular events. Intramolecular events are a major source of background in many cloning experiments primarily because self-ligation of vector molecules produces undesired *E. coli* transformants. However, since intramolecular ligation can occur only if the ends of the molecule are cohesive or blunt, it can be almost completely eliminated by using molecules with heterologous ends. This is achieved by cleaving the vector with two restriction endonucleases that produce incompatible ends. For situations where the vector must be cleaved with a single endonuclease, intramolecular joining can be prevented by removing both 5' phosphates of each molecule with calf intestinal phosphatase. These dephosphorylated vector molecules can be ligated to phosphorylated insert DNAs even though at each end only 1 of the 2 strands will be covalently joined in vitro. *Escherichia coli* can repair the single-stranded nicks in vivo to generate the desired DNA molecules.

Intramolecular ligation of insert fragments does not generally affect the background of unwanted colonies. However, it strongly influences the frequency of obtaining the correct colonies because self-ligated insert DNA cannot be joined to the vector. Thus, in situations where the insert DNA fragments can cyclize, relatively high concentrations of DNA (20 to 100 µg/ml) should be used in order to favor

intermolecular ligation events. This is particularly true for short DNA fragments which are much more likely to cyclize than large fragments (for a theoretical discussion, see Dugaiczky et al., 1975).

Intermolecular events. Almost all cloning experiments using plasmid vectors require the joining of two or more separate DNA molecules followed by circularization of the product. Obviously, intermolecular ligation events become increasingly favored over self-joining as the total concentration of the relevant ends becomes higher. Thus, optimal cloning efficiency occurs at DNA concentrations that are high enough to permit sufficient intermolecular joining, but not so high as to reduce intramolecular ligation. For situations when the background is low, DNA concentrations between 1 and 50 µg/ml are acceptable.

If we exclude self-ligation events, the frequency of joining different DNA segments is directly related to the molarity of each component in terms of specific ends to be joined. For example, if equimolar amounts of vector (V) and insert (I) are present, 50% of the bimolecular products will be V–I, 25% will be V–V, and 25% will be I–I. However, because in most cases only molecules containing vector sequences will generate *E. coli* transformants, it is preferable to use higher molar concentrations of insert fragment(s) because this will favor the desired V–I products over the V–V background. This consideration becomes less important if V–V events are precluded by phosphatase treatment or if V–V events cannot generate viable molecules.

Amount of DNA. In general, it is not necessary to use very much DNA. For simple hybrid constructions, roughly 1 to 10% of the vector DNA molecules are converted to the recombinant DNA of interest. With normal transformation efficiencies, 10⁶ colonies per microgram of pure vector DNA, ligated products containing as little as 1 ng of treated vector DNA should generate 10 to 100 transformants. This is more than enough if the background is not a problem. In practical terms, if starting DNA fragments are easily visualized by conventional ethidium bromide staining, there is enough for most experiments. This is true even when performing ligation in gel slices (see alternate protocol) where only a fraction of the electrophoretically separated DNA is used.

More difficult constructions such as those involving blunt ends, three fragments, or *Bal* 31 nuclease usually require more DNA. How-

ever, even in these cases, there is sufficient DNA in a fraction of a gel slice such that the alternate protocol can be used. In general, 25 to 100 ng of each DNA component (in a standard 20- μ l reaction) is usually enough to obtain the desired recombinants. Of course, the cloning efficiency will be increased by using higher concentrations of the components. If this proves to be necessary, the DNA can be concentrated easily after purifying it away from the agarose (UNIT 2.6).

Selection, screening, and enrichment procedures. For some hybrid constructions, colonies containing the desired DNA molecule can be distinguished from background colonies by genetic methods. In such cases, techniques for background reduction become less important, which often means that time can be saved. As an extreme but relatively infrequent example, if one fragment contains the gene for ampicillin resistance and another fragment contains the gene for tetracycline resistance, the recombinant containing both fragments can be selected directly on plates containing both drugs; there is no need to purify the component DNAs prior to ligation.

Cloning vectors have been designed to select or screen for recombinants. Perhaps those most commonly used are the pUC or M13mp series of vectors which contain the α -complementation region of the *E. coli lacZ* gene and produce blue plaques or colonies on appropriate indicator plates (UNIT 1.4). Insertion of a DNA fragment into the *lacZ* region generally causes a white colony or plaque, which is easily seen among a background of thousands of blue transformants. Another common vector, pBR322, contains two selectable markers, ampicillin and tetracycline resistance. Insertion into one of these marker genes renders the colony sensitive to that drug; such colonies can be screened by replica plating (UNIT 1.5).

In many cases, the desired recombinant contains (or lacks) specific regions of DNA that are present in either or both of the starting molecules. Such recombinants can be identified by colony or plaque filter hybridization (UNITS 6.1 and 6.2) using an appropriate 32 P-labeled probe (UNIT 3.5). These screening procedures can identify the correct recombinant from a background of hundreds or thousands of transformants. However, they take several days to perform and are unnecessary if the background is acceptably low.

Finally, the proportion of correct colonies can be increased by appropriate enzymatic

treatment after the ligation reaction. For example, if the desired product lacks an *EcoRI* site, but undesired products contain such a site, the background can be reduced simply by *EcoRI* cleavage after the ligation reaction. Most restriction endonucleases are active in ligation buffer.

Controls. It is critical to perform appropriate control experiments simultaneously with the reaction of interest. In this way, it is often possible to determine the relative success of the hybrid construction. Such knowledge is particularly important because preparation and analysis of prospective recombinant DNAs is the most time-consuming part of the overall process. Obviously, it is worth minimizing the number of colonies to be examined from successful experiments as well as avoiding further analysis from cloning attempts that were clearly unsuccessful.

NOTE: *The basic controls for any experiment are to set up and analyze parallel ligation reactions, each lacking a single DNA component.* In order to keep the volume of the ligation reactions constant, the omitted DNA should be replaced by an equal volume of water. In a successful hybrid construction, the number of colonies obtained when all DNA components are present should be higher than any of the control reactions. If this is the case, many or most of the colonies should contain the molecule of interest.

Two additional controls should be carried out as part of the transformation procedure. First, an aliquot of competent cells should be incubated in the absence of DNA. The appearance of transformants is indicative of contamination in the cells or transformation buffers. Second, another aliquot of competent cells should be incubated with 1 ng of a control DNA (either plasmid or phage depending on the experiment) to measure the transformation efficiency; 1000 colonies or plaques should be achieved routinely.

Anticipated Results

For simple hybrid constructions, approximately 100 to 10,000 colonies or plaques should be generated, most of which should be the desired molecule. For more complex situations, the expected number of colonies should be between 1 and 1000; depending on the individual situation 5 to 80% of the molecules should contain the desired structure. For many cloning experiments, one correct colony is enough.

Time Considerations

The enzyme reactions can usually be performed in 1 to 4 hr (except in experiments involving ligation of oligonucleotide linkers). Gel electrophoresis and DNA fragment purification should take an additional 1 to 4 hr; shorter times are obtained by using minigels (UNIT 2.5) and by using the alternate protocol. Thus, in one day, it should be possible to go from uncleaved starting DNAs to the ligation reaction. On day 2, the ligated products can be introduced into *E. coli*, and the resulting transformants will be obtained on day 3. After colony or plaque purification, DNA from the transformants can be prepared and analyzed on day 4.

EXAMPLES

Example 3.16.1: Subcloning DNA Fragments with Homologous and Cohesive Ends

Consider the cloning of a 2-kb *EcoRI* fragment into a vector containing a single *EcoRI* site. The major source of background is uncleaved or self-ligated vector DNA. In most cases, self-ligation should be reduced by treating the *EcoRI* cleaved vector DNA with calf intestinal alkaline phosphatase (see Fig. 3.16.1 below and UNIT 3.10). Although phosphatase treatment does lower the absolute efficiency of obtaining the desired DNA molecule, the great

reduction in background is necessary to obtain a decent relative frequency of the desired molecule. The concentration of insert DNA(s) should be relatively high in order to facilitate ligation to the vector. It should also be noted that the insert DNA can contribute to background transformants by self-ligation, especially when it is difficult to purify away from “vector” fragments derived from the original plasmid.

Because all *EcoRI* ends are equivalent, the 2-kb insert can be cloned in either of the two possible orientations with respect to the vector sequences. These two outcomes can be distinguished only by restriction mapping using an enzyme that cleaves asymmetrically within the insert DNA. In addition, it is possible to insert multiple copies of the fragment into the vector. Generally, multiple insertion is infrequent unless the DNA concentrations are very high. When multiple insertions occur, the inserts are essentially always oriented in the same direction. Molecules containing tandem copies oriented in the opposite direction are incapable of replication in *E. coli* unless the insert fragment is very short (less than 30 bp).

For all the reasons mentioned above, cloning of fragments with homologous and cohesive ends is best avoided when possible. Directional cloning, discussed below, is preferable.

Figure 3.16.1 Treatment of cleaved vector with CIP in order to reduce background.

Example 3.16.2: Directional Cloning Using Fragments with Heterologous Ends

This is by far the most efficient method for cloning, and it should be used wherever possible. In the simplest example, consider the joining of two fragments, each produced by cleavage with enzymes A and B. Self-ligation of either fragment is theoretically eliminated, and ligation of two vector fragments produces a “perfect inverted repeat” molecule that cannot be stably maintained in *E. coli*. Thus, the background is very low, and if enzymes A and B produce 5′ or 3′ overhangs, the efficiency is very high. Moreover, almost all the transformants will contain recombinant molecules in which one copy of the insert DNA is oriented in a defined direction with respect to the vector. Molecules containing two copies of the insert cannot be formed, and those with three copies will be very rare.

The major problems associated with directional cloning come from errors in generating the DNA segments, particularly incomplete cleavage of the vector by one of the restriction endonucleases. Vector molecules that are singly cleaved can self-ligate and generate background. Ideally, molecules cleaved by both enzymes can be purified away from those that are incompletely cleaved by gel electrophoresis. However, this is not possible when the sites for cleavage by enzymes A and B are close together. Moreover, if the two sites are extremely close together, as is the case for the polylinkers in the pUC and M13mp vectors, it can be difficult to cleave the molecules with both enzymes.

The high efficiency of directional cloning makes it possible to create molecules composed of three or more segments. A typical three-piece ligation will consist of fragments generated by enzymes A + B, B + C, and A + C. The desired recombinant will occur less frequently than in the case for two-fragment ligation. However, the low background makes it possible to obtain the desired molecule at high enough frequency to permit individual analysis of colonies.

Example 3.16.3: Blunt-End Ligation

Although T4 DNA ligase can join fragments with blunt ends, ligation efficiency is greatly reduced as compared to fragments with cohesive ends. Blunt-end ligation is facilitated by using higher concentrations of DNA and ~10 times more ligase. Unlike the ligation of cohesive ends which requires compatible termini, blunt fragments are equally ligatable no matter which endonuclease is used to produce the

ends. The joining of blunt ends produced by different enzymes almost always results in a product that cannot be cleaved by either enzyme.

The most difficult ligations are those in which all the relevant ends are blunt (e.g., cloning an *Sma*I fragment into an *Sma*I cleaved vector). The problems are similar to those described in Example 3.16.1 and are compounded by the inefficiency of blunt-end ligation.

Cloning involving blunt ends is considerably easier if one of the ligation events involves cohesive ends. For example, two fragments generated by *Sma*I and *Eco*RI are much more easily joined than two *Sma*I-generated segments. In addition, such heterologous ends permit directional cloning and the background is very low (see Example 3.16.2).

Example 3.16.4: Joining DNA Fragments with Incompatible Ends

Consider the case of joining an *Eco*RI end (overhang 5′ AATT) to an *Sac*I end (overhang 3′ AGCT). To join such incompatible termini, it is necessary to convert them to blunt ends. For 5′ overhangs, this is accomplished by “filling in” the ends with the Klenow fragment of *E. coli* DNA polymerase I in the presence of all 4 dNTPs (see Fig. 3.16.2 below and UNIT 3.5). This reaction should be carried out in the presence of all 4 dNTPs in order to prevent more extensive exonuclease action. For 3′ overhangs, the 3′ to 5′ exonuclease activity of T4 DNA polymerase or Klenow enzyme is used to remove the protruding nucleotides (UNIT 3.5). The T4 enzyme is preferred because it has a much more active exonuclease. However, the Klenow enzyme will do the job, and it is considerably less expensive than T4 DNA polymerase. Both polymerases are active in all restriction endonuclease buffers and hence can be added (along with the 4 dNTPs) directly to the reaction mixture after cleavage.

Once the relevant ends have been blunted, the ligation procedure proceeds as in Example 3.16.3. However, the additional step for generating the blunt ends usually results in a lowered efficiency of ligation; the more ends to be blunted, the worse the problem. The fill-in reaction for 5′ overhangs is usually more efficient than the trimming reaction for 3′ extensions. Thus, when incompatible ends must be joined, it is preferable if some of the required ligation reactions involve joining of cohesive ends; e.g., the joining of a *Bam*HI–*Eco*RI (filled) fragment to a *Bam*HI–*Sac*I (trimmed) fragment.

Figure 3.16.2 Joining DNA fragments with incompatible ends.

In many cases, the joining of incompatible ends generates a product that cannot be cleaved by either of the restriction enzymes used to produce the ends. In such cases, the structure of the molecule at the fusion point can be determined only by DNA sequencing.

Sometimes, however, one of enzyme sites should be regenerated, thus making it possible to analyze the prospective molecules by restriction mapping. For example, a filled in *EcoRI* site has the terminal sequence GAATT. If this is joined to a fragment whose 5' terminal nucleotide is C, the *EcoRI* site will be restored. In principle, a *SacI* site (GAGCTC) that has been trimmed will regenerate an *EcoRI* site that has been filled in. Products where the *EcoRI* and *SacI* ends have been joined aberrantly will not result in the regeneration of the *EcoRI* site.

Example 3.16.5: Ligation of Fragments Generated by Partial Cleavage

Sometimes a given DNA fragment will contain internal restriction sites that are the same as those on one (or both) of the ends. In this case, the fragment can be obtained only by partial restriction endonuclease digestion. Contrary to popular opinion, it is not difficult to obtain hybrid DNA molecules when one or more of the components is generated by partial cleavage by a restriction endonuclease(s). By gel purifying the desired partial cleavage product(s), the ligation reactions can be set up in the normal way, and they should be equally efficient. The main difficulty with partial cleavage,

obtaining enough of the specific fragment, can usually be overcome by starting with more DNA (1 to 5 μg should be enough) prior to gel electrophoresis. To ensure the proper degree of partial digestion, the method of serial enzyme dilution should be performed (UNIT 3.1).

In some cases, it will be difficult to purify the desired partial cleavage product from undesired products. This is especially true if the starting molecule contains many cleavage sites or if cleavage sites are close together. However, if the ligation reaction has a low background, such impurities are only a minor problem. For example, if the “band” that is cut from the gel contains four different clonable fragments, roughly 25% of the transformants should be the ones of interest. Moreover, if the fragment is generated by partial cleavage at one end and complete cleavage by another enzyme at the other end, many of the contaminating fragments cannot be cloned into the vector and hence will not contribute to the background.

Example 3.16.6: Ligations Involving Oligonucleotide Linkers

Synthetic linkers are self-complementary oligonucleotides, typically 8 to 12 bases in length, that anneal to form blunt-ended, double-stranded DNA which contains a site for restriction endonuclease cleavage. For example, GGAATTCC is an 8-bp *EcoRI* linker (the underlined nucleotides represent the recognition site). Oligonucleotide linkers facilitate

the cloning of blunt-ended DNA fragments, and they are valuable for “introducing” new restriction sites at desired positions. A wide variety of linkers, each containing a specific recognition sequence, is available from commercial suppliers. Linkers are usually obtained in the nonphosphorylated form. For most applications, they are phosphorylated using ATP and T4 polynucleotide kinase (UNIT 3.10). After the kinase reaction, the phosphorylated linkers can be added directly to the ligation reaction.

Ligations involving linkers are performed in three stages. First, the DNA of interest, which must contain blunt ends, is joined to the linker, as illustrated in Figure 3.16.3. This reaction is performed with 0.1 to 1 µg of linker, which represents a 100- to 1000-fold molar excess of linker over fragment. The high concentration of ends makes this blunt-end ligation reaction more efficient than normal. Generally, the linker is phosphorylated prior to ligation. In this case, the ligation products will typically contain several linkers on each end of the fragment. Some experiments involve ligation of nonphosphorylated linkers, in which case the products will contain only one linker on each end.

Second, after heat treatment to inactivate the ligase, the products of this reaction are cleaved with the restriction enzyme that recognizes the linker, as illustrated in Figure 3.16.3. Because of the high concentration of restriction sites due to the linker, this step usually requires incubation for several hours with a large amount of restriction enzyme (20 to 50 U). It is important that the fragment does not contain an internal site that is recognized by the restriction enzyme (unless the fragment has been methylated previously by the methylase corresponding to the

restriction enzyme). If possible, the ligation products should be cleaved with a second restriction enzyme to produce a fragment with heterologous ends suitable for cloning (see Example 3.16.2).

Third, the fragment is purified by gel electrophoresis and then ligated by conventional methods. The gel purification step also removes unligated linkers, which would interfere with this second ligation step. Linkers can also be removed by other methods (chromatography on Sepharose CL-4B or Sephacryl S-300; see UNITS 2.6 and 5.6), but electrophoresis is more efficient and allows for purification of the desired fragment away from undesired fragments.

Example 3.16.7: Cloning Synthetic Oligonucleotides

Double-stranded oligonucleotides suitable for cloning can be obtained by annealing two single-stranded oligonucleotides that have been synthesized chemically. Generally, such oligonucleotides are phosphorylated with T4 kinase (UNIT 3.10) prior to annealing. Double-stranded and phosphorylated oligonucleotides can also be generated by “mutually primed synthesis” of appropriate single-stranded oligonucleotides (UNIT 8.2). Oligonucleotides obtained by either method can be cloned by standard ligation procedures using cohesive or blunt ends.

The main problem associated with cloning oligonucleotides is that of multiple insertion. This is because small amounts of oligonucleotide represent a large molar excess. This problem is best dealt with by making a series of 10-fold serial dilutions of oligonucleotide and setting up parallel ligation reactions using

Figure 3.16.3 Joining blunt-ended DNA to *EcoRI* linker.

these various concentrations. If single insertions are desired, transformants should be picked off plates that represent the lowest amount of oligonucleotide needed to increase the number of colonies significantly above the background (i.e., the absence of oligonucleotide). In general, optimal conditions for single insertion occur when the oligonucleotide is present in a 5- to 20-fold molar excess over the other fragments in the ligation mixture.

Constructing Recombinant DNA Molecules by the Polymerase Chain Reaction

UNIT 3.17

Any two segments of DNA can be ligated together into a new recombinant molecule using the polymerase chain reaction (PCR). The DNA can be joined in any configuration, with any desired junction-point reading frame or restriction site, by incorporating extra nonhomologous nucleotides within the PCR primers. Cloning by PCR is often more rapid and versatile than cloning with standard techniques that rely on the availability of naturally occurring restriction sites and require microgram quantities of DNA. It is not necessary to know the nucleotide sequence of the DNA being subcloned by this technique, other than the two short flanking regions (~20 bp) that serve as anchors for the two oligonucleotide primers used in the amplification process. Moreover, PCR can be performed on low-abundance or even degraded DNA (or RNA) sources.

This unit describes using PCR to construct hybrid DNA molecules. The main objective is to give an overview of how PCR can be exploited to accomplish numerous cloning strategies; it is assumed that the reader is already familiar with basic molecular biology techniques including PCR amplification (UNIT 15.1) and subcloning (UNIT 3.16). The basic protocol outlines the PCR amplification and cloning strategies. A troubleshooting guide for problems most frequently encountered in PCR cloning, and three specific examples of this technique—for creating (1) in-frame fusion proteins, (2) recombinant DNA products, and (3) deletions and inversions by inverse PCR—are presented in the Commentary.

SUBCLONING DNA FRAGMENTS

In this protocol, synthetic oligonucleotides incorporating new unique restriction sites are used to amplify a region of DNA to be subcloned into a vector containing compatible restriction sites. The amplified DNA fragment is purified, subjected to enzymatic digestion at the new restriction sites, and then ligated into the vector. Individual subclones are analyzed by restriction endonuclease digestion and either sequenced or tested in a functional assay. The procedure is summarized in Figure 3.17.1.

Materials

Template DNA (1 to 10 ng of plasmid or phage DNA; 20 to 300 ng of genomic or cDNA)

Oligonucleotide primers (0.6 to 1.0 mM; UNIT 8.5)

Mineral oil

TE-buffered phenol (UNIT 2.1) and chloroform

100% ethanol

TE buffer, pH 8.0 (APPENDIX 2)

Klenow fragment of *E. coli* DNA polymerase I (UNIT 3.5)

Vector DNA

Calf intestinal phosphatase (UNIT 3.10)

Additional reagents and equipment for phosphorylating synthetic oligonucleotides (UNIT 3.10), enzymatic amplification of DNA by PCR (UNIT 15.1), agarose and polyacrylamide gel electrophoresis (UNITS 2.5 & 2.7), DNA extraction and precipitation (UNIT 2.1), purification of DNA by glass beads, electroelution from agarose gels, or from low-gelling/melting temperature agarose gels (UNIT 2.6), restriction endonuclease digestion (UNIT 3.1), ligation of DNA fragments (UNIT 3.16), transformation of *E. coli* (UNIT 1.8), plasmid DNA minipreps (UNIT 1.6), and DNA sequence analysis (UNIT 7.4)

3.17.1

Supplement 24

Amplify the target DNA

1. Prepare the template DNA. If using an impure DNA preparation (i.e., not purified by CsCl gradients), heat sample 10 min at 100°C to inactivate nucleases.

Plasmid, phage, genomic, or cDNA, obtained from either rapid preparations or purified on CsCl gradients, can be used as the source of target DNA.

2. Prepare the oligonucleotide primers. If the PCR product is to be cloned by blunt-end ligation, phosphorylate the 5' hydroxyl of the oligonucleotide primers.

A 5' phosphate on the ends of the PCR products will be needed to form the phosphoester linkage to the 3'OH of the vector during ligation. This step is essential if the vector has been treated with a phosphatase.

Because the purity of the oligonucleotides does not seem to affect the PCR reaction, primer purification (as detailed in UNIT 8.5) may not be necessary.

3. Set up a standard amplification reaction and overlay with mineral oil as described in UNIT 15.1. Carry out PCR in an automated thermal cycler for 20 to 25 cycles under the following conditions: denature 60 sec at 94°C, hybridize 1 min at 50°C, and extend 3 min at 72°C. Extend an additional 10 min at 72°C in the last cycle to make products as complete as possible.

Include negative controls of no template DNA and each oligonucleotide alone, as well as several different oligonucleotide:template ratios.

For a discussion of optimization of amplification conditions see UNIT 15.1. A thermostable DNA polymerase with 3'→5' exonuclease proofreading activity can be used instead of Taq DNA polymerase to reduce the amount of nucleotide misincorporation during amplification. Pfu DNA polymerase (Stratagene) and Vent DNA polymerase (New England Biolabs) have this activity (follow manufacturers' instructions).

Recover the amplified fragment

4. Analyze an aliquot (e.g., 4 to 8 µl) of each reaction mix by agarose or polyacrylamide gel electrophoresis to verify that the amplification has yielded the expected product.
5. Recover amplified DNA from PCR reaction mix. Remove mineral oil overlay from each sample, then extract sample once with buffered chloroform to remove residual mineral oil. Extract once with buffered phenol and then precipitate DNA with 100% ethanol.

Carrier tRNA may be added during precipitation if desired.

6. Microcentrifuge DNA 10 min at high speed, 4°C. Dissolve pellet in 20 µl TE buffer. Purify desired PCR product from unincorporated nucleotides, oligonucleotide primers, unwanted PCR products, and template DNA using glass beads, electroelution, or phenol extraction of low gelling/melting temperature agarose.

Unused oligonucleotide primers can inhibit the ability of the restriction enzymes to digest the amplified PCR product. Amplified DNA that is greater than 100,000 Da (>150 bp) can be rapidly separated from the primers using a Centricon 100 microconcentrator unit from Amicon (follow manufacturers' instructions). If the gel analysis in step 4 shows that amplification yielded only the desired PCR product, this microconcentrated DNA can be used directly for cloning.

Prepare amplified fragment and vector for ligation

- 7a. If the PCR fragment is to be cloned by blunt-end ligation, repair the 3' ends with DNA polymerase I (Klenow fragment).

This step is necessary because Taq DNA polymerase adds a nontemplated nucleotide (usually dA) to the 3' ends of PCR fragments.

- 7b. If primers contain unique restriction sites, digest half the amplified DNA in 20 μ l with the appropriate restriction enzyme(s). Use an excess of enzyme, and digest for several hours.

Reserve the undigested half for future use, if necessary.

8. Prepare the recipient vector for cloning by digesting 0.2 to 2 μ g in 20 μ l with compatible restriction enzymes. If necessary, treat vector DNA with calf intestinal phosphatase (*UNIT 3.1*) to prevent recircularization during ligation.
9. Separate the linearized vector from uncut vector by agarose or low-gelling/melting temperature gel electrophoresis. Recover linearized vector from the gel by adsorption to glass beads, electroelution, or phenol extraction of low-gelling/melting temperature agarose.

Ligate amplified fragment and vector

10. Ligate the PCR fragment into the digested vector following the procedure outlined in *UNIT 3.16*.
11. Transform an aliquot of each ligation into *E. coli*. Prepare plasmid miniprep DNA from a subset of transformants.

Analyze recombinant plasmids

12. Digest the plasmid DNA of the selected transformants with the appropriate restriction endonuclease. Analyze the digestions by agarose gel electrophoresis to confirm fragment incorporation.
13. Sequence the amplified fragment portion of the plasmid DNA to check for mutations. Alternatively, screen the subset of transformants using a biochemical or genetic functional assay if available.

This analysis is critical because the Taq DNA polymerase can introduce mutations into the amplified fragment.

COMMENTARY

Background Information

The main benefit of cloning by PCR is that unique restriction sites can be introduced on either side of any segment region of amplified DNA to allow its ligation into a recipient vector (Mullis and Faloona, 1987; Chapter 15) in any configuration. The incorporation of additional nucleotides at the 5' ends of the oligonucleotide primers permits the creation of novel restriction sites or changes in reading frame and coding sequence. The oligonucleotide primers can also be designed to contain mismatches, deletions, or insertions in the region of homology (*UNIT 8.5*). However, it is not necessary to always incorporate a new restriction site in the primer. Amplified PCR fragments can also be subcloned by blunt-end or sticky-end ligation using preexisting restriction sites within the amplified DNA. For example, PCR might be used to amplify a target DNA that already contains appropriate restriction sites, but is available in limited quantities. Finally, sequential polym-

erase chain reactions can be used to generate more complex recombinant PCR products which can subsequently be subcloned into a recipient vector.

The most obvious disadvantage of PCR cloning is the need to verify that the subcloned PCR product does not contain mutations generated during the polymerase chain reaction. In cases where longer DNA segments (i.e., >1 kb) are being amplified, it may be more advantageous to use a polymerase which has a 3'→5' exonuclease activity (e.g., Pfu polymerase, Stratagene) to reduce the chances of generating mutations. After subcloning, several independent PCR products should be analyzed by DNA sequencing to be sure that the recombinant DNA molecule is not mutated. Sequencing can be laborious when a large fragment of DNA is subcloned. However, subcloned PCR products can be prescreened by either biological or biochemical functional assays if they are available. In some instances, it may be more desir-

able to break down the cloning into several steps that might involve the introduction of a needed restriction site within a short piece of DNA first.

Critical Parameters

In general, the DNA preparation, purification, and ligation guidelines outlined in *UNIT 3.16* should be applied to PCR cloning to ensure recovery of the desired ligation products. However, the following points deserve special consideration.

Design of oligonucleotide primers. Primers should only hybridize to the sequence of interest. This can be predicted in instances where sequence information is available. In general, primers with homology of 16 to 20 nucleotides to the target DNA and a GC content of ~50% should be chosen. A longer oligonucleotide of ~25 nucleotides should be used for AT-rich regions. In instances where genomic DNA is the source of the target DNA, the oligonucleotide primers should contain at least 20 nucleotides of homology to the target DNA to ensure that they anneal specifically (Arnheim and Erlich, 1992).

When using primers to introduce a specific restriction site, a sequence within the target DNA should be selected that requires the addition of the fewest noncomplementary nucleotides to create the new site, if possible. Special consideration should be given to the choice of site itself, as restriction endonucleases vary in their ability to cleave recognition sequences within ten nucleotides of the end of a DNA duplex (consult Table 8.5.1 for the efficacies of different restriction enzymes in cleaving terminal recognition sequences). It is also recommended that four to five additional nucleotides be added on the 5' side of the restriction site in the primer. Because DNA duplexes "breathe" at termini, potentially interfering with the ability of a restriction enzyme to cleave (Innis et al., 1990), it is useful to use the GCGC "clamp" sequence that is most thermostable (Sheffield et al., 1989).

Finally, the sequence of the primer should be checked for internal complementarity to avoid secondary structure formation that will interfere with hybridization of the primer to the target DNA. The 3' ends of the two primers being used must not be complementary, so that the formation of primer-dimers that will compete with the synthesis of the desired PCR product will be avoided.

Additional details on primer design are discussed in *UNIT 15.1*.

DNA polymerase. Commercially available *Taq* DNA polymerase (Perkin-Elmer Cetus) lacks the 3'→5' proofreading exonuclease activity used by DNA polymerase I Klenow fragment and T4 DNA polymerase to reduce error frequency (Kornberg, 1992). This absence of proofreading activity in *Taq* DNA polymerase is thought to result in a heightened error frequency. Old estimates indicate that the average rate of misincorporation is 8.5×10^{-6} nucleotides per cycle (Goodenow et al., 1989; Fucharoen et al., 1989). Two other thermostable DNA polymerases possessing proofreading 3'→5' exonuclease activity have recently become commercially available: Pfu DNA polymerase, purified from *Pyrococcus furiosus* (Stratagene) and Vent DNA polymerase, purified from *Thermococcus litoralis* (New England Biolabs and Promega). Both are more thermostable than *Taq* DNA polymerase. Pfu DNA polymerase is 12-fold more accurate than *Taq* DNA polymerase, as assayed by the method of Kohler et al. (1991). Vent DNA polymerase is 4-fold more accurate than *Taq* DNA polymerase (Cariello et al., 1991). Although it is difficult to compare the relative error frequencies of three enzymes because they were assayed by different methods, the use of either Vent or Pfu DNA polymerases may reduce the amount of misincorporation.

Removal of unincorporated nucleotide triphosphates. It is recommended that the amplified PCR fragment be purified from unincorporated nucleotides and primers. Any method of purification that involves electrophoresis can also separate the desired PCR product from any undesired DNA species produced during amplification. Typical methods of DNA purification include electrophoresis through low-gelling/melting temperature agarose or electrophoresis through agarose followed by DNA purification by electroelution or adsorption to glass beads (*UNIT 2.6*). However, amplified DNA can be more rapidly purified from unincorporated nucleotide triphosphates and primers using a Centricon microconcentration unit (Amicon). The disadvantage of using the microconcentrator is that undesirable PCR products and the starting template DNA will copurify with the amplified PCR fragment.

Troubleshooting

PCR amplification. The use of appropriately designed primers should allow the amplification of the DNA segment of interest. Occasionally, however, primers may not be specific, leading to the amplification of undesired DNA

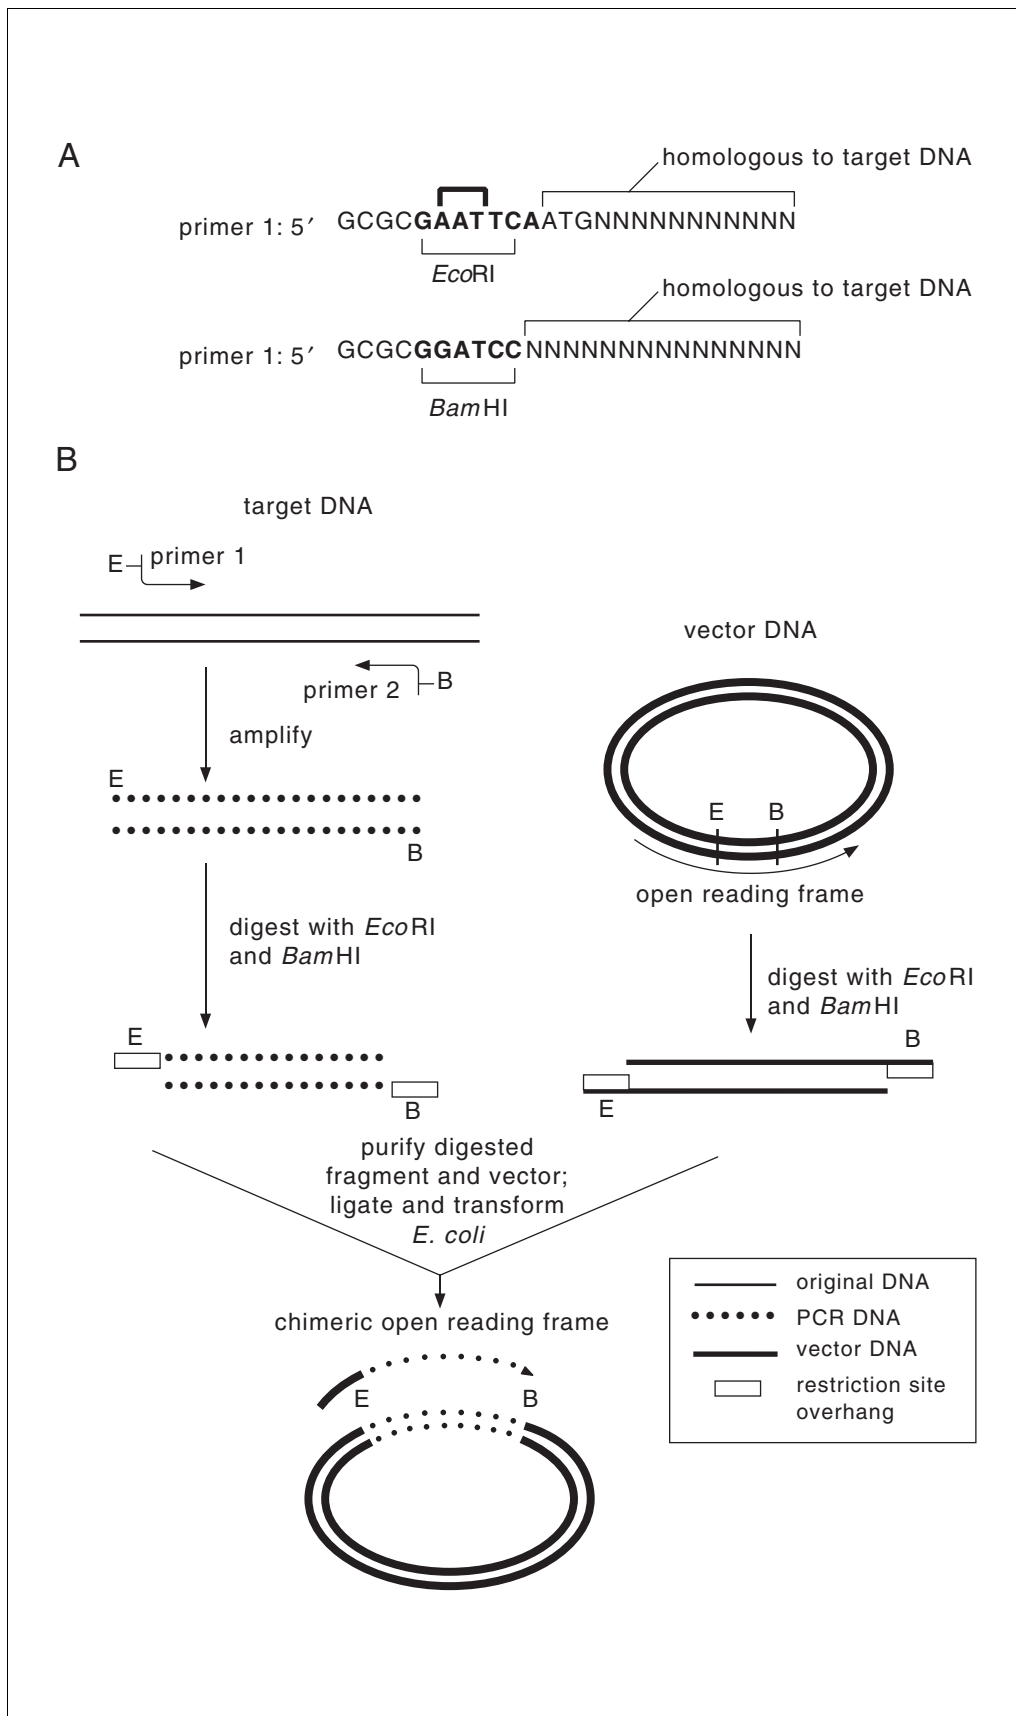

Figure 3.17.1 Introducing unique restriction sites and creating an in-frame fusion protein by PCR. Abbreviations: E, *EcoRI*; B, *BamHI*. For a full description, see Example 3.17.1 in Commentary.

segments. The specificity of primer to template hybridization will depend upon temperature and salt (see *UNITS 15.1 & 6.4* for a thorough discussion). The highest annealing temperature possible should be used to reduce nonspecific associations. Some nonspecific amplifications can be avoided by employing a “hot-start” technique—i.e., adding the DNA polymerase to a prewarmed sample (D’Aquila et al., 1991). In addition, purifying the PCR product by gel electrophoresis will help ensure that the proper DNA fragment is subcloned. If the synthesized primer does not bind with specificity, it may be simplest to have another one synthesized.

In setting up the amplification cycle, keep in mind that for cloning, fidelity is more important than yield, so it is better to keep a low cycle number and not to raise the MgCl₂ concentration too much. 1.5 mM MgCl₂ in the amplification buffer should be sufficient for most primers.

Cloning of the amplified fragment. “Sticky-end” ligation of the amplified DNA can sometimes be difficult, due to poor cutting of the terminal restriction site by the desired restriction endonuclease. Careful choice of restriction sites and the addition of extra nucleotides to the 5′ end of the primer (see critical parameters) will facilitate digestion.

Other common explanations for poor cutting by restriction endonucleases include:

(1) Blockage of the duplex terminus by bound *Taq* DNA polymerase. If this is the case, the amplified DNA can be treated with proteinase K to remove associated protein. This is done by adding 50 μg/ml proteinase K in 10 mM Tris-Cl (pH 7.8)/5 mM EDTA/0.5% (v/v) SDS to the sample and incubating 30 min at 37°C. The sample must be extracted with phenol/chloroform (*UNIT 2.1*) to remove the proteinase K.

(2) Inefficient extension by *Taq* DNA polymerase. The nonduplex ends generated in this fashion can be repaired by filling in with Klenow fragment (*UNIT 3.5*).

(3) An insufficient number of extra nucleotides 5′ to the restriction site in the primer. In this case, the primer should be resynthesized. Prolonged (typically overnight) DNA digestion should also be tried.

(4) 5′ terminal breathing of duplex DNA. Duplex formation can be stabilized by the inclusion of 0.1 mM spermidine in the digestion reaction.

An alternative approach is to internalize the restriction site by concatemering the PCR products prior to restriction endonuclease di-

gestion (Jung et al., 1990). To do this, 5′ phosphorylated oligonucleotide primers are used in the PCR amplification, or following amplification, the DNA fragment is phosphorylated using T4 polynucleotide kinase (*UNIT 3.10*). The amplified fragments are then concatemered by ligation using T4 DNA ligase (*UNIT 3.16*) prior to restriction endonuclease treatment. Aliquots of the amplified DNA before and after concatemering, and after digestion, can be compared on an agarose gel to confirm that the procedure worked.

Blunt-end ligations are often inhibited by nonflushed ends in the PCR fragment, due to the presence of a nontemplate-directed nucleotide (usually dATP) added by *Taq* DNA polymerase (Clark, 1988). Treatment of the PCR fragment with Klenow polymerase in the presence of dNTPs (*UNIT 3.5*) to make the ends flush should circumvent this problem. In the event that this simple approach does not work, the PCR fragment can be subcloned into a *MstII* (or *Bsu36 I*) site (CC↓TNAGG) which leaves a 5′ dT overhang. This approach requires a recipient vector with a unique *MstII* site.

Anticipated Results

All of the cloning approaches outlined are reliable and should result in efficient recovery of the desired recombinant molecules.

Time Considerations

Once the oligonucleotides have been synthesized, the PCR amplification, purification, ligation, and transformation steps can all be done within 2 days. The appropriate subclones can then be sequenced or tested in a functional assay immediately thereafter.

EXAMPLES

Example 3.17.1: Creating In-Frame Fusion Proteins by PCR

PCR cloning is particularly useful for creating in-frame fusions between two open reading frames, as is often done for synthesizing fusion proteins with *E. coli* expression vectors (Chapter 16). The essence of this type of subcloning involves incorporating additional noncomplementary nucleotides within the oligonucleotide primer that will encode the junction sequences of the amplified PCR fragment. Consider the introduction of a unique *EcoRI* site into a piece of target DNA that is to be fused with an open reading frame in the recipient vector, as depicted in Figure 3.17.1.

For this experiment, the primers should be

designed as indicated in panel A. Each primer is designed to contain a unique restriction site not present within the target DNA. The primer carrying the *Eco*RI site contains an additional nucleotide (shown in bold) to allow the ATG of the amplified target DNA to be in-frame with the open reading frame in the vector (bold bracket). The second primer contains a unique *Bam*HI site. Both oligonucleotide primers are designed to be homologous to and anneal with ~20 nucleotides of DNA flanking the target DNA. They are oriented such that their 3' hydroxyl ends point toward the target DNA. These unique restriction sites are 5' to the region of the primer that is homologous to the target DNA. Each new restriction site is separated from the 5' end of the oligonucleotide by four additional nucleotides to facilitate enzymatic digestion of the amplified DNA. Shown in this example is a GC clamp (Myers et al., 1985) which favors duplex formation at the ends of the amplified fragment.

Panel B depicts the sequence of events in this experiment. Following primer annealing and PCR amplification, the amplified DNA is first digested with restriction endonucleases that cleave at the new restriction sites, then purified by gel electrophoresis. The recipient vector DNA is digested with either the same or compatible restriction endonucleases and is purified before being ligated to the recipient vector.

In this example, one oligonucleotide contains additional bases to create an in-frame fusion with the plasmid-borne open reading frame. More elaborate primers can be designed to include additional restriction sites in different reading frames to allow subcloning of the same PCR fragment into multiple recipient fusion vectors that may have nonidentical cloning sites. This is efficient both in terms of labor and the cost of having to synthesize a new oligonucleotide primer. Note that an ATG can also be incorporated into the 5' oligonucleotide primer to create an open reading frame with a new translational start (e.g., in the construction of a promoter-exon fusion).

Example 3.17.2: Creating a Recombinant DNA Molecule by Sequential PCR Amplifications

Consider creating a chimeric DNA molecule by sequential polymerase chain reactions rather than by ligation. This technique is useful for complex cloning schemes that involve fusing together more than two pieces of DNA, as depicted in the creation of the gene fusion

shown in Figure 3.17.2. In this example, two PCR products are made from noncontiguous regions of DNA (that are also nonhomologous) in separate reactions.

Two of the first-round amplification primers are designed to contain 5' extensions that are homologous to a portion of the other target gene (see primers 1b and 1c). In this example, the primers for target gene 1 are labeled as 1a and 1b. Primer 1a contains a unique *Eco*RI site; primer 1b contains a 5' extension that is homologous to a region in target gene 2 that will be amplified (thin line of arrow). Primers 1c and 1d are for amplifying target gene 2: primer 1c contains a 5' extension that is homologous to a portion of target gene 1 that will be amplified (bold line of arrow), and primer 1d contains a unique *Bam*HI restriction site.

Because primers 1b and 1c contain complementary 5' extensions, two PCR products containing a region of overlapping homology are generated. The two PCR fragments are purified away from the primers, then mixed together and annealed by denaturation and renaturation. Four DNA species are generated in this reaction: two heteroduplexes associating at the region of overlapping homology and two parental homoduplexes. The recessed 3' ends of the heteroduplexes are extended by *Taq* DNA polymerase to produce a single fragment that is equal in length to the sum of the two overlapping fragments.

In a second round of amplification, the combined heteroduplex DNA species is amplified by adding the outside set of primers (1b and 1d) to the PCR assay. These primers will now have complete homology to the amplified heteroduplex DNA species. (Note that the parental homoduplexes will not be amplified because only one of each outside primers will anneal to each parental homoduplex.)

The complementary primers used in the first polymerase chain reaction step can be designed to either insert a restriction site at the junction between the joined PCR products, or alter a reading frame.

Example 3.17.3: Inserting a Restriction Site by Inverse PCR

Consider deleting a segment of DNA from a plasmid by inserting a unique restriction site by inverse PCR as depicted in Figure 3.17.3. Divergent primers containing the same novel restriction site (R) are annealed to two portions of the plasmid. (Note that R can be any restriction site not found in the plasmid.) The primers are oriented with their 3' ends facing away from

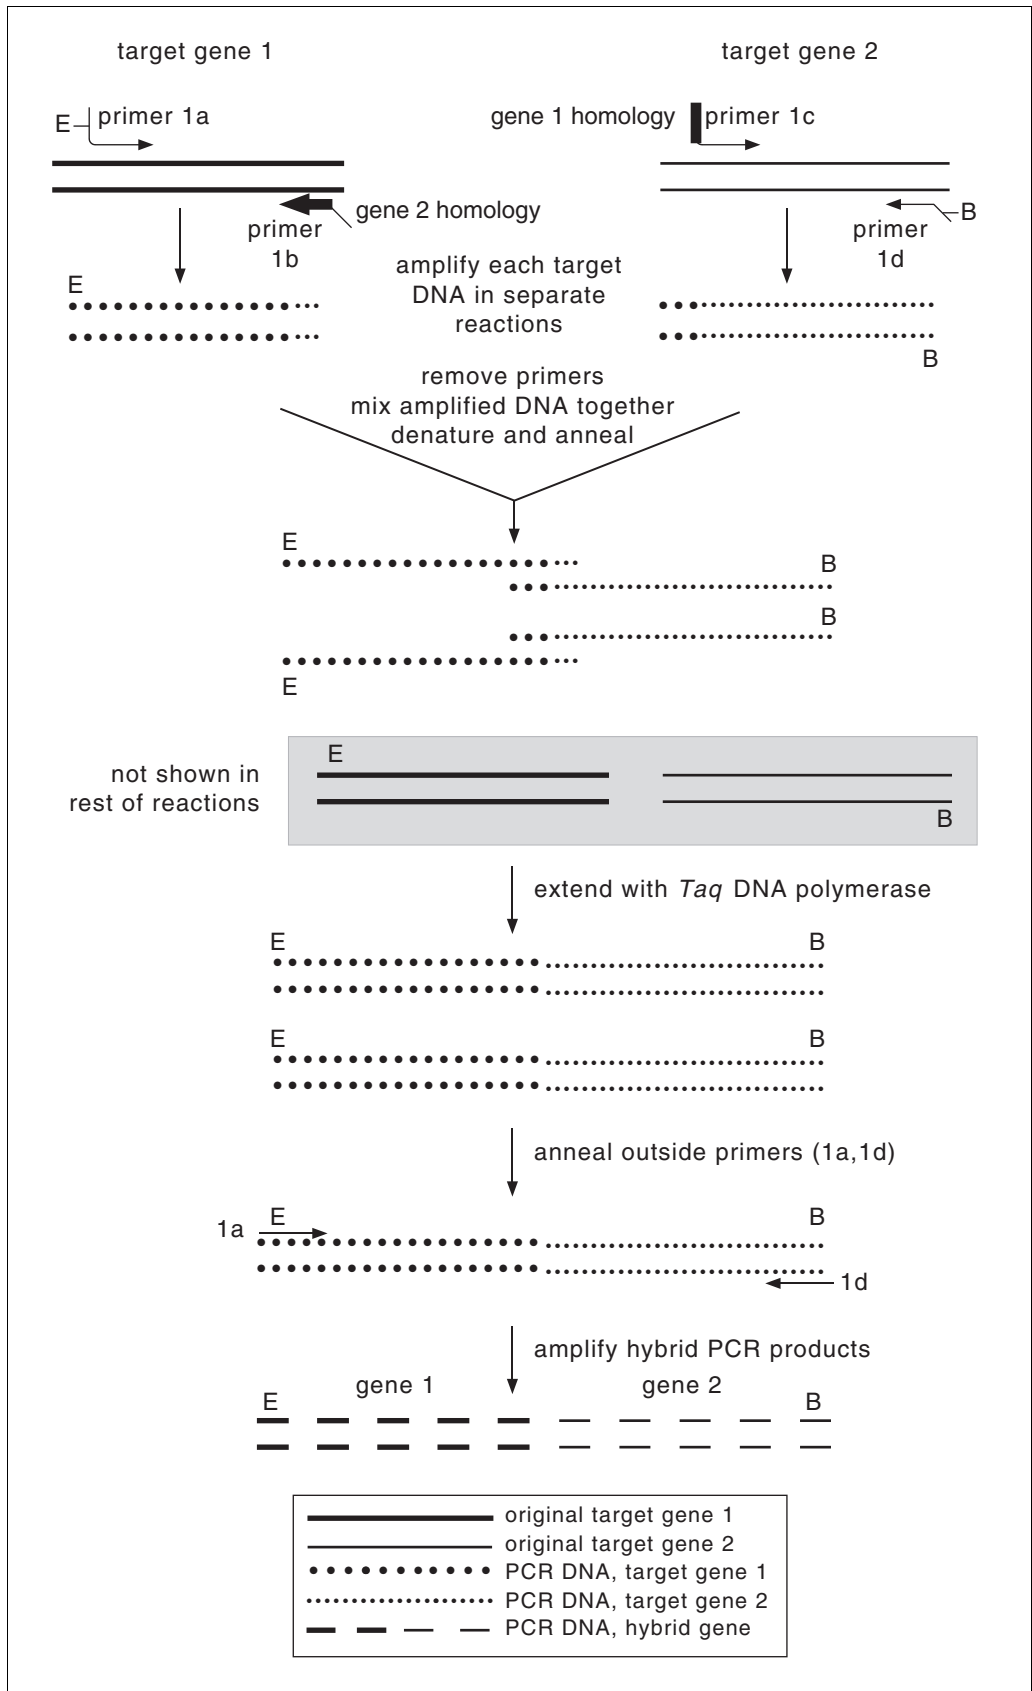

Figure 3.17.2 Creating a recombinant DNA molecule by sequential PCR amplifications. Primer 1b has a region of homology to target gene 2 (open box); primer 1c has a region of homology to target gene 1 (closed box). Abbreviations: E, *Eco*RI; B, *Bam*HI. For a complete description, see Example 3.17.2 in Commentary.

Figure 3.17.3 Inserting a restriction site by inverse PCR. Abbreviation: R, restriction enzyme not found in target plasmid. For a complete description, see Example 3.17.3 in Commentary.

each other so that sequences flanking the region to be deleted will be amplified. The full-length PCR product is purified and digested at the new restriction site and the ends are ligated in a unimolecular reaction. The amount of spacing between the two primers will determine whether the final product contains all of the original sequence or a deletion. Insertions can also be made at specific sites by including 5' extensions in the primers. Mismatches within the body of the primer can also be used to introduce mutations.

This method is useful for rapid introduction of desired restriction sites, and is limited only by the size of the plasmid and the ability of

DNA polymerase to synthesize complete products. This methodology allows the amplification of DNA flanking a region of known sequence. It is also useful for cloning DNA that has not yet been sequenced and for making hybridization probes (Ochman et al., 1990).

Labeling and Colorimetric Detection of Nonisotopic Probes

UNIT 3.18

Although a number of different nonisotopic labels have been described in the literature, biotin and digoxigenin are used most frequently and are commercially available. Either label can be easily incorporated into DNA probes and be detected colorimetrically; a number of fluorochromes, as well as alkaline phosphatase and horseradish peroxidase (which produce colored precipitates) are available directly conjugated to anti-digoxigenin antibodies and to avidin. Chemiluminescent detection methods (UNIT 3.19) and indirect immunofluorescent techniques (UNIT 14.6) also provide sensitive alternatives for many molecular biology applications. Because one of the advantages of nonisotopically labeled probes is their long shelf life (≥ 2 years), many micrograms of DNA can be labeled in one reaction to provide probes of constant quality for multiple experiments.

The two basic protocols describe incorporating biotinylated nucleotides into DNA probes by nick translation and random-primed synthesis. The support protocol describes colorimetric detection of the probes, which also serves to check the extent of nucleotide incorporation. An alternate protocol describes adaptations of the basic protocols for incorporation of digoxigenin-modified nucleotides.

PREPARATION OF BIOTINYLATED PROBES BY NICK TRANSLATION

BASIC
PROTOCOL

Nick translation is frequently used to label DNA probes for nonisotopic detection procedures. The DNA to be labeled can be an isolated fragment or—as is often the case for in situ hybridization probes—the intact phage, cosmid, or plasmid clone. The biotin-avidin system is the most widely used nonisotopic labeling method and the biotinylated deoxynucleotides and detection reagents required are commercially available from several sources.

The protocol is quite similar to the standard nick translation procedure (UNIT 3.5) except for some modifications—the biotin-11-dUTP is substituted for dTTP in a standard nick translation reaction mixture and the DNase I concentration is adjusted to ensure a size range of 100 to 500 nucleotides. A minimum of 2 hr incubation time is necessary for optimal incorporation of the modified deoxynucleotide. The reaction provides sufficient probe for 15 to 50 in situ hybridizations or 2 to 5 Southern blots.

Materials

- E. coli* DNA polymerase I (UNIT 3.5) and 10 \times buffer (UNIT 3.4)
 - 0.5 mM 3dNTP mix (minus dTTP; UNIT 3.4)
 - 0.5 mM biotin-11-dUTP stock
 - 100 mM 2-mercaptoethanol (2-ME)
 - Test DNA
 - 1 mg/ml DNase I stock (UNIT 3.12) prepared in 0.15 M NaCl/50% glycerol
 - DNA molecular weight markers (UNIT 2.5A)
 - 0.5 M EDTA, pH 8.0 (APPENDIX 2)
 - 10% (w/v) SDS
 - 100% ethanol
 - SDS column buffer
 - 1-ml syringe
- Additional reagents and equipment for agarose gel electrophoresis (UNIT 2.5) and removal of unincorporated nucleotides by Sephadex G-50 spin columns (UNIT 3.4)

Enzymatic
Manipulation
of DNA and RNA

1. Prepare a 100- μ l reaction mix as follows:

10 μ l 10 \times *E. coli* DNA polymerase I buffer
10 μ l 0.5 mM 3dNTP mix
10 μ l 0.5 mM biotin-11-dUTP stock
10 μ l 100 mM 2-ME
2 μ g DNA
20 U *E. coli* DNA polymerase I
DNase I stock diluted 1:1000 in cold H₂O immediately before use
H₂O to 100 μ l.

Incubate reaction 2 to 2.5 hr at 15°C.

Other biotinylated nucleotides such as biotin-14-dATP and biotin-16-dUTP can be used. Adjust the mixture of unsubstituted deoxynucleotides accordingly. The quantity of DNase I depends on the individual lot used. The enzyme can be diluted in water as described, or in a buffer that is compatible with the nick translation reaction. See notes on DNase I titration in critical parameters.

2. Place reaction on ice. Remove a 6- μ l aliquot, boil it 3 min and place on ice 2 min.
3. Load aliquot on an agarose minigel, along with suitable size markers (0.1- to 10-kb range). Run gel quickly (15 V/cm) in case additional incubation is necessary.
4. If the digested DNA is between 100 and 500 nucleotides, proceed to step 5. If the probe size is between 500 and 1000 nucleotides (or larger) add a second aliquot of DNase I and incubate further.

Additional DNase I is added in a more concentrated form than in the initial reaction to avoid significant volume changes. For example, if 10 μ l of a 1:1000 dilution of DNase I is added initially, the second addition might be 1 μ l of a 1:100 dilution incubated for ~1 hr. Monitor the additional incubation carefully to avoid complete digestion of the probe. If little or no digestion occurs, purify a new DNA sample by phenol extraction and ethanol precipitation (UNIT 2.1) and repeat the nick translation.

5. Add 2 μ l of 0.5 M EDTA, pH 8.0 (10 mM final) and 1 μ l of 10% SDS (0.1% final) to the reaction. Heat 10 min at 68°C to stop the reaction and inactivate the DNase I.
6. Prepare a Sephadex G-50 spin column in a 1-ml syringe. Wash syringe and silanized glass wool plug with 2 ml of 100% ethanol, then 4 ml water. Pack G-50 resin to the 1-ml mark. Wash column 3 to 4 times with 100 μ l SDS column buffer before loading the sample. An additional wash after loading the sample is not necessary.

Alternatively, the G-50 resin can be stored in SDS column buffer, reducing the number of times the column should be washed to 2 to 3 times. SDS prevents the biotinylated DNA from sticking nonspecifically to the resin and the glass wool plug.

7. Separate the biotinylated probe from unincorporated nucleotides. The eluted probe concentration should be ~20 ng/ μ l (for 2 μ g nick-translated DNA) and is ready to use without further treatment. Probe can be stored at -20°C for years without loss of activity.

Biotinylated DNA should not be subjected to phenol extraction, as biotin causes the probe to partition to the phenol/water interface or completely into the phenol if heavily biotinylated.

8. Assess the extent of the biotinylation reaction and the probe quality by colorimetric (support protocol) or chemiluminescent (UNIT 3.19) detection.

Chemiluminescent detection is 5×10^3 times more sensitive than colorimetric detection (Beck and Koster, 1990).

PREPARATION OF BIOTINYLATED PROBES BY RANDOM OLIGONUCLEOTIDE-PRIMED SYNTHESIS

BASIC PROTOCOL

This protocol outlines a priming reaction using random octamers that have been biotinylated at the 5' end. Octamers are the optimal length for efficient hybridization of 5'-labeled oligonucleotides because the additional two bases act to minimize the steric hindrance from the 5' end label. This ensures that every probe molecule generated contains at least one biotin, but biotin-16-dUTP is also included in the reaction so that additional biotin is incorporated into some of the probe molecules. Other biotinylated nucleotides (e.g., biotin-14-dATP and biotin-11-dUTP) can be used in place of the biotin-16-dUTP.

The starting DNA template should be linear. Best results are obtained with isolated insert DNA that is ≥ 200 bp. The use of shorter templates will lead to ineffective probe synthesis because of the inability for many random primers to bind on a short target. The amount of template that can be labeled by this procedure ranges from 25 ng to 2 μ g.

Materials

Linear template DNA
Biotinylated random octamers
dNTP/biotin mix
5 U/ μ l Klenow fragment (UNIT 3.5)
TE buffer, pH 7.5 (APPENDIX 2)
0.5 M EDTA, pH 8.0 (APPENDIX 2)
4 M LiCl
100% and 70% ethanol, ice-cold

1. Place 500 ng to 1 μ g template DNA in a 1.5-ml microcentrifuge tube. Add nuclease-free water to a total volume of 34 μ l.

Up to 2 μ g template DNA can be biotinylated without scaling up the reaction volumes.

2. Denature the DNA for 5 min in boiling water. Place on ice 5 min and microcentrifuge briefly.
3. Add the following to the sample in the order listed:
 - 10 μ l biotinylated random octamers
 - 5 μ l dNTP/biotin mix
 - 1 μ l (5 U) Klenow fragment.

Incubate 1 hr at 37°C.

If desired, an additional 2.5 U of Klenow fragment can be added after 30 min of incubation to "boost" the reaction. Continuing the incubation for up to 6 hr can increase the yield.

4. Terminate reaction by adding 3 μ l of 0.5 M EDTA, pH 8.0. Precipitate the probe by adding 5 μ l of 4 M LiCl and 150 μ l ice-cold 100% ethanol. Place 30 min on dry ice.
5. Microcentrifuge 10 min at top speed, room temperature, and wash DNA pellet with ice-cold 70% ethanol.
6. Resuspend DNA pellet in 20 μ l TE buffer, pH 7.5. Assess the quality of the biotinylation reaction by colorimetric (support protocol) or chemiluminescent (UNIT 3.19) detection.

Chemiluminescent detection is 5×10^3 times more sensitive than colorimetric detection (Beck and Koster, 1990).

COLORIMETRIC DETECTION OF BIOTINYLATED PROBES

This support protocol provides a method for checking the extent of the biotinylated incorporation into the labeled probe and serves as the basis for detecting biotinylated DNA probes hybridized to Southern blots. Because the detectability of biotinylated probes is a function of the number of biotin molecules per kilobase, rather than the specific activity of a corresponding radiolabeled probe, the extent of biotinylated deoxynucleotide incorporation is checked by a colorimetric assay (similar assessment can be made by chemiluminescent detection; *UNIT 3.19*). Under the standard nick translation conditions provided, ~50 biotin molecules are incorporated per kilobase of DNA.

In this procedure, biotinylated DNA is spotted on a nitrocellulose filter. The streptavidin–alkaline phosphatase conjugate binds strongly to the biotin and is visualized when the enzyme is provided with substrates that produce a colored precipitate. As little as 2 pg biotinylated DNA should be visible. If the protocol is being utilized as a method for detecting DNA probes by Southern analysis, follow standard Southern blot protocols (*UNIT 2.9*) substituting the biotinylated probe (~100 ng/ml) for the radiolabeled probe and proceed to steps 3 to 8 below.

Additional Materials

- Biotinylated standard DNA (basic protocols or GIBCO/BRL) and test DNA
- DNA dilution buffer
- Alkaline phosphatase pH 7.5 (AP 7.5) buffer
- Blocking buffer: 3% (w/v) BSA fraction V in AP 7.5 buffer
- 1 mg/ml streptavidin–alkaline phosphatase (AP) conjugate (GIBCO/BRL)
- Alkaline phosphatase pH 9.5 (AP 9.5) buffer
- 75 mg/ml nitroblue tetrazolium (NBT)
- 50 mg/ml 5-bromo-4-chloro-3-indoyl phosphate (BCIP)
- TE buffer, pH 8.0 (*APPENDIX 2*)

- Small piece of membrane (e.g., 5 × 3 cm²): nitrocellulose *or* uncharged nylon
- Sealable bags

NOTE: To avoid nonspecific background, wear powder-free gloves when handling the membranes.

1. Prepare biotinylated standard DNA in concentrations of 0, 1, 2, 5, 10 and 20 pg/μl in dilution buffer. Dilute the biotinylated test DNA in a similar fashion.

6× SSC in the dilution buffer prevents the DNA spot from spreading on the nitrocellulose, which diminishes the color intensity of the spot.

- 2a. *For nitrocellulose membrane:* Spot 1 μl of each dilution on a small piece of nitrocellulose. Bake the membrane ~1 hr at 80°C. Proceed directly to step 3.

*Nitrocellulose membranes cannot be used in chemiluminescent detection procedures (*UNIT 3.19*).*

- 2b. *For nylon membrane:* Spot 1 μl of each dilution on the nylon membrane. Air-dry and cross-link DNA to the membrane by UV illumination (*UNIT 3.19*). Proceed to step 3 or develop membrane as described for chemiluminescent detection (*UNIT 3.19*).

This cross-linking step is critical. If done incorrectly, ≤50% of the DNA can be washed off the membrane during the detection steps, resulting in inaccurate probe assessment.

If chemiluminescent detection is used, the test DNA should be diluted in a series from 10⁻¹ to 10⁻⁶, and must be visible at a 10⁻³ dilution. If it is not, the probe is not sufficiently biotinylated.

3. Float membrane in a small volume of AP 7.5 buffer for 1 min to rehydrate. Place membrane and 10 ml blocking buffer in a sealable bag (cut to size). Avoid trapping air bubbles when sealing. Block for 1 hr at 37°C.
4. Dilute 10 µl streptavidin–AP conjugate with 10 ml AP 7.5 buffer (1 µg/ml final). Cut corner of bag and squeeze out blocking buffer. Replace with the streptavidin–AP solution and reseal. Incubate 10 min at room temperature with agitation on a platform shaker.

Do not allow the membrane to dry out at any stage.

5. Remove membrane from bag and transfer to a shallow dish. Wash in 200 ml AP 7.5 buffer (twice, 15 min each time) and in 200 ml AP 9.5 buffer (once, 10 min) with gentle agitation.
6. Add 33 µl of 75 mg/ml NBT to 7.5 ml AP 9.5 buffer and invert to mix. Add 25 µl of 50 mg/ml BCIP and mix gently.

Be sure to add reagents in this order and mix gently to prevent precipitation of the reagents.

7. Incubate membrane with NBT/BCIP solution in a shallow dish in low light, checking periodically until color development is satisfactory (usually 15 to 60 min).
8. Stop reaction by washing with TE buffer, pH 8.0. Check incorporation of biotinylated dUTP by comparing the intensities of standard and test DNA. If the probe is at least half as intense as the standard DNA at the corresponding dilution, it should be suitable as an in situ hybridization probe.

PREPARATION AND DETECTION OF DIGOXIGENIN-LABELED DNA PROBES

ALTERNATE PROTOCOL

The digoxigenin-based detection system is an alternative nonisotopic labeling method offered by Boehringer Mannheim. Detection is achieved by incubation with antidigoxigenin antibodies coupled directly to one of several fluorochromes or enzymes, or by indirect immunofluorescence (*UNIT 14.6*). The availability of uncoupled antibodies also permits signal-amplification protocols to be employed. Biotin- and digoxigenin-labeled probes can be visualized simultaneously using a different fluorochrome for each probe.

Digoxigenin-11-dUTP can be incorporated into DNA by either of the nick translation or random oligonucleotide–primed synthesis protocols. Boehringer Mannheim advises that nick translation incorporation is not as efficient as random-priming; however, nick translation affords greater control over the final probe size. Nick translated probes perform well with in situ hybridizations, with no apparent sensitivity problems.

The protocol is virtually identical to that for biotin-11-dUTP incorporation by nick translation. The standard 100-µl reaction is set up as described in the basic protocol, but 10 µl of a 10× digoxigenin-11-dUTP/dTTP stock solution (see reagents and solutions) is substituted for 10 µl of a 10× biotin-11-dUTP stock solution. The amount of DNase I added to the sample and the time of incubation remain the same and do not depend on the modified deoxynucleotide in the reaction. After incubation at 15°C for 2 hr, an aliquot is run on a minigel to check the probe size. When the correct size has been obtained, the reaction is stopped and the probe is separated from the unincorporated nucleotides using a G-50 spin column. It is advisable to avoid phenol extraction of digoxigenin-labeled probes.

The support protocol for colorimetric detection of biotinylated probes can be modified for use with digoxigenin-labeled probes. If incorporation is to be checked, one can use as a control either digoxigenin-labeled standard DNA (obtained from Boehringer Mannheim as part of the Genius kit) or digoxigenin-labeled DNA that has already been used

Enzymatic Manipulation of DNA and RNA

3.18.5

successfully. Anti-digoxigenin antibody conjugated to alkaline phosphatase is substituted for streptavidin–alkaline phosphatase. Boehringer Mannheim recommends a 1:5000 dilution. The other steps in the support protocol are unchanged and can be followed exactly. A protocol for chemiluminescent detection of digoxigenin-labeled probes is discussed in *UNIT 3.19*.

REAGENTS AND SOLUTIONS

Alkaline phosphatase pH 7.5 (AP 7.5) buffer

0.1 M Tris·Cl, pH 7.5
0.1 M NaCl
2 mM MgCl₂
Autoclave or filter sterilize and store at room temperature

Alkaline phosphatase pH 9.5 (AP 9.5) buffer

0.1 M Tris·Cl, pH 9.5
0.1 M NaCl
50 mM MgCl₂
Autoclave or filter sterilize and store at room temperature ≤1 yr

Biotin-11-dUTP, 0.5 mM

Prepare a 0.5 mM stock of lyophilized biotin-11-dUTP (e.g., Sigma) in 20 mM Tris·Cl, pH 7.5 (at 289 nm, the molar extinction coefficient $\epsilon = 7100$; see Table A.3D.1). Check the pH of the stock; if <7.5, add a few microliters of 1 M Tris·Cl, pH 7.5, to adjust the pH to 7.5. Store at -20°C .

Biotinylated random octamers

Obtain commercially (e.g., Millipore or New England Biolabs) or prepare on a DNA synthesizer (*UNIT 2.11*). Prepare a 5 \times stock (60 O.D./ml) in 250 mM Tris·Cl, pH 8.0 (*APPENDIX 2*), 1 M HEPES, pH 6.6, 25 mM MgCl₂, and 10 mM DTT. Store at -20°C .

Digoxigenin-11-dUTP/dTTP, 10 \times stock

0.375 mM dTTP
0.125 mM digoxigenin-11-dUTP
20 mM Tris·Cl, pH 7.8
Store at -20°C

DNA dilution buffer

0.1 $\mu\text{g}/\mu\text{l}$ sheared salmon sperm DNA prepared in 6 \times SSC (*APPENDIX 2*)
Store at 4°C (for long-term storage, aliquot and store at -20°C)

dNTP/biotin mix

Prepare a mixture of 1 mM dATP, 1 mM dCTP, 1 mM dGTP, and 0.65 mM dTTP. Add biotin-16-dUTP (Enzo Biochem) to 0.35 mM final. Store at -20°C .

SDS column buffer

10 mM Tris·Cl, pH 8.0
1 mM EDTA
0.1% (w/v) SDS
Autoclave or filter sterilize

COMMENTARY

Background Information

Nonisotopically labeled probes have become increasingly popular in recent years, with researchers using them to complement or even replace radioactive probes in techniques such as in situ hybridization (Chapter 14), or Southern (UNIT 2.9) and northern (UNIT 4.9) blotting. These probes eliminate the concerns of working with radioisotopes and accumulating hazardous radioactive waste. A further advantage of this method of generating probes is their stability and long shelf life (~2 yr).

The synthesis of biotinylated nucleotides was first described by Langer et al. (1981). Biotin, a water-soluble vitamin, is covalently attached to the C5 position of the pyrimidine ring via an allylamine linker arm. Langer and colleagues demonstrated that biotin-11-dUTP can replace dTTP as a substrate for *E. coli* DNA polymerase I, although the initial incorporation rate is lower. Furthermore, denaturation and hybridization characteristics are basically unchanged (provided that incorporation does not exceed 50 biotin molecules/kb), making biotinylated probes suitable for nonisotopic in situ hybridization. The biotinylated dNTPs used in the protocols (biotin-11 and biotin-16-dUTP; biotin-14-dATP) vary in the length of the allylamine linker arm (i.e., biotin-16-dUTP has five more CH₂ groups than biotin-11-dUTP). The linker provides sufficient distance between the nucleotide and biotin to minimize steric hindrance between the synthesized probe and the streptavidin bridge needed for detection (see below).

For many, nick translation is the method of choice for biotinylating DNA and the technique outlined in UNIT 3.5 has been adapted successfully to incorporate biotinylated nucleotides (first basic protocol; Cherif et al., 1989). The DNA need not be linearized first, biotin incorporation is routinely efficient, and the probe length can be adjusted according to experimental needs. Although DNA fragments <500 nucleotides can be nick translated, oligomers are not labeled efficiently this way. Random-priming using biotinylated octamers (second basic protocol; Feinberg and Vogelstein, 1983) is probably a more efficient method for preparing biotinylated probes, as every probe molecule labeled will have at least one biotin reporter molecule incorporated into it. In addition, Moyzis et al. (1988) describe labeling oligomers with biotinylated nucleotides using terminal deoxynucleotidyl transferase (UNIT 3.6) and sub-

sequent use of these probes for in situ hybridization.

Biotin is detected directly by avidin or streptavidin conjugated to a fluorochrome or enzyme such as alkaline phosphatase or horseradish peroxidase (Lichter et al., 1988). Avidin is a 68,000-Da glycoprotein derived from egg white and has a very high affinity for biotin ($K_d = 10^{-15}$). Streptavidin is a 60,000-Da protein from *Streptomyces avidinii* that also has a high affinity for biotin ($K_d = 10^{-15}$). Either protein may be used for biotin detection. Reaction of the alkaline phosphatase conjugated to the avidin- or streptavidin-biotin complex with enzyme substrates results in formation of colored precipitates (support protocol). Detection of biotinylated and digoxigenin-labeled probes can also be accomplished via anti-biotin (Langer-Safer et al., 1982) or anti-digoxigenin antibodies, followed by a secondary antibody conjugated to a fluorochrome or enzyme.

Although there are many references in the literature for the use of biotinylated probes in Southern blotting, most researchers still prefer autoradiographic methods, citing superior sensitivity as the primary reason. With the advent of chemiluminescent techniques (UNIT 3.19; Carlson et al., 1990; Wilchek and Bayer, 1988) the use of biotinylated probes for Southern and northern blotting is becoming more common.

For in situ hybridizations, biotinylated probes are rapidly approaching the level of sensitivity afforded by using radioactively labeled probes. Detection of probes as small as 1 kb can be accomplished within a few hours post-hybridization. This is in contrast to using probes generated by isotopic techniques, where developing the emulsion film may take anywhere from several days to several weeks.

However, there are disadvantages to using biotinylated probes. First is the relative difficulty of determining the success of a probe synthesis. Unlike radioactive probes, one cannot get a quick gauge of the success of a biotinylation reaction by using a mini-monitor or by putting a sample in a scintillation counter. Biotinylated probes require a comparative dilution series with a known biotinylated standard (support protocol) and even then, quantitation is difficult because assessing the intensities cannot be done via densitometry. Second, biotinylated probes are inefficient in detecting extremely rare mRNA transcripts, because background noise of the membrane occurs at a rate constant to that of the signal.

Critical Parameters and Troubleshooting

In the nick translation protocol, optimal DNase I concentration must be determined by titration, as the size distribution of the probe depends on the amount of DNase I added. For nonisotopic *in situ* hybridizations, the optimal probe size is between 100 and 500 nucleotides, since larger probes sometimes have trouble accessing the target DNA and tend to cause increased background. Each new stock of DNase I should be tested when it is prepared to determine the appropriate working concentration. This is best accomplished by setting up several reactions and varying the amount of DNase I added. The time of incubation should not be shortened; at least 2 hr are necessary for optimal incorporation, as the initial incorporation rate of biotinylated nucleotides is less than that of unsubstituted dNTP. Even once a DNase I stock has been titrated, different amounts of the enzyme may be needed for different samples. In general, phage and miniprep DNA require more DNase I than CsCl-purified plasmid or cosmid DNA.

For optimal incorporation, the test DNA should be as free of impurities as possible. CsCl-purified DNA is nick translated more efficiently than miniprep DNA, although the latter can certainly be labeled successfully. Miniprep DNA should be treated with RNase A (UNIT 3.13), then reextracted and ethanol precipitated. Biotinylated DNA should never be phenol extracted, as biotin causes the DNA to partition to the phenol-water interface. It is advisable to avoid phenol when working with digoxigenin-labeled probes as well.

In the random-priming protocol, it is easy to forget the DNA denaturation that precedes the reaction. Biotinylation will not occur if the DNA is not denatured. As above, the optimal probe size for *in situ* hybridizations is 100–500 nucleotides and the parameters of this protocol account for this. If the probe yield is low (see below), increase the incubation (step 3) up to 6 hr and add an additional 2.5 U Klenow enzyme to boost the reaction.

For the colorimetric detection protocol, nylon membranes must be cross-linked correctly (UNIT 3.19) to properly assess probe quality. If crosslinking is omitted, the signal will be much weaker and can account for the loss of $\leq 50\%$ of the DNA.

Anticipated Results

Nick translation of 2 μg DNA yields a biotinylated probe digested to a size range of 100 to

500 nucleotides at a final concentration of 20 ng/ μl . Approximately 50 biotin molecules/kb will be incorporated.

A random priming reaction that begins with 1 μg of starting template yields ~ 260 ng biotinylated probe. Because the random priming reaction uses biotinylated random octamers, every probe molecule that is generated contains at least 1 biotin molecule. Additional incorporation of biotinylated dUTP provides more highly biotinylated probes for increased sensitivity.

Colorimetric detection of the probe spotted on nitrocellulose using streptavidin-conjugated alkaline phosphatase should allow visualization of as little as 2 pg DNA. Note that nylon membranes can also be used in chemiluminescent detection procedures (UNIT 3.19); ≥ 100 fg of DNA can be detected in a standard dot blot assay.

Time Considerations

Setting up and incubating the nick translation reactions will take ~ 3 hr. During this time, the agarose minigel and spin columns can be prepared. Running, staining, and photographing the gel takes ~ 1 hr. If the probe is the proper size, the reaction can be terminated and loaded on the spin column and be ready to use in 15 min. Probes that are not sufficiently digested will require more time for additional incubation and gel steps. As long as EDTA and SDS are not added to the tubes, the reactions can be stored at -20°C for additional incubation at a later time. If dot blots are desired, an additional 3.5 to 4.5 hr will be required.

The random priming reaction requires ~ 2 hr to denature the DNA, incubate with the primers, and precipitate and recover the labeled product.

The detection procedure requires ~ 1.5 hr to dilute the samples and prepare the membrane, ~ 2 hr to link the streptavidin-AP conjugate to the samples on the membrane, and 15 to 60 min to develop the membrane.

Chemiluminescent Detection of Nonisotopic Probes

UNIT 3.19

With recent advances in techniques for detecting chemiluminescent substrates, hybridization with nonisotopic rather than radiolabeled probes is becoming more common. In the basic protocol, nylon membranes carrying transferred nucleic acids are prepared for hybridization with biotinylated probes (UNIT 3.18) by UV cross-linking. This is a critical step in the procedure and the support protocol provides a detailed description of light-source calibration. After hybridization, the target nucleic acid is detected through a series of steps that lead to an enzyme-catalyzed light reaction.

The alternate protocol describes chemiluminescent detection based upon antibody recognition of digoxigenin-labeled probes. For both biotinylated and digoxigenin-labeled probes, chemiluminescent detection is more sensitive than colorimetric detection (UNIT 3.18) and has the added advantage that the membrane can be used for multiple film exposures, then stripped and redetected with different probes.

CAUTION: Exposure to UV radiation poses a significant health hazard. Wear UV-protected goggles and shield exposed skin.

CHEMILUMINESCENT DETECTION OF BIOTINYLATED PROBES

This protocol describes the series of steps leading to the reaction of alkaline phosphatase with a chemiluminescent substrate that results in the highly sensitive detection of hybridized target DNA. Nylon membranes carrying immobilized nucleic acid are first subjected to UV cross-linking, then hybridized with biotinylated probes. Subsequent detection reactions link the biotinylated probes to alkaline phosphatase through a streptavidin bridge. The alkaline phosphatase then cleaves a chemiluminescent dioxetane substrate to give a localized light emission (Fig. 3.19.1). Many of the reagents used in the protocol are available commercially; Table 3.19.1 lists suppliers of these detection kits.

Materials

Uncharged nylon membrane blotted via neutral transfer with DNA (UNIT 2.9) or RNA (UNIT 4.9)

Biotinylated probes (UNIT 3.18)

Blocking solution

Wash buffers I and II

1 mg/ml streptavidin (see reagents and solutions)

0.38 mg/ml biotinylated alkaline phosphatase

Chemiluminescent dioxetane substrate (Table 3.19.2)

Substrate buffer, pH 9.6

Blotting paper (Whatman 3MM or equivalent)

Calibrated UV source (support protocol)

Heat-sealable hybridization bags

Additional reagents and equipment for Southern and northern hybridizations (UNITS 2.9 & 4.9)

Cross-link and hybridize the membrane

1. Fasten the corners of the blotted membrane to a dry piece of blotting paper, nucleic acid-side up, with paper clips. Place in an incubator and dry. The drying time and temperature can range from 15 to 30 min at 42° to 80°C. Alternatively, dry overnight at room temperature.

When dry, the membrane will have curled-up edges. It is very important that the membrane be completely dry to ensure even, reproducible cross-linking and successful detection.

2. Expose membrane, nucleic acid-side up, to the UV source. Cross-link for the calculated optimal time period.

Determine optimal cross-linking time as described in the support protocol. The UV source should have sufficient power at 254 nm to generate a minimum of 100 $\mu\text{W}/\text{cm}^2$. Most transilluminators have power outputs in the 500 to 1000 $\mu\text{W}/\text{cm}^2$ range. Hand-held lamps will have slightly lower outputs.

3. Hybridize membrane with biotinylated probes.

Both Southern (UNIT 2.9) and northern (UNIT 4.9) blots may be hybridized to biotinylated probes. Nitrocellulose membranes will quench the chemiluminescence reactions and must not be used.

Figure 3.19.2 Hybridization bag spout. After a buffer has been added to the bag, the spout is folded over and held closed with a bulldog clamp or several paper clips. It is important to leave sufficient room for the membrane to float free in solution and the bag should be free of trapped air to ensure maximum contact between the reagents and the membrane.

Detect the hybridized nucleic acids

The amount of wash and detection solutions needed during the procedure depend on the size of the membrane being used. Calculate the volume of the membrane as 1 vol (V) = membrane area ($\text{cm}^2 \times 0.05 \text{ ml/cm}^2$). For example, a 10×10 -cm membrane would have $V = 100 \text{ cm}^2 \times 0.05 \text{ ml/cm}^2 = 5 \text{ ml}$. All subsequent reaction volumes are based on this calculation.

4. Following hybridization, place membrane in a hybridization bag.

Be careful not to touch the membrane with bare hands or gloves that contain powder, as both oil and powder residues will contribute to nonspecific background on the membrane.

5. Seal bag, leaving a small area in one corner that can be made into a spout through which buffers can be easily added and removed (Fig. 3.19.2).
6. Carefully add 1 vol blocking solution to hybridization bag. Incubate 1 min at room temperature with moderate shaking. Drain and discard solution.
7. Add 1 mg/ml streptavidin to 1 vol blocking solution such that its final concentration is $1 \mu\text{g/ml}$ and add to hybridization bag. Incubate 4 min at room temperature with moderate shaking. Drain and discard solution.
8. Add 10 vol of wash buffer I to hybridization bag. Wash membrane 4 min at room temperature with moderate shaking. Drain and discard solution. Repeat once and discard solution.
9. Add biotinylated alkaline phosphatase to 1 vol blocking solution such that its final concentration is $0.5 \mu\text{g/ml}$ and add to hybridization bag. Incubate 4 min at room temperature with moderate shaking. Drain and discard solution.
10. Wash membrane twice as in step 9, using 10 vol of wash buffer II.
11. Dilute chemiluminescent dioxetane substrate to $1 \times$ final concentration with substrate buffer. Add 0.5 vol of substrate to hybridization bag. Incubate 4 min at room temperature with moderate shaking. Open bag and drain as thoroughly as possible.

The chemiluminescent substrate should be brought to room temperature before use.

Table 3.19.2 Chemiluminescent Substrates for Detection of Nonisotopic Probes^a

Dioxetane substrate	Buffer	Source ^c

^aAbbreviations: AMPPD, disodium 3-(4-methoxyspiro{1,2-dioxetane-3,2-tricyclo[3.3.1.1^{3,7}] decan}-4-yl)phenyl phosphate; CSPD, AMPPD with substituted chlorine group on adamantane chain; CTAB, cetyltrimethylammonium bromide; DEA, diethanolamine; Lumigen-PPD and Lumi-Phos 530: 4-methoxy-4-(3-phosphate phenyl)-spiro-(1,2,-dioxetane-3,2-adamantane), disodium salt.

^bLumi-Phos 530 has a fluorescence enhancer; Lumigen-PPD does not.

^cAbbreviations: BM, Boehringer Mannheim; GB, GIBCO/BRL; LU, Lumigen; MI, Millipore; NEB, New England Biolabs; TR, Tropic. Addresses and phone numbers of suppliers are provided in APPENDIX 4.

Observe chemiluminescent reaction

- Smooth out any wrinkles in bag and reseal. Place in a film cassette with the nucleic acid side of the membrane facing up and put X-ray film on top.

It is important that there be uniform contact between the bag and X-ray film to insure sharp images.

- Close cassette and expose 10 to 20 min.

The chemiluminescent reaction starts immediately and reaches a plateau after several hours, remaining constant for days. If necessary, adjust exposure times to optimize the signal.

ALTERNATE PROTOCOL

CHEMILUMINESCENT DETECTION OF DIGOXIGENIN-LABELED PROBES

An alternative to the biotinylated streptavidin–alkaline phosphatase method of detecting blotted nucleic acids is a system based on antibody detection—the digoxigenin system. It utilizes an anti-digoxigenin antibody conjugated to alkaline phosphatase which recognizes digoxigenin-dUTP that has been incorporated into the probe (UNIT 3.18). The detection procedure is similar to that for the biotinylated probes (basic protocol) except that longer blocking steps are required for the antibody detection.

A positively charged nylon membrane blotted with DNA (UNIT 2.9) or RNA (UNIT 4.9) is hybridized to a digoxigenin-labeled probe (UNIT 3.18). Chemiluminescent detection is based on the use of the Genius kit (Boehringer-Mannheim; see Table 3.19.1), the only kit that works with digoxigenin-labeled probes. Follow manufacturer's instructions for blocking, antibody-binding, and developing steps. The membrane is exposed to X-ray film for ~20 min. The enzymatic reaction reaches a steady state after 3 to 5 hr at room temperature. If necessary, adjust exposure times to optimize the signal. The membrane can be used for multiple exposures, and can be stripped and redetected with different probes.

CALIBRATING AN ULTRAVIOLET LIGHT SOURCE

SUPPORT PROTOCOL

Additional Materials

UV source: transilluminator, hand-held UV lamp, homemade box with germicidal bulbs, or cross-linker (e.g., Stratalinker, Stratagene #400071)
Radiometer and radiometer sensor

UV cross-linking of nucleic acids to nylon membrane is a critical step that significantly affects the quality of the data. Inadequate cross-linking will lead to insufficient binding and the nucleic acids will wash off the membrane. Excessive cross-linking renders the nucleic acids inaccessible to the probe. Therefore, calibration of the UV source is important.

UV sources are calibrated with a radiometer, which determines the power output in $\mu\text{W}/\text{cm}^2$. Radiation safety offices at academic research institutions can often provide radiometers for calibration. The UV light must be turned on and the bulbs warmed up for 1 to 2 min before calibration. The calibration procedure itself takes only a few minutes and should be repeated as the bulbs age. Transilluminator power output is calibrated at the glass surface and hand-held lamp output is calibrated at the distance at which the entire membrane will be evenly exposed to the UV light. The two Stratalinker instruments—models 1800 and 2400—have power outputs of 3000 and 4000 $\mu\text{W}/\text{cm}^2$, respectively.

Once the power output is measured, the optimal exposure time for the light source can be calculated as follows:

$$T = \frac{(33,000 \mu\text{W}/\text{cm}^2) (1 \text{ sec})}{P \mu\text{W}/\text{cm}^2}$$

where T is the exposure time in seconds and P is the power output of the UV source in $\mu\text{W}/\text{cm}^2$. For example, if the radiometer indicates a power output of 752 $\mu\text{W}/\text{cm}^2$, the time required for cross-linking with that transilluminator is:

$$T = \frac{(33,000 \mu\text{W}/\text{cm}^2) (1 \text{ sec})}{752 \mu\text{W}/\text{cm}^2} = 44 \text{ sec}$$

This determination can also be done empirically. Transfer duplicate lanes of nucleic acid to a membrane and expose different portions to UV light for increasing amounts of time varying by 1-min increments. Remember to cover previously exposed portions of the membrane with aluminum foil. There should be a marked difference in the amount of detectable and hybridizable nucleic acids.

REAGENTS AND SOLUTIONS

Biotinylated Alkaline Phosphatase

0.38 mg/ml biotin conjugate
3M NaCl
1 mM MgCl_2
0.1 mM ZnCl_2
30 mM triethanolamine acetate (TEA), pH 7.5
Store at 4°C

Blocking Solution

5% w/v SDS

17 mM Na₂HPO₄

8 mM NaH₂PO₄

Store at room temperature

Filter sterilize with a 0.45- μ m filter if necessary

Streptavidin, 1 mg/ml

Prepare a 1 mg/ml solution by reconstituting lyophilized streptavidin powder in 0.01 M sodium phosphate, pH 7.2/0.15 M NaCl/0.05% (v/v) NaN₃.

CAUTION: NaN₃ is hazardous. Handle very carefully.

To make a 0.01 M sodium phosphate (pH 7.4) solution, combine 68.4 ml of 0.1 M Na₂HPO₄ and 31.6 ml of 0.1 M NaH₂PO₄ and dilute 1:10 with H₂O.

Wash buffer I

Dilute blocking solution 1:10 with water just prior to use

Wash buffer II, 10 \times stock

100 mM Tris·Cl, pH 9.5

100 mM NaCl

10 mM MgCl₂

Prepare stock and store at 4°C

Dilute 1:10 with water just prior to use

COMMENTARY

Background Information

Chemiluminescent detection systems have proven to be particularly adaptable to current molecular biology techniques. The reaction is based on the use of enzyme-cleavable dioxetanes, first described by Schaap et al. (1987), and can be carried out at ambient temperature, in aqueous buffer, and at a moderate alkaline pH (for review, see Beck and Koster, 1990). Chemiluminescent detection can be used in Southern and northern hybridizations (UNITS 2.9 & 4.9); the UV cross-linking and membrane detection described here are simple variations on the traditional method of visualizing nucleic acids with radioactive probes. This technique has also been applied to DNA sequencing (Creasey et al., 1991) with the development of sequencing kits for this purpose (Uniplex and Multiplex sequencing kits, Millipore). Phage and colony hybridizations (UNITS 6.3 & 6.4) and immunoblotting and immunodetection (UNIT 10.8) also lend themselves to this technology and kits are available for these procedures as well (Amersham and U.S. Biochemicals).

The chemiluminescent substrate used in these protocols is typically a 1,2-dioxetane substituted with adamantyl and phosphate-protected aryl moieties (Fig. 3.19.1). The large adamantyl moiety imparts stability because of steric hindrance. To activate chemilumines-

cence, the following reactions are carried out. Streptavidin, which has several binding sites for biotin, is applied to the membrane and binds to the biotin incorporated into the probe. After washing, biotinylated alkaline phosphatase is added to the membrane and in turn binds the streptavidin. The streptavidin thus serves as a bridge linking alkaline phosphatase to the hybridized probe. Addition of chemiluminescent dioxetane substrates to alkaline phosphatase initiates cleavage of the phosphate group. The resulting 1,2-dioxetane anion decomposes to produce light (Fig. 3.19.1).

In addition to the obvious safety and disposal advantages, chemiluminescence affords several other benefits. The probes are stable and large amounts of probe can be synthesized at one time and stored, because only small amounts are used in an experiment. In addition, hybridization buffer containing the probe can be reused several times before the signal becomes weak. Another advantage is the sensitivity of the technique—chemiluminescent detection is 5×10^3 times more sensitive than colorimetric detection (Beck and Koster, 1990). Short exposure times are also advantageous—in many cases a 10- to 20-min exposure is all that is required. Moreover, the chemiluminescent reaction is sustained for many days; thus, one blot can easily be exposed many times. Furthermore, because the reaction

Table 3.19.3 Guide to Troubleshooting Chemiluminescent Detection Techniques

Problem	Possible cause	Solution
Low or insufficient signal	Insufficient biotin labeling—check by comparing sample and control dilution series	If probe is only visible at 10^{-1} and 10^{-2} dilutions, repeat the biotinylation reaction. If visible at dilutions of 10^{-3} or greater, consider other possible causes.
	Inadequate cross-linking	Make sure the membrane is completely dry before cross-linking. Calibrate UV source with a radiometer.
	Incorrect pH of the chemiluminescent substrate	Check pH of substrate buffer and adjust to pH 9.6.
Uniform or uneven high background	Inadequate washing	Increase number of washes, ensuring the membrane floats freely in bag during detection steps.
	Contaminated wash solutions	Mold can grow in the Wash I solution, leading to spotting on the membrane. Filter through a 0.45- μ m filter.
	Unbuffered blocking and Wash I solutions	Make sure that SDS solutions are made up in phosphate buffer as described.

produces light, photographic paper can be placed directly on the blot, eliminating the need to photograph data captured on X-ray film. However, photographic paper is significantly slower than X-ray film, and the exposure time must be increased. Finally, as for blots probed with radioactivity, those probed with chemiluminescence can be stripped and reprobed.

Critical Parameters

Several parameters are critical to the detection of chemiluminescent probes. Most important of these is the cross-linking of nucleic acids to the membrane. The membrane should be completely dry in order for cross-linking to be uniform and reproducible. The UV source should be calibrated either quantitatively or qualitatively (support protocol). If the nucleic acids are inadequately cross-linked, they will wash off the membrane. If the cross-linking is excessive, the nucleic acids will become inaccessible to the probe.

For detection, it is important that the pH of the substrate buffer be near pH 9.6 (a range of pH 9.5 to 9.7 is acceptable) to ensure optimal steady light emission. If the pH is too low, the reaction will be quenched and no light will be given off. If the pH is too high, the reaction will occur instantly and a flash of light will be given off. Nonfat dry milk, a popular component of

blocking solutions, cannot be used in this procedure because it contains biotin and will cause intense background problems.

It is important to adhere to the length of time detailed, as well as concentration of reagents needed, for both the streptavidin and the biotinylated alkaline phosphatase incubation steps. If either of these parameters is significantly altered, the signal:noise ratio will drastically change.

In the detection procedure, the minimum number of washes needed are detailed. If necessary, the wash times may be lengthened and the number of washes can be increased to eliminate background signal. The wash with buffer II directly precedes addition of the chemiluminescent substrate and is perhaps the most critical because it removes residual SDS and establishes the correct pH of the membrane. An attempt should be made to thoroughly drain the hybridization bag prior to adding the chemiluminescent reagent.

Troubleshooting

Low or insufficient signal and high or uneven background are two commonly encountered detection problems. Possible causes and solutions for these problems are described in Table 3.19.3.

Anticipated Results

Chemiluminescent visualization of Southern blots has proven to be sensitive enough to detect a single-copy gene from as little as 1 μ g of human genomic DNA. When applied to northern blots, this approach can detect abundant to mildly rare transcripts. At this time chemiluminescent detection is not recommended for the detection of very rare mRNA transcripts.

Time Considerations

Successful detection reactions can be done in ~30 min. Increasing in the duration of any of the wash steps will have little or no ill effect on the final results, but will obviously increase the total length of the protocol.

Recombinational Cloning

Large-scale experiments requiring protein expression from thousands of genes require an efficient method for cloning the genes into protein expression vectors. Traditional cloning methods based on restriction enzyme digestion and ligation are not practical. Recombinational cloning, by contrast, allows high-throughput cloning of genes into protein expression vectors. Recombinational cloning is based on site-specific recombination for transferring DNA sequences into multiple expression systems. It can be used to transfer a single insert into multiple different expression systems (Fig. 3.20.1), or to simultaneously transfer many different DNA sequences into a single expression vector.

The methods described in this unit are designed for use with two commercially available recombinational cloning systems, Gateway (a registered trademark of Invitrogen) and Creator (a registered trademark of BD Clontech). Basic Protocol 1 describes the amplification of target genes and addition of the required recombination sites by PCR, Basic Protocols 2 and 3 describe generation of master clones, and Basic Protocols 4 and 5 address generation of expression clones.

Figure 3.20.1 Advantages of universal cloning technology. Recombination-based universal cloning technology enables efficient parallel transfer of your favorite gene (YFG) from a master clone into various different expression systems for protein production and functional analysis.

AMPLIFICATION OF TARGET GENES BY PCR

The sequence of PCR primer used to amplify a gene sequence is composed of a gene-specific portion along with a common tail sequence for adding flanking recombination sites. If the required flanking recombination sequences are long, as is often the case in the Gateway scheme, the primers may acquire errors during their synthesis. In this case, the gene-specific primers can be designed to contain a tail sequence including only part of the recombination site. The rest of the recombination site can then be added efficiently by a secondary PCR employing a universal primer set (Gateway scheme; Fig. 3.20.2). It is best to use just one PCR step to build a recombination-competent fragment, which is usually possible with the Creator cloning scheme (Fig. 3.20.2).

All primers must have a similar melting temperature and must be anchored in start or stop positions of the open reading frame. The gene-specific 5' primer must start with ATG, and the 3' primer must start at the end of the common stop codon. On a practical level, such a primer is designed using bases from the relevant end (5' or 3') of the target sequence and adding additional bases until the desired melting temperature (often 60°C) is reached. The recombination sequence can be appended once the design of the gene-specific portion is complete (Fig. 3.20.3). The primers place the coding sequences in-frame with the recombination sites. The Kozak sequence is added in front of ATG in all 5' oligonucleotides for better protein expression; the common stop codon, in the case of the 3'-open oligonucleotide, can be changed to encode leucine to generate C-terminal fusion proteins.

Materials

- 10× *Pfx* amplification buffer (Invitrogen)
- 10× *PCRx* enhancer (Invitrogen)
- 10 mM 4dNTPs (Invitrogen)
- 50 mM MgSO₄

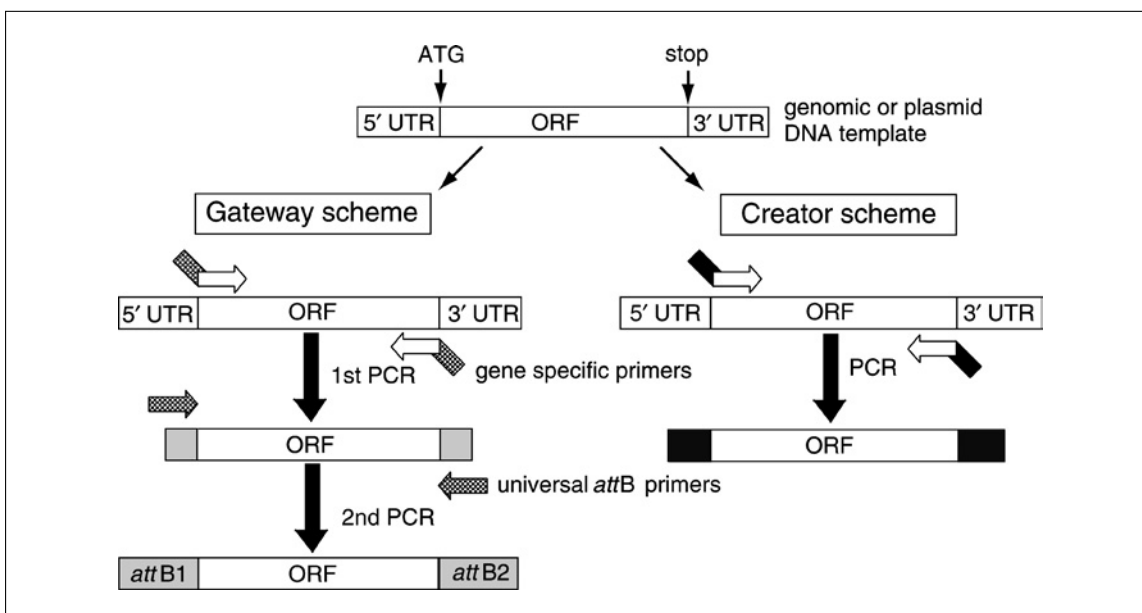

Figure 3.20.2 Schematic view of primer design and PCR amplification. Only the open reading frame (ORF) will be amplified from ATG to the stop codon, using gene-specific primers. Note that in the Gateway scheme the gene of interest will be amplified first with a gene-specific primer set (containing partial *attB* sequences) and then reamplified with a universal primer set. In the Creator scheme only one primer set is used.

Gateway scheme		
gene specific	5' oligo	5'- <u>AAAGCAGGCTCCACC</u> ^{Kozak} <i>atg[18-25 gene-specific nucleotides]</i> -3'
	3' closed oligo	5'- <u>ACAAGAAAGCTGGGTC</u> <i>cta[18-25 gene-specific nucleotides]</i> -3' stop anticodon
	3' open oligo	5'- <u>ACAAGAAAGCTGGGTC</u> <i>caa[18-25 gene-specific nucleotides]</i> -3' Leu anticodon
universal	5' oligo	5'-GGGGACAAGTTTGTACAAA <u>AAAGCAGGCTCCACC</u> <i>atg</i> -3'
	3' oligo	5'-GGGGACCACTTTGTACA <u>AAAGCTGGGT</u> -3'
Creator scheme		
	5' oligo	5'- <u>GAAGTTATCAGTCGACACC</u> ^{Kozak} <i>atg[18-25 gene-specific nucleotides]</i> -3'
	3' closed oligo	5'- <u>ATGGTCTAGAAAGCTTCC</u> <i>cta[18-25 gene-specific nucleotides]</i> -3' stop anticodon
	3' open oligo	5'- <u>ATGGTCTAGAAAGCTTCC</u> <i>caa[18-25 gene-specific nucleotides]</i> -3' Leu anticodon

Figure 3.20.3 Sequence information for primers. Kozak sequences (CACC) were placed just in front of ATG sequences in both schemes. In the Gateway scheme, the partial *att* sequences are underlined in the case of gene-specific primers. Universal primers contain complete *att* sequences and the matching sequences to gene-specific primers are underlined. In the Creator scheme, the homologous sequences to pDNR-Dual vector are underlined. To obtain C-terminal fusion proteins in the case of open primers in both schemes, the common stop anticodon (CTA) is changed to the leucine anticodon (CAA).

2.5 U/μl *Pfx* DNA polymerase (Invitrogen)

DNA template: 10 ng/μl first-strand cDNA mix (1:4 brain/placenta) or 20 ng/μl plasmid DNA

830 nM gene specific 5'-oligonucleotide primer in sterile H₂O (for primer design see Basic Protocol 1 introduction)

830 nM gene specific 3'-oligonucleotide primer in sterile H₂O (for primer design see Basic Protocol 1 introduction)

200 μM universal 5'-oligonucleotide primer (BD Clontech; dilute from stock with sterile H₂O and store up to 6 months at -20°C)

200 μM universal 3'-oligonucleotide primer (BD Clontech; dilute from stock with sterile H₂O and store up to 6 months at -20°C)

PCR tubes (thin-walled) or 96-well plates

Multichannel pipettor (optional)

Thermal cycler

Perform first-round PCR

1. Prepare the master mix for the first-round 50-μl PCR (multiply the volume for each component by the number of reactions plus two or three to allow for losses during transfer) as follows (38 μl per tube or well):

5 μl 10× *Pfx* amplification buffer (1× final)

5 μl 10× PCR_x enhancer (1× final)

1.5 μl 10 mM 4dNTPs (0.3 mM final)

1 μl 50 mM MgSO₄ (1.0 mM final)

0.4 μl 2.5 U/ml *Pfx* DNA polymerase (1 U final)

10 μl DNA template (100 or 200 ng final)

15.1 μl PCR-quality H₂O.

For cloning human genes, a first-strand cDNA mix of brain plus placenta (1:4) works well as template. First-strand cDNA, 100 ng per reaction, can be added to the master mix. To clone genes from specific tissue sources or other organisms, genomic DNA or an appropriate first-strand cDNA sample can be used (see UNIT 5.5 & 15.5 for making first-strand cDNA).

Prepare plasmid DNA using any commercially available miniprep kit or standard miniprep method (e.g., UNIT 1.6), but note that the DNA quantitation (APPENDIX 3D) is important. A total of 200 ng of plasmid DNA should be sufficient.

2. Dispense 38 μ l master mix into PCR tubes for individual reactions or into each well of a 96-well plate for a large-scale format.

For 96-well plate format a multichannel pipettor should be used.

3. Add 6 μ l 830 nM gene-specific 5'-oligonucleotide primer and 6 μ l 830 nM gene-specific 3'-oligonucleotide primer to each reaction (final concentration 100 nM each primer).

When primer stocks are delivered at 200 μ M, they may be diluted to 830 nM in two steps. (1) Add 5 μ l primer stock to 115 μ l PCR quality water and mix well. (2) Add 20 μ l diluted primer to 180 μ l PCR-quality water and mix well.

- 4a. For amplification with first-strand cDNA as a template: Carry out PCR using the following amplification cycles:

Initial step:	2 min	94°C	(denaturation)
20 cycles:	15 sec	94°C	(denaturation)
	1 min	52°C	(annealing)
	4 to 6 min	68°C	(extension)
Final step:	12 min	68°C	(polishing).

- 4b. For amplification with plasmid DNA as a template: Carry out PCR using the following amplification cycles:

Initial step:	2 min	94°C	(denaturation)
6 cycles:	15 sec	94°C	(denaturation)
	1 min	52°C	(annealing)
	4 to 6 min	68°C	(extension)
Final step:	12 min	68°C	(polishing).

For target ORF sequences <2 kb, an extension time of 4 to 6 min is enough. If the target is larger (2 to 4 kb), extension times of up to 8 to min are recommended. The extension time for larger genes (>4 kb) should be determined experimentally.

For the Creator cloning scheme, as little as a total of 15 cycles for first-strand cDNA or 6 cycles for plasmid DNA have been shown to amplify enough PCR fragments for use with In-Fusion enzyme reactions in creating master clones (unpub. observ). Amplification with a second primer set is not needed. Proceed to step 9.

Perform second-round PCR (Gateway system only)

5. Prepare the master mix for the second-round 50- μ l PCR (multiply the volume for each component by the number of reactions plus two or three to allow for losses during transfer) as follows (30 μ l per tube or well):

0.125 μ l 200 μ M universal 5' primer (0.5 μ M final)

0.125 μ l 200 μ M universal 3' primer (0.5 μ M final)

3 μ l 10 \times Pfx amplification buffer (1 \times final)

3 μl 10 \times PCR \times enhancer (1 \times final)
1.5 μl 10 mM 4dNTPs (0.3 mM final)
0.6 μl 50 mM MgSO₄ (1.0 mM final)
0.4 μl 2.5 U/ μl Pfx DNA polymerase (1 U final)
21.25 μl PCR-quality H₂O.

6. Aliquot 30 μl of the master mix into fresh PCR tubes or 96-well plates.
7. Add 20 μl amplified DNA from step 4a or 4b.
8. Carry out PCR using the following amplification cycles:

Initial step:	2 min	94°C	(denaturation)
6 cycles:	15 sec	94°C	(denaturation)
	1 min	52°C	(annealing)
	4 to 6 min	68°C	(extension)
Final step:	12 min	68°C	(polishing).

9. Store amplified DNA up to 6 months at -20°C . Proceed to purification (see Support Protocol) or preparation of the master clone (see Basic Protocol 2 or 3).

RAPID GEL PURIFICATION OF PCR PRODUCTS

Amplification of a gene of interest from known plasmid DNA template using PCR is almost 100% efficient in generating the expected PCR fragment; however, it has been observed that several additional minor products can be amplified from the first-strand cDNA mix. Small products, especially in the Gateway scheme, will recombine with higher efficiency than the larger expected product, resulting in vectors containing aberrant sequences instead of the desired product. Moreover, PCR reaction mixtures may contain unused recombination site primers that could later interfere with the site-specific recombination reaction. When smaller, nonspecific PCR products are present in the reaction, it is advisable to purify the desired PCR products using agarose gel electrophoresis to avoid cloning contaminants or undesirable PCR products.

Materials

PCR samples (Basic Protocol 1)
GelStar nucleic acid stain (Cambrex; <http://www.cambrex.com>)
Razor blades *or* 15-ml syringe with attached intramedic polyethylene tubing (Becton Dickinson PE330) or comparable
Low-frequency UV light table
Eye protection for UV light
Filter tubes (Ultrafree-DA) and collection tubes (Millipore) *or* 96-well filter plates (Unifilter 350 GF/D plate) and collection plates (Millipore or equivalent)
Benchtop centrifuge (adaptor for 96-well plates, optional)
Additional reagents and equipment for agarose gel electrophoresis (UNIT 2.5A) and determination of DNA concentration (APPENDIX 3D)

1. Prepare a 1% agarose gel containing 0.001% (v/v) GelStar nucleic acid stain, load PCR samples, and run the gel (see UNIT 2.5A).

In large cloning projects, a saw-tooth well arrangement will reduce the chance of contamination from neighboring bands (see Critical Parameters and Troubleshooting).

SUPPORT PROTOCOL

Enzymatic Manipulation of DNA and RNA

3.20.5

- After separation, excise bands using a razor blade or a 15-ml syringe with intramedic polyethylene tubing, while visualizing the bands with GelStar nucleic acid stain on a low-frequency UV light box. Collect the gel fragments into filter tubes for individual clones or into wells of a 96-well filter plate for larger-scale experiments.

Stiff tubing mounted on a 15-ml syringe allows quick excision of the bands and rapid ejection (under air pressure) into the filter plate. After ejecting the plugged band, cut off the tip of the tubing to create a clean end for the next band extraction.

- Place the filter tube into a new collection tube. For large-scale experiments, place the filter plate on top of a matching empty 96-well collection plate.
- Freeze the plate at -20°C for 1 hr, then thaw quickly at 37°C .

This step is optional because most PCR fragments <2 kb can be eluted easily without it. This step helps for fragments >2 kb.

- Centrifuge 15 min at $3000 \times g$, room temperature.

The eluate contains the DNA fragment, which can be verified by examining over a UV box.

- Discard the top filter tube or plate. Store the bottom tube or plate up to 6 months at -20°C . Determine DNA concentration (see APPENDIX 3D)

BASIC PROTOCOL 2

CAPTURE OF ORFS TO MAKE MASTER CLONES FOR THE GATEWAY SYSTEM: BP REACTION

The amplified PCR fragment of a gene of interest must first be transferred into a master vector to generate a master clone. The transfer process requires recombination between the PCR fragment and the master vector. This protocol describes the BP recombination reaction, so called because it mediates transfer of a gene of interest from an *attB*-PCR fragment or *attB*-expression clone to an *attP*-containing master vector to create a master clone (Fig. 3.20.4). For an efficient BP reaction, the *attB* substrate should be in linear form (PCR fragment or restriction-digested linearized plasmid), and the *attP*-containing master vector should be supercoiled. Because the master vector has the *ccdB* gene, which is toxic to common *E. coli* strains, the *ccdB*-resistant *E. coli* strain DB3.1 is used for propagation of any *ccdB*-containing vectors. M13 forward and reverse primers can be used for sequence verification of master clone DNA.

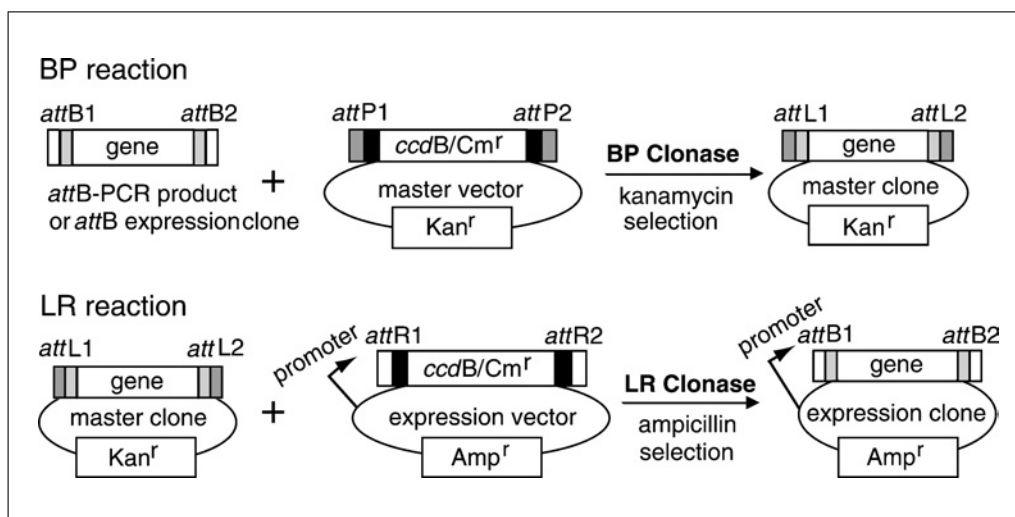

Figure 3.20.4 Gateway BP and LR reactions. BP and LR Clonase (registered trademarks of Invitrogen) facilitate the recombination between *attB* and *attP* and between *attL* and *attR*, generating *attL* and *attB* sequences, respectively.

Materials

- 150 ng/μl master vector (e.g., pDONR221; Invitrogen)
- 5× BP Clonase buffer (Invitrogen)
- BP Clonase enzyme mix (Invitrogen)
- 10 to 20 ng/μl *attB*-PCR product: prepared according to the Gateway scheme (Basic Protocol 1) and purified (Support Protocol)
- 2 μg/μl proteinase K (Invitrogen)
- LB plates supplemented with 50 μg/ml kanamycin (or other appropriate antibiotic; *UNIT 1.1*)
- LB medium supplemented with 50 μg/ml kanamycin (or other appropriate antibiotic; *UNIT 1.1*)
- 50% (v/v) glycerol, sterile
- Plasmid DNA isolation kit (e.g., Qiagen; optional)
- 96-well plate or 1.5-ml microcentrifuge tubes
- Multichannel pipettor
- 25°C incubator (optional)
- Additional reagents and equipment for growth of *E. coli* competent cells (*UNIT 1.8*), DNA miniprep (*UNIT 1.6*), and DNA sequencing (Chapter 7)

1. Prepare the master reaction mix on ice for the 10-μl BP reaction (multiply the volume for each component by the number of reactions plus two or three to allow for losses during transfer) as follows (5 μl per tube or well):

- 1 μl 150 ng/μl pDONR221 (15 ng/μl final)
- 2 μl 5× BP Clonase buffer (1× final)
- 2 μl BP Clonase enzyme mix.

2. Dispense 5 μl master reaction mix into 1.5-ml microcentrifuge tubes or each well of a 96-well plate.

For the 96-well plate format, a multichannel pipettor should be used.

3. Add 5 μl 10 to 20 ng/μl PCR product (50 to 100 ng).

3. Incubate 1 hr at 25°C.

Although, the manufacturer's instructions call for incubation at room temperature, reactions incubated at a controlled temperature of 25°C are more robust.

4. Add 2 μl 2 μg/μl proteinase K solution and incubate 10 min at 37°C.

5. Add 1 to 2 μl BP reaction mixture to 50 μl *E. coli* competent cell culture, and perform transformation.

The BP reaction mixture may be stored up to 6 months at -20°C.

Transformation efficiency of $>1 \times 10^8$ cfu/μg DNA is recommended. Successful transformation with larger genes can sometimes be increased by using cells with higher transformation efficiencies.

Refer to UNIT 1.8 for more information about bacterial transformation.

6. Plate the transformation mix on an LB plate supplemented with 50 μg/ml kanamycin.

Antibiotics should be carefully chosen to be appropriate to the master vector (in this case, pDONR221).

7. Incubate the plate overnight at 37°C.
8. Pick several (one to four) colonies and inoculate each into 1 ml LB medium containing 50 µg/ml kanamycin. Incubate overnight at 37°C.
9. Combine 0.7 ml overnight culture with 0.3 ml 50% (v/v) glycerol and store up to 6 months at –80°C.
10. Isolate plasmid DNA from the remainder of the culture using standard miniprep methods (e.g., *UNIT 1.6*) or a commercial kit (e.g., Qiagen).
11. Sequence the master clone plasmid DNA covering the ORF and recombinational sequence region (see Chapter 7). Verify the sequence against the targeted DNA sequence information using bioinformatics tools (e.g., BLAST at <http://www.ncbi.nlm.nih.gov/blast> or Sequencher at <http://www.genecodes.com/sequencher>).

The BP reactions are not perfect. Smaller fragments can be cloned more efficiently than the desired fragment and occasionally aberrant recombination products can be observed.

It is highly recommended to fully sequence the insert and recombination sites to confirm that the correct, high-quality clone is captured in the master vector.

The authors usually pick four isolates per gene, fully sequence them, and choose only one isolate to represent the high-quality, fully sequenced clone.

Once validated, it is not necessary to verify the sequence again in the expression clone. Refer to Chapter 7 for more information.

12. Pick the clone with the highest quality gene sequence.

**BASIC
PROTOCOL 3**

CAPTURE OF ORFS TO MAKE MASTER CLONES FOR THE CREATOR SYSTEM: IN-FUSION CLONING

Capturing the coding sequences into the Creator master vector is mediated by homologous recombination between the end sequences of PCR fragments and the end sequences of linearized master vector (Fig. 3.20.5). Thus, there are no sequence constraints on this flanking sequence as long as the ends of the PCR product match the ends of the linearized master vector; therefore, this reaction can work well with other vector and sequence combinations. Moreover, because this reaction is based on homologous recombination, many thermostable polymerases in addition to the In-Fusion enzyme listed here, could be adapted to this process. In theory, any proofreading thermostable DNA polymerase can be adapted with enhancer agents (i.e., DMSO, polyethyleneglycol (PEG), *E. coli* single-stranded DNA-binding protein (SSB), Gene 32 protein) instead of commercial In-Fusion enzyme kit (BD Clontech). M13 or T7 forward primers can be used for DNA sequencing.

Materials

- 20 U/µl In-Fusion polymerase (BD Clontech; diluted from 10× stock before use with provided buffer)
- 500 µg/ml bovine serum albumin (BSA)
- 10× In-Fusion reaction buffer (BD Clontech)
- 100 ng/µl linearized pDNR master vector (BD Clontech)
- 10 to 20 ng/µl PCR product: prepared according to the Creator scheme (Basic Protocol 1) and purified (Support Protocol)
- TE buffer, pH 8.0 (*APPENDIX 2*)
- E. coli* high-efficiency competent cell culture (e.g., DH5α; Invitrogen)
- LB plates supplemented with 100 µg/ml ampicillin (or other appropriate antibiotic) and 40 µg/ml Xgal (*UNIT 1.1*)

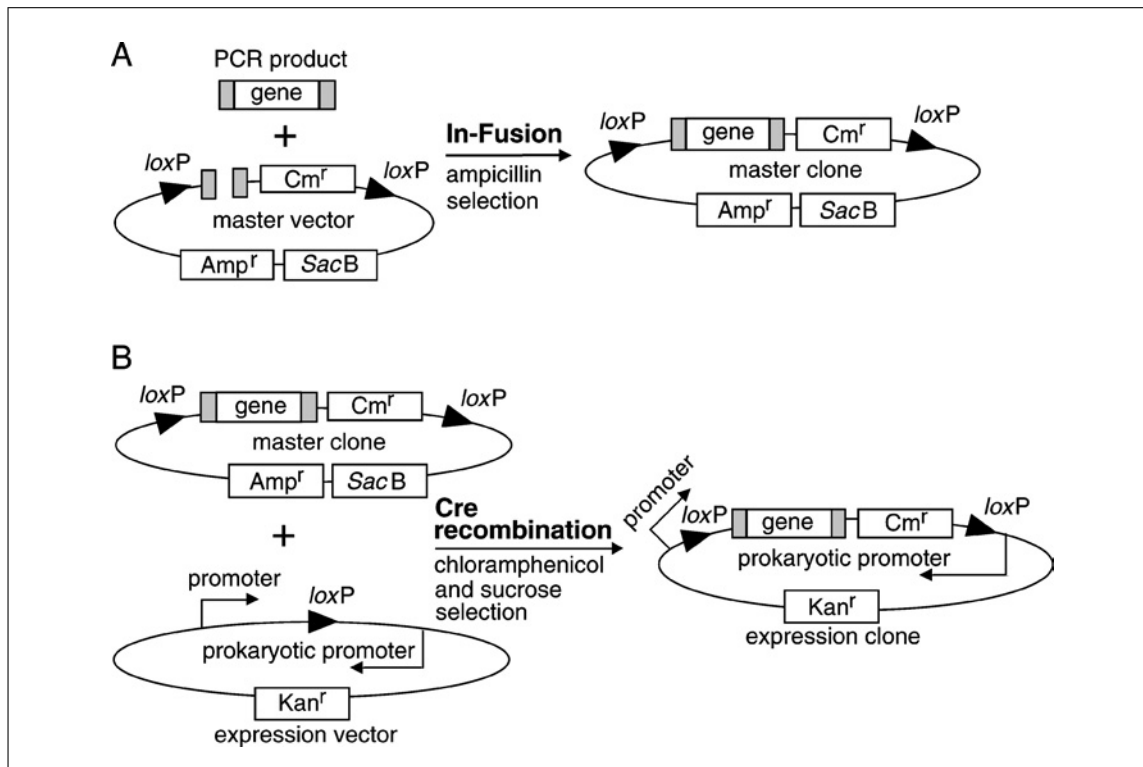

Figure 3.20.5 Schematic diagram of Creator In-Fusion and Cre transfer reactions. In-Fusion facilitates the homologous sequence recombination between PCR product and linearized pDNR-Dual vector. Cre facilitates the transfer of the insert from master clone to expression vector generating expression clones. The chloramphenicol resistance (Cm^r) gene is then under the control of the prokaryotic promoter and is actively expressed.

LB medium supplemented with 100 µg/ml ampicillin (or other appropriate antibiotic; *UNIT 1.1*)

50% (v/v) glycerol, sterile

Plasmid DNA isolation kit (e.g., Qiagen; optional)

96-well plate or 1.5-ml-microcentrifuge tubes

Multichannel pipettor

25°C incubator (optional)

Additional reagents and equipment for growth of *E. coli* competent cells (*UNIT 1.8*), DNA miniprep methods (*UNIT 1.6*) and DNA sequencing (see Chapter 7)

1. Prepare the master reaction mix on ice for the 10-µl In-Fusion reaction (multiply the volume for each component for the number of reactions plus two or three to allow for losses during transfer) as follows (3 µl per tube or well):

0.5 µl 20 U/µl diluted In-Fusion polymerase (10 U final)

1 µl 500 µg/ml BSA (500 ng final)

1 µl 10× In-Fusion reaction buffer (1× final)

0.5 µl 100 ng/µl linearized pDNR master vector (50 ng final).

2. Dispense 3 µl master reaction mix into 1.5-ml microcentrifuge tubes or each well of a 96-well plate.

For 96-well plate format, a multichannel pipettor should be used.

3. Add 7 μ l 10 to 15 ng/ μ l PCR product (50 to 100 ng).
4. Incubate 30 min at 25°C.

Although, the manual calls for room temperature, reactions incubated at a controlled temperature of 25°C are more robust. A longer incubation time is not beneficial.
5. Dilute the reaction mix with 20 μ l TE buffer, pH 8.0.
6. Add 2.5 μ l of In-Fusion reaction mixture to 50 μ l *E. coli* high-efficiency competent cell culture and perform transformation.

Transformation efficiency of $>1 \times 10^8$ cfu/ μ g DNA is recommended. Low efficiencies may result in failed reactions. Do not use more than 5 μ l of diluted reaction mix for 50 μ l competent cells.

Refer to UNIT 1.8 for more information about bacterial transformation.
7. Plate the transformation mix on an LB plate supplemented with 100 μ g/ml ampicillin and 40 μ g/ml Xgal.

Antibiotics should be carefully chosen to be appropriate to the master vector (in this case, pDNR).
8. Incubate the plate overnight at 37°C.
9. Pick several (one to four) white colonies and inoculate each into 1 ml LB medium containing 100 μ g/ml ampicillin. Incubate overnight at 37°C.
10. Proceed as in Basic Protocol 2, steps 9 through 12, to create glycerol stock cultures and sequence plasmid DNA covering the ORF and recombinational sequence region.

Even though the blue-white selections work well, it is necessary to verify the identity of the master clone insert by sequencing.

**BASIC
PROTOCOL 4**

GENERATING GATEWAY EXPRESSION CLONES

Expression clones are generated by the LR reaction between the *attL*-containing master clone and *attR*-containing Gateway-compatible expression vectors (see Fig. 3.20.4). Either the commercial Gateway expression vectors or Gateway-compatible expression vectors generated in-house can be used. Conversion to a Gateway-compatible vector involves a simple insertion of a blunt-ended conversion cassette by ligation into the blunt-ended expression vector that is to be adapted to the Gateway system. The conversion cassette, commercially available for the Gateway system, includes a *ccdB* death gene and a chloramphenicol resistance (*Cm^r*) gene flanked by *attR* sites at the ends (Fig. 3.20.6).

Materials

- Expression vector (e.g., pDual; Stratagene; or any expression vector with a different selectable marker than the master clone)
- Appropriate restriction enzymes (e.g., NEB)
- T4 DNA polymerase *or* Klenow fragment (e.g., NEB)
- Calf intestine alkaline phosphatase (CIAP) and buffer (e.g., NEB; optional)
- TE buffer, pH 8.0 (APPENDIX 2)
- T4 DNA ligase and buffer (e.g., NEB)
- Gateway recombination cassette (rfA, rfB, or rfC; Invitrogen), for making in-house Gateway-compatible expression vectors
- Sterile H₂O
- E. coli* competent cell cultures (e.g., DB3.1 and DH5 α ; Invitrogen)
- LB plates supplemented with 30 μ g/ml chloramphenicol (or other antibiotic appropriate for the expression vector; UNIT 1.1)

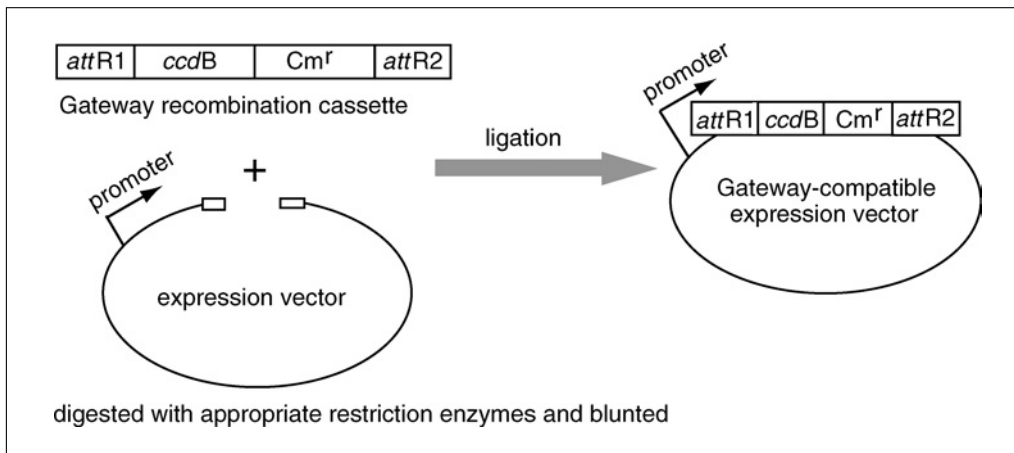

Figure 3.20.6 Conversion of an expression vector into a Gateway-compatible vector. An expression vector of choice is linearized and blunted at favorable restriction sites. It is then ligated with an available blunt-ended cassette containing *ccdB* and *Cm^r* genes. The Gateway-compatible expression vector sequence should be analyzed to confirm the correct orientation.

- LB medium supplemented with 30 $\mu\text{g}/\text{ml}$ chloramphenicol (or other antibiotic appropriate for the expression vector; *UNIT 1.1*)
- 50% (v/v) glycerol, sterile
- 150 ng/ μl Gateway expression vector (e.g., pDEST27; Invitrogen), for commercial expression vector
- LR Clonase (Invitrogen)
- 5 \times LR Clonase buffer (Invitrogen)
- 150 ng/ μl master clone plasmid DNA (Basic Protocol 2)
- 2 $\mu\text{g}/\mu\text{l}$ proteinase K (Invitrogen)
- LB plates supplemented with 100 $\mu\text{g}/\text{ml}$ ampicillin (or other appropriate antibiotic; *UNIT 1.1*)
- LB medium supplemented with 100 $\mu\text{g}/\text{ml}$ ampicillin (or other appropriate antibiotic; *UNIT 1.1*)
- 96-well plates or 1.5-ml microcentrifuge tubes
- Multichannel pipettor
- 25°C incubator
- Additional reagents and equipment for growth of *E. coli* competent cells (*UNIT 1.8*), linearizing the expression vector at the multiple cloning sites using restriction enzymes (*UNIT 3.1*), generating blunt ends using T4 DNA polymerase or Klenow fragment (*UNITS 3.5 & 3.16*), and analyzing plasmid DNA using restriction enzymes (*UNIT 3.1*)

Prepare a Gateway-compatible expression vector (optional)

1. Linearize the expression vector at the multiple cloning sites using restriction enzymes (*UNIT 3.1*), and generate blunt ends using T4 DNA polymerase or Klenow fragment (*UNITS 3.5 & 3.16*).
If necessary, perform dephosphorylation using CIAP (see UNIT 3.10) to decrease background from self-ligation of the vector.
2. Adjust the linearized expression vector to a final concentration of 20 to 50 ng/ μl in TE buffer, pH 8.0.
3. Prepare the ligation reaction mix in a microcentrifuge tube as follows:
 - 1 to 5 μl of 20 to 50 ng/ μl dephosphorylated linearized vector
 - 1 μl 10 \times T4 DNA ligase buffer
 - 2 μl 5 ng/ μl Gateway recombination cassette

1 μl 1 U/ μl T4 DNA ligase
Sterile H_2O to a final volume of 10 μl .

If a polypeptide fusion is to be added at either end of the gene, ensure that the Gateway recombination cassette is in the appropriate reading frame.

4. Incubate 1 hr at room temperature.
5. Add 1 to 2 μl reaction mixture to 50 μl *E. coli* DB3.1 competent cell culture and perform transformation.

DB3.1 is a strain modified to allow growth of plasmids containing ccdB. Cells other than DB3.1 will be killed by the new expression vector that will carry a copy of the ccdB death gene.

Transformation efficiency of $>1 \times 10^8$ cfu/ μg DNA is recommended.

Refer to UNIT 1.8 for more information about bacterial transformation.

6. Plate the transformation mix on an LB plate supplemented with 30 $\mu\text{g}/\text{ml}$ chloramphenicol. Incubate overnight at 37°C.

Antibiotics should be carefully chosen to be appropriate to the recombination cassette (in this case chloramphenicol).

7. Pick several (one to four) colonies and inoculate each into 1 ml LB supplemented with 30 mg/ml chloramphenicol. Incubate overnight at 37°C.

8. Combine 0.7 ml overnight culture with 0.3 ml 50% glycerol and store up to 6 months at -80°C .

9. Isolate plasmid DNA from the remainder of the culture using standard miniprep methods (e.g., UNIT 1.6) or a commercial kit (e.g., Qiagen). Analyze plasmid DNA using appropriate restriction enzymes (UNIT 3.1) or by sequencing to identify clones with the proper orientation. Quantify plasmid DNA from a selected clone (APPENDIX 3D).

Transformants need to be screened for orientation because both orientations will be generated after blunt-end ligation. Appropriate restriction enzymes will cut the vector and cassette in an asymmetric fashion, yielding fragment lengths that depend on orientation.

Transfer an ORF into the expression vector using the Gateway LR reaction

10. Prepare the master reaction mix on ice for the 20- μl LR reaction (multiply the volume for each component for the number of reactions plus two or three to allow for losses during transfer) as follows (18 μl per tube or well):

2 μl 150 ng/ μl commercial Gateway (e.g., pDEST27) or Gateway-compatible (from step 9) expression vector
4 μl LR Clonase
4 μl 5 \times LR Clonase buffer
8 μl TE buffer, pH 8.0.

11. Mix well and dispense 18 μl master reaction mix into each well of a 96-well plate or 1.5-ml microcentrifuge tube.

For a 96-well plate format, a multichannel pipettor should be used.

12. Add 2 μl master clone plasmid DNA to the 18 μl master reaction mix.

13. Incubate the reaction 1 hr at 25°C.

Although, the manual calls for room temperature, reactions incubated at a controlled temperature of 25°C are recommended.

14. Add 2 μl proteinase K solution and incubate at 37°C for 10 min.
The reaction mixture can be stored up to 6 months at –20°C after this step.
15. Add 2 to 3 μl of reaction mixture to 50 μl *E. coli* competent cell culture (e.g., DH5 α) and perform transformation.
Any standard cloning strain is fine.
Transformation efficiency of $>1 \times 10^8$ cfu/ μg DNA is recommended.
Refer to UNIT 1.8 for more information about bacterial transformation.
16. Plate the transformation mix on an LB plate supplemented with 100 $\mu\text{g}/\text{ml}$ ampicillin. Incubate overnight at 37°C.
Antibiotics should be carefully chosen to be appropriate to the expression vector, in this case, ampicillin for the commercial vector pDEST27.
17. Pick colonies and analyze the plasmid DNA using restriction enzymes.
Typically, the transfer reaction is very efficient (90% to 95%). For large-scale projects, in many cases, it is not necessary to pick several colonies and analyze them.
18. Choose the best clone and prepare for the desired use or store as a 15% glycerol stock up to 6 months at –80°C.

GENERATING CREATOR EXPRESSION CLONES

Cre recombinase facilitates the transfer reaction of the ORF from the master clone to a Creator-compatible expression vector in generating expression clones (Fig. 3.20.5). The process can be performed using the commercially available vectors or Creator-compatible vectors generated in-house. The generation of Creator-compatible expression vectors involves (1) the amplification of the Creator conversion cassette with primers that contain restriction sites, (2) restriction of expression vector, and (3) ligation of the prepared cassette into the target expression vector (Fig. 3.20.7).

Materials

- Creator expression vector (e.g., pLP-CMVneo; BD Clontech) or other expression vector to make Creator-compatible vector
- LoxP* primers (BD Clontech)
- LoxP* template (e.g., Creator acceptor vector; BD Clontech)
- Restriction enzymes and buffers (NEB)
- T4 DNA ligase and buffer (NEB)
- E. coli* competent cell culture (e.g., DH5 α ; Invitrogen)
- LB plates supplemented with 100 $\mu\text{g}/\text{ml}$ kanamycin (or other appropriate antibiotic; *UNIT 1.1*)
- LB plates supplemented with 30 $\mu\text{g}/\text{ml}$ chloramphenicol (or other appropriate antibiotic; *UNIT 1.1*) and 7% (w/v) sucrose
- Cre recombinase (New England Biolabs)
- 10 \times Cre reaction buffer (New England Biolabs)
- 20 ng/ μl master clone plasmid DNA (Basic Protocol 3)
- 96-well plate or 1.5-ml microcentrifuge tubes
- Multichannel pipettor
- Additional reagents and equipment for PCR (Basic Protocol 1), agarose gel electrophoresis (Support Protocol; *UNIT 2.5A*), growth of *E. coli* competent cells (*UNIT 1.8*), and analyzing the plasmid DNA using restriction enzymes (*UNIT 3.1*) or recombination-specific PCR methods (BD Clontech)

BASIC PROTOCOL 5

Enzymatic Manipulation of DNA and RNA

3.20.13

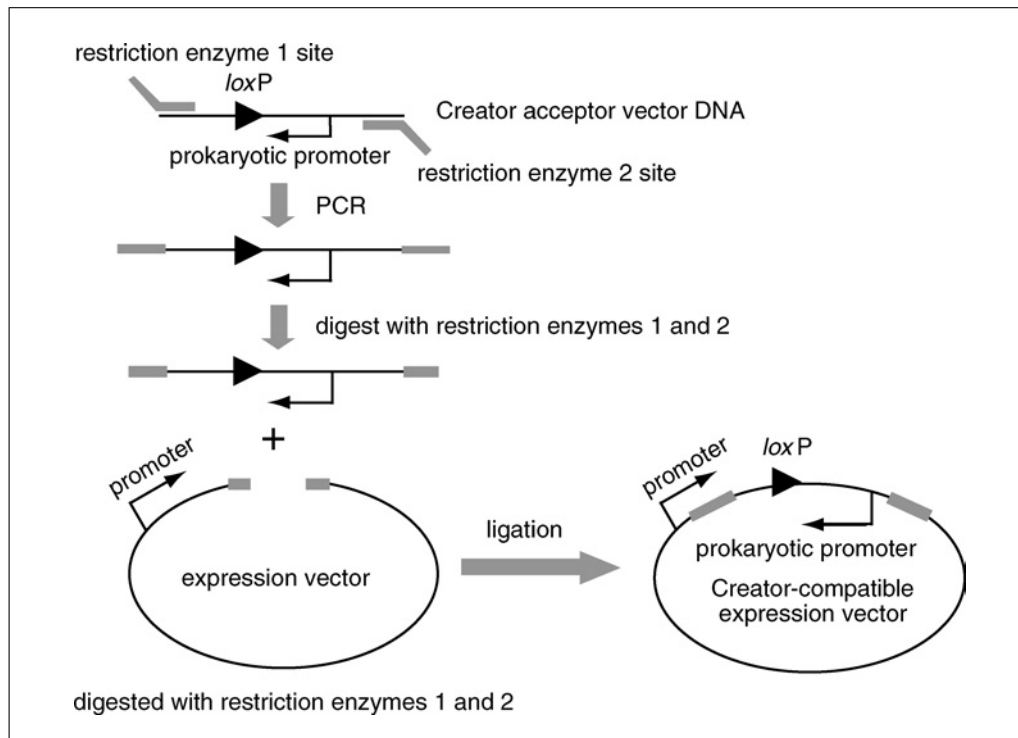

Figure 3.20.7 Conversion of an expression vector into a Creator-compatible vector. The region flanking the *loxP* site and prokaryotic promoter is amplified with specific PCR primers containing specific restriction enzyme sites. Then, the PCR products and an expression vector are digested with appropriate restriction enzyme. A ligation reaction generates a Creator-compatible expression vector.

Prepare Creator-compatible expression vector (optional)

1. Design PCR primers to amplify the *loxP* template as follows:

5' primer: 5'-RS-ATA ACT TCG TAT AGC ATA CAT TAT-3'
 3' primer: 5'-RS-CAC GTC AGG TGG CAC TTT TCG-3'.

*Restriction sites (RS) should be added, allowing the ligation of the cassette into the target vector. The target vector should have restriction enzyme sites that are not present in the *loxP* cassette.*

Available restriction sites can be found in the Creator Acceptor vector construction manual.

2. Amplify the *loxP* cassette by PCR (see Basic Protocol 1, steps 1 to 3 and 4b).
3. Digest the PCR *loxP* fragment and the expression vector with the selected restriction enzymes.
4. Purify the digested PCR fragment (161 bp) by agarose gel electrophoresis (UNIT 2.5A).
5. Ligate (see Basic Protocol 4, step 3) the PCR-amplified *loxP* cassette and the linearized expression vector.

*Use of the appropriate matched restriction enzymes for preparing the *loxP* cassette and the linearized expression vector are necessary for the ligation reaction to occur.*

6. Add 2.5 μ l of ligation mixture to 50 μ l *E. coli* competent cell culture, e.g., DH5 α , and perform transformation.

Transformation efficiency of $>1 \times 10^8$ cfu/ μ g DNA is recommended.

Refer to UNIT 1.8 for more information about bacterial transformation.

7. Plate the transformation mix on an LB plate supplemented with 100 µg/ml kanamycin. Incubate overnight at 37°C.

Antibiotics should be carefully chosen to be appropriate to the expression vector.

8. Pick colonies and prepare overnight cultures and glycerol stocks (see Basic Protocol 4, steps 7 and 8). Prepare plasmid DNA (UNIT 1.6 or Qiagen) and quantify (APPENDIX 3D).

Transfer an ORF into the expression vector using Creator Cre reaction

9. Prepare the master reaction mix on ice for the 20-µl LR reaction (multiply the volume for each component for the number of reactions plus two or three to allow for losses during transfer) as follows (10 µl per tube or well):

Reaction mix per well includes:

200 ng commercial Creator (e.g., pLP-CMVneo) or Creator-compatible (step 8) expression vector

1 µl Cre recombinase

2 µl 10× Cre reaction buffer

Bring volume to 10 µl with H₂O.

10. Dispense 10 µl master reaction mix into each well of a 96-well plate.

For a 96-well plate format, a multichannel pipettor should be used.

11. Add 10 µl 20 ng/µl master clone plasmid DNA to the 10 µl master reaction mix.

Master clone plasmid DNA (150 to 200 ng) per reaction works well.

12. Incubate 30 min at 37°C.

13. Heat inactivate the reaction 15 min at 70°C.

14. Add 2 to 3 µl reaction mixture to 50 µl *E. coli* competent cell culture, e.g., DH5α, and perform transformation.

Transformation efficiency of $>2 \times 10^8$ cfu/µg DNA is recommended.

More than 5 µl of reaction mix can be toxic to bacterial competent cells.

Refer to UNIT 1.8 for more information about bacterial transformation.

15. Plate the transformation mix on an LB plate supplemented with 30 µg/ml chloramphenicol and 7% (w/v) sucrose. Incubate the plates overnight at 37°C.

Antibiotics should be carefully chosen to be appropriate to the expression vector (in this case, pLP-CMVneo).

16. Pick good-sized colonies.

It is important to pick good-sized colonies rather than small ones. It has been reported that the small colonies could be background and may harbor undesirable recombinants (Creator DNA cloning kit manual).

17. Analyze the plasmid DNA of picked colonies using restriction enzymes (UNIT 3.1) or recombination-specific PCR methods (BD Clontech).

Typically, the transfer reaction is very efficient (90% to 95%). For large-scale projects, in many cases, it is not necessary to pick several colonies and analyze them.

18. Choose the best clone and and prepare for the desired use or store as a 15% glycerol stock up to 6 months at –80°C.

COMMENTARY

Background Information

Overview of universal cloning strategy

As molecular biology has matured, the number of experimental approaches that can be conceived and executed with a cloned cDNA copy of a gene has grown exponentially. Proteins can be expressed *in vitro* or *in vivo* in a wide variety of organisms, ranging from bacteria to human cells; their expression can drive the production of purified protein for structural studies, or their regulated expression can be used for complementing genetic phenotypes; epitope tags (e.g., green fluorescent protein, GST, or HA) can be added as markers for localization, for use in purification, or as part of two-hybrid assay systems. Each of the myriad applications that utilize protein expression demands the subcloning of the relevant cDNA into an appropriate plasmid vector that adds the relevant selectable markers, transcriptional and/or translational signals, any needed polypeptide tags, and other relevant sequences. Using traditional subcloning methods based on restriction enzymes and ligation, the effort required to transfer cDNAs from vector to vector can be substantial and time consuming. If one aspires to do large-scale experiments involving the examination of thousands of genes simultaneously using automated and parallel approaches, it would be impossible using standard methods. To move the focus of the community's efforts away from the mechanics of subcloning and put it back on biology, recombinational cloning has been developed. This approach facilitates the transfer of DNA molecules from one vector to another in a single concerted step that is highly efficient, *in-frame*, and does not introduce mutations.

Recombinational cloning is based on site-specific recombination to transfer DNA sequences into multiple expression systems (Walhout et al., 2000; Reboul et al., 2001, 2003; Brizuela et al., 2002; Yamada et al., 2003; Marsischky and LaBaer, 2004). It is independent of the insert DNA sequence to be cloned, separating it from the limitations of classical restriction enzyme-based cloning. It enables rapid and efficient transfer of single inserts into multiple different expression systems for protein expression and functional analysis. It also allows the simultaneous transfer of a many different DNA sequences into an expression vector in parallel, enabling high throughput applications (Fig. 3.20.1). Presently, the Gateway system (Invitrogen)

and the Creator system (BD Clontech) are commercially available.

The strategy employs the use of a set of master clones from which numerous different expression clones can be easily produced. The master clones contain the coding sequences (also called open reading frames, ORFs) situated in inert (non-protein-expressing) vectors, which are endowed with recombinational sequences. The use of inert vectors for the master clones avoids inadvertent protein expression and consequent negative selection of clones that contain inserts toxic to the propagating bacteria. Using recombination, the coding sequences can then be transferred to any protein expression vector that has the recombination sequences situated in the appropriate position and reading frame. Virtually any existing expression vector can be easily adapted to contain recombinational sequences for either of the existing commercial systems. Based upon the design of the original master clones, the expression clones can either produce native protein (when master clones contain a naturally positioned stop codon) or carboxyl-terminal tagged proteins (when the stop codon is omitted from the master clone). The transfer process is a conservative molecular reaction. Once the sequence of the master clones has been verified, there is no need to verify the daughter clones. Thus, one library of clones in master vectors becomes many libraries of clones in expression vectors.

The steps involved in making expression-ready master clones include (1) identifying the genes that will be cloned, (2) obtaining sequence information regarding the coding sequences, (3) determining whether to include or exclude the stop codon, (4) designing gene-targeted oligos for PCR, (5) constructing master clones using high-fidelity PCR and capture into the master vector, (6) bacterial transformation and picking colonies, (7) DNA sequencing of the insert and important flanking sequences, and (8) sequence analysis and selection of master clones that meet the acceptance criteria. Once the master clones are constructed and their sequences verified, they can be transferred to appropriately constructed expression vectors to generate expression-ready clones.

As a matter of a common lexicon, the term vector is used to describe plasmids without an insert, whereas the term clone refers to a vector containing an insert. For example, one

might state that the coding sequences from a set of master clones were transferred to an expression vector to produce expression clones. Each commercial system also uses its own terminologies. The Gateway system refers to master vectors as entry vectors and expression vectors as destination vectors. The Creator system refers to master vectors as donor vectors and expression vectors as acceptor vectors. Each system supports the insertion of a simple cassette that adds the appropriate recombinational signals and relevant selectable markers into virtually any existing expression vector adapting it for use in that system.

The recombination reactions themselves are equilibrium reactions that result in a mixture of end products, starting substrates, and intermediates. The desired product may only be present as a small fraction of this mix, but by using the appropriate positive and negative selections, it is the only viable product that is recovered. This results in an overall efficiency that exceeds 96% in most cases, which can enable high throughput automation. Experiments can be easily expanded to genome scale once a complete high-quality collection has been constructed in a recombinational cloning system.

The Gateway system

Gateway technology is based on the bacteriophage lambda (λ) site-specific recombination system, which facilitates the integration of λ genome into the *Escherichia coli* (*E. coli*) chromosome and the switch between the lytic and lysogenic pathways (Ptashne, 1992; Hartley et al., 2000; Walhout et al., 2000). Lambda-based recombination involves the DNA recombination sequences and the proteins that mediate the recombination reaction (*i.e.*, Clonase enzyme mix). Recombination occurs between specific attachment (*att*) sites on the interacting DNA molecules. The DNA segments flanking the recombination sites are changed such that after recombination the *att* sites become hybrid sequences from the *att* sequences of each parental vector. For example, *attL* sites comprise sequences from *attB* and *attP* sites. Strand exchange occurs within a core region that is common to all *att* sites. For more detailed information about λ recombination, see published references and reviews (Landy, 1989; Ptashne, 1992; <http://www.invitrogen.com/gateway>).

The *att* sites serve as the binding site for recombination proteins and have been well characterized (Weisberg and Landy, 1983). Upon λ integration, recombination occurs between

attB (bacteria) and *attP* (phage) sites to give rise to *attL* (left) and *attR* (right) sites. The *attB* and *attP* sites are different sizes, and because the *attL* and *attR* sites are hybrids, their sizes fall in between. The actual crossover occurs between homologous core regions (15 bp) on the two sites, but surrounding sequences are required as they contain the binding sites for the recombination proteins (Landy, 1989). In developing the Gateway system, mutations were introduced into the core of the *att* sites to create different sets that are incompatible with each other, generating *attB1* and *attP1* sites and *attB2* and *attP2* sites. The *attB1* recombine only with *attP1*, not with *attP2*. This allows a gene to be flanked by *attL1* and *attL2* sites on either side that can recombine with the corresponding *attR* sites and maintain the correct orientation. The different species of recombination sites (*attB*, *attP*, *attL*, and *attR*) are found in different vector constructs. The system is designed so that the *attB* site, the smallest of the four, appears in the final expression clone introducing an additional 9 amino acids into any fusion proteins.

Lambda recombination is catalyzed by a mixture of enzymes that bind to specific *att* sequences. The recombination proteins differ depending upon which direction the reaction is run. When the reaction is run to mix *attB* and *attP* sites, such as when making master clones, it is catalyzed by the bacteriophage λ integrase (Int) and *E. coli* integration host factor (IHF) proteins (BP Clonase enzyme mix), whereas, if the reaction is between *attL* and *attR* sites it is catalyzed by the bacteriophage λ Int and excisionase (Xis) proteins, and the *E. coli* IHF protein (LR Clonase enzyme mix). For more information about the recombination enzymes, see published references and reviews (Nash, 1977; Nash and Robertson, 1981; Landy, 1989; Ptashne, 1992). Two recombination reactions constitute the basis of the Gateway technology. BP reaction, catalyzed by BP Clonase enzyme mix, facilitates recombination of an *attB* substrate (*attB*-PCR product or a linearized *attB*-containing expression clone) with an *attP* substrate (master vector) to create an *attL*-containing master clone (Fig. 3.20.4). The BP cloning efficiency tends to drop rapidly with increasing insert DNA size larger than 2 kb (Marsischky and LaBaer, 2004). On the other hand, LR Reaction, catalyzed by LR Clonase enzyme mix, facilitates recombination of an *attL* substrate (master clone) with an *attR* substrate (expression vector) to create an *attB*-containing expression clone (Fig. 3.20.4).

Recombination reaction is an equilibrium reaction; therefore tight selection is required to ensure that only the desired product is obtained. In the Gateway system, positive selection for the correct master clone is mediated by an antibiotic resistance marker. To avoid contamination from starting vectors, there is counter-selection by the death gene (*ccdB*), which is toxic to general cloning bacteria (Bernard and Couturier, 1992). Thus, only bacteria that contain master clones where the death gene has been successfully replaced by the desired insert will survive selection. Vectors carrying the death gene can be propagated using a special *E. coli* strain (DB3.1), which is resistant to the *ccdB* gene. The combined positive and negative selection provides an overall BP or LR reaction efficiency of 95% to 100%. For more detail refer to the Gateway manual from the manufacturer.

The Creator system

The BD Clontech Creator system relies on homologous recombination and Cre-*loxP* recombination generating master clone and expression clone, respectively. PCR amplified ORF containing homologous sequences in each ends will be transferred into a master vector in the In-Fusion reaction. Because it is simply a homologous recombination event, many thermostable DNA polymerase could be adapted in place of the In-Fusion enzyme. The Cre-*loxP* site-specific recombination reaction catalyzes the transfer of ORF from a master clone to an expression vector creating expression clone (Fig. 3.20.5). Cre, a 38-kDa recombinase protein from bacteriophage P1, mediates recombination between or within DNA sequences at specific locations called *loxP* sites (Sternberg et al., 1981; Abremski and Hoess, 1984; Sauer, 1994). These sites consist of two 13-bp inverted repeats separated by an 8-bp spacer region that provides directionality to the recombination reaction (<http://www.clontech.com/clontech/products/families/creator>). The 8-bp spacer region in the *loxP* site has a defined orientation that forces a gene to be transferred in a fixed orientation and reading frame.

Master vectors contain two *loxP* sites that flank a multicloning site (MCS) and the open reading frame for the chloramphenicol resistance gene (*Cm^r*; Fig. 3.20.5). Master vectors also contain the ampicillin gene for propagation and selection in *E. coli*, and the sucrose gene (*sacB*) from *B. subtilis* for negative selec-

tion of correct recombinants. Expression vectors contain a single *loxP* site, followed by a bacterial promoter, which drives expression of the chloramphenicol marker after Cre-*loxP*-mediated recombination. After transfer, the gene of interest will become linked to the specific expression elements for which the expression vector was designed. Furthermore, if the coding sequence for the gene of interest is in frame with the upstream *loxP* site in the master vector, it will automatically be in frame in the expression vector. The expression of C-terminal fusion proteins is complicated because the chloramphenicol resistance gene blocks access to C-terminal fusion tags. To enable C-terminal fusions, the gene of interest should be collected into a master vector that has a splice donor site (pDNR-Dual), and any C-terminal tag will be spliced in-frame to the gene of interest.

During the recombination reaction, the DNA sequences between the *loxP* sites on the master clone are inserted at the *loxP* site of the expression vector. This reaction will put the chloramphenicol resistance gene under control of the constitutively active bacterial promoter and the gene of interest under control of the heterologous promoter (Fig. 3.20.5). Because the recombination is site-specific, the reading frame is always maintained. Correct recombinants can be selected using positive selection on chloramphenicol (selects for the recombinant) and counter selection on sucrose (selects against the master vector). Sucrose in the presence of endogenous sucrose is toxic to general *E. coli* strains (Pelicic et al., 1996). For more details, refer to the Creator manual from the manufacturer.

Modification for use with other vectors

The Gateway and Creator recombinational cloning technology platforms provide various forms of expression systems (e.g., bacterial, mammalian, insect, and in vitro transcription/translation). In many cases, however, users may want to modify their own expression vectors into recombination-compatible systems (Figs. 3.20.6 and 3.20.7). For that purpose, those commercial systems also provide a way to convert other expression vectors into recombination-compatible ones by simply inserting the recombination cassette, using PCR and restriction-mediated cloning steps. For this purpose, refer to standard cloning manuals or to the Gateway and Clontech vector conversion manuals for more details.

Critical Parameters and Troubleshooting

Amplification of target DNA

Primer mapping. When performing agarose gel electrophoresis in handling multiple genes or large cloning projects using a 96-well plate format, it is helpful if the resulting gel bands form a saw tooth pattern in which the expected fragments progressively increase in size across the gel lanes, but alternate in size to avoid lane-to-lane contamination (Fig. 3.20.8). This effect is most easily planned at the stage of primer design, so that the genes are amplified in an order that will result in this pattern.

DNA polymerase. Fidelity and PCR success rate (% of genes with positive PCR product) are crucial parameters in high-throughput PCR cloning. The choice of polymerase has a dramatic effect on the success rate. In the authors' experience, *Pfu* Turbo (Stratagene) and *Pfx* (Invitrogen) were comparable and gave the highest success rates in cloning up to 4 kbp from human brain and placenta first-strand cDNA mix. In addition, Herculase (Stratagene), GC-rich polymerase (Roche), and Elongase (Invitrogen) were successfully used in other systems (Walhout et al., 2000; Reboul et al., 2001). Running pilot experiments on small subsets of clones is recommended before executing a large-scale experiment in order to

adjust reaction parameters, e.g., the amount of polymerase, melting temperature, cycle number, Mg^{2+} concentration, and GC content of the primers.

Template. PCR reactions using plasmid template are highly efficient. As little as 200 ng of template plasmid DNA is enough to reduce the number of PCR cycles and the rate of mutations. When the plasmid form for the target gene is not available, the cDNAs must be amplified from cDNA libraries, first-strand cDNA, or genomic DNA. Genomic DNA is an excellent source for a simple organism because it is essentially a normalized library where each gene is represented equally. For eukaryotes, the authors have found increased success rates from first-strand cDNA with highest rates in the brain and placenta first-strand cDNA mixture (1:4) for general human gene cloning purposes; however, for cloning certain cell- or tissue-type-specific genes, use of template DNA generated from those cells or tissues is recommended.

Generation of master clones

Pilot experiments. The concentration of purified PCR product can vary from gene to gene, especially in large-scale projects, and can influence the success rate of generating master clones, even though all were successfully amplified. Consequently, running a pilot

Figure 3.20.8 Examples of a saw-tooth pattern in agarose gel analysis of PCR product. PCR mixtures (96 samples) were run on a 1% agarose gel. A primer-ordering algorithm generates a map of oligonucleotide primers in 96-well format with alternating expected product size, so that the expected PCR bands would appear in a saw-tooth fashion. The letter M indicates DNA size markers.

experiment with a small number of genes is strongly recommended, using positive and negative controls for estimating the range of PCR product concentration against the fixed master vector concentration.

Transformation. The efficiency of transformation into competent *E. coli* cells is critical, especially in dealing with large-scale projects in a 96-well format. Transformation efficiencies of $>1 \times 10^8$ cfu/ μ g DNA are recommended. For high-throughput projects LB agar can be prepared in 48-well grid square bioassay trays (Genetix), and the bacterial colonies can be automatically picked using robotics.

Selection. Because the recombination reaction does not go to completion, a mixture containing the starting plasmids, one or more intermediates, the desired product, and one or more byproducts is obtained. Thus, stringent antibiotic selection conditions are required to select only the desired recombinant containing the target gene in its correct orientation.

Verification. Enzymatic amplification using PCR can introduce unwanted random mutations in the DNA sequence. In addition, primer mutations can be introduced during synthesis of the oligonucleotide primers. The enzymatic contribution to this mutation rate can be decreased by reducing the number of amplification cycles. Nevertheless, each clone should be sequenced in its full length to verify the correct sequence of the target gene and the recombination site has been obtained. Once a master clone is verified, it is not necessary to resequence after it is transferred into an expression vector.

Generation of expression clones

Transformation. As in generation of the master clone, the efficiency of transformation into competent *E. coli* cells is critical in dealing with large-scale projects in a 96-well format. Bacterial competent cells with transformation efficiencies of $>2 \times 10^8$ cfu/ μ g DNA are recommended for the Creator system pipeline.

Pilot experiments. Unusual recombination events occasionally occur, especially in retroviral expression vectors. It is advisable to confirm that the expression clones harbor correct inserts in proper orientation by analyzing plasmid DNA of some expression clones using specific restriction enzymes in a pilot experiment.

Anticipated Results

Amplification of target DNA

From both plasmid DNA or genomic DNA (especially prokaryotic cells) as a template,

PCR should amplify only the gene of interest, and the overall success rate is $>95\%$. In the case of first-strand cDNA, the PCR success rate is $\sim 70\%$ because of the complexity and relatively low representation of each gene. Upon electrophoresis of first-strand PCR product the authors frequently observe a few bands in addition to those for the desired products, most likely because of the complexity of the mixture. Purification of the desired products alleviates that problem except in cases where the product bands are smears. In those cases PCR conditions should be optimized again.

Generation of master clones

In the authors' experience, a $>95\%$ success rate for generating master clones from plasmid DNA can be expected, but with first-strand cDNA the situation is a bit more complicated. Generally, upon electrophoresis, the PCR product band is faint compared to those from plasmid DNA template because of a lower DNA concentration. This is a result of the lower success rate in PCR steps ($\sim 70\%$) for first-strand DNA templates. Moreover, after DNA sequencing and analysis, more clones may be eliminated for the first-strand cDNA template because of more random mutations introduced during higher numbers of PCR cycles required as a result of the more complex and heterogeneous DNA template. Overall, based on the authors' experience, a $>50\%$ success rate is expected from a first-strand cDNA cloning scheme, compared to $>95\%$ overall success rate using plasmid DNA as template.

Generation of expression clones

The transfer reaction is robust, and a $\sim 95\%$ success rate is expected. The few ineffective transfers should be easily rescuable after an additional round of transfer reaction. Their failure is most often due to random losses during plasmid DNA preparation in the 96-well format. Using highly competent cells (2×10^8 cfu/ μ g DNA competency), at least fifty colonies in a 10-cm petri dish are normally obtained from a standard bacterial transformation protocol.

Because the entire process of transferring inserts into expression vectors is very robust, it is easily automated. In addition, because the reaction does not involve any amplification or rearrangements, if the insert DNA sequence has been fully verified and is in-frame with the recombination sites, it is not necessary to resequence the insert DNA sequence again after constructing expression clones.

Any functioning expression vector can be converted to accept inserts in the Gateway or Creator systems. It should be noted that the final expression vector is in the same reading frame, which will ensure that all fusion proteins will be in-frame. The expression vector should not use the same antibiotic marker as those of the master vector.

Time Considerations

The basic procedures can be completed in ~1 week with activities broken down as follows: 1 day for PCR and gel plugging, 1 day for capture reactions and transformation, 1 day for colony picking and DNA minipreps, 1 to 2 days for sequencing, 1 day for transfer of ORF into expression vector, and 1 to 2 days for DNA preparation and analysis.

CHAPTER 4

Preparation and Analysis of RNA

INTRODUCTION

The ability to isolate clean intact RNA from cells is essential for experiments that measure transcript levels, for cloning of intact cDNAs, and for functional analysis of RNA metabolism. RNA isolation procedures frequently must be performed on numerous different cell samples, and therefore are designed to allow processing of multiple samples simultaneously. This chapter begins by describing several methods commonly used to isolate RNA, and concludes with methods used to analyze RNA expression levels and synthesis rates.

The difficulty in RNA isolation is that most ribonucleases are very stable and active enzymes that require no cofactors to function. The first step in all RNA isolation protocols therefore involves lysing the cell in a chemical environment that results in denaturation of ribonuclease. The RNA is then fractionated from the other cellular macromolecules under conditions that limit or eliminate any residual RNase activity. The cell type from which RNA is to be isolated and the eventual use of that RNA will determine which procedure is appropriate. No matter which procedure is used, it is important that the worker use care (e.g., wearing gloves) not to introduce any contamination that might include RNase during work up of the samples, and particularly when the samples are prepared for storage at the final step.

While the RNA isolation protocols describe methods that can be performed using common laboratory reagents, several kits for RNA isolation are commercially available. These kits offer the dual advantage of ease of use and (at least in theory) of reagents that have been tested for effectiveness. These kits frequently work well and are widely used. The disadvantages of using kits are that they are more expensive per sample than isolations that are done using “home made” solutions, and that the kits do not offer flexibility for cell types that require special conditions. The cost disadvantage is frequently outweighed in situations where only a few RNA isolations are performed; however, preparing reagents from scratch can take time, and in the event that any of the reagents are not working properly, troubleshooting will require further time. In situations where numerous samples are routinely processed, significant cost savings can be realized by avoiding the use of kits.

One of the primary uses of RNA isolation procedures is the analysis of gene expression. In order to elucidate the regulatory properties of a gene, it is necessary to know the structure and amount of the RNA produced from that gene. The second part of this chapter is devoted to techniques that are used to analyze RNA. Procedures such as S1 nuclease analysis and ribonuclease protection can be used to do fine-structure mapping of any RNA. These techniques allow characterization of 5' and 3' splice junctions as well as the 5' and 3' ends of RNA. Both of these procedures, as well as northern analysis, can also be used to accurately determine the steady-state level of any particular message.

After determining the steady-state level of a message, many investigators wish to examine whether that level is set by the rate of transcription of the gene. Alterations

in steady-state level might also reflect changes in processing or stability of the RNA. The final section of the chapter describes the “nuclear run-off” technique, which determines the number of active RNA polymerase molecules that are traversing any particular segment of DNA. This procedure is used to analyze directly how the rate of transcription of a gene varies when the growth state of a cell is changed.

Robert E. Kingston

PREPARATION OF RNA FROM EUKARYOTIC AND PROKARYOTIC CELLS

Three methods are presented for preparing RNA from eukaryotic cells. The first two are rapid and can be used to prepare several RNA samples at the same time. As written, they are intended for production of RNA to be used for analysis by S1 nuclease or ribonuclease protection. Modifications of each protocol are given that should be used if intact full-length RNA is a priority.

Both of these protocols require limited hands-on time. The first (*UNIT 4.1*) utilizes a gentle detergent to lyse the cell. Its main advantage is that it requires no high-speed centrifuge spins, thus allowing preparation of numerous samples without having to find several high-speed rotors. In the second protocol (*UNIT 4.2*) cells are lysed using 4 M guanidinium isothiocyanate. This protocol requires very few manipulations, gives clean RNA from many sources, and is the method of choice when working with tissues that have high levels of endogenous RNase. It does require a high-speed centrifuge run, which limits the number of samples that can be prepared at the same time.

In the third protocol (*UNIT 4.3*) the cell is lysed with phenol and SDS. It produces clean, full-length RNA from large quantities of plant cells. This protocol also works well with several mammalian cells and tissues. All three protocols can be used with cells from any higher eukaryote. In particular, many laboratories use the guanidinium procedure when preparing RNA from plant tissue.

These protocols produce total RNA, which contains primarily ribosomal RNA and transfer RNA. Many techniques require messenger RNA that is largely free of contaminating rRNA and tRNA. The isolation of poly(A)⁺ RNA, which is highly enriched for mRNA, is described in *UNIT 4.5*. A protocol is also presented for extracting RNA from gram-negative and gram-positive bacteria (*UNIT 4.4*).

The major source of failure in any attempt to produce RNA is contamination by ribonuclease. RNases are very stable enzymes and generally require no cofactors to function. Therefore, a small amount of RNase in an RNA preparation will create a real problem. To avoid contamination problems, the following precautions can be taken:

1. *Solutions.* Any water or salt solutions used in RNA preparation should be treated with the chemical diethylpyrocarbonate (DEPC). This chemical inactivates ribonucleases by covalent modification. Solutions containing Tris cannot be effectively treated with DEPC because Tris reacts with DEPC to inactivate it. See Reagents and Solutions for instructions regarding DEPC treatment.
2. *Glassware and plastic.* Labware used in the preparation of RNA should be treated to remove residual RNase activity. Autoclaving will not fully inactivate many RNases. Glassware can be baked at 300°C for 4 hr. Certain kinds of plasticware (e.g., some conical centrifuge tubes and pipets) can be rinsed with chloroform to inactivate RNase. When done carefully, this rinse is an effective treatment. Keep in mind, however, that many plastics (e.g., gel boxes) will melt when treated with chloroform. Plasticware straight out of the package is generally free from contamination and can be used as is.
3. Hands are a major source of contaminating RNase. Wear gloves.

Preparation of Cytoplasmic RNA from Tissue Culture Cells

BASIC PROTOCOL

Cells are washed with ice-cold phosphate-buffered saline and kept on ice for all subsequent manipulations. The pellet of harvested cells is resuspended in a lysis buffer containing the nonionic detergent Nonidet P-40. Lysis of the plasma membranes occurs almost immediately. The intact nuclei are removed by a brief microcentrifuge spin, and sodium dodecyl sulfate (SDS) is added to the cytoplasmic supernatant to denature protein. Protein is digested with protease and removed by extractions with phenol/chloroform and chloroform. Cytoplasmic RNA is recovered by ethanol precipitation and quantitated by measuring its absorbance at 260 and 280 nm.

Materials

Cell monolayer or suspension
 Phosphate-buffered saline, ice cold (PBS; *APPENDIX 2*)
 Lysis buffer, ice cold (see recipe)
 20% (w/v) sodium dodecyl sulfate (SDS)
 20 mg/ml proteinase K
 25:24:1 phenol/chloroform/isoamyl alcohol (*UNIT 2.1A*)
 24:1 chloroform/isoamyl alcohol
 3 M DEPC-treated (see recipe) sodium acetate, pH 5.2 (*APPENDIX 2*)
 100% ethanol
 75% ethanol/25% 0.1 M DEPC-treated (see recipe) sodium acetate, pH 5.2
 Beckman JS-4.2 rotor or equivalent
 Rubber policeman

Additional reagents and equipment for removing contaminating DNA (see Support Protocol)

CAUTION: Diethylpyrocarbonate (DEPC) is a suspected carcinogen and should be handled carefully (*APPENDIX 1H*).

IMPORTANT NOTE: Water and sodium acetate should be treated with DEPC (see recipe).

Wash cells

1a. *For monolayer cells:* Rinse cell monolayer three times with ice-cold PBS. Scrape cells into a small volume of cold PBS with a rubber policeman. Transfer to a centrifuge tube on ice. Collect cells by centrifuging in a Beckman JS-4.2 rotor 5 min at $300 \times g$ (1000 rpm), 4°C, or in a microcentrifuge 15 sec at maximum speed, 4°C.

For a 10-cm dish, collect cells in 1 ml PBS. For a 15-cm dish collect in 3 to 5 ml PBS.

1b. *For suspension cultures:* Pellet by centrifuging in a Beckman JS-4.2 rotor 5 min at $300 \times g$ (1000 rpm), 4°C. Resuspend pellet in one-half original culture volume ice-cold PBS. Repeat once.

This procedure, as written, is used for up to 2×10^7 cells (two 10-cm dishes or ~20 ml suspension culture). The procedure can be scaled up for larger cell quantities by increasing volumes appropriately and using larger, conical tubes.

Lyse cells

2. Resuspend cells in 375 μ l ice-cold lysis buffer. Incubate 5 min on ice.

The suspension should clear rapidly, indicating cell lysis.

Cells are best suspended by careful but vigorous vortexing. Avoid foaming.

3. If the cells are not already in a microcentrifuge tube, transfer them into one. Microcentrifuge 2 min at maximum speed, 4°C.
4. Transfer supernatant to a clean tube containing 4 µl of 20% SDS. Mix immediately by vortexing.

The supernatant is the cytoplasmic extract. It is usually slightly cloudy and yellow-white, depending on the cells. The pellet, which contains nuclei and some cell debris, should be considerably smaller than the whole cell pellet obtained in step 1a or 1b and white in color.

5. Add 2.5 µl of 20 mg/ml proteinase K. Incubate 15 min at 37°C.

Extract with phenol/chloroform/isoamyl and chloroform/alcohol

6. Add 400 µl of 25:24:1 phenol/chloroform/isoamyl alcohol, room temperature. Vortex thoroughly—i.e., at least 1 min. Microcentrifuge ≥5 min at maximum speed, room temperature.

With protease treatment, there should be only a small amount of precipitate at the interface between the two phases, although this can vary depending on the cell type. For some cells, the protease step can be safely omitted. In this case, the white precipitate at the interface can be considerable. If a very large precipitate forms after the first organic extraction and little or no aqueous phase can be recovered, first try spinning for a few minutes more. If the precipitate fails to collapse to the interface, remove and discard the organic phase from the bottom of the tube. Add 400 µl chloroform/isoamyl alcohol. Vortex well and spin ~2 min. The precipitate should have largely disappeared. Recover the upper aqueous phase and proceed.

7. Transfer the aqueous (upper) phase to a clean tube, avoiding precipitated material from the interface. Add 400 µl phenol/chloroform/isoamyl alcohol and repeat the extraction.
8. Transfer the aqueous phase to a clean tube. Add 400 µl of 24:1 chloroform/isoamyl alcohol. Vortex 15 to 30 sec and microcentrifuge 1 min at maximum speed, room temperature.
9. Again, transfer the aqueous (upper) phase to a clean tube.

Precipitate RNA

10. Add 40 µl of 3 M DEPC-treated sodium acetate, pH 5.2, and 1 ml of 100% ethanol. Mix by inversion. Incubate 15 to 30 min on ice or store at –20°C overnight.
11. Recover the RNA by microcentrifuging for 15 min at maximum speed, 4°C.
12. If necessary, remove contaminating DNA (see Support Protocol).
13. Rinse the pellet with 1 ml of 75% ethanol/25% 0.1 M sodium acetate, pH 5.2 solution.

Analyze purity

14. Dry and resuspend in 100 µl DEPC-treated water. Dilute 10 µl into 1 ml water to determine the A_{260} and A_{280} . Store the remaining RNA at –70°C.

REMOVAL OF CONTAMINATING DNA

If RNA is isolated from cells transiently transfected with cloned DNA, substantial amounts of this DNA will copurify with the RNA in this procedure. This contaminating DNA will interfere with analysis of the RNA by nuclease protection assays, especially if uniformly labeled probes are used. To remove this DNA, perform the following steps after step 11 of the preparation (see Basic Protocol).

Additional Materials (also see *Basic Protocol*)

TE buffer, pH 7.4 (*APPENDIX 2*)
100 mM MgCl₂/10 mM dithiothreitol (DTT; see *APPENDIX 2* for both components)
2.5 mg/ml RNase-free DNase I (see recipe)
25 to 50 U/μl placental ribonuclease inhibitor (e.g., RNAsin from Promega Biotec)
or vanadyl-ribonucleoside complex
DNase stop mix (see recipe)

1. Redissolve the RNA in 50 μl TE buffer, pH 7.4.
2. Prepare on ice a cocktail containing (per sample) 10 μl of 100 mM MgCl₂/10 mM DTT, 0.2 μl of 2.5 mg/ml RNase-free DNase, 0.1 μl of 25 to 50 U/μl placental ribonuclease inhibitor or vanadyl-ribonucleoside complex, and 39.7 μl TE buffer. Add 50 μl of this cocktail to each RNA sample. Mix and incubate 15 min at 37°C.
3. Stop the DNase reaction by adding 25 μl DNase stop mix.
4. Extract once with phenol/chloroform/isoamyl alcohol and once with chloroform/isoamyl alcohol.
5. Add 325 μl of 100% ethanol and precipitate 15 to 30 min on ice or overnight at -20°C.

Resume Basic Protocol at step 13.

REAGENTS AND SOLUTIONS

Diethylpyrocarbonate (DEPC) treatment of solutions

Add 0.2 ml DEPC to 100 ml of the solution to be treated. Shake vigorously to get the DEPC into solution. Autoclave the solution to inactivate the remaining DEPC. Many investigators keep the solutions they use for RNA work separate to ensure that “dirty” pipets do not go into them.

CAUTION: *Wear gloves and use a fume hood when using DEPC, as it is a suspected carcinogen (also see APPENDIX 1H).*

DNase stop mix

50 mM EDTA
1.5 M sodium acetate
1% (w/v) sodium dodecyl sulfate (SDS)

The SDS may come out of solution at room temperature. Heat briefly to redissolve.

Lysis buffer

50 mM Tris·Cl, pH 8.0 (*APPENDIX 2*)
100 mM NaCl
5 mM MgCl₂
0.5% (v/v) Nonidet P-40
Prepare with DEPC-treated H₂O (see recipe)
Filter sterilize

If the RNA is to be used for northern blot analysis or the cells are particularly rich in ribonuclease, add ribonuclease inhibitors to the lysis buffer: 1000 U/ml placental ribonuclease inhibitor (e.g., RNAsin) plus 1 mM DTT or 10 mM vanadyl-ribonucleoside complex.

RNase-free DNase I

Commercially prepared enzymes such as Worthington grade DPRF are satisfactory. If supplied as a powder, redissolve in TE buffer containing 50% (v/v) glycerol and store at -20°C . See also *UNIT 4.10*, reagents and solutions, for homemade preparation of RNase-free DNase.

COMMENTARY

Background Information

Most procedures for isolating RNA from eukaryotic cells involve lysing and denaturing cells to liberate total nucleic acids. Additional steps are then required to remove DNA. This procedure allows rapid preparation of total cytoplasmic RNA by using a nonionic detergent to lyse the plasma membrane, leaving the nuclei intact. The nuclei and hence the bulk of the cellular DNA are then removed with a simple brief centrifugation.

Variations of this technique are in wide use, and its precise origins are obscure. Versions of this procedure were used in some of the early S1 nuclease mapping papers (Berk and Sharp, 1977; Favoloro et al., 1980). The protocol described here is a considerable simplification of the earlier methods, omitting, for example, removal of nuclei by centrifugation through sucrose. It is fast and streamlined, designed for preparing total cytoplasmic RNA from many cultures simultaneously for nuclease protection analysis. It is scaled for small cultures—i.e., 1 to 2 dishes of adherent cells or 10 to 20 ml of suspension culture.

The Basic Protocol works well for many cell types. The protocol takes no special precautions for ribonucleases and may not yield northern blot-quality RNA from some cells. If full-length RNA is required, ribonuclease inhibitors should be added to the lysis buffer (as described; see Reagents and Solutions) or the guanidinium isothiocyanate method should be used (*UNIT 4.2*). Finally, if RNA is isolated from transiently transfected cells, the RNA should be further treated with deoxyribonuclease to remove transfected DNA (see Support Protocol). This modification is especially critical if the RNA is to be assayed by nuclease protection using uniformly labeled probes.

Troubleshooting

Degradation of RNA by ribonuclease is best avoided by working quickly and keeping everything cold until SDS is added to the cytoplasmic

extract. For cells with which ribonuclease is a problem, inhibitors can be added to the lysis buffer (see Reagents and Solutions), but in most cases this is unnecessary.

Note that for some cell lines, it may be possible to omit the proteinase K step and to proceed directly to organic extraction after removal of the nuclei and addition of SDS.

DNA contamination is only a problem when preparing RNA from cells transfected with cloned DNA in a transient expression assay. In this case, add the DNase digestion steps outlined in the Support Protocol.

Anticipated Results

Yields vary widely, depending on the cell line. Expect 30 to 100 μg from a confluent 10-cm dish of most fibroblast lines or 1×10^7 lymphoid cells. Ratios of A_{260} to A_{280} should fall in the range 1.7 to 2.0. RNA at 1 mg/ml has an A_{260} of 25.

Time Considerations

Depending on the number of samples being processed, it is possible to proceed from harvesting the cells to the ethanol precipitation step in 1 to 2 hr. This is the best interim stopping point. The RNA may be recovered, redissolved, and quantitated later the same day or the following day.

Guanidine Methods for Total RNA Preparation

Three different methods for RNA preparation using guanidine are presented in this unit — a single-step isolation method employing liquid-phase separation to selectively extract total RNA from tissues and cultured cells (see Basic Protocol) and two methods that rely on a CsCl step gradient to isolate total RNA (see Alternate Protocols 1 and 2).

SINGLE-STEP RNA ISOLATION FROM CULTURED CELLS OR TISSUES

BASIC PROTOCOL

Cultured cells or tissues are homogenized in a denaturing solution containing 4 M guanidine thiocyanate. The homogenate is mixed sequentially with 2 M sodium acetate (pH 4), phenol, and finally chloroform/isoamyl alcohol or bromochloropropane. The resulting mixture is centrifuged, yielding an upper aqueous phase containing total RNA. In this single-step extraction the total RNA is separated from proteins and DNA that remain in the interphase and in the organic phase. Following isopropanol precipitation, the RNA pellet is redissolved in denaturing solution (containing 4 M guanidine thiocyanate), reprecipitated with isopropanol, and washed with 75% ethanol.

Materials

- Denaturing solution (see recipe)
- 2 M sodium acetate, pH 4 (see recipe)
- Water-saturated phenol (see recipe)
- 49:1 (v/v) chloroform/isoamyl alcohol or bromochloropropane
- 100% isopropanol
- 75% ethanol (prepared with DEPC-treated water; UNIT 4.1)
- DEPC-treated water (UNIT 4.1) or freshly deionized formamide (see recipe)
- Glass Teflon homogenizer
- 5-ml polypropylene centrifuge tube
- Sorvall SS-34 rotor (or equivalent)

CAUTION: Phenol is a poison and causes burns. When handling phenol, use gloves and eye protection.

NOTE: Carry out all steps at room temperature unless otherwise stated.

Homogenize cells

- 1a. *For tissue:* Add 1 ml denaturing solution per 100 mg tissue and homogenize with a few strokes in a glass Teflon homogenizer.
- 1b. *For cultured cells:* Either centrifuge suspension cells and discard supernatant, or remove the culture medium from cells grown in monolayer cultures. Add 1 ml denaturing solution per 10^7 cells and pass the lysate through a pipet seven to ten times.

Do not wash cells with saline. Cells grown in monolayer cultures can be lysed directly in the culture dish or flask.

The procedure can be carried out in sterile, disposable, round-bottom polypropylene tubes with caps; no additional treatment of the tubes is necessary. Before using, test if the tubes can withstand centrifugation at $10,000 \times g$ with the mixture of denaturing solution and phenol/chloroform.

2. Transfer the homogenate into a 5-ml polypropylene tube. Add 0.1 ml of 2 M sodium acetate, pH 4, and mix thoroughly by inversion. Add 1 ml water-saturated phenol,

Preparation and Analysis of RNA

4.2.1

mix thoroughly, and add 0.2 ml of 49:1 chloroform/isoamyl alcohol or bromochloropropane. Mix thoroughly and incubate the suspension 15 min at 0° to 4°C.

Make sure that caps are tightly closed when mixing. The volumes used are per 1 ml denaturing solution.

Bromochloropropane is less toxic than chloroform and its use for phase separation decreases possibility of contaminating RNA with DNA (Chomczynski and Mackey, 1995).

3. Centrifuge 20 min at $10,000 \times g$ (9000 rpm in SS-34 rotor), 4°C. Transfer the upper aqueous phase to a clean tube.

The upper aqueous phase contains the RNA, whereas the DNA and proteins are in the interphase and lower organic phase. The volume of the aqueous phase is ~1 ml, equal to the initial volume of denaturing solution.

Isolate RNA

4. Precipitate the RNA by adding 1 ml (1 vol) of 100% isopropanol. Incubate the samples 30 min at -20°C . Centrifuge 10 min at $10,000 \times g$, 4°C, and discard supernatant.

For isolation of RNA from tissues with a high glycogen content (e.g., liver), a modification of the single-step method is recommended to diminish glycogen contamination (Puissant and Houdebine, 1990). Following this isopropanol precipitation, wash out glycogen from the RNA pellet by vortexing in 4 M LiCl. Sediment the insoluble RNA 10 min at $5000 \times g$. Dissolve the pellet in denaturing solution and follow the remainder of the protocol.

5. Dissolve the RNA pellet in 0.3 ml denaturing solution and transfer into a 1.5-ml microcentrifuge tube.
6. Precipitate the RNA with 0.3 ml (1 vol) of 100% isopropanol for 30 min at -20°C . Centrifuge 10 min at $10,000 \times g$, 4°C, and discard supernatant.
7. Resuspend the RNA pellet in 75% ethanol, vortex, and incubate 10 to 15 min at room temperature to dissolve residual amounts of guanidine contaminating the pellet.
8. Centrifuge 5 min at $10,000 \times g$, 4°C, and discard supernatant. Dry the RNA pellet in a vacuum for 5 min.

Do not let the RNA pellet dry completely, as this greatly decreases its solubility. Avoid drying the pellet by centrifugation under vacuum. Drying is not necessary for solubilization of RNA in formamide.

9. Dissolve the RNA pellet in 100 to 200 μl DEPC-treated water or freshly deionized formamide by passing the solution a few times through a pipe tip. Incubate 10 to 15 min at 55° to 60°C . Store RNA dissolved in water at -70°C and RNA dissolved in formamide at either -20° or -70°C .

RNA dissolved in formamide is protected from degradation by RNase and can be used directly for formaldehyde-agarose gel electrophoresis in northern blotting (Chomczynski, 1992). However, before use in RT-PCR, RNA should be precipitated from formamide by adding 4 vol ethanol and centrifuging 5 min at $10,000 \times g$.

Quantitate RNA

10. Quantitate RNA by diluting 5 μl in 1 ml alkaline water and reading the A_{260} and A_{280} (APPENDIX 3D).

Water used for spectrophotometric measurement of RNA should have $\text{pH} > 7.5$. Acidic pH affects the UV absorption spectrum of RNA and significantly decreases its A_{260}/A_{280} ratio (Willfinger et al., 1996). Typically, distilled water has $\text{pH} < 6$. Adjust water to a slightly alkaline pH by adding concentrated Na_2HPO_4 solution to a final concentration of 1 mM.

CsCl PURIFICATION OF RNA FROM CULTURED CELLS

ALTERNATE PROTOCOL 1

Cells are washed free of medium and are then lysed by placing them in a 4 M guanidine solution. The viscosity of the solution is reduced by drawing the lysate through a 20-G needle and the RNA is pelleted through a CsCl step gradient. The supernatant fluid from this gradient is then carefully removed to allow complete separation of RNA, found in the pellet, from contaminating DNA and protein. Finally, the RNA in the pellet is dissolved, ethanol precipitated, and quantitated spectrophotometrically at A_{260} .

Additional Materials (also see Basic Protocol)

Phosphate-buffered saline (PBS; *APPENDIX 2*)

Guanidine solution (see recipe)

5.7 M cesium chloride (CsCl), DEPC-treated (see recipe)

TES solution (see recipe)

3 M sodium acetate, pH 5.2 (*APPENDIX 2*)

100% ethanol

Rubber policeman

6-ml syringe with 20-G needle

Beckman JS-4.2 and SW 55 rotors (or equivalents)

13 × 51-mm silanized (*APPENDIX 3B*) and autoclaved polyallomer ultracentrifuge tube

Additional reagents and equipment for quantitating RNA (*APPENDIX 3D*)

CAUTION: DEPC is a suspected carcinogen and should be handled carefully.

NOTE: The following solutions should be treated with DEPC to inhibit RNase activity: sodium acetate, water, and 5.7 M CsCl (*UNIT 4.1*).

NOTE: Carry out steps 1 to 4 at room temperature.

Lyse the cells

For monolayer culture

- 1a. Wash cells at room temperature by adding 5 ml PBS per dish, swirling dishes, and pouring off. Repeat wash.
- 2a. Add 3.5 ml guanidine solution for $\leq 10^8$ cells, dividing the solution equally between the dishes. The cells should immediately lyse in place. Recover the viscous lysate by scraping the dishes with a rubber policeman. Remove lysate from dishes using a 6-ml syringe with 20-G needle. Combine lysates.

For suspension culture

- 1b. Pellet $\leq 10^8$ cells by centrifuging 5 min at $300 \times g$ (1000 rpm in JS-4.2 rotor), room temperature, and discarding supernatant. Wash cells once at room temperature by resuspending the pellet in an amount of PBS equal to half the original volume and centrifuging. Discard supernatant.
- 2b. Add 3.5 ml guanidine solution to the centrifuge tube.
3. Draw the resultant extremely viscous solution up and down four times through a 6-ml syringe with 20-G needle. Transfer the solution to a clean tube.

It is critical that chromosomal DNA be sheared in this step in order to reduce viscosity. This allows complete removal of the DNA in the centrifugation step.

Isolate the RNA

4. Place 1.5 ml of 5.7 M CsCl in a 13 × 51–mm silanized and autoclaved polyallomer ultracentrifuge tube. Layer 3.5 ml of cell lysate on top of CsCl cushion to create a step gradient. The interface should be visible.

Silanizing the tube decreases the amount of material that sticks to the sides of the tube and thus decreases the level of contamination of the final RNA.

5. Centrifuge 12 to 20 hr at $150,000 \times g$ (35,000 rpm in SW 55 rotor), 18°C. Set centrifuge for slow acceleration and deceleration in order to avoid disturbing the gradient.
6. Remove the supernatant very carefully (see Fig. 4.2.1). Place the end of the Pasteur pipet at the top of the solution and lower it as the level of the solution lowers. Leave ~100 μ l in the bottom, invert the tube carefully, and pour off the remaining liquid.

There should be a white band of DNA at the interface—care must be taken to remove this band completely, as it contains cellular DNA.

7. Allow the pellet to drain 5 to 10 min, then resuspend it in 360 μ l TES solution by repeatedly drawing the solution up and down in a pipet. Allow the pellet to resuspend 5 to 10 min at room temperature. Transfer to a clean microcentrifuge tube.

It is critical to allow ample time for resuspension of this pellet or the yield of RNA will be significantly decreased.

8. Add 40 μ l of 3 M sodium acetate, pH 5.2, and 1 ml of 100% ethanol. Precipitate the RNA 30 min on dry ice/ethanol. Microcentrifuge 10 to 15 min at 4°C and discard supernatant.

Figure 4.2.1 Technique for removing supernatant from a CsCl step gradient.

9. Resuspend the pellet in 360 μ l water and repeat step 8.

RNA dissolves more readily in water than in a salt solution.

Quantitate the RNA

10. Drain the pellet 10 min and dissolve in \sim 200 μ l water. Quantitate by diluting 10 μ l to 1 ml in alkaline water and reading the A_{260} and A_{280} (see Basic Protocol, step 10, and APPENDIX 3D). Store RNA at -70°C either as an aqueous solution or as an ethanol precipitate.

This protocol produces RNA that is clean enough for northern, S1, or SP6 analysis. If cleaner RNA is desired, step 7 can be modified with the following: After resuspending the pellet in TES solution, extract with 360 μ l of 4:1 (v/v) chloroform/1-butanol and save the supernatant. Extract the chloroform by adding 360 μ l TES solution. Combine the supernatants, add 0.1 vol of 3 M sodium acetate, pH 5.2, and ethanol precipitate as in step 8.

CsCl PURIFICATION OF RNA FROM TISSUE

Additional precautions must be taken when purifying RNA from tissue, as certain organs such as pancreas and spleen have very high endogenous levels of RNase. (Liver and intestine, however, have relatively low levels.) This protocol was originally described in Chirgwin et al. (1979) and modified by Richard Selden.

Additional Materials (also see Alternate Protocol 1)

Liquid nitrogen
Tissue guanidine solution (see recipe)
20% (w/v) *N*-lauroylsarcosine (Sarkosyl)
Cesium chloride (CsCl)
Tissue resuspension solution (see recipe)
25:24:1 phenol/chloroform/isoamyl alcohol (UNIT 2.1)
24:1 chloroform/isoamyl alcohol
Tissuemizer
Sorvall SS-34 and Beckman SW 28 rotors (or equivalents)
SW 28 polyallomer tube silanized (APPENDIX 3B) and autoclaved

1. Rapidly remove tissue from the animal and quick-freeze it in liquid nitrogen.

The sample should be removed from the animal in pieces \leq 2 g or it will be difficult to do the further workup.

RNA is very unstable in tissue once removed from the body so it is critical to quick-freeze the tissue. Placing the tissue in guanidine and then waiting to grind it will result in degraded RNA.

2. Add 20 ml tissue guanidine solution for \sim 2 g of tissue. Immediately grind the tissue in a tissuemizer with two or three 10-sec bursts for complete grinding.

Tissue guanidine solution, unlike the guanidine solution used in the Basic Protocol, lacks Sarkosyl. It is important that Sarkosyl not be present at this stage or a frothy mess will result.

3. Centrifuge 10 min at $12,000 \times g$ (10,000 rpm in SS-34 rotor), 12°C .
4. Collect the supernatant and add 0.1 vol of 20% Sarkosyl. Heat 2 min at 65°C .
5. Add 0.1 g CsCl/ml of solution, dissolve the CsCl, then layer the sample over 9 ml of 5.7 M CsCl in an SW 28 silanized, autoclaved polyallomer tube. Centrifuge overnight at $113,000 \times g$ (25,000 rpm in SW 28 rotor), 22°C .

ALTERNATE PROTOCOL 2

Preparation and Analysis of RNA

4.2.5

6. Carefully remove the supernatant (see Alternate Protocol 1, step 6, and Fig. 4.2.1). Invert the tube to drain. Cut off bottom of tube (containing RNA pellet) and place it in a 50-ml plastic tube.
7. Add 3 ml tissue resuspension buffer and allow pellet to resuspend overnight at 4°C.
It is difficult to resuspend this pellet. Occasionally the sample may have to be left longer than overnight. The high concentrations of 2-mercaptoethanol and Sarkosyl prevent RNA degradation during this resuspension.
8. Extract the solution sequentially with 25:24:1 phenol/chloroform/isoamyl alcohol, then with 24:1 chloroform/isoamyl alcohol (see UNIT 2.1).
9. Add 0.1 vol of 3 M sodium acetate, pH 5.2, and 2.5 vol of 100% ethanol. Precipitate RNA 30 min on dry ice/ethanol, microcentrifuge 10 to 15 min at 4°C, discard supernatant, and resuspend in water. Quantitate the RNA and store (see Alternate Protocol 1, step 10).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

5.7 M CsCl, DEPC-treated

Dissolve CsCl in 0.1 M EDTA, pH 8.0. Add 0.002 vol DEPC, shake 20 to 30 min, and autoclave. Weigh the bottle of solution before and after autoclaving and make up the weight lost to evaporation during autoclaving with DEPC-treated water (UNIT 4.1) to ensure that the solution is actually 5.7 M when used.

Denaturing solution

Stock solution: Mix 293 ml water, 17.6 ml of 0.75 M sodium citrate, pH 7.0, and 26.4 ml of 10% (w/v) *N*-lauroylsarcosine (Sarkosyl). Add 250 g guanidine thiocyanate and stir at 60° to 65°C to dissolve. Store up to 3 months at room temperature.

Working solution: Add 0.35 ml 2-mercaptoethanol (2-ME) to 50 ml of stock solution. Store up to 1 month at room temperature.

Final concentrations are 4 M guanidine thiocyanate, 25 mM sodium citrate, 0.5% Sarkosyl, and 0.1 M 2-ME.

Formamide

Prepare freshly deionized formamide by stirring with 1 g AG 501-X8 ion-exchange resin (Bio-Rad) per 10 ml formamide for 30 min and filter at room temperature. Alternatively, use a commercially available stabilized, ultrapure formamide (Formazol, Molecular Research Center).

Guanidine solution

Mix 550 ml water with 1.64 g sodium acetate (anhydrous) and 472.8 g guanidine thiocyanate, and stir to dissolve, heating slightly (to 65°C) if necessary to get the guanidine into solution. Add 15.4 mg dithiothreitol (DTT) and 50 ml of 10% (w/v) *N*-lauroylsarcosine (Sarkosyl). Adjust pH to ~5.5 with acetic acid, dilute solution to 1 liter with water, and filter through a Nalgene filter. Store up to one month at room temperature.

Final concentrations are 4 M guanidine isothiocyanate, 20 mM sodium acetate, 0.5% Sarkosyl, and 0.1 mM DTT.

Sodium acetate, 2 M

Add 16.42 g sodium acetate (anhydrous) to 40 ml water and 35 ml glacial acetic acid. Adjust solution to pH 4 with glacial acetic acid and dilute to 100 ml final with

continued

water (solution is 2 M with respect to sodium ions). Store up to 1 year at room temperature.

TES solution

10 mM Tris-Cl, pH 7.4
5 mM EDTA
1% (w/v) SDS
Store up to 1 year at room temperature

Tissue guanidine solution

Dissolve 590.8 g guanidine thiocyanate in ~400 ml DEPC-treated water (*UNIT 4.1*). Add 25 ml of 2 M Tris-Cl, pH 7.5, and 20 ml of 0.5 M Na₂EDTA, pH 8.0 (*APPENDIX 2*). Stir overnight. Adjust the volume to 950 ml and filter. Finally, add 50 ml of 2-mercaptoethanol. Store up to three months at room temperature.

Tissue resuspension solution

5 mM EDTA
0.5% (w/v) *N*-lauroylsarcosine (Sarkosyl)
5% (v/v) 2-mercaptoethanol
Store up to 1 month at room temperature

Water-saturated phenol

Dissolve 100 g phenol crystals in water at 60° to 65°C. Aspirate the upper water phase and store up to 1 month at 4°C.

Do not use buffered phenol in place of water-saturated phenol.

COMMENTARY

Background Information

Guanidine thiocyanate is one of the most effective protein denaturants known. The use of guanidine to lyse cells was originally developed to allow purification of RNA from cells high in endogenous ribonucleases (Cox, 1968; Ullrich et al., 1977; Chirgwin et al., 1979).

The single-step method of RNA isolation described in the Basic Protocol is based on the ability of RNA to remain water soluble in a solution containing 4 M guanidine thiocyanate, pH 4, in the presence of a phenol/chloroform organic phase. Under such acidic conditions, most proteins and small fragments of DNA (50 bases to 10 kb) will be found in the organic phase while larger fragments of DNA and some proteins remain in the interphase. The fragmentation of DNA during homogenization helps to remove DNA from the water phase.

Since its introduction (Chomczynski and Sacchi, 1987), the single-step method has become widely used for isolating RNA from a large number of samples. In addition, the procedure permits recovery of total RNA from small quantities of tissue or cells, making it suitable for gene expression studies whenever the quantity of tissue or cells available is limited. The protocol presented here is an updated version of the original method that further

shortens the time for RNA isolation. All commercial application of the method is restricted by a U.S. patent (Chomczynski, 1989).

The two alternate protocols present methods, based on the observed fact that RNA is denser than DNA or protein, for separating RNA from other cellular macromolecules in the guanidine lysate on a CsCl step gradient (Glisin et al., 1974). A method using hot phenol and guanidine thiocyanate has also been described (Ferimisco et al., 1982).

In Alternate Protocol 1, cultured cells are lysed with a solution that contains 4 M guanidine as well as a mild detergent. This lysis is virtually instantaneous and the cells are thus rapidly taken from an intact state to a completely denaturing environment. In Alternate Protocol 2, tissues are homogenized in a guanidine solution without detergent. The protocols then take advantage of the fact that RNA can be separated from DNA and protein by virtue of its greater density. These protocols have received widespread use because they require very few manipulations. This increases the chance of producing intact RNA and reduces hands-on time for the experimenter. The disadvantage is that they require an ultracentrifuge and rotor, which generally limits the number of samples that can easily be processed

Figure 4.2.2 Rat liver RNA (5 μ g) isolated using the Basic Protocol was electrophoresed in a formaldehyde 1% agarose gel containing ethidium bromide (left), transferred to a hybridization membrane and stained with methylene blue stain (Molecular Research Center; Herrin and Schmidt, 1988, right). Shown are 28S (4.7 kb) and 18S (1.9 kb) ribosomal RNAs, and 4S to 5S (0.10 to 0.15 kb) RNA containing mix of tRNA and 5S ribosomal RNA.

simultaneously. These protocols should be used when very high quality RNA from a limited number of samples is required.

There are several commercial kits for total RNA isolation utilizing guanidine-based methods, the majority based on the single-step method. They can be divided into two groups. The first group, exemplified by the RNA Isolation Kit from Stratagene, includes kits containing denaturing solution, water-saturated phenol, and sodium acetate buffer prepared according to the single-step protocol described here (see Basic Protocol). The use of these kits saves the time needed to make components of the single-step method, but at a substantially higher price. The second group of kits is based on a commercial version of the single-step method combining denaturing solution, phenol, and buffer in a single monophasic solution. These kits offer an improved yield and shorter RNA isolation time (Chomczynski and Mackey, 1995). In this second group, the authors have tested and can recommend the following kits: Isogen (Nippon Gene), RNA-Stat 60 (Tel-Test), RNAzol B (Cinna Scientific), Tri-Pure Isolation Reagent (Boehringer Mannheim), TRI Reagent (Molecular Research Center), and TRIzol Reagent (Life Technologies). All the kits in the second group, except RNAzol B, allow simultaneous isolation of DNA and proteins from a sample used for RNA isolation.

Critical Parameters

As with any RNA preparative procedure, care must be taken to ensure that solutions are free of ribonuclease. Solutions that come into contact with the RNA after adding the guanidine solution are all treated with DEPC, with the exception of the TES solution (Tris inactivates DEPC). Most investigators wear gloves at all times when working with RNA solutions, as hands are a likely source of ribonuclease contamination (see introduction to Chapter 4).

The two Alternate Protocols rely on a thorough separation of DNA and protein from RNA in the step gradient. The use of silanized tubes, as well as careful technique when removing the supernatant, are important. Finally, low yields may result from failing to allow sufficient time for resuspension of the RNA pellet after centrifugation. This pellet is not readily soluble, and sufficient time and vortexing should be allowed to dissolve it.

There are two important points to consider when using the single-step protocol. First, fresh tissue is preferable for RNA isolation. Alternatively, tissue should be frozen immediately in liquid nitrogen and stored at -70°C . In the latter case, tissue should be pulverized in liquid nitrogen and homogenized, using a Polytron or Waring blender, in denaturing solution without thawing. Second, it is important not to let the final RNA pellet dry completely, as that will greatly decrease its solubility. This is critical in

all RNA isolation methods. Partially solubilized RNA has an A_{260}/A_{280} ratio <1.6 . Solubility of RNA can be improved by heating at 55° to 60°C with intermittent vortexing or by passing the RNA solution through a pipet tip.

Anticipated Results

The single-step method yields the whole spectrum of RNA molecules, including small (4S to 5S) RNAs. The amount of isolated RNA depends on the tissue used for isolation. Typically, 100 to 150 μg of total RNA is isolated from 100 mg of muscle tissue and up to 800 μg is isolated from 100 mg of liver. The yield of total RNA from 10^7 cultured cells ranges from 50 to 80 μg for fibroblasts and lymphocytes and 100 to 120 μg for epithelial cells. The A_{260}/A_{280} ratio of the isolated RNA is >1.8 .

The electrophoretic pattern of RNA isolated by the single-step method is exemplified in Figure 4.2.2 which shows the results of formaldehyde-agarose gel electrophoresis of rat liver RNA.

Time Considerations

The isolation of total RNA by the single-step method can be completed in <4 hr. The procedure can be interrupted at one of the isopropanol precipitations or at the ethanol wash steps. Store samples at -20°C if the procedure is interrupted at these steps. Avoid keeping samples in denaturing solution for >30 min.

In the alternate protocols, harvesting the RNA and setting up the gradient takes very little time (~ 1 hr for six samples) and is conveniently done in the evening, allowing the high-speed centrifuge run to go overnight. In a pinch, the guanidine cell lysate can be quick frozen in dry ice/ethanol and stored at -70°C . When the RNA is dissolved after the gradient, it can be stored as an ethanol precipitate indefinitely at any of the precipitation steps. The entire protocol requires 2 to 3 hr of hands-on time for 6 to 12 samples.

Phenol/SDS Method for Plant RNA Preparation

UNIT 4.3

**BASIC
PROTOCOL**

This protocol is divided into two stages: (1) lysis of the cells and removal of proteins by phenol/SDS extraction, and (2) separation of RNA from DNA and other impurities by selective precipitation using LiCl.

Materials

Diethylpyrocarbonate (DEPC)
Liquid nitrogen
Grinding buffer
Phenol equilibrated with TLE solution
Chloroform
8 M and 2 M LiCl
3 M sodium acetate
100% ethanol

Polytron (Brinkmann PT 10/35)
Beckman JA-10, JA-20, and JA-14 rotors (or equivalent)
50-ml Oak Ridge tube
Sarstedt tube

Sodium acetate, water, and LiCl solutions should be treated with DEPC to inhibit RNase activity. See *UNIT 4.1*, reagents and solutions, for instructions. **CAUTION:** *DEPC is a suspected carcinogen and should be handled carefully.*

Homogenize tissue and extract protein

1. Cool a mortar and pestle by pouring a little liquid nitrogen over it.
2. Weigh 15 g frozen plant tissue. If using freshly harvested tissue, quick-freeze in liquid nitrogen.

The time between harvesting of the tissue and freezing should be minimized; once tissue is frozen, work quickly so it does not have a chance to thaw.

3. Grind plant tissue in the mortar and pestle until tissue becomes a fine powder.

Add liquid nitrogen as needed to keep tissue frozen.

4. Immediately transfer to a 500-ml beaker containing 150 ml grinding buffer plus 50 ml TLE-equilibrated phenol.
5. Homogenize the mixture with Polytron for ~2 min at moderate speed (setting 5-6).
6. Add 50 ml chloroform. Use Polytron at low speed to mix in the added chloroform.

It is not necessary to add isoamyl alcohol to the chloroform for the following extractions.

7. Pour the slurry into a 500-ml Nalgene centrifuge bottle and heat 20 min at 50°C.

All extractions involving TLE-equilibrated phenol and chloroform should be done in screw-cap tubes or bottles resistant to those chemicals.

8. Centrifuge mixture 20 min at 10,000 rpm (17,700 × g), 4°C, in JA-10 rotor.
9. Take off as much aqueous layer as possible without disturbing the interface and transfer it to a clean 500-ml Nalgene bottle. Add 50 ml TLE-equilibrated phenol to this aqueous layer, shake bottle to mix phenol and aqueous phase, then add 50 ml chloroform.

TLE-equilibrated phenol and chloroform are added to the freshly removed aqueous layer

**Preparation and
Analysis of RNA**

4.3.1

to reduce possibility of degradation of RNA while steps 10 and 11 are performed.

10. Remove remaining aqueous layer together with interface from initial phenol extraction and transfer it to a 50-ml Oak Ridge tube. Centrifuge this material 20 min at 10,000 rpm ($17,700 \times g$), 4°C, in JA-20 rotor.

11. Remove aqueous layer and combine with aqueous phase already separated in step 9.

Steps 10 and 11 are done to recover the large volume of aqueous phase that is difficult to separate from the interface in a 500-ml bottle.

12. Vigorously shake the 500-ml bottle containing the combined aqueous layers to mix TLE-equilibrated phenol and chloroform with aqueous phase. Centrifuge mixture 15 min at 10,000 rpm ($17,700 \times g$), 4°C, in JA-10 rotor and remove aqueous layer to fresh 500-ml bottle.

13. Reextract the aqueous phase with TLE-equilibrated phenol and chloroform until no interface is obtained (usually a total of three extractions).

The interface should be small on these steps, so recentrifuging as in steps 10 and 11 is not necessary.

14. Extract aqueous phase one last time with chloroform.

This removes traces of TLE-equilibrated phenol in the aqueous layer which can cause problems with the lithium chloride precipitation.

Selectively precipitate RNA

These steps result in removal of contaminating DNA. If there is no need to remove DNA—for example, when poly(A)⁺ selection is the next step—simply ethanol precipitate the nucleic acid.

15. Transfer the aqueous phase to a clean 250-ml Nalgene bottle and add 8 M LiCl ($\frac{1}{3}$ vol) to bring solution to a final concentration of 2 M LiCl. Precipitate overnight at 4°C.

16. Collect precipitate by centrifugation for 20 min at 10,000 rpm ($15,300 \times g$), 4°C, in JA-14 rotor. Rinse pellet with a few milliliters of 2 M LiCl.

17. Resuspend pellet in 5 ml water and transfer to a 15-ml Sarstedt tube. Add 8 M LiCl to bring concentration of LiCl to 2 M and precipitate the RNA at 4°C for at least 2 hr.

18. Recover the RNA by centrifugation for 20 min at 10,000 rpm ($12,100 \times g$), 4°C, in JA-20 rotor. Rinse pellet with 2 M LiCl.

19. Resuspend RNA pellet in 2 ml water. Add 200 μ l of 3 M sodium acetate and 5.5 ml 100% ethanol. Precipitate at -20° overnight or in dry ice/ethanol for 30 min.

RNA can be stored in ethanol at -20° or -70° C indefinitely.

20. Recover RNA by centrifugation for 15 min at 10,000 rpm ($17,700 \times g$), 4°C, in JA-20 rotor. Resuspend RNA in 1 ml water. Dilute 10 μ l to 1 ml and measure the A_{260} and A_{280} . $1 \text{ OD}_{260} = 40 \mu\text{g/ml RNA}$.

REAGENTS AND SOLUTIONS

Grinding buffer

0.18 M Tris
0.09 M LiCl
4.5 mM EDTA
1% sodium dodecyl sulfate (SDS)
pH to 8.2 with HCl

This buffer is equivalent to TLE solution with $1/10$ vol 10% SDS added.

Phenol

Equilibrate freshly liquefied phenol (250 ml for a 15-g prep) with TLE solution (see below) on the day of preparation. First, extract with an equal volume of TLE solution plus 0.5 ml of 15 M NaOH (this should bring the pH close to 8.0), then extract two more times with TLE solution.

TLE solution

0.2 M Tris
0.1 M LiCl
5 mM EDTA
pH to 8.2 with HCl

COMMENTARY

Background Information

The method described here can be used to prepare RNA from a variety of eukaryotic tissues. The critical factor in isolating RNA from eukaryotic tissues is inactivating the endogenous RNase and preventing introduction of RNase from external sources. In general, protocols for making RNA from eukaryotic organisms involve lysing the cells in the presence of a strong denaturant and deproteinizing agent which inhibits RNase as well as strips the protein away from the RNA. In this protocol, the RNA is then separated from DNA and other impurities by selective precipitation in high salt.

Literature Review

The use of phenol in RNA preparations originated with a method described by Kirby (1968). The phenol/SDS procedure for RNA extraction described here is taken most directly from a protocol developed by Palmiter (1974). However, this procedure has evolved from Palmiter's through contributions from many different laboratories. The most widely used alternative method, developed by Chirgwin et al. (1979), involves the use of guanidinium isothiocyanate instead of the phenol/SDS mixture to disrupt cells and inactivate nucleases.

Critical Parameters

The most essential factor in making high-quality RNA from eukaryotic tissues is to eliminate RNase activity. The endogenous RNase is quickly inactivated by the phenol/SDS extraction. After the extractions, it is very important not to introduce RNase from external sources. In making RNA from plant tissues, special attention must be paid to effectively grinding up the tissue. Plant tissues are frequently fibrous and contain organic compounds that can make fresh tissue difficult to break up. Therefore, it is recommended that the tissue is frozen before grinding in a mortar and pestle.

Anticipated Results

The yield of RNA varies widely, depending on the plant tissue from which the RNA is extracted. A tissue that is good for making RNA, such as pea seedlings, should yield about 7 mg of total RNA from 15 g of starting material; however, mature *Arabidopsis* plants yield only about 3 mg from the same amount of tissue. The quality of RNA will also vary due to differences in levels of carbohydrates and secondary metabolites in the tissues used.

This protocol can easily be scaled up or down by appropriate changes in the volumes used. It can be successfully used with less than 1 g of tissue.

Time Considerations

Two samples will take 2 to 3 hr to process to the first LiCl precipitation. After the addition of LiCl to the aqueous phase of the phenol extractions, the RNA can be stored at 4°C for days or even weeks.

Preparation of Bacterial RNA

UNIT 4.4

Procedures for isolating RNA from bacteria involve disruption of the cells, followed by steps to separate the RNA from contaminating DNA and protein. Lysis strategies differ in the protocols presented below, including chemical degradation of gram-negative cell walls using sucrose/detergent or lysozyme, and sonication to break open gram-positive cell walls. Combinations of enzymatic degradation, organic extraction, and alcohol or salt precipitation are employed in the procedures to isolate the RNA from other cellular components, and various inhibitors of ribonuclease activity (diethylpyrocarbonate, vanadyl-ribonucleoside complex, and aurintricarboxylic acid) are described. If extremely high-quality RNA is required (e.g., for gene expression studies), the first basic protocol employs CsCl step-gradient centrifugation to remove all traces of contaminating DNA.

NOTE: Water and all other solutions should be treated with DEPC to inhibit RNase activity. See UNIT 4.1, reagents and solutions, for instructions.

CAUTION: DEPC is a suspected carcinogen and should be handled carefully with gloves. ATA causes irritation on contact with skin, eyes, and respiratory system. VRC is harmful if inhaled or swallowed. Use only in a well-ventilated area. Avoid contact with skin.

ISOLATION OF HIGH-QUALITY RNA FROM GRAM-NEGATIVE BACTERIA

BASIC
PROTOCOL

This protocol produces high-quality RNA suitable for northern blotting, S1 mapping, and primer extension from *E. coli* or cyanobacteria. Bacterial cells are lysed in a sucrose/Triton X-100 solution; subsequent organic extraction and ethanol precipitation yield total nucleic acids. The high quality of the resulting RNA is due to removal of contaminating DNA and proteins in a CsCl step-gradient centrifugation. A Beckman TL-100 ultracentrifuge with a TLA-100.3 rotor reduces the time required for RNA pelleting, but because many laboratories may not have access to this rotor, conditions for using an SW-41 rotor are also provided. In addition, two effective RNase inhibitors—vanadyl-ribonucleoside complex (VRC) and aurintricarboxylic acid (ATA; Hallick et al., 1977)—are included in this procedure. Lysozyme and proteinase digestions are not required.

Materials

- 100-ml *E. coli* culture or 500-ml cyanobacteria culture
- Stop buffer
- STET lysing solution
- Buffered phenol (UNIT 2.1)
- Chloroform (UNIT 2.1)
- 3 M sodium acetate, pH 6.0
- 200 mM and 10 mM vanadyl-ribonucleoside complex (VRC; GIBCO/BRL)
- 1:1 buffered phenol/chloroform
- DEPC-treated water (UNIT 4.1)
- Cesium chloride, solid
- CsCl cushion: 5.7 M CsCl in 100 mM EDTA, pH 7.0
- 100% and 70% ethanol, ice cold

Preparation and
Analysis of RNA

4.4.1

Beckman JA-14 and JA-17 rotors
15-ml polypropylene tube (Sarstedt)
Beckman TL-100 ultracentrifuge with TLA-100.3 rotor and 13 × 51-mm polycarbonate centrifuge tubes, *or* Beckman L5-65 ultracentrifuge with SW-41 rotor and 14 × 89-mm ultraclear centrifuge tubes

Lyse the bacteria

1. Grow a 100-ml culture of *E. coli* or 500-ml culture of cyanobacteria to log phase and stop growth by adding $\frac{1}{20}$ vol stop buffer. Place the culture on ice.

Ice cubes can be added directly to the culture to reduce the temperature.

Stop buffer contains the nuclease inhibitor ATA. This inhibitor can affect certain enzymes and should not be used if RNA will be needed for primer extension or S1 nuclease analysis (see critical parameters).

2. Harvest cells by centrifuging 5 min in a Beckman JA-14 rotor at 6000 rpm (5500 × g), 4°C. Resuspend pellet in 2 ml STET lysing solution and add 100 μl of 200 mM VRC. Transfer to 15-ml polypropylene tube.
3. Add 1 ml buffered phenol and vortex 1 min. Add 1 ml chloroform and vortex 1 min. Centrifuge 10 min in a JA-17 rotor at 8500 rpm (10,000 × g), 4°C, and collect the top aqueous phase.

After centrifugation, the cellular debris will form a thick crust at the interphase. Avoid disturbing the interphase while collecting upper aqueous phase.

4. Precipitate nucleic acids by adding $\frac{1}{10}$ vol of 3 M sodium acetate and 2 vol ice-cold 100% ethanol. Centrifuge 10 min in a JA-17 rotor at 8500 rpm (10,000 × g), 4°C. Resuspend pellet in 2 ml of 10 mM VRC.

The nucleic acid will form a visible precipitate immediately after the addition of cold ethanol. There is no need to place tubes at low temperatures. Formation of nucleic acid precipitate is a good indication that the cells lysed properly.

5. Extract twice with 1:1 phenol/chloroform and reprecipitate as in step 4.

This step further reduces protein contamination. The size of the nucleic acid pellet should be smaller than the pellet seen in step 4.

Purify RNA on CsCl gradients

- 6a. *If using TLA-100.3 rotor:* resuspend the nucleic acid pellet in 2 ml DEPC-treated water. Add 1 g solid CsCl and dissolve it completely. Layer 2.25 ml of this solution onto a 0.75-ml CsCl cushion in a 13 × 51-mm TLA-100.3 polycarbonate tube.

- 6b. *If using SW-41 rotor:* resuspend the nucleic acid pellet in 6 ml DEPC-treated water. Add 4.5 g solid CsCl and adjust volume to 9 ml with DEPC-treated water. Layer this solution onto a 3-ml CsCl cushion in a 14 × 89-mm ultraclear SW-41 tube.

Whichever rotor is employed, it is very important that the two layers remain well-separated. Gently overlay the cushion by releasing the liquid in a controlled manner.

Other swinging-bucket ultracentrifuge rotors may be used, but the sample volume, rotor speed, and run time must be adjusted accordingly (MacDonald et al., 1987).

- 7a. *For TLA-100.3 rotor:* centrifuge 1 hr at 80,000 rpm (280,000 × g), 20°C.

- 7b. *For SW-41 rotor:* centrifuge 24 hr at 30,000 rpm (150,000 × g), 20°C.

Recover RNA

8. Immediately after centrifugation, carefully remove the DNA at the interface and then remove the upper CsCl layer with a sterile Pasteur pipet. Pour off remaining supernatant and mark the position of the RNA pellet. Wipe walls of centrifuge tube with tissue.

Do not let the centrifuge tubes sit after the completion of run. The RNA pellet may become loosened which will cause difficulty in removing all liquid from the pellet.

9. Resuspend RNA pellet in 0.36 ml DEPC-treated water and transfer to a 1.5-ml microcentrifuge tube using a 1000- μ l pipettor.
10. Add $\frac{1}{10}$ vol of 3 M sodium acetate and 2.5 vol ice-cold 100% ethanol. Precipitate 20 min at -70°C . Microcentrifuge 5 min at high speed, 4°C , to pellet RNA.
11. Add 1 ml ice-cold 70% ethanol and microcentrifuge 5 min at high speed, 4°C .
12. Air dry the RNA pellet and dissolve in 200 μ l DEPC-treated water. Quantify by measuring the A_{260} and A_{280} (APPENDIX 3). Adjust to a final concentration of 4 $\mu\text{g}/\mu\text{l}$. Place at -70°C for long-term storage or store as an ethanol precipitate.

ISOLATION OF RNA FROM GRAM-POSITIVE BACTERIA

This protocol—designed primarily for use with gram-positive cells—uses sonication to break open the cell wall, detergent to lyse the membranes, and protease digestion to degrade cellular protein. Organic extraction and ethanol precipitation yield total nucleic acids. DNA is removed enzymatically and the RNA is repurified.

Materials

- 10-ml bacteria culture
- Lysis buffer
- 25:24:1 phenol/chloroform/isoamyl alcohol (UNIT 2.1)
- 24:1 chloroform/isoamyl alcohol
- 5 M NaCl
- 100% and 70% ethanol, ice-cold
- DNase digestion buffer
- 2.5 mg/ml RNase-free DNase I (UNIT 4.1)
- TE buffer, pH 8.0 (APPENDIX 2)
- Sorvall SS-34 rotor (or equivalent)
- Microtip sonicator

Lyse the bacteria

1. Harvest the cells from a 10-ml bacteria culture by centrifuging in a Sorvall SS-34 rotor 10 min at 10,000 rpm ($12,000 \times g$), 4°C .
2. Resuspend cells in 0.5 ml lysis buffer. Transfer to microcentrifuge tube and freeze on dry ice.
3. Thaw and sonicate three times for 10 sec with a microtip sonicator. Use a power setting of about 30 W. The cell suspension should clear, indicating lysis.

Avoid foaming the lysate.

4. Incubate 60 min at 37°C .

This incubation allows digestion of bacterial protein.

BASIC PROTOCOL

Preparation and Analysis of RNA

4.4.3

Isolate and recover RNA

5. Add an equal volume of 25:24:1 phenol/chloroform/isoamyl alcohol and microcentrifuge 5 min at high speed, room temperature. Remove aqueous (top) layer to a clean microcentrifuge tube.
6. Reextract once with an equal volume of 25:24:1 phenol/chloroform/isoamyl alcohol, then extract once with an equal volume of 24:1 chloroform/isoamyl alcohol.
7. To 400 μ l aqueous phase, add 15 μ l of 5 M NaCl and fill microcentrifuge tube with ice-cold 100% ethanol. Mix and incubate 15 to 30 min on ice or overnight at -20°C .
8. Spin down precipitated RNA in microcentrifuge tube 15 min at 4°C . Rinse pellet with 500 μ l ice-cold 70% ethanol and air dry.
9. Redissolve pellet in 95 μ l DNase digestion buffer. Add 4 μ l of 2.5 mg/ml RNase-free DNase I. Incubate 60 min at 37°C .
10. Extract once with 25:24:1 phenol/chloroform/isoamyl alcohol. Add 100 μ l TE buffer to remaining organic phase, mix thoroughly, and microcentrifuge 5 min at high speed, room temperature. Pool the two aqueous phases.
11. Extract once with chloroform/isoamyl alcohol.
12. Add 10 μ l of 5 M NaCl to the aqueous phase and mix. Add 600 μ l of 100% ethanol. Precipitate overnight at -20°C or 15 min on dry ice/ethanol. Collect the precipitate by microcentrifuging 15 to 30 min at high speed, 4°C .
13. Rinse pellet with 500 μ l ice-cold 70% ethanol and air dry. Redissolve in 100 μ l DEPC-treated water. Dilute 10 μ l into 1 ml water and quantify RNA by measuring the A_{260} and A_{280} (APPENDIX 3). Store the remaining RNA at -70°C or as an ethanol precipitate.

ALTERNATE PROTOCOL

RAPID ISOLATION OF RNA FROM GRAM-NEGATIVE BACTERIA

The following rather simple procedure works well for *Escherichia coli* and other gram-negative bacteria. Lysozyme is used to strip off the cell walls and the resulting protoplasts are lysed with detergent. Diethylpyrocarbonate (DEPC), a potent inactivator of ribonuclease, is added to the lysate. Salt is then added to coprecipitate the detergent, protein, and chromosomal DNA, which are removed by centrifugation. RNA is the predominant component of the supernatant fluid and is recovered by ethanol precipitation. RNA prepared by this method contains small amounts of DNA and protein but should be adequate for most kinds of analyses.

Additional Materials

- 10-ml gram-negative bacteria culture
- Protoplasting buffer
- 50 mg/ml lysozyme
- Gram-negative lysing buffer
- Diethylpyrocarbonate (DEPC)
- Saturated NaCl: 40 g NaCl in 100 ml DEPC-treated H_2O (stir until solution reaches saturation)

Lyse the bacteria

1. Collect the cells from a 10-ml gram-negative bacteria culture by centrifuging 10 min in a Sorvall SS-34 rotor at 10,000 rpm ($12,000 \times g$), 4°C .

2. Resuspend in 10 ml protoplasting buffer. Add 80 μ l of 50 mg/ml lysozyme. Incubate 15 min on ice.

Lysozyme digests the cell walls, leaving behind protoplasts (in effect, naked cells).

3. Collect the protoplasts by centrifuging 5 min in an SS-34 rotor at 7000 rpm (5900 \times g), 4°C.

The gentler spin is used because protoplasts are fragile.

4. Resuspend in 0.5 ml gram-negative lysing buffer. Add 15 μ l DEPC. Mix gently and transfer to a microcentrifuge tube.

The lysate should become clear and viscous. Avoid excessive agitation which shears DNA.

5. Incubate 5 min at 37°C.

Isolate and recover RNA

6. Chill on ice. Add 250 μ l saturated NaCl. Mix by inversion. A substantial precipitate should form.

The precipitate contains SDS, protein, and DNA.

7. Incubate 10 min on ice. Microcentrifuge 10 min at high speed, at room temperature or 4°C.

8. Remove the supernatant to two clean microcentrifuge tubes. Add to each tube 1 ml ice-cold 100% ethanol and precipitate 30 min on dry ice or overnight at -20°C.

9. Microcentrifuge 15 min at high speed, 4°C.

10. Rinse pellet in 500 μ l ice-cold 70% ethanol and air dry. Redissolve in 100 μ l DEPC-treated water. Dilute 10 μ l into 1 ml water and determine the A_{260} and A_{280} (APPENDIX 3). Store the remaining RNA at -70°C.

REAGENTS AND SOLUTIONS

Stop buffer

200 mM Tris·Cl, pH 8.0
20 mM EDTA
20 mM sodium azide
20 mM aurintricarboxylic acid (ATA; Sigma)

Do not include ATA if RNA is needed for primer extension or S1 nuclease mapping.
Store in a brown bottle at room temperature.

DNase digestion buffer

20 mM Tris·Cl, pH 8.0
10 mM MgCl₂
Store at room temperature

Gram-negative lysing buffer

10 mM Tris·Cl, pH 8.0
10 mM NaCl
1 mM sodium citrate
1.5% (w/v) sodium dodecyl sulfate (SDS)
Store at room temperature

Lysis buffer

30 mM Tris, pH 7.4
100 mM NaCl
5 mM EDTA
1% (w/v) SDS
Add proteinase K to 100 µg/ml just before use
Store at room temperature

Protoplasting buffer

15 mM Tris-Cl, pH 8.0
0.45 M sucrose
8 mM EDTA
Store at 4°C

STET lysing solution

8% (w/v) sucrose
5% (v/v) Triton X-100
50 mM EDTA
50 mM Tris-Cl, pH, 7.0
Prepare from DEPC-treated stock solutions and store at 4°C.

COMMENTARY

Background Information

The RNA isolation procedures presented here involve disruption of the bacteria, removal of DNA and protein, and precipitation of the remaining RNA. The purity of the RNA preparation varies, depending on the protocol followed.

For many experiments, including gene expression studies, obtaining high-quality RNA is crucial. The high-quality RNA procedure (first basic protocol) employs a lysing regime that does not involve lysozyme or protease digestions to separate total nucleic acids from cell debris. The purity of the RNA preparation is the result of pelleting through a CsCl step gradient.

Traditionally, RNA isolated from DNA and protein on CsCl step gradients by high-speed centrifugations (UNIT 4.2; Glisin et al., 1974) required 4.5 to 26 hr, depending upon the type of ultracentrifugation conditions used (MacDonald et al., 1987). The use of a TL-100 ultracentrifuge and TLA-100.3 rotor significantly reduces the time needed to pellet the RNA, making this a quick procedure as well.

The second basic protocol is an adaptation of published methods for preparing RNA from eukaryotic cells (McKnight, 1978; Thomas, 1980) for use with the gram-positive bacterium *Bacillus subtilis* (Gilman and Chamberlin, 1983). It is a relatively straightforward tech-

nique that uses protease digestion and organic extraction to remove protein and nuclease digestion to remove DNA. The main complication is that sonication is often required to facilitate lysis of *B. subtilis*. This procedure may also be used for *E. coli*.

A rapid procedure for obtaining bacterial RNA is detailed in the alternate protocol. This protocol provides a relatively simple method for rapidly isolating RNA from *E. coli*—without organic extractions, protease, or nuclease treatment (Summers, 1970). As a result, the RNA preparation may contain small amounts of DNA and protein, but these contaminants will not usually interfere with subsequent analysis.

Critical Parameters

As with any RNA preparative procedure, care must be taken to ensure that solutions are free of ribonuclease. Solutions that come into contact with the RNA should be treated with DEPC to inhibit RNase activity. Most investigators wear gloves at all times when working with RNA solutions, as hands are a likely source of ribonuclease contamination (see introduction to Chapter 4).

In all three protocols, lysis is an important step. Cell lysis must be complete in the first basic RNA protocol, which can be easily confirmed during the first ethanol precipitation (step 4). In a well-lysed culture, the nucleic acid present in the aqueous phase will form a

visible precipitate immediately after the addition of ice-cold ethanol. In the second basic protocol, care should be taken to avoid foaming the lysate (which contains SDS) during sonication. In the alternate protocol, care should be exercised to avoid manipulations that might shear the chromosomal DNA. Sheared fragments of DNA will not be efficiently removed from the lysate by the salt precipitation.

Also critical when preparing RNA by the first basic protocol is the volume limitation of the centrifuge tubes. Although the TLA-100.3 rotor will complete the RNA pelleting in 1 hr, it will only accommodate a 3-ml volume of sample/CsCl cushion. The SW-41 rotor takes longer but can accommodate a 9-ml sample. When preparing the gradient, care must be taken to maintain the layers—the interface between the CsCl cushion and the solution of RNA layered on top should be clearly visible.

The final RNA pellet may appear pink due to bound ATA. This will not affect northern blot hybridizations. ATA affects certain enzymes and should be omitted from the stop buffer if the RNA is to be used for primer extension or S1 mapping. RNA obtained without ATA in the stop buffer can still be used for primer extension and S1 mapping because other RNase inhibitors (VRC and DEPC) are used in the procedure.

Anticipated Results

For the first basic protocol, it is possible to get ~5 mg total RNA from 100 ml *E. coli*, of which ~95% is ribosomal. With cyanobacteria cultures, 500 ml yields 0.2 to 1 mg total RNA.

For the second basic and alternate protocols, from 10 ml cells at $OD_{600} = 1$ in rich medium, expect yields of 0.5 to 1 mg RNA, more than 95% of which is stable rRNA and tRNA. Yields from cells growing more slowly in poorer media are lower, but this difference is predominantly due to the stable RNAs whose rate of synthesis is tightly coupled to growth rate.

Time Considerations

The first basic protocol requires 90 min for cell lysis, deproteinization, and setup of CsCl gradients. Centrifugation times are 1 and 24 hr for the TLA-100.3 and SW-41 rotors, respectively. Recovery and precipitation of the RNA pellet requires 40 min.

For the second basic protocol, allow ~3 hr

to get to the first ethanol precipitation. The RNA can be stored indefinitely at this stage. The alternate protocol is more rapid. It can be completed (i.e., to the ethanol precipitation) in <2 hr.

Preparation of Poly(A)⁺ RNA

UNIT 4.5

BASIC
PROTOCOL

This protocol separates poly(A)⁺ RNA from the remainder of total RNA, which is largely rRNA and tRNA. Total RNA is denatured to expose the poly(A) (polyadenylated) tails. Poly(A)-containing RNA is then bound to oligo(dT) cellulose, with the remainder of the RNA washing through. The poly(A)⁺ RNA is eluted by removing salt from the solution, thus destabilizing the dT:rA hybrid. The column can then be repeated to remove contaminating poly(A)⁻ RNA.

Materials

Diethylpyrocarbonate (DEPC)
5 M NaOH
Oligo(dT) cellulose
0.1 M NaOH
Poly(A) loading buffer
10 M LiCl
Middle wash buffer
2 mM EDTA/0.1% sodium dodecyl sulfate (SDS)
3 M sodium acetate
RNase-free TE buffer

Silanized column (APPENDIX 3)
Silanized SW-55 centrifuge tubes (APPENDIX 3)
Beckman SW-55 rotor or equivalent

The following solutions should be treated with DEPC to inhibit RNase activity: water, 10 M LiCl, 3 M sodium acetate. See UNIT 4.1, reagents and solutions, for instructions. CAUTION: DEPC is a suspected carcinogen and should be handled carefully.

Pour oligo(dT) column

1. Wash a silanized column with 10 ml of 5 M NaOH, then rinse it with water.
A silanized glass Pasteur pipet plugged with silanized glass wool or a small disposable column with a 2-ml capacity can be used. It is important to silanize the column to prevent RNA from sticking to the glass or plastic.
2. Add 0.5 g dry oligo(dT) cellulose powder to 1 ml of 0.1 M NaOH. Pour the slurry into the column and rinse the column with ~10 ml water.
3. Equilibrate the column with 10 to 20 ml of loading buffer. The pH of the output should be near 7.5 at the end of the wash.

Fractionate of poly(A)⁺ RNA

4. Heat ~2 mg total RNA in water to 70°C for 10 min. Add LiCl to 0.5 M final concentration from a 10 M LiCl stock solution.

Heating the RNA is necessary to disrupt any secondary structure that might form. It is important not to have too large a column for the amount of RNA selected. This is because the final poly(A)⁺ RNA will be so dilute that precipitation and workup of the sample will be very inefficient. Therefore, use a much smaller column when poly(A)⁺-selecting 500 µg or less of RNA, and scale down all of the steps accordingly. Generally, 1 ml of oligo(dT) cellulose is sufficient for 5 to 10 mg input RNA.

5. Pass the RNA solution through the oligo(dT) column. Wash the column with 1 ml poly(A) loading buffer. Make certain to save the eluant from this loading step.
6. Pass the eluant through the column twice more.

The starting RNA is passed through the column three times to ensure that all of the poly(A)⁺ RNA has stuck to the oligo(dT).

Preparation and
Analysis of RNA

Supplement 21

7. Rinse the column with 2 ml middle wash buffer.
8. Elute the RNA into a fresh tube with 2 ml of 2 mM EDTA/0.1% SDS.
9. Reequilibrate the oligo(dT) column, as in step 3. Take the eluted RNA and repeat the poly(A)⁺ selection, as described in steps 4 to 8.

This second oligo(dT) column removes small levels of contaminating poly(A)⁻ RNA. It can be omitted if such contaminants will not create a problem, e.g., when RNA is to be used for S1 analysis.

10. Precipitate the eluted RNA by adjusting the salt concentration to 0.3 M sodium acetate using a 3 M sodium acetate stock solution. Add 2.5 vol ethanol and transfer the solution to two silanized SW-55 tubes.
11. Incubate RNA overnight at -20°C or on dry ice/ethanol for 30 min. Collect the precipitate by centrifuging 30 min at 50,000 rpm (304,000 × g), 4°C, in a Beckman SW-55 rotor.

This high speed centrifugation is required to pellet the very dilute RNA.

12. Pour off ethanol and allow pellets to air dry. Resuspend RNA in 150 μl of RNase-free TE buffer and pool the samples. Quality of RNA can be checked by heating 5 μl at 70°C for 5 min and analyzing on a 1% agarose gel (UNIT 2.5).

REAGENTS AND SOLUTIONS

Middle wash buffer

0.15 M LiCl
10 mM Tris·Cl, pH 7.5
1 mM EDTA
0.1% sodium dodecyl sulfate

Poly(A) loading buffer

0.5 M LiCl
10 mM Tris·Cl, pH 7.5
1 mM EDTA
0.1% sodium dodecyl sulfate

COMMENTARY

Background Information

Most messenger RNAs contain a poly(A) tail, while structural RNAs do not. Poly(A) selection therefore enriches for messenger RNA. The technique has proved essential for construction of cDNA libraries. It is also useful when analyzing the structure of low-abundance mRNAs. Removing the ribosomal and tRNAs from a preparation increases the amount of RNA that can be clearly analyzed by S1 analysis, for example, thus allowing detection of a low level message.

Literature Review

Aviv and Leder (1972) first used oligo(dT)

cellulose to bind poly(A)⁺ message and thus achieved fractionation of mRNA. The basic technique has undergone slight modification since then. Some protocols substitute poly(U) Sephadex for oligo(dT) (e.g., Moore and Sharp, 1984). Poly(U) Sephadex has somewhat longer stretches of nucleotides and a better flow rate than does oligo(dT) cellulose.

Critical Parameters

It is critical—even more so than in most RNA techniques—to have RNase-free solutions when doing poly(A) selection. This is because in most instances the 5' end of the message is needed. Therefore, no breaks be-

tween the 5' and 3' end of the message can be tolerated, as the broken message is separated from its poly(A)⁺ tail.

A second critical aspect is that the size of the column be matched to the amount of RNA being selected. The size of the column determines the volume in which the poly(A)⁺ RNA is eluted. If this volume is very large, then the poly(A)⁺ RNA will be extremely dilute. The more dilute the RNA, the more difficult it is to quantitatively precipitate. Also, a greater fraction of a dilute RNA solution will be lost due to nonspecific sticking of the RNA to the sides of the column and tubes used during the preparation. The capacity of oligo(dT) cellulose is generally supplied by the manufacturer and tends to be quite high. Thus, a very small column should be used when doing poly(A) selection on small quantities of RNA, and the elution volumes should be scaled down as well.

Anticipated Results

Approximately 1% of the input RNA should be retrieved as poly(A)⁺ RNA. The RNA should

appear as a smear from 20 kb down (with greatest intensity in the 5- to 10-kb range) on an agarose gel, with no evidence of rRNA bands.

Time Considerations

It will take approximately 1 hr to prepare and equilibrate the column. Running the column will take half an hour. The RNA is stable once it is in ethanol.

ANALYSIS OF RNA STRUCTURE AND SYNTHESIS

This section presents methods used to determine the level, structure, size, and synthesis rate of RNA. The first four protocols describe commonly used methods for analyzing in detail RNA structure and amount: S1 analysis, ribonuclease protection, primer extension, and northern blots. Both S1 analysis (UNIT 4.6) and ribonuclease protection (UNIT 4.7) use a single-stranded probe that is complementary to the sequence of the measured RNA. These protocols can be used to determine both the endpoint and the amount of a specific RNA. The S1 technique uses an end-labeled single-stranded DNA probe. This allows unambiguous determination of the 5' end of a message and results in low background on the final gel; this means, however, that the technique is not as sensitive as ribonuclease protection. The latter technique increases sensitivity by utilizing a body-labeled RNA probe, although high background problems may occur.

Primer extension (UNIT 4.8) employs a labeled oligomer of defined sequence that is extended to the end of any homologous RNA by the enzyme reverse transcriptase. The major strengths of this technique are that no extensive probe preparation is needed and that it allows mapping of RNA across discontinuities, such as splice sites. High background may also occur with this technique, resulting in lowered sensitivity. This background is caused by random priming as well as possible termination and pause sites in the RNA for reverse transcriptase.

The fourth technique presented for analysis of RNA structure is northern blot hybridization (UNIT 4.9). In this protocol, RNA is separated on an agarose gel and transferred to nitrocellulose. The size and amount of any specific RNA is determined by hybridizing a labeled specific probe to the nitrocellulose filter. This allows determination of the size of the entire message and also is very sensitive to message level. One cannot determine precise endpoints of a message using this protocol.

The final section of the chapter describes the nuclear runoff technique (UNIT 4.10), which allows determination of the number of active RNA polymerase molecules on a given eukaryotic gene. It is commonly used to determine how the transcription rates of genes vary in response to the growth state of a cell.

UNIT 4.6

S1 Analysis of Messenger RNA Using Single-Stranded DNA Probes

This method takes advantage of the ability of oligonucleotides to be efficiently labeled to a high specific activity at the 5' end through the use of kinase. The oligonucleotide is hybridized to a specific single-stranded template containing the complementary sequence to the oligonucleotide, and this hybrid is extended through the use of the Klenow fragment of *E. coli* DNA polymerase I. The mixture is cut with a restriction enzyme to give the probe a defined 3' end, and the probe is isolated on an alkaline agarose gel. Before using this protocol it is first helpful to have an M13 clone. If this is unavailable, a double-stranded plasmid clone of the region to be studied may be used, as described in the alternate protocol. A second alternate protocol is presented that describes the use of long oligonucleotides as probes for S1 analysis. This alternate protocol is useful for rapid and easy quantitation of the level of mRNA produced from a characterized promoter.

For the mapping of the 5' end of an RNA species, hybridization of the probe to RNA is then carried out. S1 nuclease is added to digest all of the unhybridized portion of the probe (see Fig. 4.6.1). Electrophoresis of the hybrid on a denaturing polyacrylamide

gel allows a determination of the length of the remaining DNA fragment. This length equals the distance between the 5' end of the probe to the 5' end of the RNA, defining the transcriptional start site to the nucleotide. By performing the hybridization reaction in vast probe excess, quantitation of the relative amounts of RNA can be estimated between samples.

S1 ANALYSIS OF mRNA USING M13 TEMPLATE

Materials

- Diethylpyrocarbonate (DEPC)
- Low gelling/melting temperature agarose (UNIT 2.6)
- Alkaline pour buffer
- Alkaline running buffer
- [γ - 32 P]ATP (10 mCi/ml, 6000 Ci/mmol)
- 100 μ g/ml oligonucleotide primer (UNIT 2.11)
- 10 \times polynucleotide kinase buffer
- T4 polynucleotide kinase (UNIT 3.10)
- 18 μ g M13mp template DNA containing sequence of interest
- 10 \times TM buffer (APPENDIX 2)
- 4 mM dNTP mix (UNIT 3.4)
- Klenow fragment of *E. coli* DNA polymerase I (UNIT 3.5)
- 10 \times restriction buffer (UNIT 3.1)

BASIC PROTOCOL

Figure 4.6.1 S1 mapping of RNA 5' ends and intron boundaries.

Preparation and Analysis of RNA

4.6.2

40 U restriction endonuclease (Table 3.1.1)
5 M ammonium acetate
100% ethanol
Alkaline loading buffer
TE buffer (APPENDIX 2)
10 mg/ml tRNA
Buffered phenol (UNIT 2.1A)
3 M and 0.3 M sodium acetate, pH 5.2
70% ethanol/30% DEPC-treated H₂O
S1 hybridization solution
2× S1 nuclease buffer (UNIT 3.12)
2 mg/ml single-stranded calf thymus DNA
S1 nuclease (UNIT 3.12)
S1 stop buffer
Formamide loading buffer (UNIT 2.12)

Additional reagents and equipment for ethanol precipitation (UNIT 2.1A) and agarose and denaturing polyacrylamide gel electrophoresis (UNITS 2.5 and 7.6, respectively)

Water and sodium acetate should be treated with DEPC to inhibit RNase activity. See UNIT 4.1, reagents and solutions, for instructions. CAUTION: DEPC is a suspected carcinogen and should be handled carefully.

Synthesize single-stranded probe

1. Prepare a 1.2% low gelling/melting temperature agarose gel in 1× alkaline pour buffer (see UNIT 2.5 for a description of how to pour horizontal agarose gels). Use a comb with fairly wide teeth (8 mm works well). When the gel has solidified, soak it overnight in 1× alkaline running buffer.

If the agarose is boiled in alkaline buffer, the gel will not form properly, hence the overnight soaking step. An alternative that eliminates soaking, but is somewhat more work, is to boil the agarose in water. When the agarose has cooled to 50° to 60°C, add alkaline running buffer to 1× and cast the gel.

2. To prepare kinased oligonucleotide, mix the following and incubate 30 min at 37°C:

20 µl [γ -³²P]ATP (10 mCi/ml, 200 µCi total)
1 µl 100 µg/ml oligonucleotide primer (100 ng; ideally a 20- to 30-mer)
2.5 µl 10× polynucleotide kinase buffer
4 U T4 polynucleotide kinase

The oligonucleotide used must hybridize to the RNA of interest and should be selected to produce a probe that results in a 50- to 250-base-long protected fragment after S1 analysis.

3. Heat 5 min at 65°C to inactivate kinase.
4. Anneal oligonucleotide to probe template. If a single-stranded template (e.g., an M13mp clone) is used, add the following to the kinased oligonucleotide: 18 µg template DNA in 55 µl water plus 9 µl of 10× TM buffer. Hybridize 15 min at 40°C.

To make probe using a double-stranded template, see alternate protocol.

5. Extend oligonucleotide primer to synthesize a full-length probe. To hybridized probe template, add the following: 9 µl of 4 mM dNTP mix (final concentration 400 µM) plus 2 µl Klenow fragment of *E. coli* DNA polymerase I (10 U). Incubate 30 min at 37°C. Heat 5 min at 65°C to inactivate Klenow fragment, then place on ice.
6. Cut probe to an appropriate length with 10 µl of 10× appropriate restriction buffer plus 40 U appropriate restriction enzyme.

Incubate 45 min at 37°C. Inactivate restriction enzyme by heating 5 min at 65°C.

This step creates the 3' unlabeled end of the probe. When analyzing a specific transcription start site, for example, this end of the probe should be 20 to 300 bases upstream of the start site. This allows easy separation of undigested probe from the band that forms as a result of hybridization to appropriately initiated RNA.

7. Add 100 µl of 5 M ammonium acetate and 500 µl ethanol. Precipitate at –20°C overnight or in dry ice/ethanol for 15 min. Spin 15 min in microcentrifuge, then dry pellet.

Isolate single-stranded probe

8. Load the alkaline agarose gel (see UNIT 2.5). Resuspend the probe in 25 µl of alkaline loading buffer and load carefully onto gel. Note which lane you load as the dye may not be visible by the end of the run. Run 4 hr at 1.8 V/cm maximum.

Gel can heat up and melt readily in alkaline running buffer if voltage is too high.

CAUTION: Follow all rules for safe electrophoresis as outlined in UNIT 2.5—cover gel box to provide radioactive shielding.

9. Isolate the probe from the gel. Shut off power and carefully slide the gel onto a glass plate behind a radiation shield; cover the gel with plastic wrap. In a darkroom, place a piece of X-ray film on the gel such that a corner of the film and the gel are in alignment. Expose 3 min, then develop the film.
10. Check alignments of the bands shown on the film with the gel by using a minimonitor. The upper, darker band is the probe, the lower band is unhybridized oligonucleotide (see Fig. 4.6.2). Trim away excess agarose with a razor, using the minimonitor to be sure you are not accidentally discarding probe. When down to a small block of agarose, cut into thin slices starting at the bottom of the rectangle (see Fig. 4.6.2). Check each slice with the minimonitor and remove the slice(s) that contains the upper

Figure 4.6.2 Excision of single-stranded end-labeled probe from alkaline low gelling/melting temperature agarose gel.

radioactive band to one or two microcentrifuge tubes.

CAUTION: *Minimize exposure—use radioactive shielding.*

11. Melt the slice(s) at 65°C and determine the approximate volume with a pipettor. Add an equal volume of TE buffer. Heat at 65°C for 10 min.
12. Add 1 µl of 10 mg/ml tRNA; phenol extract (*NOT* phenol/chloroform) twice, avoiding the white interface both times.
Chloroform can dramatically reduce the yield from these extractions.
13. Add $\frac{1}{10}$ vol of 3 M sodium acetate (pH 5.2), 2 vol ethanol, and precipitate. Resuspend pellet(s) in 100 µl of 0.3 M sodium acetate.
14. Count 1 µl for Cerenkov counts in a scintillation counter to determine cpm/µl.

Hybridize single-stranded probe and digest with S1 nuclease

This hybridization protocol uses an 80% formamide solution, and thus is very stringent. In our hands, it produces very low background. Less stringent hybridization conditions may be used; in particular, aqueous hybridization (steps 8 to 14 of the second alternate protocol).

15. Add amount of probe equal to 5×10^4 Cerenkov counts to up to 50 µg RNA on ice. Adjust final volume to 100 µl and the salt to 0.3 M sodium acetate. Add 250 µl ethanol and precipitate. Wash with 70% ethanol/30% DEPC-treated water and dry pellet inverted on Kimwipes for 30 min.

Do not use a Speedvac evaporator, as pellet will become virtually impossible to resuspend.

If the purpose of performing the S1 analysis is to quantitate RNA levels, it is important have probe excess. For most uses, 5×10^4 Cerenkov counts will be a large excess of probe. This can be verified empirically either by using 2- to 3-fold different amounts of the same RNA sample and affirming that there is an appropriate change in signal (see support protocol).

16. Resuspend the pellet in 20 µl S1 hybridization solution. Draw liquid through pipettor tip at least 50 times and vortex vigorously.

It is critical to resuspend well.

17. Denature the samples 10 min at 65°C. Hybridize overnight at 30°C.

18. The next morning, prepare following mix (volumes are per reaction):

150 µl 2× S1 nuclease buffer
3 µl 2 mg/ml single-stranded calf thymus DNA
147 µl H₂O
300 U S1 nuclease

Add 300 µl mix to each hybridization reaction. Incubate 60 min at 30°C.

The optimal amount of S1 nuclease may vary somewhat according to nuclease lot and the precise probe and RNA structure. Generally, between 100 and 1000 U/ml in the reaction works best.

19. Add 80 µl S1 stop buffer to each reaction, then add 1 ml 100% ethanol and precipitate. Wash pellet with 70% ethanol; dry 5 min in a Speedvac evaporator.
20. Resuspend pellet in 3 µl TE buffer and add 4 µl formamide loading dye. Boil tubes 3 min and place on ice.
21. Analyze 3 to 5 µl on a denaturing polyacrylamide/urea gel (*UNIT 7.4*) of the appropriate percentage for the expected size of the protected band (see commentary).

**PREPARATION OF SINGLE-STRANDED END-LABELED PROBE
AND S1 ANALYSIS OF mRNA**

1. Pour a 1.2% low gelling/melting temperature alkaline agarose gel.
2. To prepare kinased oligonucleotide mix the following and incubate 30 min at 37°C:
 - 20 μ l [γ -³²P]ATP (10 mCi/ml, 6000 Ci/mmol)
 - 1 μ l 100 μ g/ml oligonucleotide primer
 - 2.5 μ l 10 \times polynucleotide kinase buffer
 - 4 U polynucleotide kinaseHeat 5 min at 65°C to inactivate kinase.
3. Anneal oligonucleotide to probe template: Add 9 μ l of 10 \times TM buffer to 18 μ g template DNA in 55 μ l water and incubate 15 min at 40°C.
4. Extend oligonucleotide primer to make full-length probe: Add 9 μ l of 4 mM dNTP mix, then add 2 μ l Klenow fragment, and incubate 30 min at 37°C. Heat inactivate Klenow fragment 5 min at 65°C.
5. Cut probe to defined length: Add 10 μ l of 10 \times restriction buffer and 40 U appropriate restriction enzyme; incubate 45 min at 37°C. Treat 5 min at 65°C to inactivate restriction enzyme.
6. Ethanol precipitate (100 μ l of 3 M ammonium acetate, 500 μ l ethanol) and load onto the alkaline gel in 25 μ l alkaline loading buffer. Run gel at 1.8 V/cm for 4 hr.
7. Isolate probe. Add equal volume of TE buffer and incubate 10 min at 65°C.
8. Phenol extract twice, add 1 μ l of 10 mg/ml tRNA, ethanol precipitate, and quantitate.
9. Make up a 100- μ l solution containing 5×10^4 counts probe and up to 50 μ g RNA on ice.
10. Ethanol precipitate (250 μ l ethanol) and dry inverted 30 min.
11. Resuspend pellet thoroughly in 20 μ l S1 hybridization solution. Denature 10 min at 65°C. Hybridize overnight at 30°C.
12. The next morning, add the following mix to each reaction and incubate 60 min at 30°C:
 - 150 μ l 2 \times S1 nuclease buffer
 - 3 μ l 2 mg/ml single-stranded calf thymus DNA
 - 147 μ l H₂O
 - 300 U S1 nuclease
13. Add 80 μ l S1 stop buffer and ethanol precipitate. Wash pellet with 70% ethanol and dry 5 min in Speedvac evaporator. Resuspend pellet in 3 μ l TE buffer and add 4 μ l formamide loading dye. Boil 3 min and place on ice.
14. Load 3 to 5 μ l on denaturing polyacrylamide/urea gel.

**ALTERNATE
PROTOCOL**

**SYNTHESIS OF SINGLE-STRANDED PROBE FROM DOUBLE-STRANDED
PLASMID TEMPLATE**

A double-stranded plasmid can also be used as template for making the single-stranded S1 probe. It is first necessary, however, to denature the template as described here.

Additional Materials

- 10× NaOH/EDTA solution
- 1.5 M ammonium acetate, pH 4.5

1. To 18 µg DNA, add enough 10× NaOH/EDTA to achieve a 1× final concentration. Incubate 5 min at room temperature.
2. Add 1.5 vol of 1.5 M ammonium acetate, pH 4.5, to neutralize the solution. Add 2.5 vol ethanol and precipitate at -70°C for 15 min.
3. Collect the pellet by centrifugation, rinse with 70% ethanol, and dry 5 min in a Speedvac evaporator.
4. Resuspend the pellet in 55 µl water and add the template to the reaction of step 4 of basic protocol in place of the single-stranded template.

**ALTERNATE
PROTOCOL**

**QUANTITATIVE S1 ANALYSIS OF mRNA USING OLIGONUCLEOTIDE
PROBES**

This protocol is ideal for measuring the amount of RNA in situations where the structure of the RNA is already known. It is similar to the basic protocol except that the hybridization probes are synthetic oligonucleotides (40 to 80 nucleotides in length) that are ^{32}P -labeled at the 5' end. Necessary controls for this procedure are described in the support protocol.

Additional Materials

- 2 pmol each oligonucleotide probe
- 4 M ammonium acetate
- BioGel P-2 (or equivalent resin; optional)
- 3× aqueous hybridization solution (optional)
- 0.5 M EDTA
- 0.1 M NaOH

Additional reagents and equipment for acid precipitation (*UNIT 3.4*) and denaturing polyacrylamide gel electrophoresis (*UNIT 7.6*)

Design of the oligonucleotides

1. For each RNA to be analyzed, the oligonucleotide should contain at least 40 residues that are complementary to the RNA coding strand. It is essential that the 5' end of the oligonucleotide be complementary to the RNA, and it is useful if the 5' terminal nucleotides contain dG or dC residues.

The rate and optimal conditions of forming RNA:DNA duplexes as well as their stability are strongly influenced by the length of the duplex region. Oligonucleotides with 40 to 80 complementary residues are preferred over shorter oligonucleotides. The use of dG or dC residues at the 5' terminus minimizes fraying at the ends of the RNA:DNA duplex.

2. For experiments in which it is also desired to determine the 5' termini of the RNA(s), the 3' end of the oligonucleotide should extend at least 4 nucleotides beyond the RNA coding sequence (i.e., upstream of the upstream-most RNA initiation site). If the levels of RNA species with different 5' ends are to be quantitated, the oligonucleotide should be designed so that each RNA species will contain at least 40 complementary residues; this minimizes variability in physical properties of RNA:DNA duplexes.

By including the additional nucleotides, bands resulting from RNA:DNA duplexes are easily distinguished from the band representing the probe. A single probe can be used to quantitate RNA species provided that the 5' end of these RNAs map relatively close together (less than 20 to 30 nucleotides). If the 5' ends map further apart, individual (preferably non-overlapping) oligonucleotides must be used.

3. For the probe representing the control RNA, 5' end determination is unimportant, so the oligonucleotide can be complementary to internal RNA sequences. However, the 3' end of the oligonucleotide should contain at least 4 additional oligonucleotides that are not complementary to the RNA. The additional nucleotides should be chosen such that in the RNA:DNA hybrids purines are opposite purines and pyrimidines are opposite pyrimidines.

A major advantage of using the "internal probe" for the control RNA is that the resulting RNA:DNA duplexes generate a single band on the autoradiogram. Maximizing the mismatch at the noncomplementary nucleotides facilitates S1 cleavage and hence the distinction between bands resulting from RNA:DNA duplexes and from the band representing the probe.

4. It is crucial to design the oligonucleotides such that the RNA:DNA duplexes from the expected transcripts are sufficiently different in size to be separated by gel electrophoresis. A minimal spacing of 4 nucleotides among different species is desirable.

Prepare the hybridization probe

5. Set up the following T4 polynucleotide kinase reaction in a final volume of 25 μ l as described in *UNIT 3.10*:

2 pmol each oligonucleotide
150 μ Ci [γ -³²P]ATP (3000 to 7000 Ci/mmol)
2.5 μ l 10 \times T4 polynucleotide kinase buffer
10 U T4 polynucleotide kinase

For optimal sensitivity, use [γ -³²P]ATP at the highest possible specific activity. Crude preparations of "carrier-free" [γ -³²P]ATP work equally as well as more purified preparations which have a somewhat lower specific activity. If supplies of an oligonucleotide are limiting or if few samples are to be analyzed, the amount of oligonucleotide can be reduced. Conversion factor: 1 pmol of an oligonucleotide of length 45 = 15 ng.

6. Incubate at 37°C for 30 to 60 min. Stop the reaction by heating at 75°C for 10 min.

*It is useful to monitor the extent of phosphorylation by acid precipitation of the oligonucleotide (*UNIT 3.4*). Assuming that 2 pmol of 2 oligonucleotides are incubated in the above reaction conditions, the theoretical incorporation of labeled ATP into DNA should be 5% to 15%.*

7. Add 1 μ l of 10 mg/ml tRNA, 26 μ l of 4 M ammonium acetate, and 110 μ l ethanol and carry out an ethanol precipitation as described in *UNIT 2.1*. Resuspend the sample in 26 μ l H₂O, add 26 μ l of 4 M ammonium acetate and 110 μ l ethanol, and repeat the ethanol precipitation.

Ethanol precipitation from a 2 M ammonium acetate solution precipitates the oligonucleotide, but not the unincorporated ATP. Alternatively, the unincorporated precursors can be separated from the labeled oligonucleotide by column chromatography (see Fig. 3.4.1). Due to the small size of the oligonucleotide, it is necessary to use a resin such as BioGel P-2. This procedure generates sufficient probe for at least 50 to 100 hybridization reactions. The probe can be used for at least 6 weeks (store at -20°C) with minor effect on the quality of the results (of course, the exposure time must be increased to compensate for radioactive decay).

Hybridize, treat with S1 nuclease, and analyze product

Hybridization, S1 digestion, and product analysis using the oligonucleotide probe can be done exactly as described in the basic protocol (start at step 15). Care should be taken to ensure that the temperature and time of hybridization are such that hybridization goes to completion (see support protocol and critical parameters). Alternatively, an aqueous hybridization can be performed, as described below:

8. For each RNA preparation to be analyzed, set up the following 30 μ l hybridization reaction.

20 μ l RNA (containing up to 50 μ g RNA)
9 μ l 3 \times aqueous hybridization solution
1 μ l probe mixture (0.3 ng each oligonucleotide or approximately 10⁵ cpm)

It is useful to make up a premix containing enough hybridization solution and probe mixture for all the hybridization reactions. If supplies of the oligonucleotide are limiting, the amount of oligonucleotides can be reduced further (probably at least as low as 0.1 ng for each). In this case, control reactions should be carried out to determine if hybridization was complete.

9. Heat the reaction mixture to 75°C for 10 min, and then incubate overnight at 55°C (or other optimal hybridization temperature—see support protocol and critical parameters).

It is best to carry out the reactions in an incubator or covered waterbath to minimize evaporation to the top of the tube.

10. Briefly spin each tube in a microcentrifuge to collect the condensate from the top of the tube. Place tubes at 37°C.

11. To each tube, add 270 μ l of S1 nuclease mix containing 100 to 300 U of S1 nuclease (see basic protocol, step 18, for preparation of S1 nuclease mix). Incubate 30 to 60 min at 37°C. Stop the reaction by adding 3 μ l of 0.5 M EDTA, 1 μ l of 10 mg/ml tRNA, and 0.7 ml ethanol.

For any specific application, the amount of S1 nuclease should be determined empirically. The optimal amount of S1 nuclease should completely degrade the unhybridized probe but should not degrade the RNA:DNA hybrids.

12. Place the mixture on dry ice for 10 to 15 min, ethanol precipitate, and wash with ethanol as described in UNIT 2.1. Resuspend in 10 μ l of 0.1 M NaOH.

13. Combine 3 μ l of the resuspended products with 3 μ l of formamide loading dye. Heat to 90°C for 2 min and analyze on a denaturing polyacrylamide gel (UNIT 7.4).

14. Scan the resultant autoradiogram with a densitometer and measure the band intensities corresponding to the RNA(s) of interest and the control RNA(s). In this way, the amount of the RNA of interest is normalized to the amount of control RNA.

The absolute intensities of the bands will depend on the relative amount of the RNA species and the total amount of RNA loaded. When comparing RNA levels for a number of samples, it is often useful to run a second gel in which the volumes of the samples remaining from step 13 are adjusted to equalize the band intensities for the control RNA.

CONTROLS FOR QUANTITATIVE S1 ANALYSIS OF mRNA

For accurate quantitation, it is essential that (1) the probe is in excess, (2) the hybridization reaction goes to completion, (3) the RNA:DNA duplexes are equally stable, and (4) the S1 nuclease reaction proceeds properly. Although these conditions should be satisfied with the basic and alternate protocols described above, it is important to verify them with appropriate controls. First, varying amounts of a given RNA sample should be hybridized to a constant amount of probe to ensure that the band intensity is directly proportional to the amount of RNA added; i.e., the assay should be linear. Second, samples from a given hybridization reaction should be taken at various times after combining the RNA and DNA, and the resultant aliquots should be treated with S1 nuclease. Hybridization is complete when the band intensity does not increase after further incubation. This control is particularly important when using low concentrations of the labeled oligonucleotides. Third, the hybridization temperature should be varied to determine the optimal temperature. The temperature should be high enough to promote efficient hybridization, but low enough such that there is no preferential loss of RNA:DNA duplexes (shorter duplexes are less stable than longer ones). Fourth, for a standard determination, the level of S1 nuclease should be varied to ensure complete degradation of the probe without loss of the desired signal. Once the parameters for a given assay are established, it is unnecessary to repeat them for subsequent RNA determinations.

REAGENTS AND SOLUTIONS***Alkaline loading buffer***

30 mM NaOH
1 mM EDTA, pH 8
10% Ficoll
0.025% bromocresol green

Alkaline pour buffer, 50×

2.5 M NaCl
50 mM EDTA, pH 8
Dilute to 1× for working solution

Alkaline running buffer, 50×

1.5 M NaOH
50 mM EDTA, pH 8
Dilute to 1× for working solution

3× aqueous hybridization solution

3 M NaCl
0.5 M HEPES, pH 7.5
1 mM EDTA, pH 8

S1 hybridization solution

80% deionized formamide
40 mM PIPES, pH 6.4
400 mM NaCl
1 mM EDTA, pH 8
Store in 1-ml aliquots at -70°C

10× NaOH/EDTA solution

2 N NaOH
2 mM EDTA, pH 8

10× polynucleotide kinase buffer

700 mM Tris·Cl, pH 7.5
100 mM MgCl₂
50 mM dithiothreitol
1 mM spermidine·Cl
1 mM EDTA

2× S1 nuclease buffer

0.56 M NaCl
0.1 M sodium acetate, pH 4.5
9 mM ZnSO₄
Filter sterilize and store at 4°C

S1 stop buffer

4 M ammonium acetate
20 mM EDTA, pH 8
40 µg/ml tRNA
Store at 4°C

10 mg/ml tRNA

Dissolve in H₂O at 10 to 20 mg/ml and extract repeatedly with buffered phenol.

COMMENTARY**Background Information**

S1 mapping can be used to do the following: (1) map 5' and 3' ends of a transcript using an end-labeled probe (Weaver and Weissman, 1979); (2) quantitate the level of a particular RNA; (3) determine the direction of transcription; and (4) map the location and size of introns in primary eukaryotic transcripts (see Fig. 4.6.1).

The S1 enzyme is a single-stranded endonuclease that will digest both single-stranded RNA and DNA. The principle of S1 analysis is first to hybridize a DNA probe fragment to cellular RNA. S1 nuclease is then added to digest all single-stranded regions: 5' overhangs, 3' overhangs, and introns, depending on the specific probe fragment used. The double-stranded RNA-DNA hybrid is resistant to cleavage. The labeled DNA fragment then reflects the amount and size of RNA in the hybrid that is homologous to the DNA probe.

The use of oligonucleotide probes as described in the alternate protocol is advantageous for several reasons. First, probe preparation is rapid as it is accomplished by a simple T4 polynucleotide kinase reaction. Second, by including equimolar amounts of two or more oligonucleotides in the kinase reaction, hybridization probes for the RNA of interest as well as a control RNA(s) can be prepared simultaneously. Hybridization of RNA to such a probe mixture makes it possible to measure the

amount of a given RNA with respect to an internal control(s). Third, the ability to obtain large amounts of a labeled oligonucleotide ensures that the probe is in considerable excess over RNA and that the hybridization reaction goes to completion, conditions that are essential for accurate quantitation. Fourth, as the probes are derived from synthetic oligonucleotides and hence completely single-stranded, complications due to variable amounts of the complementary strand are avoided. Fifth, as the probes are short, reasonable results can be obtained even when the RNA sample is somewhat degraded (this is not a recommendation).

Literature Review

Berk and Sharp (1977) developed the technique of S1 mapping and used it to examine early adenovirus transcripts using unlabeled RNA hybridized to high-specific-activity ³²P-labeled DNA. By using overlapping restriction fragments, they were able to map the sizes and endpoints of these transcripts. Weaver and Weissman (1979) modified the original protocol through the use of end-labeled probes, which allows both determination of which DNA strand is being transcribed and which part of the probe is protected from S1 degradation, yielding map distances directly. Favalaro et al. (1980) described a method of using

two-dimensional gel analysis to map introns more quickly. In addition, this paper provides a great deal of information about one-dimensional S1 gel analysis of RNAs both by direct autoradiography or by Northern analysis.

The protocol given here has the advantage of *not* requiring an empirical determination of the correct hybridization temperature. In the original Berk-Sharp protocol, a double-stranded probe was used; this dictated that a hybridization temperature be found in the “window” above the T_m for the DNA-DNA duplex, but below the T_m for RNA-DNA duplexes. This must be done to prevent probe renaturation while promoting hybridization to RNA (Casey and Davidson, 1977). As each probe is different, this empirical determination must be done for each probe. Hybridization is then carried out at the $T_m \text{ DNA-DNA} + 1^\circ\text{C}$. The protocol presented describes a simple method of isolating a strictly single-stranded probe, and hence probe renaturation is irrelevant.

Critical Parameters

There are two major problems, opposite in nature, that occur during S1 analysis: no signal and excessive background. There are three primary reasons for obtaining no signal. First, the specific activity of the probe is lower than it should be. One should obtain 1 to 2×10^7 cpm of single-stranded probe after starting with 0.1 μg of a 20-mer (specific activity $\sim 10^7/\mu\text{g}$ for a 400-base single-stranded probe). If the yield of probe is significantly lower than this, one possibility is that the kinase reaction has not worked efficiently. Some oligonucleotide preparations contain residual chemicals used in preparation that can inhibit kinase. These can sometimes be removed by adjusting the oligonucleotide solution to 10 mM MgSO_4 and precipitating with 5 vol ethanol.

Second, the RNA is degraded. Check the RNA by running the preparation on an agarose gel and staining with ethidium bromide.

Third, there is very little of the specific RNA present. If S1 analysis is being performed after transfection of mammalian cells, the level of specific RNA is frequently very low. The level can be enriched by oligo(dT) selection (UNIT 4.5). Alternatively, transfection efficiency may be lower than is possible, and the transfection protocol should be optimized (see introduction to Section I of Chapter 9). Finally, the use of SP6 probes (UNIT 4.7) will increase sensitivity ~ 10 -fold and may result in detection of a signal.

Problems with excessive background are not usually seen with the protocol presented here.

Generally, the final gel can be left on film for over 2 weeks without significant background appearing. One cause of background is inclusion of DNA homologous to the single-stranded probe in the probe preparation. This can be excluded by making probes that are much shorter than the single-stranded template (e.g., 400 bases or less) and being careful when cutting the probe out of the gel to avoid contamination by the unlabeled high-molecular-weight species. A second cause is incomplete S1 digestion. A control in which tRNA is hybridized to the probe will be informative—if there is background, one of these first two problems is probably the cause. It is also possible that the RNA sample could be extensively degraded.

Finally, if formamide hybridization was used, the RNA and probe mixture may never have been solubilized in the hybridization. This results in an intense probe band and very little signal. If RNA pellets dry completely, they become virtually impossible to resuspend. Allow pellets to remain moist, and try to monitor resuspension with a minimonitor. It is advisable to be overly zealous in resuspending pellets in buffers containing formamide.

See support protocol for controls that will help to ensure accurate quantitation.

Anticipated Results

One should obtain 1 to 2×10^7 cpm of single-stranded probe from a preparation that starts with 0.1 μg of oligo. As isolation of DNA from low gelling/melting temperature agarose is about 50% efficient, this should allow a rough estimate of specific activity at about 1 to 2×10^7 cpm/ μg of a completed 400-base probe. The probe can be used as long as the specific activity remains high enough to detect the transcript of interest (up to 6 weeks). Gels will become somewhat “noisier” with older probe due to decay of the probe during storage. The following percentage gel should be used:

<i>Polyacrylamide urea gel (%)</i> :	<i>Size of band (base pairs)</i> :
4	>200
5	80 to 200
8	40 to 100
12	10 to 50

Time Considerations

Labeling and digesting the probe takes 2 to 3 hr. Running the gel and isolating the finished

probe takes another 7 hr. It is advisable when using a double-stranded plasmid template for the probe to denature the plasmid DNA as a first step before kinasing the oligo.

Setting up the S1 hybridizations takes 2 hr at most; however, it is advisable to hybridize overnight to be sure that all the RNA sequences being analyzed have hybridized to the probe. Performing S1 digestion takes 1 hr; subsequent sample workup and running of the denaturing polyacrylamide gel should take no more than 5 hr total, and very little of this is hands-on time.

Ribonuclease Protection Assay

UNIT 4.7

BASIC
PROTOCOL

Sequence-specific hybridization probes of high specific activity are prepared by cloning the probe sequence downstream of a bacteriophage promoter. The plasmid is cleaved with a restriction enzyme, and the plasmid DNA is transcribed with bacteriophage RNA polymerase, which efficiently transcribes the cloned sequence into a discrete RNA species of known specific activity and high abundance. The RNA is purified by removal of the DNA template with deoxyribonuclease, the protein with phenol/chloroform, and the unincorporated label by ethanol precipitation in the presence of 2 M ammonium acetate. Alternatively, the probe is purified by gel electrophoresis (support protocol). The probe RNA is hybridized to sample RNAs. The hybridization reactions are treated with ribonuclease to remove free probe, leaving intact fragments of probe annealed to homologous sequences in the sample RNA. These fragments are recovered by ethanol precipitation and analyzed by electrophoresis on a sequencing gel. The presence of the target mRNA in the samples is revealed by the appearance of an appropriately sized fragment of the probe.

Materials

Diethylpyrocarbonate (DEPC)
5× transcription buffer
200 mM dithiothreitol (DTT)
3NTP mix (ATP, UTP, and GTP at 4 mM each; *UNIT 3.4*)
[α - 32 P]CTP (10 mCi/ml, 400 to 800 Ci/mmol)
Placental ribonuclease inhibitor (e.g., RNasin from Promega Biotec)
0.5 mg/ml template DNA (support protocol)
Bacteriophage RNA polymerase (*UNIT 3.8*)
2.5 mg/ml RNase-free DNase I (*UNIT 4.1*)
10 mg/ml tRNA (*UNIT 4.6*)
25:24:1 phenol/chloroform/isoamyl alcohol
2.5 M ammonium acetate
100% ethanol
75% ethanol/25% 0.1 M sodium acetate, pH 5.2
Hybridization buffer
Ribonuclease digestion buffer
40 μ g/ml ribonuclease A
2 μ g/ml ribonuclease T1
20% (w/v) sodium dodecyl sulfate (SDS)
20 mg/ml proteinase K (store at -20°C)
RNA loading buffer

Additional reagents and equipment for phenol extraction (*UNIT 2.1*) and denaturing polyacrylamide gel electrophoresis (*UNIT 2.12* & *UNIT 7.6*)

Water and sodium acetate should be freshly treated with DEPC to inhibit RNase activity. See *UNIT 4.1*, reagents and solutions, for instructions. CAUTION: *DEPC is a suspected carcinogen and should be handled carefully.*

Prepare the probe

1. Mix in an autoclaved microcentrifuge tube:
 - 4 μ l 5× transcription buffer
 - 1 μ l 200 mM DTT
 - 2 μ l 3NTP mix
 - 10 μ l [α - 32 P]CTP (10 mCi/ml, 400 to 800 Ci/mmol)
 - 1 μ l placental ribonuclease inhibitor (20 to 40 U)

Preparation and
Analysis of RNA

4.7.1

Supplement 24

- 1 μ l 0.5 mg/ml template DNA (25 μ g/ml final)
- 1 μ l bacteriophage RNA polymerase (5 to 10 U)

The first four ingredients should be added before the template DNA to avoid precipitation of the DNA by the spermidine present in the transcription buffer.

2. Incubate 30 to 60 min at 40°C for SP6 RNA polymerase or 37°C for T7 and T3 RNA polymerases.

Incubating for longer periods of time is not productive because the labeled nucleoside triphosphate is rapidly used up. Adding more enzyme will not help either. In fact, the presence of excess enzyme leads to random transcription of the template. Some of these transcripts will be complementary to the probe, resulting in high backgrounds in the hybridizations.

3. Add 5 μ g or 10 U RNase-free DNase I (typically 2 μ l of a 5000 U/ml or 2.5 mg/ml stock solution); incubate 15 min at 37°C.

This digestion removes the template DNA. It is critical to the success of the procedure (see commentary).

4. Add 2 μ l of 10 mg/ml tRNA as carrier and water to a final volume of 50 μ l.
5. Extract with phenol/chloroform/isoamyl alcohol.
6. Add to the aqueous phase 200 μ l of 2.5 M ammonium acetate and 750 μ l of 100% ethanol. Mix and precipitate the RNA by incubating 15 min on ice and centrifuging 15 min at 4°C.

If the RNA probe is to be gel purified (see commentary), proceed with support protocol.

7. Redissolve the pellet in 50 μ l water and add 200 μ l of 2.5 M ammonium acetate and 750 μ l of 100% ethanol; precipitate as in step 6.
8. Repeat step 7.

These three precipitations remove virtually all of the unincorporated label. Other methods for separating the polymerized RNA from the free nucleoside triphosphates (e.g., spin columns) may be substituted as long as care is exercised to avoid contamination with ribonuclease.

9. Rinse the pellet with 75% ethanol/25% 0.1 M sodium acetate, pH 5.2.
10. Dry and redissolve in 100 μ l hybridization buffer.
11. Count 1 μ l in liquid scintillation counter to determine incorporation.

The specific activity of the probe is $\sim 10^9$ cpm/ μ g, and the probe breaks down rapidly due to radiolysis. Thus, the probe is best if used the day it is prepared. Acceptable results are obtained with probes stored at 4°C for a few days. After a week, the probe is largely degraded.

Hybridize probe RNA to sample RNAs

12. Precipitate the sample RNAs with 100% ethanol or, if RNA is stored in water, lyophilize.

For total cellular or cytoplasmic RNA, 10 μ g is usually sufficient for most messages. It is often possible to use less for abundant species. Include a sample containing tRNA. This reaction serves as a control for background hybridization and completion of the ribonuclease digestion. This hybridization reaction should yield no protected probe.

13. Redissolve in 30 μ l hybridization buffer containing 5×10^5 cpm of probe RNA.

Care should be exercised to ensure that the RNA pellet is completely redissolved. This is best accomplished by repeated pipetting. Note that more than one probe may be included in the hybridization buffer, allowing multiple mRNAs to be assayed in a single sample. Background increases with the amount of probe added to the hybridization reaction. Therefore, do not add more than necessary to achieve a linear increase in signal with input RNA.

14. Incubate 5 min at 85°C to denature RNA.
15. Rapidly transfer to desired hybridization temperature. Incubate overnight (>8 hr).

Because the RNA probe cannot reanneal as can a double-stranded DNA probe in an S1 nuclease assay, hybridization temperature is not absolutely critical. For each probe, however, there is an optimal temperature, perhaps because of secondary structures that can form in the probe. A good temperature to try is 45°C, but it is advisable to test a range of temperatures from 30° to 60°C. For some RNAs, hybridization may be complete in as little as 4 to 6 hr.

Digest the ribonuclease

16. Add to each hybridization reaction 350 µl ribonuclease digestion buffer containing 40 µg/ml ribonuclease A and 2 µg/ml ribonuclease T1. Incubate 30 to 60 min at 30°C.

The final hybridization signal is relatively insensitive to changes in these incubation conditions. However, if problems are suspected with this step, incubation temperatures ranging from 15° to 37°C should be tested. If internal cleavage of the RNA duplexes is observed, omit ribonuclease A (see commentary).

17. Add 10 µl of 20% (w/v) SDS and 2.5 µl of 20 mg/ml proteinase K. Incubate 15 min at 37°C.
18. Extract once with 400 µl phenol/chloroform/isoamyl alcohol, removing the aqueous phase to a clean microcentrifuge tube containing 1 µl of 10 mg/ml yeast tRNA.
19. Add 1 ml ethanol and precipitate.
20. Dry pellet and redissolve in 3 to 5 µl RNA loading buffer.
21. Incubate 3 min at 85°C to denature.
22. Analyze on a denaturing polyacrylamide/urea (sequencing) gel.

RNA has a lower mobility in these gels than DNA of the same length. If DNA markers are used to estimate the size of a protected RNA fragment, the correct size is 5% to 10% smaller than this estimate. For example, if an RNA species runs with a DNA marker of 100 nucleotides, its actual length is 90 to 95 nucleotides.

GEL PURIFICATION OF RNA PROBES

The following protocol is used for purification of full-length probe, which may be necessary under certain conditions.

Additional Materials

TBE buffer (APPENDIX 2)
Elution buffer

1. Dry the RNA after the first ethanol precipitation and redissolve in 10 µl RNA loading buffer.

It is important that the RNA be completely dried and then fully redissolved.

**SUPPORT
PROTOCOL**

**Preparation and
Analysis of RNA**

4.7.3

2. Heat 5 min at 85°C to denature the RNA.
3. Load onto a gel containing 6% polyacrylamide (29:1 acrylamide/bisacrylamide) and TBE buffer. The gel is 0.4 mm thick and 14 cm long (sequencing-length gels may also be used). Run at 300 V (higher for longer gels) until the bromphenol blue dye has run one-half to two-thirds down the gel.

Nondenaturing gels are used in the interest of speed, but it is important that the RNA be fully denatured before loading. Denaturing gels containing urea may be used, if desired.

4. Disassemble the gel, leaving it on one plate. Wrap in plastic wrap, mark with hot ink, and expose to film for 30 sec. Using the film as a template, excise the full-length RNA band.

Don't be greedy. The RNA actually occupies a narrower band than the band on the film. Cleaner hybridizations result from smaller gel slices.

5. Elute the RNA in 400 µl elution buffer and shake 2 to 4 hr at 37°C.

The elution buffer generally precipitates at room temperature. Warm briefly before use. Small probes (<200 nucleotides) will elute in 90 min. Large probes (>400 nucleotides) require longer elution times, but amounts sufficient for the experiment may elute in 2 hr.

6. Remove the eluate to a fresh microcentrifuge tube and add 1 ml of 100% ethanol.
7. Incubate 15 min on ice and spin 15 min in a microcentrifuge.

Monitor the eluate and the gel slice. There should be more counts in the former. All counts in the eluate should precipitate with ethanol.

8. Redissolve the RNA pellet in 50 µl hybridization buffer and count 1 µl in a liquid scintillation counter.

Yields will be lower than those obtained without gel purification, but this procedure should yield sufficient probe for more than 50 hybridizations. Background will be substantially lower.

SUPPORT PROTOCOL

PREPARATION OF TEMPLATE DNA

Template DNA is prepared by inserting the sequences of interest into a plasmid vector carrying a bacteriophage promoter. Strategies for constructing such plasmids are discussed in the commentary. Vectors containing bacteriophage promoters are commercially available.

Digest the DNA with a restriction enzyme (Table 3.1.1) that cuts immediately downstream of the probe sequence. This allows the generation of a uniquely sized runoff transcript. The enzyme chosen may cut the plasmid in several places as long as it does not cut within the phage promoter, the probe sequence, or intervening vector DNA. Restriction enzymes that generate 5' overhangs are best. (Do not cut with enzymes that leave 3' overhangs because these overhangs serve as initiation sites for the polymerase, leading to synthesis of RNA complementary to the probe.) Cut the DNA to completion but do not grossly overdigest. Extract cut DNA with phenol/chloroform, precipitate with ethanol, and redissolve at 0.5 mg/ml in RNase-free TE buffer. As little as 100 ng of template DNA will yield a reasonable amount of probe.

REAGENTS AND SOLUTIONS

Bacteriophage RNA polymerase

SP6, T3, or T7, depending on the vector in which probe sequences are cloned. All are functionally equivalent.

[...-³²P]CTP

Purchased commercially as an aqueous solution at a concentration of 10 mCi/ml. Specific activities of 400 to 800 Ci/mmol should be used. Higher specific activities yield a probe too unstable to use.

Labeled GTP or UTP may be substituted (see commentary). Be sure to use an appropriate mix of the three unlabeled nucleoside triphosphates.

Elution buffer

2 M ammonium acetate
1% SDS
25 µg/ml tRNA

Hybridization buffer

5× stock solution:
200 mM PIPES, pH 6.4
2 M NaCl
5 mM EDTA

Working solution:
4 parts formamide
1 part 5× stock buffer

Prepare hybridization buffer fresh as needed from frozen 5× stock and formamide freshly deionized by vortexing with mixed bed resin beads. Alternatively, store in small aliquots at -70°C.

3NTP mix

4 mM each ATP, UTP, and GTP
0.5 mM EDTA, pH 8
Store at -20°C

Ribonuclease digestion buffer

10 mM Tris·Cl, pH 7.5
300 mM NaCl
5 mM EDTA
Add 1/50 vol of 50× ribonuclease mix:
2 mg/ml ribonuclease A
0.1 mg/ml ribonuclease T1

RNase digestion buffer may be stored at room temperature. Add RNases from frozen stocks as needed. Be sure to use disposable tubes to make up this reagent.

RNA loading buffer

80% (v/v) formamide 1 mM EDTA, pH 8.0
0.1% bromphenol blue
0.1% Xylene Cyanol

Do not use Maxam-Gilbert loading buffer or any buffer containing NaOH.

5× transcription buffers

<i>T7, T3 RNA polymerases:</i>	<i>SP6 RNA polymerase:</i>
200 mM Tris·Cl, pH 8	200 mM Tris·Cl, pH 7.5
40 mM MgCl ₂	30 mM MgCl ₂
10 mM spermidine	10 mM spermidine
250 mM NaCl	

Use freshly prepared DEPC-treated water (see UNIT 4.1).

COMMENTARY

Background Information

Bacteriophage RNA polymerases possess several properties that make them well suited for the preparation of high-specific-activity hybridization probes (for review, see Chamberlin and Ryan, 1982). They are single subunit enzymes that are relatively stable and easy to purify. Moreover, because their genes reside on phage genomes, they have been fairly straightforward to clone and express in uninfected *E. coli*, thereby increasing the ease and economy of purification. Second, they polymerize RNA at an exceedingly high rate—200 to 300 nucleotides per minute—approximately 10 times faster than *E. coli* RNA polymerase and faster than DNA polymerases. Thus, large amounts of probe are easily prepared. Third, they are very specific in their action, recognizing fairly long promoter sequences that are unlikely to appear fortuitously in other DNA. Therefore, the probes are very homogeneous in sequence and usually require little further purification.

To make a probe for use in this assay, it is first necessary to subclone a fragment containing the sequences of interest downstream of a phage promoter (see Fig. 4.7.1). The sequence to be analyzed must be cloned such that the RNA produced by the phage polymerase is complementary to the RNA to be analyzed. Ideally, this construct should be able to be digested with a restriction enzyme to produce a linear template that will be transcribed into a 100- to 300-base runoff transcript. For example, if one wished to analyze the level of appropriately initiated transcription from a promoter, a DNA fragment from that promoter with endpoints at +150 and -100 could be cloned such that the +150 site is immediately adjacent to the

phage promoter. Cleaving the resultant clone at a restriction site adjacent to the -100 site would then allow runoff synthesis of a 250-base probe that would give a 150-base signal in the assay.

Literature Review

This protocol is a substitute for the widely used S1 nuclease mapping technique (Berk and Sharp, 1977; Weaver and Weissman, 1979; UNIT 4.6, this manual). It was first reported in the literature by Zinn et al. (1983) and subsequently described in detail by Melton et al. (1984). These developments were made possible by the isolation and characterization of the phage-encoded RNA polymerase of the *S. typhimurium* phage SP6 (Butler and Chamberlin, 1982) and the mapping and cloning of a bacteriophage promoter sequence (Kassevetis et al., 1982; Melton et al., 1984). Subsequently, the RNA polymerase produced by the related *E. coli* phages T3 and T7 have been similarly employed. The advantages of this technique over classical S1 nuclease mapping are as follows: (1) the ease of probe preparation—gel purification is not usually required; (2) unlike end-labeled or nick-translated probes, the specific activities of these RNA probes are fixed by the specific activity of the labeled ribonucleoside triphosphate, not by the efficiency of the enzymatic reaction; (3) the probes are prepared in large quantities and at much higher specific activity than classical end-labeled S1 probes, dramatically increasing the sensitivity of detection; (4) the probes are single-stranded and therefore cannot reanneal, and they generate more stable duplexes than would a DNA probe; and (5) treatment of RNA-RNA duplexes with ribonuclease is a more

Figure 4.7.1 Structure of a typical transcription template for synthesizing an RNA probe.

reliable and reproducible reaction than is treatment of RNA-DNA hybrids with S1 nuclease, which can be sensitive to temperature and enzyme concentration. Many of these advantages may also be achieved, however, by carrying out S1 nuclease mapping with body-labeled single-stranded DNA probes (Ley et al., 1982).

RNA probes may also be substituted for DNA probes in blot hybridizations (UNIT 2.9).

Troubleshooting

The most common problems encountered with this procedure are probes that do not reach full length and high background in the hybridizations (i.e., excessive signal in the tRNA control). Incomplete transcripts may be caused by ribonuclease contamination or by pausing or termination of the RNA polymerase before completion of the transcript. Pausing and termination are sequence-specific phenomena which are further exacerbated by the low concentration of the labeled ribonucleoside triphosphate. They are best avoided by choosing a relatively small probe (100 to 300 nucleotides in length).

The appearance of incomplete transcripts can also depend on the choice of labeled ribonucleoside triphosphate. Therefore, changing the labeled nucleotide may help. In addition, specific activity may be sacrificed by adding unlabeled ribonucleoside triphosphate to increase the absolute concentration. If the problem persists, full-length probe may be gel purified (see support protocol), taking care to avoid ribonuclease contamination.

Background hybridization is most commonly caused by incomplete digestion of the template DNA in the transcription reaction. Residual DNA fragments copurify with the probe and will hybridize efficiently to the probe, generating a smear of bands which will appear in all lanes. This problem can usually be solved by trying a fresh preparation of DNase, by preparing a new batch of template DNA, or by gel purifying the probe. While the hybridization and digestion conditions listed in the protocol work satisfactorily for most probes, parameters that should be varied to optimize the signal-to-noise ratio include the hybridization temperature, amount of probe, and ribonuclease digestion conditions.

A second source of background is the presence of traces of sense RNA in the probe. This RNA can arise from excess enzyme in the transcription reaction or from the use of a template cleaved with a restriction enzyme that leaves 3' overhangs. These overhangs are in-

itiation sites for RNA polymerase. Even exceedingly small amounts of sense RNA in the antisense probe will create very high background in the hybridizations. Sense RNA contamination in the probe, whatever the cause, may be the explanation for persistent background problems. This situation is best resolved simply by gel purifying the probe (see support protocol).

Another problem that occasionally arises is internal cleavage of RNA duplexes during ribonuclease digestion. This leads to a loss of the full-length protected product and the generation of small subfragments. The bacterial CAT gene, for example, contains a long run of A residues near its 5' end. This region can "breathe" during ribonuclease treatment and then get cut by RNase A. This problem is solved simply by omitting RNase A from the digestions. Treatment with 2 $\mu\text{g}/\text{ml}$ RNase T1 alone is sufficient for most reactions, although it does not allow mapping of RNA ends at highest resolution.

Anticipated Results

Over half the label in the transcription reaction is typically incorporated into probe ($\sim 10^8$ cpm), often more. If substantially lower incorporation is achieved, the specific activity of the probe is just as high, but the yield is reduced. In principle, therefore, this probe should work just as well as probe from an efficient transcription reaction. In practice, however, greater backgrounds usually result when probes from low-incorporation reactions are used. When the probe is purified by gel electrophoresis (support protocol), yields are lower—typically $2\text{--}5 \times 10^7$ cpm—enough for at least 40 typical hybridizations.

The hybridization signal resulting from a fairly low abundance mRNA in 10 μg of total RNA should be detectable with an overnight exposure using an intensifying screen. Often, shorter exposures or exposures without a screen will suffice.

Time Considerations

Probe synthesis takes ~ 3 hr, mostly incubation time. With gel purification of probes, elapsed time—including probe electrophoresis and elution—is 6 to 8 hr. RNA samples for hybridization may be ethanol precipitated during this time. The probes are best used the day they are synthesized. Thus, a convenient arrangement is to prepare the probes and set up the hybridizations the same day. The following morning, nuclease digestions and gel

electrophoresis are performed. Allow 2 to 3 hr for the digestions and subsequent purification steps.

Primer Extension

UNIT 4.8

BASIC
PROTOCOL

This protocol can be used to map the 5' terminus of an RNA and to quantitate the amount of a given RNA by extending a primer using reverse transcriptase. The primer is an oligonucleotide (or restriction fragment) that is complementary to a portion of the RNA of interest. The primer is end-labeled, hybridized to the RNA, and extended by reverse transcriptase using unlabeled deoxynucleotides to form a single-stranded DNA complementary to the template RNA. The resultant DNA is analyzed on a sequencing gel. The length of the extended primer maps the position of the 5' end of the RNA, and the yield of primer extension product reflects the abundance of the RNA.

Materials

Diethylpyrocarbonate (DEPC; UNIT 4.1)
10× T4 polynucleotide kinase buffer (UNIT 3.4)
0.1 M and 1 M dithiothreitol (DTT; APPENDIX 2)
1 mM spermidine
50 to 100 ng/μl oligonucleotide primer (5 to 10 μM; UNIT 2.11)
10 μCi/μl [γ -³²P]ATP (3000 Ci/mmol)
20 to 30 U/μl T4 polynucleotide kinase (UNIT 3.10)
0.5 M EDTA, pH 8.0 (APPENDIX 2)
TE buffer, pH 8.0 (APPENDIX 2)
Cation-exchange resin (e.g., Bio-Rad AG 50W-X8), equilibrated in 0.1 M Tris-Cl (pH 7.5)/0.5 M NaCl
Anion-exchange resin (e.g., Whatman DE-52), equilibrated in TEN 100
TEN 100 buffer: 100 mM NaCl in TE buffer, pH 7.5 (APPENDIX 2)
TEN 300 buffer: 300 mM NaCl in TE buffer, pH 7.5 (APPENDIX 2)
TEN 600 buffer: 600 mM NaCl in TE buffer, pH 7.5 (APPENDIX 2)
Total cellular RNA (UNITS 4.1-4.3)
10× hybridization buffer
0.1 M Tris-Cl, pH 8.3 (APPENDIX 2)
0.5 M MgCl₂
1 mg/ml actinomycin D (store at 4°C protected from light; UNIT 1.4)
10 mM 4dNTP mix (UNIT 3.4)
25 U/μl AMV reverse transcriptase (UNIT 3.7)
RNase reaction mix
3 M sodium acetate (APPENDIX 2)
25:24:1 (v/v/v) phenol/chloroform/isoamyl alcohol (UNIT 2.1)
100% and 70% ethanol
Stop/loading dye (UNIT 7.4)
9% acrylamide/7 M urea gel (UNIT 2.12)
Silanized glass wool and 1000-μl pipet tip (APPENDIX 3)
65°C water bath
Additional reagents and equipment for denaturing gel electrophoresis (UNITS 2.12 & 7.6), phenol extraction and ethanol precipitation of DNA (UNIT 2.1), and autoradiography (APPENDIX 3)

NOTE: Water should be treated with DEPC to inhibit RNase activity. See UNIT 4.1, reagents and solutions, for instructions.

CAUTION: DEPC is a suspected carcinogen and should be handled carefully.

Supplement 20

Label and purify the oligonucleotide

1. Mix the following reagents in the order indicated (10 μ l final):

2.5 μ l H₂O
1 μ l 10 \times T4 polynucleotide kinase buffer
1 μ l 0.1 M DTT
1 μ l 1 mM spermidine
1 μ l 50-100 ng/ μ l oligonucleotide primer
3 μ l 10 μ Ci/ μ l [γ -³²P]ATP
0.5 μ l 20-30 U/ μ l T4 polynucleotide kinase.

Incubate 1 hr at 37°C.

In this step, 5 to 10 pmol of oligonucleotide are radiolabeled. Oligonucleotides used as primers should be 20 to 40 nucleotides long; shorter primers may not hybridize efficiently under the conditions described in step 7. Generally, primers should be selected to yield an extended product of <100 nucleotides to reduce the likelihood of premature termination of reverse transcriptase activity.

To avoid the possibility of precipitating the oligonucleotide, do not premix spermidine and oligonucleotide alone.

2. Stop reaction by adding 2 μ l of 0.5 M EDTA and 50 μ l TE buffer. Incubate 5 min at 65°C.
3. Prepare a small ion-exchange column by inserting a small plug of silanized glass wool into the narrow end of a silanized 1000 μ l pipet tip. Add 20 μ l of AG 50W-X8 resin and 100 μ l of DE-52 resin. Wash the column with 1 ml TEN 100 buffer.

This column will be used to purify the labeled oligonucleotide away from residual ATP. The plug for the column should consist of just enough glass wool to retain the chromatographic matrix.

4. Load the labeling reaction from step 2 onto the column. Collect flowthrough and reload it onto column.
5. Wash the column with 1 ml TEN 100, then with 0.5 ml TEN 300 (unincorporated nucleotide will be washed from the column; discard eluate as radioactive waste).
6. Elute radiolabeled oligonucleotide using 0.4 ml TEN 600. Collect eluate as a single fraction and store at -20°C in an appropriately shielded container until needed.

Other methods of purifying labeled oligonucleotides can be used, including repeated precipitation by ethanol in the presence of 2 M ammonium acetate (UNITS 2.12 & 8.2), gel-filtration chromatography using spin columns (UNIT 3.4), preparative gel electrophoresis (UNIT 2.12), and Sep-Pak chromatography (Sambrook et al., 1989).

Hybridize radiolabeled oligonucleotide and RNA

7. For each RNA sample, combine the following in a separate microcentrifuge tube (15 μ l final):

10 μ l total cellular RNA (10 to 50 μ g)
1.5 μ l 10 \times hybridization buffer
3.5 μ l radiolabeled oligonucleotide (from step 6).

Seal tubes securely and submerge 90 min in a 65°C water bath. Remove tubes and allow to cool slowly to room temperature.

Carry out primer extension reaction

8. For each sample, prepare the following reaction mix in a microcentrifuge tube on ice (multiply the indicated volumes by the number of samples plus one; 30.33 μ l final per sample):

0.9 μ l 1 M Tris-Cl, pH 8.3
0.9 μ l 0.5 M MgCl₂
0.25 μ l 1 M DTT
6.75 μ l 1 mg/ml actinomycin D
1.33 μ l 5 mM 4dNTP mix
20 μ l H₂O
0.2 μ l 25 U/ μ l AMV reverse transcriptase.

The 10 \times reverse transcriptase buffer defined in UNIT 3.4 is NOT used here because of the salt present in the hybridization reaction. Alternatively, the nucleic acids from this reaction may be precipitated and resuspended in 27 μ l water and 3 μ l of 10 \times RT buffer (UNIT 3.4).

Actinomycin D inhibits the initial DNA product from acting as both primer and template (as when portions of the product have complementary sequences that might hybridize), thus preventing synthesis of double-stranded "hairpin" DNA molecules.

9. To each tube containing RNA and oligonucleotide (from step 7), add 30 μ l reaction mix (from step 8). Incubate 1 hr at 42°C.

Reverse transcriptase stops less frequently when the reaction is carried out at 42°C than at lower temperatures.

Stop the reaction and analyze the product

10. Add 105 μ l RNase reaction mix to each primer extension reaction tube. Incubate 15 min at 37°C.

RNase digestion helps prevent aberrant electrophoresis of the primer extension products by reducing the amount of total RNA in the sample and by degrading the template RNA, leaving a cleanly labeled single-stranded DNA product.

11. Add 15 μ l of 3 M sodium acetate. Extract with 150 μ l phenol/chloroform/isoamyl alcohol, and remove aqueous (top) phase to a fresh tube.
12. Precipitate DNA by adding 300 μ l of 100% ethanol. Wash the pellet with 100 μ l of 70% ethanol. Remove all traces of ethanol using a pipet. Air dry the pellet with the cap open for 5 to 10 min.
13. Resuspend pellet in 5 μ l stop/loading dye. Heat tubes 5 min in a 65°C water bath.
14. Load samples on a 9% acrylamide/7 M urea gel and electrophorese until bromphenol blue reaches end of gel.
15. Dry gel and expose to X-ray film with an intensifying screen.

REAGENTS AND SOLUTIONS

10 \times hybridization buffer

1.5 M KCl
0.1 M Tris-Cl, pH 8.3
10 mM EDTA

RNase reaction mix

100 μ g/ml salmon sperm DNA
20 μ g/ml RNase A (DNase-free; UNIT 3.13) in TEN 100 buffer

COMMENTARY

Background Information

Primer extension is commonly used both to measure the amount of a given RNA and to map the 5' end of that RNA. The method employs reverse transcriptase, also known as RNA-dependent DNA polymerase. Like all DNA polymerases, this enzyme requires both a template to copy and a primer to be extended. Reverse transcriptase utilizes an RNA template for the synthesis of a complementary strand of DNA. In this analytical application of reverse transcriptase, a short piece of single-stranded DNA (the primer) hybridized to the RNA is extended until the 5' end of the RNA template is reached. The amount of DNA product is a reflection of the amount of the corresponding RNA present in the original sample. (Another major use for reverse transcriptase, the creation of cDNA libraries from mRNA, is covered in *UNIT 5.5*.)

Two other techniques, S1 protection (*UNIT 4.6*) and ribonuclease protection (*UNIT 4.7*), can also be used to define amounts and endpoints of RNA. Primer extension analysis is frequently used in conjunction with one of these protection methods to confirm 5'-end mapping results. Primer-extension differs from the protection assays, however, in one important aspect. With the protection methods, the defined DNA probe will be cleaved at any discontinuity between the probe and the RNA. Thus, either the end of the RNA or a splice junction will give discrete bands. Primer extension, on the other hand, will extend across splice sites or other discontinuities until the end of the RNA is reached. Thus, primer extension can be used to ensure that the signal observed in the protection assays truly reflects the 5' end of a transcript and not merely a splice junction.

Primer extension analysis is frequently employed for detecting transcripts produced during transient transfection assays or in vitro transcription assays (McKnight and Kingsbury, 1982; Jones et al., 1985). In such experiments, it is often easy to include internal controls to ensure that all technical aspects of the experiment—transfection, RNA isolation, and primer-extension reactions—are working properly. Such an internal control might be a heterologous RNA detected with its own specific primer. Alternatively, a single primer might be used for related RNA molecules, each containing sequences complementary to the primer, but differing in the distance between the

5' end and the primer binding site (Graves et al., 1985). In this latter case, variations in labeling efficiencies of the oligonucleotides can also be excluded to further reduce experimental error.

Additional applications of reverse transcriptase in primer extension experiments have been described in detail elsewhere. These include the determination of DNA sequences (Mierendorf and Pfeffer, 1987) and mapping sites on nucleic acids where proteins bind (Sasse-Dwight and Gralla, 1991).

Critical Parameters and Troubleshooting

The major difficulty in primer extension is encountering regions of RNA that cause the reverse transcriptase to pause or terminate. The resulting "short stops" show up as bands of intermediate size on the gel, both confusing interpretation and reducing the yield of fully extended primer. Such termination sites may be caused by extensive GC rich stretches of RNA or by secondary structures within the RNA. The protocol described here includes several measures to reduce such artifacts. The primer should be chosen so that the extension products are <100 nucleotides, to reduce the distance traversed by reverse transcriptase, thus minimizing the likelihood of encountering a significant secondary structure. Nucleotide concentrations well in excess of the apparent K_m of reverse transcriptase help to reduce pausing by the enzyme. A high incubation temperature (42°C) minimizes the effect of secondary structure.

Ideally, reverse transcriptase proceeds completely to the 5' terminus of the RNA, yielding a single discrete primer-extension product. Frequently, however, there is a cluster of primer-extension products which vary in size by increments of a single nucleotide, near the expected position. These incomplete extension products are probably caused by difficulties encountered by reverse transcriptase due to the methylated nucleotides of the 5' cap of eukaryotic mRNA.

Anticipated Results

Approximately 10^7 dpm of ^{32}P can be incorporated into 50 ng of a 30-base oligonucleotide. This primer should be able to detect messages that are 0.001% to 0.01% of the total RNA in a 10- to 50- μg sample. Primer-exten-

sion products should be detected after 15 to 30 hr of exposure to X-ray film with an intensifying screen.

Time Considerations

Labeling and purification of the oligonucleotide requires ~3 hr. The oligonucleotide can be used for up to 2 weeks, although best results are obtained within 1 week of labeling. The hybridization mixtures take ~15 min to prepare, with 90 min required for the hybridization itself. Primer extension reactions and sample preparation for electrophoresis require ~3 hr. Gel electrophoresis requires 2 hr, with another hour needed to dry the gel using a vacuum-type gel dryer.

Analysis of RNA by Northern and Slot Blot Hybridization

Specific sequences in RNA preparations can be detected by blotting and hybridization analysis using techniques very similar to those originally developed for DNA (UNITS 2.9A, 2.9B, & 2.10). Fractionated RNA is transferred from an agarose gel to a membrane support (northern blotting); unfractionated RNA is immobilized by slot or dot blotting. The resulting blots are studied by hybridization analysis with labeled DNA or RNA probes. Northern blotting differs from Southern blotting largely in the initial gel fractionation step. Because they are single-stranded, most RNAs are able to form secondary structures by intramolecular base pairing and must therefore be electrophoresed under denaturing conditions if good separations are to be obtained. Denaturation is achieved either by adding formaldehyde to the gel and loading buffers or by treating the RNA with glyoxal and dimethyl sulfoxide (DMSO) prior to loading. Basic Protocol 1 describes blotting and hybridization of RNA fractionated in an agarose-formaldehyde gel. This is arguably the quickest and most reliable method for northern analysis of specific sequences in RNA extracted from eukaryotic cells. Alternate Protocol 1 gives details of the glyoxal/DMSO method for denaturing gel electrophoresis, which may provide better resolution of some RNA molecules. Alternate Protocol 2 describes slot-blot hybridization of RNA samples, a rapid method for assessing the relative abundance of an RNA species in extracts from different tissues. Stripping hybridization probes from blots can be done under three different sets of conditions; these methods are outlined in the Support Protocol.

Analysis of small noncoding RNA (microRNA, or miRNA) has received much attention as a new tool for analyzing gene expression. Because these miRNAs range from 20 to 30 nucleotides, traditional agarose gels will not separate the products adequately. Basic Protocol 2 describes a hybridization procedure using a polyacrylamide gel, adapted for these small RNAs. Alternate Protocol 3 describes a hybridization procedure for miRNAs that uses a non-formamide-containing hybridization solution.

NOTE: The ubiquity of contaminating RNases in solutions and glassware and the concomitant difficulties in ensuring that an RNA preparation remains reasonably undegraded throughout the electrophoresis, blotting, and hybridization manipulations can make it difficult to obtain good hybridization signals with RNA. To inhibit RNase activity, all solutions for northern blotting should be prepared using sterile deionized water that has been treated with diethylpyrocarbonate (DEPC) as described in UNIT 4.1. The precautions described in the introduction to Section I of this chapter (e.g., baking of glassware) should be followed religiously. In addition, RNA should not be electrophoresed in gel tanks previously used for DNA separations—a new tank plus accessories should be obtained and saved exclusively for RNA work. For full details on the establishment of an RNase-free environment, see Wilkinson (1991).

CAUTION: DEPC is a suspected carcinogen and should be handled carefully. Because DEPC reacts with ammonium ions to produce ethyl carbamate, a potent carcinogen, special care should be exercised when treating ammonium acetate solution with DEPC.

CAUTION: Investigators should wear gloves for all procedures involving radioactivity and should be careful not to contaminate themselves or their clothing. When working with ^{32}P , investigators should frequently check themselves and the working area for radioactivity using a hand-held radiation monitor. Any radioactive contamination should be cleaned up using appropriate procedures. Radioactive waste should be placed in appropriately designated areas for disposal. Follow the guidelines provided by the local radiation safety adviser; also see APPENDIX 1F.

**NORTHERN HYBRIDIZATION OF RNA FRACTIONATED BY
AGAROSE-FORMALDEHYDE GEL ELECTROPHORESIS**

The protocol is divided into three sections: electrophoresis of an RNA preparation under denaturing conditions in an agarose-formaldehyde gel, transfer of the RNA from the gel to a nylon or nitrocellulose membrane by upward capillary transfer, and hybridization analysis of the RNA sequences of interest using a labeled DNA or RNA probe. Hybridization is carried out in formamide solution, which permits incubation at a relatively low temperature, reducing degradation of the membrane-bound RNA. Nitrocellulose and nylon membranes are equally effective for northern hybridization analysis, although high backgrounds are likely with nylon membranes if the protocol is not followed carefully.

This protocol should be read in conjunction with *UNITS 2.9A & 2.10*, which describe the equivalent Southern procedures for DNA blotting and hybridization. Details of alternative transfer systems (upward capillary blots, electroblotting, and vacuum blotting) can be found in *UNIT 2.9A*. Modifications to the Southern hybridization procedure described in the Commentary to *UNIT 2.10* can also be used with northern blots, and the troubleshooting guide for DNA blotting and hybridization is also applicable to northern analysis. Other relevant units are located elsewhere in the manual: *UNIT 2.5A* covers the general features of agarose gel electrophoresis; *UNITS 3.18 & 3.19* describe the preparation of alternate non-radioactive probes and their use in hybridization analysis; and *UNIT 6.4* explains how to use labeled oligonucleotides as hybridization probes.

Materials

- 10× and 1× MOPS running buffer (see recipe for 10× buffer)
- 12.3 M (37%) formaldehyde, pH >4.0
- RNA sample: total cellular RNA (*UNITS 4.1-4.4*) or poly(A)⁺ RNA (*UNIT 4.5*)
- Formamide
- Formaldehyde loading buffer (see recipe)
- 0.5 μg/ml ethidium bromide in 0.5 M ammonium acetate *or* 10 mM sodium phosphate (pH 7.0; see recipe)/1.1 M formaldehyde with and without 10 μg/ml acridine orange
- 0.05 M NaOH/1.5 M NaCl (optional)
- 0.5 M Tris·Cl (pH 7.4; *APPENDIX 2*)/1.5 M NaCl (optional)
- 20×, 2×, and 6× SSC (*APPENDIX 2*)
- 0.03% (w/v) methylene blue in 0.3 M sodium acetate, pH 5.2 (optional)
- DNA suitable for use as probe *or* for in vitro transcription to make RNA probe (Table 2.10.1)
- Formamide prehybridization/hybridization solution (*UNIT 2.10*)
- 2× SSC/0.1% (w/v) SDS
- 0.2× SSC/0.1% (w/v) SDS, room temperature and 42°C
- 0.1× SSC/0.1% (w/v) SDS, 68°C
- 55°, 60°, and 100°C water baths
- Oblong sponge slightly larger than the gel being blotted
- RNase-free glass dishes (*UNIT 4.1*)
- Whatman 3MM filter paper sheets
- UV-transparent plastic wrap (e.g., Saran Wrap or other polyvinylidene wrap)
- Nitrocellulose or nylon membrane (see Table 2.9.1 for list of suppliers)
- Glass plate of appropriate size (Fig. 2.9.1)
- Vacuum oven
- UV transilluminator, calibrated (*UNIT 2.9A*)
- Hybridization oven (e.g., Hybridiser HB-1, Techne) and tubes

Additional reagents and equipment for agarose gel electrophoresis (UNIT 2.5A), radiolabeling of DNA by nick translation or random oligonucleotide priming (UNIT 3.5), RNA labeling by in vitro synthesis (UNIT 2.10), measuring specific activity of labeled nucleic acids and separating unincorporated nucleotides from labeled nucleic acids (UNIT 3.4), and autoradiography (APPENDIX 3A)

NOTE: All solutions should be prepared with sterile deionized water that has been treated with DEPC as described in UNIT 4.1; see unit introduction for further instructions and precautions regarding establishment of an RNase-free environment.

Prepare gel

1. Dissolve 1.0 g agarose in 72 ml water and cool to 60°C in a water bath (see UNIT 2.5A).

UNIT 2.5A provides details on preparing, pouring, and running the agarose gel; vary as described here.

This step will make a 1.0% gel, which is suitable for RNA molecules 500 bp to 10 kb in size. A higher-percentage gel (1.0 to 2.0%) should be used to resolve smaller molecules or a lower-percentage gel (0.7 to 1.0%) for longer molecules. The recipe may be scaled up or down depending on the size of gel desired; the gel should be 2 to 6 mm thick after it is poured and the wells large enough to hold 60 μ l of sample.

2. When the flask has cooled to 60°C, place in a fume hood and add 10 ml of 10 \times MOPS running buffer and 18 ml of 12.3 M formaldehyde.

CAUTION: Formaldehyde is toxic through skin contact and inhalation of vapors. All operations involving formaldehyde should be carried out in a fume hood.

The formaldehyde concentration in the gel is 2.2 M. Lower concentrations (down to 0.4 M) may be used; these result in less brittle gels but may not provide adequate denaturation for runs longer than 2 to 3 hr.

3. Pour the gel and allow it to set. Remove the comb, place the gel in the gel tank, and add sufficient 1 \times MOPS running buffer to cover to a depth of ~1 mm.

Prepare sample and run gel

4. Adjust the volume of each RNA sample to 11 μ l with water, then add:

5 μ l 10 \times MOPS running buffer
9 μ l 12.3 M formaldehyde
25 μ l formamide.

Mix by vortexing, microcentrifuge briefly (5 to 10 sec) to collect the liquid, and incubate 15 min at 55°C.

CAUTION: Formamide is a teratogen and should be handled with care.

5. Add 10 μ l formaldehyde loading buffer, vortex, microcentrifuge to collect liquid, and load onto gel.

0.5 to 10 μ g of RNA should be loaded per lane (see Commentary). Duplicate samples should be loaded on one side of the gel for ethidium bromide or acridine orange staining.

6. Run the gel at 5 V/cm until the bromphenol blue dye has migrated one-half to two-thirds the length of the gel.

This usually takes ~3 hr. Lengthy electrophoresis (>5 hr) is not recommended for northern transfers as this necessitates more formaldehyde in the gel (e.g., the recipe for a gel run overnight would be 1.0 g agarose, 60 ml water, 10 ml of 10 \times MOPS, and 30 ml of 12.3 M formaldehyde). Increasing the amount of formaldehyde causes the gel to become more brittle and prone to breakage during transfer and also increases the health hazard from volatilization of formaldehyde during electrophoresis.

Stain and photograph gel

- 7a. Remove the gel and cut off the lanes that are to be stained. Place this portion of the gel in an RNase-free glass dish, add sufficient 0.5 M ammonium acetate to cover, and soak for 20 min. Change solution and soak for an additional 20 min (to remove the formaldehyde). Pour off solution, replace with 0.5 $\mu\text{g/ml}$ ethidium bromide in 0.5 M ammonium acetate, and allow to stain for 40 min.

If necessary (i.e., if background fluorescence makes it difficult to visualize RNA fragments), destain in 0.5 M ammonium acetate for up to 1 hr.

- 7b. Alternatively, remove gel, cut off lanes, and stain 2 min in 1.1 M formaldehyde/10 mM sodium phosphate containing 10 $\mu\text{g/ml}$ acridine orange.

If necessary, destain 20 min in the same buffer without acridine orange.

8. Examine gel on a UV transilluminator to visualize the RNA and photograph with a ruler laid alongside the gel so that band positions can later be identified on the membrane.

*Molecular weight markers are not usually run on RNA gels as the staining causes rRNA molecules present in cellular RNA to appear as sharp bands that can be used as internal markers. In mammalian cells, these molecules are 28S and 18S (corresponding to 4718 and 1874 nucleotides respectively; Fig. 4.9.1). Mitochondrial rRNAs (16S and 12S in mammalian cells) may also be visible in some extracts, and plant extracts usually contain chloroplast rRNAs (23S and 16S). Bacterial rRNAs are smaller than the eukaryotic nuclear counterparts (*E. coli*: 23S and 16S, 2904 and 1541 nucleotides) and in some species one or both of the molecules may be cleaved into two or more fragments. If poly(A)⁺ RNA is being fractionated, commercial RNAs (e.g., 0.24- to 9.5-kb RNA ladder from Life Technologies) can be used as molecular weight markers.*

Prepare gel for transfer

9. Place unstained portion of gel in an RNase-free glass dish and rinse with several changes of sufficient deionized water to cover the gel.

The rinses remove formaldehyde, which would reduce retention of RNA by nitrocellulose membranes and hinder transfer onto nylon. The portion of the gel that will be blotted is not stained with ethidium bromide as this can also reduce transfer efficiency.

Figure 4.9.1 Rat liver RNA (5 μg) was electrophoresed on a formaldehyde 1% agarose gel containing ethidium bromide (left), transferred to a hybridization membrane and stained with methylene blue stain (Molecular Research Center; Herrin and Schmidt, 1988, right). Shown are 28S (4.7 kb) and 18S (1.9 kb) ribosomal RNAs, as well as 4S to 5S (0.10 to 0.15 kb) RNA containing mix of tRNA and 5S ribosomal RNA.

10. Add ~10 gel volumes of 0.05 M NaOH/1.5 M NaCl to dish and soak for 30 min. Decant and add 10 gel volumes of 0.5 M Tris·Cl (pH 7.4)/1.5 M NaCl. Soak for 20 min to neutralize.

This step is optional. It results in partial hydrolysis of the RNA which in turn leads to strand cleavage; the length reduction improves transfer of longer molecules. However, RNA is extremely sensitive to alkaline hydrolysis and smaller molecules may be fragmented into lengths too short for efficient retention by the membrane. Neutralization should be carried out only if efficient transfer of molecules >5 kb is required from a gel that has an agarose concentration of >1.0% and is >5 mm thick.

11. Replace solution with 10 gel volumes of 20× SSC and soak for 45 min.

This step is also optional but improves transfer efficiency with some brands of membrane.

Transfer RNA from gel to membrane

12. Place an oblong sponge slightly larger than the gel in a glass or plastic dish (if necessary, use two or more sponges placed side by side). Fill the dish with enough 20× SSC to leave the soaked sponge about half-submerged in buffer.

Refer to Figure 2.9.1A for a diagram of the transfer setup. The sponge forms the support for the gel. Any commercial sponge will do, but before a sponge is used for the first time, it should be washed thoroughly with distilled water to remove any detergents that may be present. Two or more sponges can be placed side by side if necessary. As an alternative, a solid support with wicks made out of Whatman 3MM paper (Fig. 2.9.1B) may be substituted. Do not use an electrophoresis tank, as the high-salt transfer buffer will corrode the electrodes.

If using a nylon membrane, a lower concentration of SSC (e.g., 10×) may improve transfer of molecules >4 kb; reduction of the SSC concentration is not recommended for a nitrocellulose membrane as the high salt is needed for retention of RNA.

13. Cut three pieces of Whatman 3MM paper to the same size as the sponge. Place them on the sponge and wet them with 20× SSC.
14. Place the gel on the filter paper and squeeze out air bubbles by rolling a glass pipet over the surface.
15. Cut four strips of plastic wrap and place over the edges of the gel.

This is to prevent buffer from “short-circuiting” around the gel rather than passing through it.

16. Cut a piece of nylon or nitrocellulose membrane just large enough to cover the exposed surface of the gel. Pour distilled water ~0.5 cm deep in an RNase-free glass dish and wet the membrane by placing it on the surface of the water. Allow the membrane to submerge. For nylon membrane, leave for 5 min; for nitrocellulose membrane, replace the water with 20× SSC and leave for 10 min.

Avoid handling nitrocellulose and nylon membranes even with gloved hands—use clean blunt-ended forceps instead.

17. Place the wetted membrane on the surface of the gel. Try to avoid getting air bubbles under the membrane; remove any that appear by carefully rolling a glass pipet over the surface.
18. Flood the surface of the membrane with 20× SSC. Cut five sheets of Whatman 3MM paper to the same size as the membrane and place on top of the membrane.
19. Cut paper towels to the same size as the membrane and stack on top of the Whatman 3MM paper to a height of ~4 cm.

20. Lay a glass plate on top of the structure and add a weight to hold everything in place. Leave overnight.

The weight should be sufficient to compress the paper towels to ensure good contact throughout the stack. Excessive weight, however, will crush the gel and retard transfer.

An overnight transfer is sufficient for most purposes. Make sure the reservoir of 20× SSC does not run dry during the transfer.

Prepare membrane for hybridization

21. Remove paper towels and filter papers and recover the membrane and flattened gel. Mark in pencil the position of the wells on the membrane and ensure that the up-down and back-front orientations are recognizable.

Pencil is preferable to pen, as ink marks may wash off the membrane during hybridization. With a nylon membrane only, the positions of the wells can be marked by slits cut with a razor blade (do not do this before transfer or the buffer will short-circuit). The best way to record the orientation of the membrane is by making an asymmetric cut at one corner.

22. Rinse the membrane in 2× SSC, then place it on a sheet of Whatman 3MM paper and allow to dry.

The rinse has two purposes: to remove agarose fragments that may adhere to the membrane and to leach out excess salt.

Immobilize the RNA and assess transfer efficiency

- 23a. *For nitrocellulose membranes:* Place between two sheets of Whatman 3MM filter paper and bake in a vacuum oven for 2 hr at 80°C.

Baking results in noncovalent attachment of RNA to the membrane; the vacuum is needed to prevent the nitrocellulose from igniting.

- 23b. *For nylon membranes:* Bake as described above or wrap the dry membrane in UV-transparent plastic wrap, place RNA-side-down on a UV transilluminator (254-nm wavelength), and irradiate for the appropriate length of time (determined as described in UNIT 2.9A, Support Protocol).

CAUTION: *Exposure to UV irradiation is harmful to the eyes and skin. Wear suitable eye protection and avoid exposure of bare skin.*

UV cross-linking is recommended for a nylon membrane as it leads to covalent attachment and enables the membrane to be reprobed several times. The membrane must be completely dry before UV cross-linking; check the manufacturer's recommendations, which may suggest baking for 30 min at 80°C prior to irradiation. The plastic wrap used during irradiation must be UV transparent—e.g., polyvinylidene (Saran Wrap). A UV light box (e.g., Stratagene Stratalinker) can be used instead of a transilluminator (follow manufacturer's instructions).

24. If desired, check transfer efficiency by either staining the gel in ethidium bromide or acridine orange as in steps 7 and 8 or (if using nylon membrane) staining the membrane in 0.03% (w/v) methylene blue in 0.3 M sodium acetate, pH 5.2, for 45 sec and destaining in water for 2 min.

If significant fluorescence is observed in the gel, not all the RNA has transferred. RNA bands on a nylon membrane will be stained by the methylene blue (Herrin and Schmidt, 1988).

Membranes can be stored dry between sheets of Whatman 3MM filter paper for several months at room temperature. For long-term storage they should be placed in a desiccator at room temperature or 4°C.

25. Prepare DNA or RNA probe labeled to a specific activity of $>10^8$ dpm/ μ g and with unincorporated nucleotides removed.

Probes are ideally 100 to 1000 bp in length. DNA for a double-stranded probe is obtained as a cloned fragment (Chapter 1) and purified from the vector by restriction digestion (UNIT 3.1) followed by recovery from an agarose gel (UNIT 2.6). The DNA is labeled by nick translation or random oligonucleotide priming (UNIT 3.5) to create the radioactive probe. A single-stranded DNA probe is created in the same fashion but using a single-stranded vector; the probe should be antisense so it will hybridize to the sense RNA strands that are bound to the membrane. An RNA probe, which should also be antisense, is created by in vitro synthesis from a single-stranded sense DNA fragment (UNIT 2.10).

26. Wet the membrane carrying the immobilized RNA (from step 23) in $6\times$ SSC.
27. Place the membrane RNA-side-up in a hybridization tube and add ~ 1 ml formamide prehybridization/hybridization solution per 10 cm^2 of membrane.

Prehybridization and hybridization are usually carried out in glass tubes in a commercial hybridization oven. Alternatively, a heat-sealable polyethylene bag and heat-sealing apparatus can be used. The membrane should be placed in the bag, all edges sealed, and a corner cut off. Hybridization solution can then be pipetted into the bag through the cut corner and the bag resealed.

28. Place the tube in the hybridization oven and incubate with rotation 3 hr at 42°C (for DNA probe) or 60°C (for RNA probe).

If using a bag, it can be shaken slowly in a suitable incubator or water bath. If using a nylon membrane, the prehybridization period can be reduced to 15 min.

29. If the probe is double-stranded, denature by heating in a water bath or incubator for 10 min at 100°C . Transfer to ice.
30. Pipet the desired volume of probe into the hybridization tube and continue to incubate with rotation overnight at 42°C (for DNA probe) or 60°C (for RNA probe).

The probe concentration in the hybridization solution should be 10 ng/ml if the specific activity is 10^8 dpm/ μ g or 2 ng/ml if the specific activity is 10^9 dpm/ μ g.

For denatured probe, add to hybridization tube as soon after denaturation as possible.

If using a bag, a corner should be cut, the probe added, and the bag resealed. It is very difficult to do this without contaminating the bag sealer with radioactivity. Furthermore, the sealing element (the part that gets contaminated) is often difficult to clean. Hybridization in bags is therefore not recommended.

Wash membrane and perform autoradiography

31. Pour off hybridization solution and add an equal volume of $2\times$ SSC/0.1% SDS. Incubate with rotation 5 min at room temperature, change wash solution, and repeat.

CAUTION: Hybridization solution and all wash solutions must be treated as radioactive waste and disposed of appropriately.

To reduce background, it may be beneficial to double the volume of the wash solutions. If using a bag, transfer the membrane to a plastic box for the washes.

32. Replace wash solution with an equal volume of $0.2\times$ SSC/0.1% SDS and incubate 5 min with rotation at room temperature. Change wash solution and repeat (this is a low-stringency wash; see UNIT 2.10 Commentary).
33. If desired, carry out two further washes using prewarmed (42°C) $0.2\times$ SSC/0.1% SDS for 15 min each at 42°C (moderate-stringency wash).

34. If desired, carry out two further washes using prewarmed (68°C) 0.1×SSC/0.1% SDS for 15 min each at 68°C (high-stringency wash).
35. Remove final wash solution and rinse membrane in 2× SSC at room temperature. Blot excess liquid and cover in UV-transparent plastic wrap.

Do not allow membrane to dry out if it is to be reprobbed.

36. Perform autoradiography.

If the membrane is to be reprobbed, the probe can be stripped from the hybridized membrane without removing the bound RNA (see Support Protocol). Do not add NaOH. The membrane must not be allowed to dry out between hybridization and stripping, as this may cause the probe to bind to the matrix.

ALTERNATE PROTOCOL 1

NORTHERN HYBRIDIZATION OF RNA DENATURED BY GLYOXAL/DMSO TREATMENT

In this procedure denaturation of the RNA is achieved by treating samples with a combination of glyoxal and DMSO prior to running in an agarose gel made with phosphate buffer. The glyoxal/DMSO method produces sharper bands after northern hybridization than do formaldehyde gels, but is more difficult to carry out as the running buffer must be recirculated during electrophoresis.

Additional Materials (also see Basic Protocol 1)

- 10 mM and 100 mM sodium phosphate, pH 7.0 (see recipe)
 - Dimethyl sulfoxide (DMSO)
 - 6 M (40%) glyoxal, deionized immediately before use (see recipe)
 - Glyoxal loading buffer (see recipe)
 - 20 mM Tris·Cl, pH 8.0 (APPENDIX 2)
- Apparatus for recirculating running buffer during electrophoresis
50° and 65°C water baths

NOTE: All solutions should be prepared with sterile deionized water that has been treated with DEPC as described in UNIT 4.1; see unit introduction for further instructions and precautions regarding establishment of an RNase-free environment.

Denature and carry out agarose gel electrophoresis

1. Prepare a 1.0% agarose gel by dissolving 1.0 g agarose in 100 ml of 10 mM sodium phosphate, pH 7.0. Cool to 60°C in a water bath, pour gel, and allow to set. Remove comb, place gel in gel tank, and add 10 mM sodium phosphate (pH 7.0) until gel is submerged to a depth of ~1 mm (see UNIT 2.5A).

UNIT 2.5A provides details on preparing, pouring, and running the agarose gel; vary as described here.

A 1.0% gel is suitable for RNA molecules 500 bp to 10 kb in size. A higher-percentage gel (1.0 to 2.0%) should be used to resolve smaller molecules or a lower percentage (0.7 to 1.0%) for longer molecules. The recipe may be scaled up or down depending on the size of gel desired; the gel should be 2 to 6 mm thick after it is poured and the wells large enough to hold 60 µl of sample.

2. Adjust volume of each RNA sample to 11 µl with water, then add:

- 4.5 µl 100 mM sodium phosphate, pH 7.0
- 22.5 µl DMSO
- 6.6 µl 6 M glyoxal.

Mix samples by vortexing, spin briefly (5 to 10 sec) in a microcentrifuge to collect the liquid, and incubate 1 hr at 50°C.

- Cool samples on ice and add 12 μ l glyoxal loading buffer to each sample. Load samples onto gel.

0.5 to 10 μ g of RNA should be loaded per lane (see Commentary). Duplicate samples should be loaded at one side of gel for ethidium bromide staining.

- Run the gel at 4 V/cm with constant recirculation of running buffer for ~3 hr or until bromphenol blue dye has migrated one-half to two-thirds the length of the gel.

Recirculation is needed to prevent an H^+ gradient forming in the buffer. If a gradient forms, the pH in parts of the gel may rise to >8.0, resulting in dissociation of the glyoxal from the RNA followed by renaturation. If no recirculation apparatus is available, electrophoresis should be paused every 30 min and the tank shaken to remix the buffer.

- Remove the gel, cut off lanes, and stain with ethidium bromide (see Basic Protocol 1, steps 7a and 8).

The RNA transfer (using the remaining portion of the gel) should be set up as soon as the gel is cut, before starting the staining.

Carry out northern transfer and hybridization analysis

- Transfer RNA (see Basic Protocol 1, steps 9 to 24).
- Immediately before hybridization, soak the membrane in 20 mM Tris·Cl (pH 8.0) for 5 min at 65°C to remove glyoxal.
- Continue with hybridization analysis (see Basic Protocol 1, steps 25 to 36).

NORTHERN HYBRIDIZATION OF UNFRACTIONATED RNA IMMOBILIZED BY SLOT BLOTTING

ALTERNATE PROTOCOL 2

RNA slot blotting is a simple technique that allows immobilization of unfractionated RNA on a nylon or nitrocellulose membrane. Hybridization analysis is then carried out to determine the relative abundance of target mRNA sequences in the blotted samples. The technique is based on the DNA dot- and slot-blotting procedure (UNIT 2.9B), the main difference being the way in which the samples are denatured prior to immobilization.

RNA dot blots can be prepared by hand but slot blots constructed using a manifold apparatus are preferable because the slots make it easier to compare hybridization signals by densitometry scanning.

Additional Materials (also see Basic Protocol 1)

0.1 M NaOH

10 \times SSC (APPENDIX 2)

20 \times SSC (APPENDIX 2), room temperature and ice-cold

Denaturing solution (see recipe)

100 mM sodium phosphate, pH 7.0 (see recipe)

Dimethyl sulfoxide (DMSO)

6 M (40%) glyoxal, deionized immediately before use (see recipe)

Manifold apparatus with a filtration template for slot blots (e.g., Bio-Rad Bio-Dot SF, Schleicher and Schuell Minifold II)

50° and 60°C water baths

NOTE: All solutions should be prepared with sterile deionized water that has been treated with DEPC as described in UNIT 4.1; see unit introduction for further instructions and precautions regarding establishment of an RNase-free environment.

Preparation and Analysis of RNA

4.9.9

Set up membrane for transfer

1. Clean the manifold with 0.1 M NaOH and rinse with distilled water.
2. Cut a piece of nylon or nitrocellulose membrane to the size of the manifold. Pour 10× SSC (for nylon membrane) or 20× SSC (for nitrocellulose membrane) into a glass dish; place membrane on top of liquid and allow to submerge. Leave for 10 min.

Avoid handling nitrocellulose and nylon membranes even with gloved hands—use clean blunt-ended forceps instead.

3. Place the membrane in the manifold. Assemble the manifold according to manufacturer's instructions and fill each slot with 10× SSC. Ensure there are no air leaks in the assembly.

Denature RNA samples

- 4a. Add 3 vol denaturing solution to RNA sample. Incubate 15 min at 65°C, then place on ice.

Up to 20 µg of RNA can be applied per slot. Total cellular RNA (UNITS 4.1-4.4) or poly(A)⁺ RNA (UNIT 4.5) can be used, although the latter is preferable (see Commentary).

- 4b. Alternatively, mix:

11 µl RNA sample
4.5 µl 100 mM sodium phosphate, pH 7.0
22.5 µl DMSO
6.6 µl 6 M glyoxal.

Mix by vortexing, spin briefly in a microcentrifuge to collect liquid, and incubate 1 hr at 50°C.

5. Add 2 vol ice-cold 20× SSC to each sample.

Pass samples through manifold

6. Switch on the suction to the manifold device and allow the 10× SSC added in step 3 to filter through. Leave the suction on.

The suction should be adjusted so that 500 µl buffer takes ~5 min to pass through the membrane. Higher suction may damage the membrane. Slots that are not being used can be blocked off by placing masking tape over them or by applying 500 µl of 3% (w/v) gelatin to each one. The former method is preferable as use of gelatin may lead to a background signal after hybridization. Alternatively, keep all slots open and apply 10× SSC instead of sample to the slots not being used.

7. Load each sample to the slots and allow to filter through, being careful not to touch the membrane with the pipet tip.
8. Add 1 ml of 10× SSC to each slot and allow to filter through. Repeat.
9. Dismantle the apparatus, place the membrane on a sheet of Whatman 3MM paper, and allow to dry.

Immobilize RNA and carry out hybridization

10. Immobilize the RNA (see Basic Protocol 1, step 23).

If glyoxal/DMSO denaturation has been used, immediately before hybridization soak the membrane in 20 mM Tris-Cl (pH 8.0) for 5 min at 65°C to remove glyoxal.

11. Carry out hybridization analysis as described in steps 25 to 36 of Basic Protocol 1.

REMOVAL OF PROBES FROM NORTHERN BLOTS

Hybridization probes can be removed from northern blots on nylon membranes without damage to the membrane or loss of the transferred RNA. Some probes (particularly RNA probes) are more resistant to stripping. In these cases, higher temperatures, longer incubation periods, or the inclusion of formamide may be necessary for complete probe removal. The following stripping procedures are appropriate for both radioactive and chemiluminescent probes. Begin with the mildest conditions (step 1a) and monitor results to determine the extent of stripping. If the hybridization signal is still evident, proceed with the more stringent treatments (steps 1b and 1c) until stripping is complete.

Materials

Northern hybridization membrane containing probe (see Basic Protocol 1, Alternate Protocol 1, or Alternate Protocol 2)

Stripping solution (see recipe)

Hybridization bags

65°, 80°, or 100° (boiling) water bath

UV-transparent plastic wrap (e.g., Saran Wrap or other polyvinylidene wrap)

Additional reagents and equipment for autoradiography (*APPENDIX 3A*)

CAUTION: If hybridization probes include a radioactive label, dispose of stripping solutions as radioactive waste. Observe appropriate caution when working with the toxic compound formamide.

- 1a. *To remove probes at 80°C:* Place membrane in a hybridization bag containing stripping solution without formamide. Place bag in water preheated to 80°C for 5 min. Pour out solution, then repeat this washing process three to four times.

Add sufficient solution to cover the membrane completely when using a bag; alternatively, stripping can be done in an open container, again with sufficient solution to cover the membrane.

- 1b. *To remove probes at 100°C:* Place membrane in a hybridization bag containing stripping solution without formamide. Place bag in boiling water for 5 min. Pour out solution, then repeat this washing process three to four times.

- 1c. *To remove probes with formamide:* Place membrane in a hybridization bag containing stripping solution with formamide. Place bag in water preheated to 65°C for 5 min. Pour out solution, then repeat this washing process three times using stripping solution with formamide and once using stripping solution without formamide.

2. Place membrane on filter paper to remove excess solution. Wrap membrane in plastic wrap and perform autoradiography to verify probe removal.

If a chemiluminescent probe was used, verify probe removal by chemiluminescent detection (UNIT 3.19). The membrane may be immediately rehybridized or air-dried and stored for future use.

NORTHERN HYBRIDIZATION OF SMALL RNA FRACTIONATED BY POLYACRYLAMIDE GEL ELECTROPHORESIS

This protocol is adapted for analysis of small RNAs. The major differences between this procedure and the traditional northern hybridization procedure are the fractionation system and the transfer system applied. Fractionation using denaturing polyacrylamide gel electrophoresis (PAGE) allows better separation of small RNAs. The introduction of a semidry transfer system reduces the time of the experimental procedure to 2 days.

Tissue or cell samples
TRIzol reagent (Invitrogen)
RNase-free H₂O (*UNIT 4.1*)
15% denaturing polyacrylamide sequencing (urea/TBE) gel (*UNIT 7.6*)
0.5× TBE electrophoresis buffer (*APPENDIX 2*)
Formamide loading dye (see recipe)
2× SSC (*APPENDIX 2*)
50 μM probe oligonucleotide (DNA or RNA; *UNIT 2.11*) in RNase-free H₂O
≥10 mCi/ml [γ -³²P]ATP (6000 Ci/mmol; ICN Biomedicals)
10× T4 polynucleotide kinase buffer (New England Biolabs)
200 U/μl T4 polynucleotide kinase (New England Biolabs)
Prehybridization/hybridization solution (see recipe), prewarmed to 37°C
2× SSC (*APPENDIX 2*) containing 0.1× (w/v) SDS, prewarmed to 37°C

95°C heating block or water bath
Hybond N+ Nylon Transfer Membrane (Amersham Biosciences)
Extra-thick blotting paper (Bio-Rad), slightly larger than the gel being blotted
Semi-dry transfer apparatus (e.g., Bio-Rad Trans-Blot SD cell)
Sephadex G-25 spin column
Hybridization oven with rotating glass hybridization bottles, 37°C
Image-analysis software (also see *UNIT 10.5*): e.g., QuantityOne (Bio-Rad) or
ImageGauge (Fuji)

Additional reagents and equipment for denaturing polyacrylamide gel
electrophoresis (*UNIT 7.6*), phosphor imaging (*APPENDIX 3A*), and digital
electrophoresis analysis (*UNIT 10.5*)

Prepare RNA sample and run the gel

1. Isolate total RNA from tissue or cell samples with TRIzol reagent according to the manufacturer's instructions. At the end of the procedure, dissolve the RNA to a final concentration of 10 μg/μl in RNase-free water.
2. Prerun 15% denaturing polyacrylamide sequencing (urea/TBE) gel for 15 min at 25 W in 0.5× TBE electrophoresis buffer. Mix 5 μl RNA sample (10 μg/μl) with equal volume of formamide loading dye. Heat 2 min at 95°C, and load onto gel (*UNIT 7.6*).
3. Run the gel at 25 W until the bromophenol blue dye has migrated to the bottom of the gel.

Transfer RNA from gel to membrane

4. Cut a piece of Hybond N+ nylon membrane slightly larger than the gel. Soak the membrane and four pieces of blotting paper of appropriate size in 0.5× TBE buffer for 10 min.
5. Stack two pieces of blotting paper on the anode platform of the transfer cell. Avoid getting air bubbles under or between the papers; remove any that appear by carefully rolling a glass pipet over the surface.
6. Place the membrane on top of the blotting paper and squeeze out air bubbles by rolling a glass pipet over the surface.
7. Carefully transfer the gel from glass plate to the top of the membrane and squeeze out air bubbles.
8. Stack another two pieces of blotting paper on the gel and squeeze out air bubbles.
9. Set the cathode assembly and the safety lid on the sandwich. Transfer for 1 hr at 300 mA.

Prepare membrane for hybridization

10. Disassemble the transfer cell. Remove the paper and the gel. Rinse the membrane in 2× SSC, then place it on a sheet of filter paper and allow it to air dry.
11. Place membrane RNA-side-down on a UV transilluminator (254-nm wavelength) or in a UV light box for the appropriate length of time to covalently attach the RNA to the membrane.

Prepare probe

The authors typically use a chemically synthesized 21–22 nt DNA or RNA oligonucleotide (see *UNIT 2.11* for oligonucleotide synthesis) perfectly complementary to the small RNA to be detected.

12. Set up the 5′-end-labeling reaction by combining the following reagents:

1 μl of 50 μM probe oligonucleotide (DNA or RNA)
1 μl of [γ -³²P]ATP (6000 Ci/mmol, ≥10 mCi/ml)
4 μl of 10× T4 polynucleotide kinase buffer
H₂O to a final volume of 40 μl
1 μl of 200 U/μl T4 polynucleotide kinase.

Incubate reaction 1 hr at 37°C.

13. Pass reaction mixture through Sephadex G-25 spin column (centrifuging per manufacturer's instructions) to remove unincorporated [γ -³²P]ATP.

Perform prehybridization and hybridization

14. Place membrane (from step 11) RNA-side-up in a hybridization bottle and add ~1 ml prewarmed (37°C) prehybridization/hybridization solution per 10 cm² of membrane. Place the bottle in a hybridization oven and incubate with rotation for 30 min at 37°C.
15. Pipet the entire reaction mix (from step 13) into the hybridization bottle and continue to incubate with rotation overnight at 37°C.

Wash membrane

16. Pour off hybridization solution and wash the membrane briefly with 2× SSC for 5 min. Add prewarmed (37°C) 2× SSC containing 0.1% SDS to the bottle. Incubate with rotation for 15 min at 37°C. Replace solution with fresh solution and repeat. Remove final wash solution, blot excess liquid, and wrap with plastic wrap.

Do not allow membrane to dry out if it is to be reprobbed.

Perform phosphor imaging and analyze the hybridization signals

17. Visualize the hybridization signals by phosphor imaging (*APPENDIX 3A*). Analyze hybridization result using appropriate software (*UNIT 10.5*). Subtract the background from the original signal to obtain the specific hybridization.
18. To compare the amount of small RNA in different samples, normalize the amount of small RNA detected to the nonspecific hybridization of the probe to 5S rRNA.

Alternatively, the blot can be reprobbed with a probe specific for 5S rRNA (for Drosophila 5′-CAA CAC GCG GTG TTC CCA AGC CG-3′) or, for Drosophila, the 2S RNA (5′-TAC AAC CCT CAA CCA TAT GTA GTC CAA GCA-3′).

The precise amount (pmol or molecules) of small RNA can be determined if concentration standards of synthetic RNA are included on the blot. The assay is typically linear with respect to concentration over a 10,000-fold range.

NORTHERN HYBRIDIZATION OF RNA USING CHURCH'S HYBRIDIZATION BUFFER

Church's hybridization buffer can be used as an alternative for the standard prehybridization/hybridization solution in this assay. It provides similar sensitivity.

Additional Materials (also see Basic Protocol 2)

Church's hybridization buffer without BSA (see recipe)

1. Perform northern blotting and prepare probe (see Basic Protocol 2, steps 1 through 13).
2. Perform prehybridization and hybridization (see Basic Protocol 2, steps 14 to 15) using Church's hybridization buffer (without BSA) in place of the prehybridization/hybridization solution.
3. Wash membrane and proceed with development and analysis (see Basic Protocol 2, steps 16 to 18).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Church's hybridization buffer without BSA

0.5 M sodium phosphate buffer, pH 7.2 (APPENDIX 2)

1 mM EDTA, pH 8.0 (APPENDIX 2)

7% (w/v) SDS

Store up to 1 year at room temperature

Denaturing solution

500 μ l formamide

162 μ l 12.3 M (37%) formaldehyde

100 μ l MOPS buffer (see recipe)

Make fresh from stock solutions immediately before use

If formamide has a yellow color, deionize as follows: add 5 g of mixed-bed ion-exchange resin (e.g., Bio-Rad AG 501-X8 or X8(D) resins) per 100 ml formamide, stir 1 hr at room temperature, and filter through Whatman #1 filter paper.

CAUTION: Formamide is a teratogen. Handle with care.

Formaldehyde loading buffer

1 mM EDTA, pH 8.0 (APPENDIX 2)

0.25% (w/v) bromphenol blue

0.25% (w/v) xylene cyanol

50% (v/v) glycerol

Store up to 3 months at room temperature

Formamide loading dye

98% (v/v) deionized formamide

10 mM EDTA pH 8.0 (APPENDIX 2)

0.025% (w/v) xylene cyanol

0.025% (w/v) bromphenol blue

Store indefinitely at -20°C

Glyoxal, 6 M, deionized

Immediately before use, deionize glyoxal by passing through a small column of mixed-bed ion-exchange resin (e.g., Bio-Rad AG 501-X8 or X8(D) resins) until the pH is >5.0 .

Glyoxal loading buffer

10 mM sodium phosphate, pH 7.0 (see recipe)
0.25% (w/v) bromphenol blue
0.25% (w/v) xylene cyanol
50% (v/v) glycerol
Store up to 3 months at room temperature

MOPS buffer

0.2 M MOPS [3-(*N*-morpholino)-propanesulfonic acid], pH 7.0
0.5 M sodium acetate
0.01 M EDTA
Store up to 3 months at 4°C
Store in the dark and discard if it turns yellow.

MOPS running buffer, 10×

0.4 M MOPS, pH 7.0
0.1 M sodium acetate
0.01 M EDTA
Store up to 3 months at 4°C

Prehybridization/hybridization solution

5× SSPE (see recipe)
5× Denhardt solution (*APPENDIX 2*)
50% (v/v) formamide
0.5% (w/v) SDS
72 µg/ml denatured herring sperm DNA (Promega)
Make fresh from stock solutions immediately before use
The herring sperm DNA is denatured by heating 10 min at 75°C just before it is added.

Sodium phosphate, pH 7.0, 100 mM and 10 mM

100 mM stock solution:
5.77 ml 1 M Na₂HPO₄
4.23 ml 1 M NaH₂PO₄
H₂O to 100 ml
Store up to 3 months at room temperature

10 mM solution:
Dilute 100 mM stock 1/10 with H₂O
Store up to 3 months at room temperature

SSPE, 10×

1.5 M NaCl
50 mM NaH₂PO₄·H₂O
5 mM EDTA
Store indefinitely at room temperature

Stripping solution

1% (w/v) SDS
0.1× SSC (*APPENDIX 2*)
40 mM Tris·Cl, pH 7.5 to 7.8 (*APPENDIX 2*)
Store up to 1 year at room temperature
Where formamide stripping is desired, prepare the above solution and add an equal volume of formamide just before use.

COMMENTARY

Background Information

The development of Southern blotting (*UNIT 2.9A*; Southern, 1975) was quickly followed by an equivalent procedure for the immobilization of gel-fractionated RNA (Alwine et al., 1977). The term northern blotting, initially used in a humorous fashion, has become enshrined in molecular biology jargon. Northern hybridization is a standard procedure for identification and size analysis of RNA transcripts and RNA slot blotting is frequently used to assess the expression profiles of tissue-specific genes (Kafatos et al., 1979).

Procedures for the removal of hybridization probes from northern blots are similar to those for Southern blots, except that NaOH is omitted to prevent hydrolysis of the RNA, and formamide may be included.

The recent discovery of microRNAs (miRNAs) revealed an entire new class of molecules that regulate gene expression. miRNAs are small noncoding RNAs that range from 20 to 30 nucleotides, making traditional formaldehyde-agarose gel electrophoresis unsuitable for their size fractionation. The modified northern protocol here (Basic Protocol 2) combines denaturing polyacrylamide gel electrophoresis (PAGE), which is ideal for the separation of small RNAs, with standard blotting and hybridization procedures.

Critical Parameters

Gel electrophoresis and northern blotting

The main distinction between northern and Southern blotting lies with the initial gel fractionation step. Because single-stranded RNA can form secondary structures, samples must be electrophoresed under denaturing conditions to ensure good separation.

A variety of denaturants for RNA gels have been used, including formaldehyde (Basic Protocol 1; Lehrach et al., 1977), glyoxal/DMSO (Alternate Protocol 1; Thomas, 1980), and the highly toxic methylmercuric chloride (Bailey and Davidson, 1976). Because of the substantial health risks, use of methylmercuric chloride is not advised. Formaldehyde gels are recommended, as they are easy to run and reasonably reliable. The formaldehyde must be rinsed from the gel before the transfer is set up, but this is a minor inconvenience compared to assembling the buffer recirculation system required for electrophoresis of glyoxal-denatured RNA.

Total cellular RNA (*UNITS 4.1-4.4*) or poly(A)⁺ RNA (*UNIT 4.5*) can be used for northern transfers and slot blots. Total RNA is less satisfactory because nonspecific hybridization, however slight, to one or both of the highly abundant rRNA molecules will lead to a substantial hybridization signal. Any hybridizing band that appears in the vicinity of an rRNA should be treated with suspicion and its identity confirmed by blotting with poly(A)⁺ RNA.

Under ideal conditions, a band that contains as little as 1 pg of RNA can be detected by northern hybridization with a probe labeled to a specific activity of 10⁹ dpm/μg. In practice, the effective detection limit with an overnight exposure is ~5 pg RNA. An mRNA is usually considered to be abundant if it constitutes >1% of the mRNA fraction. In a typical mammalian cell, the mRNA fraction makes up about 0.5% of total RNA, so >5 pg of an abundant mRNA should be present in just 100 ng of total RNA. If 10 μg of total RNA is transferred, abundant mRNAs should give strong hybridization signals and less abundant ones (down to 0.01% of the mRNA population) should be detectable with an overnight exposure. For rarer molecules, the poly(A)⁺ fraction must be prepared. In this sample 3 μg is sufficient for detecting an mRNA that makes up 0.0002% of the polyadenylated population.

Unlike probing for mRNA, which often requires enrichment by poly(A) selection prior to analysis, total cellular RNA can always be used for the detection of miRNA, because individual miRNA species can be present in thousands to tens of thousands of copies per cell. The highly abundant rRNA and microRNAs are well separated in a 15% denaturing polyacrylamide gel; thus, the nonspecific hybridization to rRNA will not affect the interpretation of the desired hybridizing signal.

RNA slot blots

Although easy to perform, RNA slot-blot hybridization is one of the most problematic techniques in molecular biology. A number of criteria must be satisfied if slot blotting is to be used to make meaningful comparisons of mRNA abundance in different extracts. The first requirement is that equal amounts of RNA must be loaded in each slot. In practice this is difficult to achieve, especially if RNA concentrations are estimated by absorbance spectroscopy (*APPENDIX 3D*), which is subject to errors

due to the small quantities being measured and the presence of contaminants such as protein and DNA.

Even if equal amounts of RNA are loaded, a difference in hybridization signal does not necessarily mean that the gene whose transcript is being studied is more active in a particular tissue. The analysis provides information on the abundance of an mRNA (i.e., the fraction of total RNA that it constitutes), not its absolute amount. To illustrate this point, consider a tissue in which a highly active gene is switched on at time t , where the transcripts of this gene constitute 0% of the mRNA at $t - 1$ but 20% of the mRNA at $t + 1$. If the slot blots of RNA from $t - 1$ and $t + 1$ are probed with the highly active gene, there will be a clear increase in hybridization signal after time t . In contrast, hybridization of the same slot blots with a second gene whose transcription rate is unchanged will show a decreased hybridization signal at $t + 1$. Transcripts of this gene are present in the same absolute amounts at $t - 1$ and $t + 1$, but their abundance decreases as the total mRNA population becomes larger due to activation of the highly expressed gene. To the unwary, the result of the hybridization analysis could appear to indicate down-regulation of a gene whose expression rate in fact remains constant.

Choice of membrane and transfer system

General information relating to the choice of membrane for a nucleic acid transfer is given in the Commentary to *UNIT 2.9A*. Because of the greater tensile strength of nylon, together with the fact that the RNA can be bound covalently by UV cross-linking, most transfers are now carried out using nylon rather than nitrocellulose. Nylon has the added advantage of being able to withstand the highly stringent conditions (50% formamide at 60°C) that may be required during hybridization with an RNA probe; nitrocellulose tends to disintegrate under these conditions.

For DNA transfer, a major advantage of positively charged nylon is that nucleic acids become covalently bound to the membrane if the transfer is carried out with an alkaline buffer. RNA can also be immobilized on positively charged nylon by alkaline transfer, but the procedure is not recommended as the alkaline conditions result in partial hydrolytic degradation of the RNA. This hydrolysis is difficult to control and smaller molecules are easily broken down into fragments too short for efficient retention by the membrane (see Table 2.9.1). This results in a loss of signal after hybridiza-

tion, a problem that is exacerbated by the increased background caused by lengthy exposure of the membrane to the alkaline solution. Only if the signals are expected to be strong should an alkaline transfer be considered. In this case, Basic Protocol 1 should be modified as follows: omit the pre-transfer alkaline hydrolysis (step 10), use 8 mM NaOH rather than 20× SSC as the transfer buffer, do not transfer for more than 6 hr, and rinse the membrane in 2× SSC/0.1% (w/v) SDS rather than plain SSC immediately after transfer (step 22). If using Alternate Protocol 1, omit step 7 as well, as the alkaline transfer buffer removes glyoxal from the RNA.

The standard northern transfer system can be modified as described for Southern blotting (*UNIT 2.9A*). Aqueous transfers onto nylon can be performed using a variety of buffers, although SSC is still most frequently used. Changes can be made to the transfer time and architecture of the blot (e.g., downward transfer; Chomczynski, 1992), and alternative methods such as electroblotting (Smith et al., 1984) and vacuum transfer (Peferoen et al., 1982) can be used.

Hybridization procedures

Hybridization analysis of an RNA blot is subject to the same considerations as DNA hybridization (see *UNIT 2.10* Commentary). The factors that influence sensitivity and specificity are the same, and incubation times, hybridization solutions, probe length, and mechanics of hybridization all have similar effects. There are just two additional points that need to be made with respect to RNA blots.

The first point is that formamide is almost always used in RNA hybridization solutions. The primary reason for this is to permit a lower hybridization temperature to be used, minimizing RNA degradation during the incubations.

The second point concerns the stability of the hybrids formed between the immobilized RNA and the probe molecules. For a DNA probe the relevant equation is (Casey and Davidson, 1977):

$$T_m = 79.8^\circ\text{C} + 18.5(\log M) + 0.58(\%GC) + 11.8(\%GC)^2 - 0.50(\%form) - \frac{820}{L}$$

and for an RNA probe (Bodkin and Knudson, 1985):

$$T_m = 79.8^\circ\text{C} + 18.5(\log M) + 0.58(\%GC) + 11.8(\%GC)^2 - 0.35(\%form) - \frac{820}{L}$$

where T_m is the melting temperature, M is the molarity of monovalent cations, %GC is the

percentage of guanosine and cytosine nucleotides in the DNA, %form is the percentage of formamide in the hybridization solution, and L is the length of the hybrid in base pairs. What these equations indicate is that an RNA-RNA hybrid is more stable than a DNA-RNA hybrid: if %form is 50%, the T_m for an RNA-RNA hybrid is 7.5°C higher than that for an equivalent RNA-DNA hybrid. The greater stability of the RNA-RNA hybrid means that an RNA probe requires a more stringent hybridization and washing regime than a DNA probe (e.g., hybridization at 60°C in 50% formamide and final wash at 68°C in 0.1× SSC/0.1% SDS).

Reprobing conditions

Nitrocellulose presents problems regarding both membrane integrity and RNA retention (see UNIT 2.10). UV cross-linking of RNA to a neutral nylon membrane presents optimal conditions for northern blot reprobing.

Because of the sensitivity of RNA to alkaline hydrolysis, NaOH, which is included in protocols for probe removal from Southern blots, should not be used when removing probes from northern blots. It is recommended that probes be removed prior to membrane storage, because unstripped probes remain permanently attached if the blot dries.

Troubleshooting

The appearance of the agarose gel after staining gives a first indication of how successful a northern experiment is likely to be. If total RNA has been used, the rRNA bands should be clear and sharp (Fig. 4.9.1) with no “smearing” toward the positive electrode. The only exception is when the RNA has been prepared by the guanidinium isothiocyanate procedure (UNIT 4.2), in which case some smearing is normal. If the rRNA bands are not sharp, the RNA preparation may be of poor quality (usually because insufficient care has been taken in establishing an RNase-free environment) or the denaturing gel electrophoresis system may not have worked adequately. If the latter problem is suspected, make sure that the formaldehyde concentration in the gel is 2.2 M or, if glyoxal denaturation has been used, that the buffer recircularization is sufficient to maintain the gel pH at 7.0. Whatever the problem, if the rRNAs are not distinct, there is no point in proceeding with the transfer as the bands obtained after hybridization will also be fuzzy. In fact, even if the rRNA bands are clear there is no guarantee that the mRNAs are intact.

An indication of the efficiency of transfer onto nylon can be obtained by staining the membrane with methylene blue (see Basic Protocol 1, step 24), but often a problem with transfer is not recognized until after hybridization. If poor signals are obtained, the troubleshooting section of UNIT 2.10 (including Table 2.10.4) should be consulted to identify the likely cause. Note that it is relatively easy to detach RNA from a membrane before immobilization, so some loss may occur when the membrane is rinsed in 2× SSC to wash off agarose fragments and leach out salt (see Basic Protocol 1, step 22). If necessary, this rinse can be postponed until immediately before hybridization, after the RNA has been immobilized.

Other problems, such as high backgrounds, extra bands, and difficulties with probe stripping, should be dealt with by referring to Table 2.10.4.

To increase the sensitivity of the miRNA assay, RNA probes can be used instead of DNA probes. In some cases, RNA probes work better to detect miRNA precursors (~60 to 70 nt long) which contain the immature miRNAs in a stem-loop whose structure can prevent the hybridization of DNA probes.

Anticipated Results

Using either a nylon or nitrocellulose membrane and a probe labeled to $\geq 5 \times 10^8$ dpm/ μ g, it should be possible to detect transcripts that represent 0.01% of the mRNA population with a blot of 10 μ g total mammalian RNA or 0.0002% of the population with a blot of 3 μ g poly(A)⁺ RNA.

It should be possible to detect small RNAs at levels as low as 0.3 fmol miRNA by following the Basic Protocol 2. Small RNAs that differ by as little as 1 nt (or even by a single phosphate group) can be separated on 15% denaturing polyacrylamide gel (50 to 100 cm), particularly when a long gel is used. For long gels, only the lower portion of the gel is used for transfer to the membrane.

Time Considerations

Traditional blots

A northern experiment can be completed in 3 days. The agarose gel is prepared and electrophoresed during the first day and the transfer carried out overnight. On the second day the blot is prehybridized and then hybridized overnight. Washes are completed early on the third day. A slot-blot experiment takes only two days, as the blot can be prepared and prehybridized

on the first day, hybridized overnight, and washed on the second day.

The length of time needed for the autoradiography depends on the abundance of the target sequences in the blotted RNA. Adequate exposure can take anything from overnight to several days.

With blots that are intended for reprobing, stripping procedures can be completed in ~1 hr, not including the verification steps.

miRNA blots

Using a semidry transfer system, the northern experiment can be completed in 2 days.

The length of time needed for the autoradiography depends on the abundance of the small RNA sequence and the detection system used. Optimal exposure can range from overnight to several days.

Under ideal conditions, a band that contains as little as 0.3 fmol of small RNA can be detected by northern hybridization with a 1-day exposure to a phosphor imager plate when scanned at 25 μm resolution. The amount of RNA loaded and the exposure time may vary with the abundance of the individual miRNA species. For abundant miRNAs, loading of 5 μg total RNA and overnight exposure will give strong hybridization signals.

Identification of Newly Transcribed RNA

Newly transcribed RNA can be identified using the nuclear runoff transcription assay. Isolated nuclei, free of membranes and cytoplasmic debris, are required for the assay. Cell lysis that does not allow the isolation of nuclei free of cell membranes and cytoplasmic material often results in poor incorporation of ^{32}P -labeled UTP into nascent transcripts. Although there is no way to predict what cell types present this problem, many adherent cell lines and lymphocytes isolated from murine spleen or thymus do. Interestingly, very few nonadherent cell lines have posed this problem. Isolating nuclei by detergent lysis of cells (basic protocol) works well for many tissue culture cell lines but may not be appropriate for all cell lines and many tissues. Detergent lysis and Dounce homogenization (first alternate protocol) or cell lysis in an isoosmotic solution and centrifugation through a sucrose cushion (second alternate protocol) are alternative methods for preparing nuclei. The support protocol describes preparation of the cDNA nitrocellulose filter strips that are used to detect the presence of specific transcripts in the nuclear runoff transcription assay.

NOTE: Experiments involving RNA require careful technique to prevent RNA degradation; see Chapter 4 Section I introduction.

BASIC PROTOCOL

NUCLEAR RUNOFF TRANSCRIPTION IN MAMMALIAN CELLS

Nuclear runoff transcription is currently the most sensitive procedure for measuring specific gene transcription as a function of cell state. Nuclei are first isolated from cultured cells or tissues and frozen in liquid nitrogen. Thawed nuclei are incubated with ^{32}P -labeled UTP and unlabeled NTPs to label nascent RNA transcripts. ^{32}P -labeled RNA is purified and used to detect specific RNA transcripts by hybridization to cDNAs immobilized on nitrocellulose membranes.

Materials

For recipes, see **Reagents and Solutions** in this unit (or cross-referenced unit); for common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.

- Cultures of mammalian cells (UNIT 9.0) or freshly isolated lymphoid cells
- Phosphate-buffered saline (PBS; APPENDIX 2), made fresh and ice cold
- Nonidet P-40 (NP-40) lysis buffer A (see recipe)
- Glycerol storage buffer (see recipe), ice cold
- 2× reaction buffer with and without nucleotides (see recipes)
- 10 mCi/ml [α - ^{32}P]UTP (760 Ci/mmol)
- 1 mg/ml DNase I (RNase-free; see recipe)
- HSB buffer (see recipe)
- SDS/Tris buffer (see recipe)
- 20 mg/ml proteinase K
- 25:24:1 (v/v/v) buffered phenol/chloroform/isoamyl alcohol (UNIT 2.1)
- 10% (v/v) trichloroacetic acid (TCA)/60 mM sodium pyrophosphate
- 10 mg/ml tRNA (UNIT 4.6)
- 5% (v/v) TCA/30 mM sodium pyrophosphate
- DNase I buffer (see recipe)
- 0.5 M EDTA, pH 8.0
- 20% (w/v) SDS
- Elution buffer (see recipe)
- 1 M NaOH
- 1 M HEPES (free acid)

3 M sodium acetate, pH 5.2
100% ethanol
TES solution (see recipe)
TES/NaCl solution (see recipe)
cDNA plasmid(s) immobilized on nitrocellulose membrane (support protocol)
2× SSC (APPENDIX 2)
10 mg/ml heat-inactivated RNase A (UNIT 7.3)
Rubber policeman
15- and 50-ml conical polypropylene centrifuge tubes
Beckman JS-4.2 and JA-20 rotors or equivalent
30° and 65°C shaking water baths
42° and 65°C water baths
0.45-µm HA filters (Millipore)
30-ml Corex tube, silanized (APPENDIX 3)
Whatman GF/F glass fiber filters
5-ml plastic scintillation vials
Whatman 3MM filter paper

NOTE: Keep cells and nuclei on ice until the nuclei are frozen.

Isolate nuclei

- 1a. *For cultures of adherent cells:* Remove medium from monolayer cultures (5×10^7 cells per assay) and place cells on ice. Rinse twice with 5 ml ice-cold PBS. Scrape flask with a rubber policeman and collect cells in a 15-ml centrifuge tube. Centrifuge 5 min at $500 \times g$ (1500 rpm in JS-4.2 rotor), 4°C. Remove supernatant.
- 1b. *For cultures of nonadherent cells:* Pipet up and down several times to resuspend cells (5×10^7 cells per assay) and transfer cells and medium to a 50-ml conical centrifuge tube. Centrifuge 5 min at $500 \times g$ (1500 rpm in JS-4.2 rotor), 4°C, and remove supernatant. Wash by gently resuspending pellet in 5 ml ice-cold PBS, adding 45-ml ice-cold PBS, and collecting cells by centrifuging 5 min at $500 \times g$. Remove supernatant. Wash cells once more with PBS and remove supernatant.
- 1c. *For freshly isolated lymphoid cells:* Transfer lymphoid cells (5×10^7 cells per assay) removed directly from organ to a 50-ml conical centrifuge tube. Centrifuge 5 min at $500 \times g$ (1500 rpm in JS-4.2 rotor), 4°C, and remove supernatant. Wash by resuspending pellet in 5 ml ice-cold PBS, adding 45 ml PBS, and collecting cells by centrifuging 5 min at $500 \times g$, 4°C. Remove supernatant. Wash cells once more with PBS and remove supernatant.

Lymphoid cell nuclei are more fragile than other cell types, so a gentle procedure (e.g., second alternate protocol) may be required to isolate intact nuclei. It is not necessary to eliminate erythrocytes from lymphoid cells prior to preparation of nuclei.

5×10^7 cells are required for each nuclear runoff transcription assay.

2. Loosen cell pellet by gently vortexing 5 sec. Add 4 ml NP-40 lysis buffer A, continuing to vortex as buffer is added. After lysis buffer is completely added, vortex cells 10 sec at half maximal speed.

Gentle vortexing (at a setting of six) uniformly resuspends cells and inhibits clumping. The same method is used to resuspend nuclei.

3. Incubate lysed cells 5 min on ice. Examine a few microliters of cell lysate on a hemacytometer with a phase-contrast microscope to ensure that cells have uniformly lysed and nuclei appear free of cytoplasmic material. Centrifuge 5 min at $500 \times g$, 4°C. Remove supernatant.

Supernatant contains cytoplasmic RNA that can be purified as described in UNITS 4.1 & 4.5, if desired.

4. Resuspend the nuclear pellet in 4 ml NP-40 lysis buffer A by vortexing as described in step 2. Centrifuge 5 min at $500 \times g$, 4°C . Discard supernatant and resuspend nuclei in 100 to 200 μl glycerol storage buffer by gently vortexing. Freeze resuspended nuclei in liquid nitrogen.

Nuclei are stable in liquid nitrogen for >1 year.

Perform nuclear runoff transcription

5. Thaw 200 μl frozen nuclei at room temperature and transfer to a 15-ml conical polypropylene centrifuge tube. Immediately add 200 μl of $2\times$ reaction buffer with nucleotides plus 10 μl of 10 mCi/ml [α - ^{32}P]UTP. Incubate 30 min at 30°C with shaking.

This reaction is done in a 15-ml polypropylene tube rather than a microcentrifuge tube to reduce the possibility of spilling radioactive materials.

6. Mix 40 μl of 1 mg/ml RNase-free DNase I and 1 ml HSB buffer. Add 0.6 ml of this solution to labeled nuclei and pipet up and down 10 to 15 times with a Pasteur pipet to mix thoroughly. Incubate 5 min at 30°C .
7. Add 200 μl SDS/Tris buffer and 10 μl of 20 mg/ml proteinase K. Incubate for 30 min at 42°C .

DNA and protein should be well digested and a fairly uniform solution should be obtained. The presence of a substantial amount of particulate matter usually indicates that either DNase I or proteinase K treatment was not effective and should be repeated. It may be necessary first to ethanol precipitate the RNA, then to repeat the treatment with DNase I and proteinase K with fresh reagents.

Extract and precipitate RNA

8. Extract sample with 1 ml 25:24:1 buffered phenol/chloroform/isoamyl alcohol. Centrifuge 5 min at $800 \times g$ (2000 rpm in JS-4.2 rotor), at or below room temperature. Transfer aqueous phase to a clean 15-ml polypropylene centrifuge tube.
9. Add 2 ml water, 3 ml of 10% TCA/60 mM sodium pyrophosphate, and 10 μl of 10 mg/ml *E. coli* tRNA carrier to aqueous phase. Incubate 30 min on ice.
10. Filter TCA precipitate onto 0.45- μm Millipore HA filter. Wash filter three times with 10 ml of 5% TCA/30 mM sodium pyrophosphate.

If the HA filter clogs and filters very slowly, a Whatman GF/A glass fiber filter can be used instead.

11. Transfer filter to a glass scintillation vial. Incubate with 1.5 ml DNase I buffer and 37.5 μl of 1 mg/ml RNase-free DNase I for 30 min at 37°C . Quench the reaction by adding 45 μl of 0.5 M EDTA and 68 μl of 20% SDS.
12. Heat sample 10 min at 65°C to elute the RNA. Remove supernatant and save. Add 1.5 ml elution buffer to filter and incubate 10 min at 65°C . Remove supernatant and combine with original supernatant.

This procedure removes >95% of the radioactivity from the filter.

13. Add 4.5 μl of 20 mg/ml proteinase K to 3 ml supernatant containing ^{32}P -labeled RNA. Incubate 30 min at 37°C .

14. Extract 3 ml RNA solution once with 3 ml of 25:24:1 buffered phenol/chloroform/isoamyl alcohol.
15. Remove aqueous phase to a silanized 30-ml Corex tube. Add 0.75 ml of 1 M NaOH to aqueous phase. Let stand 10 min on ice. Quench reaction by adding 1.5 ml of 1 M HEPES.
16. Precipitate RNA by adding 0.53 ml of 3 M sodium acetate and 14.5 ml of 100% ethanol. Incubate 30 min on dry ice or overnight at -20°C .
17. Centrifuge RNA 30 min at $10,000 \times g$ (9000 rpm in JA-20 rotor), 4°C . Remove ethanol and resuspend pellet in 1 ml TES solution. Shake 30 min at room temperature.
RNA should be completely dissolved.
18. Count a 5- μl aliquot of each sample in duplicate by spotting onto Whatman GF/F glass fiber filters. If necessary, dilute sample by adding TES solution to adjust ^{32}P -labeled RNA to $\geq 5 \times 10^6$ cpm/ml.

Hybridize RNA to cDNA

19. Mix 1 ml RNA solution with 1 ml TES/NaCl solution. In a 5-ml plastic scintillation vial, hybridize to cDNA immobilized on nitrocellulose membrane strip for 36 hr at 65°C with shaking.

Use a vial rather than a plastic bag for hybridization to ensure reproducible quantitative hybridization of the same number of cpm to each sample within a given experiment. Coil the nitrocellulose strip before inserting it into the scintillation vial and be sure the strip is completely immersed in hybridization solution.

20. After hybridization, transfer the strips to a 50-ml tube and wash filter in 25 ml of $2\times$ SSC 1 hr at 65°C . Repeat wash once with fresh $2\times$ SSC.
21. Remove filter to a glass scintillation vial containing 8 ml of $2\times$ SSC and 8 μl of 10 mg/ml RNase A. Incubate without shaking 30 min at 37°C .
22. Wash filter once more in 25 ml of $2\times$ SSC 1 hr at 37°C . Blot filter dry on Whatman 3MM filter paper. Unravel the strips, tape them to Whatman 3MM filter paper, and expose to X-ray film.

Appropriate exposure time and conditions will vary depending on the experiment.

ISOLATION OF NUCLEI BY DOUNCE HOMOGENIZATION

This protocol is used for isolation of nuclei from cell types that do not give clean nuclear preparations after lysis in NP-40 lysis buffer A. If cells are not lysed by treatment with NP-40 lysis buffer A (basic protocol), the addition of Dounce homogenization in NP-40 lysis buffer B is usually sufficient to lyse the cells.

Additional Materials

*For recipes, see **Reagents and Solutions** in this unit (or cross-referenced unit); for common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.*

- Lysis buffer (see recipe), ice cold
- Nonidet P-40 (NP-40) lysis buffer B (see recipe)
- Glycerol storage buffer (see recipe), ice cold
- Dounce homogenizer with type B pestle, ice cold
- 1.5-ml microcentrifuge tubes, chilled on dry ice

NOTE: Keep cells and nuclei on ice until the nuclei are frozen.

ALTERNATE PROTOCOL

Preparation and Analysis of RNA

4.10.4

Harvest cells

1. Harvest and wash cells as in basic protocol step 1.
2. Remove supernatant and loosen cell pellet by gently vortexing 5 sec. Resuspend cell pellet to a single-cell suspension in 5 to 10 ml ice-cold lysis buffer. Add ice-cold lysis buffer to a total of 40 ml and rock tube back and forth for several seconds to distribute the cells.
3. Pellet cells at $500 \times g$ (1500 rpm in JS-4.2 rotor), 4°C . Remove and discard supernatant. Resuspend pellet in 1 ml lysis buffer per 5×10^7 cells and vortex gently to mix.

After centrifugation, the pellet should appear to be two to three times its initial size.

4. Add 1 ml NP-40 lysis buffer B per 5×10^7 cells and mix by gently rocking the tube.

Break cells and collect nuclei

5. Transfer cells to an ice-cold Dounce homogenizer and break them with ten strokes of a B pestle or until nuclei appear free of membrane components by phase-contrast microscopy.
6. Transfer homogenized cells to a plastic 50-ml conical centrifuge tube and pellet nuclei by centrifugation 5 min at $500 \times g$, 4°C .

Pellet should now be approximately one-third to one-half the starting volume and appear opaque white.

7. Carefully remove supernatant with a Pasteur pipet attached to a vacuum supply. Tilt the tube sideways so supernatant is pulled away from the pellet. Remove any bubbles or liquid that remain on the side of the tube. Return pellet to an ice bucket.
8. Loosen pelleted nuclei by gentle vortexing. Add 200 μl ice-cold glycerol storage buffer per 5×10^7 nuclei and resuspend pellet by pipetting up and down.

Nuclei will be clumped at first but will disperse with continued pipetting. Pipetting should be steady but not hard enough to cause bubbles.

9. Aliquot 210 μl ($\sim 5 \times 10^7$ nuclei) into chilled 1.5-ml microcentrifuge tube and immediately return tube to dry ice. Store nuclei at -70°C or in liquid nitrogen.

Frozen nuclei are stable for at least 1 year.

10. Proceed with nuclear runoff transcription assay starting with basic protocol step 5.

ISOLATION OF NUCLEI BY SUCROSE GRADIENT CENTRIFUGATION

Quality of nuclei used in nuclear runoff protocols is a major determinant in the success of the experiment. Normal lymphocytes in particular can present a problem because the nuclei are more fragile. In this protocol, cells are resuspended in an isoosmotic buffer containing nonionic detergent, then lysed by Dounce homogenization. Nuclei are collected by ultracentrifugation through a sucrose cushion and are quite clean and free of contaminating membranes and cytoplasmic components. Typically, 10% to 30% more [α - 32 P]UTP is incorporated into nascent transcripts of nuclei prepared by this method. The density of nuclei varies with cell type so a pilot experiment should be performed to verify that these conditions (which work well for murine splenic lymphocytes and other vertebrate cells) result in a nuclear pellet.

Additional Materials

For recipes, see **Reagents and Solutions** in this unit (or cross-referenced unit); for common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.

Sucrose buffer I (see recipe), ice cold

Sucrose buffer II (see recipe)

Dounce homogenizer with B pestle, ice cold

Polyallomer centrifuge tubes ($\frac{9}{16} \times 3\frac{3}{4}$ in., Beckman) for SW 40.1 rotor

Ultracentrifuge and SW 40.1 rotor or equivalent

1.5-ml microcentrifuge tubes, chilled on dry ice

NOTE: Keep cells and nuclei on ice until the nuclei are frozen.

Harvest and lyse cells

1. Harvest and wash cells as in basic protocol step 1.
2. Loosen cell pellet by gently vortexing 5 sec. Resuspend cell pellet in 4 ml ice-cold sucrose buffer I. Examine a small aliquot of cells for lysis with a phase-contrast microscope.

Many cell types will lyse at this point and do not require Dounce homogenization. If cells have lysed, proceed directly to step 4.

3. Transfer cells to an ice-cold Dounce homogenizer and break the cells with five to ten strokes of a B pestle or until the nuclei appear free of cytoplasmic tags. Check a few microliters of cells with a phase-contrast microscope to be sure they are uniformly lysed.
4. Transfer nuclei to a clean 50-ml conical polypropylene centrifuge tube and add 4 ml sucrose buffer II. Mix by gentle pipetting and inversion.

The final concentration of sucrose in cell homogenate should be sufficient to prevent a large buildup of debris at the interface between homogenate and sucrose cushion. The amount of sucrose buffer II added to cell homogenate may need to be adjusted.

Collect nuclei

5. Add 4.4 ml sucrose buffer II to polyallomer SW 40.1 tube.

Sucrose buffer II serves as the sucrose cushion. Unlysed cells will not sediment through the sucrose cushion. If these conditions do not result in a nuclear pellet, adjust the concentration of sucrose in sucrose buffer II.

6. Carefully layer nuclei (from step 4) onto the sucrose cushion. Use sucrose buffer I to top off the gradient.

Do not centrifuge more than 2×10^8 nuclei per tube.

7. Centrifuge the gradient 45 min at $30,000 \times g$ (15,500 rpm in SW 40.1 rotor), 4°C.
8. Remove supernatant by vacuum aspiration. Tilt the tube sideways so supernatant is pulled away from the pellet and remove any bubbles or liquid that remain on the side of the tube. Return tube to an ice bucket.

Nuclei should form a tight pellet at the bottom of the tube and there may be some debris caught at the interface between sucrose buffers I and II. If the cells did not lyse during Dounce homogenization, nuclei will not pellet. Thus, it is important to be sure that the majority of the cells are clearly lysed in step 3. If the pellet appears as a gelatinous mass, nuclei have lysed and the pellet should be discarded.

9. Loosen nuclear pellet by gently vortexing 5 sec. Add 200 μ l ice-cold glycerol storage buffer per 5×10^7 nuclei and resuspend nuclei by pipetting up and down.

Nuclei will be clumped at first but will disperse with continued pipetting. Pipetting should be steady but should not create air bubbles.

10. Aliquot 210 μ l ($\sim 5 \times 10^7$ nuclei) into chilled microcentrifuge tube and immediately return tube to dry ice. Store frozen nuclei at -70°C or in liquid nitrogen.

Frozen nuclei are stable for at least 1 year.

11. Proceed with nuclear runoff transcription assay starting at basic protocol step 5.

SUPPORT PROTOCOL

PREPARATION OF NITROCELLULOSE FILTERS FOR NUCLEAR RUNOFF TRANSCRIPTION ASSAY

cDNA plasmids are linearized and immobilized on nitrocellulose membrane filters for hybridization in the nuclear runoff transcription assay. Filters are prepared in advance and may be stored at least 6 months. Prior to their use for hybridization, filters are cut into strips that contain the cDNA plasmids of interest.

Materials

*For recipes, see **Reagents and Solutions** in this unit (or cross-referenced unit); for common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.*

cDNA plasmid
1 M NaOH
6 \times SSC (**APPENDIX 2**)

0.45- μ m nitrocellulose membrane
Slot blot apparatus
80°C vacuum oven

Additional reagents and equipment for restriction endonuclease digestion (**UNIT 3.1**)

NOTE: Wear gloves and handle membranes with blunt-ended forceps.

1. Linearize 200 μ g cDNA plasmid by digestion with an appropriate restriction enzyme.

*It is usually not necessary to phenol extract or ethanol precipitate the DNA after digestion if BSA is absent from the restriction enzyme digestion buffer. If the buffer contains BSA, extract plasmid DNAs with phenol/chloroform/isoamyl alcohol, ethanol precipitate, and resuspend in TE or similar buffer prior to denaturation (**UNIT 2.1**).*

2. Add 49 μ l of 1 M NaOH to linearized DNA (200 μ g in 440 μ l). Incubate 30 min at room temperature to denature DNA.
3. Add 4.9 ml of 6 \times SSC to DNA and place on ice to neutralize the sample.

4. Set up slot blot apparatus with 0.45- μ m nitrocellulose membrane. Apply 125 μ l of sample (~5 μ g cDNA plasmid) to each slot under a low vacuum provided by a water aspirator. Rinse each slot with 500 μ l of 6 \times SSC.
5. Use a blue pencil to mark the location on the membrane of slots containing DNA.

It is difficult to detect the location of slots once nitrocellulose has dried. Mark the edge of the slot so that the nitrocellulose strip can be trimmed very close to the edge of the slot. It is possible to minimize the volume of hybridization solution if a narrow filter strip is used.
6. Air dry nitrocellulose filter overnight. Bake filter 2 hr in an 80°C vacuum oven. Store filter in a vacuum desiccator at either room temperature or 4°C.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.

DNase I, RNase-free (1 mg/ml)

Adjust pH of 0.1 M iodoacetic acid/0.15 M sodium acetate to 5.3 and filter sterilize. Add sterile solution to lyophilized RNase-free DNase I (Worthington) to give a final concentration of 1 mg/ml. Heat 40 min at 55°C. Cool and add 1 M CaCl₂ to a final concentration of 5 mM. Store 0.3-ml aliquots at -20°C.

DNase I buffer

20 mM HEPES, pH 7.5
5 mM MgCl₂
1 mM CaCl₂
Sterilize by autoclaving

Elution buffer

1% (w/v) SDS
10 mM Tris-Cl, pH 7.5
5 mM EDTA
Sterilize by autoclaving

Glycerol storage buffer

50 mM Tris-Cl, pH 8.3
40% (v/v) glycerol
5 mM MgCl₂
0.1 mM EDTA

HSB buffer

0.5 M NaCl
50 mM MgCl₂
2 mM CaCl₂
10 mM Tris-Cl, pH 7.4
Sterilize by autoclaving

Lysis buffer

10 mM Tris-Cl, pH 7.4
3 mM CaCl₂
2 mM MgCl₂
Sterilize by autoclaving

Nonidet P-40 (NP-40) lysis buffers

Buffer A (basic protocol)

10 mM Tris·Cl, pH 7.4
10 mM NaCl
3 mM MgCl₂
0.5% (v/v) NP-40

Buffer B (alternate protocol)

10 mM Tris·Cl, pH 7.4
3 mM CaCl₂
2 mM MgCl₂
1% (v/v) NP-40

Autoclave first three components and cool before adding NP-40.

Reaction buffer, 2×

10 mM Tris·Cl, pH 8.0
5 mM MgCl₂
0.3 M KCl
Sterilize by autoclaving

Reaction buffer with nucleotides, 2×

1 ml 2× reaction buffer (see recipe)
10 μl 100 mM ATP
10 μl 100 mM CTP
10 μl 100 mM GTP
5 μl 1 M DTT
Prepare immediately prior to use

Separate 100 mM solutions of each nucleotide should be prepared in 0.5 M EDTA (pH 8.0) and the pH of each one checked to be sure it is between 7.0 and 8.0. The solutions should be stored in aliquots at -20°C.

SDS/Tris buffer

5% (w/v) SDS
0.5 M Tris·Cl, pH 7.4
0.125 M EDTA
Sterilize by autoclaving

Sucrose buffer I

0.32 M sucrose
3 mM CaCl₂
2 mM magnesium acetate
0.1 mM EDTA
10 mM Tris·Cl, pH 8.0
1 mM DTT
0.5% (v/v) Nonidet P-40 (NP-40)

Prepare without DTT and NP-40. Autoclave and cool to room temperature. Add DTT and NP-40 just prior to use.

Sucrose buffer II

2 M sucrose
5 mM magnesium acetate
0.1 mM EDTA
10 mM Tris·Cl, pH 8.0
1 mM DTT

Prepare without DTT. Autoclave buffer and cool to room temperature. Add DTT just prior to use.

TES solution

10 mM *N*-tris(hydroxymethyl)methyl-2-aminoethanesulfonic acid (TES), pH 7.4
10 mM EDTA
0.2% (w/v) SDS
Sterilize by autoclaving

TES/NaCl solution

10 mM *N*-tris(hydroxymethyl)methyl-2-aminoethanesulfonic acid (TES), pH 7.4
10 mM EDTA
0.2% (w/v) SDS
0.6 M NaCl
Sterilize by autoclaving

COMMENTARY

Background Information

The nuclear runoff transcription assay allows direct measurement and comparison of specific gene transcription in cells in various states of growth or differentiation. It takes advantage of the fact that newly synthesized RNA can be labeled to high specific activity in isolated nuclei, something that is difficult to accomplish in intact cells. The protocol described here has the advantage that it facilitates measurement of the level of transcription for many different genes in a single experiment. A point of controversy is whether some initiation of new RNA synthesis occurs in isolated nuclei during the runoff transcription reaction. What is clear is that transcripts that have initiated prior to cell lysis are faithfully elongated. Elongation of previously initiated transcripts most likely accounts for the bulk of the radioactivity incorporated into RNA in these reactions. Therefore, the method gives a reasonably accurate measure of the level of transcription occurring at the time of cell lysis. The runoff transcription assay is often used to assess whether changes in mRNA levels of a particular gene that occur as a function of cell state reflect a change in its synthesis as opposed to a change in mRNA degradation or transport from the nucleus to the cytoplasm.

A variety of different nuclear runoff transcription protocols have been described. The procedures differ primarily in the method of isolation of ³²P-labeled RNA. The protocol described here is advantageous because very low levels of background transcription are obtained. This is attributed in part to the TCA precipitation step, which allows effective removal of unincorporated ³²P. Limited digestion of ³²P-labeled RNA with NaOH appears to facilitate hybridization. Excellent reviews of

the nuclear runoff transcription method have been published by Marzluff (1978) and by Marzluff and Huang (1985).

Critical Parameters

The most critical step in the nuclear runoff assay is isolation of nuclei. For many different types of tissue culture cells, the procedure described in the basic protocol works well. However, the isolation protocol may have to be altered somewhat for isolating nuclei from tissues and lymphocytes (Marzluff and Huang, 1985). Poor incorporation of ³²P-labeled UTP into RNA in isolated nuclei may reflect damage to the nuclei during isolation or failure to isolate nuclei free of cytoplasmic and membrane contaminants. Lymphocyte nuclei are quite fragile, and it is necessary to employ an alternative isolation procedure to obtain nuclei that incorporate significant levels of radioactive isotope. In this alternative protocol, cells are lysed by Dounce homogenization in an isoosmotic buffer with nonionic detergent and nuclei are collected by centrifugation through a sucrose cushion. A minimum of 5×10^6 nuclei is required for a successful assay, but 5×10^7 is recommended. With fewer nuclei the level of incorporation of ³²P-labeled UTP into RNA drops significantly, and the level of specific transcription is usually difficult to distinguish from background radioactivity.

In this protocol the cpm/ml of ³²P-labeled RNA is equalized in each sample prior to hybridization based on the assumption that the overall level of RNA synthesis is not changing as a function of the cell state. When analyzing gene transcription under a new set of conditions, it is critical to determine if this is a reasonable assumption. Particular care must be taken in these experiments to ensure that the

same number of nuclei is used for each cell state analyzed.

Incorporation of ^{32}P -labeled UTP into RNA appears to increase when the number of nuclei is increased between 5 and 50×10^6 nuclei. Increasing the amount of ^{32}P -labeled UTP beyond 100 μCi per sample appears to be less useful. Increasing the incubation time of nuclei with ^{32}P -labeled UTP beyond 30 min is also ineffective for increasing the amount of ^{32}P incorporated into RNA.

Anticipated Results

Beginning with 5×10^6 nuclei and 100 μCi of ^{32}P -labeled UTP, the nuclear runoff transcription protocol allows incorporation of 1–10 $\times 10^6$ cpm into total RNA. Good results have been obtained when as few as 1×10^6 cpm were used in the hybridization reaction.

Time Considerations

Nuclei to be tested are isolated and stored in liquid nitrogen. NP-40 lysis and Dounce homogenization take <1 hr. Isoosmotic lysis and sucrose gradient centrifugation require ~2 hr. Ten to 20 samples can be processed at once through transcription. Labeling and isolation of RNA are accomplished in 1 day with an overnight RNA precipitation step. Preparation of nitrocellulose filters requires ~2 hr and can be done in advance. Hybridization of filters can be set up in a morning and requires a total of 2 days plus autoradiographic exposure.

CHAPTER 5

Construction of Recombinant DNA Libraries

INTRODUCTION

Construction of recombinant DNA molecules by simply ligating vector DNA and a fragment of interest is a straightforward process, discussed in Chapters 1 and 3. Special problems arise, however, when the fragment of interest represents only a very small fraction of the total target DNA. This is the case in two commonly encountered situations: isolation of single copy genes from a complex genome and isolation of rare cDNA clones derived from a complex mRNA population. This chapter describes techniques to generate recombinant DNA libraries which contain complete representation of genomic or cDNA sequences. The major differences between genomic and cDNA libraries are discussed in Section I (Overview of Recombinant DNA libraries). Insert DNA molecules are a necessary prerequisite for the construction of any DNA library and several approaches for producing insert DNA are discussed in Section II (Preparation of Insert DNA from Genomic DNA) and Section III (Preparation of Insert DNA from Messenger RNA). Finally, approaches to producing complete libraries are described in Section IV (Production of Genomic DNA and cDNA Libraries). The production of large libraries is a complicated process and all of the necessary steps are described here. However, a number of library-making kits are now commercially available which make this process much more feasible. These kits have the additional advantage that they utilize different cloning vectors that include proprietary features, which facilitate the use of library clones.

The central issue in library production is best presented in the context of considering the production of a genomic or cDNA library from a mammalian cell. The DNA of higher organisms is remarkably complex: a mammalian haploid genome contains approximately 3×10^9 base pairs. A particular 3000-bp fragment of interest thus comprises only 1 part in 10^6 of a preparation of genomic DNA. Similarly, a particularly rare mRNA species may comprise only 1 part in 10^5 or 10^6 of total poly(A) containing RNA, a ratio that is usually unaffected by the process of copying the RNA into cDNA. Clearly, the main problem in generating a useful recombinant DNA library from either genomic DNA or cDNA is the creation of the huge population of clones necessary to ensure that the library contains at least one version of every sequence of interest. The solutions to this problem are basically similar for genomic and cDNA libraries. As diagrammed in Fig. 5.0.1, the genomic DNA or cDNA are first prepared for insertion into the chosen vector. The vector and target DNA are then ligated together and introduced into *E. coli* by either packaging into phage λ heads in vitro or by direct transformation. In some aspects, however, strategies for isolation of individual genomic or cDNA clones can be quite different. The particular problems of creating these two different types of libraries will be discussed in detail separately (UNITS 5.1 & 5.2). Over the past several years, techniques for producing improved cDNA libraries have been optimized. These techniques will be described in the near future in an update to UNIT 5.8A.

Most cDNA library screening procedures involve positive identification of cDNA clones with either antibodies or hybridizing nucleic acid probes. Subtracted cDNA libraries provide a method for identifying mRNAs (as cDNAs) that are expressed in one cell but not another. cDNAs are synthesized from the cell expressing the desired mRNA and all of the sequences expressed in a cell not expressing the RNA are removed by hybridization and selection. The remaining sequences are cloned into a bacteriophage or plasmid vector

to produce a subtracted cDNA library. Estimation of the number of clones that must be screened is difficult, as it will vary with the cell type and the gene to be identified. Some cDNA libraries such as SAGE libraries and subtracted libraries do not capture full-length or near-full-length cDNAs. Construction of these libraries is described in Chapter 25, where they are used for assessing RNA expression.

The *E. coli* vectors described in this chapter are limited with regard to the size of insert DNA that can be accommodated (~20 kb for lambda and ~40 kb for cosmid vectors). The ability to clone much larger fragments of DNA, however, has become an essential requirement for many genome analysis projects. Yeast artificial chromosome (YAC) vectors, maintained in yeast hosts, typically carry inserts ranging from 0.3 to 1.2 Mb of genomic DNA. Both the size and complexity of YAC libraries pose special considerations for production, screening, and analysis, and these concerns are addressed in *UNITS 6.9 & 6.10* in the following chapter.

Two important general points pertain to both genomic and cDNA libraries. First, it is essential that both the vector DNA and target DNA used to create the library are not contaminated by exogenous sequences detectable by the probes that will be used to isolate the clones of interest. There are obvious, potentially disastrous effects of contaminated target DNA—for example, by only 1 part in 10^5 of a plasmid containing the cDNA sequences to be used as a probe. See “Going for the gene,” *The Boston Globe Magazine*,

Aug. 2, 1987, for an account of such a mistake. Common sense dictates care and use of absolutely clean and, where possible, disposable materials throughout.

Second, libraries can be stored indefinitely. Over the past 5 to 10 years, large numbers of genomic libraries have been made from a variety of organisms and an even larger number of cDNA libraries have been produced from an astonishing number of tissues and cell lines. Many useful libraries, including examples of human and other mammalian genomic or cDNA libraries, have been made over the years. In some cases, journals (e.g., *Cell*, *Science*, *Proceedings of the National Academy of Sciences U.S.A.*, and the publications of the American Society for Microbiology) require that libraries and individual clones discussed in their pages be freely available to other investigators. Both stock and custom-made libraries are also available from a variety of commercial sources. The ability to amplify these libraries without significantly altering the distribution of clones within the library allows investigators to utilize a library many times. Protocols for amplifying libraries are described in *UNITS 5.10 & 5.11*.

J.G. Seidman

OVERVIEW OF RECOMBINANT DNA LIBRARIES

The units in this section present strategies for generating genomic DNA and cDNA libraries (UNITS 5.1 & 5.2, respectively). Production of recombinant DNA libraries can be a very laborious procedure. We strongly recommend the purchase of genomic or cDNA libraries when possible; otherwise, we recommend purchasing reagent kits for producing libraries. These kits can save considerable time and effort.

Genomic DNA Libraries

Genomic DNA libraries are almost always screened by hybridization using a radioactive nucleic acid probe. Since this approach is essentially independent of a particular vector or type of target DNA, the main problem faced when considering creation of a genomic DNA library is simply generating a large enough number of recombinant DNA clones. The basic strategies used to address this problem have included both minimizing the number of clones necessary by incorporating large fragments of genomic DNA, and maximizing cloning efficiency by using vectors based on bacteriophage λ . This unit will discuss the appropriate numerical considerations for both ordinary genomic DNA libraries and subgenomic DNA libraries, and will then describe a limited number of appropriate vectors.

REPRESENTATION AND RANDOMNESS

The size of a library of completely random fragments of genomic DNA necessary to ensure representation of a particular sequence of interest is dictated by the size of the cloned fragments and the size of the genome. The likelihood that a sequence of interest is present in such a random library can be estimated by simple statistics based on the Poisson distribution (Clarke and Carbon, 1976). Specifically, the number of independent clones, N , that must be screened to isolate a particular sequence with probability P is given by

$$N = \ln(1 - P) / \ln[1 - (I/G)]$$

where I is the size of the average cloned fragment, in base pairs, and G is the size of the target genome, in base pairs.

For a 99% chance of isolating an individual sequence from a typical mammalian genome using a typical phage λ vector

$$N = \ln(1 - 0.99) / \ln[1 - (2 \times 10^4 / 3 \times 10^9)] = 690,000.$$

This equation can be used to define a useful rule-of-thumb by calculating the probability of isolating a fragment of interest as a function of (I/G). In general, to have a 99% chance of isolating a desired sequence, the number of clones screened should be such that the total number of base pairs present in the clones screened ($I \times N$) represents a 4.6-fold excess over the total number of base pairs in the genome (G) (Seed et al., 1982).

When the desired fragment can be purified, the size of the library can be reduced. The library size can then be estimated by

$$N \cong 3 \times 1/p$$

where p = the probability of isolating a particular fragment = 1/total number of fragments in the pool.

It is important to note that this simple analysis assumes that the cloned DNA segments randomly represent the sequences present in the genome. This assumption is true only if the target DNA was cleaved completely randomly prior to insertion into the vector. In the strictest sense, this level of randomness can be approached only by the relatively inconvenient means of shearing the target DNA.

With common sense and care, however, sufficiently random cleavage of target DNA can generally be obtained using partial digestions with restriction enzymes (UNIT 5.3). One simple limitation of this approach is that fragments which are larger than the capacity of the vector as complete digestion products will be excluded from the library. Clearly, it is best to use an enzyme that cuts the DNA of interest both frequently and without any bias in selection of one site over another (such bias is seen with *EcoRI*, for example). The enzyme *Sau3A*, which recognizes the 4-bp site GATC and generates fragments compatible with several convenient phage λ and cosmid vectors (see below), has proved useful for generating partial digestion libraries.

Given an enzyme that cleaves frequently and randomly, it is not so obvious which partial digestion protocol will lead to the most random products. As described in detail by Seed et al. (1982), randomness is maximized by partial digestion to an extent where the size of the numerically most abundant class of partial products equals the vector capacity. This is not reflected by an extent of digestion in which the location on a gel of the maximum staining intensity of partial digestion products equals the fragment size of interest (a consequence of the fact that larger fragments stain more intensely than an equal number of smaller fragments). To determine the optimal extent of digestion, resolve a series of partial digestions of increasing extent on a gel and examine the amount of staining in *only* the size class of interest. The lane in which the greatest amount of DNA is seen corresponds to *twice* the appropriate extent of digestion (Seed et al., 1982).

SUBGENOMIC DNA LIBRARIES

Sometimes only a small and relatively well characterized fragment is desired. For example, if a particular 1-kb *Bam*H1 fragment is of interest, it can be purified and used to generate a smaller, potentially easier to screen library. Such libraries, which represent only a fraction of the genome, are called subgenomic DNA libraries.

Numerical considerations show that maximizing the fold of purification of target DNA is crucial for subgenomic DNA libraries. One can use the equation described above to estimate the number of clones necessary by simply assuming that the genome size is reduced by the amount of purification. For example, if the desired 1-kb mammalian DNA fragment was purified 10-fold from the rest of the genomic DNA, and the resultant library was otherwise a random representation of the remaining 10% of the genome, then

$$N = \ln(1 - 0.99) / \ln[1 - (1 \times 10^3 / 3 \times 10^8)] = 1,382,000.$$

In this case the subgenomic approach has actually *increased* the number of clones necessary as compared to the random library, due to the large decrease in the size of the insert. Increasing purification by another factor of 10 decreases the number of clones needed by a factor of 10. As a minimum, the fold of purification must exceed the ratio of genomic DNA library insert size to subgenomic insert size.

A simple way to increase the fold of purification is to use multiple, sequential digestion

strategies in cases where details of the restriction map of the sequences of interest are known. After initial purification of a given fragment, redigestion with another enzyme that gives a smaller (clonable) fragment will generally yield significant further purification relative to the original DNA.

VECTORS FOR GENOMIC DNA LIBRARIES

Because of their combination of high cloning efficiency and relatively large insert size, either bacteriophage λ vectors or hybrid plasmid vectors called cosmids (which contain particular λ sequences that direct insertion of DNA into phage particles) are generally used to construct genomic DNA libraries. The biology and general properties of these two types of vectors are described in *UNIT 1.10*.

Briefly, the high cloning efficiency of both types of vectors is a consequence of the ability of simple extracts of phage λ -infected cells to insert exogenously added λ DNA, or recombinant DNA containing appropriate λ sequences, into preformed λ heads and tails, generating infectious phage particles. Up to 10% of added concatameric phage genomes can be packaged in this way, an efficiency significantly greater than that of introduced plasmid DNA into *E. coli* by transformation. In the case of cosmid vectors, the recombinant DNA inserted into the phage contains plasmid vector sequences and replicates as a plasmid after infecting bacteria (see *UNIT 1.10*).

The cloning capacity of both types of vectors is dependent on the size of DNA that can be accommodated by λ phage heads, approximately 35 to 50 kb. However, the vectors differ significantly in the fraction of this total taken up by vector sequences. Most phage vectors designed for genomic DNA libraries can accommodate foreign DNA fragments of 10 to 20 kb generated by a limited variety of restriction enzymes. Cosmids can generally accept 30- to 40-kb fragments generated by any of a number of restriction enzymes.

The choice between phage and cosmid vectors is generally based on the size of the desired genomic DNA segment. Most investigators feel that phage libraries are easier to handle, and choose a phage vector if the desired segment is less than ~20 kb. Larger segments require the use of cosmid vectors.

Bacteriophage λ Vectors

Significant design advances over the years have resulted in the development of several

easy-to-use phage λ vectors. These vectors have two basic features in common: ability to accept fragments generated by several restriction enzymes, and biochemical and/or genetic selection against the so-called stuffer sequences present in the original vector in the place of the exogenously added DNA. As described in *UNIT 1.10*, this stuffer fragment is necessary because vectors that contain the minimum segment of the λ genome necessary for phage propagation (approximately 30 kb) are too small to be packaged into normal phage heads. Earlier vectors required rather laborious biochemical separations of vector and stuffer fragments prior to insertion of foreign DNA.

The minimal λ genome contains restriction sites for a number of enzymes frequently used for cloning in plasmid vectors. Newer vectors have partially circumvented this problem by eliminating some of these sites (notably those for *Bam*HI) and addition of new, unique sites to polylinkers which flank the stuffer fragment.

The segment of the λ genome that can be replaced by exogenous DNA contains genes whose expression prevents phage growth in bacterial hosts containing P2 prophages (see *UNIT 1.10*). Engineering the stuffer fragment to express these genes regardless of orientation relative to the rest of the genome has resulted in vectors that will grow on such P2 lysogens only if they have incorporated foreign DNA in the place of the stuffer. Such vectors obviate the need to physically remove the stuffer prior to ligation to exogenous DNA.

An alternative biochemical strategy to prevent reinsertion of the stuffer segment has also been developed. In vectors designed for this approach, two identical polylinkers flank the stuffer in an inverted orientation relative to each other. In this arrangement, double digestion of the polylinkers with two appropriate enzymes generates vector and stuffer fragments with heterologous, nonligatable ends. Simple, preferential ethanol precipitations (see *UNIT 2.1*) remove the very small polylinker fragments. Since the vector segment by itself is too short to generate a viable phage, all plaques generated by in vitro packaging of a ligation of vector and insert DNA should be recombinant.

The vector λ EMBL3 allows both the genetic and the biochemical strategies to avoid purification of stuffer fragments, and includes several useful cloning sites in the polylinker.

This versatile and modern vector has been successfully used to create many libraries.

Cosmid Vectors

Any plasmid cloning vector that contains the λ *cos* site can be used as a cosmid. A number of cosmid vectors designed for particular applications include additional elements such as genes that allow transfer to non-*E. coli* bacterial cells or dominant markers for selection in mammalian cells. Such add-ons decrease the cloning capacity of the vector and should be avoided if possible. One useful, simple cosmid vector is pJB8 (Ish-Horowitz and Burke, 1981), a 5.4-kb plasmid that accepts genomic DNA digested with *Sau*3A and can be used with several cosmid cloning strategies.

Vectors for Subgenomic DNA Libraries

It is possible to use simple plasmid vectors for subgenomic DNA libraries if the level of purification and recovery of the target fragment is sufficient to overcome the relative inefficiency inherent in plasmid cloning. In general, however, phage λ vectors designed for direct insertion of foreign DNA rather than substitution for a stuffer fragment are used. A very large number of potential insertion vectors exist to accommodate fragments generated by a variety of restriction fragments: wild-type λ is a natural insertion vector which should accommodate *Sal*I or *Xho*I fragments up to 2 to 3 kb. λ gt10 (see *UNIT 1.10*) is the only vector in general use which allows selection against nonrecombinant phages, and is recommended for cloning *Eco*RI fragments.

The most basic step in constructing a cDNA library is the process of generating a double-stranded DNA copy of the mRNA. In the last few years, preparation of this cDNA has been simplified by improved strategies and availability of higher quality enzymes. Thus, it should be straightforward to obtain essentially full-length cDNA copies for mRNAs up to the 3 to 4 kb range, and at least feasible for even larger mRNAs. As described in detail in the cDNA protocols (UNITS 5.5 & 5.6), the most important factor affecting quality of cDNA is the quality of the mRNA. Particularly for a large message, it is essential to start with the highest quality RNA available.

Two related issues dominate the strategies for constructing cDNA libraries. The first is the relative abundance of the clone of interest, which can vary over a wide range. Highly abundant messages can represent 10% or more the total mRNA, whereas very rare messages can be as low as 1 part in 10^6 , particularly if the gene of interest is only being expressed in a fraction of the cells used as a source of mRNA. The second issue is the screening method (see Chapter 6), which can range from simply sequencing several individual isolates until the desired clone is identified, through ordinary hybridization methods, to complex strategies involving expression of identifiable antigens or biological activities.

Obviously, the size of the library necessary to include the clone of interest is a direct reflection of the relative abundance of the mRNA of interest. In general, however, this abundance is not known with precision. In addition, the representation of some sequences in the cDNA library, particularly the 5' ends of large messages, will be less than expected from their mRNA abundance. It is sensible to aim for a library that contains at least 5 times more recombinants than the total indicated by the lowest abundance estimate. In some cases this number should be multiplied by various factors based on screening efficiency. If it is necessary to fuse a peptide-coding region to a vector in a particular reading frame, for example, the number of identifiable clones is only $\frac{1}{6}$ of those present in the library.

If the mRNA of interest is relatively abundant, efficiency of generating clones is not so important, and the choice of cloning strategy and vector should be based on the desired use

for the clone. If, for example, expression in *E. coli* is the object, the cDNA library can be inserted directly into an appropriate expression vector. This might involve choosing linkers or adaptors useful for insertion into the vector, and simple screening by hybridization.

In many cases, however, the mRNA of interest is relatively rare, and high cloning efficiency is of central importance. As with genomic libraries, this has led to development and use of phage λ vectors. In general, there are two types of λ vectors for cDNA cloning adapted for the two most common methods of library screening.

If the library is to be screened by hybridization with a nucleic acid probe (UNITS 6.1 & 6.3 or 6.4), any insertion vector is appropriate. A vector that is particularly good for this approach is λ gt10. As mentioned above, this insertion vector allows direct selection against nonrecombinant phages. A useful feature of this vector for cDNA cloning is that it accepts *EcoRI* inserts. Methylation of the double-stranded cDNA with *EcoRI* methylase and addition of *EcoRI* linkers is an efficient way to generate clonable cDNA (see UNITS 5.5 & 5.6).

If the library is to be screened by use of antibody probes (UNIT 6.7), it is necessary to use an appropriate *E. coli* expression vector. In general, such vectors are based on expression of a fusion protein in which a segment of the peptide of interest is fused to a highly expressed, stable *E. coli* protein. The most commonly used expression vector is λ gt11 (UNIT 1.10), in which the cloned peptide coding sequences are fused to coding sequences for β -galactosidase.

PREPARATION OF INSERT DNA FROM GENOMIC DNA

Completely or partially digested genomic DNA must be size fractionated before ligation to vector to remove irrelevant small and large fragments. If size fractionation is not performed, small fragments will ligate together and produce recombinants that are difficult to analyze. Large insert DNA fragments will not allow the vector to grow, but will ligate to vector DNA and alter vector DNA requirements. Size-purified fragments isolated from complete digests of genomic DNA are less complex than the entire genome and thus reduce the number of DNA clones that must be produced in order to obtain the desired subgenomic library.

Procedures for making insert fragments for genomic and subgenomic DNA libraries involve digestion of DNA followed by size fractionation. DNA is either partially digested for preparation of complete genomic libraries or completely digested for preparation of subgenomic libraries. Basic protocols for digesting DNA with restriction enzymes are presented in *UNIT 3.1*; however, *UNIT 5.3* presents support protocols with necessary modifications to ensure that large amounts of genomic DNA are properly digested.

Two methods for size fractionation of genomic DNA are presented. Both protocols are appropriate for the isolation of DNA fragments that will subsequently be used for library construction. These protocols aim to maximize DNA fragment yield while minimizing exposure of the DNA to reagents or conditions that inhibit subsequent ligation to vector and introduction of hybrid molecules into the bacterial cell. The sucrose gradient and preparative gel electrophoresis methods circumvent problems found in other fractionation protocols.

Sucrose gradient fractionation is generally faster than preparative gel electrophoresis. However, the latter procedure has a higher capacity for resolving large amounts of DNA, is applicable to a larger range of sizes, and has significantly better resolution.

These procedures emphasize the requirements for fractionating large quantities of DNA and producing DNA that will ligate to vector. Normally, large quantities of genomic DNA can be obtained from the species of interest so that when producing genomic libraries the investigator has the luxury of being able to work with more DNA than when producing cDNA libraries. The procedures used here all assume that genomic DNA is available (see *UNITS 2.1 & 2.4* for DNA prep procedures). The amount of DNA required varies depending on the complexity of the genome being used.

NOTE: For laboratories using recombinant DNA techniques and isolating large quantities of plasmid, bacteriophage, or cosmid DNA, remember that the smallest amount of contamination of genomic DNA with recombinant DNA is disastrous. Contamination of genomic DNA at 1 ppm with recombinant plasmid or bacteriophage will cause great difficulty because they may grow and be identified during screening procedures as the desired clones. Thus, all plasticware, glassware, and reagents used for the preparation of genomic DNA or mRNA and cDNA should be maintained separately from those used for plasmid or bacteriophage DNA preparation. The extensive use of disposable plasticware is strongly recommended.

Size Fractionation Using Sucrose Gradients

BASIC PROTOCOL

SUCROSE GRADIENT PREPARATION OF SIZE-SELECTED DNA

Partially or fully digested DNA consists of a population of DNA fragments ranging in size from hundreds of base pairs to over 100,000 bp in length. This protocol effectively separates such a mixture of DNA fragments into different size classes. To accomplish this the DNA solution is heated to dissociate aggregated DNA fragments and is then loaded onto a high-salt sucrose gradient. After centrifugation and gradient fractionation, the appropriate fractions are identified by agarose gel electrophoresis. This protocol can also be used to purify bacteriophage λ vector arms.

Materials

Completely or partially digested genomic DNA (support protocols)

STE buffer (APPENDIX 2)

10% and 40% sucrose solution

0.9% agarose gel

100% ethanol

TE buffer (APPENDIX 2)

Sucrose gradient maker

Beckman SW-28 or SW-41 rotor or equivalent

Additional reagents and equipment for ethanol precipitation (UNIT 2.1) and agarose gel electrophoresis (UNIT 2.5)

1. Begin with partially or fully restriction-enzyme digested DNA (see support protocol) at a concentration of about 1 mg/ml in STE buffer.

It is essential that the DNA be completely dissolved.

2. Prepare a linear 10% to 40% sucrose gradient in an SW-28 centrifuge tube (38-ml gradient) or SW-41 tube (12-ml gradient).

There are a variety of gradient makers; follow the manufacturer's instructions for preparing the gradient.

3. While the gradient is being poured, heat the digested DNA to 65°C for 5 min to dissociate any DNA aggregates.

4. Carefully layer the DNA solution on top of the sucrose gradient.

Do not exceed 0.5 mg genomic DNA per SW-28 centrifuge tube or 0.2 mg genomic DNA per SW-41 tube. For λ vector DNA, do not exceed 50 μ g and 20 μ g, respectively (see critical parameters).

5. Centrifuge at 20°C, 113,000 \times g (25,000 rpm in SW-28 rotor) or 154,000 \times g (30,000 rpm in SW-41 rotor) for 16 to 24 hr, depending upon the size of the desired DNA fragments. For cosmid-sized inserts (40,000 bp) centrifuge 16 to 18 hr. For phage-sized inserts (18,000 bp) centrifuge 24 hr.

6. Fractionate the gradient by carefully placing a capillary tube at the bottom of the centrifuge tube and pumping out the gradient, heavier fractions first. This prevents the mixing of smaller DNA fragments with the desired larger fragments. Collect 750- μ l fractions into microcentrifuge tubes (see Fig. 5.3.1A).

Note: 12-ml gradients can also be fractionated by removing 750- μ l aliquots from the top with a mechanical pipettor (e.g., P1000 Eppendorf pipet).

7. Determine the size of the collected DNA fractions by electrophoresing 40- μ l samples

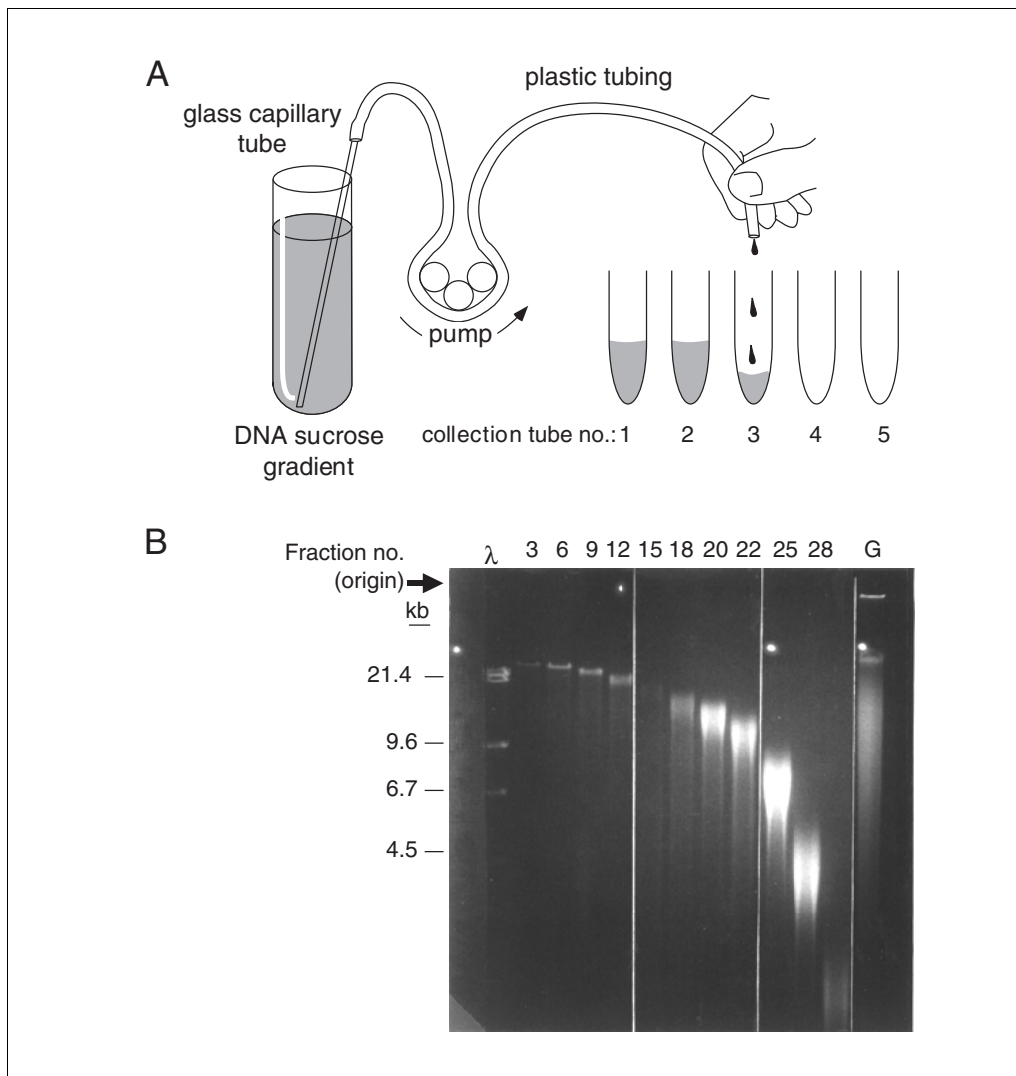

Figure 5.3.1 (A) Method for fractionating sucrose gradients. The gradient is pumped out of the tube from the bottom. The arrow indicates the flow of sucrose solution. The densest part of the gradient and the DNA of the highest molecular weight is pumped out first. The gradient is collected in 750- μ l aliquots. (B) Ethidium bromide-stained agarose gel used for characterization of sucrose gradient-fractionated genomic DNA, where G is the input genomic DNA.

of the gradient in a 0.9% agarose gel at high voltage (see *UNIT 2.5*).

8. Ethanol precipitate fractions containing correctly sized DNA. Divide each sucrose fraction into four microcentrifuge tubes, each containing \sim 180 μ l of sucrose/DNA solution. Add 320 μ l water and 1 ml ethanol to each tube and place at -20°C overnight.

For subgenomic libraries, appropriate fractions are identified by Southern blot analysis of the agarose gel using a DNA probe that will identify the desired fragment (see UNIT 2.9). For genomic libraries, the desired fractions are identified by the size of the DNA fragments. Cosmid vectors require inserts of \sim 30 to 50 kb, while bacteriophage vectors generally require inserts of 8 to 20 kb.

9. Resuspend and combine four ethanol-precipitated aliquots of DNA in a total volume of \sim 100 μ l TE buffer per sucrose gradient fraction.
10. Those fractions containing the desired size class can be used directly for ligations or can be ethanol precipitated again for long-term storage.

PARTIAL ENZYME DIGESTION

Genomic high-molecular-weight DNA is incubated with limiting amounts of a particular restriction enzyme for variable lengths of time. Samples from the digested DNA are removed at different time intervals and analyzed by agarose gel electrophoresis to determine the average length of the digested DNA. The time points of digestion that are most enriched for the desired size fractions are then used as the guide for the preparative digestion of the same DNA. In this way, size-selected DNA fragments can be prepared with a minimum of trial and error.

Additional Materials

High-molecular-weight genomic DNA (UNITS 2.2, 2.3, & 2.4)

10× restriction enzyme buffer (UNIT 3.1)

Stop solution

Restriction enzyme for DNA digestion (UNIT 3.1)

0.5% agarose gel (UNIT 2.5A)

DNA size markers (UNIT 2.5A)

1:1 phenol/chloroform (UNIT 2.1)

5 M NaCl

1. Start with genomic DNA suspended in STE or TE buffer at a concentration of ~0.1 to 0.5 mg/ml.

The size of the genomic DNA used for this procedure is critical to its success. The average size of the DNA must exceed 100 kb. If the DNA is smaller than 100 kb, very few partial digestion products will be obtained that have both ends produced by the restriction enzyme and thus be suitable for cloning into vector.

2. Transfer 100 µg DNA to a microcentrifuge tube, dilute to 900 µl, and add 100 µl of the appropriate 10× restriction enzyme buffer.

Sau3A is frequently used for mammalian genomic libraries and produces ends on the DNA that can ligate to BamHI cut vector (see commentary).

3. Incubate 10 min at 37°C.

This incubation prewarms the reagents to 37°C. Some investigators prefer to incubate at room temperature to slow down the reaction.

4. Remove 40 µl of solution, add to 10 µl stop solution, mix, and put on ice.

5. Add, in units, enough of the appropriate restriction enzyme to the remaining 960 µl of DNA solution to *fully* digest only 20% of the DNA in the tube in 60 min.

6. At 10-min intervals remove 40 µl digestion solution, add to 10 µl stop solution in a fresh microcentrifuge tube, and place on ice. Continue for 90 min.

There should be 9 separate aliquots of terminated reaction.

7. Prepare a 0.5% agarose gel and electrophorese the DNA aliquots using, as markers, uncut and *Hind*III-digested λ DNA (see UNIT 2.5).

The dye marker should be electrophoresed off the bottom of the gel because high resolution in the 20- to 50-kb region of the gel is required.

Handle 0.5% agarose gels carefully; they are extremely fragile.

8. Assess the amount of digestion. If the enzyme concentration is in the appropriate range, one should observe the high-molecular-weight genomic DNA being converted to lower-molecular-weight DNA with time. If there is very little high-molecular-weight material even in lanes representing the earliest time points, reduce the amount of restriction enzyme 10-fold and start over (step 1). If there is almost no digestion in the lane representing the longest time point, increase the amount of

enzyme 10-fold and start over (step 1). The desired time points are those in which a large amount (10 to 20%) of the DNA is in the 20- to 50-kb size range.

Most investigators prefer to choose earlier time points because they hope to find a better representation of partially digested fragments at these times than at later times. (See critical parameters for a further discussion of this subject.)

9. Once a correct time point and enzyme concentration has been determined, scale up digestion reaction to contain 1 mg DNA (10-ml reaction). Prewarm and digest.
10. Remove 3.3 ml of digest 5 min before the optimal time, add to 10 ml phenol/chloroform (1:1), and mix well. Remove 3.3 ml at the optimal time and 3.3 ml 5 min after the optimal time and add to phenol/chloroform mixture.

For unclear reasons, scaling up this reaction does not always work. If scale-up results in either over- or underdigestion, use 10 identical 1-ml reactions.

11. Centrifuge 5 min at 5000 to 10,000 \times g until the phases are separated and remove the supernatant.
12. Ethanol precipitate by adding 1 ml of 5 M NaCl and 30 ml 100% ethanol, chill, and centrifuge (see UNIT 2.1).
13. Resuspend DNA in 1 ml STE buffer and analyze the product on a 0.5% agarose gel (see step 8 this protocol, and UNIT 2.5).

Resuspend gently to avoid shearing the large DNA.

Assuming that a significant fraction (10 to 20%) of the DNA is in the 20- to 50-kb range it is suitable for library construction.

COMPLETE ENZYME DIGESTION

One approach to cloning a gene from a particular cell or tissue involves the production of a subgenomic library. A subgenomic library is constructed by completely digesting DNA with a particular restriction enzyme and then isolating the particular size class of DNA that contains the desired restriction fragment (see overview, UNIT 5.1).

0.1 to 1 mg of completely digested genomic DNA (see UNIT 3.1) is generally required to produce a subgenomic library. We suggest performing a trial digest of 1 to 10 μ g DNA

Figure 5.3.2 This 0.9% agarose minigel contains samples of genomic digests performed with increasing concentrations (left to right) of restriction enzyme. As the digest approaches completion, high-molecular-weight fragments become less prominent and faint satellite bands become visible. 10 μ g genomic DNA was incubated with 10, 20, and 50 U restriction enzyme for 2 hr, and 40 μ l (about 1 μ g) DNA was loaded on the gel.

SUPPORT PROTOCOL

Construction of Recombinant DNA Libraries

5.3.5

to determine the optimum enzyme concentration (Fig. 5.3.2), need for spermidine, etc., before attempting the large-scale digest. Overdigestion of the DNA is undesirable because the ends of the DNA fragments are sometimes destroyed by nuclease. It is desirable to limit the quantity of enzyme and length of incubation to prevent any nonspecific digestion and exonuclease activity which can interfere with ligation and cloning.

Occasionally, difficulty is encountered digesting genomic DNA. This is usually because of contamination of the DNA with proteins that inhibit the activity of the restriction enzyme. Also, even modest amounts of NaCl trapped in the DNA during ethanol precipitation can inhibit the activity of low-salt enzymes such as *SacI* and *KpnI*. If the DNA is resistant to digestion, it may be helpful to phenol extract, chloroform extract, and ethanol precipitate the DNA to remove contaminants.

When appropriate reaction conditions have been determined, scale up the digest (increase all reagent volumes proportionally) to include the entire genomic DNA sample to be used for cloning. Again, 0.1 to 1 mg mammalian genomic DNA should be sufficient for construction of a subgenomic library. Confirm completion of digestion by running ~1 µg digested DNA on a minigel. The completely digested DNA should be phenol/chloroform extracted and ethanol precipitated as described in *UNIT 2.1* to remove enzyme and salt.

REAGENTS AND SOLUTIONS

Stop solution

- 10 mM Tris·Cl, pH 7.5
- 20% glycerol
- 0.1% sodium dodecyl sulfate
- 0.1% bromphenol blue

10% sucrose solution

- 10% sucrose (10 g sucrose/100 ml solution)
- 1 M NaCl
- 20 mM Tris·Cl, pH 7.5
- 5 mM EDTA

40% sucrose solution

- Same as above except with 40% sucrose

COMMENTARY

Background Information

Sucrose gradients. DNA fragments migrate through a linear sucrose gradient at a rate that is dependent on their size. Other gradients (e.g., sodium chloride gradients) have also been proposed; however, we find that sucrose gradients are easier to prepare and provide equally good resolution. This procedure provides good resolution for DNA fragments 5 to 60 kb in size. Thus, partially digested genomic DNA can be fractionated for the production of cosmid or bacteriophage libraries and completely digested DNA can be fractionated for subgenomic DNA libraries. Sucrose gradients are also useful for purification of bacteriophage λ vector arms.

This is an extremely reliable, easy, and rapid method for fractionating digested genomic DNA. The technology has been used for many years. DNA fragments obtained by this procedure can normally be ligated to vector. The major weakness of the procedure is that it does not produce the resolution of some preparative agarose gel techniques and it does not have the capacity of those techniques (see *UNIT 5.4*). Despite these weaknesses this is probably the most widely used method for producing inserts for genomic and subgenomic libraries. Sucrose gradients can also be used for purification of bacteriophage λ vector arms.

Partial digestion. The preferred method

for producing the random collection of DNA fragments required to make a genomic library is to partially digest high-molecular-weight genomic DNA with a restriction enzyme. An extensive discussion of the theory of partial restriction enzyme digestion is provided in *UNIT 3.1*. Partial digestion can be achieved by limiting the reaction time or amount of restriction enzyme. *UNIT 3.1* presents a protocol in which the amount of enzyme is limited; the protocol described here involves limiting the time of digestion. Regardless of the method of creating partial digestion products, the products created earlier in the reaction are probably more random than the products produced later in the reaction (Seed et al., 1982).

Restriction enzymes that recognize 4-base sequences produce a more random collection of insert fragments than enzymes that recognize 6-base sequences. The most random collection of fragments is produced by shearing the DNA. However, because the techniques for cloning sheared DNA are not very efficient most investigators produce the random collection of DNA fragments by partial digestion with restriction enzymes. The theory of using restriction enzymes to produce inserts for genomic libraries is discussed by Seed et al. (1982). Restriction enzymes that produce the most random collection of fragments are those that cleave DNA most frequently.

A second reason for choosing a particular restriction enzyme is that it must produce fragments that can be ligated into the desired vector. Because they produce fragments that can be ligated into *Bam*HI-cut vectors and because they recognize a 4-base sequence (GATC), the enzymes *Sau*3A or *Mbo*I are normally used for this purpose.

Complete digestion. See second support protocol.

Critical Parameters

Sucrose gradients. The digested DNA must be completely dissolved and disaggregated. Undissolved or aggregated DNA will form a pellet at the bottom of the centrifuge tube.

The gradients must not be overloaded. If more than 0.5 mg of genomic DNA is loaded on a 38-ml sucrose gradient or 0.2 mg of genomic DNA on a 12-ml gradient, then the DNA will aggregate and fractionation will not occur. The amount of λ DNA that can be loaded is 10-fold less.

The distance the DNA migrates in the sucrose gradient affects the resolution of different size DNA fragments. The distance that the

DNA migrates is approximately proportional to the time of centrifugation and the rpm². The resolution in a particular size range can frequently be improved by altering the rate or time of centrifugation.

The gradients are relatively stable. Nevertheless, they must be handled with care and not jarred or mixed during preparation or fractionation. They should not be stored for long periods before or after use.

Partial digestion. The quality of the genomic DNA and the restriction enzymes used for this purpose are critical for success. The DNA must be high-molecular-weight. A useful insert fragment must have both ends generated by the restriction enzyme so it can be ligated to vector. In order to generate a majority of the random fragments with two “good” ends, the starting material must on average be at least 2, and preferably 3 or more times greater in length than the insert to be used in the cloning procedure. Furthermore, the genomic DNA must be cleavable with the restriction enzyme chosen to produce the partial digest. Procedures for producing high-molecular-weight DNA are described in *UNITS 2.2, 2.3, & 2.4*.

The restriction enzyme used for this procedure should be of high quality. Some batches of *Sau*3A or *Mbo*I do not produce DNA fragments with ends that can be ligated. New batches of these enzymes should be tested to ensure that the DNA fragments produced by digestion can be ligated.

In order for this procedure to be useful the partial digestion products should represent a set of random fragments that include the entire genome. Unfortunately, some restriction enzyme sites appear to be somewhat preferred by the enzyme to other sites. These preferred sites lead to the production of nonrandom partial digestion products and can eventually lead to an under- or overrepresentation of particular sequences in the library. Several methods have been proposed to ensure the randomness of the partial digestion. We recommend that conditions are chosen such that at least 30% of the genomic DNA remains undigested as high-molecular-weight DNA.

Complete digestion. See second support protocol.

Anticipated Results

Sucrose gradients. 0.5 mg of digested mammalian genomic DNA produces 5 to 10 μ g of size-fractionated DNA suitable for preparing bacteriophage or cosmid libraries. Nearly quantitative recovery of bacteriophage λ arms

can be expected.

Enzyme digestion. When available, 1 mg of mammalian genomic DNA is partially digested to produce enough DNA for a cosmid or bacteriophage library. Approximately 0.1 to 1 mg of genomic DNA is completely digested to produce a subgenomic library. By optimizing procedures, the outcome of digestion should be collection of random fragments with ends that can be ligated to vector.

Time Considerations

Partial or complete digestion of DNA requires 1 hr. However, preparation of the digested DNA for size fractionation usually requires several more hours.

Gradients can be poured in ~1 hr. Centrifugation of gradients is performed overnight (~16 hr) and the fractions collected in ~1 hr. Identifying the desired fractions can be very

rapid if the fractions are identified by mobility of DNA on agarose gel or considerably longer if the gel must be analyzed by Southern blot analysis (*UNIT 2.9*).

Size Fractionation Using Agarose Gels

UNIT 5.4

ELECTROPHORESIS ON A SLAB AGAROSE GEL

BASIC
PROTOCOL

Digested genomic DNA can be size fractionated on a slab agarose gel (see also *UNIT 2.5*). The capacity of a 20 × 20 × 1 cm agarose gel is limited to <2 mg DNA. After fractionation, the appropriate region of the gel is defined by Southern blot analysis (for subgenomic libraries) or by size (for genomic libraries) and the DNA is eluted.

Materials

400 μg to 2 mg digested genomic DNA (*UNIT 5.3*)
DNA size markers

Additional reagents and equipment for agarose gel electrophoresis (*UNIT 2.5*), Southern blot transfer (*UNIT 2.9*), ethanol precipitation (*UNIT 2.1*), and hybridization (*UNITS 2.9 & 6.3*)

1. Construct a 20 × 20 × 1 cm gel with a large preparative well. A small well is placed along one edge of the gel for running a size marker or a small quantity (10 μg) of the digested genomic DNA.
2. Identify the region of the gel with the fragment size of interest by comparing to the size marker or the autoradiogram produced by blotting and hybridizing the small genomic lane that has been removed from the gel.
3. Cut out and elute three adjacent 1-cm slices of gel spanning the region of interest as described in *UNIT 2.6*.
4. Concentrate the DNA by ethanol precipitation, run on a gel, blot, and hybridize to determine which fraction has the highest relative concentration of the fragment of interest. DNA from this fraction is used for constructing the subgenomic library.

ELECTROPHORESIS ON THE BULL'S-EYE AGAROSE GEL APPARATUS

ALTERNATE
PROTOCOL

Digested genomic DNA is loaded onto a large preparative circular agarose gel in a Bull's-eye apparatus. The DNA fragments are electrophoresed toward the center of the gel and eluted. Fragments leaving the gel are pooled and constitute a fraction. Fractions containing the gene of interest are identified by Southern blotting of a small aliquot of alternate fractions. This procedure allows the purification of large amounts of size-fractionated DNA that is particularly well suited for genomic library construction and normally allows creation of large numbers of recombinant clones.

Additional Materials

TAE buffer (*APPENDIX 2*)
Chloroform
0.5 M EDTA, pH 7.5
Buffered phenol (*UNIT 2.1*)
TE buffer (*APPENDIX 2*)

Bull's-eye electrophoresis apparatus (Hoefer)
Bull's-eye electronic control apparatus (Hoefer)
Dialysis tubing (flat width >1.69 in.)
Peristaltic pump, fixed rate (20 ml/min)
Peristaltic pump, variable rate
Fraction collector (capable of holding 16 × 150 mm tubes; fraction time adjustable up to 1.5 hr)

Construction of
Recombinant
DNA Libraries

Contributed by Thomas Quertermous

Current Protocols in Molecular Biology (1987) 5.4.1-5.4.4

Copyright © 2000 by John Wiley & Sons, Inc.

5.4.1

1. Place the gel mold in the electrophoresis apparatus (see manufacturer's directions) and seal joints with molten agarose. Size of gel is determined by the quantity of DNA to be run; ≥ 2 mg can be run on a 350-ml gel while 10 mg requires a maximum size 700-ml gel. Add agarose to TAE buffer, boil, and pour when it cools to 55°C (see UNIT 2.5A for discussion of percentage agarose). Set overnight.
2. Slip a segment of moist dialysis tubing over the central electrode assembly and fasten in place with O rings. Fill this chamber with water and check for leaks. If a leak occurs, adjust the O rings or replace the dialysis tubing.
3. Set up the Bull's-eye apparatus following manufacturer's instructions. Use the fixed-rate peristaltic pump in the recirculation circuit, and the adjustable peristaltic pump in the fraction collection circuit. Set the rate of the adjustable pump to allow all the fraction to elute during the collection period. Fill the apparatus with 3 liters of TAE buffer; set the level of the upper reservoir to the height of the gel by adjusting the drain height. This height also determines the sample size, which varies from 5 to 8 ml.
4. Apparatus settings:
 - Power supply—125 mA
 - Control unit:
 - Electrophoresis—30 min
 - Reverse—40 sec
 - Elution—5 min (depending on sample volume and peristaltic pump speed)
 - Fraction collector—38 min
5. Operate the machine for several cycles to identify difficulties before the sample is loaded. The DNA sample volume that can be loaded depends on the gel former used, but generally the sample slot can hold 5 ml (375-ml gel) to 10 ml (700-ml gel). Add 0.1 ml gel loading buffer per ml sample volume. Save ~ 50 μ g DNA to run as total genomic DNA on the fraction blots.

Fractions collected should range from 0.5 to 20 kb and, depending on the gel running length and gel percentage, a complete run may require 5 to 7 days. Large DNA fragments elute slowly from the gel, so it is advisable to increase the electrophoresis time to 60 or 90 min after ~ 50 fractions have been collected. The fraction collector intervals also have to be increased accordingly.
6. Samples can be conveniently stored in scintillation vials. To each vial, add several drops of chloroform and 50 μ l of 0.5 M EDTA, pH 7.5.
7. Run a preliminary minigel with 50 μ l of every third to fifth fraction to determine DNA concentration and size distribution. Then run a gel for Southern blot analysis that contains every second or third fraction in the size range of interest, including a lane of the total digested genomic DNA saved in step 5.

Of each fraction, 400 to 500 μ l generally provides enough DNA for an adequate blot and can be concentrated by ethanol precipitation or simply lyophilized to dryness.
8. Extract the fraction of interest with phenol and chloroform. Ethanol precipitate ~ 500 μ l. Resuspend the DNA in a small volume of TE buffer (10 to 20 μ l) and determine the concentration by fractionating a small portion on a minigel (UNIT 2.5A).

COMMENTARY

Background Information

Electrophoretic size fractionation of digested DNA permits enrichment of a restriction fragment over 100-fold (Carreira et al., 1980). DNA fragments obtained from a Bull's-eye gel are usually better resolved than DNA fractionated on a slab gel. This high resolution is particularly useful for the construction of subgenomic libraries. Use of the enriched fragment in constructing a subgenomic library allows one to clone even a single-copy gene by screening a fraction of the number of clones required to represent the entire genome.

This technology requires that one's interest is confined to a single restriction fragment (or at most 2 to 3), and thus requires some prior knowledge of the restriction map of the locus. It is possible to clone several restriction fragments and reconstruct a locus, but this is technically difficult. One very successful application of subgenomic libraries has been the cloning of multiple genomic rearranged immunoglobulin and T-cell receptor genes. In this case, knowledge of the restriction map in the joining region allows one to choose a restriction fragment that is likely to contain all the variable region sequences of interest.

Literature Review

The concept of simplifying cloning by gene enrichment has been reviewed by Edgell et al. (1979). They describe a two-step DNA fractionation procedure involving RPC5 column chromatography followed by preparative electrophoresis. Bott et al. (1980) have used preparative agarose electrophoresis to fractionate the *Bacillus subtilis* genome to produce DNA fragments for transformation analysis and cloning. The degree of enrichment achieved with preparative electrophoresis alone is adequate and allows one to start with a smaller quantity of DNA.

Methods for constructing an apparatus that allows collection of multiple samples of size-fractionated DNA from a slab horizontal gel have been described (Polisky et al., 1978; Southern, 1979a,b). The resolution on a preparative agarose slab gel is adequate (although not as good as the Bull's-eye apparatus). The primary difficulty with some preparative agarose gels is that the DNA that is eluted contains impurities that inhibit DNA ligase and prevent cloning. The Bull's-eye apparatus is discussed here because it is commercially available, yields DNA that can be ligated, and produces large numbers

of clones. Further, the Bull's-eye machine allows size fractionation and concentration of large amounts of DNA. The theory of design of the Bull's-eye apparatus and specifications for construction have been published (Southern, 1979a,b; Carreira et al., 1980).

Critical Parameters

Resolution of DNA in a preparative agarose gel is dependent on the conditions of electrophoresis, and can be defined by the thickness of the imaginary slice of gel that contains all of the fragment of interest but no additional larger or smaller fragment. In general, experience indicates that the thinnest slice is likely to be >3 mm thick. Resolution in the Bull's-eye apparatus is determined by several factors, including the concentration of the gel (Southern, 1979a,b). As the concentration of the gel increases, so does the time required for a DNA fragment of a certain size to elute. There is an upper limit to gel concentration, however, because with higher concentrations the time required for separation becomes unacceptably long, and the DNA concentration in each sample is reduced. Generally, a gel concentration of 1.2% is optimal for separation of fragments for cloning.

Troubleshooting

Using the preparative agarose gel technique, fragments can generally be identified and eluted. Problems sometimes arise in that not enough clones can be obtained to make a subgenomic library (see below). Generally, if this occurs, it is best to start over with another fractionation technique.

The Bull's-eye apparatus is not easy for the beginner. Setting up the apparatus can be difficult, and instruction from someone skilled in the use of this machine is advised. In particular, placement of the dialysis tubing over the central anode is a tricky and crucial step in assembly. However, once assembled correctly the machine rarely malfunctions.

Occasionally, bubbles will impede flow of buffer in one of the circuits. This is prevented by clearing the tubing of bubbles before starting a run. Failure of the tubing leading to the fraction collector to run dry in less than 7 min usually means that either the peristaltic pump in this circuit is too slow or that there is a leak into the sample collection chamber. Such a leak occurs through the dialysis tubing that covers the anode and is corrected by replacing the

dialysis tubing.

DNA fractionated in this fashion and cleaned by ethanol precipitation and chloroform extractions usually can be ligated efficiently into bacteriophage or plasmid vectors. If appropriate controls point to the fractionated DNA as the source of difficulty, it may help to repeat the phenol and chloroform extractions or to pass the DNA over an Elutip column (UNIT 2.6). If the DNA still cannot be ligated it probably means that the restriction fragment ends were damaged by exonuclease activity.

Anticipated Results

Up to 80% of the DNA applied to a gel (either a slab gel or a Bull's-eye gel) should be recovered. If 1 mg DNA is digested and loaded onto the gel, and 100 fractions collected, each fraction will contain several micrograms of DNA. This is enough DNA to produce a number of subgenomic libraries. The size distribution of the fragments will vary, depending on the enzyme used, but fractions around 4 kb will usually contain the most DNA.

Time Considerations

Fractionation in a preparative agarose slab gel is rapid, generally <24 hr. However, the identification of the desired region and elution of the fragment from the gel by Southern blotting will require 2 to 5 days.

Fractionation with a Bull's-eye apparatus is usually slower. Depending on the percentage of gel used, the current, and other parameters, the time required for a complete size fractionation is several days. It is easy to monitor the size of fragments coming off the gel by running a small quantity of eluted fractions on an

agarose minigel. The run may then be terminated as soon as the desired size DNA is eluted. Because the DNA fractions can be stored for years, however, it is wise to collect all the DNA for future cloning projects.

PREPARATION OF INSERT DNA FROM MESSENGER RNA

Construction of cDNA libraries from mRNA requires a series of steps similar to those outlined in Figure 5.5.1. Conversion of mRNA into double-stranded DNA suitable for insertion into a vector requires the action of at least six different enzymes. This conversion is described in two separate units: (1) conversion of mRNA into double-stranded cDNA (UNIT 5.5) and (2) methylation and addition of linkers to double-stranded cDNA (UNIT 5.6). After completion of the protocols described in these units, the double-stranded DNA should be suitable for insertion into a vector. Although the procedure is divided into two parts, there are several convenient stopping places as noted in the Commentaries of the two units.

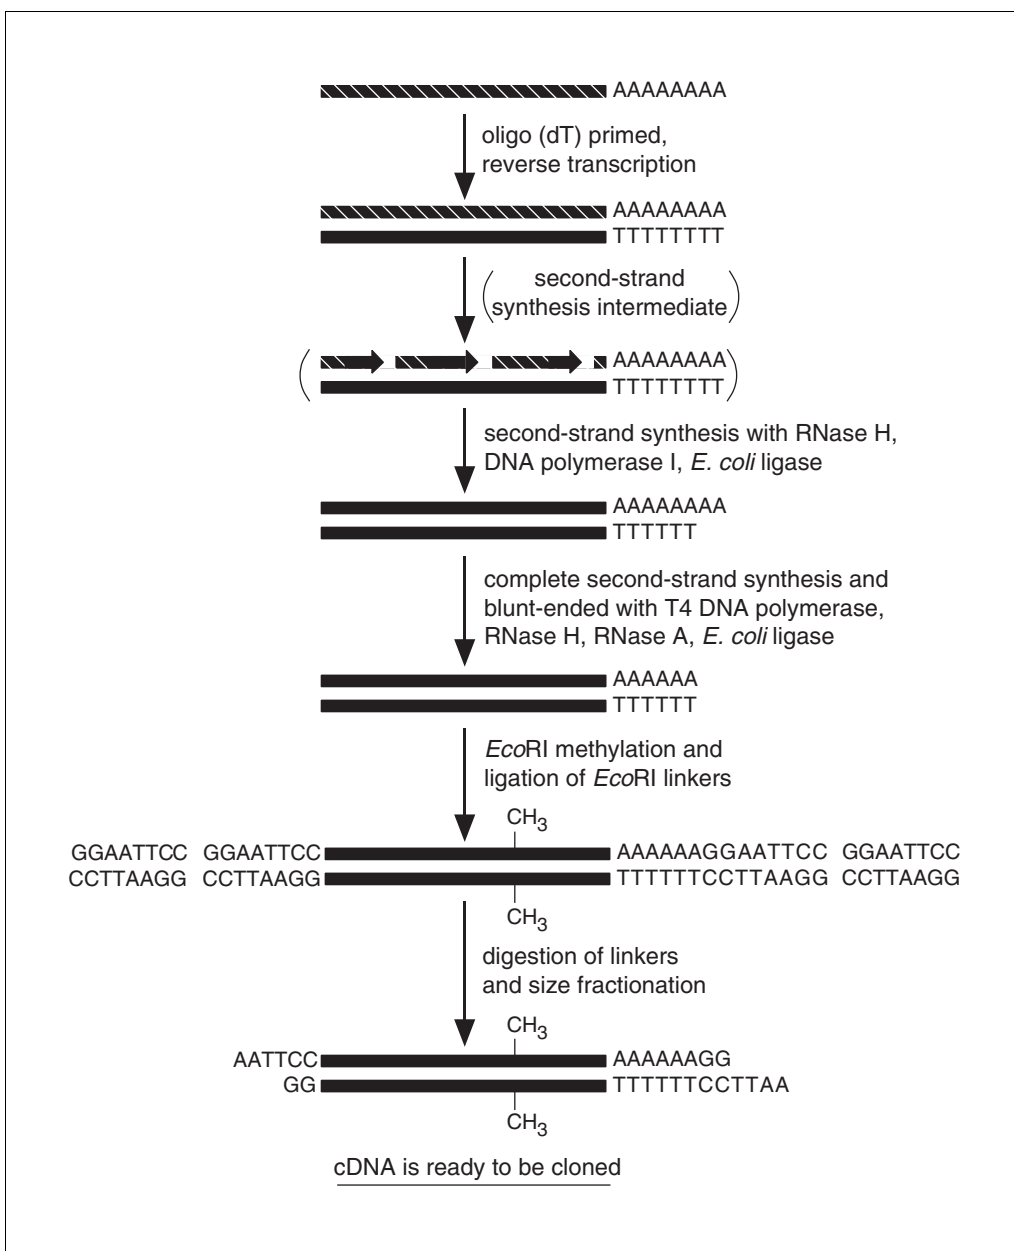

Figure 5.5.1 Outline of cDNA synthesis and preparation for insertion into a vector.

Conversion of mRNA into Double-Stranded cDNA

Enzymatic conversion of mRNA into double-stranded insert DNA can be accomplished by a number of different procedures. All of them involve the action of reverse transcriptase and oligonucleotide-primed synthesis of cDNA. After that, the procedures in common use diverge considerably. There are a number of methods for synthesizing the second strand and several procedures for producing suitable ends for making clonable DNA. The major goals of these procedures are to construct insert DNA that is as long as possible, with a high yield of conversion of mRNA into DNA that can ligate to vector DNA. The following protocols require only commercially available reagents and are usually successful in producing good cDNA libraries. The basic protocol describes a method for making blunt-ended cDNA that can then be ligated to linkers (UNIT 5.6) for subsequent cloning into a unique restriction site such as *EcoRI*. The alternate protocol is a variation that requires fewer enzymatic manipulations and allows construction of directional cDNA libraries, which are particularly desirable when the goal is to generate expression cDNA libraries. The alternate protocol takes advantage of a linker-primer consisting of (in order from 3' to 5') an oligo(dT) primer, a restriction site for the *XhoI* endonuclease, and a (GA)₂₀ repeat to protect the restriction site during generation of the blunt-ended cDNA. The internal *XhoI* sites on the individual cDNA molecules are protected by incorporation of 5-methyl-dCTP in the first-strand nucleotide mix. The resulting cDNAs having unique ends can be cloned into *EcoRI/XhoI*-digested vectors after ligation of *EcoRI* adaptors to the 5' end and digestion by *XhoI* to release the 3' *XhoI* sites that were incorporated into the cDNA by the linker-primer. These changes result in a considerably streamlined procedure that is substantially faster and easier than the basic protocol.

The quality and yield of insert DNA are in large part determined by the quality of the mRNA. An important feature of these procedures is that the yield at each step determines the yield at subsequent steps. Monitoring the efficiency of each reaction and determining the yield at each step is thus critical to the overall success of the project (and making yield determinations is strongly recommended). Guidelines for measuring the yield at each step are provided in the protocol. Because these protocols each consist of a series of sequential reactions, the quality of the enzymes used at each step is critical.

NOTE: For laboratories using recombinant DNA techniques and isolating large quantities of plasmid, bacteriophage, or cosmid DNA, remember that the smallest amount of contamination of genomic DNA or cDNA with recombinant DNA is disastrous. Contamination of cDNA at 1 ppm will cause great difficulty. Thus, all plasticware, glassware, and reagents used for the preparation of mRNA and cDNA should be maintained separately from those used for plasmid or bacteriophage DNA preparation. Extensive use of disposable plasticware is strongly recommended.

BASIC PROTOCOL

CONVERSION OF mRNA INTO BLUNT-ENDED DOUBLE-STRANDED cDNA

The conversion of mRNA into double-stranded cDNA for insertion into a vector is carried out in two parts. First, intact mRNA hybridized to an oligo(dT) primer is copied by reverse transcriptase and the products isolated by phenol extraction and ethanol precipitation. Then, in a single reaction vessel, the following reactions are carried out. The RNA in the RNA-DNA hybrid is removed with RNase H as *E. coli* DNA polymerase I fills in the gaps, similar to a nick translation. The second-strand fragments thus produced are ligated by *E. coli* DNA ligase. Second-strand synthesis is completed, residual RNA degraded, and cDNA made blunt with RNase H, RNase A, T4 DNA polymerase, and *E. coli* DNA ligase.

Conversion of
mRNA into
Double-Stranded
cDNA

5.5.2

Materials

- 5 mM 4dNTP mix (UNIT 3.4)
 - 5× reverse transcriptase (RT) buffer (see recipe)
 - 200 mM dithiothreitol (DTT)
 - 0.5 mg/ml oligo(dT)_{12–18} (Pharmacia Biotech; store at –80°C) *or* 15- to 40-mer antisense primer *or* random-hexamer primers
 - RNasin ribonuclease inhibitor (Promega; store at –20°C)
 - AMV (avian myeloblastosis virus) reverse transcriptase (Life Sciences; UNIT 3.7)
 - 10 μCi/μl [α -³²P]dCTP (10,000 Ci/mmol)
 - 0.5 M EDTA, pH 8.0
 - Buffered phenol (UNIT 2.1)
 - TE buffer, pH 7.5 (APPENDIX 2)
 - Diethyl ether or 24:1 chloroform/isoamyl alcohol
 - 7.5 M ammonium acetate
 - 95% and 70% ethanol, ice-cold
 - 10% trichloroacetic acid (TCA), ice-cold
 - 5× second-strand buffer I (see recipe)
 - 5 mM β-NAD⁺ (Sigma; store at –80°C)
 - RNase H (Pharmacia Biotech; UNIT 3.13)
 - E. coli* DNA ligase (New England Biolabs; UNIT 3.14)
 - E. coli* DNA polymerase I (New England Biolabs; UNIT 3.5)
 - 5× TA buffer (see recipe)
 - 2 μg/ml RNase A, DNase-free (see recipe and UNIT 3.13)
 - T4 DNA polymerase (Boehringer Mannheim; UNIT 3.5)
 - 10 mg/ml tRNA (store at –20°C)
 - 42° and 65°C water baths
 - Nitrocellulose membrane filter
 - 14°C incubator
- Additional reagents and equipment for preparation of poly(A)⁺ RNA (UNIT 4.5) and purification and concentration of DNA (UNIT 2.1)

Synthesize cDNA

1. Prepare ≥10 μg poly(A)⁺ RNA at a concentration of 1 μg/μl.

A small amount of ribosomal RNA will not interfere.

The quality of the mRNA is very important for full-length cDNA insert production. One approach to evaluating the mRNA is to perform northern blot analyses with a probe specific for a relatively abundant mRNA species known to be present (e.g., actin). The band in the northern blot should be distinct, with minimal trailing or smearing from the band toward the bottom of the gel. Other tests for determining the quality of the mRNA are suggested in UNIT 4.9.

2. Heat RNA (10 μg in 10 μl) in a tightly sealed microcentrifuge tube 5 min at 65°C, then place immediately on ice.

Alternatively, methylmercuric hydroxide denaturation of the RNA can be performed prior to first-strand synthesis. However, this is usually not necessary to achieve full-length synthesis of even long (>5 kb) cDNA.

3. In a separate tube add in the following order (180 μ l total):

20 μ l 5 mM dNTPs (500 μ M final each)
40 μ l 5 \times RT buffer (1 \times final)
10 μ l 200 mM DTT (10 mM final)
20 μ l 0.5 mg/ml oligo(dT)₁₂₋₁₈ (50 μ g/ml final)
60 μ l H₂O
10 μ l (10 U) RNasin (50 U/ml final).

Mix by vortexing, briefly microcentrifuge, and add the mixture to the tube containing the RNA. Add 20 μ l (200 U) AMV reverse transcriptase for a final concentration of 1000 U/ml in 200 μ l. Mix as above and remove 10 μ l to a separate tube containing 1 μ l of [α -³²P]dCTP. Leave both tubes at room temperature 5 min, then place both tubes at 42°C for 1.5 hr.

The aliquot is removed to determine incorporation and permit an estimation of recovery. The remainder of the cDNA will be labeled during second-strand synthesis. Labeling cDNA during first-strand synthesis to a high enough specific activity to permit easy detection with a hand-held radiation monitor during all subsequent steps requires a relatively large amount of label, which may then interfere with reverse transcription due to buffer effects.

Some investigators check the quality of the cDNA by fractionating the radiolabeled cDNA on an alkaline agarose gel and detecting it by autoradiography. Much of the cDNA should be >1000 bp long.

For a specifically primed library, substitute an equal weight of antisense 15- to 40-mer primer for the oligo(dT)₁₂₋₁₈. Expect a 100-fold enrichment of specific clones in the library. For a randomly primed library, substitute an equal weight of random-hexamer primers for oligo(dT)₁₂₋₁₈ (or use a 50:50 mix), and perform the reverse transcription at 37° instead of 42°C.

4. Add 1 μ l of 0.5 M EDTA, pH 8.0, to the radioactive reaction and freeze it at -20°C. It will be used later to estimate the amount of cDNA synthesized.
5. To the main reaction add 4 μ l of 0.5 M EDTA, pH 8.0, and 200 μ l buffered phenol. Vortex well, microcentrifuge at room temperature for 1 min to separate phases, and transfer the upper aqueous phase to new tube.

Save the tube containing the phenol layer, too.

6. Add 100 μ l TE buffer, pH 7.5, to the phenol layer and vortex and microcentrifuge as in step 5. Remove the aqueous layer and add it to the aqueous phase from the first extraction.

The volume of aqueous phase is now about 300 μ l; the phenol may be discarded.

Back extraction of the organic phase at each phenol extraction significantly improves the yield. See UNIT 2.1 for a discussion of phenol extraction and ethanol precipitation.

7. Add 1 ml diethyl ether, vortex, and microcentrifuge as in step 5. Remove and discard the upper (ether) layer with a glass pipet. Repeat the extraction with an additional 1 ml of ether.

A single chloroform/isoamyl alcohol extraction followed by back extraction of the organic phase may be substituted for the two ether extractions; however, the yield is normally slightly lower.

8. Add 125 μ l of 7.5 M ammonium acetate to the aqueous phase (final concentration 2.0 to 2.5 M) and 950 μ l of 95% ethanol. Place in dry ice/ethanol bath 15 min, warm

to 4°C, and microcentrifuge at 10 min at full speed, 4°C, to pellet nucleic acids. A small, yellow-white pellet may be visible.

Precipitation from ammonium acetate leaves short oligonucleotides in the supernatant, thus removing the oligo(dT) primer and enriching the pellet in longer cDNAs. Do not substitute sodium acetate for ammonium acetate.

9. Remove the supernatant with a pipet, fill the tube with ice-cold 70% ethanol, and microcentrifuge 3 min at full speed, 4°C. Again remove the supernatant, then dry the tube containing the precipitated nucleic acids briefly in a vacuum desiccator.
10. Thaw the tube containing the radioactive aliquot of the first-strand synthesis reaction and spot the sample onto a nitrocellulose membrane filter.
11. Wash the membrane with ice-cold 10% TCA and determine the radioactivity bound to the filter with a fluor and scintillation counter. Use the specific activity of the radiolabel in the reaction, the amount of RNA used, the counts incorporated, and the efficiency of the β -counter to calculate the amount of cDNA synthesized (see Sample Calculation for Determining Amount of cDNA Synthesized, in Commentary).

From 1 to 4 μ g is typical even though the theoretical maximum is 10 μ g.

Convert cDNA into double-stranded cDNA

12. Resuspend the pellet from the first-strand synthesis in 284 μ l water and add to the tube in the following order (400 μ l total):

4 μ l 5 mM dNTPs (50 μ M final each)
80 μ l 5 \times second-strand buffer I (1 \times final)
12 μ l 5 mM β -NAD⁺ (150 μ M final)
2 μ l 10 μ Ci/ μ l [α -³²P]dCTP (50 μ Ci/ml final).

Mix by vortexing, briefly microcentrifuge, and add:

4 μ l (4 U) RNase H (10 U/ml final)
4 μ l (20 U) *E. coli* DNA ligase, (not T4 DNA ligase; 50 U/ml final)
10 μ l (100 U) *E. coli* DNA polymerase I (250 U/ml final).

Mix by vortexing, briefly microcentrifuge, and incubate 12 to 16 hr at 14°C.

*Unrelated cDNA fragments are not ligated in this reaction because *E. coli* DNA ligase does not catalyze blunt ligations.*

13. After second-strand synthesis, remove 4 μ l of the reaction to a new tube and freeze at -20°C. Later, when time permits, determine the incorporation of radiolabel into acid-insoluble material as outlined in steps 10 and 11.

Expect 1-10 $\times 10^6$ cpm incorporated in the total reaction.

14. Phenol extract the second-strand synthesis reaction with 400 μ l buffered phenol and back extract the phenol phase with 200 μ l TE buffer, pH 7.5, as in steps 5 and 6.
15. Pool the two aqueous phases and extract twice with 900 μ l ether, as in step 7. The volume of the aqueous phase is now ~600 μ l.
16. Divide the aqueous phase evenly between two tubes, add ammonium acetate, and ethanol precipitate as in steps 8 and 9.

Unincorporated radioactive dCTP is removed by the ethanol precipitation and wash steps. From this point on, the cDNA may be followed with a hand-held radiation monitor.

Create blunt ends on double-stranded cDNA

17. Complete second-strand synthesis and blunt the double-stranded cDNA by resuspending the pooled pellets in 42 μ l water. Add in the following order (80 μ l total):

- 5 μ l 5 mM dNTPs (310 μ M final each)
- 16 μ l 5 \times TA buffer (1 \times final)
- 1 μ l 5 mM β -NAD⁺ (62 μ M final).

Mix by vortexing, microcentrifuge briefly, and add:

- 4 μ l of 2 μ g/ml RNase A (100 ng/ml final)
- 4 μ l (4 U) RNase H (50 U/ml final)
- 4 μ l (20 U) *E. coli* DNA ligase (250 U/ml final)
- 4 μ l (8 U) T4 DNA polymerase (100 U/ml final).

Mix as above and incubate 45 min at 37°C.

Volume of T4 DNA polymerase used to obtain 8 U may require adjustment depending on batch.

If the library is to be screened with an antiserum, some investigators (see Tamkun et al., 1986) digest the cDNA at this point with AluI or HaeIII to prepare small inserts that may produce more stable fusion proteins in λ gt11. Do this after the T4 polymerase step by diluting the 80- μ l reaction to 170 μ l with water; add 24 μ l of 5 \times TA buffer and 6 μ l of one of the above restriction enzymes. Incubate 1 hr at 37°C, then proceed to step 18, except do not add any TE buffer. An insert isolated from an immunological screen may then be used to screen a second library of full-length inserts.

18. Add 120 μ l TE buffer, pH 7.5, and 1 μ l of 10 mg/ml tRNA. Extract with 200 μ l buffered phenol and back extract the phenol phase with 100 μ l TE buffer as described in steps 5 and 6.

19. Pool the two aqueous phases and extract twice with 1 ml ether, as in step 7.

20. Ethanol precipitate the cDNA as in steps 8 and 9.

The cDNA is now ready to be tailed or linked to create compatible ends for subsequent cloning steps.

ALTERNATE PROTOCOL

CONVERSION OF mRNA INTO DOUBLE-STRANDED cDNA FOR DIRECTIONAL CLONING

Generation of cDNA that has unique ends for directional cloning is carried out in two parts, as in the basic protocol. First, the mRNA is hybridized to a linker-primer that incorporates a poly(dT) tract (at its 3' end) as well as a restriction site for *Xho*I (Fig. 5.5.2). The linker-primer is extended using an RNase H⁻ version of the Moloney murine leukemia virus reverse transcriptase (SuperScript) and a nucleotide mix in which dCTP is replaced with 5-methyl-dCTP. When first-strand synthesis is completed, the reaction mixture is transferred into a second tube that contains the prechilled second-strand mixture. The second strand is synthesized using RNase H and *E. coli* DNA polymerase I. Finally, a blunting step (consisting of treatments with mung bean nuclease and Klenow fragment) is carried out to prepare the cDNA for the *Eco*RI adaptor ligation.

Additional Materials (also see Basic Protocol)

- 5 \times SuperScript buffer (RNase-free; see recipe)
- 0.1 M DTT (RNase-free)
- 3dNTP/methyl-dCTP mix: 10 mM each dATP, dGTP, dTTP, and 5-methyl-dCTP (Pharmacia Biotech)

continued

Figure 5.5.2 Synthesis of cDNA with unique ends for directional cloning.

0.25 $\mu\text{g}/\mu\text{l}$ oligonucleotide primer (*UNIT 2.11*) incorporating (from 5' to 3'):
 (dGdA)₁₀, *Xho*I restriction site, and (dT)₁₈

200 U/ μl SuperScript or SuperScript II (GIBCO/BRL)

5 \times second-strand buffer II (see recipe)

10 mM and 2 mM 4dNTP mix (Pharmacia Biotech)

10 $\mu\text{Ci}/\mu\text{l}$ [α -³²P]dATP (3000 Ci/mmol)

0.8 U/ μl RNase H (Pharmacia Biotech)

10 U/ μl *E. coli* DNA polymerase I (New England Biolabs)

100% ethanol ice-cold

10 \times Klenow buffer (see recipe)

5 U/ μl Klenow fragment of *E. coli* DNA polymerase I (New England Biolabs)

10 \times mung bean nuclease buffer (see recipe)

10 U/ μl mung bean nuclease (New England Biolabs)

1 M Tris·Cl, pH 8.0 (*APPENDIX 2*)

16°C incubator

Additional reagents and equipment for agarose gel electrophoresis (*UNIT 2.5*)

Synthesize cDNA

1. Prepare 5 to 7 μg poly(A)⁺ RNA.

If mRNA is prepared as in UNIT 4.5, store under ethanol in a microcentrifuge tube until ready to proceed. If mRNA is in aqueous solution, add 3 M sodium acetate (RNase-free) to 0.3 M and 3 vol of 100% ethanol, chill ≥ 20 min at -20°C , and microcentrifuge 20 min at maximum speed, 4°C , to collect mRNA. Rinse the pellet with 70% ethanol (RNase-free), and invert the tube to air dry.

2. Prepare first-strand premix (45 μl final by mixing in the order listed):

10 μl 5 \times SuperScript buffer

5 μl 0.1 M DTT

2.5 μl 3dNTP/methyl-dCTP mix

1 μl RNasin

12 μl 0.25 $\mu\text{g}/\mu\text{l}$ oligonucleotide primer

14.5 μl H₂O.

3. Resuspend RNA pellet directly into premix. Incubate 15 min at room temperature, then add 5 μl of 200 U/ μl SuperScript and incubate 1 hr at 42°C .

4. Shortly before end of incubation, prepare second-strand premix (336 μ l final) containing:

80 μ l 5 \times second-strand buffer II
6 μ l 10 mM 4dNTP mix
2.5 μ l 10 μ Ci/ μ l [α -³²P]dATP
247.5 μ l H₂O.

Place on ice.

5. Continuing to work on ice, add the first-strand mix from step 3 (50 μ l total) to prechilled second-strand premix from step 4.
6. In a second microcentrifuge tube combine 4 μ l of 0.8 U/ μ l RNase H (3.2 U) and 10 μ l of 10 U/ μ l *E. coli* DNA polymerase I (100 U). Add combined enzymes to the tube from step 5 containing the cDNA and mix by rapidly inverting a few times.

In order to prevent formation of "snapbacks" during second-strand synthesis it is important to prechill the premix and add the RNase H and DNA polymerase simultaneously.

7. Microcentrifuge 5 sec at maximum speed, then incubate reaction 1 hr at 16°C and 1 hr at room temperature.

At this step, second-strand synthesis is completed.

8. Electrophorese ~2% to 5% of total reaction on a 0.7% agarose gel, and monitor size range of labeled cDNA by autoradiography.

Optimally, a smear ranging from ~200 bp to >8 kb will be seen, with a peak at 1 to 2 kb.

The reaction can be frozen overnight (or longer) at -20°C, or one can immediately proceed to blunting and linker ligation.

Create blunt-ends on double-stranded cDNA

9. Add 500 μ l of 1:1 phenol/chloroform to reaction. Microcentrifuge 5 min at maximum speed to separate phases.

If reaction was frozen, thaw by vortexing with the phenol/chloroform.

10. Remove upper phase to a fresh tube, add 200 μ l of 7.5 M ammonium acetate, and mix by inversion.
11. Divide sample evenly between two tubes (300 μ l in each). Add 600 μ l ice-cold 100% ethanol to each tube, place both tubes 5 min at -80°C, then microcentrifuge 20 min at maximum speed, 4°C.

This and the following series of steps involve transfer of labeled cDNA from tube to tube, and require a number of extractions and precipitations. After this initial precipitation, the bulk of the radiolabel is incorporated in the cDNA. It is important to monitor using a Geiger counter to ensure that all cDNA is transferred from step to step and not lost during the extractions.

12. Pour off supernatants and rinse pellets with ice-cold 70% ethanol. Dry briefly in a Speedvac evaporator. Add 30 μ l water to one of the two tubes, vortex to resuspend cDNA pellet, then transfer contents to the second tube.
13. Add an additional 10 μ l water, 5 μ l of 10 \times Klenow buffer, and 5 μ l of 2 mM 4dNTP mix to the first tube. Vortex and transfer to the second tube. Add 5 μ l of 10 U/ μ l Klenow fragment to the second tube and incubate 30 min at 37°C.

The aim of the first Klenow treatment is to ensure that the 3' end of the cDNA is

completely blunted so that the XhoI restriction site will not be harmed by the subsequent enzymatic manipulations.

14. Add 50 μl of 1:1 phenol/chloroform to reaction, extract, and transfer upper phase to new tube. Back extract lower phase with an additional 50 μl water and combine it with the first extraction.
15. Add 50 μl of 7.5 M ammonium acetate and 300 μl ice-cold 100% ethanol. Place at -80°C for 5 min, then microcentrifuge 20 min at maximum speed, 4°C .
16. Pour off supernatant and rinse pellet with cold 70% ethanol. Dry pellet briefly in a Speedvac evaporator. Resuspend cDNA in 225 μl water.
17. Add 25 μl of 10 \times mung bean nuclease buffer and 1 μl of 1 U/ μl mung bean nuclease. Incubate 15 min at 37°C .

This mung bean exonuclease treatment removes any residual single-stranded nucleic acid extensions (i.e., single-stranded DNA, RNA overhangs, or small hairpins) from the 5' end of the cDNA.

18. Add 25 μl of 1 M Tris-Cl, pH 8.0. Extract with 200 μl 1:1 phenol/chloroform and back extract with 50 μl water, pooling the upper phases in a new tube.
19. Add 175 μl of 7.5 M ammonium acetate and fill tube with ice-cold 100% ethanol. Place at -80°C for 5 min, then microcentrifuge 20 min at maximum speed, 4°C .
20. Rinse pellet with 70% ethanol and air dry briefly. Resuspend in 20 μl water, then add 2.5 μl of 10 \times Klenow buffer and 1 μl of 5 U/ μl Klenow fragment. Incubate 5 min at 37°C . Add 2.5 μl of 2 mM dNTP mix to the reaction and incubate an additional 25 min at room temperature.

Do not overdry pellet (i.e., if Speedvac evaporation is used, do not dry >5 min).

The goal of this second Klenow fragment treatment is to effectively blunt any short single-stranded extensions that might remain after the mung bean exonuclease treatment or be caused by the "sloppiness" of this enzyme. This series of steps effectively causes essentially all the cDNA to become blunt-ended.

21. Add 25 μl of 1:1 phenol/chloroform to the reaction and extract, removing upper phase to a new tube. Back extract lower phase with an additional 25 μl water and pool with first upper phase. Store sample frozen at -20°C until ready for the *EcoRI* adaptor ligation step.

EcoRI adaptor ligation is carried out as it is described in UNIT 5.6. Subsequently, XhoI digestion of the EcoRI adaptor-ligated cDNA results in a 5' end that has an EcoRI-compatible overhang and a 3' end with XhoI-compatible overhang.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see *APPENDIX 2*; for suppliers, see *APPENDIX 4*.

Buffer stock solutions

Evaluate water and buffers for nuclease activity by incubating 5 μ l solution with 3 μ g of intact total cellular RNA or 0.5 μ g of a DNA fragment, whichever is relevant, for 30 min. Check the RNA or DNA by agarose gel electrophoresis to be sure it was not degraded.

Prepare at least 10 ml of each of the following 1 M stock solutions. Use RNA-grade water (see *UNIT 4.1*) and pass each solution through a sterile 0.45- μ m filter. Store at room temperature unless otherwise indicated.

1 M Tris·Cl, pH 8.2, 42°C

1 M Tris·acetate: titrate aqueous Tris base to pH 7.8 with acetic acid

1 M KCl

1 M MgCl₂

1 M (NH₄)₂SO₄

1 M potassium acetate

1 M magnesium acetate

1 M DTT, -20°C, in tightly capped tube

5 mg/ml nuclease-free BSA, -20°C

The pH of Tris buffers varies considerably with temperature. Be sure to measure the pH at the indicated temperature and use an electrode that accurately measures the pH of Tris buffers.

Enzymes

Enzymes should be of the highest quality available. Before starting a cDNA cloning experiment with a rare or hard-to-obtain RNA prep, it is advisable to check the activities of all the enzymes used.

Klenow buffer, 10×

0.5 M Tris·Cl, pH 7.6

0.1 M MgCl₂

Prepare 1.0 ml buffer using high-quality water and buffer stock solutions (see recipe), then check for nuclease activity as described in buffer stock solution recipe.

Freeze in 200- μ l aliquots in screw-cap microcentrifuge tubes at -80°C.

Mung bean nuclease buffer, 10×

0.3 M sodium acetate, pH 4.5

0.5 M NaCl

10 mM ZnCl₂

50% (v/v) glycerol

Prepare 1.0 ml buffer using high-quality water and buffer stock solutions (see recipe), then check for nuclease activity as described in buffer stock solution recipe.

Freeze in 200- μ l aliquots in screw-cap microcentrifuge tubes at -80°C.

Reverse transcriptase (RT) buffer, 5×

250 μ l 1 M Tris·Cl, pH 8.2

250 μ l 1 M KCl

30 μ l 1 M MgCl₂

470 μ l H₂O

Prepare 1.0 ml buffer using high-quality water and buffer stock solutions (see recipe), then check for nuclease activity as described in buffer stock solution recipe.

Freeze in 200- μ l aliquots in screw-cap microcentrifuge tubes at -80°C.

RNase A (DNase-free)

Dissolve 1 mg/ml RNase A (Sigma) in TE buffer (*APPENDIX 2*); boil 10 min to remove contaminating DNase and store in aliquots at -20°C . Dilute to 2 $\mu\text{g}/\text{ml}$ in TE buffer when needed.

Second-strand buffer I, 5 \times

100 μl 1 M Tris-Cl, pH 7.5
500 μl 1 M KCl
25 μl 1 M MgCl_2
50 μl 1 M $(\text{NH}_4)_2\text{SO}_4$
50 μl 1 M DTT
50 μl 5 mg/ml BSA
225 μl H_2O

Prepare 1.0 ml buffer using high-quality water and buffer stock solutions (see recipe), then check for nuclease activity as described in buffer stock solution recipe. Freeze in 200- μl aliquots in screw-cap microcentrifuge tubes at -80°C .

Second-strand buffer II, 5 \times

94 mM Tris-Cl, pH 6.9
453 mM KCl
23 mM MgCl_2
50 mM $(\text{NH}_4)_2\text{SO}_4$

Prepare 1.0 ml buffer using high-quality water and buffer stock solutions (see recipe), then check for nuclease activity as described in buffer stock solution recipe. Freeze in 200- μl aliquots in screw-cap microcentrifuge tubes at -80°C .

SuperScript buffer, 5 \times

250 mM Tris-Cl, pH 8.3
375 mM KCl
15 mM MgCl_2

Prepare 1.0 ml buffer using high-quality water and buffer stock solutions (see recipe), then check for nuclease activity as described in buffer stock solution recipe. Freeze in 200- μl aliquots in screw-cap microcentrifuge tubes at -80°C .

TA buffer, 5 \times

200 μl 1 M Tris-acetate, pH 7.8
400 μl 1 M potassium acetate
60 μl 1 M magnesium acetate
3 μl 1 M DTT
105 μl 5 mg/ml BSA
432 μl H_2O

Prepare 1.2 ml buffer using high-quality water and buffer stock solutions (see recipe), then check for nuclease activity as described in buffer stock solution recipe. Freeze in 200- μl aliquots in screw-cap microcentrifuge tubes at -80°C .

COMMENTARY

Background Information

cDNA synthesis and subsequent library preparation are necessary for the study of most mRNAs because no technology for conveniently manipulating and propagating RNA sequences is currently available. Of fundamental importance is that the cDNAs faithfully represent the sequence, size, and complexity of the mRNA population. The high quality of commercially available enzymes and reagents has dramatically changed the major concerns of the scientist preparing a cDNA library. In the past, considerable attention was paid to the source of reverse transcriptase, the quality of other enzymes, methods for their further purification, and conditions for optimum activity (Maniatis et al., 1982). These issues have been successfully addressed and full-length cDNAs of 5 to 8 kb mRNAs are now obtainable. The major focus currently is on the preparation of libraries of full-length cDNAs that will contain copies of even the rarest mRNA.

There are several relatively recent innovations incorporated into these protocols. First, it is recommended that size fractionation of the mRNA be omitted in order to minimize the opportunities for degradation of the mRNA template. Size fractionation of the cDNA, which is much more stable, is discussed in *UNITS* 5.3 & 5.4. Second-strand synthesis employs RNase H, *E. coli* DNA ligase, and *E. coli* DNA polymerase I as described by Okayama and Berg (1982) and modified by Gubler and Hoffman (1983). More recently, Neve et al. (1986) introduced during the blunting process the additional second-strand synthesis step, which increases the yield and size of the cDNA. Using this modification, S1 nuclease cleavage of the 5' "hairpin loop" generated by reverse transcriptase, a problematic step in the past, is avoided. The cDNA produced is ready to be prepared for insertion into an appropriate vector. Variations such as omitting the DNA ligase, (e.g., as per Gubler and Hoffman, 1983), omitting the additional second-strand synthesis, or substituting Klenow fragment for the intact *E. coli* DNA polymerase I have been successfully employed by others. Finally, the basic protocol uses AMV (avian myeloblastosis virus) reverse transcriptase (RT), but the alternate protocol uses SuperScript, a genetically engineered derivative of Moloney murine leukemia viral (MoMuLV) RT that has had its RNase H activity removed (Kotewicz et al., 1988) and its polymerase activity enhanced, resulting in a

greater size and yield of cDNA from first-strand synthesis.

A number of variations of the protocols in this unit exist for particular applications. Random hexamers can be used to prime first-strand synthesis rather than oligo(dT)-containing primers: resulting cDNAs will be enriched for the 5'-end sequences of very long transcripts, although average cDNA length will be shorter than with the methods described here. Another method that has gained popularity for a variety of analytical techniques is to perform a standard first-strand synthesis from an mRNA of interest, and then amplify specific rare transcripts using PCR.

Over the last several years, a number of kits for cDNA synthesis have become commercially available (e.g., from GIBCO/BRL, Stratagene, Promega, Amersham, and Pharmacia Biotech), and generally yield excellent results.

Critical Parameters

RNA used to generate the cDNA must be undegraded and of the highest quality obtainable. It must also be DNA-free.

Buffers and solutions must be nuclease-free. These may be divided into aliquots, frozen, and stored for long periods; thus, it is worthwhile to check each by incubating intact RNA or DNA, whichever is appropriate, with a sample of the solution and checking for degradation by agarose gel electrophoresis.

Enzymes (and all reagents) should be the highest quality available. If experimenting with a rare or hard-to-isolate RNA preparation, it is advisable to check the activities of all enzymes used. Enzymes should be relatively fresh and stored at -20°C in a freezer that is not frost-free (because the warming and cooling cycles of a frost-free freezer cause the enzymes to lose activity). The RNasin added in the first-strand synthesis is a potent though reversible inhibitor of RNase and must be added after the DTT, as its activity is dependent on the presence of a reducing agent.

Troubleshooting

Once high-quality mRNA has been obtained, the cDNA synthesis usually proceeds well. Difficulties, if any, only occur later—when the cDNA is ligated to the vector. If the yield of cDNA is low, likely causes are inactive reverse transcriptase, inactive *E. coli* polymerase I, or deteriorated dNTP mixes. If the calculated yield is low, double-check the result

Sample Calculation for Determining Amount of cDNA Synthesized

1. Assume 2×10^{12} cpm/Ci; thus, if $[\alpha\text{-}^{32}\text{P}]\text{dCTP}$ is at a specific activity of 3000 Ci/mmol, there are 6×10^{15} cpm/mmol.
2. The second-strand synthesis aliquot representing 1% of the total contains 10^5 TCA-precipitable cpm, thus

$$\frac{10^5 \text{ cpm} \times 100}{6 \times 10^{15} \text{ cpm/mmol}} = 1.67 \times 10^{-9} \text{ mmol } [\alpha\text{-}^{32}\text{P}]\text{dCTP incorporated.}$$

3. The initial concentration of $[\alpha\text{-}^{32}\text{P}]\text{dCTP}$ was

$$\frac{50 \mu\text{Ci/ml}}{3000 \text{ Ci/mmol}} = 1.67 \times 10^{-2} \mu\text{M.}$$

4. Thus, the total dCTP incorporated is

$$\frac{50 \mu\text{M}}{1.67 \times 10^{-2} \mu\text{M}} \times 1.67 \times 10^{-9} \text{ mmol} \times \frac{0.3 \text{ g dCMP}}{\text{mmol}} = 1.5 \mu\text{g.}$$

5. There were four deoxynucleotides present in the reaction, so the total cDNA synthesized in the second-strand reaction is $6 \mu\text{g}$ and since the cDNA is double-stranded, there are $12 \mu\text{g}$ of cDNA total.

by running 5% of the total sample on an agarose minigel and staining with ethidium bromide, or by determining the amount of DNA in the sample by optical density or DAPI fluorescence. If the radiolabel was old or deteriorated, incorporation will be low but the amount of cDNA synthesis will be correct.

Very small cDNA is usually the result of DNase contamination. This is readily evaluated by adding a restriction fragment of DNA to the reaction mixes and checking the fragment after incubation by gel electrophoresis.

Anticipated Results

The typical amount of poly(A)⁺ RNA used to generate a library is $10 \mu\text{g}$; however, the protocol may be scaled down should RNA availability be limiting. The $10 \mu\text{g}$ of poly(A)⁺ RNA will yield 2 to $10 \mu\text{g}$ of double-stranded cDNA. An aliquot representing 2% to 5% of the total volume may be checked by agarose gel electrophoresis, ethidium bromide staining, and autoradiography. The aliquots removed from the first- and second-strand synthesis should contain 2 to 8×10^5 cpm and 2 to 10×10^4 cpm TCA-insoluble counts, respectively (basic protocol). 100 ng double-stranded cDNA should generate a full-complexity library (1×10^6 recombinants) if a phage vector such as $\lambda\text{gt}10$ is employed.

To determine the amount of cDNA synthesized, see Sample Calculation for Determining Amount of cDNA Synthesized.

Time Considerations

Either of these protocols can usually be completed in two days. In the basic protocol, first-strand synthesis should be started in the morning to permit the initial second-strand synthesis to proceed overnight. The final second-strand synthesis should be carried out the following morning. In the alternate protocol, 4 hr should be allowed for synthesis of the double-stranded cDNA and 4 to 5 hr for generation of blunt ends. The cDNA may be linker or tailed as described in UNIT 5.6 later the same day. If necessary, the protocol may be interrupted at any ethanol precipitation step.

Ligation of Linkers or Adapters to Double-Stranded cDNA

UNIT 5.6

Linkers or adapters can be ligated to double-stranded cDNA (UNIT 5.5) to provide restriction endonuclease sites used in the production of a cDNA library (UNIT 5.8). For cloning purposes, only one linker or adapter must be present on each end of the cDNA. However, multiple linkers are usually ligated to the cDNA because both ends are phosphorylated and contain cohesive sequences. As a result, cDNA must first be methylated to protect it from a subsequent restriction digest designed to remove the multiple linkers (basic protocol). The procedure for ligating adapters to the cDNA is much simpler than that for linkers because only one end is phosphorylated, resulting in the ligation of just one adapter (alternate protocol). Linkered or adapted cDNA is then passed over a Sepharose CL-4B column to remove unligated linkers or adapters and other low-molecular-weight material (<350 bp) that would interfere with cloning (support protocol). This double-stranded cDNA is concentrated by ethanol precipitation and may be cloned directly (UNIT 5.8) or further fractionated by agarose gel electrophoresis (UNITS 2.5 & 2.6).

METHYLATION OF cDNA AND LIGATION OF LINKERS

BASIC
PROTOCOL

To convert blunt-ended, double-stranded cDNA into DNA suitable for ligation to a vector, it is methylated by *EcoRI* methylase, ligated to *EcoRI* linkers, and digested with *EcoRI*. The methylation step protects *EcoRI* sites in the cDNA from *EcoRI* digestion. Linkered cDNA is then purified as described above.

Materials

- Blunt-ended, double-stranded radiolabeled cDNA (UNIT 5.5)
- 2× methylase buffer (Table 3.1.3)
- 50× *S*-adenosylmethionine (SAM), freshly prepared (or from New England Biolabs with order of methylase)
- EcoRI* methylase (New England Biolabs; UNIT 3.1)
- TE buffer (APPENDIX 2)
- Buffered phenol (UNIT 2.1)
- Diethyl ether
- 7.5 M ammonium acetate
- 95% and 70% ethanol, ice-cold
- 10× T4 DNA ligase buffer (UNIT 3.4) containing 5 mM ATP
- 1 μg/μl phosphorylated *EcoRI* linkers, 8- or 10-mers (Collaborative Research)
- T4 DNA ligase (measured in cohesive-end units; New England Biolabs; UNIT 3.14)
- EcoRI* restriction endonuclease and 10× buffer (UNIT 3.1)
- 10× loading buffer without Xylene Cyanol (UNIT 2.5A)
- CL-4B column buffer
- Agarose, electrophoresis-grade
- TBE electrophoresis buffer (APPENDIX 3)
- Ethidium bromide solution (UNIT 2.5A)
- DNA molecular weight markers (UNIT 2.5A)
- 10 mg/ml tRNA
- 3 M sodium acetate
- 65°C water bath
- 5-ml CL-4B column (see support protocol)

Construction of
Recombinant
DNA Libraries

5.6.1

Additional reagents and equipment for cDNA synthesis (*UNIT 5.5*), quantitation of DNA (*APPENDIX 3*), agarose gel electrophoresis (*UNIT 2.5A*), and fragment purification (*UNIT 2.6*)

NOTE: See discussion of preparation of buffer stocks in reagents and solutions section.

Methylate blunt-ended, double-stranded cDNA

1. Dissolve blunt-ended, double-stranded cDNA pellet from *UNIT 5.5* in 23 μ l water and add in the following order (50 μ l final volume):

25 μ l 2 \times methylase buffer (1 \times final)
1 μ l 50 \times SAM (20 μ g/ml final).

Mix gently by pipetting up and down with a pipettor. Add 1 μ l (20 U) *EcoRI* methylase to 400 U/ml final, mix as above, and incubate 2 hr at 37°C.

2. Add 150 μ l TE buffer and extract with 200 μ l buffered phenol beginning with the vortexing as in step 5 of the cDNA synthesis protocol in *UNIT 5.5*. Back extract the phenol phase with 100 μ l TE buffer and pool the aqueous phases as described in step 6 of the cDNA synthesis protocol in *UNIT 5.5*.

The cDNA, if prepared as described in the cDNA synthesis protocol, may be followed at all stages with a hand-held radiation monitor.

3. Extract 300 μ l of aqueous phase twice with 1 ml diethyl ether as described in step 7 of the cDNA synthesis protocol in *UNIT 5.5*.
4. Ethanol precipitate with 125 μ l of 7.5 M ammonium acetate and 950 μ l of 95% ethanol, then wash with ice-cold 70% ethanol as described in steps 8 and 9 of the cDNA synthesis protocol in *UNIT 5.5*.

Ligate EcoRI linkers

5. Dissolve DNA in 23 μ l water and add in the following order (30 μ l final volume):

3 μ l 10 \times T4 DNA ligase buffer containing 5 mM ATP (1 \times and
0.5 mM ATP final)
2 μ l 1 μ g/ μ l phosphorylated *EcoRI* linkers (67 μ g/ml final).

Mix gently by pipetting up and down with a pipettor. Add 2 μ l (800 U) T4 DNA ligase to 27,000 U/ml final, mix as above, and incubate overnight at 4°C.

6. Microcentrifuge the ligation briefly and place tube in a 65°C water bath 10 min to inactivate the ligase.

Digest with EcoRI

7. Place tube on ice 2 min, then add in the following order:

95 μ l H₂O
15 μ l 10 \times *EcoRI* buffer (1 \times final).

Mix gently by pipetting up and down with a pipettor. Add 10 μ l (200 U) *EcoRI* restriction endonuclease to 1300 U/ml final, mix as above, and incubate 4 hr at 37°C.

During incubation, prepare the CL-4B column described in the support protocol.

8. Add an additional 3 μ l (60 U) *EcoRI* restriction endonuclease to the cDNA, mix, and incubate another hour at 37°C to ensure complete digestion of the linkers.
9. Place the tube containing the reaction mixture in a 65°C water bath 10 min to inactivate the endonuclease.

Remove excess linkers

10. Add 2 μl of 10 \times loading buffer without Xylene Cyanol to the reaction and load the cDNA onto a 5-ml CL-4B column prepared in a 5-ml disposable plastic pipet.
11. Allow the loaded sample to enter the column just until the top of the gel becomes dry. Fill the pipet with CL-4B column buffer and allow the column to flow by gravity, collecting $\sim 200\text{-}\mu\text{l}$ fractions manually. Follow the cDNA with a hand-held radiation monitor; the bromphenol blue indicates the position of digested linkers. Stop collecting fractions after the main peak of counts has eluted and before the dye begins to elute.
12. Count 2- μl aliquots of each fraction and plot the results—the elution profile should appear similar to what is shown in Figure 5.6.1.
13. Pool the first one-half of the peak (save the rest as an ethanol precipitate, just in case); add 2.5 vol ethanol (using two or three microcentrifuge tubes as necessary), mix, and place 15 min on dry ice.

The column buffer has sufficient NaCl for precipitation and no more should be added. If the cDNA is not to be ligated or further size-fractionated immediately, store it as an ethanol precipitate.

14. Remove the tubes from dry ice, let thaw, and microcentrifuge 10 min at full speed, 4°C; remove most of the supernatant, fill the tubes with ice-cold 70% ethanol, and microcentrifuge again. Remove most of the supernatant and dry the pellets under vacuum. Resuspend pellets in a total of 50 μl TE buffer.
15. Determine the cDNA concentration. Determine the amount of ^{32}P in 1 μl by scintillation counting and fractionate 2.5 μl on a 1% agarose minigel (see UNIT 2.5) to check the average cDNA size by ethidium fluorescence or autoradiography. A significant fraction of the double-stranded cDNA should be larger than 1.5 kb. If the double-stranded cDNA is to be cloned with no further size fractionation, proceed to ligation protocols in UNIT 5.8; otherwise, continue with step 16.

Approximately 50% to 70% of the starting radioactivity (1 to 3 μg of cDNA) should be recovered and most of the cDNA should be >1.5 kb.

Since only 50 to 100 ng of cDNA are required to produce a full complexity library with a phage vector, it is recommended that a library be produced at this stage in any event. A

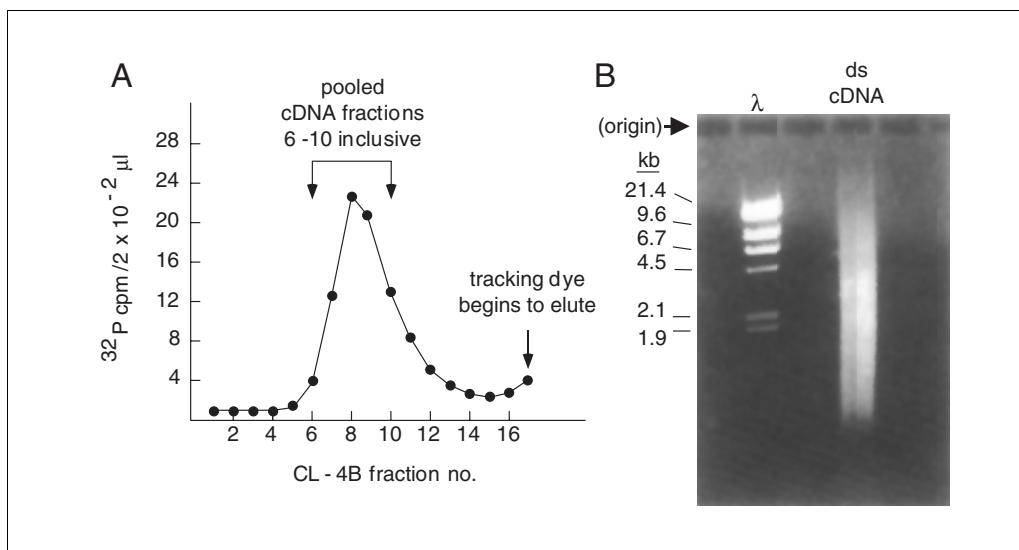

Figure 5.6.1 Fractionation of *Eco*RI-digested cDNA by (A) Sepharose CL-4B chromatography and (B) agarose gel electrophoresis.

library may be stored for years and may be useful in the future. For example, sequences related to the gene of interest may be identified that were excluded from a size-fractionated library.

Size-select the cDNA to obtain long inserts

16. Pour a 0.8% TBE agarose minigel—the gel should be thick enough such that all of the cDNA will fit into a single well. Rinse the gel box, tray, and comb thoroughly, and use fresh TBE electrophoresis buffer.

High-quality, nuclease-free agarose that does not inhibit ligation is essential. Most commercial agarose advertised as molecular biology grade is adequate. The agarose may be checked by first carrying an EcoRI fragment of a plasmid through the procedure and comparing its cloning efficiency in the cDNA vector, expressed as recombinants/ng insert, to the cloning efficiency of the same fragment prior to fractionation. Wash the gel box thoroughly afterward!

17. Add 10× loading buffer to 1× final to the cDNA and load it into a well near the center. Load DNA molecular weight standards (e.g., an HindIII digest of λ phage) two wells away from the sample. Electrophorese at 70 V until adequate resolution is achieved as determined by ethidium bromide fluorescence, usually 1 to 4 hr.

Be sure not to use standards with EcoRI ends.

18. Elute double-stranded cDNA of the desired size as estimated by comparison with the comigrated standards.

λgt10 and λgt11 have a maximum insert size of 7 kb, so collecting cDNA larger than this won't be useful unless a plasmid vector or a phage vector such as Charon 4A or EMBL 4 will be used.

19. Add 10 mg/ml tRNA to 20 μg/ml final, 1/10 vol of 3 M sodium acetate, pH 5.2 (APPENDIX 2), and 2.5 vol ice-cold 95% ethanol and place 15 min on dry ice. Microcentrifuge, wash and dry as in step 14, and resuspend pellet in 20 μl TE buffer.

Ethanol precipitation also extracts the ethidium from the DNA.

20. Determine radioactivity in 1 μl using a fluor and scintillation counter and then calculate the recovery of double-stranded cDNA (see commentary). Proceed to library construction protocols in UNIT 5.8.

ALTERNATE PROTOCOL

LIGATION OF BstXI SYNTHETIC ADAPTERS

Blunt-ended, double-stranded cDNA is ligated to phosphorylated *Bst*XI adapters and then purified as described in the basic protocol. Alternatively, *Eco*RI or *Eco*RI-*Not*I adapters may be used for cDNA to be cloned in vectors with the *Eco*RI site (Fig. 5.6.2). This protocol is simpler than that for linkers because the methylation and restriction digestion steps are unnecessary.

Additional Materials

*Bst*XI adapters (UNIT 2.11; Invitrogen), *Eco*RI adapters (New England Biolabs), or *Eco*RI-*Not*I adapters (Invitrogen)

1. Dissolve blunt-ended, double-stranded cDNA pellet in 23 μl water and add in the following order (30 μl final volume):
 - 3 μl 10× T4 DNA ligase buffer containing 5 mM ATP (1× and 0.5 mM ATP final)
 - 2 μl 1 μg/μl *Eco*RI, *Eco*RI-*Not*I, or phosphorylated *Bst*XI adapters (67 μg/ml final).

Figure 5.6.2 Noncomplementary adapter strategy. The insert and vector ends are compatible with each other but cannot self-ligate because the cohesive ends are not self-complementary. The *Bst*XI sites (underlined and bold) are not regenerated.

Mix gently by pipetting up and down with a pipettor. Add 2 μ l (800 U) T4 DNA ligase to 27,000 U/ml final, mix as above, and incubate overnight at 4°C.

It is helpful to use 32 P-labeled cDNA to follow the DNA on the subsequent CL-4B column. If the cDNA is not 32 P-labeled, it may be labeled at this step by using [32 P]labeled adapters, prepared with [γ - 32 P]ATP as in the T4 polynucleotide kinase exchange reaction (UNIT 3.10). Alternatively, if the adapters are not yet phosphorylated, they may be labeled with [γ - 32 P]ATP as in the T4 polynucleotide kinase forward reaction (UNIT 3.10).

2. Add 100 μ l TE buffer and remove excess adapters as in steps 10 to 15 of the basic protocol. If desired, size-select the cDNA as in steps 16 to 20 of the basic protocol. Resuspend purified cDNA pellet (obtained from either the CL-4B column or the gel) in 10 to 15 μ l TE buffer. Proceed to library construction protocols in UNIT 5.8.

Because adapter dimers formed during the ligation reaction will clone into the vector very efficiently, removal of the excess adapters is essential.

PREPARATION OF A CL-4B COLUMN

The CL-4B column (Fig. 5.6.3) effectively removes linkers or adapters that would otherwise interfere in subsequent cloning steps; it also allows selection of cDNA \geq 350 bp (see basic and alternate protocols). The column may be prepared while the cDNA is being digested with *Eco*RI, as described in steps 7 and 8 of the basic protocol.

Additional Materials

- Preswollen Sepharose CL-4B (Pharmacia), 4°C
- CL-4B column buffer
- Silanized glass wool
- Plastic tubing (new) with clamp

SUPPORT PROTOCOL

Construction of Recombinant DNA Libraries

5.6.5

Figure 5.6.3 CL-4B column used for removal of *Eco*RI-digested linkers and selection of cDNA ≥ 350 bp.

1. Transfer 10 ml of preswollen Sepharose CL-4B to a 50-ml polypropylene tube and fill the tube with CL-4B column buffer. Mix by inverting several times and let the Sepharose CL-4B settle by gravity for 10 to 15 min. Aspirate the buffer above the settled gel, removing also the unsettled “fines.”
2. Fill the tube two times with CL-4B column buffer—allow the Sepharose CL-4B to settle each time and remove the fines as in step 1.
3. Add 10 ml CL-4B column buffer and mix by inverting several times. Incubate the tube 10 min at 37°C, then proceed at room temperature.

Outgassing may occur if the column is poured cold. The bubbles thus formed in the gel will interfere with the chromatography.

4. Break off the top of the 5-ml plastic pipet. Wearing gloves, use the 1-ml pipet to push a small piece (3- to 4-mm³) of silanized glass wool down to the tip of the 5-ml pipet. Push a 3-cm length of plastic tubing firmly onto the tip of the 5-ml pipet. Clamp the tubing and attach the column to the ring stand as shown in Figure 5.6.3.
5. With a pipet, carefully fill the column with the gel slurry from step 3. After a few minutes, release the clamp on the tubing and allow the column to flow. Periodically add more slurry to the column as the level drops until the volume of packed gel in the column is at the 5-ml mark.
6. Allow the level of buffer in the column to drop until it is just above the level of the gel and clamp the tubing to stop the flow. The column is ready to be loaded (see basic or alternate protocols).

REAGENTS AND SOLUTIONS

Buffer stock solutions

Prepare ≥ 10 ml of each of the following stock solutions. Use autoclaved water and pass each solution through a sterile 0.45- μm filter. Store at room temperature unless otherwise indicated.

1 M Tris·Cl, pH 8.0 and pH 7.5

0.5 M EDTA, pH 8.0

3 M sodium acetate, pH 5.2

5 M NaCl (prepare 100 ml)

1 M MgCl_2

7.5 M ammonium acetate

20% *N*-lauroylsarcosine (Sarkosyl)

1 M DTT; store at -20°C in tightly capped tube

0.1 M ATP, pH 7.0 (prepare 1.0 ml); neutralize as described in *UNIT 3.4*;
store at -20°C

From these stock solutions, prepare the following buffers, which should be checked for nuclease activity as described in *UNIT 5.5*. Enzyme buffers should be frozen in 200- μl aliquots at -80°C in screw-cap microcentrifuge tubes. Enzyme buffers prepared and stored as described will last for years.

Several of these solutions are routine and may be already available. Nonetheless, to help ensure success, it is best to prepare separate stocks for critical applications such as library preparation.

CL-4B column buffer, 500 ml

5 ml 1 M Tris·Cl, pH 8.0

60 ml 5 M NaCl

1 ml 0.5 M EDTA, pH 8.0

2.5 ml 20% Sarkosyl

431.5 ml H_2O

Filter sterilize and store at room temperature

50 \times S-adenosylmethionine (SAM)

1 mg SAM

1.0 ml 50 \times SAM dilution buffer (see below)

Prepare fresh just prior to use. Store dry SAM at -80°C for no longer than 2 months.

50 \times SAM dilution buffer, 7 ml

330 μl 3 M sodium acetate, pH 5.2

6.67 ml H_2O

Store in 1-ml aliquots

Silanized glass wool

Submerge the glass wool in a 1:100 dilution of a silanizing agent such as Prosil 28 (VWR) for 15 sec with shaking. Rinse the glass wool extensively with distilled H_2O . Autoclave the glass wool for 10 min and store at room temperature.

COMMENTARY

Background Information

The most common method currently employed to create compatible ends on cDNA prior to cloning is the attachment of synthetic linkers (basic protocol). This has for the most part superseded homopolymeric tailing (Maniatis et al., 1982), since linkerage is relatively efficient, and its use eliminates the need for the sometimes tricky procedure of titrating the tailing reaction conditions. Other methods, such as the sequential ligation of two different linkers (Maniatis et al., 1982), are now rarely used. The linked cDNA may be cloned into a plasmid or a phage vector. The use of synthetic adapters that ligate at high efficiency instead of linkers eliminates the methylation and restriction digestion steps (alternate protocol). The recently developed noncomplementary adapter strategy (see below) may ultimately supersede all the above methods as vectors with appropriate sites become available.

Size fractionation of cDNA is preferable to size fractionation of the initial mRNA primarily because DNA is considerably less susceptible to degradation than is RNA. In addition, the small fragments that are generated during the cDNA synthesis process (e.g., due to contaminating nucleases) are removed. These would otherwise be preferentially inserted and decrease the yield of long cDNA clones in the library. RNA enrichment procedures were undertaken in the past because cloning efficiencies then were not high enough to ensure the representation of very rare mRNAs in the library. Currently, the most common reason for using mRNA fractionation or enrichment is in preparation of subtracted libraries (UNIT 5.8; Hedrick et al., 1984).

The strategy of noncomplementary adapters (Fig. 5.6.2), developed by Brian Seed and co-workers (Seed, 1987), overcomes the loss of library complexity due to self-ligation of the cDNA inserts or the vector. This enables a high efficiency for the ligation of the vector to the insert since there are no competing reactions and the vector ends are similarly noncomplementary and do not self-ligate. The much higher yield of desirable ligation products ultimately results in a greater number of clones in the library. Furthermore, the occasional "scrambles" produced as a consequence of two unrelated cDNAs ligating together during the vector ligation step are eliminated; however, "scrambles" at the stage of adapter ligation

remain possible, though infrequent.

Adapters are favored over linkers in general because the methylation and restriction digestion steps are bypassed, thus simplifying the procedure. Adapters are required in the alternate protocol procedure to ensure that all of the cDNA will have the proper, noncomplementary "sticky ends." The use of *EcoRI-NotI* adapters for cloning with *EcoRI* compatible vectors introduces the rare *NotI* site at both ends of the insert, allowing the insert to be cut out of the vector as one fragment, which is not always possible with *EcoRI* linkers if there are internal *EcoRI* sites present.

The development of noncomplementary adapters has enabled the production of high-complexity cDNA libraries in multifunctional plasmid vectors such as CDM8 (Seed, 1987). These vectors permit library screening by functional expression in eukaryotic cells and production of single-stranded DNA for mutagenesis or subtraction, in addition to conventional hybridization methods. For some specialized applications and for selectable markers other than the *supF* present in CDM8, other vectors that employ the noncomplementary linker strategy (and use the same *BstXI* sequence) include several available from Invitrogen with different antibiotic resistances and eukaryotic selectable markers. Other available vectors include AprM8, an ampicillin-resistant version of CDM8 (L.B. Klickstein, unpublished results), and retroviral vectors in the pBabe series (Morgenstern and Land, 1990).

Critical Parameters

In order to maximize the length and cloning efficiency of the cDNA, it is essential that contamination by endo- and exonucleases be avoided. EDTA, an inhibitor of most nucleases, should be present whenever feasible. Reagents, solutions, and enzymes should be of the highest quality obtainable.

The SAM reagent in the methylation step is very unstable, must be freshly dissolved prior to use, and should not be kept >2 months, even if stored dry at -80°C and never thawed. Stabilized SAM is supplied free of charge with methylases purchased from New England Biolabs.

Methylation conditions may be checked by methylating λ DNA under the conditions described in step 1 of the basic protocol, digesting methylated and unmethylated DNA with

EcoRI, and comparing the two samples by agarose gel electrophoresis. Methylated λ DNA should be protected from *EcoRI* digestion.

Digested linkers must be completely removed. Because of their small size, even as a small weight percentage of the total DNA, they will comprise a large mole fraction; thus, if not completely removed, most clones in the library will contain only linkers. Some investigators remove digested linkers by three sequential precipitations from 2 M ammonium acetate. However, column chromatography provides better resolution of the cDNA from the linkers. The CL-4B column also removes small double-stranded cDNA molecules. Purification of cDNA by gel electrophoresis after ligation of the linkers or adapters may be performed as an alternative to the CL-4B column, but the yield usually is not as high and the separation of linkers or adapters from cDNA is not as complete.

If *noncomplementary* adapters are employed, both 5' ends should be phosphorylated for optimum results. If *complementary* adapters are used, only the blunt end should have a 5' phosphate. The other end is phosphorylated after ligation to the cDNA.

Because *BstXI* produces a cohesive end with a sequence not specified by the restriction site sequence, the adapters and vector must correspond—e.g., the cohesive ends of the adapters used for the cDNA must be complementary to that of the vector. The vectors CDM8, AprM8, pCDNAI, pCDNAII, and the pBabe series all use the same sticky ends (Fig. 5.6.2).

Troubleshooting

Methylation and addition of linkers to double-stranded DNA are important to the successful construction of a cDNA library, but cannot be evaluated immediately. Unmethylated cDNA will clone efficiently and the problem will only be detected if the isolated inserts all end at an internal *EcoRI* site. This possibility may be minimized by prior evaluation of the quality of the SAM used in the methylation reaction (see reagents and solutions), or by use of the stabilized SAM that accompanies New England Biolab's *EcoRI* methylase.

Incomplete addition of linkers or adapters will be detected as a poor cloning efficiency in the next step of ligating the inserts to the vector. The problem may be any of the following: (1) cDNA was not blunted properly; (2) linkers or adapters were not kinased well or not annealed; (3) multiple linkers were not cut off with

EcoRI; (4) ligation reaction did not work. However, the problem is usually improperly blunted cDNA or linkers that do not ligate well. Evaluate the linker cDNA (after the CL-4B column) by ligating 5% of the sample with no vector and running the reaction on a 1% agarose minigel next to an equal amount of unligated cDNA. Properly linker cDNA should significantly increase in size as determined by ethidium bromide staining or autoradiography of the dried gel. Poorly linker cDNA may often be salvaged by repeating the blunting and linking steps with fresh reagents.

Inadequate separation of linkers or adapters from cDNA will be detected as cloning efficiency that is too high and as clones with no inserts detectable by gel electrophoresis (white plaques with no inserts in λ gt11 or plaques on C600hflA with λ gt10 that have no insert). The remainder of this cDNA may be salvaged by repeating the CL-4B column chromatography.

Anticipated Results

Approximately 50% to 70% of the starting radioactivity present in the blunt-ended, double-stranded cDNA should be collected after the CL-4B column. This typically represents 1 to 3 μ g of cDNA. In a human tonsil library prepared in λ gt11 where the inserts were thoroughly evaluated, the mean insert size was 1.4 kb and actin clones represented 0.34% of all recombinants. Three-quarters of the actin cDNAs were nearly full length (actin mRNA = 2.1 kb).

Time Considerations

The methylation can be done on the same day as the blunting step from the cDNA synthesis protocol. The linker ligation is then set up overnight. *EcoRI* digestion and CL-4B chromatography are performed the following day, and the cDNA is either ligated to the vector overnight (UNIT 5.8) or stored as an ethanol precipitate overnight and further size selected by agarose gel electrophoresis the next day. At any ethanol precipitation in the procedure, the cDNA may be stored for several days as an ethanol precipitate.

The use of adapters rather than linkers eliminates the need for the methylation and linker digestion steps. The adapted cDNA is immediately loaded onto the CL-4B column after the adapter ligation and is used directly from the column after ethanol precipitation. The subsequent ligation of the adapted cDNA and the vector is performed overnight, requiring the same amount of time with adapters as with linkers.

PRODUCTION OF GENOMIC DNA AND cDNA LIBRARIES

In this section the insert DNA (prepared in *UNIT 5.2* or *5.3*) is ligated to vector DNA and then the ligated DNA is propagated in *Escherichia coli*. The technical problems associated with joining DNA molecules together with ligase are described in *UNIT 3.14*. The creation of genomic and complete or subtracted cDNA libraries requires the production of large numbers of recombinant clones and this causes further complications. To recover large numbers of recombinant clones without using large amounts of packaging mixture, vector, or insert DNA, the optimal ratio of insert DNA to vector DNA must be determined prior to the production of the library. Without this optimization, the library will frequently not be large enough to contain the entire genome.

After ligation of vector DNA to insert DNA the ligated DNA must be introduced into *E. coli*. The introduction of bacteriophage or cosmid DNA into *E. coli* is carried out most efficiently by packaging the DNA into bacteriophage particles then allowing these bacteriophage particles to infect *E. coli* (see *UNIT 1.11* for a detailed description of this process). Unfortunately, plasmid DNAs cannot be packaged and thus must be introduced into *E. coli* by bacterial transformation (*UNIT 1.8*). Because of the high efficiency of introducing DNA into *E. coli* by the packaging procedure, we recommend producing genomic and complete or subtracted cDNA libraries using bacteriophage vectors whenever possible.

In this section the protocols required to ligate vector DNA to insert DNA and to introduce these molecules into *E. coli* are described. The protocols are divided into two parts—one for genomic DNA libraries and the other for complete or subtracted cDNA libraries—because the amount of insert DNA required for genomic libraries is usually considerably more than for cDNA libraries.

Production of a Genomic DNA Library

A number of small-scale ligations are performed using a set amount of vector and varying amounts of insert. Test ligations are transformed into bacteria (plasmid vectors) or packaged and plated on host bacteria (λ and cosmid vectors). The number of clones in the different ligations is compared, and the optimum ratio of vector to insert is indicated by the ligation with the most recombinant clones. A large-scale ligation is then set up using this optimum ratio. This protocol employs a bacteriophage vector; however, cosmid or plasmid vectors can be used with minor modifications (see commentary).

Determining the number of clones required to make a genomic DNA library is discussed in the chapter introduction. A library with a base of about 700,000 clones is required for a complete bacteriophage library of mammalian DNA.

Materials

Vector DNA (phage arms, cosmid arms, or linearized plasmid)

Insert fragment (*UNITS 5.3-5.6*)

10× DNA ligase buffer (*UNIT 3.4*)

T4 DNA ligase (measured in cohesive-end units; New England Biolabs; *UNIT 3.14*)

Packaging extract (phage and cosmid) or competent *E. coli* (plasmid)

LB or LB/ampicillin plates (*UNIT 1.1*)

Top agarose containing 10 mM MgSO₄ (*UNIT 1.1*)

Additional reagents and equipment for plating, packaging, and titrating bacteriophage (*UNIT 1.11*)

Ligating insert DNA to vector DNA

1. Perform a series of test ligations that bracket equimolar concentrations of vector and insert, i.e., insert/vector molar ratios of 5:1, 2:1, 1:1, 0.5:1, and 0.2:1. (Keep the vector constant and vary the insert DNA.) Since only the relative quantities of recombinants obtained are important, a small quantity of vector can be used for each reaction (40 to 100 ng). A control tube containing only ligated vector (tube no. 6 in Table 5.7.1.) is important to assess the yield of recombinants (see below). Conditions of the ligation reaction are as described in *UNIT 3.14* (1× ligase buffer, 100 U T4 DNA ligase) and should be in a *total volume* of 5 to 10 μ l. See Table 5.7.1 for a sample set of reactions.

Vectors should be chosen as described in UNIT 5.1. Genomic DNA libraries should be constructed only with vectors that provide a selection for insert DNA.

Table 5.7.1 Sample Set of Reactions for Ligating λ Vector to Insert DNA

Reaction component (μ l)	Tube number					
	1	2	3	4	5	6
Vector DNA (100 ng/tube)	1	1	1	1	1	1
Insert DNA (20 kb, 100 ng/ μ l)	2	—	—	—	—	—
Insert DNA (20 kb, 50 ng/ μ l)	—	2	1	0.5	—	—
Insert DNA (20 kb, 10 ng/ μ l)	—	—	—	—	1	—
10× ligation buffer	0.5	0.5	0.5	0.5	0.5	0.5
Water	1	1	2	2.5	2	3
T4 DNA ligase	0.5	0.5	0.5	0.5	0.5	0.5

2. Package the phage recombinants as described in *UNIT 1.11*. Normally, commercially prepared packaging extract is designed for approximately 1 μ g of λ DNA, so it is possible to divide such an aliquot of packaging extract among several test ligations.
3. Dilute packaged extract to 0.5 ml and plate 1 μ l and 10 μ l of packaged bacteriophage per plate. Grow overnight.
4. Compare the number of plaques on the plates to determine the optimum relative concentrations of arms and insert. The yield of plaques with insert DNA (from ligation tubes 1 to 5) should be at least twice and preferably 5 times the yield of colonies on the control plate (from tube 6) containing vector DNA alone.
5. Prepare a large-scale ligation reaction using the optimum ratio of insert DNA to vector DNA determined in step 4. The amount of DNA is determined by the size of the library that is desired.

See UNIT 5.1 to determine total number of desired recombinants. If the expected number of recombinants that can be made uses too much insert DNA or vector DNA, either the insert DNA or the vector DNA is probably defective. The quality of the vector or insert DNA can be tested by ligating them together and fractionating the ligated DNA on a gel (see UNITS 3.14, 2.5A, & 2.5B) using commercially prepared extracts.

Introducing ligated DNA into *E. coli*

6. Package the ligated DNA. Remember that bacteriophage packaging extracts can be saturated by too much DNA.

Because producing extracts that efficiently package DNA can be quite difficult, we recommend the use of commercially available packaging kits (see UNIT 1.11).

The number of recombinants that can be obtained with 1 μg λ DNA from large-scale ligation will depend on the efficiency of the packaging extract or competent cells, but can be as high as 10^8 for phage vectors. For cloning from size-fractionated DNA, this represents a vast excess of recombinants. It is frequently possible to obtain over 10^6 recombinant phage from the test ligations, and this is often enough recombinants to clone a single-copy gene. Thus, it is useful to save the test ligations.

7. Package and titer the large-scale ligation and store at 4°C.

Plate the bacteriophage for amplification or screening as soon as possible after the titer is known, as the titer will drop 3- to 10-fold within 48 hr of packaging.

COMMENTARY

Background Information

The theory of the ligation reaction is presented in UNIT 3.16 and is well outlined by Williams and Blattner (1980). From these theoretical considerations it is possible to predict the optimum concentration of vector and insert. However, because of the difficulty of estimating small quantities of DNA and the inability of some ends to ligate, it is helpful to conduct a series of test ligations as outlined here to determine the ratio of reagents that will result in the maximum number of clones. The theory of ligation reactions suggests that the optimum concentration for a ligation reaction varies for different sized molecules. However, the conditions suggested here are optimal for most vectors and inserts used for making genomic and cDNA libraries.

The production of a cosmid library is identical to the procedure described here except that a cosmid vector is used rather than a bacteriophage vector. Different amounts of cosmid vector are used because cosmids are smaller (about 5 kb) than bacteriophages (50 kb). Thus the weight of vector DNA should be reduced 10-fold.

Production of a plasmid library involves the same procedure except that ligated DNA is introduced into *E. coli* cells by transformation (see UNIT 1.8) rather than by packaging.

Critical Parameters

The quality of the insert DNA and vector DNA are critical to the success of these experiments. The most frequent cause of failure is that one of these DNAs has defective ends and thus the molecules are not able to ligate efficiently.

Quality of packaging extracts is also critical. Normally, commercial packaging extracts are of high quality and yield large numbers of bacteriophage. However, an occasional bad lot

of packaging extract is obtained.

Troubleshooting

A large number of clones in all the test ligations, or a large number of clones with extremely small quantities of insert, may indicate a high background of nonrecombinant clones. Background is determined by ligating the vector in the absence of insert. A large number of clones in this control ligation indicates inadequate dephosphorylation, inadequate purification from stuffer, or possibly that the bacterial strain being used for genetic selection is not correct.

If few recombinants are obtained, there are a number of possible explanations. The packaging extract should be evaluated by appropriate control experiments. Usually, the commercially available packaging extract kits contain a suitable control fragment. At the same time a test ligation can be run on an agarose gel and compared to the unligated vector and insert. If both the insert and vector DNA appear intact (i.e., not degraded), either the sticky ends of the vector or insert have been damaged or one of the DNA samples (usually the insert) contains an inhibitor of the ligase reaction. Clonability of these two reagents can be evaluated by determining the ability of insert or vector DNA to ligate to itself or to an appropriate control. Inhibiting contaminants can sometimes be removed by phenol/ chloroform extraction followed by ethanol precipitation, or by passing the DNA over an Elutip column (UNIT 2.6).

Anticipated Results

The number of clones obtained will depend on a number of factors including the efficiency of ligation, transformation, and packaging. At best, in a λ vector, over 10^8 recombinants per μg of insert DNA can be achieved. Cloning into

plasmid usually produces fewer recombinants per quantity of insert because transformation into competent *E. coli* is 10 to 100 times less efficient than the in vitro packaging of λ phage. In a plasmid, it may be necessary to use 1 to 2 μg insert DNA to achieve 10^6 recombinant clones. Cosmid clones usually are obtained at 10^5 to 10^6 colonies per μg insert DNA.

Time Considerations

Test ligations are incubated overnight at 13°C (alternatively, incubate 2 hr at room temperature). The ligation reactions are packaged and then titered on the second day. Results are available late on the second day or the morning of the third day.

Production of a Complete cDNA Library

UNIT 5.8A

A complete cDNA library is one that contains at least one cDNA clone representing each mRNA in the cell. There are about 34,000 different types of mRNA in a mammalian cell and about 500,000 mRNA molecules per cell. For any cDNA library there is a probability, P , that each mRNA will be represented at least once. A useful method for calculating the required base of a cDNA library is to calculate the probability, q , that a single cDNA clone will not be found in the library after choosing, at random, N clones:

$$q = 1 - P = [1 - (n/T)]^N$$

where n is the number of molecules of the rarest mRNA in a cell and T is the total number of mRNA molecules in a cell. The desired base, B , is the number of clones that should be screened to achieve a 99% probability that a cDNA clone will exist in the library, defined as:

$$q = 1 - 0.99 = 0.01 = [1 - (n/T)]^B$$

where n is 8 and T is 562,800 (for one mammalian cell), and the base B , is 324,000. In general, if 500,000 to 1,000,000 independent cDNA clones are obtained, the library should contain at least one copy of every mRNA.

Either a phage or plasmid vector can be used in constructing a complete cDNA library (first basic and alternate protocols). Procedures for evaluating these cDNA libraries are described in the first support protocol. If necessary, the quality of the λ arms used in constructing complete phage cDNA libraries can be evaluated as described in the second support protocol.

A subtracted DNA library is useful when a specific DNA or antibody probe for the desired clone is unavailable. A method for constructing a subtracted cDNA library is presented in UNIT 25B.1.

LIGATION AND TRANSFECTION FOR A COMPLETE λ PHAGE LIBRARY

BASIC
PROTOCOL

Double-stranded cDNA with *EcoRI* ends is ligated to a 2-fold molar excess of phage vector DNA that has been digested with *EcoRI* and phosphatased to prevent ligation without a cDNA insert. The ligation mixture is packaged into infectious phage particles in vitro and transformed into host bacteria. Currently C600*hflA* is used to propagate λ gt10-based libraries and Y1088 is the host for λ gt11 libraries (see Table 1.4.5).

Materials

EcoRI-cut, phosphatased λ gt10, λ gt11, or λ gt11 DNA or other phage vector DNA

Double-stranded cDNA with *EcoRI* ends (UNIT 5.6)

10 \times DNA ligase buffer (UNIT 3.4)

T4 DNA ligase (measured in cohesive-end units; UNIT 3.14)

Cold 10 mM MgSO₄

λ phage packaging extract (Stratagene)

Suspension medium (SM; UNIT 1.11)

Chloroform

E. coli C600*hflA* (λ gt10) or Y1088 (λ gt11)

IPTG (λ gt11 only; UNIT 1.4)

Xgal (λ gt11 only; UNIT 1.4)

Additional reagents and equipment for plating and titering bacteriophage (UNIT 1.11)

Construction of
Recombinant
DNA Libraries

5.8.1

Supplement 18

1. Resuspend *Eco*RI-digested, phosphatased λ gt10 or λ gt11 DNA at 1 μ g/ μ l.

*λ gt10 and λ gt11 phosphatased phage arms are available commercially. Alternatively, prepare the phage DNA as described in UNIT 1.13 and digest with *Eco*RI and phosphatase (UNITS 3.1 & 3.10). Evaluate “homemade” phage arms as described in the second support protocol of this unit.*

Both λ gt10 and λ gt11 grow well and milligram quantities of DNA are routinely obtained from a 1-liter culture.

2. To a fresh tube add the following (final volume 19 μ l):

100 ng cDNA with *Eco*RI ends (5 μ g/ml final)
10 μ l (10 μ g) λ gt10 or λ gt11 DNA from step 1 (500 μ g/ml final)
2 μ l of 10 \times ligase buffer (1 \times final)
H₂O to 19 μ l.

Mix by gently pipetting up and down and add 1 μ l (400 U) T4 DNA ligase to 20 U/ μ l final. Mix gently and incubate overnight at 4°C. Inoculate an overnight culture of plating bacteria.

The objective is to maximize the number of recombinants obtained per microgram of cDNA and to minimize both the probability of two unrelated cDNA sequences ligating to each other and the probability of the cDNA forming an intramolecular loop. The 100-fold weight excess of vector used above is a 2-fold molar excess if the rough assumption is made that the average insert size is 1/50 that of the vector. Since the rate of intramolecular ligation is independent of cDNA concentration, the ligation is performed in a relatively small volume to favor intermolecular reactions.

3. Inoculate 50 ml broth with 0.5 ml of the overnight culture of host bacteria. When the OD₆₀₀ = 0.5, pellet the bacteria by centrifugation 2 to 4 hr at 28,000 \times g (3000 rpm in a tabletop centrifuge), 4°C, and resuspend in 5 ml cold 10 mM MgSO₄. Store at 4°C prior to use.
4. While the culture is growing, incubate the ligation for 30 min at –20°C, and thaw at room temperature. Package the DNA mixture with a λ phage packaging extract.

Use enough extracts such that the capacity of each is not saturated—typically 1 to 2 μ g ligated DNA per extract.

Commercially available packaging extracts are recommended. High-efficiency in vitro packaging extracts (>10⁸/ μ g intact phage DNA) are critical to successful preparation of the library as are freshly prepared plating bacteria. A test packaging is not recommended as the components of ligation cannot be recovered if ligation fails.

5. Add SM to the packaging mixtures and pool into a single 5-ml polypropylene tube such that the total volume is 2 ml. Add a few drops of chloroform and shake by hand 3 sec. Place the tube containing the unamplified library on ice.
6. Determine the titer of the library. Use *E. coli* C600*hflA* as the host for a λ gt10-based library or Y1088 as the host for a λ gt11-based library. Include IPTG and Xgal in the case of a λ gt11-based library to determine the fraction of the clones that represents recombinants. While the titer plates are incubating, store the library at 4°C.

In vitro packaged phage are unstable. If stored for more than a day or so, the titer of the stock will drop noticeably. Thus, the library must be amplified at this time or no later than the following day (see UNIT 25B.2).

7. Calculate the cloning efficiency as recombinants/ μ g cDNA.

Approximately 1–5 \times 10⁷ clones/ μ g cDNA are typical. For a λ gt11-based library, at least 90% of the plaques should be clear. The library is ready to be plated for amplification and/or screening.

LIGATION AND TRANSFORMATION FOR A COMPLETE PLASMID LIBRARY

ALTERNATE
PROTOCOL

Double-stranded cDNA with noncomplementary *Bst*XI ends is ligated to an equimolar amount of plasmid vector DNA that has been linearized at the two inverted *Bst*XI sites and purified by gel electrophoresis. The ligation is introduced into bacteria either by transfection of competent cells or by electroporation, and the bacterial cells are plated and grown overnight.

Additional Materials

CDM8 plasmid DNA (Invitrogen) or similar plasmid vector DNA, CsCl-purified *Bst*XI and 10× *Bst*XI buffer (UNIT 3.1)

Low melting temperature agarose for fragment purification (UNIT 2.6)

TE buffer (APPENDIX 2)

Double-stranded cDNA with *Bst*XI ends (UNIT 5.6)

Competent cells: MC1061/P3 (Invitrogen) is required for CDM8; MC1061, DK1, DH1, DH5, or HB101 are suitable for other vectors

LB medium (UNIT 1.1)

150-mm LB agar plates (UNIT 1.1) with appropriate antibiotics (10 µg/ml ampicillin + 7.5 µg/ml tetracycline for CDM8 in MC1061/P3; 50 to 100 µg/ml ampicillin for the other vectors and strains above)

80% glycerol in H₂O

Additional reagents and equipment for plating and growth of *E. coli* (UNITS 1.1-1.4), isolation of DNA from agarose gels (UNIT 2.6), alkaline lysis/CsCl gradient preparation of plasmid DNA (UNIT 1.7), and introduction of plasmid DNA into cells (UNIT 1.8)

Prepare vector DNA

1. Digest CDM8 plasmid DNA with *Bst*XI restriction enzyme by adding to a 500-µl tube (final volume 100 µl):

30 µg CDM8 DNA (300 mg/ml final)

10 µl 10× *Bst*XI buffer

H₂O to 92 µl

8 µl *Bst*XI (60 to 100 U).

Mix by vortexing; microcentrifuge at high speed briefly; incubate 3-4 hr at 55°C.

2. Purify the large vector fragment by electrophoresis through a low-melting-point agarose gel, by electroelution, or using DEAE-cellulose paper. Resuspend DNA at 1 µg/µl in TE buffer.

A purification step is essential, because all vectors employing the noncomplementary adapter strategy have two nearby (inverted) BstXI sites, and the fragment between them (several basepairs in pcDNA1 and pBabeNeo, ~300 bp in CDM8 and AprM8) must be completely removed for optimum cloning efficiency.

Ligate cDNA, transform of competent cells and store library

3. In a 500 µl microcentrifuge tube, add in the following order (final volume 20 µl):

1 µg cDNA with *Bst*XI ends (100 µg/ml final)

5 µl (5 µg) vector DNA from step 2 (500 µg/ml final)

1.5 µl of 10× DNA ligase buffer

H₂O to 19 µl.

Construction of
Recombinant
DNA Libraries

5.8.3

Mix by pipetting up and down with a micropipet and add 1 μl (400 U) T4 DNA ligase to 20 U/ μl final. Mix gently and incubate overnight at 4°C.

The above ligation employs equimolar amounts of vector and insert, assuming an average cDNA size of 1 kb and a vector size of 5 kb. An excess of vector is not required, because neither the vector nor the cDNA is able to self-ligate.

4. Transform 0.75 μl of the ligation mixture into each of twenty 100- μl aliquots of competent cells (as described in UNIT 1.8 or manufacturer's protocol).

High efficiency competent cells are critical to the successful production of a full complexity cDNA library. Whether competent cells are purchased commercially or are made in the laboratory, they should be tested prior to use. Efficiency yields should be $\geq 1 \times 10^8$ colonies per μg supercoiled pUC18 DNA. Electroporation is an excellent alternative if the special apparatus is available; it yields even higher efficiencies and has been employed successfully for cDNA libraries (UNIT 1.8).

5. Pool the transformed cells in a single 50-ml polypropylene tube, grow with shaking 1 hr at 37°C, and plate on 10 to 20 15-cm agar plates containing the appropriate antibiotic(s) (UNIT 1.3). Incubate overnight at 37°C.

The transformed bacteria may be grown in liquid culture, but there is a greater likelihood of altering the representation of the library due to overgrowth of relatively rapidly growing cells. For this reason, growth on agar plates is recommended.

If the library is to be screened by hybridization without amplification, a detergent-free nitrocellulose filter may be placed on the plate prior to plating the bacteria. Replica filters can then be prepared after incubation (UNIT 6.2)

6. Count the number of colonies in a sector of a plate to determine the library complexity expressed as colonies per microgram cDNA. Add 5 ml LB medium to each plate and gently elute the bacteria with a spreader (UNIT 1.3) to form a dense suspension. Wash each plate with an additional 1 ml LB medium to recover residual bacteria. Pool bacteria in a single sterile tissue culture flask.

Library complexities of 5×10^5 to 2×10^6 colonies per μg input cDNA are typical for libraries prepared with competent cells. Efficiencies 10-fold higher are possible for libraries prepared by electroporation (UNIT 1.8).

7. Take half of the pooled bacteria and perform an alkaline lysis/CsCl gradient purification of the plasmid DNA. This DNA represents the unamplified library and is suitable for transfection of mammalian cells. To the remainder of the pooled bacteria, add 0.2 vol of 80% glycerol and mix thoroughly by inverting the flask. Dispense 1-ml aliquots into sterile 1.5-ml microcentrifuge tubes and freeze at -80°C .

Up to 50 aliquots may be obtained with this procedure. Each aliquot will inoculate 500 ml of liquid culture for preparation of additional DNA.

8. Evaluate the library as described in the first support protocol. Note that the *Bst*XI sites are not reconstituted with the adaptors commonly used, thus flanking restriction sites must be used to cut out the inserts.

EVALUATION OF A cDNA LIBRARY

To ensure that a negative result upon screening is not the result of a technical error during the construction of the library, evaluate the library by (1) screening for an abundant mRNA sequence, such as actin, known to be present; (2) screening with a total mixed cDNA probe; or (3) examining the inserts from twelve or more randomly chosen clones. Evaluation of the library is carried out after amplification (*UNIT 25B.2*) or concurrently with screening if no amplification is done.

An amplified library is stable for years and may be screened thousands of times. Due to the expense and time involved in generating a cDNA library, amplification is recommended. If $>2 \times 10^6$ clones are obtained, some investigators plate $4-5 \times 10^5$ clones for immediate screening and amplify the remainder of the library, against the possibility that the target clones will be underrepresented as a result of the amplification procedure. A cDNA cloning efficiency within the expected range is a good initial indication that all is well; however, further evaluation by at least one of the following methods is necessary because although screening a library is conceptually simple, in practice, identification of a positive clone is not always straightforward. Thus, in the case of an evaluated library, a negative result upon screening implies problems with the probe, the screening method, or the source of the RNA.

Evaluate the library by screening duplicate lifts from a single plating of 10,000 to 50,000 clones (from a plasmid or phage library) with an actin hybridization probe, using the protocol in *UNIT 6.3*. Each duplicating signal on the film is scored as a positive. Table 5.8.1 gives a range of actin cDNAs for various tissues expressed as a percentage of total recombinant clones screened.

Actin is a good choice of probes with which to evaluate the library because its sequence is highly conserved across species and probes are widely available; however, any abundant mRNA known to be present, for which a probe is available, will do. This probe can be labeled by methods described in *UNIT 3.4*.

An alternative to a specific probe is to screen a single plating as above with a cDNA hybridization probe prepared from the same mRNA used to construct the library. Use the hybridization conditions for cloned probes outlined in the steps for screening libraries (*UNIT 6.3*). Approximately 50% to 90% of the clones in the plating should hybridize, depending in part upon the source of the RNA.

A third means of evaluating the library is to pick 12 single recombinant clones, often from the initial titer plate from step 6 of the basic protocol, and carry them through the phage DNA miniprep described in *UNIT 1.13*. Resuspend the miniprep DNA in 25 μ l water and digest 10 μ l with *EcoRI*. Analyze the digest by electrophoresis through a 1.5% agarose gel in TBE buffer. At least 10 of the 12 recombinant clones should have inserts visible by ethidium fluorescence, with an average size of ~ 1 kb or more.

Table 5.8.1 Frequency of Actin cDNA Clones in Various Mammalian cDNA Libraries

Tissue or cell type	Actin-hybridizing clones (% of clones screened)
Liver	0.02 to 0.06
Lymphoid tissue or cells	0.1 to 0.5
Fibroblastoid cell line	1 to 4

PREPARATION OF TEST INSERT FOR EVALUATION
OF PHOSPHATASED PHAGE ARMS

This protocol describes a procedure for testing the quality of λ arms. Bacteriophage DNA is ligated to test insert DNA and the efficiency of the vector is tested by packaging and plating the ligated DNA.

Additional Materials

Genomic DNA

1:1 phenol/chloroform (UNIT 2.1A)

Additional reagents and equipment for restriction endonuclease digestions (UNIT 3.1) and plating bacteriophage libraries (UNIT 6.1)

1. Digest 20 μg genomic DNA to completion with *EcoRI*. Bring to 300 μl with TE buffer.
2. Extract with 300 μl phenol/chloroform, add 30 μl of 3 M sodium acetate and 700 μl of 95% ethanol, and place on dry ice for 15 min to precipitate the DNA.
3. Thaw, microcentrifuge 10 min at high speed, wash the pellet with 70% ethanol, and resuspend in 1.7 ml TE buffer. The test insert DNA concentration is ~ 10 ng/ μl .
4. Ligate 1 μg of arms to 10 μl (10 ng) of test insert in 10 μl as described in step 2 of the first basic protocol. Also ligate 1 μg of arms without a test insert as a control. Package and titer 2 μl of each ligation (UNIT 1.11).
5. To determine the efficiency (no. PFU per microgram test insert), multiply the number of plaques from the packaging mixture by 500. Usable arms will give 1×10^7 to 2×10^8 PFU/ μg test insert. In the case of $\lambda\text{gt}11$ plaques $\leq 10\%$ of these should be blue on an Xgal plate. At least a 100-fold increase in the number of plaque-forming units should be observed in the presence of the test insert, compared with its absence from the ligation mixture.

Perhaps because of a large number of short fragments or because of a greater fraction of fragments with the correct ends, an EcoRI genomic digest gives a higher cloning efficiency than does cDNA.

COMMENTARY**Background Information**

Significant technological advances over the past few years permit the construction of cDNA libraries that closely reflect the size and complexity of the corresponding mRNA. Historically the two most troublesome steps were S1 nuclease digestion of the cDNA and G-C tailing of the cDNA and vector, both of which require laborious adjustment of reaction conditions (see Sambrook et al., 1989). These, for the most part, have been superseded by the RNase H/E. *coli* polymerase I second-strand synthesis method of Okayama and Berg (1982) and the ligation of synthetic linkers (Huynh et al., 1984), respectively. The commercial availability of high-quality enzymes and reagents has made these newer methods quite reliable. The introduction of $\lambda\text{gt}10$ and $\lambda\text{gt}11$ phage vectors (Young and

Davis, 1983) allowed the high efficiencies of in vitro packaging systems to be applied to the preparation of cDNA libraries. It is now nearly routine to generate libraries containing millions of independent recombinant clones, many of which will contain the entire protein-coding region of interest. A limited cDNA library may also be obtained by following the basic protocol for the production of subtracted cDNA libraries (UNIT 25B.2).

Compared with phage libraries, plasmid libraries usually contain fewer clones and are more complicated to screen by hybridization or with antibody. They are most useful when prepared for particular applications, such as functional screening in COS cells with the vector CDM8 (Seed, 1987; UNIT 16.12). One advantage of functional screening is that

clones may be identified when no antibody or hybridization probes are available. A second advantage is that, for the most part, only full-length clones are detected, although some clones may contain residual introns. A disadvantage is that cDNAs encoding large proteins (>140 kDa) are unlikely to be found, as are cDNAs for proteins requiring other subunits for function.

Critical Parameters

Vector DNA, whether phage or plasmid, must be completely digested and phosphatased. A small amount of intact vector will transform the host bacteria very efficiently and contribute to a high background of nonrecombinant clones in the library. Of course, phosphatasing is not necessary for vectors employing the noncomplementary linker strategy. Commercially available phosphatased λ gt10 or λ gt11 arms and *Eco*RI-cut, phosphatased pBR322 or *Bst*XI-cut CDM8 work well in these procedures. If the vector is prepared by the investigator, the steps outlined to evaluate the vector should be followed before it is used. High-efficiency in vitro packaging extracts are crucial to the successful preparation of a high complexity cDNA library. Commercially available extracts work well.

The CDM8 vector requires a bacterial host containing the P3 plasmid, e.g., MC1061/P3. P3 is a low copy number, ~60-kb plasmid containing an origin of replication able to coexist with ColE1. The *supF* gene carried by CDM8 suppresses the amber mutations in the structural sequence for tetracycline and ampicillin carried on P3 and allows expression of the antibiotic resistance phenotype (UNIT 1.4). P3 also carries a functional kanamycin resistance to allow for its selection. If a particular host is necessary for an experiment, the P3 plasmid can be readily recovered by an alkaline lysis miniprep of MC1061/P3 (UNIT 1.6) and transformed into the desired host to enable propagation of CDM8. The *supF* selectable marker minimizes the size of the vector, and may allow isolation of genomic clones by an elegant recombination-based screening method (Seed, 1983). Alternate vectors that utilize a conventional antibiotic resistance and contain the noncomplementary *Bst*XI cloning sites are mentioned above and in UNIT 5.6.

High-efficiency transformation of bacteria with the ligated cDNA is probably the single most important step. Commercial competent cells may be worthwhile, if the investigator has difficulty preparing competent cells $\geq 1 \times 10^8$

CFU/ μ g supercoiled pUC18 DNA. Transformation of bacteria by electroporation is superior to the use of competent cells.

Several methods of evaluating a library are presented; screening for a known abundant clone, such as actin, is probably the best of these. Thorough evaluation of a library is of particular value when a screen turns out negative. If a problem exists in an evaluated library it is usually due to the probe, the screening method, or the source of the RNA.

Troubleshooting

The major problem at this stage is usually too few clones and is often due to a problem in previous steps. The second most likely problem is inefficient packaging extracts or competent cells, which can be tested by packaging or transforming, respectively, with uncut vector. The best diagnostic test at this point is ligation of a test insert to the vector and preparation of a test insert library. For phage or plasmid vectors with an *Eco*RI cloning site, use the *Eco*RI digest of genomic DNA as a test insert (second support protocol). For vectors with a noncomplementary *Bst*XI cloning site, obtain new phosphorylated *Bst*XI adapters and self-ligate 1 μ g in 20 μ l to form linker dimers. Precipitate the DNA by dilution to 300 μ l with dH₂O, add 3 μ l of 1 M MgCl₂, 20 μ g of carrier tRNA and 4 vol ethanol, precipitate 30 min in dry ice and recover the oligonucleotide DNA by thawing, and then microcentrifuging at top speed for 15 min. Resuspend the adapter dimers (the test insert) in 10 μ l TE, and ligate 1 μ l (100 ng) to 1 μ g of vector. Transform *E. coli* (UNIT 1.11) and plate an aliquot to determine the efficiency, which should be $\geq 1 \times 10^5/100$ ng test insert.

Anticipated Results

A complete cDNA library constructed in either phage vector should contain in the range of 10^6 to 10^7 independent recombinants from 100 ng of cDNA. This is sufficiently complex to contain even the rarest mRNA. A cDNA library prepared in a plasmid vector employing the noncomplementary adapter strategy should contain 5×10^5 to 2×10^6 colonies per μ g input cDNA if prepared by transformation of competent cells. Ten-fold higher complexities should be obtained with electroporation.

Time Considerations

The initial ligation of cDNA to the phage arms is an overnight step. The ligation may be packaged or transformed the following day or stored at -20°C over the weekend. Once the

library is packaged in vitro it should be plated within 24 hr for amplification and/or screening since these in vitro packaged phage are unstable and the titer of the library will drop if stored at this stage. An amplified library is stable for years when stored at -80°C in 8% DMSO as outlined in the phage library amplification protocol (UNIT 25B.2), and evaluation and screening may be performed at the investigator's convenience.

For plasmid libraries, the ligation may be stored for several days at -20°C . Transformed competent cells should be plated the same day. As above, an amplified plasmid library may be stored for years at -80°C in glycerol.

Construction of Bacterial Artificial Chromosome (BAC/PAC) Libraries

Large-insert genomic libraries are important reagents for physical mapping of large chromosomal regions, for isolation of complete genes including all regulatory sequences, and for use as intermediates in DNA sequencing of entire genomes. There is a need for libraries of large insert clones in which rearrangements and cloning artifacts are minimal. With recent developments in host/vector systems, it is now possible to efficiently create large-insert libraries using low-copy-number bacterial plasmid vectors. Suitable vector systems have been developed using *Escherichia coli* F factor or P1 phage replicons, which are capable of producing large insert clones by bacterial transformation.

Construction of BAC and PAC libraries is detailed first (see Basic Protocol). Two vectors, pCYPAC2 (Ioannou et al., 1994) and pPAC4 (E. Frengen et al., unpub. observ.) have been used for preparing PAC libraries, and a new BAC vector pBACe3.6 (Frenge et al., 1999) has been developed for construction of BAC libraries. All vectors are illustrated in Figure 5.9.1. Support Protocol 1 describes preparation of PAC or BAC vector DNA for cloning by digestion with *Bam*HI or *Eco*RI, simultaneous dephosphorylation with alkaline phosphatase, and subsequent purification through pulsed-field gel electrophoresis (PFGE). For the preparation of high-molecular weight DNA for cloning, Support Protocols 2 and 3 provide procedures for embedding total genomic DNA from lymphocytes or animal tissue cells, respectively, in InCert agarose. Support Protocol 4 details the next steps for the genomic DNA: partial digestion with *Mbo*I or with a combination of *Eco*RI endonuclease and *Eco*RI methylase (including appropriate methods for optimizing the extent of digestion), and subsequent size fractionation by preparative PFGE. Finally, Support Protocol 5 covers the isolation of BAC and PAC plasmid DNA for analyzing clones. Isolation of BAC and PAC plasmid DNA is somewhat more difficult than standard plasmid extraction, because it requires more attention to cell concentration during extraction and resuspension of ethanol-precipitated DNA.

In order to construct, for example, a 10-fold redundant human library with 150-kb average insert size, 200,000 clones must be generated. The *Eco*RI-*Eco*RI ligation efficiency seems to be higher than the *Mbo*I-*Bam*HI ligation. A reasonable transformation efficiency from *Eco*RI-*Eco*RI ligation is ~2,000 colonies per transformation using 2 μ l ligation mixture and 20 μ l electrocompetent cells. In comparison, the efficiency of *Mbo*I-*Bam*HI ligation is ~800 colonies per transformation. Thus, it is necessary to perform at least 100 individual transformations for an *Eco*RI partially digested 10-fold redundant library, and 250 individual transformations for an *Mbo*I partially digested library. In order to perform 100 electroporations, 200 μ l of concentrated ligation mixture is required, thus five individual 250- μ l ligations must be prepared. For 250 transformations, 500 μ l of ligation mixture is needed, so thirteen individual 250- μ l ligations are required. Note that it will be necessary to repeat the Basic Protocol and Support Protocol 4 multiple times until enough clones are generated to complete the library. Steps 24 to 30 of the Basic Protocol are designed to handle the amount of size-fractionated genomic DNA that can reasonably and comfortably be generated from a single preparation as described in Support Protocol 4. It is advisable to prepare at least 20 DNA plugs (20 to 40 μ g/plug) for the entire library construction procedure; up to four plugs may be needed to optimize the partial digestion, and as many as sixteen plugs may be needed for library construction.

CAUTION: Radioactive, biological, and chemical substances require special handling; see APPENDIX 1F & 1H for guidelines.

Figure 5.9.1 (at left) The (A) pCYPAC2, (B) pBACe3.6, and (C) pPAC4 vectors contain common features for positive selection of cloned inserts. The insert-containing *E. coli* cells can be grown in preference over cells containing plasmids without an insert by including sucrose in the medium. Sucrose is converted into toxic metabolites by levansucrase encoded by the *sacBII* gene present in all three vectors. The pUC-link segment contains a functional high-copy-number plasmid that includes the ampicillin resistance gene (Ap^r ; not shown). The pUC-link sequence is removed in the cloning procedure and is not present in the PAC and BAC clones. The digested genomic DNA fragment replaces the fragment containing the pUC-link in the PAC or BAC vectors. The *loxP* recombination sites are not used in cloning. A detailed description of vector elements is given elsewhere (see, Background Information, vector elements). (A) The pCYPAC2 vector contains the P1 plasmid replicon, which maintains recombinant clones at around one copy per cell. Alternatively, the P1 lytic replicon can be induced to provide higher copy numbers by adding the *lac* inducer IPTG into the medium. The kanamycin resistance gene (Km^r) is also present in this vector. (B) The pBACe3.6 vector contains the chloramphenicol resistance gene (Cm^r) and the F plasmid replicon, maintaining recombinant clones at one copy per cell. The multiple cloning sites flanking the pUC-link segment allow positive selection for cloned inserts using any of the restriction enzymes *Bam*HI, *Sac*II, *Eco*RI, *Sac*I, *Mlu*I, or *Nsi*I. The Tn7att sequence permits specific Tn7-based retrofitting of BAC clones. (C) The pPAC4 vector contains four elements from pCYPAC2: the P1 plasmid replicon, the kanamycin resistance gene, the *sacBII* gene, and the pUC-link. The P1 plasmid replicon ensures low-copy-number maintenance of recombinant clones; the P1 lytic replicon is removed. In addition, the *oriP* and *bsr*^r cassette have been included to facilitate the use of PAC clones for functional analysis of genes carried on the cloned inserts. The Tn7att sequence is also present, enabling specific retrofitting of PACs.

PREPARATION OF BAC/PAC CLONES USING pCYPAC2, pPAC4, OR pBACe3.6 VECTOR

Preparation of large-insert bacterial and P1-derived artificial chromosome (BAC and PAC) clones is conceptually similar to procedures used for preparing small plasmid clones. A single vector fragment with dephosphorylated *Bam*HI or *Eco*RI ends (see Support Protocol 1) is ligated to size-fractionated *Mbo*I- or *Eco*RI-digested genomic DNA fragments that are recovered from agarose slices using an electroelution procedure (see Support Protocol 4). Ligations are performed at low genomic DNA concentrations to favor the formation of circular molecules. A number of 120- to 300-kb fractions from the preparative gel are tested initially to identify the fraction giving the largest average insert size at an acceptable cloning efficiency. Once the optimal fraction is identified, a large-scale ligation is performed to make sufficient clones for a several-fold redundant library.

Size fractionation of the partially digested DNA is important to select for the desired size fragments and to remove smaller digestion products, which otherwise would result in an overwhelming background of small BAC or PAC clones. Circular plasmid ligation products are introduced directly into host cells by electroporation. Although this procedure is conceptually easy, there are several aspects of the Basic and Support protocols that are critical for successful preparation of BAC and PAC libraries (see Critical Parameters).

Materials

- ≥2 to 10 ng/μl size-fractionated *Mbo*I- or *Eco*RI-digested genomic DNA (see Support Protocol 4)
- 10 to 50 ng/μl pBACe3.6, pCYPAC2, or pPAC4 vector DNA prepared for cloning (see Support Protocol 1)
- 1 Weiss U/μl T4 DNA ligase (Life Technologies) and 5× buffer (see recipe)
- 0.5 M EDTA, pH 8.0 (APPENDIX 2)
- 10 mg/ml proteinase K

BASIC PROTOCOL

Construction of Recombinant DNA Libraries

5.9.3

100 mM phenylmethylsulfonyl fluoride solution (PMSF; see recipe)
 TE/PEG solution: 0.5× TE buffer, pH 8.0 (*APPENDIX 2*) containing 30% (w/v)
 polyethylene glycol 8000 (PEG 8000)
 Electrocompetent bacterial cells (ElectroMAX DH10B; Life Technologies)
 SOC medium (Life Technologies; also see *UNIT 1.8*, but reduce yeast extract to
 0.5%)
 LB plates (*UNIT 1.1*) containing 5% (w/v) sucrose and either 25 µg/ml kanamycin
 (for PAC clones) or 20 µg/ml chloramphenicol (for BAC clones):
 100 × 15–mm petri dishes for test transformation
 22 × 22–cm trays for picking colonies
 LB medium (*UNIT 1.1*) containing 20 µg/ml chloramphenicol (BAC clones) or 25
 µg/ml kanamycin (PAC clones)
 TE buffer, pH 8.0 (*APPENDIX 2*)
NotI restriction endonuclease and buffer (New England Biolabs)
 1% (w/v) ultrapure agarose solution (Life Technologies)
 0.5× TBE buffer (*APPENDIX 2*)
 Low-range PFG markers in agarose containing a mixture of lambda *HindIII*
 fragments and lambda concatemers (New England Biolabs)
 0.5 µg/ml ethidium bromide in 0.5× TBE buffer (*APPENDIX 2*)
 80% (v/v) glycerol, sterile

 Dry ice/ethanol bath
 16° and 37°C water baths
 0.025-µm-pore-size microdialysis filters (Millipore): 25-mm diameter for
 small-scale test ligation and 47-mm diameter for large-scale ligation
 Wide-bore pipet tips, sterile
 Disposable microelectroporation cuvettes with a 0.15-cm gap (Life Technologies
 or equivalent)
 Electroporator (Cell Porator equipped with a voltage booster; Life Technologies or
 equivalent)
 15-ml snap-cap polypropylene tubes, sterile
 Orbital shaker, 37°C
 Automated plasmid isolation system (AutoGen 740, Integrated Separation
 Systems, optional)
 Flexible plastic 96-well plate (Falcon or equivalent)
 Contour-clamped homogeneous electrical field (CHEF; *UNIT 2.5B*) apparatus
 (Bio-Rad) or field-inversion gel electrophoresis (FIGE; *UNIT 2.5B*) apparatus
 (Bio-Rad or equivalent)
 Digital imager (Alpha Innotech IS1000 or equivalent)
 50-ml disposable centrifuge tube (Corning or equivalent)

 Additional reagents and equipment for modified alkaline lysis preparation of BAC
 or PAC clone DNA (see Support Protocol 5; optional)

CAUTION: To prevent shearing, use sterile wide-bore pipet tips for all steps involving the handling of genomic DNA.

Perform small-scale test ligation

1. Mix ~50 ng of each 120- to 300-kb size fraction of *MboI*- or *EcoRI*-digested genomic DNA (see Support Protocol 4) with 25 ng *BamHI*- or *EcoRI*-digested and dephosphorylated pBACe3.6 vector DNA, or 50 ng *BamHI*-digested and dephosphorylated pCYPAC2 or pPAC4 vector DNA prepared for cloning (see Support Protocol 1).

Suitable ligation controls include reactions with vector only or without ligase.

The vector fragment is 8.7 kb for pBACe3.6, ~15.5 kb for pCYPAC2, and 16.8 kb for pPAC4. The average size of fractionated genomic DNA is ~150 to 200 kb. Thus, a 10/1 molar ratio of vector to insert is obtained by using approximately half quantity of pBACe3.6 vector to insert DNA in the ligation reaction, or equal quantities of vector and insert DNA for PAC cloning. The genomic DNA concentration in the final reaction is maintained at a low value (1 ng/ μ l) to favor circle formation over concatemer formation.

Ligation schedules will vary somewhat depending on the restriction endonuclease used in preparing the vector and insert DNA. For a typical EcoRI-EcoRI ligation schedule, perform step 1 through step 6 in a day and then dialyze the solution against TE/PEG solution at 4°C overnight. For BamHI-MboI cloning, incubate the ligation mixture in a thermal cycler at 16°C for 8 hr, then hold at 4°C overnight, and start step 4 the following day.

2. To each tube, add 10 μ l of 5 \times T4 DNA ligase buffer (1 \times final) and sterile water to bring the total volume to 50 μ l. Mix very gently.
3. Add 1 Weiss unit T4 DNA ligase and incubate at 16°C for 4 hr for EcoRI-EcoRI cloning or 8 hr for BamHI-MboI cloning.

Keep in mind that the vector preparation can always contain a very low fraction of shortened fragments caused by BamHI or EcoRI degenerate (star) activities. Ligation could occur at those unspecific sites after long incubation, which could result in a small portion (<10%) of noninsert clones in the library. The ligation time in this protocol has been optimized to generate a (near) maximum level of recombinant clones with a minimum ratio of nonrecombinant clones.

4. To stop the reaction, add 1 μ l of 0.5 M EDTA, pH 8.0, and 1 μ l of 10 mg/ml proteinase K and incubate at 37°C for 1 hr.

Inactivation of the T4 DNA ligase with proteinase K is preferable to that by heating. Heating high-molecular-weight DNA is not recommended.

5. To inactivate proteinase K, add 1 μ l of 100 mM PMSF solution and incubate at room temperature for 1 hr.

Generate test clones by electroporation

6. Spot the ligation mixture on the middle of a 25-mm-diameter, 0.025- μ m-pore-size microdialysis filter floating on sterile distilled deionized water in a disposable petri dish. Dialyze for \geq 2 hr at room temperature.

The salts in the ligation mixture must be removed to reduce heat development during the subsequent electrical pulse. After 2 hr dialysis, the volume will increase ~150 μ l due to the higher osmotic pressure in the ligation buffer (which contains PEG 8000) as compared to water (see Background Information, concentration of ligation mixture).

7. Carefully recover the dialyzed ligation mixture from the membrane using a sterile wide-bore pipet tip and transfer to a microcentrifuge tube.
8. Discard the water from the petri dish and pour ~15 ml TE/PEG solution in the dish. Transfer the empty membrane onto this solution.
9. Drop the recovered solution (step 7) onto the membrane again and continue dialysis for ~5 hr at room temperature until it is equilibrated.

Concentrating ligation solution reduces the number of transformations necessary (see Background Information, concentration of ligation mixture).

Dialysis that is to go longer than ~5 hr can be done at 4°C (see ligation/dialysis schedules in step 1).

10. Transfer the membrane (still containing the concentrated solution) onto a petri dish cover, recover the ligation mixture from the dialysis membrane using a sterile wide-bore pipet tip, and transfer it to a microcentrifuge tube. Keep on ice.

*After concentration, ~8 μ l should be recovered from 50 μ l ligation solution; thus, the solution will not be dispersed into the outside solution during the membrane transfer. The solution should be transformed into *E. coli* as soon as possible. Keeping it for long periods will cause transformation efficiency to drop significantly.*

11. Precool disposable microelectroporation cuvettes (0.15-cm gap) and microcentrifuge tubes on ice. The microelectroporation cuvette can be used up to 10 times as long as the same transformation is repeated.

The test transformation should be done in duplicate or triplicate to better estimate the average transformation efficiency.

12. Thaw the required amount of electrocompetent bacterial cells on ice and transfer 20- μ l aliquots into precooled microcentrifuge tubes. Keep on ice.

Thaw a total of $(n + 1) \times 20 \mu$ l cells, where n is the number of electroporations, to provide sufficient cells for the transformation.

13. Using a sterile wide-bore pipet tip, transfer 2 μ l ligation mixture to each aliquot and gently mix with the pipet tip.

14. Transfer the solution into a precooled electroporation cuvette, placing the droplet carefully between the electrodes and avoiding the formation of any air bubbles.

15. Place the cuvette into the electroporation chamber and deliver a pulse according to the following conditions:

voltage booster settings:
resistance on voltage booster, 4000 Ω

Cell-Porator settings:
voltage gradient, 13 kV/cm
capacitance, 330 μ F
impedance, low Ω
charge rate, fast.

16. Collect the droplet of cells and dilute immediately into 500 μ l SOC medium in a 15-ml snap-cap polypropylene tube. Incubate 1 hr at 37°C in an orbital shaker at 200 rpm.

This incubation allows time for the antibiotic resistance gene to be expressed.

Under these conditions the cell concentration is considerably higher than can be achieved at the stationary phase of growth, and thus there is less chance of cell division.

Analyze test clones

17. Spread the entire aliquot of cells on a 100 \times 15-mm LB plates containing 5% sucrose and either 20 μ g/ml chloramphenicol (for BAC clones) or 25 μ g/ml kanamycin (for PAC clones).

Alternatively, recover the cells by centrifugation and concentrate to a final volume of 100 to 200 μ l before plating. If the whole volume is to be plated without concentration, ensure that the plates are dried under a hood prior to plating. A thoroughly dried plate is used to speed up absorption of the solution.

18. Grow overnight at 37°C, count colonies, and estimate the titer per transformation.

If a series of size fractions are tested simultaneously, the cloning efficiency is seen to drop precipitously as the size of the fractions increases above 200 kb. The factors contributing to this sharp decline in cloning efficiency are not well understood at present.

Construction of a total genomic mammalian BAC or PAC library with 10-fold redundancy requires creation of >200,000 clones. It is important to achieve as high a cloning efficiency as possible with the largest possible insert size, because this will reduce the number of electroporations that are subsequently required.

Isolate and characterize individual test clones

19. Pick 40 clones with a sterile toothpick and grow the cells overnight in 1.5 ml LB medium containing 20 µg/ml chloramphenicol (BAC clones) or 25 µg/ml kanamycin (PAC clones).
20. Extract DNA using an automated plasmid isolation system (AutoGen 740) or the modified alkaline lysis procedure (see Support Protocol 5).
21. Dissolve DNA (0.5 to 1 µg) in 100 µl TE buffer. Digest 5 to 10 µl DNA with 0.1 U *NotI* in a 20-µl volume to separate the vector and insert DNA fragments.

It is convenient to perform the reaction in a flexible 96-well plate at 37°C for 2 hr.

22. Analyze digested DNA using a CHEF or a FIGE apparatus. Use a 1% agarose gel, 0.5× TBE buffer, low-range PFG markers, and the following conditions:

For CHEF: 14°C, 6 V/cm, 16 hr, 0.1 to 40 sec pulse time, and 120° angle.

For FIGE: Room temperature, 180 V forward voltage, 120 V reverse voltage, and 16 hr with 0.1 to 14 sec switch time linear shape.

The FIGE system is much less expensive than CHEF, and is able to obtain enough resolution for this purpose.

23. Stain the gel with 0.5 µg/ml ethidium bromide solution and calculate the molecular weight of inserts using a digital imager.

*Most of the clones will give two bands—a vector fragment (8.7 kb for pBACe3.6, 15.5 kb for pCYPAC2, and 16.8 kb for pPAC4) and the insert DNA of variable size. If the insert contains internal *NotI* sites, additional bands will be seen. Incomplete digestion usually leads to a characteristic doublet, where the two bands differ by the size of the vector.*

Create library

24. Repeat the ligation procedure using a size fraction of genomic DNA that gives the desired average insert size and cloning efficiency. Scale up the ligation reaction to 500 to 1000 µl using the entire remaining electroeluted insert DNA.

The ligation reaction is usually performed in several microcentrifuge tubes at 250 µl per tube. Otherwise, the increase in volume may cause the solution to be dispersed into the water during subsequent dialysis, even though a 47-mm-diameter filter is used.

25. Dialyze and concentrate the ligation mixture as described (steps 6 to 10), but use a 47-mm-diameter microdialysis filter for each 250-µl aliquot.

After concentration, ~40 µl should be recovered from each 250-µl ligation solution.

26. Add 12 µl concentrated DNA to tubes containing ~110 µl each of electrocompetent bacterial cells. Mix well by gentle stirring using a wide-bore pipet tip. Thaw enough electrocompetent cells to complete all transformations using the entire recovered ligation mixture.

27. Perform identical transformations at 20 μ l per electroporation and collect the transformed cells from 10 electroporations into a 50-ml disposable centrifuge tube containing 5 ml SOC medium at room temperature.

The transformation efficiency will drop if the medium containing transformed cells is kept at 4°C during the transformation experiment.

28. Incubate the cells on an orbital shaker at 200 rpm at 37°C for 1 hr.
29. Add 800 μ l of 80% sterile glycerol solution into the bacterial culture and mix very well. Spread 200 μ l on two individual 100 \times 15-mm LB plates containing 5% sucrose and the appropriate antibiotic to examine the titer from each tube.

The amount of culture spread per plate is determined based on the titer estimated from the test ligation and transformation (step 18). The number of colonies on a plate should be between 300 and 700 to estimate the accurate titer for colony picking.

It is easier to homogeneously spread 200 μ l culture when 300 μ l SOC medium is also added to the plate.

30. Freeze the remaining cells in a dry ice/ethanol bath and keep at -80°C until colony picking can be scheduled. To pick colonies, spread culture at 1600 clones/plate on 22 \times 22-cm LB plates containing 5% sucrose and the appropriate antibiotic. Grow overnight at 37°C.

The colony picking is usually scheduled within a couple of months. The frozen cells should be able to be stored for at least 1 year.

SUPPORT PROTOCOL 1

PREPARATION OF BAC/PAC VECTOR FOR CLONING

The integrity of the vector's cohesive ends and the absence of uncut vector molecules are prerequisites for success in preparing BAC and PAC libraries. This protocol describes steps for preparing the vectors to maximize cloning efficiency and to minimize the level of nonrecombinant clones.

Preparation of pBACe3.6, pCYPAC2, and pPAC4 for cloning involves a single restriction endonuclease digestion with *Bam*HI or *Eco*RI. These plasmids contain the pUC-link insert at the cloning site, thus inactivating the *sacB* gene and enabling clones containing the original plasmid to grow in the presence of sucrose. Clones containing uncut vectors cannot be distinguished from truly recombinant clones, and great care should be taken to ensure complete digestion of the original vector with *Bam*HI or *Eco*RI during vector preparation. Depending on the source and activity of the different enzymes used, it is necessary to optimize the conditions for each digestion. The following conditions have been found to yield good vector preparations using the recommended enzymes.

Additional Materials (also see Basic Protocol)

pBACe3.6, pCYPAC2, or pPAC4 stock in *E. coli* DH10B cells (P. de Jong; pieter@dejong.med.buffalo.edu)

LB plates (UNIT 1.1) containing:

25 μ g/ml kanamycin (for PAC) or 20 μ g/ml chloramphenicol (for BAC)

5% (w/v) sucrose and either kanamycin or chloramphenicol

5% (w/v) sucrose, 100 μ g/ml ampicillin, and either kanamycin or chloramphenicol

*Bam*HI and *Eco*RI restriction endonucleases and 10 \times buffers (New England Biolabs or equivalent)

0.7% (w/v) agarose gels (for standard electrophoresis)

Calf intestine alkaline phosphatase (AP; Boehringer Mannheim)

10 mg/ml proteinase K (Boehringer Mannheim) stock solution

95% (v/v) ethanol
1.0% (w/v) ultrapure agarose solution (Life Technologies; for CHEF system)
6× loading buffer (UNIT 2.5A), not containing xylene cyanol FF or SDS
1-kb ladder or lambda *Hind*III markers
T4 polynucleotide kinase (New England Biolabs)
30% (w/v) polyethylene glycol (PEG) 8000
1.5-mm-thick electrophoresis comb for CHEF apparatus
Dialysis tubing of $\frac{3}{4}$ in. diameter, mol. wt. exclusion limit of 12,000 to 14,000 daltons (Life Technologies or equivalent)
Dialysis clip
Additional reagents and equipment for agarose gel electrophoresis (UNIT 2.5A), plasmid extraction (e.g., UNIT 1.7), CsCl/ethidium bromide equilibrium centrifugation (e.g., UNIT 1.8), electroelution (see Support Protocol 4), and ethanol precipitation (UNIT 2.1A)

Test vector DNA

1. Streak recombinant DH10B cells harboring BAC or PAC vectors onto an LB plate containing the appropriate antibiotic (chloramphenicol or kanamycin, respectively). Incubate overnight at 37°C.
2. Isolate five single colonies and inoculate into separate 15-ml snap-cap polypropylene tubes containing 3 ml LB medium with the appropriate antibiotic. Grow cultures overnight at 37°C.
3. Use 1.5 ml of each culture to prepare DNA using an automated plasmid isolation system (AutoGen 740) or the modified alkaline lysis protocol (see Support Protocol 5). Store the remainder of each culture at 4°C.
4. Resuspend DNA in 100 µl TE buffer.
5. Digest 5 µl DNA from each preparation with *Not*I, 5 µl with *Bam*HI, and 5 µl with *Eco*RI, using the manufacturers' recommended conditions.
6. Analyze digested DNA in a 0.7% agarose gel (UNIT 2.5A). Discard clones that contain any rearrangements of the vector.

PAC vectors do not contain EcoRI sites. Otherwise all enzymes should liberate pUC19-link from the vectors, producing fragments of ~2.7 kb (the pUC19 stuffer fragment) and ~8.7 kb (pBACe3.6), 15.5 kb (pCYPAC2), or 16.8 kb (pPAC4).

Prepare vector for large-scale ligation

7. Dilute the selected culture into 1 liter LB medium containing the appropriate antibiotic. Grow to saturation at 37°C.

This culture is used for making a large-scale preparation of the PAC or BAC vectors.

8. Prepare a crude lysate of the culture by the alkaline lysis or cleared lysate method.

Any standard protocol for plasmid extraction may be used here (UNIT 1.7).

9. Purify vector plasmid from crude lysate by CsCl/ethidium bromide equilibrium centrifugation.

Any standard protocol for CsCl/ethidium bromide equilibrium centrifugation may be applied (see UNIT 1.8).

Digest vector with BamHI or EcoRI

10. To establish the minimal amount of restriction enzyme required for complete digestion of the vector, first digest 50 ng vector DNA with 0.1, 0.2, 0.5, and 1 U of either *Bam*HI or *Eco*RI for pBACe3.6, and *Bam*HI for PAC vectors, in separate 10- μ l reactions for 1 hr at 37°C. Perform conventional agarose gel electrophoresis and ethidium bromide staining to view the digestion.

It is essential to establish the minimal amount of enzyme required for complete digestion. If too little enzyme is used, many nonrecombinant clones containing undigested vector can be expected. On the other hand, excess enzyme results in a very high ratio of noninsert clones, which are most likely induced by star activity.

11. Next, to establish the maximal amount of DNA in the reaction (and the minimum scale up volume), digest 100, 200, and 400 ng vector DNA with 2, 4, and 8 times the minimal amount of enzyme in separate 10- μ l reactions (total 9 reactions) for 1 hr at 37°C. Perform conventional agarose gel electrophoresis and ethidium bromide staining to view the digestion.

*High-quality vector preparation is difficult. If necessary, the vector can be digested with *Apa*LI for pBACe3.6 or *Scal*I for pCYPAC2 and pPAC4 to destroy the pUC-stuffer fragment in the vectors nearly completely. Note that a precipitation step is needed in order to change the reaction buffer and that optimal enzyme concentration must be determined.*

12. Incubate ~30 μ g vector DNA with the defined amount of the appropriate enzyme at 37°C for 15 min.
13. Add 1 U calf intestine AP and continue incubating at 37°C for 1 hr.
14. To stop the reaction, add 0.5 M EDTA to a final concentration of 15 mM, add 10 mg/ml proteinase K to 200 μ g/ml final, and incubate at 37°C for 1 hr.
15. To inactivate proteinase K, add 100 mM PMSF solution to 2 mM final and incubate at room temperature for 1 hr.

Perform PFGE

16. During step 15, clean a 1.5-mm-thick electrophoresis comb with 95% ethanol and cover teeth with autoclave tape to create a large preparative slot with sufficient space to load the reaction mixture. Leave enough empty wells for a 1-kb ladder or lambda-*Hind*III markers on both sides and at least one empty well between the markers and the preparative slot.
17. Prepare a 1% agarose gel in a CHEF mold using the preparative comb. While the gel is solidifying, add 2 liters of 0.5 \times TBE buffer to the CHEF apparatus tank and equilibrate the unit at 14°C.
18. Place the gel in the precooled unit. Add 6 \times gel loading buffer to the samples (final 1 \times) and load samples in the large preparative well. Load 1-kb ladder or lambda *Hind*III markers in both side wells. Perform electrophoresis at 14°C and 6 V/cm for 16 hr with 0.1 to 40 sec pulse time at 120° angle.

Use of xylene cyanol FF in the gel loading buffer is not recommended because this dye migrates with the vector band under these electrophoresis conditions.

Recover vector DNA

19. Cut away two flanking gel slices that contain the markers as well as 1 to 2 mm from each side of the central vector lane. Wrap the remaining middle portion of the preparative lane in plastic wrap and store at 4°C.
20. Stain the flanking slices with ethidium bromide to detect the major vector fragment.

21. Cut linear vector DNA lacking the pUC-stuffer fragment from the central lane and recover by electroelution (see Support Protocol 4, steps 38 to 46).
22. Load sample into $\frac{3}{4}$ -in.-diameter dialysis tubing with a 12,000- to 14,000-Da mol. wt. exclusion limit, and dialyze once against 1 liter TE buffer at 4°C for >2 hr.
23. Recover solution from the dialysis tubing and precipitate DNA with sodium acetate and either ethanol or isopropanol (*UNIT 2.1A*). Dissolve DNA in 100 μ l TE buffer.

Check efficiency of dephosphorylation

24. Place four microcentrifuge tubes on ice and number them 1 to 4. Add 4 μ l of 5 \times T4 DNA ligase buffer and 50 ng of digested and AP-treated vector DNA into the tubes, and adjust the volume to 20 μ l with sterile distilled and deionized water.
25. Add 1 U T4 polynucleotide kinase to tubes 3 and 4. Incubate all four tubes at 37°C for 1 hr.

T4 polynucleotide kinase will be active in 1 \times ligase buffer.

26. Heat at 65°C for 20 min, then place on ice to inactivate the enzyme.
27. Add 1 U T4 DNA ligase to tubes 2 and 4. Incubate all four tubes at 16°C for >4 hr.
Thus, tube 1 contains no enzyme, tube 2 contains T4 DNA ligase, tube 3 contains T4 polynucleotide kinase, and tube 4 contains T4 polynucleotide kinase and T4 DNA ligase.
28. Run samples in a 0.7% agarose gel, stain the gel with ethidium bromide, and view.
Closed circular DNA should not be seen in samples 1, 2, and 3. Sample 4 should have closed circular DNA but no linear DNA.
29. Perform a ligation using all the remaining vector DNA solution in a 200- μ l reaction volume with 4 U T4 DNA ligase.
30. Purify the linear monomeric vector DNA away from the background of ligated vector by PFGE in a CHEF apparatus (see steps 16 through 23).

Check ratio of background clones

31. Perform test ligations using vector DNA alone (25 ng pBACe3.6, 50 ng PAC vectors) and vector plus 50 ng control DNA (see Basic Protocol, steps 1 to 5).
32. Dialyze against water and 30% PEG 8000, and perform transformation as described (see Basic Protocol, steps 6 to 16).
33. Spread transformed cells on LB plates containing 5% sucrose and either kanamycin or chloramphenicol, as appropriate. Grow overnight at 37°C.

Kanamycin/sucrose and chloramphenicol/sucrose plates are used to determine the level of recombinant clones and nonrecombinant clones. If the number of colonies obtained from vector DNA alone is high (>100), vector must be prepared again, beginning with enzyme titration (step 10). If the plasmid is isolated from these background clones and analyzed by PFGE after NotI digestion, smaller vector sizes will be observed. Presumably, star activity causes nonspecific digestion in the sacB gene (either promoter or coding sequence), thus inactivating the gene, and the nonspecifically digested, nondephosphorylated DNA is circularized by self-ligation. Thus, these colonies can grow on sucrose plates without insert DNA.

34. To examine the complete removal of stuffer fragment from the vector, spread the transformed cells with self-ligated vector on LB plates containing 5% sucrose, 100 μ g/ml ampicillin, and either kanamycin or chloramphenicol, as appropriate. Grow overnight at 37°C.

Kanamycin/ampicillin/sucrose and chloramphenicol/ampicillin/sucrose plates are used to determine the remaining level of undigested vector containing the pUC-link. Ideally, there should be zero Amp^R colonies.

PREPARATION OF HIGH-MOLECULAR-WEIGHT DNA FROM LYMPHOCYTES IN AGAROSE BLOCKS

Construction of a total genomic library demands that some consideration be given to the source of DNA to be used. Although DNA from cultured cell lines has been extensively used in constructing cosmid libraries, it is well known that passage in tissue culture may result in chromosomal rearrangements; therefore, it is considered more desirable to use DNA obtained directly from human or animal sources. A convenient source of DNA for this purpose is whole blood, and more specifically, the circulating lymphocytes. Assuming an average of $\sim 5 \times 10^6$ lymphocytes per milliliter of blood and 6 pg DNA per cell, as much as 30 μ g DNA can be recovered per ml of blood, making it a very convenient and inexpensive source of DNA. This method depends on preferential lysis of red blood cells (RBC) using a gentle procedure that does not affect lymphocytes. The method can be applied equally well to cultured cells by omitting the RBC-lysis step; however, the cells should be collected as quickly as possible, especially when using attached cells in culture. Other protocols for embedding high-molecular-weight mammalian DNA from tissues (see Support Protocol 3 and UNIT 2.5B) should also produce acceptable results.

Materials

Healthy human volunteer
PBS (APPENDIX 2), ice cold
1 \times RBC lysis solution (see recipe)
InCert agarose (FMC Bioproducts)
Proteinase K lysis solution (see recipe)
TE₅₀ buffer: 10 mM Tris·Cl, pH 8.0 (APPENDIX 2)/50 mM EDTA
0.1 mM PMSF solution: 100 mM PMSF solution (see recipe) diluted 1/1000 in
TE₅₀ buffer immediately before use
0.5 M EDTA, pH 8.0 (APPENDIX 2)
Blood-drawing equipment
Blood collection tubes containing EDTA
Automated hematology counter
50-ml conical screw-cap polypropylene tubes, sterile
Refrigerated centrifuge with rotor/adapters for 50-ml tubes (e.g., Sorvall RI6000D
centrifuge with H-1000B swinging-bucket rotor or equivalent)
Roller mixer (Robbins Scientific or equivalent)
50°C water bath
10 \times 5 \times 1.5-mm disposable DNA plug mold (Bio-Rad)

Collect blood and remove red blood cells

1. Use blood-drawing equipment to obtain 45 ml venous blood from a healthy human volunteer in blood collection tubes containing EDTA. Mix well to avoid clot formation.
2. Count the total number of lymphocytes using an automated hematology counter.
The total number should be 2.25 to 3.3 $\times 10^8$ in 45 ml.
3. Transfer blood to two 50-ml conical screw-cap polypropylene tubes, add 10 ml ice-cold PBS to each, and mix gently.
4. Centrifuge at 1876 $\times g$ for 5 min at 4°C. Discard the supernatant using a 10-ml disposable pipet, being careful not to remove any lymphocytes from the fuzzy coat layer.

Centrifugation results in a large pellet of red blood cells at the bottom of the tube and a very thin layer of lymphocytes (the fuzzy coat layer) at the interface with the plasma layer.

5. Repeat wash with ice-cold PBS ten times.
6. Discard the final supernatant, mix the cell suspension well, and divide into four 50-ml tubes.
7. Add 25 ml of 1× RBC lysis solution to each tube, mix samples gently on a roller mixer, and incubate on mixer ~20 min at room temperature.

During this time, an exchange process catalyzed by carbonic anhydrase results in accumulation of ammonium chloride inside the cells; this accumulation increases the internal osmotic strength and causes swelling and bursting of RBCs. Lymphocytes have much lower carbonic anhydrase activity and do not undergo lysis.

8. Visually monitor the progress of RBC lysis. When it appears complete (usually <30 min), centrifuge the tubes for 10 min at $208 \times g$, 4°C.

When examined against a light source, the suspension originally appears cloudy. The cloudiness will disappear as the red cells lyse. After centrifugation, a pellet of lymphocytes should be obvious at the bottom of each tube.

9. Discard the supernatant by gentle inversion, taking care not to disturb the lymphocyte pellet. Rinse the inside of the tubes with 2 ml ice-cold PBS, being careful not to disturb the pellet. Discard the supernatant with a micropipet tip.
10. Resuspend lymphocytes in 10 ml ice-cold PBS and combine in one 50-ml tube. Centrifuge 5 min at $208 \times g$, 4°C, and discard the supernatant carefully to remove most of the remaining lysate debris.

A variable amount of red cell debris may stay with the pellet.

11. Repeat wash with ice-cold PBS until most of the red color is removed.
12. Resuspend the pellet in ice-cold PBS at 1×10^8 cells/ml (~600 µg DNA/ml).

Embed cells in agarose

13. Dissolve 0.1 g InCert agarose in 10 ml PBS (1%) in a microwave oven and keep at 50° in a water bath.
14. Mix the cell suspension well and transfer 400 µl to a microcentrifuge tube. Warm the tube by hand for 3 min.
15. Add 400 µl of 1% molten InCert agarose and mix gently. Avoid making any bubbles.

The final agarose concentration is 0.5% and the cell concentration is 5×10^7 /ml, equivalent to ~300 µg DNA/ml.

16. Transfer the cell/agarose suspension as quickly as possible to $10 \times 5 \times 1.5$ -mm disposable DNA plug molds using a micropipet tip.

Each mold takes ~80 µl cell/agarose suspension, containing ~25 µg DNA. From 45 ml blood, it is possible to make ~45 plugs.

17. Place the molds on ice for 30 to 60 min to solidify the agarose.

Extract high-molecular-weight DNA

18. Extrude the DNA plugs from the mold directly into a 50-ml tube containing 50 ml proteinase K lysis solution.

The number of DNA plugs per tube should be <50.

- Stand the tube in a 50°C water bath, mix periodically, and incubate for 48 hr. Replace solution with fresh proteinase K lysis solution after the first 24 hr.

Residual amounts of hemoglobin from the RBC lysate remain trapped in the blocks and act as a convenient marker to monitor the digestion process. The residual color disappears within a few hours, but digestion is extended to 48 hr to ensure thorough protein removal.

- Rinse plugs several times with sterile distilled, deionized water.
- Add 50 ml TE₅₀ buffer and mix on a roller mixer at 4°C for 24 hr. Replace the solution with fresh TE₅₀ buffer at least twice during the 24 hr.
- To inactivate proteinase K, wash plugs twice for 2 hr each with 50 ml of 0.1 mM PMSF solution on the roller mixer at 4°C.
- Wash plugs with TE₅₀ buffer on the roller mixer at 4°C for 24 hr. Replace the solution with fresh TE₅₀ buffer at least once during the 24 hr.
- Store DNA plugs in 0.5 M EDTA at 4°C.

The DNA plugs can be stored under these conditions for more than a year.

SUPPORT PROTOCOL 3

PREPARATION OF HIGH-MOLECULAR-WEIGHT DNA FROM ANIMAL TISSUE CELLS IN AGAROSE BLOCKS

Animal tissues are also useful as sources of DNA for library preparation, since it is often difficult to obtain enough lymphocytes from small model organisms (e.g., mice, rats). Here, an alternate method is described for preparation of DNA plugs from animal tissue cells (e.g., spleen, kidney, and brain).

Additional Materials (also see Support Protocol 2)

Healthy animal (e.g., ~5-week-old mice, rats)

Sterile dissecting tools

Sterile Dounce homogenizer

15-ml conical screw-cap polypropylene tubes, sterile (Corning or equivalent)

Counting chambers (VWR)

Additional reagents and equipment for euthanasia with CO₂ (Donavan and Brown, 1995)

- Euthanize mice or rats in a plastic bag or desiccator containing CO₂ gas.
- Immediately dissect animal using sharp sterile scissors, remove desired tissue(s) from the animal, and transfer them to a petri dish on ice.

Spleen, kidney, and brain are all good sources for extraction of high-molecular-weight DNA.

- Rinse tissues with ice-cold PBS and remove fat and other associated tissues with sterile forceps.
- Transfer 1 to 2 spleens, kidneys, or brains to a precooled sterile Dounce homogenizer on ice.

Spleen, kidney, and brain should be homogenized separately.

- Add ~2.5 ml ice-cold PBS into the homogenizer and grind ~5 times on ice.
- Transfer the supernatant carefully from the homogenizer into a chilled 50-ml conical screw-cap polypropylene tube, taking care to leave behind as much tissue as possible.

7. Repeat steps 5 and 6 four times, adding the PBS to the chilled conical tube until most tissue is disrupted.
8. Remove debris from the homogenizer with forceps and repeat steps 4 to 7 for all spleens, kidneys, and brains.
9. Fill all tubes to 50 ml with ice-cold PBS.
10. Stand tubes on ice for 2 to 3 min and carefully transfer supernatants to new 50-ml tubes.

Large tissue debris sinks to the bottom of the old tubes and is removed in this step.

11. Centrifuge at $208 \times g$ (e.g., 1000 rpm in a Sorvall H1000B rotor) for 10 min at 4°C .
12. Discard supernatant by gentle inversion, taking care not to disturb the cell pellet.
13. Add ~ 1 ml ice-cold PBS, resuspend cells by pipetting gently, and remove large debris that cannot be suspended with a micropipet.
14. Fill tubes to 50 ml with ice-cold PBS, mix gently, and repeat centrifugation.
15. Decant the supernatant and resuspend the cells in the residual PBS on ice.
16. Add 1 ml ice-cold PBS and transfer to a 15-ml conical screw-cap polypropylene tube.
17. Rinse the 50-ml tubes with 1 ml ice-cold PBS and add to the 15-ml tubes.
18. Prepare 20 μl of a 20-fold dilution of the cell suspension in a 1.5-ml microcentrifuge tube.
19. Count the number of cells using a counting chamber.

Assume that 40% of the cells counted are red blood cells (erythrocytes), which do not contain chromosomal DNA.

20. Subtract the estimated number of red blood cells, then adjust the concentration of cells that contain chromosomal DNA to 1×10^8 cells/ml by adding ice-cold PBS.

A single cell carries 6 to 10 pg DNA; thus, 1×10^6 cells correspond to 6 to 10 μg DNA.

21. Embed cells in agarose and extract high-molecular-weight DNA (see Support Protocol 2, steps 13 to 24).

PARTIAL DIGESTION AND SIZE FRACTIONATION OF GENOMIC DNA

The PAC vectors utilize *Bam*HI restriction sites for cloning; however, it is not advisable to use *Bam*HI for partial digestion of genomic DNA, because there may be regions of DNA relatively devoid of the *Bam*HI site. Instead, it is preferable to use the four-base cutter *Mbo*I, which produces four-base overhangs that are compatible with the *Bam*HI overhangs on the vector. *Mbo*I sites are expected to occur on average every 256 bases, not taking into account the base composition of the genomic DNA. The sizes of inserts in PAC clones range from 120 to 300 kb, so it is reasonable to expect that it should be possible to generate overlapping clones from most, if not all, areas of the human genome. The pBACe3.6 vector has *Bam*HI and *Eco*RI cutting sites for cloning; therefore, it is possible to use either *Mbo*I or *Eco*RI for partial digestion. Although there are some other restriction sites in the vector, it is not advisable to use them for construction of highly redundant genomic libraries. These restriction sites are more useful for cloning a specific large fragment or region.

SUPPORT PROTOCOL 4

Construction of Recombinant DNA Libraries

5.9.15

In the following protocol, genomic DNA in agarose plugs (see Support Protocols 2 and 3) is partially digested using *Mbo*I or *Eco*RI. The *Mbo*I partial digestion is accomplished by allowing the enzyme to diffuse into the gel in the absence of MgCl₂, then allowing 10 mM MgCl₂ to diffuse into the gel at 4°C, and finally initiating digestion by transferring the plugs to 37°C. The concentration of enzyme and the length of incubation determine the degree of digestion. On the other hand, competition of *Eco*RI restriction enzyme and *Eco*RI methylase accomplish the *Eco*RI partial digestion. Both enzymes are permitted to diffuse into the gel simultaneously, and the degree of digestion is determined by the concentration of both enzymes. Alternative procedures for controlling *Mbo*I partial digestion (e.g., limiting Mg²⁺ concentration or *Mbo*I/dam methylase competition) may also be used; however, dam methylase is relatively expensive. After partial digestion is completed, the DNA is size fractionated by pulsed-field gel electrophoresis (PFGE; also see UNIT 2.5B) in high-melting-point agarose rather than low-melting-point agarose. The DNA is isolated from the appropriate gel slices by electroelution. Approximately 300 μl of a 2 to 20 ng/μl solution of size-fractionated DNA is obtained. The procedure must be performed multiple times to generate enough DNA for the construction of a library.

Materials

Agarose plugs with embedded high-molecular-weight genomic DNA stored in 0.5 M EDTA (see Support Protocols 2 and 3)
0.5× TBE buffer (APPENDIX 2), sterile
95% (v/v) ethanol
1% (w/v) ultrapure agarose gel (Life Technologies) in 0.5× TBE buffer
Low-range PFG markers in agarose containing a mixture of lambda *Hind*III fragments and lambda concatemers (New England Biolabs)
0.5 M EDTA, pH 8.0 (APPENDIX 2)
0.5 μg/ml ethidium bromide solution in 0.5× TBE buffer (APPENDIX 2)
1× *Mbo*I buffer (see recipe)
10 U/μl *Mbo*I restriction endonuclease (Life Technologies)
1 M MgCl₂
10 mg/ml proteinase K (Boehringer Mannheim) stock solution
10% (w/v) *N*-lauroylsarcosine
TE₅₀ buffer: 10 mM Tris·Cl, pH 8.0 (APPENDIX 2)/50 mM EDTA
100 mM PMSF solution (see recipe)
10 mg/ml BSA (New England Biolabs)
10× *Eco*RI endonuclease/methylase buffer (see recipe)
0.1 M spermidine
20 U/μl *Eco*RI endonuclease (New England Biolabs)
40 U/μl *Eco*RI methylase (New England Biolabs)
TE buffer, pH 8.0 (APPENDIX 2)
1× TAE buffer (APPENDIX 2; optional)
Lambda DNA
50-ml conical screw-cap polypropylene tubes, sterile
Contour-clamped homogeneous electrical field (CHEF) apparatus (Bio-Rad or equivalent; UNIT 2.5B) with 1.5-mm-thick, 20-well comb
Digital imager (Alpha Innotech IS1000 or equivalent)
Disposable γ-ray-sterilized inoculating loops
15-ml conical screw-cap polypropylene tubes, sterile
Dialysis tubing, 3/4-in. diameter, mol. wt. exclusion limit 12,000 to 14,000 daltons (Life Technologies or equivalent)
Dialysis clips

Submarine gel electrophoresis apparatus (Bio-Rad Sub-Cell GT DNA Electrophoresis Cell, 31-cm length × 16-cm width, or equivalent)

Wide-bore pipet tips

Additional reagents and equipment for analytical pulsed-field gel electrophoresis
(UNIT 2.5B)

CAUTION: To prevent shearing, use sterile wide-bore pipet tips in all steps involving the handling of genomic DNA.

Pre-electrophoresis DNA plugs

1. Remove six agarose plugs with embedded genomic DNA from 0.5 M EDTA and transfer the DNA plugs to a 50-ml conical screw-cap polypropylene tube containing 50 ml sterile 0.5× TBE buffer.
2. Dialyze the plugs against 0.5× TBE buffer at 4°C for ≥3 hr.
3. Clean a 1.5-mm-thick comb with 95% ethanol and cover teeth with autoclave tape to create a large preparative slot with sufficient space to place the DNA plugs. Leave enough empty wells for PFG markers on both sides and at least one empty well between the markers and the preparative slot.
4. Place the preparative comb along the short axis of a CHEF mold and prepare a 1% agarose gel of sufficient thickness to cover the sample gel blocks when laid along their length. While the gel is solidifying, add 2 liters of 0.5× TBE buffer to the CHEF apparatus tank and equilibrate the unit at 14°C.
5. Remove the comb gently and load the plugs in the large preparative slot. Load low-range PFG markers in the outer lanes on each side of the preparative lane.

Do not seal the wells with 1% agarose.

6. Place the gel in the precooled unit and run the gel along the long axis using 0.5× TBE buffer at 14°C and 4 V/cm for 10 hr with a 5-sec pulse time.

This step removes inhibitors and results in a more homogeneous partial digestion.

7. Remove the plugs from the preparative slot and place in 50 ml TE buffer and store at 4°C for short periods (up to 2 weeks). If needed, change storage solution to 0.5 M EDTA, pH 8.0.

To avoid DNA deterioration from nuclease, it is advisable to store the plugs in 0.5 M EDTA for longer periods. The DNA plugs can be stored in EDTA for >1 year.

8. Stain the gel in 0.5 µg/ml ethidium bromide solution and examine on a digital imager.

The embedded chromosomal DNA cannot migrate out of the agarose plug under these electrophoresis conditions. However, sheared DNA would be seen on the gel. Thus, it is possible to check the quality of the DNA plug.

Partially digest DNA

For MboI:

- 9a. Transfer pre-electrophoresed DNA plugs into 50 ml 1× *MboI* buffer and continue dialysis at 4°C overnight.
- 10a. Cut a DNA plug into four pieces, and transfer each piece into separate microcentrifuge tubes with a disposable γ-ray-sterilized inoculating loop.

- 11a. Add 400 μ l of 1 \times *Mbo*I buffer and 2.5 U *Mbo*I (diluted with 10 mM Tris·Cl, pH 8.0, just before use) to each tube. Keep the plugs on ice for 1 hr.
- 12a. Add 5 μ l of 1 M MgCl₂ to each tube and stand the tubes on ice for 15 min.
- 13a. Incubate the tubes for 20 to 40 min at 37°C. Test for optimal partial digestion by using various incubation times or amounts of enzyme in step 11a.
- 14a. Immediately place the tubes on ice and add 150 μ l of 0.5 M EDTA, 30 μ l of 10 mg/ml proteinase K, and 75 μ l of 10% *N*-lauroylsarcosine. Mix well and incubate at 37°C for 1 hr to inactivate *Mbo*I.
- 15a. Pour the solution and plugs to a petri dish and remove the solution with a micropipettor.
- 16a. Rinse plugs with TE buffer. Transfer plugs to a 15-ml conical screw-cap polypropylene tube using a disposable γ -ray-sterilized inoculating loop.
- 17a. Add 15 ml TE₅₀ buffer and 15 μ l of 100 mM PMSF solution and dialyze three times for 20 min each at 4°C.
- 18a. Dialyze twice for 30 min each with TE₅₀ buffer at 4°C. Proceed to step 19.

For EcoRI and EcoRI methylase:

- 9b. Transfer pre-electrophoresed DNA plugs into separate microcentrifuge tubes using a disposable γ -ray-sterilized inoculating loop.
- 10b. Add 25 μ l of 10 mg/ml BSA, 50 μ l of 10 \times *Eco*RI endonuclease/methylase buffer, and 13 μ l of 0.1 M spermidine and mix well.

The magnesium concentration is a critical parameter. EcoRI methylase retains only 50% activity in 4 mM Mg²⁺ and EcoRI endonuclease may not work well below 2 mM Mg²⁺. The commercial EcoRI methylase buffer does not contain Mg²⁺ and thus cannot be used for this reaction.

- 11b. Test for optimal partial digestion by varying 1 to 2 U *Eco*RI endonuclease and 0 to 200 U *Eco*RI methylase. Adjust the volume to 500 μ l with sterile distilled deionized water, and put the tubes on ice for 1 hr to allow the enzymes to penetrate into the plugs.
- 12b. Incubate the tubes at 37°C for 2.5 hr and then put on ice.
- 13b. Add 150 μ l of 0.5 M EDTA, 30 μ l of 10 mg/ml proteinase K, and 75 μ l of 10% *N*-lauroylsarcosine and mix well. Incubate the samples at 37°C for 1 hr.
- 14b. Wash plugs with TE₅₀ buffer and PMSF as described (steps 15a to 18a) and then proceed to step 19.

Analyze partial digestion results and optimize conditions

19. Determine the optimal partial digestion condition using a CHEF apparatus. Use the same conditions as in the Basic Protocol step 22.
20. Perform the same experiment using the optimal partial digestion conditions from steps 9 to 18. Use two entire plugs, cut into four pieces, and carry out eight identical partial digestion. Store plugs in TE₅₀ buffer at 4°C until use (up to a month).

Size fractionate DNA by CHEF

21. Clean a 1.5-mm-thick, 20-well comb with 95% ethanol and cover four to six teeth in the middle of the comb with autoclave tape to create a wide tooth for preparative use.

The overall arrangement of cells is seven to eight small wells, a large preparative well, and seven to eight small wells.

22. In a small CHEF gel mold, pour a 1% agarose gel of sufficient thickness to cover the sample gel blocks when laid in along their length. Allow the gel to solidify ~1 hr at room temperature. While the gel is solidifying, pour 2 liters of 0.5× TBE buffer in the CHEF tank and equilibrate the unit at 14°C.
23. Gently remove the comb and array two agarose plugs or eight small agarose pieces in the large preparative slot. Load low-range PFG markers on each side of the preparative lanes, and fill the remaining space in the preparative and marker slots with molten 1% agarose.

There should be two empty wells between the markers and the preparative slots.

24. Size fractionate the DNA by three sequential stages of gel electrophoresis with one exchange of the polarity, as outlined in Figure 5.9.2. In stage 1, orient the gel so that the field forces the DNA to migrate from the wells toward the nearest gel edge (1 cm away from the wells; Fig. 5.9.2). Perform gel electrophoresis at 14°C for 6 hr using 5.0 V/cm, with a 15-sec pulse time at 120° angle in 0.5× TBE buffer.

This is the most important step for successful large insert cloning (see Critical Parameters and Troubleshooting, discussion of size fractionation). It might be necessary to optimize the voltage (4.5 to 5.5 V/cm) depending on the concentration of insert DNA. The insert DNA usually migrates slower than the marker DNA because of its higher concentration. The conditions should be optimized so that fragments <120 kb run out from the gel.

If small-fragment contamination is a problem, due to the very high concentration of DNA, the agarose plugs in the preparative slot can be removed and discarded after this stage of electrophoresis. The preparative slot should then be sealed with 1% molten agarose.

25. Change the electrophoresis buffer.
26. In stage 2, rotate the gel 180° in the tank and use the same electrophoresis conditions to bring all fragments remaining in the gel back to the original starting wells.
27. Apply new marker DNA to flanking wells that were not previously used.
28. In stage 3, resolve high-molecular-weight fragments at 6 V/cm for 16 hr with 0.1 to 40 sec pulse time.
29. Cut the outer lanes containing markers as well as 1 to 2 mm from each side of the preparative lanes to assess the success of the partial digestion. Wrap the remaining portions of the preparative lanes in plastic wrap and store at 4°C.

The lanes containing DNA for cloning must never come into contact with ethidium bromide solution or be exposed to UV light.

30. Stain the outer portions of the gel with ethidium bromide and examine with a fluorescent ruler on a digital imager to ascertain the size ranges.

The stained portion of the preparative lanes of genomic DNA should contain a broad smear extending from ~120 kb to >1 Mb. Most of the smaller fragments (<120 kb) should be run out of the gel during size fractionation.

Prepare size-fraction blocks

31. Slice genomic DNA lanes by cutting horizontally at 0.5-cm intervals to obtain size-fraction blocks in the range of 150 to 500 kb.

The lowest cutoff point is normally 4.5 cm below the well.

Figure 5.9.2 Isolation of insert DNA from agarose blocks by PFGE. **(A)** Agarose blocks containing partially digested DNA are applied to the center wells of a 1% agarose gel and low-range PFG markers are applied to flanking wells. **(B-D)** Size fractionation is performed in a CHEF apparatus. The DNA separation occurs in three stages, all with pulse directions at a 120° angle. **(B)** The initial direction of the field allows the DNA to migrate from the wells toward the nearest gel edge (1 cm away from the well), using 0.5× TBE at 14°C and 5.0 V/cm for 6 hr with 15-sec pulse time. **(C)** The same conditions are then used after turning the direction of the gel to bring all fragments remaining in the gel back to the original starting wells. **(D)** After the second run, new marker DNA is applied to additional flanking wells that were not previously used. The old markers are useful for checking the electrophoresis condition for the first run by comparing the new markers. The new markers are used to identify the size range after the final electrophoresis. High-molecular-weight fragments are then resolved in the third run, which is performed at 6 V/cm for 16 hr with 0.1- to 40-sec pulse time. After this procedure (not shown), the flanking marker lanes are removed from the gel and stained with ethidium bromide to indicate the location of the size ranges. Gel slices are then cut from the genomic DNA lanes by horizontal cuts at 0.5-cm intervals to obtain gel slices in the range of 150 to 500 kb.

32. Cut an ~1-mm-wide slice from each size-fraction block and store size-fractionated DNA blocks in 0.5 M EDTA at 4°C until use.

If eluting the DNA within a few days, it is possible to store the agarose slice in sterile 0.5× TBE at 4°C and omit the dialysis in step 36.

33. Load 1-mm slices directly into separate wells in 1% agarose gel and perform electrophoresis with 0.5× TBE buffer, using the following conditions in a CHEF apparatus: 120° angle, 6 V/cm for 16 hr with 0.1 to 40 sec pulse time at 14°C to assess the quality and size distribution of the DNA fragments in each block.
34. Stain the remaining gel pieces in 0.5 µg/ml ethidium bromide solution, and assemble the gel pieces on a digital imager. Take a picture with a fluorescent ruler to ascertain the size fractionation and cutoff point.

35. Stain the analytical gel from step 32 in 0.5 $\mu\text{g}/\text{ml}$ ethidium bromide solution and take a picture on the imager. Select one or two fractions from the blocks cut in step 33 that show 150- to 200-kb size range.

The slanted appearance of the DNA from left to right (or right to left) in each lane is a result of the orientation of high- and low-molecular-weight DNA in the 1-mm slice. The 1-mm slices contain higher-molecular-weight DNA at the top edge and lower-molecular-weight DNA at the bottom. As the 1-mm slices are rotated to load into the gel, the higher-molecular-weight DNA is on the left or right side of the lane, depending on which side of block the slice is taken from and which direction it is rotated.

36. Dialyze the selected size-fraction blocks against 15 ml sterile 0.5 \times TBE buffer for 3 hr.

If the sliced agarose block was stored in sterile 0.5 \times TBE buffer at step 32, omit this step.

Recover size-fractionated DNA by electroelution

37. Cut an \sim 10-cm-long piece of dialysis tubing and rinse it with sterile distilled deionized water. Close one end of the dialysis tubing with a dialysis clip and remove the residual water completely.

Use one piece of dialysis tubing per fraction block.

38. Place the fraction block and 300 μl sterile 0.5 \times TBE buffer in the dialysis tubing.
39. Completely remove air bubbles and seal the other end of the tubing with a clip. Orient the long axis of the gel parallel to the tubing.
40. Prepare 0.5 \times TBE buffer in a submarine gel electrophoresis tank and immerse the bag in a shallow layer of the 0.5 \times TBE. Place a plastic cover on the top of the clip to keep it down.

Additional dialysis bags can be electroeluted simultaneously.

41. Pass electric current through the dialysis bag(s) with 3 V/cm (100 V for the Sub-Cell GT DNA Electrophoresis Cell) for 3 hr.
42. Reverse the polarity of the current for 30 sec to release the DNA from the wall of the bag.
43. Transfer the bag (still containing the agarose block) to 1 liter TE buffer and dialyze at 4 $^{\circ}\text{C}$ for \geq 2 hr.

It is important to remove borate ions completely in this step, as they may inhibit the ligation reaction.

44. Open the bag and carefully transfer all of the solution to a fresh microcentrifuge tube using a wide-bore pipet tip.
45. Load 3 to 5 μl DNA into a 0.7% to 1.0% agarose gel in 0.5 \times TBE or 1 \times TAE buffer and perform electrophoresis with various amounts (5 to 50 ng) of lambda DNA. Estimate the DNA concentration using lambda DNA as a standard. Keep the eluted DNA at 4 $^{\circ}\text{C}$.

The partially digested genomic DNA fractions are ready to test in ligation reactions (see Basic Protocol). Use the eluted DNA within 10 days to prevent DNA deterioration and do not freeze the solution. The DNA concentration would be 2 to 20 ng/ μl in \sim 300 μl .

**MODIFIED ALKALINE LYSIS MINIPREP FOR RECOVERY OF DNA FROM
BAC/PAC CLONES**

It has been repeatedly observed that the standard alkaline lysis miniprep procedure gives a very low yield of plasmid DNA from BAC and PAC clones with large inserts. This procedure has thus been modified to improve yield. The most crucial factor appears to be increasing the dilution during lysis. Under the conditions described here, the yield of plasmid DNA is almost quantitative for clones with insert sizes ≤ 100 kb. The yield appears to be reduced for much larger clones, due either to trapping and loss in the debris or to the greater susceptibility to shearing. Clones with insert sizes ≤ 380 kb have been recovered in good yield with this protocol. This protocol yields DNA of sufficient quality for restriction endonuclease digestion and PCR analysis. Further purification may be necessary for other applications.

Materials

- BAC or PAC clones (see Basic Protocol)
- LB medium or terrific broth (*UNIT 1.1*) containing 25 $\mu\text{g/ml}$ kanamycin (for PAC clones) or 20 $\mu\text{g/ml}$ chloramphenicol (for BAC clones)
- Resuspension solution (see recipe)
- Alkaline lysis solution (see recipe)
- Precipitation solution (see recipe)
- Isopropanol
- 70% (v/v) ethanol
- TE buffer, pH 8.0 (*APPENDIX 2*)
- NotI* restriction endonuclease and buffer (New England Biolabs)
- Toothpicks, sterile
- 12- to 15-ml snap-cap polypropylene tubes
- Forceps, sterile
- Orbital shaker, 37°C
- 1.5-ml microcentrifuge tubes or 2-ml screw-cap tubes
- Additional reagents and equipment for agarose gel electrophoresis (*UNIT 2.5A*)

Culture PAC or BAC clones

1. Using a sterile toothpick, inoculate a single isolated BAC or PAC clone into 2 ml LB medium or terrific broth containing either 25 $\mu\text{g/ml}$ kanamycin (PAC) or 20 $\mu\text{g/ml}$ chloramphenicol (BAC) in a 12- to 15-ml snap-cap polypropylene tube. Remove toothpick using sterile forceps. Grow overnight (≤ 16 hr) at 37°C in an orbital shaker at 200 rpm.
2. Remove snap cap from the tube and centrifuge 5 min at $1600 \times g$.

The temperature of this centrifugation is not critical.

Lyse cells

3. Discard supernatant and resuspend (vortex) pellet in 0.3 ml resuspension solution.
4. Add 0.3 ml alkaline lysis solution and gently shake tube to mix contents. Let stand at room temperature ~ 5 min.

The appearance of the suspension should change from very turbid to almost translucent.

5. While gently shaking, slowly add 0.3 ml precipitation solution. Stand tube on ice ≥ 5 min.

A thick white precipitate of protein and E. coli DNA will form.

6. Centrifuge 15 min at $16,000 \times g$, 4°C , to remove the white precipitate.

Recover plasmid DNA

7. Remove tube from centrifuge and place on ice. Using a micropipettor or disposable pipet, transfer supernatant to a 1.5-ml microcentrifuge tube containing 0.8 ml isopropanol. Mix by inverting a few times. Stand on ice ≥ 5 min.

Avoid transferring any of the white precipitate.

At this stage, samples can be stored overnight at -20°C .

8. Centrifuge 15 min at maximum speed in a microcentrifuge.

Temperature is not critical for this centrifugation, but better recovery may be achieved at room temperature.

9. Aspirate as much of the supernatant as possible. Add 0.5 ml of 70% ethanol and invert tube several times to wash the DNA pellet. Centrifuge 5 min at maximum speed, 4°C .

Occasionally, the pellet will become dislodged from the tube, so it is better to carefully aspirate the supernatant using a gel-loading pipet tip rather than pour it off.

10. Aspirate as much of the supernatant as possible. Air dry pellet at room temperature until the pellet becomes translucent.

When pellet changes from white to translucent, most of the ethanol is evaporated.

11. Resuspend in 100 μl TE buffer.

Do not use a narrow-bore pipet tip to mechanically resuspend DNA sample. Allow the solution to sit, occasionally tapping the bottom of the tube gently to mix the contents. For large BAC/PAC clones, resuspension may take >1 hr.

12. Use 5 to 10 μl DNA for digestion with 0.1 U *NotI*. Analyze insert size by pulsed-field gel electrophoresis.

*There are *NotI* sites flanking the SP6 and T7 promoter regions of the vectors; therefore, this is a very useful enzyme for analyzing insert size.*

*Use 18 μl DNA for digestion with more frequent-cutting enzymes such as *BamHI* or *EcoRI*.*

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Alkaline lysis solution

0.2 N NaOH

1% (w/v) SDS

Prepare before use

***EcoRI* endonuclease/methylase buffer, $10\times$**

100 μl 32 mM *S*-adenosylmethionine (New England Biolabs; final 0.8 mM)

80 μl 1 M MgCl_2 (final 20 mM)

800 μl 5 M NaCl (final 1 M)

2 ml 1 M Tris-Cl, pH 7.5 (APPENDIX 2; final 0.5 M)

40 μl 1 M dithiothreitol (DTT; final 10 mM)

980 μl sterile H_2O (total volume 4 ml)

Store up to 1 year at -80°C in small aliquots (0.21 ml)

Mbol buffer, 10× and 1×

For 10× buffer: Prepare 100 mM Tris·Cl, pH 8.0 (APPENDIX 2), containing 1 M NaCl and store up to 1 year at room temperature.

For 1× buffer: Dilute 1 part 10× buffer in 9 parts water and add 10 mM 2-mercaptoethanol. Prepare immediately before use.

Phenylmethylsulfonyl fluoride (PMSF) solution, 100 mM

Prepare a 100 mM stock solution in isopropanol and store up to 1 year at −20°C. Mix well by vortexing and dilute as appropriate immediately before use.

CAUTION: PMSF is hazardous. See APPENDIX 1H for guidelines on handling, storage, and disposal.

Precipitation solution

3 M potassium acetate, pH 5.5

Autoclave

Store indefinitely at 4°C

Proteinase K lysis solution

10 ml filtered 10% *N*-lauroylsarcosine (sodium salt; Sigma; final 2%)

40 ml 0.5 M EDTA, pH 8.0 (APPENDIX 2; final 0.4 M)

100 mg proteinase K (Boehringer Mannheim; final 2 mg/ml)

Prepare fresh and use immediately after adding proteinase K

RBC lysis solution, 10×, 1×

9.54 g NH₄Cl (1.78 M final)

0.237 g NH₄HCO₃ (0.03 M final)

Dissolve in 100 ml

Sterilize using 0.2-μm filter

Store up to 1 month at 4°C in a tightly closed container. Dilute to 1× concentration with sterile distilled deionized water before use.

Resuspension solution

15 mM Tris·Cl, pH 8.0 (APPENDIX 2)

10 mM EDTA

100 mg/ml DNase-free RNase A (UNIT 3.13)

Sterilize using a 0.2 μm filter

Store up to 6 months at 4°C

T4 DNA ligase buffer, 5×

2 M Tris·Cl, pH 7.6 (APPENDIX 2)

50 mM MgCl₂ (APPENDIX 2)

5 mM ATP

5 mM dithiothreitol (DTT; APPENDIX 2)

25% (w/v) polyethylene glycol 8000 (PEG 8000)

Store up to 1 year at −20°C

COMMENTARY**Background Information****Large-insert cloning**

Large-insert clones are of particular importance for preparing long-range physical maps consisting of clusters of contiguous clones (contigs). In this respect, YAC clones filled a

vital role in the beginning of various initiatives for the mapping of very complex genomes, such as that of humans. In recent years, it has become increasingly important to have clones available that represent the genome in a contiguous and nonrearranged format with better fidelity than YAC clones, that exhibit fewer

stability problems and fewer cloning artifacts. This has become important for two reasons: to have good intermediates for shotgun sequencing of large genomic regions and to have clones containing unaltered complete genes for functional analysis. In addition, much lower levels of cloning artifacts should facilitate positional cloning efforts, because the clones can be used without much verification for exon trapping, for hybrid selection, and for other gene-hunting procedures.

In view of these considerations, there has been an effort in various laboratories to develop bacterial plasmids with inserts considerably larger than can be contained in cosmids (35 to 45 kb). An elegant packaging system based on bacteriophage P1 and corresponding vectors was developed by Sternberg and collaborators (Sternberg, 1990; Pierce et al., 1992); however, the size of the bacteriophage particle restricts the maximum insert to ~95 kb, to fit within the total capacity of 110 kb for vector plus insert. A very useful expansion of this work was the cloning system developed by Shizuya et al. (1992), which combined the high transformation efficiencies obtainable by electroporation with a plasmid vector based on the F factor replicon. Insert sizes as large as 300 kb were originally reported; however, most clones have inserts closer to 100 kb in size. Because the F replicon provides for about one copy per cell, like the *Escherichia coli* chromosome, the resulting clones have been designated as bacterial artificial chromosome (BAC) clones. Some useful genomic libraries have been developed for human and mouse (see Chapter 5 introduction), various plant species (Wang et al., 1995; Woo et al., 1994), and hybrid cells (Wang et al., 1994).

The hybrid cloning system developed by Ioannou et al. (1994), which was based on a combination of the original BAC cloning procedures and P1 vectors, was thus designated P1-derived artificial chromosome (PAC) cloning. The PAC system permits generation of large-insert plasmids with insert sizes similar to BACs. In the BAC system, recombinant clones are picked from a mixture of colonies based on screening for recombinant clones using probe hybridization or a blue/white *lacZ*- α color assay. PAC clones are mostly recombinant as a consequence of positive selection for insert-containing clones, which is based on sucrose-sensitivity of clones lacking inserts. All of the procedures for screening and characterizing P1 clones are identical for PACs.

Since the pCYPAC vectors were directly derived from pAd10SacBII, these vectors share many features, including an inducible plasmid copy number and positive selection for inserts. The pCYPAC2 vectors have been used successfully to prepare a 16-fold redundant human PAC library (de Jong et al., unpub. observ.). The first 3.5-fold redundant segment of this library, designated RPCI-1, has been made available to over 40 genome centers, resource centers, and commercial screening companies (see Chapter 5 introduction). To facilitate the use of large-insert bacterial clones for functional studies, the authors have prepared a new PAC vector, designated pPAC4, with a dominant selectable marker gene (blasticidin gene), an EBV replicon, and modification sites (E. Frengen, P.J. de Jong, et al., unpub. observ.). The pPAC4 vector has been applied to generate several libraries, including a four-fold redundant human PAC library with average inserts of 135 kb (P.J. de Jong, et al., unpub. obser.), a 12-fold redundant mouse library (K. Osoegawa et al., unpub. observ.), and a 10-fold redundant rat library (Woon et al., 1998).

A new BAC vector, named pBACe3.6, has been developed at Roswell Park Cancer Institute (RPCI; E. Frengen et al., in press) and has the same system for selecting recombinant clones. BAC clones produced using the pBACe3.6 vector are mostly recombinant as a consequence of positive selection for insert-containing clones, which is based on sucrose-sensitivity of clones lacking inserts instead of using probe hybridization or a blue/white *lacZ*- α color assay. Sucrose is much less expensive than isopropyl- β -D-thiogalactopyranoside (IPTG) and Xgal. Also, it is unnecessary to distinguish recombinant and nonrecombinant clones for colony picking. Although it is possible to distinguish blue and white colonies by a colony-picking machine, the picking error is still high (~15%). From these points of view, it is considered that the pBACe3.6 is superior to the other BAC vectors.

It has been difficult to prepare highly redundant BAC or PAC libraries with average insert sizes larger than 150 kb. A new procedure for preparation of BAC and PAC libraries has been improved at RPCI (Osoegawa et al., 1998). Included in this unit is the improved protocol that enables the generation of highly redundant BAC/PAC libraries with larger and relatively uniform insert sizes. Better vector preparation protocols and improved DNA-sizing procedures minimize the generation of nonrecombinant clones and the number of small-insert

clones. Efficient methods for recovering insert DNA by electroelution and for concentrating ligation products without DNA deterioration result in higher transformation efficiencies. These factors are discussed in greater detail below. The improved methods have been applied at RPCI to prepare PAC and BAC libraries from human, murine, rat, canine, baboon, bovine, feline, silkworm, and fruit fly DNA, with average insert sizes ranging between 160 and 235 kb. It is now possible to construct highly redundant BAC/PAC libraries from various organisms applying this improved approach within a time period of a few months.

Choice of host strains

A critical aspect of any large-insert cloning endeavor is the choice of the host. It is important that inserts be cloned with little bias for sequence content, that most or all sequences be cloneable without artifacts, and that the sequences be maintained without rearrangements. Furthermore, clones should grow well and be easy to maintain or revive after freezing. Finally, the particular host strain(s) should be compatible with the cloning procedures and provide high transformation efficiencies with large-insert DNA ligation products, with minimal bias in favor of smaller inserts. Of course, this is a utopia and none of the available hosts exhibit all of these desirable features; however, it is important to understand why one particular host (DH10B) was selected for construction of PAC (Ioannou et al., 1994) and BAC libraries (Shizuya et al., 1992). This will allow users of this technology to make informed decisions for selecting alternative hosts. Extensive reviews on *E. coli* host strains for cloning have been published elsewhere (Hanahan et al., 1991; Raleigh, 1987; Wyman and Wertman, 1987).

The most important requirement for large-insert libraries is that the recombinant DNA be stable, so that multiple researchers can use the same clones over and over again. This is particularly important for libraries used as a reference resource by the scientific community or used for DNA sequence analysis of large genomic regions. The most important host gene for stabilizing inserts is *recA*. A defective *recA* allele is an absolute requirement for large-insert propagation with minimal chance of rearrangement. The *recA* gene product fulfills a central role in homologous recombination in *E. coli*, and a defective allele appears to stabilize, in particular, direct repeat structures in the insert DNA (Wyman and Wertman, 1987). The DH10B host used for PAC and BAC library

construction carries the stringent *recA1* allele (Hanahan et al., 1991).

Other stabilizing mutations in the host recombination pathways have been reported. In particular, defects in one or more of the *recB*, *recC*, or *recD* genes have been correlated with higher stability of palindromic DNA sequences (Wyman and Wertman, 1987); however, most of these studies have been done in double-mutant strains that are also mutated in *recA*. Such strains usually grow poorly and often accumulate revertants or pseudorevertants that grow better. These revertants have been designated as *sbc* mutants (suppressor of the *recBC* phenotype). A consequence of the reversion of the poor growth phenotype in *recBC* mutants is that some of the stability correlations previously attributed to *recB* or *recC* alleles may actually be the result of *sbc* mutations. Supporting this view, studies by Leach and co-workers (Chalker et al., 1988; Gibson et al., 1992) demonstrated that *sbcC* and *sbcD* mutations can stabilize palindromic DNA sequences irrespective of the *recBC* alleles present. All of the studies correlating the stability of particular DNA sequences with host mutations have been undertaken with earlier vector systems, mostly using the lambda cloning system. Thus, it remains to be demonstrated how these mutations affect the stability of large inserts in low-copy-number plasmid systems based on the P1 or F replicons (PACs or BACs).

Eukaryotic DNA sequences are methylated at the cytosine positions in many CpG dinucleotide sequences. The levels of methylation are highly variable and depend on sequence context and DNA source; therefore, any hosts that preferentially restrict DNA sequences containing 5-methylcytosine will result in a cloning bias with respect to sequence content. In addition, longer inserts will, in general, contain more methylated sequences, thus biasing against establishing larger-insert clones. Several host systems (*mcr*) restricting DNA containing 5-methylcytosine have been reported: *mcrA*, *mcrB*, and *mcrC* (for review, see UNIT 1.4 and Raleigh, 1987). These restriction pathways have different specificity with respect to the sequences flanking the methylated CpG sites (Hanahan et al., 1991). Indeed, mutations in these pathways greatly improve the cloning efficiencies for methylated DNA sequences and improve cloning large DNA inserts in cosmids and P1 clones (UNIT 5.3). With respect to BAC or PAC libraries, it is very likely that cloning success depends on the presence of the *mcr* mutations. The DH10B host contains an *mcrA*

mutation and a deletion of the *mcrBC* genes (Grant et al., 1990). The *mcr* mutations are important only for the initial entry of the foreign DNA sequences into *E. coli*. After propagation in *E. coli*, these sequences will lose their methylation patterns and the *mcr* status of the host becomes irrelevant. Hence, to stabilize an unstable clone, the PAC or BAC DNA can be transferred to any host strain with different recombination deficiencies, irrespective of the *mcr* status.

Large-insert cloning by the PAC or BAC systems requires that the host strain provide good transformation efficiencies for large-insert DNA. Not only should the host be highly electrocompetent, it should also have minimal bias in favor of shorter DNA inserts. The maximum efficiency of transformation for small plasmids is a factor of the genetic background of the host, which is not well understood. Derivatives of the MC1061 strain have, in general, been very good for use in chemical transformation procedures. The DH10B strain has been the best host for electrotransformation of small plasmid DNA molecules. A host mutation (*deoR*) that allows *E. coli* to grow on medium containing inosine as the sole carbon source appears to have a fortuitous effect on plasmid transformation using chemical procedures (Hananan et al., 1991). Small plasmid transformation for pUC and pBR322 was reportedly ~4-fold higher in a *deoR* derivative and ~30-fold higher for a larger 66-kb plasmid. The same *deoR* mutation also appears to have an important impact on cloning success using electroporation procedures, and it is, indeed, part of the DH10B genetic background (Grant et al., 1990).

In view of all previous considerations, DH10B appears to be a good host for general cloning with PAC and BAC vectors; however, a small percentage of PAC and BAC clones are nonetheless unstable in DH10B, and it would be desirable to have a strain available that exhibits increased stability while maintaining the viability and electrotransformation competency of the DH10B host.

Vector elements

The pCYPAC1 and pCYPAC2 vectors (Ioannou et al., 1994) are highly similar to the earlier P1 vector pAd10SacBII. The main differences of the pCYPAC vectors are the absence of the adenovirus-derived stuffer fragments and the presence, at a different location, of removable pUC plasmid sequences. Both pUC and the adenovirus sequences are re-

moved during the construction of recombinant clones. Hence, the differences in recombinant DNA structure disappear during cloning. As a consequence of the different cloning approaches, insert sizes for PACs can exceed the limits imposed on P1 clones by the packaging approach. In addition, as a consequence of the different transformation protocols (electroporation versus packaging and viral particle DNA injection), different host strains are used for P1 clones and PAC clones. In all other aspects, PAC clones can be used identically to P1 clones. Much as with P1 clones, PAC copy number can be enhanced using IPTG to inactivate the *lac* repressor, thus inducing the high-copy-number P1-lytic replicon mode. In the absence of IPTG, the low-copy-number P1-plasmid replicon is used for maintenance of the PAC DNA; however, it is advisable not to add IPTG in culture medium, because the PAC clone is maintained more stably as a single copy than in multiple copies.

The pPAC4 vector has been developed for the purpose of using PACs for functional analysis of genes carried on cloned inserts. Four elements are identical in the pPAC4 and the pCYPAC vectors: the P1 plasmid replicon, the kanamycin resistance gene, the *sacB* gene, and the pUC-link. The IPTG inducible P1 lytic replicon has been removed in this vector. The authors have observed that the quantities of recombinant DNA isolated from PAC clones constructed in the pPAC4 vector are 3- to 4-fold lower compared to yields from pCYPAC-based clones. This is probably because the P1 lytic replicon in the pCYPAC vectors is partly functional (due to a leaky *lac* repressor function), resulting in 3 to 4 copies of PAC clones per cell. In pPAC4-based recombinant molecules, however, the P1 plasmid replicon is the only replicon present, ensuring that the copy number is maintained at one per cell.

The pBACe3.6 vector carries the F plasmid replicon and the chloramphenicol resistance gene from the BAC vector pBAC108L (Shizuya et al., 1992). pBACe3.6, presenting the advantage of positive selection in a relatively small modular vector, is an excellent tool for the construction of the complex libraries needed for large-scale mapping and sequencing. Similar to the PAC vectors, this vector contains a modified pUC19 plasmid located within the *sacB* gene. The pUC-link is flanked by multiple cloning sites, allowing positive selection for recombinants by using any of the restriction enzymes *Bam*HI, *Sac*II, *Eco*RI, *Sac*I, *Mlu*I, or *Nsi*I (Fig. 5.9.1). Support Proto-

col 4 makes use of partial *EcoRI* digestion, controlled by *EcoRI* methylase, in the preparation of insert DNA for cloning in the pBACe3.6 vector.

The attachment site for the Tn7 transposon (Tn7att), which has been introduced into pPAC4 and pBACe3.6 vectors, facilitates highly specific Tn7-based retrofitting of BAC/PAC clones. This allows the engineering of clones—e.g., prior to transfection of BAC/PAC clones into mammalian cells for functional studies. In addition, sequences for linearization of the BAC/PAC clones facilitate large-scale mapping (e.g., optical mapping studies; Schwartz et al., 1993). The specific linearization of BAC/PAC clones can be achieved by the intron-homing endonuclease *PI-SceI*, or conceivably by using linear *loxP* fragments in Cre-mediated recombination with the corresponding *loxP* sites in the vector. Furthermore, the mutant *loxP* site *loxP*⁵¹¹, which recombines inefficiently with the wild-type *loxP* site, will also allow Cre-mediated exchange of the vector modules in selected BAC/PAC clones.

In order to facilitate the use of PAC clones for transfection into mammalian cells, two new genetic elements have been included in the pPAC4 vector. The *bsrr* cassette contains the blasticidin deaminase gene, which is placed in a eukaryotic expression cassette to enable selection of the desired mammalian clones by using the nucleoside antibiotic blasticidin. In addition, the Epstein-Barr virus latent origin of replication, *oriP*, has been included to ensure stable extrachromosomal maintenance of the PAC clones in mammalian cells. Furthermore, the pPAC4 vector has an hCMV-promoter-ATG-*loxP* targeting element that facilitates Cre-mediated integration of the cloned inserts into *loxP* target sites in mammalian chromosomes (Fukushige and Sauer, 1992). In vivo site-specific recombination with a complementary *loxP* site in the mammalian genome, coupled to a truncated promoterless *neo* gene, allows activation of G418 resistance under control of the hCMV promoter and ATG start codon. Thus, the PAC clones have the potential of being transferred either to mammalian cells or to the germ line of mutant mice as a replicon or integrated form in a specific chromosome site, allowing molecular complementation of a mutant phenotype. This would be a useful strategy for the identification of new genes or validation of genes or gene complexes present on the PACs by functional cloning.

The vectors contain ampicillin and kanamycin (the PAC vectors) or chloramphenicol (the pBACe3.6 vector) resistance genes, but in the recombinant clones only kanamycin or chloramphenicol resistance is maintained. Because of the low copy number of the P1 or F plasmid replicon (one copy per cell), including a removable high-copy-number replicon (pUC-link) in the BAC/PAC vectors facilitates obtaining large amounts of vector DNA. Single digestion of the vector with *BamHI* (PAC and BAC vectors) or *EcoRI* (BAC vector) is required to separate the P1 or F plasmid replicon fragment from the smaller stuffer fragment generated from the pUC-link plasmid. Adequate removal of the pUC-link sequences is essential to prevent interference with the library construction. The pUC-link plasmid also serves another role, which is the appropriate disruption of the *sacB* gene to keep strains containing the vector viable. Expression of the *sacB* gene in the presence of sucrose leads to the production of a toxic metabolite of sucrose; however, even in the absence of sucrose, considerable toxicity can be observed when the *sacB* gene is expressed (the probable mechanism is unknown). In recombinant clones, foreign DNA sequences are substituted for the pUC-link sequences. Hence, recombinant clones can be grown on agar plates with kanamycin and sucrose. Under such conditions, noninsert clones generated by direct ligation of the *BamHI* or *EcoRI* ends should not grow.

Another aspect of P1, PAC, and pBACe3.6 vectors is the presence of the *sacB* positive selection system. It has been observed that $\geq 30\%$ higher cloning efficiencies are obtained when sucrose selection is not applied. Even in the absence of sucrose selection, it is possible to obtain PAC libraries containing mostly recombinant clones; however, the number of noninsert clones certainly increases more than the number of recombinant clones, and sucrose selection is thus preferred. Does the increased number of recombinants reflect a cloning bias, which is removed when sucrose is not applied? Yes, many recombinant clones obtained without sucrose selection ($\sim 30\%$ in a particular human PAC library; P.A. Ioannou and P.J. de Jong, unpub. observ.) are sensitive to sucrose. Most likely, such clones are the result of fortuitous *E. coli* promoter-like sequences in the inserted DNA; these promoter-like sequences drive expression of the *sacB* gene. The occurrence in eukaryotic DNA of sequences that can function as promoter elements in bacteria has previously been reported (Gibson et al., 1987).

It is, however, quite unlikely that this bias presents a serious problem for cloning contiguous sections of eukaryotic genomes. It is likely that most promoter-like elements will be too far removed from the vector/insert junction and will, therefore, have no effect on *sacB* expression. Because of the approach used—random shotgun cloning by partial digestion—it is likely that each region has many opportunities to be cloned with different endpoints, and in most cases the promoter-like elements will not interfere. This notion is supported by the observation that it is quite easy to establish PAC contigs over large genomic regions. Gaps appear not to be present above statistical expectations.

Critical Parameters and Troubleshooting

Although BAC and PAC cloning is conceptually easy, there are several parts of the procedure that are critical for success in preparing BAC and PAC libraries.

Genomic DNA preparation

Genomic DNA fragments are generated by partial *Mbo*I or *Eco*RI digestion of DNA embedded in agarose. A pre-electrophoresis step before partial digestion removes inhibitors of the cloning process, which permits more homogeneous partial digestion. Over- or underdigestion of the genomic DNA can greatly affect the subsequent cloning efficiency of large DNA fragments, either by presenting many smaller and better cloneable fragments or by creating concentrations of desirable size fragments too low for efficient cloning.

Vector preparation

It is critical that some of the restriction and dephosphorylation steps for preparing the vector DNA be optimized carefully. The *Bam*HI or *Eco*RI digestion should be done quite carefully and overdigestion should be avoided. If a large fraction of noninsert clones is found upon library construction, then it is very probable that overdigestion with *Bam*HI or *Eco*RI resulted in cutting at a secondary *Bam*HI or *Eco*RI star site. If the alkaline phosphatase treatment is not complete, then the vector can religate between a *Bam*HI site and a *Bam*HI star site, or between an *Eco*RI site and an *Eco*RI star site, resulting in small deletions in the vector and affecting the expression of the *sacB* gene. Deletions around the *Bam*HI or *Eco*RI site thus result in sucrose resistance similar to that observed upon

insertion of foreign sequences into the cloning site. There are two ways to diminish the abundance of such undesirable noninsert clones in enzymatic manipulation: improving dephosphorylation of the restriction site (and restriction star) ends or lowering the level of enzyme in restriction endonuclease digestion. It has often been observed that excessive alkaline phosphatase treatment results in lower yields of desirable ligation products, perhaps through damage to the restriction ends; therefore, it is important to suppress *Bam*HI or *Eco*RI star activity as much as possible. Using minimal levels of *Bam*HI (two or three fold over digestion in optimal *Bam*HI buffer), it is possible to prepare libraries in which $\leq 1\%$ of clones lack inserts. Thus, each step in preparing the vector for cloning requires optimization by titration of restriction enzyme and alkaline phosphatase treatments, such that low nonrecombinant background levels at maximum cloning efficiency are obtained.

An alternative protocol to achieve the removal of deleted, still phosphorylated, vector molecules prior to the ligation step is implemented to circumvent this labor-intensive process. In this procedure, the vector DNA is simultaneously treated with suboptimized restriction enzymes and alkaline phosphatase. Then, vector preparation is accomplished by ligating the restricted, alkaline phosphatase-treated vector DNA and reisolating the majority of the nonligated monomeric vector DNA through pulsed-field gel electrophoresis. The background of ligated DNA is easily removed by exploiting the different mobility of circular and dimeric linear DNA from linear monomeric DNA on pulsed-field gels. The sizing step will also remove most of the nonligated, deleted vector molecules if the deletions are substantial.

Other clones lacking inserts found in the RPCI PAC and BAC libraries contain the complete vector sequence. Such clones are resistant to sucrose because the pUC-link sequences are present between the promoter and *sacB* open reading frame sequences and prevent *sacB* expression. The identity of these colonies can easily be confirmed by their ability to grow on ampicillin. If digestion and dephosphorylation are properly optimized, 0.01% to 0.05% of clones should be expected to be ampicillin resistant. The presence of such background clones has consequences for screening libraries by DNA probe hybridization. If the probes are derived from plasmid clones, these nonrecombinant clones will also frequently hybridize and

may initially mask the true probe-positive clones. If properly recognized, these nonrecombinants can facilitate rather than confuse screening by allowing better alignment between the autoradiograms and the colony patterns. To eliminate possible confusion, each library should be screened initially with a pUC-derived probe to establish the location of all nonrecombinant clones in the arrayed PAC or BAC library. These clones can then be inactivated or their hybridization results can be discounted in subsequent hybridization with different probes.

Size fractionation

Size fractionation of the DNA is the most critical factor affecting successful cloning of large inserts. RPCI human PAC libraries have been prepared using a single sizing procedure for partially digested genomic DNA. These libraries have a rather wide distribution of insert sizes, at or below the fragment size range selected prior to cloning. The average insert sizes are 110 to 120 kb. A paradoxical decrease of average clone insert sizes has been observed when larger fragment sizes were selected for cloning. The sharp decrease in cloning efficiency with increasing fragment size is likely the result of a conglomerate of different factors. It can be hypothesized that smaller-than-selected insert fragments result from contamination of small restriction fragments combined with preferential ligation, a lower transformation efficiency of larger ligation products, and a lower circularization rate for the larger plasmids. In addition, larger fragments are more susceptible to damage (nicks, gaps, or adducts) in the genomic DNA, thus decreasing their cloning success; therefore, it is critical to remove as many small DNA fragments as possible by using a size fractionation step. Small fragments that comigrate with large DNA fragments can be removed more completely by subjecting the DNA to a pseudo-double size fractionation procedure (Osoegawa et al., 1998). The double sizing procedure provides a more uniform insert DNA size than a single sizing procedure. The removal of small fragments and improved integrity of large fragments has made it feasible to routinely generate clone libraries with inserts averaging 160 to 180 kb, or even having inserts in the range of 220 to 280 kb.

Electroelution and electrophoresis buffer

Size-fractionated DNA fragments are recovered by electroelution at improved DNA integ-

riety and with higher recovery efficiency as compared to DNA extraction from gel slices by β -agarase treatment. These observations are consistent with a report by Strong et al. (1997). A further advantage of the electroelution method is the ability to use regular high-melting-point agarose, which facilitates gel handling and exhibits better resolving capabilities than the low-melting-point agarose required for enzyme-based DNA extraction. The TAE buffer system has previously been employed in the electrophoretic separation of partially digested DNA, as borate ions may inhibit the ligation reaction used in the construction of BAC and PAC libraries (Ioannou et al., 1994; Woo et al., 1994; Strong et al., 1997); however, large DNA fragments are optimally resolved on pulsed-field gels in 0.5 \times TBE buffer. Since it is desirable to achieve the best separation possible, 0.5 \times TBE buffer is used and the borate ions are easily removed after electroelution by dialysis against TE prior to ligation.

Concentration of ligation mixture

As described below, another important element is the transformation efficiency for construction of highly redundant libraries from complex genomes. A major limitation with respect to constructing BAC/PAC-based libraries for complex genomes is the number of transformations required to generate the library. For instance, to prepare a 20-fold redundant collection of PAC clones for the human genome, ~10,000 electroporation reactions were performed (P.J. de Jong et al., unpub. data). The laborious aspect of this work and the cost of commercial electrocompetent cells created an incentive to increase the number of colonies generated per electroporation to reduce the number of transformations. Previously, ligation products were dialyzed on a floating dialysis membrane against a low salt buffer to reduce heat development during the subsequent electrical pulse (Ioannou et al., 1994). This usually resulted in a two-fold volume increase of the ligation reaction from 50 μ l to ~100 μ l. The increase is due to the higher osmotic pressure in the ligation buffer, which contains PEG 8000, as compared to the dialysis buffer. The use of 30% PEG 8000 in the dialysate in order to obtain higher concentrations of ligation products allows higher transformation efficiencies, resulting in a 6- to 12-fold reduction in the number of electroporations required to generate a library compared to previous efforts (Osoegawa et al., 1998).

Electroporation

Another critical factor is the efficiency of transformation that can be obtained with a particular batch of DH10B host cells. It is the experience that the procedures to prepare competent host batches described by Hanahan et al. (1991) result in high transformation efficiencies. Nevertheless, it is hard to meet the level of electrocompetency obtained for DH10B by commercial suppliers, such as Life Technologies. It is advisable, therefore, to use commercially available electrocompetent DH10B cells if large libraries from complex genomes need to be constructed. It may be advisable to buy samples of an electrocompetent DH10B cell batch for testing in electroporation of large and small plasmids. If the sample passes the test, then a sufficient number of vials from the same batch should be bought, so that the entire library can be completed with a single batch of competent cells. In order to standardize the testing of such batches, it is good to have a stable mixture of small plasmids (pUC19, with ampicillin resistance) and large plasmids (a selected 150-kb PAC, with kanamycin resistance). The large plasmids degrade during storage in a refrigerator and even more during freezing and thawing procedures. It is thus best to prepare a mixture of the two plasmids and freeze many aliquots at -70°C and utilize each aliquot only once for testing. If the large plasmid degrades, then this will be evident from the change in the relative ratio of ampicillin- versus kanamycin-resistant colonies.

It has been reported by Sheng et al. (1995), and confirmed by the authors of this unit, that lower voltage gradients during electroporation decrease the transformation efficiencies of plasmids; however, the decrease is most significant for small plasmids, thus improving the relative transformation efficiency of large plasmids. As a result, the optimum voltage gradient should be in the range of 9 to 12 kV/cm and not in the higher range recommended by the suppliers of electrocompetent bacteria.

Anticipated Results

Under optimal conditions, one can obtain as many as 1800 transformants per 2 μl dialyzed solution with an average insert size of 160 kb, and as many as 250 transformants per 2 μl at 230 kb for BAC. Due to the low DNA concentrations in the ligation, a typical 10-fold redundant mammalian BAC or PAC library requires anywhere from a few hundred up to 2000 electroporations. Each electroporation should result in 300 to 2000 colonies for fragments in

the 150- to 180-kb range. Control plates generated with ligations lacking genomic DNA typically show less than ten colonies, provided that the vector is prepared well. A sharp dropoff in cloning efficiency for larger fragments (>200 kb) is always observed. This results from at least three factors: (1) DNA fragments and circular ligation products being increasingly more fragile, subject to shearing or nuclease action; (2) a lower efficiency in the formation of circular ligation intermediates; and (3) a dropoff in transformation efficiency of plasmids with increasing size, expressed as a molecular efficiency, and becoming more pronounced when expressed per DNA weight. It is imperative that highly competent bacterial cells are used to ensure that reasonable numbers of clones are obtained per electroporation. As a consequence of the dropoff in cloning efficiency with size, it is difficult to prepare BAC and PAC libraries with insert sizes averaging in 200 to 250 kb, and nearly impossible to construct highly redundant libraries with an average size >250 kb using the presented technology.

Once a provisional BAC or PAC library has been constructed, it is essential to characterize the clones and isolate plasmid DNA. The use of Support Protocol 5 or an automatic plasmid isolation machine (AutoGen 740) will result in ~ 0.5 to 1 μg PAC DNA (170 kb) per 1.5 ml of overnight culture (not induced with IPTG). When the pCYPAC2, pPAC4, or pBACe3.6 vector is used for library construction, two *NotI* sites flank the insert in recombinant plasmids; therefore, most clones should show only two bands when analyzed by PFGE: the vector (at ~ 15.5 kb for pCYPAC2, 16.8 kb for pPAC4, and 8.7 kb for pBACe3.6) and the insert of variable size from clone to clone. Additional bands may be seen if the insert contains internal *NotI* sites. Incomplete digestion usually leads to a very characteristic doublet, where the two bands differ by the size of the vector.

Time Considerations

It takes several days to prepare agarose-embedded high-molecular-weight DNA starting from a blood or animal tissue sample and at least another week for testing various conditions of partial digestion and analyzing the results using pulsed-field gel electrophoresis (weeks 1 and 2). Ligations and transformations take 3 to 5 days, and another 3 to 4 days are required to characterize candidate colonies by pulsed-field gel electrophoresis of *NotI*-restricted plasmids (weeks 2 and 3). If the par-

ticular ligation gives desirable results (good cloning efficiency, low nonrecombinant levels, and large inserts), another week (week 4) should be dedicated to the 200 to 2000 electroportations required for a 10-fold redundant mammalian BAC or PAC library. It is often convenient, perhaps necessary, and possibly desirable to take a break at this point. The arraying of the BAC or PAC libraries can be done at a different time and place, as it requires other facilities. Picking of colonies (e.g., 100,000) will take about one week and will require at least two people to prepare and label microtiter dishes and spread all the cells, provided that there is access to a facility equipped with microtiter plate fillers and a colony-picking robot. Hence, under the most optimal laboratory conditions and with the appropriate skills, a 10-fold redundant mammalian BAC or PAC library can be constructed in 1 to 3 months, requiring at least two people; however, it is more realistic to expect that most of the time will be invested in acquiring the skills and optimizing the various critical parameters. Anytime between 6 months and a year should be dedicated by a single person, who should be able to count on assistance from others from time to time.

AMPLIFICATION OF TRANSFORMED OR PACKAGED LIBRARIES

After libraries are packaged (or transformed) they can be amplified for storage. Amplification of a library involves replicating each clone in the library. This is frequently a worthwhile procedure for genomic or cDNA libraries because the libraries can then be used many times to isolate clones corresponding to different sequences. Procedures for amplifying bacteriophage, cosmid, and plasmid libraries are presented in this section.

Amplification of a Bacteriophage Library

UNIT 5.10

This protocol may be used for genomic DNA or cDNA libraries. A freshly packaged and titered library is adsorbed to log phase plating bacteria. The mixture is then plated at high density and allowed to grow until the plaques are just subconfluent. The phage are eluted from the plate by overnight incubation with phage buffer and the library is titered and stored at both 4°C and -80°C.

BASIC
PROTOCOL

Materials

LB medium containing 0.2% maltose and 10 mM MgSO₄ (UNIT 1.1)

Suitable host (Table 5.10.1)

In vitro packaged phage library (UNITS 5.7 & 5.8)

Top agarose (UNIT 1.1), warmed to 47°C

150-mm H plates (UNIT 1.1), warmed to 37°C

Suspension medium (SM; UNIT 1.11)

Chloroform

Dimethyl sulfoxide (DMSO)

Additional reagents and equipment for titering bacteriophage (UNIT 1.11)

1. Inoculate 250 ml LB medium containing 0.2% maltose and 10 mM MgSO₄ with 2.5 ml of a fresh overnight culture of host bacteria. Shake vigorously 2 to 4 hr at 37°C until the OD₆₀₀ ≅ 0.5.
2. Prepare *E. coli* cells for plating as described in UNIT 1.11.

The integrity of λ phage particles requires the presence of Mg²⁺. Maltose induces the expression of the λ phage receptor. To maximize the complexity of the library, it is important that the number of nonviable cells among the host bacteria be minimized; these represent “dead ends” for phage.

Table 5.10.1 Suitable *Escherichia coli* Host Strains for Amplifying Lambda-Constructed Libraries

Vector	<i>E. coli</i> host	Relevant host genotype
λgt10	C600 <i>hflA</i>	<i>hflA</i>
λgt11	Y1088	<i>SupF</i> , <i>lacI^q</i> (no antibiotics needed)
EMBL 3 or 4	P2392, Q359, NM539	P2 lysogen
Charon 4A	LE392	<i>SupF</i>

3. Shake by hand and then briefly microcentrifuge the tube containing the library to separate out the chloroform in the packaged library. Add the packaged, titered phage (but no chloroform) to plating bacteria, using 0.25 ml of host cells for every 1×10^5 phage. Incubate 15 min at 37°C to allow phage to adsorb to bacteria.
4. Add 0.5 ml of the host/phage mixture to 8 ml of 47°C top agarose, mix by inverting a few times, and pour onto a fresh 150-mm H plate, warmed to 37°C. Use as many plates as necessary to plate the entire mixture. Spread the top agarose by gently rotating the plate on the benchtop, and allow the agarose to harden for 5 min. Invert and incubate 6 to 7 hr at 37°C (39° to 41°C for λ gt11 libraries amplified in Y1088).

A myriad of tiny plaques should barely be visible at ~4 to 5 hr. These should expand and be just less than confluent at 6 hr. If the plaques are growing slowly, continue the incubation for up to 8 hr.

5. Remove plates from incubator, cover each lawn with 10 ml SM, and place on a level surface at 4°C for 2 to 16 hr to elute the phage.
6. Using a pipet, combine the SM from all plates into a single glass or polypropylene tube. Centrifuge 5 min at 3000 rpm (2800 \times g) and transfer the supernatant to a new tube. Add 0.5 ml chloroform and mix by inverting several times. Titer the amplified library as described in UNIT 1.11. Expect a titer of 10^{10} to 10^{11} /ml.

The volume of SM recovered from each plate will be nearly 1 ml less than what was added. If the plates were not fresh, greater losses of volume will occur. The total volume of the library will, of course, depend on the number of plates used in the amplification and may approach 100 ml in the case of large libraries.

7. Store the library at 4°C in Teflon-capped glass tubes with 0.5 ml chloroform. The library is stable in this form for years. (Storage in plastic results in a 100- to 1000-fold drop in titer.) For added security, transfer 930 μ l-aliquots of amplified library (no chloroform) to screw-cap microcentrifuge tubes, add 70 μ l of DMSO (final concentration 7%), mix thoroughly by inverting several times, and place at -80°C.

COMMENTARY

Background Information

Amplification is not essential to the successful creation and screening of a λ phage library; however, an unamplified library must be used right away and the number of times the library may be screened is limited by the life of the nitrocellulose filters or the primary plates which dry out in a few weeks to a month. In contrast, amplification allows the library to be stored nearly indefinitely and to be screened as many times as necessary. The principle of amplification is to allow each in vitro packaged phage to produce thousands of identical clones by a limited infection of a host. A potential disadvantage is that the composition of the library may change as a consequence of differences in growth rate during the amplification step, some clones being overrepresented compared to the corresponding mRNA abundance in the total cellular mRNA and others being underrepresented. The preadsorption of the li-

brary to the bacteria, the high plating density, and the relatively short incubation period all help minimize changes in the composition.

An alternative approach used by some is amplification in liquid culture. This method is not recommended, since rapidly growing phage are overrepresented to a greater degree than when plates are used. Furthermore, there are more steps involved, since the phage must be purified from the relatively large volume by PEG precipitation and CsCl-gradient centrifugation.

Critical Parameters

Amplification should be carried out as soon as possible after the library is packaged. Phage particles stored in the in vitro packaging mixture are unstable because the phage particles adsorb to bacterial debris in the mixture and are inactivated. A decrease in titer at this point decreases the complexity of the library. Fresh,

log-phase host cells are important to ensure that each phage infects a viable cell and makes a phage burst and thus is successfully amplified. A phage that injects its DNA into a dead cell is lost from the library.

For libraries constructed in vectors such as λ gt10 or the EMBL series, which allow selection for recombinants, amplification should be done under selective conditions since this eliminates nonrecombinants. Subsequent platings of the amplified library may be done on either selective or nonselective hosts. The titer of a library stored as described in the basic protocol will usually drop only 2- to 3-fold over the years. If stored in plastic, then the titer may drop as much as 100- to 1000-fold.

Troubleshooting

The only difficulties that can occur here are a failure of the phage to infect the host or a failure of the host to grow. This may be avoided if the plates, media, and host strain are first tested with nonrecombinant phage prior to amplifying the library. Causes of problems include top agarose that is too hot, incorrect host strain, incorrect plates, incorrect incubator temperature, and so forth. Losing a library because a tube was dropped or contaminated may be avoided by splitting the packaged ligation into two tubes and amplifying in duplicate. A library stored over chloroform at 4°C may occasionally drop in titer due to fungal contamination

that occurred during the elution of the plates. Storing the library in several tubes and freezing aliquots will circumvent loss of library due to this problem.

Anticipated Results

The titer of an amplified phage library will be in the range of $1-10 \times 10^{10}$ pfu/ml. The volume obtained will depend on the number of plates used, which in turn depends on the initial complexity of the library. For example, a library initially containing 2×10^6 clones in 1.5 ml requires ten 150-mm plates, so ~100 ml of SM will be recovered in total. Thus, the library will have been amplified by a factor of roughly 10^5 .

Time Considerations

After in vitro packaging, the library is stored overnight at 4°C while a titer plate is incubating. The library should be amplified the next day by starting step 1 early in the day. The plaques should develop in 6 to 10 hr. Suspension medium is added and the plates elute overnight at 4°C. Alternatively, step 1 may be started in the late afternoon and the plates grown overnight for 7 hr.

Amplification of Cosmid and Plasmid Libraries

UNIT 5.11

Bacteria containing the recombinant clones are grown on agar plates, washed off the plates, and stored in glycerol. This procedure produces about a million-fold amplification of the library.

**BASIC
PROTOCOL**

Materials

LB plates containing appropriate antibiotic (UNIT 1.1)

LB medium (UNIT 1.1)

Sterile glycerol

Nitrocellulose membrane filters (Millipore HATF)

Sterile rubber policeman

1. Plate drug-resistant bacteria on nitrocellulose filters that have been placed on LB plates (containing antibiotic to which the colonies are resistant), as described in UNIT 6.2.

The filters are used so that the colonies remain small and do not grow together. Be sure to use commercially available triton-free filters to ensure bacterial growth.

2. Grow bacteria until colonies are just confluent.
3. Flood each plate with LB medium. Use ~2 ml/10-cm plate and 4 ml/15-cm plate.
4. Using a sterile rubber policeman, rub colonies off from nitrocellulose filter, making a bacterial suspension.
5. Pool the suspensions from the different plates into one 50-ml plastic tube.
6. Add sterile glycerol to give a final glycerol concentration of 15%.
7. Mix the solution thoroughly and dispense 500 μ l into 1-ml tubes.
8. Freeze the aliquots of the library at -70°C . They should remain viable without appreciable loss of bacteria for over 1 year.
9. To screen the library, simply thaw an aliquot, titer the bacteria concentration (UNIT 1.3), and plate the appropriate numbers of cosmid- or plasmid-containing bacteria on the screening filters.

COMMENTARY

Background Information

Amplification of phage libraries is an established procedure, but the effective amplification of plasmid and especially cosmid libraries has proven to be more difficult. The major concern in amplifying a plasmid or cosmid library is that the doubling times of bacteria are often altered, depending upon the type of insert included within the plasmid or cosmid vector. This disproportionate growth of recombinant bacteria can easily be visualized by plating out a portion of a library and noting the variable colony size after 16 hr at 37°C . However, there is ample incentive to amplify the library. The advantages of obtaining thousands of copies of a cosmid or plasmid library from a single li-

brary are obvious. When amplifying a cosmid or bacterial library the individual must weigh the concern of the possible underrepresentation of particular clones because of overgrowth of some colonies, against the time required to create a library de novo for each screening or for the dissemination of the library to other researchers.

Critical Parameters

The major concern with any amplification step is that each original recombinant be equally represented. Differences in the duplication rate of any recombinant bacteria will result in over- or underrepresentation in the amplified library. This concern is less for sim-

Supplement 34

ple plasmid libraries than for cosmid libraries, which contain bacteria that grow at markedly different rates.

Anticipated Results

The purpose of amplification is to provide a reagent library that can be used many times. An amplified cosmid or plasmid library will contain one library's equivalence in 10 to 100 μ l. By producing 100 μ l of such a library frozen in 100 1-ml tubes, over 1000 platings can be expected.

Time Considerations

After the transformation or transfection step in the preparation of the plasmid or cosmid libraries, respectively, the plating of the out-growths will require 1 to 2 hr. The plates are then incubated overnight at 30° to 37°C, depending upon the desired colony size and the density of the platings. The filter wash, glycerol mix, and aliquoting into freezer tubes require an additional 2 hr.

CHAPTER 6

Screening of Recombinant DNA Libraries

INTRODUCTION

The usual approach to isolating a recombinant DNA clone encoding a particular gene or mRNA sequence is to screen a recombinant DNA library. As described in Chapter 5, a recombinant DNA library consists of a large number of recombinant DNA clones, each one of which contains a different segment of foreign DNA. Since only a few of the thousands of clones in the library encode the desired nucleic acid sequence, the investigator must devise a procedure for identifying the desired clones. The optimal procedure for isolating the desired clone involves a positive selection for a particular nucleic acid sequence. If the desired gene confers a phenotype that can be selected in bacteria, then the desired clone can be isolated under selective conditions (*UNIT 1.4*). However, most eukaryotic genes and even many bacterial sequences do not encode a gene with a selectable function. Clones encoding nonselectable sequences are identified by screening libraries: the desired clone is identified either because (1) it hybridizes to a nucleic acid probe, (2) it expresses a segment of protein that can be recognized by an antibody, or (3) it promotes amplification of a sequence defined by a particular set of primers.

Screening libraries involves the development of a rapid assay to determine whether a particular clone contains the desired nucleic acid sequence. This assay is used first to identify the recombinant DNA clone in the library and then to purify the clone (see Fig. 6.0.1). Normally, this screening procedure is performed on bacterial colonies containing plasmids or cosmids or on bacteriophage plaques. To test a large number of clones at one time, the library is spread out on agarose plates (*UNIT 6.1*), then the clones are transferred to filter membranes (*UNIT 6.2*). The clones can be simultaneously hybridized to a particular probe (*UNITS 6.3 & 6.4*) or bound to an antibody (*UNITS 6.7 & 6.11*). When the desired clone is

Figure 6.0.1 Flow chart for screening libraries.

Current Protocols in Molecular Biology (1994) 6.0.3-6.0.5

Copyright © 2005 by John Wiley & Sons, Inc.

first identified, it is usually found among many undesirable clones; an important feature of library screening is the isolation of the desired clones (*UNITS 6.5, 6.6 & 6.12*). Another method for identifying the desired clone involves hybrid selection (*UNIT 6.8*), a procedure by which the clone is used to select its mRNA. This mRNA is characterized by its translation into the desired protein. Libraries consisting of large genomic DNA fragments (~1 Mb) carried in yeast artificial chromosome (YAC) vectors have proven to be tremendously useful for genome analysis. In general, these libraries (which are usually produced by large “core” laboratories) are initially screened using a locus-specific PCR assay (*UNIT 6.9*); the clone resulting from the initial round of screening is subsequently analyzed by more conventional hybridization methods (*UNIT 6.10*).

To screen a DNA library, one must first devise the screening procedure. The next important choice is the selection of a recombinant DNA library. When choosing which library to screen the investigator should consider whether he or she wants to isolate clones encoding the gene or the mRNA sequence. cDNA clones encode the mRNA sequence and allow prediction of the amino acid sequence, whereas genomic clones may contain regulatory as well as coding (exon) and noncoding (intron) sequences. The differences between genomic and cDNA libraries are discussed in Chapter 5.

Another critical parameter to be determined before proceeding with a library screen is the number of clones in the library that must be screened in order to identify the desired clone. That is, what is the frequency of the desired clone in the library? This frequency is predicted differently for genomic and cDNA libraries, as described below.

Screening a genomic library. In general, genomic libraries can be made from DNA derived from any tissue, because only two copies of the gene are present per cell or per diploid genome. The predicted frequency of any particular sequence should be identical to the predicted frequency for any other sequence in the same genome. The formula for predicting the number of clones that must be screened to have a given probability of success is presented in *UNIT 5.1*. This number is a function of the complexity of the genome and the average size of the inserts in the library clones. For amplified libraries, the base (see *UNIT 5.1*) must exceed this number. Usually about 1 million bacteriophage clones or 500,000 cosmid clones must be screened to identify a genomic clone from a mammalian DNA library. Many of the clones that are screened from an amplified library will be screened more than once; the total number of clones that must be screened is 30 to 40% greater than the number calculated by the formula.

Screening a cDNA library. The optimal cDNA library is one made from a particular tissue or cell that expresses the desired mRNA sequence at high levels. In highly differentiated cells, a particular mRNA may comprise as many as 1 of 20 of the poly(A)⁺ mRNA molecules, while some mRNAs are either not present at all or comprise as low as 1 molecule in 100,000 poly(A)⁺ mRNA molecules. When choosing a cDNA library the investigator must make every effort to obtain a library from a cell where the mRNA is being expressed in large amounts. Of course, the number of clones that must be screened is determined by the abundance of the mRNA in the cell. The amount of protein that is found in the cell is frequently a good indicator of the abundance of the mRNA. Thus, proteins that comprise 1% of the total cell protein are made by mRNAs that usually comprise 1% of the total poly(A)⁺ mRNA, and the desired cDNA clones should comprise about 1% of the clones in the cDNA library.

Screening a YAC library. In the typical genomic libraries maintained in *E. coli* (described in Chapter 5), the size of the insert is limited to 20 to 25 kb for lambda vectors or to 40 to 45 kb for cosmid vectors. Yeast artificial chromosome (YAC) vectors, by contrast, are designed to carry much larger genomic DNA fragments and thereby facilitate genomic analysis, with inserts ranging from 0.3 to ~1 Mb in size. Conventional screening of YAC

libraries by hybridization is difficult, both because of the unfavorable signal-to-noise ratio and the sheer numbers of replica films required to represent an entire library.

For example, a standard YAC library representing 5 to 8 genome equivalents requires over 500 microtiter plates (and corresponding filters for screening by hybridization). Thus, most core laboratories screen YAC libraries using a locus-specific PCR assay whose primers define a particular sequence. The PCR screening is initially performed using pools (representing up to 4 microtiter plates or 384 YAC clones) or superpools (representing up to 20 microtiter plates or nearly 2000 clones), followed by subsequent rounds of screening to narrow down the possible candidates.

Specialized screening strategies. For particular applications, there exist specialized approaches to screening. For example, cloned cDNAs encoding cell surface or intracellular proteins can be identified by expression screening, involving rounds of transient expression of a library and subsequent screening by immunoselection (*UNIT 6.11*). The technique of recombination-based screening provides a rapid and efficient approach for screening a complex genomic library in bacteriophage lambda (*UNIT 6.12*). The library is screened for homology against a plasmid carrying a particular cloned target sequence. If homology exists, a recombination event occurs, resulting in integration of the plasmid into the phage, and the recombinant is isolated by genetic selection.

General considerations. When selecting the library it is critical that the base be larger than the number of clones to be screened. One problem with predicting the number of clones to screen is that most libraries are amplified and in the process of amplifying the library some clones are lost while others may grow more rapidly. Thus, if the desired clone is not found in a particular library, another independent library should be screened.

Having selected the library, the investigator is ready to begin screening for the desired clone. The technologies used to screen libraries are mostly extensions of the techniques that have been described earlier in the manual. Libraries are plated out, transferred to nitrocellulose filters, and hybridized to ^{32}P -labeled probes or bound to antibodies. The major problem associated with this technique is that “false” positives can be identified: the probe may hybridize to clones that do not encode the desired sequence. Approaches to minimize this problem are discussed in *UNIT 6.7*. A second source of undesired clones arises from the power of the screening procedures that are normally used to screen these libraries. The investigator will be screening as many as one million clones. If the library contains any contaminating recombinant DNA clones that have been previously grown in the laboratory, it will be identified in the screening procedure. Thus, extreme care must be exercised to prevent contamination of the library with previously isolated recombinant clones. Despite these problems the ability to screen large DNA libraries to isolate the desired clone provides a powerful tool for molecular biologists.

J.G. Seidman

PLATING LIBRARIES AND TRANSFER TO FILTER MEMBRANES

The basic principle of screening recombinant DNA libraries is that bacteriophage plaques, or bacterial colonies containing plasmids or cosmids, contain relatively large amounts of insert DNA that can be detected either directly by hybridization (see below) or indirectly by the protein that may be expressed from the cloned segment (UNIT 6.7). The first step in the nucleic acid hybridization screening procedure is to grow large numbers of colonies or plaques on agar plates. Replica copies of these colonies are transferred to nitrocellulose filters, where they can be screened. In this section the techniques for producing large numbers of colonies and plaques, and for transferring these to filter membranes, are discussed. Prerequisites to these procedures are that the library must already be chosen and the number of clones to be screened must be determined (see introduction to this chapter).

Plating and Transferring Bacteriophage Libraries

Bacteriophage are plated onto agar plates at high density so that as many as 1 million different plaques can be screened. The bacteriophage plaques are then transferred to nitrocellulose filters, denatured, and baked. The library and the number of clones to be screened are predetermined. Principles for choosing the plaque density and the number of plates to be used are outlined in the commentary.

Materials

- Host bacteria, selection strain if applicable (UNIT 1.10; Table 1.4.5; Table 5.10.1)
- Recombinant phage (UNIT 5.10)
- 0.7% top agarose (prewarmed; UNIT 1.1)
- 82-mm or 150-mm LB plates; or 245 × 245-mm Nunc bioassay LB plates (UNIT 1.1)
- 0.2 M NaOH/1.5 M NaCl
- 0.4 M Tris·Cl, pH 7.6/2× SSC
- 2× SSC (APPENDIX 2)
- Nitrocellulose membrane filters (or equivalent)
- 20-G needle
- 46 × 57-cm Whatman 3MM or equivalent filter paper
- 80°C vacuum oven or 42°C oven

Plating bacteriophage

1. Determine the titer of the library by serial dilution as described in UNITS 1.11 & 5.7.
For λ vectors that allow genetic selection against nonrecombinants, plating should be done on the appropriate bacterial strain (e.g., P2 lysogen for EMBL vectors). LB plates should be poured several days in advance to allow them to dry prior to plating. The large Nunc plates are particularly prone to condensation on the surface of the agar, but this can be alleviated by allowing them to sit on the benchtop with covers removed for a few minutes to several hours before use.
2. Mix recombinant phage and plating bacteria (prepared as described in UNIT 1.11) in a culture tube as outlined in Table 6.1.1 and incubate 20 min at 37°C.
3. Add 0.7% top agarose to culture tube and transfer mixture to LB plates. Disperse bacteria and agarose on plates by tilting the plates back and forth. Mix cells and agarose for the large Nunc plates by gently inverting several times in a capped 50-ml tube prior to plating.

Top agarose rather than top agar should be used as agar tends to lift off with the nitrocellulose filter.

Melt the top agarose and cool to 45° to 50°C before use. If top agarose is too hot it will kill the bacteria, while if it is too cold the library will solidify in the tube.

4. Incubate plates at 37°C until plaques cover the plate but are not confluent. Incubation time varies between 6 and 12 hr and depends on type of phage and bacteria used. Store at 4°C.

Do not incubate unattended overnight, but rather place at 4°C and allow to continue growth the next day. Allowing phage plaques to incubate for the correct amount of time is critical. The object is to optimize two parameters. First, the plaques must be large enough to contain sufficient DNA to give a good signal. Second, if the plaques are too large and become confluent they are difficult to purify in subsequent steps. Because most nucleic acid probes give a very strong signal, we tend to prefer having smaller plaques and weaker signals.

5. Incubate plates at 4°C for at least 1 hr before applying filters.

Transferring to nitrocellulose filters

6. Label nitrocellulose filters with a ballpoint pen and apply face down (ink side up) on cold LB plates bearing bacteriophage plaques. This is best accomplished by touching first one edge of the filter to the agarose and progressively laying down more of the filter as it wets. Bubbles should be avoided. If difficulties are encountered the filter should not be adjusted on the plate, but rather removed and replaced with a new filter.

Nitrocellulose filters should be handled only with forceps or gloved hands.

7. Leave filters on plates for 1 to 10 min to allow transfer of phage particles to the filter. During this transfer period the orientation of the filter to the plate is recorded by stabbing a 20-G needle through the filter into the agar at several asymmetric points around the edge of the plate. Up to five replicas can be made from each plate. Remove the filter slowly from the plate with blunt, flat forceps and place face up on paper towels or filter paper.

Some investigators dip the needle used to orient the filter in India ink to more clearly mark the filter and agar. Other investigators mark the back of the agar plate with a black marker.

Making two replicas from each filter, hybridizing both to the DNA probe, and comparing the autoradiographs of the replica filters eliminates many possible artifacts. This is particularly helpful when screening with an oligonucleotide probe.

8. Dry the filters on the benchtop for at least 10 min.

This drying process binds the plaques to the filter.

Table 6.1.1 Recommended Mixtures for Plating Bacteriophage Libraries

LB plate ingredient	Plate size		
	82 mm	150 mm	245 × 245 mm ^a
Bacteria ^b (ml)	0.2	0.5	2
Phage, pfu	5,000	20,000-30,000	150,000
Top agarose, ml	3	7	30

^aNunc Bioassay plates distributed by Vanguard International.

^bPlating bacteria are prepared as described in Chapter 1.

Denaturation and baking

9. Place 46 × 57-mm Whatman 3MM paper on the benchtop and saturate with 0.2 M NaOH/1.5 M NaCl. Place filters on the paper face up for 1 to 2 min.

The 3MM paper should be wet enough to allow immediate saturation of the filters, but not so wet that the solution pools on the surface.

10. Transfer filters (face up) to 3MM paper saturated with 0.4 M Tris·Cl, pH 7.6/2× SSC for 1 to 2 min and then to 3MM paper saturated with 2× SSC for 1 to 2 min.

Some investigators immerse the filters in all three solutions. This procedure can make the plaques detected by hybridization appear diffuse.

11. Dry filters in a vacuum oven 90 to 120 min at 80°C or overnight in a regular oven at 42°C. Store at room temperature in folded paper towels or other absorbent paper until needed for hybridization (described in *UNIT 6.3* or *6.4*).

COMMENTARY

Background Information

There are two parts to this protocol—plating the library and preparing filters. The number of bacteriophage per plate determines the number of plates that must be poured. This number is defined by the number of recombinants in the library (i.e., base of the library) and the frequency of the expected clone in the library. There is no advantage to screening more than 3 to 5 times the base of the library. The frequency of the clone in the library is determined as follows.

cDNA libraries: the expected frequency of the desired RNA among the total RNA of the cell, ranging from $1/100$ to $1/50,000$.

Genomic libraries: the size of the insert divided by the total genome size.

Subgenomic libraries: the size of insert per total genome size times the fold purification of the DNA fragment (usually 10- to 50-fold).

The usefulness of a recombinant phage library depends on the ability to screen a large number of phage and identify the clone that carries the DNA sequence of interest. This has been made possible by the technique of in situ plaque hybridization described by Benton and Davis (1977). The phage are allowed to multiply in host bacteria in a thin layer of agarose on regular bacterial plates. When nitrocellulose is applied to the agarose, phage particles and unpackaged DNA adsorb to the filter to produce a replica of the plate surface. If the agarose surface is not excessively wet, there will be little spreading of the phage on the filter. Subsequent treatment of the filter with sodium hydroxide destroys the phage particles and denatures the phage DNA which then binds to the nitrocellulose. Neutralization of the filters is required to maintain the integrity of the nitrocellulose. Hy-

bridization of these filters to a DNA or RNA probe will identify the location of the phage plaque of interest, which can then be recovered from the plate.

A common variation of this technique is the substitution of one of the nylon-based membranes for nitrocellulose (see *UNIT 2.9*). The advantage of nylon membranes is their durability, which allows multiple hybridizations to the same filter and allows one to sequentially clone several genes from the same library using a single set of filters. However, nylon filters do not offer an improvement in sensitivity and are often more expensive than nitrocellulose filter paper.

Literature Review

The molecular basis of λ phage replication and the adaptation of the λ genome for molecular cloning has been reviewed by Arber et al. (1983) and Williams and Blattner (1980). Principles governing the plating of λ phage have been outlined by Arber (1983); see also *UNIT 1.10*. Thorough understanding of these principles has led to a universal approach to plating phage libraries.

Critical Parameters

To prevent recombination between different phage, do not allow them to overgrow, and grow them in recombination-minus hosts where possible. Calculations of the amount of phage stock to be used per plate should be based on a recent titration, and plating cells should be fresh.

Filters must not become brittle during this procedure; brittle filters will be destroyed during the hybridization process. This can be avoided by limiting the time in the hydroxide solution to less than 5 min, making certain that

the 0.4 M Tris-Cl, pH 7.6/2× SSC brings the filters to neutral pH, and limiting the baking to 2 hr.

Troubleshooting

Plaques should be visible on the plate before filters are made. If there appears to be poor bacterial growth, it is possible that the top agarose was too warm and many bacteria were killed, or that the phage titer was higher than expected and most host cells were lysed. Lower than expected phage titer could be due to an inaccurate titration of the phage stock, poor host-cell preparation, or too little time for adsorption.

The preparation of the nitrocellulose filters will only be tested after hybridization is complete. Occasionally, hybridization to a plaque will produce a streak instead of a discrete circle on the autoradiograph, making location of the correct plaque difficult. Steps that will often correct this problem include: (1) drying plates with the cover removed for 1 to 2 hr before applying the filter, (2) drying the filters well before the hydroxide treatment, and (3) making certain that the face (phage side) of the filters is not directly in contact with the solutions.

Anticipated Results

This plating procedure characteristically produces plates with an even distribution of dense phage particles. It is sensitive enough to allow identification of a phage by hybridization even when the phage are plated at high density (>5000 plaques per 82-mm plate). A signal is easily visible after 18 to 24 hr, when filters are hybridized to a nick-translated DNA probe with activity of $>10^7$ counts/ μ g DNA.

Time Considerations

Usually plaques will become visible within 6 to 10 hr after plating. Bacteriophage should generally not be allowed to grow longer than necessary to visualize the plaques. Using the procedure outlined, even a large number of filters can be processed in a single day.

Plating and Transferring Cosmid and Plasmid Libraries

UNIT 6.2

**BASIC
PROTOCOL**

A bacterial suspension is suctioned through a porous membrane, leaving the bacteria bound to the membrane surface. The membrane is transferred, bacteria up, to an agar plate upon which the bacteria will receive enough nutrients to grow into colonies. These filters can then be used for replica platings and for hybridization with specific DNA probes.

Materials

- LB plates containing antibiotic (UNIT 1.1)
- LB medium (UNIT 1.1)
- LB plates containing 50 µg/ml chloramphenicol (UNIT 1.1)
- 0.5 M NaOH
- 1 M Tris·Cl, pH 7.5
- 0.5 M Tris·Cl, pH 7.5/1.25 M NaCl
- 10- or 15-cm Whatman 3MM or equivalent filter paper discs
- Sintered glass filter with vacuum
- Nitrocellulose membrane filters (10- or 15-cm, Millipore HATF)
- 20 × 20-cm Whatman 3MM or equivalent filter paper
- 20 × 20-cm glass plate
- 20-G needle
- 46 × 57-cm Whatman 3MM or equivalent filter paper
- 80°C vacuum oven

NOTE: All materials coming into contact with *E. coli* must be sterile.

Plating cosmids

1. Start with plasmid or cosmid library produced after transformation, transfection, or amplification (UNIT 5.7).
2. Determine titer of the library by serial dilutions using plates containing antibiotics (see UNIT 1.3).

Remaining library suspension can be held at 4°C overnight with only minimal loss of viable bacteria.

A 10-cm nitrocellulose filter can accommodate 10,000 to 20,000 colonies, while a 15-cm filter can hold up to 50,000.

3. Calculate the appropriate amount of the bacterial suspension for plating and dilute the suspension in LB medium such that there is the desired amount of bacteria in 5 ml (10-cm filter) or 10 ml (15-cm filter) of solution.
4. Meanwhile, prepare a layer of 10- or 15-cm Whatman 3MM paper discs on either the bottom part of a sintered glass Buchner funnel or on a porcelain filter funnel. Pour 10 to 20 ml LB medium over two or three layers of 3MM paper discs to make a level bed. The same pad of discs can be used for many filters.

Sterilize filter apparatus and filter paper before use. The 3MM and nitrocellulose filters can be sterilized by autoclaving them while wrapped in aluminum foil.

The purpose of this step is to spread the bacteria uniformly across the surface of a nitrocellulose filter. The filtering apparatus must be level, it must create a uniform suction to all the surface of the filter, and it should be easy to move the filters to and from the apparatus.

**Screening
Recombinant
DNA Libraries**

Supplement 68

5. Label a nitrocellulose filter with a ballpoint pen on the side opposite that where the bacteria will be plated. Place the filter on the surface of the LB/antibiotic plate to wet it.

The antibiotic plate must be permissive for cosmid- or plasmid-bearing bacterial cells and usually is ampicillin or tetracycline.

Most ballpoint pen inks do not smudge during the hybridization reaction. If the one you choose runs, try another type.

6. Remove the wet filter from an antibiotic plate to the filtration apparatus.

The suction should be off.

Carefully pipet the 5 to 10 ml of bacterial suspension onto the surface of the nitrocellulose filter, leaving the outer 4 to 5 mm of the filter free of solution.

This outside bacteria-free ring leaves enough surface area to work with the filter without smearing or losing the colonies.

7. Slowly suction the solution down through the filter, taking care not to create any preferential suction pockets that would concentrate the bacteria. After suctioning all of the solution through the filter, transfer the filter back to the antibiotic plate on which it was wetted.

In laying the filter down on the agar surface, take care to avoid trapping any air bubbles between the surface of the plate and the filter.

8. Plate the entire library in this way and incubate the plates upside down (agar side up) at 37°C until the colonies are ~1 mm in diameter.

Do not overgrow the filters, as smaller colonies can be lost beneath larger, faster-growing recombinant bacteria.

Preparing replica filters

9. Label and wet another set of nitrocellulose filters, as described in step 5.

10. Remove the initial library filter from its plate and place on several sheets of 20 × 20 cm 3MM paper, bacteria side up. While wearing gloves, carefully position the wetted replica filter above the bacterial lawn. Lay the second filter upon the first, leaving the two filters offset by 2 to 3 mm.

This overlap will help in the separation of the two filters after the replica transfer.

Do not allow air bubbles to form between the two filters. These are excluded by touching the second filter to the first in the middle and then allowing the edges to fall.

11. Lay three sheets of 20 × 20-cm 3MM paper on the two filters, followed by a 20 × 20 cm glass plate. Using the palms of your hands, press with all your weight down on the glass plate, thus transferring the bacterial colonies from the library filter to the replica filter.
12. Remove the glass plate and the filter paper and, using a 20-G needle, punch holes 2 to 4 cm apart through both of the filters. These holes will allow the orientation of the film produced from the replica filter down on the library filter for the isolation of the correct clones.
13. Carefully peel the two filters apart, placing them both bacteria up, on their respective agar plates. Grow the replica colonies at 37°C overnight, leaving the library filters at 25°C overnight. After overnight growth, store the library filters on the agar plates at 4°C, while screening the replica filters.

Multiple replica filters can be made from the same library filter. Incubate library filters 2 to 4 hr at 37°C or overnight at 25°C to allow regrowth of the colonies.

5. Label a nitrocellulose filter with a ballpoint pen on the side opposite that where the bacteria will be plated. Place the filter on the surface of the LB/antibiotic plate to wet it.

The antibiotic plate must be permissive for cosmid- or plasmid-bearing bacterial cells and usually is ampicillin or tetracycline.

Most ballpoint pen inks do not smudge during the hybridization reaction. If the one you choose runs, try another type.

6. Remove the wet filter from an antibiotic plate to the filtration apparatus.

The suction should be off.

Carefully pipet the 5 to 10 ml of bacterial suspension onto the surface of the nitrocellulose filter, leaving the outer 4 to 5 mm of the filter free of solution.

This outside bacteria-free ring leaves enough surface area to work with the filter without smearing or losing the colonies.

7. Slowly suction the solution down through the filter, taking care not to create any preferential suction pockets that would concentrate the bacteria. After suctioning all of the solution through the filter, transfer the filter back to the antibiotic plate on which it was wetted.

In laying the filter down on the agar surface, take care to avoid trapping any air bubbles between the surface of the plate and the filter.

8. Plate the entire library in this way and incubate the plates upside down (agar side up) at 37°C until the colonies are ~1 mm in diameter.

Do not overgrow the filters, as smaller colonies can be lost beneath larger, faster-growing recombinant bacteria.

Preparing replica filters

9. Label and wet another set of nitrocellulose filters, as described in step 5.

10. Remove the initial library filter from its plate and place on several sheets of 20 × 20 cm 3MM paper, bacteria side up. While wearing gloves, carefully position the wetted replica filter above the bacterial lawn. Lay the second filter upon the first, leaving the two filters offset by 2 to 3 mm.

This overlap will help in the separation of the two filters after the replica transfer.

Do not allow air bubbles to form between the two filters. These are excluded by touching the second filter to the first in the middle and then allowing the edges to fall.

11. Lay three sheets of 20 × 20-cm 3MM paper on the two filters, followed by a 20 × 20 cm glass plate. Using the palms of your hands, press with all your weight down on the glass plate, thus transferring the bacterial colonies from the library filter to the replica filter.
12. Remove the glass plate and the filter paper and, using a 20-G needle, punch holes 2 to 4 cm apart through both of the filters. These holes will allow the orientation of the film produced from the replica filter down on the library filter for the isolation of the correct clones.
13. Carefully peel the two filters apart, placing them both bacteria up, on their respective agar plates. Grow the replica colonies at 37°C overnight, leaving the library filters at 25°C overnight. After overnight growth, store the library filters on the agar plates at 4°C, while screening the replica filters.

Multiple replica filters can be made from the same library filter. Incubate library filters 2 to 4 hr at 37°C or overnight at 25°C to allow regrowth of the colonies.

Then repeat steps 9 to 13. Normally, two copies of the cosmid are hybridized to each probe.

14. After the bacterial colonies have grown, the cosmids or plasmids on the replica filter are amplified by transferring them to an LB plate containing 50 µg/ml chloramphenicol and incubating at 37°C for 4 to 10 hr. This step will increase the signal produced by hybridization.

Preparing filters for hybridization

15. Remove the replica filters from the LB/chloramphenicol plates, place filters bacteria side up on a sheet of 46 × 57-cm 3MM paper soaked with 0.5 M NaOH, and leave them for 5 min.
16. Carefully transfer to a sheet of 46 × 57-cm 3MM paper soaked with 1 M Tris·Cl, pH 7.5. Allow neutralization to occur for 5 min.
17. Transfer to a third 46 × 57-cm filter soaked in 0.5 M Tris·Cl, pH 7.5/1.25 M NaCl. Neutralize 5 min.
18. Transfer filter to a dry sheet of 3MM paper to allow filter to dry.

After filters are completely dry, stack them on paper towels or other adsorbent paper. Each nitrocellulose filter should be separated by paper towels from other filters.

19. Transfer the stacked filters to a vacuum oven at 80°C for 90 min. Remove filters and hybridize with a nick-translated probe, as described in *UNITS 6.3* and *6.4*.

COMMENTARY

Background Information

There are two commonly used protocols for the screening of recombinant bacteria with hybridization probes. The first method involves the spreading of bacteria on the surface of agar using a sterile spreader (*UNIT 1.3*). A nitrocellulose membrane filter is then placed on top of the colonies and most of each colony is transferred to the filter. The filter is then treated as described in steps 15 to 19. This method works well when relatively small numbers of positive colonies are being selected (up to several thousand).

The second method employs a matrix of some type (here nitrocellulose filters are used) upon which bacteria can be plated and grown when the filter is placed on top of a nutrient agar surface. Once the plated bacteria have grown into visible colonies, the filters can be used for replica plating and in situ hybridization analysis.

Critical Parameters

In order to provide a uniform lawn of recombinant bacteria for screening, it is critical to ensure that the suction applied to the filters is uniform and not spotty. The best way to accomplish this is to suction the suspension through

the filter slowly and to avoid any preferential suction sites in the filter. Make sure that the apparatus is level and that adequate layers of LB-soaked chromatography paper are used. Air bubbles will prevent bacterial growth, so be certain that air is not trapped between the filter and the agar surface.

Time Considerations

Once the apparatus is set up, it takes ~5 min per filter to wet the filter, suction the bacteria, and transfer to an LB plate. The colonies take ~15 hr to grow at 37°C, after which they can be transferred to 4°C until ready for the replica platings. Replica plating also requires 5 min per filter, and resulting filters will be ready for denaturation and hybridization after 15 hr at 37°C.

HYBRIDIZATION WITH RADIOACTIVE PROBES

After plaques or colonies have been transferred to nitrocellulose filters, the desired clone can be detected by its ability to hybridize to a DNA probe. This is a rapid, effective screening procedure that allows the identification of a single clone within a population of millions of other clones. The filters are hybridized with a ^{32}P -labeled nucleic acid probe, the excess and incorrectly matched probe is washed off the filter, and the filter is autoradiographed. Two features of the nucleic acid probe used for these experiments are critical to the successful screening of recombinant DNA libraries. First, the probe must hybridize only to the desired clones and not to any other clones. Thus, the nucleic acid sequence used for a probe must not contain any reiterated sequences or sequences that will hybridize to the vector. Second, the specific activity of the probe must be at least 10^7 cpm/ μg . Most of the procedures for labeling DNA or copy RNA molecules are described in Chapter 3, and a support protocol is presented here that allows the 5' end-labeling of a mixture of oligonucleotides.

The two basic protocols presented in this section describe steps required to hybridize labeled probes to recombinant DNA clones on filters. Two protocols are presented because conditions for hybridizing short oligonucleotide probes and longer nucleic acid probes to filters are different.

UNIT 6.3

BASIC PROTOCOL

Using DNA Fragments as Probes

HYBRIDIZATION IN FORMAMIDE

Bacteriophage plaques or bacterial colonies bound to a filter membrane are detected by hybridization with a radioactive probe. Hybridization proceeds on prewet filters placed in a sealable plastic bag. After hybridization the filters are removed from the sealed bag, excess probe is washed off, and the filters are autoradiographed to identify the clones that have hybridized with the probe.

Materials

Nitrocellulose membrane filters bearing plaques, colonies, or DNA (UNITS 6.1 & 6.2)

Hybridization solution I

Radiolabeled probe, 1 to 15 ng/ml (UNIT 3.5)

2 mg/ml sonicated herring sperm DNA

High-stringency wash buffer I

Low-stringency wash buffer I

Sealable bags

42°C incubator

Water bath adjusted to washing temperature (see commentary)

Glass baking dish

Additional reagents and equipment for autoradiography (APPENDIX 3)

Incubate filters with probe

1. Wet filters with hybridization solution I. Lay a filter membrane bearing plaques on top of 5 to 20 ml of hybridization solution I and allow solution to seep through filter. It is important to wet only one surface at a time to prevent trapping air in filter. Wet each filter in turn, producing a stack of wet filters.

When multiple filters are to be hybridized to the same probe, no more than twenty 8.2-cm discs or ten 20 × 20 cm square filters should be placed in one stack.

Using DNA Fragments as Probes

6.3.1

Contributed by William M. Strauss

Current Protocols in Molecular Biology (1993) 6.3.1-6.3.6

Copyright © 2000 by John Wiley & Sons, Inc.

Estimate the volume of hybridization solution used to wet the filters; this is a significant fraction of the volume of the hybridization reaction.

2. Transfer the stack of wetted filters to an appropriately sized sealable bag. Add enough hybridization solution to generously cover filters and seal.

Note the volume of hybridization solution used to cover the filters.

3. Prehybridize filters by placing the bag in a 42°C incubator for at least 1 hr.

Some investigators omit this step.

4. While filters are prehybridizing, pipet the radioactive probe into a screw-cap tube, add 2 mg (1 ml) sonicated herring sperm DNA, and boil 10 min. Place boiled probes directly into ice to cool.

The amount of probe used is important, and should be in the range of 1 to 15 ng/ml of hybridization reaction. The volume of the hybridization reaction can be assumed to be the amount of hybridization solution added to the filters.

5. Add 2 ml hybridization solution I to the boiled probe.
6. Remove bag containing filters from the 42°C incubator. Open bag, add probe mixture, exclude as many bubbles as possible, and reseal.

A good way to add the radioactive probe is to take it up in a syringe with an 18-G needle and then inject it into the bag. Reseal the bag after adding probe.

7. Mix probe in the bag so that filter is evenly covered. Replace bag in the 42°C incubator and let hybridize overnight.

Wash filters to remove nonhybridized probe

8. Warm 1 liter high-stringency wash buffer I to the “washing temperature” in a water bath.

The stability of washing temperature and salt concentrations are critical features of this experiment. See discussion in commentary.

9. Remove bag containing hybridizing filters from the 42°C incubator. Cut bag open and squeeze hybridization solution out of the bag.

CAUTION: Handle material carefully as it is extremely radioactive. This should be done on disposable paper bench covers.

10. Quickly immerse the filters in 500 ml low-stringency wash buffer I at room temperature in a glass baking dish. Separate all the filters, as they may stick together during hybridization.

The volume of the low-stringency wash buffer is not important as long as the filters are completely covered. The filters must not be allowed to dry as the radioactive probe will irreversibly bind the filters if the filters dry in contact with probe. (The type of container used to hold the filters is not important as long as it transfers heat well. Thus glass, metal, or enamel containers are better than plastic.)

The low-stringency wash only removes nonhybridized probe formamide and hybridization solution; it does not determine the stringency of the hybridization.

11. Rinse the filters three times with 500 ml low-stringency wash buffer. Let the filters sit 10 to 15 min at room temperature in low-stringency wash buffer with each rinse.
12. Pour off the low-stringency wash buffer and pour in 500 ml high-stringency wash buffer (prewarmed to washing temperature).

13. Replace the high-stringency wash buffer with another 500 ml of high-stringency wash buffer, then place the glass dish containing the filters in incubator at wash temperature. Make sure that the temperature in the glass dish reaches the desired washing temperature by placing a thermometer directly into the bath and measuring the temperature. Usually 15 to 20 min at the desired wash temperature is sufficient to remove most of the background radioactivity.

Of course, if the glass dish is placed in a water bath, be careful that the water from the water bath does not get into the filters.

Autoradiographing filters

14. Remove filters and mount them either wet or dry on a plastic backing. If the filter(s) is to be exposed wet, then isolate it from the film by covering it with plastic wrap.

Used X-ray film provides a good form of plastic backing for filters.

15. Mark the filters with radioactive ink to assist in alignment and autoradiograph.

An easy way to apply radioactive ink is to mark adhesive-backed paper labels with radioactive ink and then attach the stickers to the plastic wrap cover.

X-ray intensifying screens greatly decrease the amount of exposure time required.

ALTERNATE PROTOCOL

HYBRIDIZATION IN AQUEOUS SOLUTION

This method differs mainly in that formamide is not used in the hybridization solution. Follow the basic protocol except use the reagents and alternate parameters listed below.

Additional Materials

Hybridization solution II
Low-stringency wash buffer II
High-stringency wash buffer II
65°C incubator

1. Prehybridize as in basic protocol except that the filters are prehybridized at 65°C using hybridization solution II.

Hybridization solution II may have to be prewarmed to solubilize the SDS.

2. Prepare probe as in step 4 of basic protocol and dilute with 2 ml of hybridization solution II.
3. Hybridize overnight as in steps 6 and 7 of basic protocol except use a hybridization temperature of 65°C.
4. Remove bag containing hybridization from the 65°C incubator. Squeeze out the hybridization solution, taking care to avoid contamination with the excess radioactive hybridization solution.
5. Immediately rinse filters twice with low-stringency wash buffer II.

It is unnecessary to maintain a given temperature for this wash; just let the filters sit in wash buffer at room temperature until ready to proceed.

6. At 65°C, proceed to wash filters with high-stringency wash buffer II. Employ multiple quick washes (5 to 8) and immerse filter in a final wash for ~20 min. Check the radioactivity of the filters with a Geiger counter and be certain that they produce a signal only a fewfold above background levels.

REAGENTS AND SOLUTIONS

High-stringency wash buffer I

0.2× SSC (APPENDIX 2)
0.1% sodium dodecyl sulfate (SDS)

High-stringency wash buffer II

1 mM Na₂EDTA
40 mM NaHPO₄, pH 7.2
1% SDS

Hybridization solution I

Mix following ingredients for range of volumes indicated (in milliliters):

Formamide	24	48	72	120	240	480
20× SSC	12	24	36	60	120	240
2 M Tris-Cl, pH 7.6	0.5	1.0	1.5	2.5	5.0	10
100× Denhardt's solution	0.5	1.0	1.5	2.5	5.0	10
Deionized H ₂ O	2.5	5.0	7.5	12.5	25	50
50% dextran sulfate	10	20	30	50	100	200
10% SDS ^a	0.5	1	1.5	2.5	5	10
Total volume	50	100	150	250	500	1000

^aIn place of SDS, *N*-lauroylsarcosine (Sarkosyl) may be used.

Add the SDS last. The solution may be stored for prolonged periods at room temperature.

The dextran sulfate should be of high quality. Pharmacia produces acceptable-grade dextran sulfate. Recipes for SSC and Denhardt's solution are in APPENDIX 2.

Hybridization solution II

1% crystalline BSA (fraction V)
1 mM EDTA
0.5 M NaHPO₄, pH 7.2 (134 g Na₂HPO₄·7H₂O plus 4 ml 85% H₃PO₄/liter = 1 M NaHPO₄)
7% SDS

Low-stringency wash buffer I

2× SSC (APPENDIX 2)
0.1% SDS

Low-stringency wash buffer II

0.5% BSA (fraction V)
1 mM Na₂EDTA
40 mM NaHPO₄, pH 7.2
5% SDS

Sonicated herring sperm DNA, 2 mg/ml

Resuspend 1 g herring sperm DNA (Boehringer Mannheim #223636) in a convenient volume (about 50 ml of water) by sonicating briefly. The DNA is now ready to be sheared into short molecules by sonication. Place the tube containing the herring sperm DNA solution in an ice bath (the tube must be stable even if the ice begins to melt). The sonicator probe is placed in the DNA solution (without touching the bottom of the vessel). The sonicator is turned on to 50% power 20 min, or until there is a uniform and obvious decrease in viscosity. At no time should the tube containing the DNA become hot to the touch. After sonication, the DNA is diluted to a final concentration of 2 mg/ml, frozen in 50-ml aliquots, and thawed as needed.

COMMENTARY

Background Information

All hybridization methods depend upon the ability of denatured DNA to reanneal when complementary strands are present in an environment near but below their T_m (melting temperature). In a hybridization reaction involving double-stranded DNA on a filter and a single-stranded DNA probe there are three different annealing reactions occurring. First, there are the desired probe-DNA interactions which result in signal. Second, there are mismatch interactions that occur between related but non-homologous sequences; these mismatch hybrids are the ones that must be eliminated during the washing of the filters. Non-sequence-specific interactions also occur and these result in noise. The ability to extract information from a particular hybridization experiment is a function of the signal-to-noise ratio. High background or poor specific signal can both result in uninterpretable results.

Washing nitrocellulose filters is required to remove excess radioactive probe, as well as radioactive probe that has bound to the DNA on the filter as mismatch hybrids. Temperature and salt concentration dramatically affect the maintenance of specific hybrids. Detergents and other charged species can have a profound effect upon the nonspecific binding of species that contribute to background. In this protocol, hybridization is achieved in a solution containing 50% formamide. Excess probe is rinsed away under low-stringency conditions so that further hybridization will not occur. Once the hybridization solution is rinsed away, it is possible to proceed to a high-stringency wash without fear of further hybridization. When washing is complete, the filters should produce very little "noise" when monitored with a Geiger counter. Although single-copy sequence probe normally does not produce a signal that is detectable with a Geiger counter, a probe corresponding to more abundant sequences will produce a signal that can be "heard" with a Geiger counter.

Literature Review

Hybridization to filter membranes forms a basis of recombinant DNA technology and is described in detail earlier in the manual (UNIT 2.9). The protocols described here vary from those used for Southern blot filter hybridization in that the volume of the hybridization is usually larger and the washing conditions are different. Dextran sulfate is an important component of the hybridization

solution as it increases the rate of reassociation of the nucleic acids.

The protocols in this unit describe methods for hybridizing radioactive probes to membrane-bound plaques or colonies. These procedures for screening recombinant clones were first suggested by Grunstein and Hogness (1975) and by Benton and Davis (1977). The conditions of hybridization proposed in the basic protocol involving hybridization in formamide was originally described by Denhardt (1966) and Gillespie and Spiegelman (1965) while the alternate protocol using aqueous hybridization solution was introduced by Church and Gilbert (1984).

The method of washing filters under stringent conditions to remove background was first proposed by Southern (1975). Botchan et al. (1976) described the benefit of adding SDS to the wash solution. Jeffreys and Flavell (1977) first employed the wash conditions described in the protocols presented here.

Critical Parameters

Hybridization. Kinetically, the hybridization of DNA (or RNA) probes to filter-bound DNA is not significantly different from hybridization in solution. For single-stranded probes, the rate of hybridization follows first-order kinetics, since probe is available in excess. Under conditions of excess probe, the time for hybridization is inversely proportional to the probe concentration. For double-stranded probes the rate of hybridization displays a more complex relationship to the initial probe concentration. However, to a first approximation the initial probe concentration is inversely proportional to the rate of hybridization. To determine the actual time required for the successful hybridization of a given probe, either empirical data must be available or the following formula can be used to determine the length of time (in hours) required to achieve 50% hybridization (T_{50}):

$$\frac{1}{x} \times \frac{y}{5} \times \frac{z}{10} \times 2 = T_{50}$$

where x is the weight of probe in micrograms; y is the complexity of probe in kilobases; and z is the volume of hybridization solution in milliliters. The length of time T is given in hours. Maximum hybridization signal will be obtained if the reaction is allowed to proceed to $5 \times T_{50}$, although 1 to $2 \times T_{50}$ is often used.

It is also clear that nonspecific interactions

occur and that in any hybridization, sources of noise will be present. Therefore, from a practical standpoint one conventionally utilizes concentrations of nick-translated probe on the order of 1 to 15 ng/ml of hybridization, where the specific activity of the probe is from 5×10^7 cpm/ μ g to $>10^8$ cpm/ μ g. Too much probe in a hybridization is as bad as too little.

One important source of background hybridization to filters is due to the hybridization of the probe to vector sequences or to *E. coli* DNA. Be certain that there is no vector or *E. coli* DNA sequences in the probe. This can best be ensured by isolating the probe from one type of vector (e.g., plasmid) and screening a library made with a different type of vector (e.g., bacteriophage).

Washing temperature. Washing at low stringency is a straightforward proposition. Buffer is added at room temperature and washing proceeds at room temperature.

High-stringency wash is determined empirically. The relative homology between the probe and target sequence is a determining parameter. If the homology is 100%, a high temperature (65° to 75°C) can be used. As the homology drops, lower washing temperatures must be used. In general one starts at 37° to 40°C, raising the temperature by 3° to 5°C intervals until background is low enough not to be a major factor in the autoradiography.

The length of the probe is also important. Very short probes (<100 bp) must be washed at lower temperatures, even if the homology is 100%. Washing strategy is the same as for probes of differing homology.

Salt concentration. The lower the salt concentration, the higher the stringency. With this said, the protocols as outlined do not require adjustment of salt concentration for adjustment of stringency. Only the washing temperature is varied.

Probe. The nucleic acid probe must be of high specific activity and greater than 50 bp in length so that it can form stable hybrids.

Anticipated Results

After washing the filters the background

should be barely detectable with a Geiger counter.

With a high-specific-activity probe $>5 \times 10^7$ cpm/ μ g and an overnight hybridization reaction with a 1-kb unique sequence probe, hybridizing bacterial colonies or bacteriophage plaques can be visualized after a 1 to 18 hr exposure.

Time Considerations
